WELCOMING ADDRESS

Dr.-Ing. Karl-Eduard Naumann
President of the Hafenbautechnische Gesellschaft
and
Chairman, Organizing Committee, 16th ICCE

Excellencies, distinguished guests, dear colleagues and friends,
ladies and gentlemen:

On behalf of the Organizing Committee for this 16th International Conference on Coastal Engineering, it is my special privilege as its Chairman to welcome you all very heartily here in the Congress-Center Hamburg to inaugurate a week of lectures and discussions on the manifold problems of Coastal Engineering. The Organizing Committee is very happy about the large number of participants being 621 up to now coming from 41 countries all over the world.

Especially I should like to welcome Mrs. Helga Elstner, second Burgomaster, who is representing the Senate of this Free and Hanseatic City of Hamburg, the host-city for our conference this week. Thank you, Mrs. Burgomaster, for coming here and for your kind readiness to speak to us. In addition, we must give our respectful thanks for the generous sponsorship which the Senate has provided for organizing this conference.

Another special welcome is to Dr. Volker Hauff, Federal Minister for Research and Technology, who has come from Bonn to join this opening ceremony and to speak to us about the viewpoints of the German Federal Government concerning Coastal Engineering, especially the efforts made to defend the low German coast, which, because of its nature is very sensitive to the attacks of the sea. Thank you, Dr. Hauff, for coming and for the assistance and sponsoring your Ministry gave us when we were preparing this conference.

In addition to the Senate of Hamburg and the Federal Ministry for Research and Technology, there are three other sponsors of our conference. First the "Kuratorium für Forschung im Küsteningenieurwesen" which could be translated as the "Committee for Coastal Engineering Research". It is a coordinating and collaboration body of the Federal Republic and four coastal states. The KFKI is supporting our conference by publishing a special issue of the periodical "Die Küste" (the coast), which you all have in your conference-portfolio; it is written both in English and German and gives extensive information about the history and present problem of the German coast as well as pinpointing some features of the relevant research in this country. We are very grateful to the KFKI for this assistance.

The second sponsor is the "Hafenbautechnische Gesellschaft" (HTG), which may be translated as the "Association for Port and Coastal Engineering". This is a scientific association with the aim of studying scientific and practical problems of a technical and economical nature in the following fields:

- planning and constructing ports, port installations and traffic ways within ports;
- operating ports and port installations;
- planning, constructing and operating waterways;
- coastal research and coastal engineering.

This association is the local organizer of our Conference and bears the financial responsibility for it. The Organizing Committee is composed only of members of the HTG.

Last but not least I should gratefully mention the Coastal Engineering Research Council (CERC), borne by the American Society of Civil Engineers under the leadership of our "Grand Old Man" Dean O'Brien and his "Right Hand" Professor Johnson. Since the ICCEs came into existence in 1950, they all have been sponsored by the CERC at least by publishing the proceedings and thus providing the continuity of the respective literature as well as the exchange of the research results.

And now, ladies and gentlemen, let me welcome you all, the participants of this 16th ICCE in Hamburg. After a remarkably long row of conferences held in the past in different countries with different local conditions, the 16th ICCE has been convened to Hamburg, the biggest city of the Federal Republic of Germany, its most important seaport and industrial center. But we hope you will find that Hamburg is also a very beautiful city, worth visiting to enjoy its beautiful features, art treasures, opera and theaters, museums and other attractions. However, it is very difficult for Hamburg to compete with such wonderful settings as Vancouver, Copenhagen and Honolulu, to mention only the sites of the last three Conferences, which, moreover, were all favoured by excellent weather conditions. The Organizing Committee cross their fingers that similar favourable weather conditions will also be granted for this year's conference. After several summer-months spoiled by rain and terrible weather, we hope that now the celestial water reservoirs are empty and you will enjoy Hamburg generally in sunshine.

People in this country are disquieted by the increasing height and frequency of storm surges at our coast. Up to 1961 coastal and harbour engineers worked with a highest high water level, which dated back to 1825. No higher water levels had occurred up to February 1962, when the extreme water level of 1825 was exceeded by about half a meter. Then dikes were damaged heavily at many spots. But the frequency of storm surges continued to grow, and in January 1976 a new alarming water level was measured, which exceeds the peak of 1825 by

nearly one and a half meters. The reasons for this remarkable and disturbing development are contested up to now, as no scientifically founded answer is available on the question of why frequency and peak levels of storm surges at our coast have been growing so vehemently for about 25 years. We see a field of problems here, which will still take much effort to solve. Anyhow, you will understand that due to these facts the public interest in coastal engineering is very lively and widespread in this country. We hope that this conference will make a noteworthy contribution towards solving the problems.

Ladies and gentlemen, I should like to finish my welcoming speech by expressing our sincere thanks for the broad participation in this conference and wishing you all an agreeable and successful time in our country and in this Free and Hanseatic City of Hamburg.

I leave the desk first to Mrs. Burgomaster Helga Elstner, representing the Senate of Hamburg and then to Dr. Volker Hauff, Federal Minister for Research and Technology, representing the Federal Government. Thank you.

WELCOMING ADDRESS

Burgomaster Mrs. Helga Elstner
Senate of the Free and Hanseatic City of Hamburg

Ladies and Gentlemen. In the name of the Senate of the Free and Hanseatic City of Hamburg, and also personally, I welcome you most cordially here in our Congress Centre. We in Hamburg are happy that the International Conference on Coastal Engineering is being held in our city for the first time and that the "Hafenbautechnische Gesellschaft" has been entrusted with its organization.

We are pleased not only because this scientific event animates the diversity of the conference scene here in Hamburg, but also because the people and their representatives in this great seaport have an interest in the topic of coastal engineering which stems quite naturally from its geographical location. This interest in subjects of coastal research is as old as Hamburg itself and goes back almost a thousand years to Hamburg's beginnings as a centre of shipping and trade. Down the centuries they improved and enlarged the port, while the river Elbe, as its link with the sea, was regulated, deepened and protected. In the 14th century, our ancestors built an imposing defensive tower on a small island in the Elbe estuary to protect their shipping. Later on, upon the insecure ground of the shallow and hazardous coastal waters of the rough North Sea, they constructed sea marks, wooden beacons and flares, which had to be well secured against sea attack.

The construction of marks, regulating works along the Elbe as far as the estuary, dike building since the 16th century on the island of Neuwerk and on the coast at Cuxhaven--which belonged to Hamburg from the 14th century until 1937--also the experience and observations of tidal movement, currents, changes in the coastline and other natural phenomena which Hamburg seafarers and pilots collected and evaluated, are part of the knowledge which is now understood worldwide in research and teaching as "coastal engineering".

Stemming from its port interests, Hamburg has in the past made important contributions in this field. I will mention just two examples here. More than a century ago, Heinrich Hübbe, a hydraulics engineer with the authority responsible for the port and the Elbe waterway, and who later became its director, investigated the processes of sand movement in the tidal mudflats of the Elbe estuary and published the results in 1861 in a then epoch-making work. At about the same time Hugo Lentz, another engineer with the same authority, studied the tidal movements in the German Bight. After many years of careful gauge observations, he published the first tide tables for the southern and eastern North Sea coast. Even by our present state of knowledge these show a remarkably high standard of reliability.

But whatever Hamburg's pride in its long history, our attention is focussed very much on the needs of the present. In the field of coastal engineering we are engaged in two tasks which are of the greatest importance:

1. As a tidal harbour and as a city whose limits extend well into the Elbe marshland area, Hamburg is directly affected by the natural phenomena occurring in the North Sea and in the Elbe estuary. Our particular concern here is, of course, the storm tides, which advance in the tidal rivers far into the hinterland. After a long period of relative calm, a great storm tide occurred in 1962 and claimed the lives of many people as well as causing heavy material damage. Steps were immediately taken to make Hamburg safe against future storm tides, but hardly had work been completed before an even higher surge threatened us in 1976. Once again great flood damage was caused, this time particularly in the actual dockland area. These parts now are being well protected. This is a programme which includes not only the building of dikes, flood protection walls, storm barriers, etc., but also research into the problem of storm tides so as to be prepared for possible future developments and, especially, to develop reliable forecasting procedures by which precautions are possible for a good time in advance.
2. A further aspect of our coastal engineering activities is exemplified by a project directly on the North Sea coast. In 1962, following negotiations with the Land of Lower Saxony, Hamburg acquired an area of about 100 km² in the Wadden Sea of the Elbe estuary so as to prepare plans for a so-called outer port and to put these plans into effect when the time came. The location is unique on Germany's North Sea coast. The natural channel there is more than 20 m deep, so that--quite apart from the outer-port function--a harbour could be built for the largest bulk freighters which--because of the tidal conditions in the Elbe--could no longer reach Hamburg. This off-shore location is an area of complicated hydrodynamic and coastal morphologic processes and interrelations which called for extensive investigations, and a research unit was set up especially for this purpose in 1963. The concentrated and now largely completed research programme has, in addition to the immediate planning objectives, yielded valuable scientific information in the field of coastal engineering. These findings were published in the relevant technical literature and also featured in part at the coastal engineering conferences of recent years. But no doubt you all know this better than I do. My intention is merely to underline the fact that the interests of the seaport of Hamburg and your concern with coastal engineering are closely linked. Your field of interest has always been of particular importance for Hamburg as one of the world's leading ports, and it will continue to be so in the future. That is the reason for our particular pleasure in having you here as our guests.

I hope that, in spite of the demands of the Conference, you will find sufficient time to make the acquaintance of Hamburg, to enjoy its atmosphere, and to gain impressions which will remain with you when

you are back home in your own countries with which Hamburg maintains particular ties in peaceful international trade.

WELCOMING ADDRESS

Dr. Volker Hauff
Federal Minister for Research and Technology
Bonn

Ladies and Gentlemen. On behalf of the Government of the Federal Republic of Germany I would like to extend a cordial welcome to you, the participants of the 16th International Congress on Coastal Engineering in Hamburg.

We are especially pleased that you decided to hold your Congress this year near the North Sea after your last one took place on a very beautiful island in the Pacific. In general, these two places have very little in common. But for coastal engineers, both places--apart from providing a nice environment for meetings--have something to offer which is of professional interest to them: the problems of protection against extremely high water levels.

As you all know, the Federal Republic of Germany is a country with a relatively short coastline. Nevertheless, this shore line has always posed many problems to the population living near to it. Dikes have been constructed in Germany along the sea for roughly 1000 years because the coasts are generally flat, and they have to be protected against the impact of storm floods. One of the last most spectacular ones, the storm tide of 1962, caused heavy damage. The surges of 1973 and 1976 showed that the exceptional storm tide of 1962 was not an isolated incident and that even higher water levels may occur in the future--a prospect which leads to many lively discussions among experts and politicians as well as among the population. Of course, nobody knows exactly what the future has in store for us. But this problem must be regarded, as you will do during this Conference, from a scientific, an engineering and from an economic point of view.

Referring to the economic--and that means financial--aspect of coastal protection, I should like to give you a figure indicative of what the Federal Government is spending on improvements in coastal protection. In 1977 alone grants exceeding DM 120 million were provided and another DM 50 million were spent for this purpose by the Länder. But this is only one year under a long-range programme which is to secure the necessary construction work needed to protect the flat 10,000 square-kilometer near-coast areas. This figure gives you, I think, a good idea of the great importance which the government attaches to coastal protection.

There are also other coastal engineering aspects of concern to the Federal Government. In my country the extension and improvement of the navigable waterways is the task of the Federal Government. Shipping is very important for us: the importation of raw materials

and the exportation of industrial products call for safe and efficient ports. The traditional ports like Hamburg are situated on the large tidal rivers and at a distance of up to 100 km from the coast. The navigation channels from and to the harbours have to be developed for very large ships, and they have to be maintained in good condition in spite of the eternal problems of sediment transportation. Moreover, the development of new port facilities closer to the coast is under consideration by the competent authorities requiring careful planning based on a great number of environmental data.

It is obvious that all these practical aspects of coastal engineering must be supported by extensive research projects. Therefore, both the Federal and the Länder governments operate their own laboratories dealing mainly with project-oriented research, while the universities and their institutions primarily carry out basic engineering research. Cooperation between the various laboratories is of great importance because many of them are too small to handle complex projects which often require huge technical facilities and a substantial amount of support. This cooperation is ensured by the Coordinating Committee for Coastal Engineering (Kuratorium für Forschung im Küsteningenieurwesen).

As the Federal Minister responsible for research and technology, I deem it very important that there is always a continuous exchange and transfer of know-how among the institutions and disciplines involved in order to optimize the process of innovation which, in turn, is a prerequisite for progress in science and engineering. One example which illustrates these needs but also shows the possibilities in coastal engineering is the application of remote sensing techniques which permit collection of environmental data in coastal areas. Aircraft and satellites used as data collection platforms can be of considerable benefit to broaden the knowledge of actual coastal processes.

Furthermore, I should like to emphasize the role which coastal engineers can play in advising the developing countries in their needs to develop and manage their coastal areas. The advice in coastal engineering can be of considerable importance to those countries which want to make use of their natural resources, construct ports, control shore erosion or conserve the natural environment. Coastal engineers may also render advice with regard to problems related to the use of the renewable and unrenewable resources of the coastal area and problems of coastal urbanization. Many countries providing good training programmes in coastal engineering should consider the possibility of initiating training programmes for scientific and technical staff of developing countries in order to help them achieve a professional standard enabling them to manage their own coastal problems.

This International Congress provides--I trust--a good opportunity for advancement, continuation and expansion of international cooperation by the exchange of both theoretical results and experience gained in practical field work. Your programme which covers so wide a range of subjects and envisages papers by experts from so many countries will certainly stimulate discussions and will give new impulses to future research work. I therefore trust that you all will benefit

from your participation in this Congress, and I do hope that you will also enjoy your stay in this city and in this country.

Ladies and Gentlemen, I declare the 16th International Congress on Coastal Engineering open, and I sincerely wish you every success in your task.

WELCOMING ADDRESS

Dr. Hans-Werner Partenscky
Technical University of Hannover

Distinguished guests, dear colleagues and friends, ladies and gentlemen,

Dinner speeches are not very popular, neither for the speaker nor for the listeners. I nevertheless feel obliged to say a few words on this occasion.

First, I should like to extend our sincerest thanks to the American Society of Civil Engineers as well as to the Coastal Engineering Research Council, for the honour shown us in permitting the 16th International Conference on Coastal Engineering to be held in the Federal Republic of Germany here in Hamburg. Also, I should like to thank our guest speakers, Prof. Helge Lundgren from Denmark and Mr. Allan Price from the United Kingdom, for their excellent and stimulating speeches which they delivered to the audience during the Conference. Our thanks are equally extended to all authors for their presentations as well as to all those who participated actively in the scientific discussions. They all contributed in a very fine way to scientific progress in our field of Coastal Engineering.

Ladies and Gentlemen, all of you are certainly aware of the fact that Conferences of this kind are not possible without the moral and financial support of potential sponsors. I would therefore like to take this opportunity to address our sincere thanks to the Free and Hanseatic City of Hamburg and to the Federal Ministry for Research and Technology as well as to the numerous private associations, construction companies and consulting engineering firms--the list of all of them is too long to name them individually--for their generous support which helped us considerably to make possible this congress with its social events.

Ladies and Gentlemen, there is an old French saying which I have cited already on other occasions. It says:

"On ne peut pas aimer toutes les femmes du monde, mais on peut au moins essayer."

If I translate this into English, it goes like this:

"You can't be in love with all the women in the world, but you could at least try."

This is the way we felt in the German Organising Committee when we started with the first preparations for this Conference: "We

thought, we could at least try!" We did not know then what was ahead of us. It was only when we found out, that a considerable burden of our task could be delegated to the "German Convention Service", that we felt we would manage. I should therefore like to extend our sincere thanks at this occasion to Mrs. Lau-Thurner and her charming and effective young assistants for their help in preparing this conference. I should also like to mention the Secretary of our Organising Committee, Dr. Siefert, who was involved in many details of our preparations for almost two years. Thank you, Dr. Siefert, for all your efforts.

Gentlemen, there is one last, but very important thank-you, I have the privilege to extend in your name tonight. I would like to thank all ladies who have accompanied their husbands to this Conference and to this Banquet for being here with us and for being so especially beautiful tonight.

Our field of Coastal Engineering is still a relatively young science and more systematic research work is needed to cope with the impact of waves and storm surges against our coasts, and to develop better and more economical design criteria for coastal works. This is clear to us,--but not necessarily so evident to others. Therefore, when preparing this conference, I was often asked by "outsiders": "Why do we need Coastal Engineering?" The answer was of course easy for me. But being a professional, I felt that some more facts and data were needed to support my opinion on the importance of our field. So, I went deeper into the subject. I first investigated our situation in the Federal Republic of Germany by measuring the length of our coastline, the islands included. I then divided this figure by the population. The result was surprising: only a length of 1.9 m was available per person during the summer season.

Being a serious scientist, I assumed that only 30 percent of our population would be at our German beaches at the same time. The result was still unbelievable: only 6 cm of coastline per capita would then be available during the three summer months. No wonder, that it is so crowded at our German Beaches! To find out if this could have an effect on the stability of our shorelines, I consulted some experts of our German Coast Guard. The answer was astonishing: "The damage caused during the 3 month summer season by the tourists,--and especially by the nudists in the dunes,--is comparable to the damage of two average storm floods!

Now, everyone will understand why we need Coastal Engineering and Shore Protection in Germany. Going further into the subject, I found out that the situation with respect to the available length of shoreline per capita in other countries is not quite as critical as in the Federal Republic of Germany. For example, in the Netherlands we have 5 cm of shoreline per capita, in Japan 8 cm, in England 13 cm, in the USA 66 cm, Denmark 150 cm and Australia 180 cm per capita,--to name a few. However, I was informed that swimming at beaches is only allowed in restricted areas in most of these countries, i.e., the tourists are concentrated at certain spots, which certainly means that other countries need coastal engineering and "people management" too! We can be convinced, therefore, that our efforts of these last days

were not in vain and will certainly help to develop, maintain and protect our coasts all over the world.

Ladies and Gentlemen, our Conference comes to an end. We hope that the scientific program with its presentation of more than 200 contributions from 41 different countries will stimulate and help you in your own further research work and that we will all meet again in good health two years from now to the 17th International Conference on Coastal Engineering to be held in Sidney, Australia.

Let me thank all of you for coming to Hamburg. We all wish to those of you who will participate in one of the after-congress excursions much fun and good weather,—and to all of you a happy return to your home countries.

STRUGGLE OF PHYSICS AND MATHEMATICS
IN COASTAL ENGINEERING

H. Lundgren
Technical University of Denmark

ABSTRACT

This paper gives examples of the separate and combined efforts of Physics and Mathematics in coastal engineering with particular reference to the possibilities in the future. It points to the fact that physical thinking is necessary as an inspiration to mathematical and numerical work.

While there is relatively little duplication of work (among the various institutions) of a purely theoretical character, the same statement does not apply to numerical models. One may hope that the future will produce more coordination in this respect.

There are two disciplines where the establishment of high quality numerical models will require a particularly strong combination of basic research, numerical expertise and field work: three-dimensional mixing processes and sediment problems. It would seem that no single institution has available both the integrated expertise and the capital investment required. Hence, a close cooperation among several institutions is almost mandatory.

1. INTRODUCTION

A perfect Opening Ceremony has set the stage for

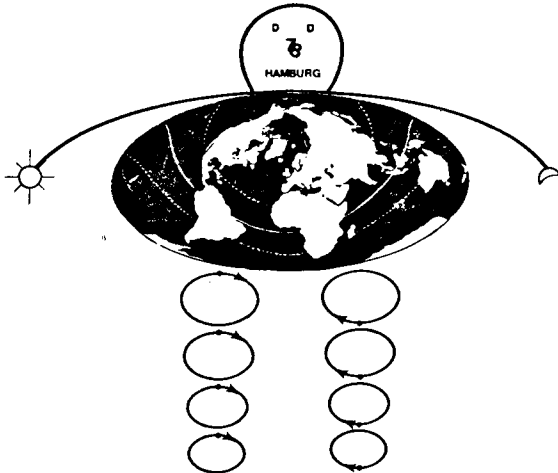

It is indeed a great honour to have been selected by the Organizing Committee to give an invited lecture at such occasion. In addition, it is a very difficult task: Let alone that more than 600 conference participants represent widespread scientific and practical interests within the various fields of coastal engineering; the lecture is also attended by the accompanying ladies.

The first play on this stage has THE CAST:

Mr. PHYSICUS, Master of the play
 Mrs. MATHEMATICA, Mr. Physicus' wife
 Miss NUMERICA, their daughter
 Mr. HARDWARE, Miss Numerica's boyfriend
 Miss SOFTWARE, young girl, often in troubles

Mathematica was married to Physicus at a quite mature age of his. As in all marriages there are both hours of happiness and hours of distress. The serious question about Numerica is: 'Is Physicus her true father or?' If not, very few coastal engineers will respect her. Miss Software is very interested in Mr. Hardware, always trying to get control of him but rarely succeeding!

Mr. PHYSICUS

Physicus was the first figure that entered the stage of Coastal Engineering, both in the sense that harbours and coasts were physical problems, and in the sense that scientific studies normally started with physical models.

Physicus' main disciplines are:

- a. Wave phenomena
- b. Tides, surges and currents
- c. Mixing phenomena
- d. Sediment problems
- e. Structures

2. WAVE PHENOMENA

Regular waves is one of the fields where Mathematica has had her greatest triumphs. She has always been very fond of closed (boundary) problems associated with Laplace' equation.

Before Physicus met her, he had made good progress with propagation considerations in shoaling and refraction by assuming that none of the energy flux was reflected from a gently sloping bed. Without improper interference from Mathematica, he should continue his propagation line of research, basing the description in each vertical of the slope on the time profile, i.e. the variation over the period T . Such approach should offer possibilities of treating the deformation of regular waves towards breaking, as well as broken waves (surf).

Mrs. MATHEMATICA

Naturally, when it comes to basic concepts, there is complete harmony between Physicus and Mathematica. For example, the latter originally derived the radiation stress for small sinusoidal waves in combination with a constant current. Physicus, on the other hand, is inclined to think of it as the wave thrust, $F_w = \bar{F}_m + \bar{F}_p$, where \bar{F}_m is the mean value over the wave period of the momentum force, and \bar{F}_p is the mean value of the pressure force. In establishing the equation of mean momentum, he considers the wave thrust as an analogy to the German 'reaction force' (Reaktionskraft), which was used around 1930 in the theory of steady state flow in hydraulic engineering (Wasserbau).

The wave thrust can be determined for any periodic flow, including breakers and surf. Physicus realizes, however, that the mean values, \bar{F}_m and \bar{F}_p , do not give any information about the variation of the momentum and pressure forces over the period. He knows that the equation of momentum is something much more universal than just its 'mean value over the period'. He likes to dream that the general equation of momentum may be used for studying important problems, such as wave deformation and breaking. Of course, the fact that F_p contains a first order term, where \bar{F}_p is of second order, presumably presents a serious difficulty.

In addition, Physicus recalls that the equation of moment of momentum has been used, in a qualitative manner, to explain the formation of sand bars on a coast as the result of water flowing along the sea bed towards the breaker line, where there is a particularly large part of the momentum force near the wave crest. Could it be that the moment of momentum could also be used to explain the skewness of waves on a slope because of the moment of the pressures exerted on the bed by a wave, the height of which increases as the depth decreases?

There is also complete agreement between Physicus and Mathematica with respect to the mean energy level, which is defined for any periodic potential flow. Physicus has difficulties, however, in seeing how the energy concept could be effectively used for the solution of general problems.

Attention should definitely be drawn to the fairly new concept, wave action, defined as E/ω_r , where E is the total energy of a periodic wave and ω_r its frequency relative to a current. For problems where regular waves are combined with currents it has been proved that the wave action flux and the conservation of wave action are concepts of a fundamental nature, analogous to the energy flux and the conservation of energy in the case of waves without currents.

Relative to the current the wave energy is propagated with the relative wave group velocity, c_{gr} , along the orthogonals. If c_{gr} is vectorially added to the current velocity, the absolute wave group velocity, c_{ga} , results. The direction of c_{ga} is called the wave ray.

For irregular waves the energy is distributed over the frequencies. Hence, it should be possible to apply the wave action concept also to the combination of currents and irregular waves, even with inclusion of the phase and direction information from the waves.

Wave description represents a field where Mathematica has long played a dominant rôle. Firstly, coastal engineers had to work with regular sinusoidal waves. Secondly, cnoidal waves came into the picture; because of the simplifying assumptions necessary, there is not one cnoidal theory but several with some secondary differences. Thirdly, Stokes waves of higher order, up to the fifth, appeared on the stage. In all these cases the waves were periodic and symmetric, even over sloping bed.

Simultaneously with this development, Mathematica transferred the concept 'energy spectrum' from a number of other physical sciences where it had served well since it was introduced in 1923 by Wiener in his 'generalized harmonic analysis'. She has used this tool unscrupulously - with a lot of success too - along our coasts for several decades in spite of two objections: (1) The spectrum is well fit only to a linear Gaussian stochastic process, i.e. a process consisting of

small sinusoidal components. (2) The spectrum throws away half the information (the phase relationships) available in a wave record.

Naturally, Physicus did not like being suppressed by his wife and, indeed, the consequences came about a decade ago when it was discovered that a model wave train with the correct spectrum did not produce one single shock force on a vertical face breakwater. Later on it was realized that the response of moored ships in models could differ much for two wave trains with the same spectrum. And, still worse, the stability of rubble mound breakwaters could be extremely different for two such wave trains.

Miss NUMERICA

Therefore, around 1970 Physicus went into action asking for natural wave trains in his models, also expressed as his desire for the correct wave grouping. The first successes of his action appeared immediately; however, he will have to work very hard together with Mathematica and Numerica before a really satisfactory result will be obtained.

To ask for natural wave trains in physical and numerical models is almost identical to a desire for a deterministic description of natural waves. In two dimensions (wave flumes) it is easy to give such a description under the (quite restrictive) assumption of linear superposition.

In three dimensions the matter is considerably more complicated. For more than a decade rough approximations to directional spectra have been determined by means of arrays of, say, three to five wave recorders. In this context, Mathematica has confined the data analysis to the determination of all the correlation coefficients that could be produced from the records.

Physicus is inclined to prefer a set of three recorders in one vertical (called Point 1): one recording the water surface elevation, η_1 , and two that record the horizontal orbital velocities, u_1 and v_1 . From

Fig. 1 Energy distribution between 0.2265 hz and 0.2535 hz

these three records it is possible, for each frequency interval, and under the assumption of linear superposition, to determine the directions, the amplitudes and the phases of the components.

From such a recording for a storm situation the components of energy in an interval centered around 0.240 hz have been plotted as the individual points shown in Fig. 1. The frequency interval chosen is the one with most energy. Each point represents a vector from the origin of the coordinate system.

With the knowledge of directions, amplitudes and phases at Point 1, the wave motion may be calculated at some other point, called Point 2. An example of this is illustrated by Fig. 2, where the calculated horizontal u_2 -component has been compared with the recorded one. As a first

Fig. 2 Horizontal velocity u_2 at point P_2

attempt the agreement is reasonably good. The discrepancies are probably mainly due to two circumstances: (1) The velocity meters were placed rather low, so their response to higher frequencies was strongly damped. (2) The nonlinear interaction of the wave components has not been taken into account. — In this connection it should be mentioned that the vector from Point 1 to Point 2 has a length of about $1.3 \bar{L}$, where \bar{L} is the mean wave length. The vector forms an angle of 22° with the mean direction of wave energy propagation.

With an embryo of a deterministic description available, Physicus suggests that F_m and F_p be investigated as stochastic processes with a view to a deterministic description of the long waves generated in harbours by the groups of short waves.

Recently this connection between long waves and the short wave groups has been demonstrated by two physical model tests with a moored ship in a harbour, as illustrated by Fig. 3. In the upper part of the figure the surge and sway of the ship, as well as the waves in the harbour, are shown with the irregular wave train $\eta(t)$ as input to the model. In the lower part the same quantities appear when the input is $\eta^2(t)$, smoothed as moving average over 30 s.

Until now the investigation of short wave disturbances in harbours, including motion of moored ships, has been a matter for

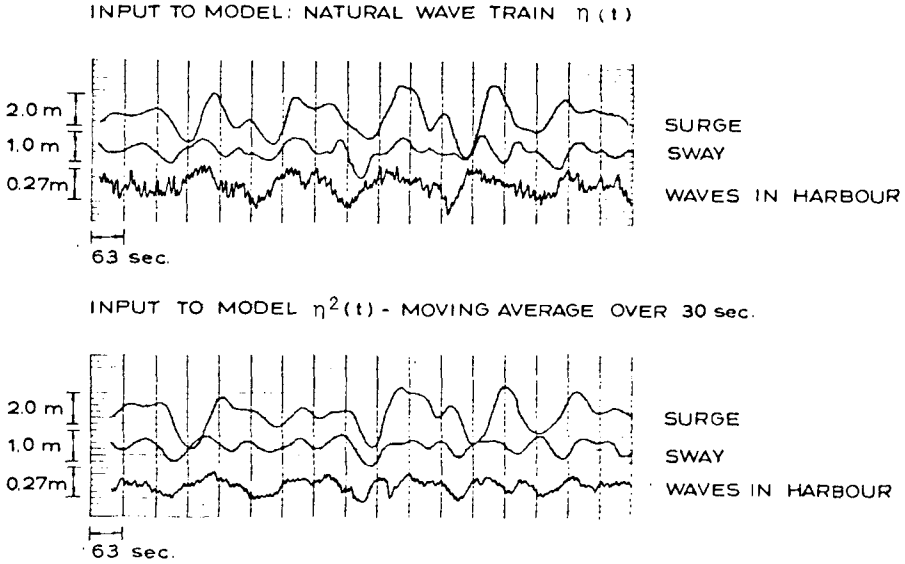

Fig. 3 Ship motions generated by irregular waves and by a simulation of drift forces

physical models exclusively. With Numerica's maturing, however, this field is now within her reach.

Miss SOFTWARE

Provided that the water depth is not too large compared with the essential wave lengths involved, the ordinary shallow water theory may be taken as the starting point. In this theory there are three dependent variables: the surface elevation η and the two horizontal fluxes (p, q) , all of them functions of $(x, y; t)$. Since the vertical accelerations must not be neglected in short waves, four Boussinesq-type terms have to be added to each of the two momentum equations. These terms are mixed derivatives of the third order, which have required special manipulations in order to make Numerica's difference schemes algorithmically efficient. Indeed, in order to handle problems of such complicated nature, Software needed many years of university education.

Fig. 4 shows a perspective plot of regular waves in a Danish harbour, as viewed from the harbour entrance.

Since Numerica handles the three difference equations by a time-step method, Software does not notice any difference whether the waves are regular or irregular. For irregular waves Fig. 5 shows the disturbance coefficients K along two wharfs in the same harbour as above, defined by $K = \bar{H}/\bar{H}_1$, where \bar{H} is the mean wave height at the wharf and \bar{H}_1 the mean height of the incoming wave at the entrance. The full curves present the results from a physical model, whereas the dotted curves are produced by Numerica.

If an essential part of the energy pertains to wavelengths that are rather short in comparison with the depth, as is the case in ocean engineering, the Boussinesq-type equations are not sufficiently accurate. Then Numerica will probably have to handle computations in several layers. This may become economical some time in the future when Hardware is willing to work for a lower salary.

Hindcasting and forecasting of the wave weather is already an important field for Numerica's activity and, without any doubt, the future will show greatly increased activity of higher and higher quality.

As illustrated in Fig. 6, the input to a wind wave model may consist of a series of barometric pressure charts. Conveniently, the output may be a series of charts of significant wave heights.

Mr. HARDWARE

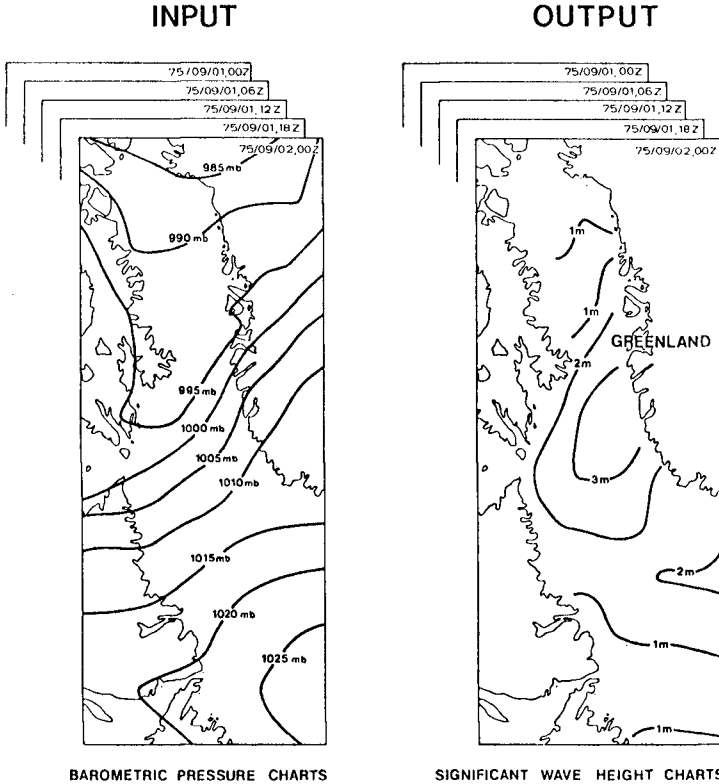

Fig. 6 Input to and output from wind wave model

In order to produce Fig. 6, Numerica discretized the sea surface in $10 \cdot 23 = 230$ grid points with a mesh of 150 km. At each grid point the wave energy was distributed over 12 directions and 10 frequencies, i.e. 120 values. The time step was 3 hours. In the energy transport equation she included both growth and decay terms.

Fig. 7 Variation of wave heights

For a check point near the centre of the area shown in Fig. 6, Fig. 7 gives the variation of the significant wave height during a storm, the full curve indicating the recorded values and the dotted curve the computed ones.

The recorded and computed spectra are compared in Fig. 8. At present the model has a tendency to give peak frequencies that are slightly on the low side. Numerica may remedy this tendency in the future.

Wave breaking has always been, and is still, the wave phenomenon in greatest need of rational treatment, particularly because of its paramount importance for most coastal sediment problems. Qualitative descriptions as spilling, plunging etc. are unsatisfactory. It is hoped that Physicus will soon come up with the combination of quantitative parameters that will characterize the initiation and development of the various breaking processes. Will his thoughts first of all go in the direction of momentum and moment of momentum?

3. TIDES, SURGES AND CURRENTS

In the field of tides and surges, Numerica has been very active in many institutions all over the world, producing a large number of two-dimensional, vertically integrated models. More international coordination at an early stage might have increased the efficiency of intellectual efforts.

Fig. 8 Spectra

In two different ways Numerica may assist Physicus:

(a) Numerica may treat a larger geographic area with Software designed to deliver data for boundary conditions as input to a smaller area physical model and, perhaps, also data for calibration of the physical model. This combination has been termed a 'hybrid model'.

(b) Numerica may study a larger number of alternatives, prior to the selection of a few for detailed studies in a physical model.

4. MIXING PHENOMENA

Numerica has initiated a large number of two-dimensional and some three-dimensional models of stratified flows of different types.

As she has grown up, one is sometimes inclined to think that she has become a member of Women's Lib, trampling upon Physicus, and believing that she could perpetuate life on this globe all by herself, for example by cloning. She could easily get into troubles, however; for example, in the following ways:

(a) By shipping Software as a package with deficiency in physical basis.

(b) By not observing that discretization can lead to scale effects, for instance, in the transport-dispersion equation where the diffusion coefficient D is dependent upon both its physical value and the grid size.

(c) By not noticing that an Eulerian solution of a Lagrangian process, e.g. transport, without special precautions will lead to a non-physical, numerical increase of the dispersion.

A large and important area for Numerica's future activity lies in the continued development of integrated hydrodynamic/water quality models.

5. SEDIMENT PROBLEMS

Because of all the scale effects inherent in physical sediment models, it has long been known that sediment problems will offer a particularly fertile ground for Numerica's activity.

In order to establish a high quality model, the cooperation of many scientists will be required, as illustrated by the following list:

- (a) Basic research on wave breaking.
- (b) Combination of waves and currents.
- (c) Basic research on sediment transport in waves and currents.
- (d) Expertise in constructing fast numerical algorithms.
- (e) Experience in organizing the various numerical modules with different scales in space and time, as illustrated by the scales of waves, currents and sedimentation.
- (f) Good field data for calibration.

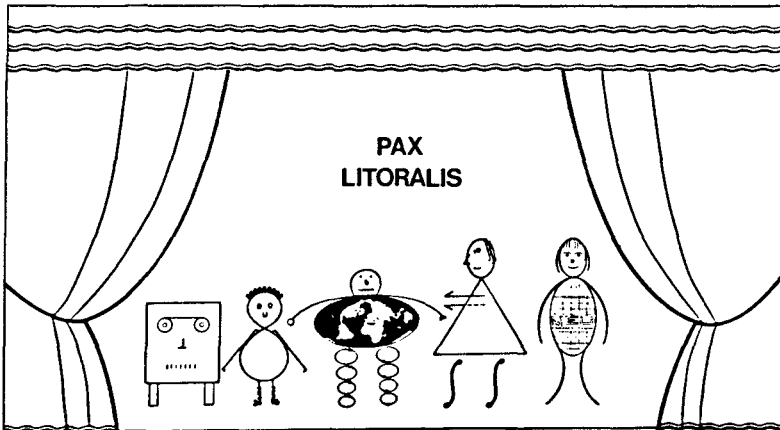

The computer capacity required is so large that Numerica might easily stress Hardware beyond his limits.

6. STRUCTURES

In many cases structures are entirely under Physicus' rule. An important exception is Morison's formula for cylinders. Here C_d has been assumed to be constant over the wave period, whereas Physicus would think that the separation points move and C_d changes with the pressure gradient. On the other hand, it is likely that the pressure gradient always imposes the value $C_m = 2$.

7. END

While the actors of this play thank the audience for their attention, they promise that they will cooperate in harmony in the future. They also express the hope that there will be extended coordination among the Coastal Engineering institutions around the world, and that there will be peace along our coasts.

ACKNOWLEDGEMENT: The author of this paper expresses his best thanks to the German Organizing Committee, as well as his sincere gratitude to all the colleagues who have contributed directly to parts of this paper or indirectly to its philosophy. He has chosen to give no reference, in accordance with the principle: Nobody named, nobody forgotten.

THEME SPEECH by W A PRICE

Senior Principal Scientific Officer
Head of Coastal and Port Engineering Division
Hydraulics Research Station, Wallingford, England

- (i) MODELS - CAN WE LEARN FROM THE PAST?
- (ii) SOME THOUGHTS ON THE DESIGN OF BREAKWATERS

I would like to deal with two quite different subjects. Firstly, the Hydraulic Modelling of Estuaries and Coasts and, secondly, Breakwaters.

MODELS - CAN WE LEARN FROM THE PAST?

Flow visualization

Leonardo da Vinci who lived some 500 years ago gave our profession a fitting motto which is especially applicable to those of us who deal with models. He is reported to have said "When dealing with water first experiment then use judgement". It is appropriate that his name be mentioned at one of our Conferences because he was one of the leading coastal engineers of his day and for part of his life planned and supervised the construction of canal and harbour works over a large part of Middle Italy. He was the first to describe a multiplicity of hydraulic phenomena - the velocity distribution in a vortex, the profiles of free jets, the formation of eddies at abrupt expansions, the propagation, interference and reflection of waves and the hydraulic jump. He was also an experimenter and suggested the technique often used today that internal currents could be observed by means of suspended particles in a glass walled tank, Ref.1. He thus spoke from experience.

One of his drawings showing water flowing past an obstruction is shown in Fig.1a. It records what he observed. However, as a working drawing he realized that it could be improved so that when he sketched

Fig.1 DRAWINGS BY LEONARDO DA VINCI

(a) Flow past an obstruction

water issuing from a rectangular hole in a dam (Fig.1b), he drew the flow like human hair; this was probably the first expression of the concept of flow in stream tubes. There are many other drawings like these which were used in connection with a project to canalise the River Arno in Italy, Ref.2.

(b) Flow from a hole in a dam

I have used these drawings to introduce and underline an important property of physical models - one that is sometimes neglected and played down - the ability to help us visualize the flow. One method of gaining this insight from models is to use floats as in Fig.2.

We have come a long way since Leonardo da Vinci. We now have good instrumentation, sophisticated control equipment, data can be acquired, logged and plotted by mini computer. These are all welcome developments so long as we remember that instruments cannot improve the quality of the processes we are trying to scale and are not a substitute for our eyes.

History of Estuary Models

River models appear to have been first used in France in 1875 when a model was constructed to investigate the suitability of certain river training schemes that had been proposed by a Monsieur Fague. It was Reynolds working about the same time in Manchester, England, who built a model of the estuary of the Mersey and introduced for the first time the general idea of dynamical similarity, Refs. 3, 4 & 5.

Broadly speaking during the history of the development of coastal and estuary models three very distinct ranges of scales have been used.

Fig.2 FLOAT TRACKS IN A MODEL

Reynolds and Vernon Harcourt at the end of the last century built to scales of about 1/30 000 to 1/40 000 although they did use others. Gibson and Allen in the 1920's, Ref.6, built to scales of about 1/3000 to 1/6000, Fig.3, and these days the major laboratories to scales of about 1/500 to 1/1000. Fig.4 shows the comparative sizes of a hypothetical estuary to these scales.

I would discard the 1/30 000 variety as being of little practical use but there are some who would disagree. I am particularly interested in the shift in scale by a factor of, say 6, that has taken place since the 1920's. Has this been entirely justified? Are we sure that it has

Fig.3 MERSEY, DEE AND LIVERPOOL BAY MODEL
Horizontal Scale 1:7040 Vertical Scale 1:190

Fig.4 AN ESTUARY TO DIFFERENT SCALES

Fig.5 SCALE OR SIZE ?

not come about partly because of larger resources and more space being available to the major laboratories?

Scale or size

I would like to pose three more questions. Have certain scales become fashionable? Do we confuse scale with size? Would the person on the right of Fig.5 build models many times larger than the person on the left? I think he might, but this would not be necessary. His house would have to be bigger because that is a question of size but not necessarily his models - that is a question of scale and the problems associated with the reproduction of physical processes. I stress that I would not deny that larger models are better than smaller ones but I would question whether we have the tools to help us decide with any confidence how much better one scale is than another.

I once took a visitor around a model I had built and he was so impressed that on leaving he asked me whether I thought the model was more accurate than the prototype. I thought for a moment and not to disappoint him I said "Yes"! Perhaps we all tend to believe that models are better than we think. What we need to know is how much does the situation improve if we move from one scale to another? My feeling is less than we think. How can we judge? There are methods.

Dimensional Analysis

Yalin has tried to provide a yardstick through the use of dimensionless analysis. The method has been the subject of considerable controversy but it is like any other mathematical tool - used correctly it is a useful device - used incorrectly it can be misleading. He has demonstrated that the theory works by building a model which for practical purposes is close to perfection, Refs. 7 & 8.

Fig.6a shows two flumes, one a 1/3 scale model of the other. From the identity of his dimensionless numbers he was able to choose the properties of the fluids and the bed materials almost exactly. By driving two pumps from a common variable speed drive he was able to obtain the necessary ratio between the model and prototype values of the flow. The bed forms were reproduced perfectly to scale, Fig.6b.

Fig. 6 YALIN'S SIMILARITY FLUMES

(a) General arrangement of flumes

(b) Enlargement of bed features

Again, while working at Wallingford, Yalin made further model/prototype comparisons in a tilting flume. Once more he had control of the variables but because it was a larger facility he was able to make more measurements. He calculated that the wave length of the "prototype" bed features should be 3.6 times greater than those in the model and Fig.7 shows that they were. The ratio of solids discharge should be 47 and that this was the case is illustrated in Fig.8.

Practical Difficulties

Yalin is the first to admit, however, that practical considerations make the criteria of similarity difficult to apply. The model and the prototype are on the same planet and hence subject to the same gravity and there are other physical reasons which make perfect similarity impossible. So of what use is the dimensional method? In the foreword to his book Yalin says "Whether applicable or not the exact solution should be determined and then when it proves impracticable used as a frame of reference to judge the degree of correctness of the adopted solution". That is, we have to compromise but in most cases we do not understand the rules.

Fig. 7 COMPARISON OF WAVE LENGTHS - MODEL AND PROTOTYPE

Fig. 8 COMPARISON OF SOLIDS DISCHARGE - MODEL AND PROTOTYPE

If we knew that the error involved in scaling a particular process was of the form shown in Fig.9 then we could choose an error which was acceptable in making our choice of scales. This hypothetical curve sums up what we need to find out and where some of our fundamental research should be directed. For example, when we relax certain parameters, like the dimensionless ones used by Yalin, what errors are involved?

It is interesting that when Reynolds had finished his studies on the Mersey estuary he set himself the task of learning more about scale by building movable bed models of hypothetical V-shaped estuaries to different scales. We could copy this example to advantage.

Until more fundamental work is carried out the choice of scales for estuary and coastal models will be based too much on practical arguments like these. (i) We need measurable tides and currents to make good measurements. (ii) To keep distortion to a minimum we need a large horizontal scale. There are other practical considerations and they are important but they should only be used as part of a total argument. The scaling of the physical processes and a greater knowledge of them is of fundamental importance.

Fig. 9 HYPOTHETICAL ERROR FUNCTION FOR A PARTICULAR PROCESS TO BE SCALED

Reynolds and Froude Numbers

Until we know more of the rules we must make the most of those we have. I sometimes think that we restrict ourselves unduly by interpreting some of them too rigidly. Take Reynold's Number as an example. The flow in the model needs to be turbulent for no other reason perhaps than that the head loss should be proportional to v^2 rather than v in the laminar case. To avoid laminar flow a limit is put on the Reynold's Number say of 1500. But is the size of this number an even approximate indicator of the level of turbulence in a tidal model? I would suggest that it is not. In this case the flow accelerates and decelerates, there are changes in geometry, there are the turns of the tide - all of which tend to induce and enhance turbulence. One could happily work at much lower Reynolds Numbers and if this is the case one argument that is used against smaller models would partly disappear. Reynolds said "For flow other than in parallel pipes the Reynold's Number at the critical velocity is of course different".

I do not think that we allow ourselves sufficient freedom with the Froude relationship either. Obviously there is little latitude if we are dealing with tidal propagation in a long estuary because the speed of propagation is proportional to $\sqrt{\text{depth}}$ or thereabouts. But there are cases where some relaxation is possible. HRS once built a model of Aberdeen Harbour, Hong Kong, Fig.10 in which we had the ability of increasing the discharges by a factor of 4 over what they would be on a Froude basis, Ref.9. You will see, Fig.11, that allowing for the change in the velocity scale the current velocities at Y, a critical

Fig.10 MODEL OF ABERDEEN HARBOUR
- HONG KONG

Fig.11 CURRENT VELOCITIES AT Y -
(FROUDE AND 4 X FROUDE)

A relaxation of both the Reynold's and Froude criteria allows greater freedom. The model is a tool or an analogue that we can manipulate by making sensible departures but the answer must be right for approximately the right reason. If it isn't then the results we obtain for any changes we make will be wrong. On the fly leaf of some works of fiction they put this phrase - "Any similarity between the characters in this book with those living or dead is purely imaginary". We want to avoid having to put at the beginning of our reports this transcription - "Any similarity between the model and prototype is purely coincidental".

position, are almost identical. I would suggest that this "distortion" in the Froudian velocity scales could be used to advantage in many studies. In sediment transport models it might be a valid way of getting over the problem of the initiation of movement of the sediment.

Instrumentation

What effect does the development of better instruments have on our attitude to model scales? With lasers we can now measure down to a velocity of zero and at a point and with no interference with the flow. This fact alone should encourage us to consider whether we dare go smaller or perhaps what is more important consider reducing vertical exaggeration.

Movable bed models

I would like to say a little more about mobile bed models because it is in this area that physical models of coasts and estuaries can border on the inadequate and where a great deal of interpretation is necessary.

We normally test the validity of a movable bed by running it for some time and then surveying it and making a comparison with nature or with changes that have taken place in nature over a given time. Provided the whole bed is mobile and the surveys agree we say that the sediment transport scale at all points over the mobile area is the same. However, we know even without measurement, that in many of our estuary models the distribution of sediment with depth is quite wrong as illustrated in Fig.12.

What we have at best is a 2 layer model and what we are assuming is that in nature a large proportion of the material is travelling in the bottom layers. It is only in exceptional circumstances, approaching the kind described earlier, that it is a true sediment transport model.

Neither is there any way around the problem of ripple formation which to scale bears no relation to features found in the prototype. In the 1950's claims were made that a material had been found which

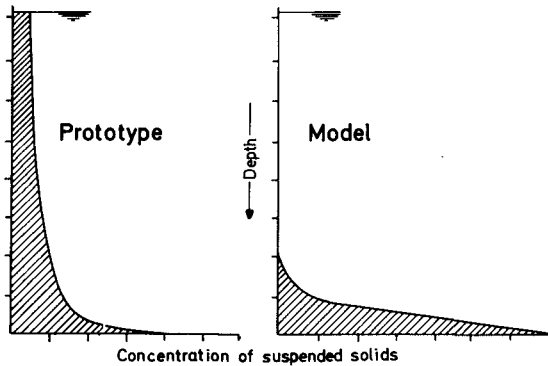

Fig. 12 SKETCH OF SOLIDS CONCENTRATION

would move without rippling. The competition reached something of the intensity that in other periods of our history alchemists tried to turn base metals into gold. At least we know for ripples that the problem is insoluble.

Nevertheless provided we use the technique with care I feel that movable bed models are useful but I would prefer to look on the loose material as an indicator or as a tracer. When used to study changes in small areas they are invaluable, as for example in the study of the improvement that might be achieved over a bar at the entrance to a tidal inlet by a training wall. Here it is justified, in my view, to mould a small area of the model in mobile material as illustrated in Fig.13. In this way the approach flows to the area of interest are maintained by the solid bed - having made the assumption that the depths at the boundaries of the mobile material will remain relatively unaffected by any works that are introduced. Wave-cum-tidal models of this type are quite reliable and relatively easy to manipulate. Littoral drift is promoted by running waves from say two predominant directions. A feature like a bar will form in the right place when the scale of sediment transport under waves equals the scale of sediment transport under tidal currents. Returning to the point made about Froude scales this is under the operator's control to some extent. For example, suppose the bar is forming too close inshore then, in my view, one is justified in dispensing with Froude tidal velocity scales by shortening the tidal period to push the bar out to sea or vice versa.

Fig. 13' TIDAL INLET MODEL

If the flow is canalised between banks as in the upper reaches of our major estuaries then loose material used as an indicator of bed deposition and erosion is a powerful technique.

I would not want to give the impression that the movable bed studies discussed so far are easy to carry out or to interpret but in my view they represent a realistic approach to these sorts of problems. Where we do strike extreme difficulty, however, is in the modelling of the wide approaches to our major estuaries with their multiplicity of banks and channels. Our inadequacies to scale sediment transport in this situation shows up most markedly.

If as I am suggesting we can model sediment transport only approximately, and at certain times hardly at all, then a small increase in the inaccuracy would be neither here nor there. In the 1920's there were movable bed models at scales of 1/3000 but their operators had one important practical advantage over us. If they didn't like the bed material they could change it overnight whereas we are reluctant to dig out 50m³ of expensive material. We tend to make the best of it.

I was in touch with Professor Jack Allen recently. He is a direct link with Reynolds through Gibson. In a letter to me he said this:-

"The reluctance of some researchers to use mobile beds or to experiment with different bed materials is partly their commitment to very large models in which the time required and the expense incurred in moulding, surveying and "proving" have encouraged them to be content in inferring, from observations of water movements alone over a fixed bed, what will happen to sand and silt in a natural estuary as a result of the construction of the proposed works. They, therefore, possibly fail to take sufficient account of the effect on the water movements of alterations to the bed created by the works themselves".

I will develop the theme later that mathematical models or computation are the eventual answers but I would not neglect the possibility that a small physical model and a mathematical model might be a good way to solve some of these problems in the future.

Sediment transport - fixed bed models

Another approach to the sediment transport problem is to build a fixed bed model, observe current velocities and integrate these with field observations of sediment flux, Fig.14.

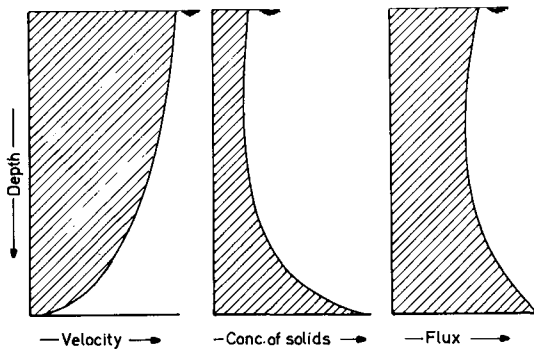

Fig. 14 SEDIMENT FLUX FROM FIXED BED MODELS

We have tried this method at the Hydraulics Research Station but have certainly not exhausted its possibilities. For studies of large areas the difficulties at the moment certainly outweigh the advantages but for studies of small areas it has its merits. The crux of the problem is that the laws of continuity so far as water movements are concerned are certainly satisfied in a physical model but the difficulty is that they cannot be established by measurement with the accuracy required using conventional instruments. I can illustrate the problem as follows. The laws of sediment transport are a high power of the velocity - let us say V^5 for the sake of argument which means that if current velocities are in error by 5% the sediment flux will be out by approximately 25%. The consequences of such an error are obvious. Better current meters of the kind mentioned earlier make this method well worth pursuing.

Mathematical Models

When we talk about problems associated with tidal propagation, current velocities, salinity intrusion, there is a case for using either a physical or a mathematical approach. When it comes to sediment transport the solutions must lie eventually with mathematics, physics and computation. Considerable advances have been made in recent years but our knowledge is still so inadequate we are well advised, as far as possible, to use both techniques together.

The term Mathematical Model, is a misnomer because it belies the important characteristic of this technique - the ability to deal with physics processes full size. Provided we know the laws everything is possible but the problems involved in discovering these laws are formidable. For example, considerable effort has been expended to establish the laws of sediment transport and yet when faced with the problem of estimating maintenance dredging in a tidal cum wave environment we would be glad to get an answer which was accurate to a factor of less than 2.

To describe the way in which topographical features like banks and channels are formed and maintained means reproducing some very complicated secondary processes. The change in velocity, suspended solids, salinity with depth can be accommodated with a multi-layer approach - water and solids being exchanged between layers, but the flow round bends can only be described adequately by building in lateral influences.

I list these difficulties not to detract from the value of Mathematical Models but to remind ourselves that more sophistication means greater costs. What we are creating in building models, both in the physical and mathematical sense, are engineering tools not basic research facilities. A certain scheme to be constructed will only warrant a certain amount of money spent on investigation. The cost of physical model studies has increased considerably over the last 10 years in real terms. In the case of Mathematical Models - new developments hardly ever increase computing time by a factor of 2 - more often a factor of 8 or more. Unless the unit cost of computing comes down to match the extra sophistication they might become too expensive to use, except on some of the larger jobs.

Although I have dealt with the subject of Mathematical modelling rather "en passant" I believe there is a need to keep the advances in this technique and that of physical modelling constantly under review. This should be done in a way that illustrates the strengths and weaknesses of both techniques and where they can be used to advantage together. More contact should be encouraged between mathematical and physical modellers because the two subjects must go hand in hand. Hybrid models will go some way to bringing about a stronger link than exists at present. The possibility of interacting physical and mathematical models in real time has considerable potential for the future.

Summary

- (1) We should not undervalue physical models as visual aids. They give us a view of a situation that we can never get from the prototype.
- (2) We should work towards solving our problems by the smallest model for the job in hand but we do not yet have all the information to make the ultimate choice of scale.
- (3) We should question the way we use the Reynolds and Froude criteria.
- (4) Mathematical and physical models are powerful techniques which should not be seen to be in competition. They should be looked on as complementary to one another. We need both methods to improve the confidence we place on our advice.

SOME IDEAS ON BREAKWATERS

(Continuation of theme speech by W A Price)

Introduction

Many of us I am sure have realized that the science of the design of breakwaters has reached a crucial point in their development. A great deal of work is being done in many parts of the world on many important aspects of the problem and if I do no more than review some of the present day thinking and suggest some lines for further research, I will be well pleased. After producing the first draft of this lecture I read a paper by Magoon & Baird (not published at the time of writing) presented at a Symposium held at the British Hovercraft Corporation on the Isle of Wight, England, which expresses the need to put more science into the subject which is very much the theme of my lecture, Ref.10.

Fig. 15 ALDERNEY BREAKWATER - CHANNEL ISLANDS

History

It would be impossible to say who built the first breakwater. Ever since man realized that he could gain protection from the waves behind a headland he used this principle to protect his boats with stone breakwaters. Hence the beginning is in antiquity. Quite recently Jacques Cousteau in searching for the lost city of Atlantis discovered underwater remains of a Minoan breakwater 4000 years old, Ref.11. However, the first empirical formula for breakwater design did not appear until 1933.

Well known names are attached to the later chapters of the story - Carvalho, Vera Cruz, Irribarren, Epstein, Tyrell, Jackson, Hudson, Davidson and no review of the subject would be complete without acknowledging the excellent pioneering work carried out by the US Army Engineer Waterways Experimental Station, Vicksburg, Refs.12 - 21.

The Hudson Equation

I would like to start by looking at the form and basis of the now famous Hudson equation.

$$W = \frac{\rho_r H^3}{K_D (\rho_r / \rho_w - 1)^3 \cot \alpha}$$

H = Wave height

ρ_r = Specific weight of armouring

ρ_w = Specific weight of water

W = Height of armour unit

α = Slope of breakwater face

K_D = Coefficient of Stability

This is a surprisingly simple equation when you think about the complexity of the phenomena involved - wave breaking, penetration of flow into the bank, run up, interblock friction, hydraulic drag, interlocking and others. It is based on the assumption that regardless of the way in which the waves break the disturbing forces due to drag or lift from plunging or collapsing breakers are proportional to the square of the wave height and displacements will be resisted by the immersed weight of the blocks alone. This theoretical analysis was supported by a series of classical experiments.

Armour Units

Subsequent to the development of this equation there was a dramatic increase in the size of ships which meant that harbours had to be built in deeper water and usually at more exposed sites. Larger stones were required and at some sites these were not available in the necessary sizes or not available at all. It was these factors that led to the development of the multiplicity of armour units we know today.

Perhaps after cubes and other rectangular blocks the Tetrapod, designed by Pierre Danel was the first of these, Fig.16. It is half the weight of an equivalent stone to resist the same wave height. Whether to escape the patent on this block or to satisfy the basic need of engineers to innovate, many other designs have followed, Fig.19.

The designers of these blocks, to a larger or lesser degree, tried to achieve an open structure to provide a permeable assembly, a low centre of gravity and projections to form interlocks with neighbouring units and thus increase their resistance to removal by waves. A saving in the amount of concrete required to make the unit was of primary

Fig. 16 TETRAPOD

Fig. 17 TRIBAR

Fig. 18 DOLOSSE

Fig. 19 ARMOUR UNITS

importance. Interblock friction was brought into play as in the regularly placed Tribar, Fig.17

Merrifield and Zwanborn exploited interlocking in designing the Dolosse which are one fifth to one sixth the weight of a stone to resist the same wave height: a considerable achievement, Ref.22, Fig.18.

One of the simplest and most effective blocks, in my view, is the Tripod designed by Muir-Wood. It is half a cube. The neat thing about it is that being half a cube once you have built one you can reproduce others with very simple form work, Fig.20. The K_D value is about 7.

Need for new approach

Through all these developments the Hudson equation appeared to stand firm and has been used to describe the stability of all blocks. Hudson never claimed that it should, but perhaps he is paying the price of all philosophers in that they are often quoted but never read. He has in fact cautioned that his equation was applicable to quarry stone only. Subsequently, however, and in my view quite rightly, he used his theoretical approach to describe the stability of Tetrapods.

Fig. 20 TRIPOD - METHOD OF CONSTRUCTION

I will develop the thesis that all blocks are not alike - they exploit different qualities to achieve stability and these individual characteristics should be recognised more so than they are at present in any equation that describes their stability. Unless we do then we will not fully understand the behaviour of complicated blocks.

Let me use an analogy. Man has always been faced with the problem of spanning gaps. Through history he has tried to span larger and larger gaps and he has had to employ new methods from beams to arches, cantilevers and catenaries.

I want to use the analogy in two ways. The first is not in the mainstream of the argument but is important and it is this. In the early stages of design do we give enough attention to methods of construction other than rubble mound breakwaters like, for example, Lundgren's caissons? I suspect that we do not but this is a whole debate in itself so I will return to using the analogy in another way.

Bridges exploit the various properties of different materials like stone, concrete, steel, for their stability and this is analysed in different ways. Armour blocks too have various qualities that contribute to their stability. Some of the important ones are weight, interlocking, interblock friction, hydraulic drag, permeability of assembly etc. Qualitatively we can assess the blocks shown in Fig.21 like this

Fig. 21 ARMOUR UNITS - SCALED TO RESIST EQUAL WAVE HEIGHTS

- the stone and the cube rely on weight for their stability, the Tetrapod on weight and a small amount of interlocking, the Tribar on interblock friction and weight and the Dolos on a small amount of weight and a great deal of interlocking. They are certainly not different shaped bits of stone. Any advance on the Hudson equation must, therefore, recognise this and describe a block's stability in terms of these parameters.

[To digress slightly - interlocking is probably difficult to quantify although I would suggest it could perhaps be determined like this. Lay cover layers in the laboratory and determine the force required to remove units from the pack. Forces will vary from those equivalent to the weight of the unit to a force required to remove a block that is fully interlocked. We could express this variation in a dimensionless number of the form say -

$$I = \frac{\text{"Average" force required to remove block}}{\text{Weight of Armour Unit}}$$

This parameter expresses the way a particular block relies on the weight of neighbouring units for its stability.]

Types of failure

Another case for reappraisal is the very different way damage occurs for compact and open forms of block. With compact forms, like stones and Tetrapods, for which no friction or little interlocking is assumed a steady increase of damage is to be expected as the wave attack is extended in time, Fig.22, Ref.23. This pattern of damage is quite different for the blocks of open form with their properties of high interblock friction and interlocking. They exhibit a stiffness which resists damage over an initially large range of wave heights but once the applied forces are high enough to disturb the cover layer a rapid removal of units results and the margin of safety between acceptable damage and failure for closed forms becomes very small and could be well within the range of uncertainty of prediction of the design wave height. We need to take this fact into account in the design. The use of blocks that interlock puts a considerable premium on a good knowledge of the wave climate. I have heard Dean O'Brien call many times for more wave recording. I wholeheartedly agree with him. Highway engineers would not be prepared to design motorways with the lack of information Coastal Engineers are sometimes asked to design breakwaters.

Fig 22 HISTORY OF DAMAGE - STONES AND DOLOSSE

Fig.23 DOLOSSE - EFFECT OF WAVE PERIOD

The influence of wave period

Let me turn to the other side of the equation - the disturbing influence of the waves. Hudson found it quite sufficient to describe the sea in terms of a wave height. Whillock, working with Dolosse and the results have been confirmed by Burcharth, Zwamborn, & Bruun, Ref.26, showed that wave period was also important so far as this armour unit was concerned, Fig.23, Ref.24. Is there a discrepancy with the early Hudson results? I do not think there is. Within the scatter of his results for stone breakwaters there was probably a small period dependence but it was so small that he was justified in ignoring it.

The explanation probably lies partly in the fact that Dolosse with their limbs projecting through the cover layer are subject to much greater drag forces than stones which tend to protect one another in times of high surface currents. These currents are likely to be at their maximum when long period waves surge rather than break on the slope. Brebner shows that the Drag to Weight ratio for stones and Dolosse are almost the same, Ref.25. Quite recently experiments carried out at HRS confirms this fact. However, this does not mean that when they are in a pack that the effective drag to weight ratios are the same. Per Bruun has pointed out the importance of wave resonance and says that "elements that protrude should be avoided", Ref. 26. How dependent on wave period are other units? I do not know but I think we should find out.

Effect of angle of attack

Tests with stone breakwaters and tests done by SOTRAMER with Tetrapods show that their stability increases with angle of attack. This behaviour is quite different for Dolosse, Fig.24. The reason is again the production of high surface currents this time caused by waves running along the breakwater and setting up high drag forces on projecting limbs. The amplification of the wave height due to the Mach-Stem effect further complicates the issue.

Fig. 24 DOLOSSE - EFFECT OF ANGLE OF ATTACK

Every now and again one reads a paper containing an idea which one would have liked to have had oneself. Such a paper was presented at the Hamburg Conference by Brebner, Ref.25. He filled shallow boxes with stones and Dolosse and gradually tipped them about their bottom edge. The failure of the rock occurred at about 50° whereas the Dolosse had an

angle of repose of at least 80° and in one remarkable test 91° . He carried out tests where he layered Dolosse and stone in a tilting flume and ran water over them. The "wipe out" velocity was essentially the same for both the quarystone bed and the one constructed of Dolos. He concluded that "the effectiveness of the Dolos unit is not materially affected by the drag to weight ratio but to its high angle of repose". Interlocking can only be brought fully into play by using Dolosse on steep slopes. Brebner puts it this way - "one can also suggest that the steeper the breakwater slope ... when attacked by normal waves the better the Dolos unit appears to be". He points out that "this is the reason why the stability of Dolosse are affected by the angle of attack whereas stones are not", Ref.24.

Random Sea Testing

Random sea testing has become fairly commonplace in our laboratories although we still continue to argue how best they should be synthesised.

Johnson and Ploeg have questioned whether seas are necessarily random - the implication being that if they are not then the wave groupings will be different, Refs.27 & 28. Shuttler at HRS has measured the frequency of wave groups for a number of wave spectra (Moskowitz, Jonswap and a bimodal spectrum generated using the HRS synthesiser). These compare very favourably with published field data. I still think, however, there is still some debate about this question and more work needs to be done because it is an important one.

Burcharth and Ploeg have shown that coastal structures respond differently when exposed to various wave patterns that contain the same maximum waves: there is a significant influence of succession, Refs.29 & 30. They stress the importance of research into the occurrence and frequency of characteristic wave patterns in wave records so that the results can be incorporated in sea conditions used in model tests. Incidentally Boucherth proposes a new form of the Hudson equation for Dolosse pointing out that it would be appropriate to plot a Stability Number defined as

$$\frac{H}{\left(\frac{W}{\rho_r}\right)^{\frac{1}{3}} \left(\frac{\rho_r}{\rho_w} - 1\right)}$$

against a Surf Similarity parameter (Batjes), Ref.31.

This dimensionless parameter was designed by Batjes and its importance has probably not as yet been fully recognised. It is a convenient way of describing the way in which the wave breaks.

$$\zeta = T \left(\frac{g}{2\pi H}\right) \tan \alpha$$

where H = Wave height

W = Weight of Dolos

- ρ_r = Specific weight of blocks
 ρ_w = Specific weight of water
 T = Zero crossing wave period
 g = acceleration due to gravity
 α = angle of slope

Summary of the Important Parameters

Abernethy, as early as 1970, Ref.32, when carrying out an investigation to provide information for the design of Tribar armouring for a large reclamation project in Botany Bay, New South Wales, developed a similar theme to the one in this lecture when he suggested that any analysis of Tribars, and he could have included other armour units, based upon the Hudson formula must be considered suspect for many reasons. He suggested that the damage function Δ is dependent upon eleven dimensionless parameters. Taking these and adding others we could write a list of some of the more important variables affecting the damage function as follows:-

- | | | |
|--|---|-----------------------|
| (1) Weight of unit | } | Block Characteristics |
| (2) Density of material | | |
| (3) Interblock friction | | |
| (4) Packing Density | | |
| (5) Permeability of Assembly | | |
| (6) Height of Bank | | |
| (7) Hydraulic drag | | |
| (8) Wave Spectrum | } | Disturbing Influences |
| (9) Wave grouping | | |
| (10) Angle of attack | | |
| (11) Water depth | | |
| (12) Number of waves impinging
on slope | | |

The list is formidable and is not complete but it indicates the size of the problem.

Structural Damage

Vasco Costa, Baird, Lalevang, Magoon and Stickland have made major contributions to the subject and have highlighted among other things the problem of wear and the structural stability of the individual units. These are subjects which are worthy of further study. It occurs to me to wonder whether with blocks that interlock there is the possibility that impact loads could be transferred from block to block, and perhaps by chance the combination of forces caused by waves breaking out of phase with loads transferred from unit to unit could be one of the reasons blocks break, Fig.25.

Dolosse

To clear up any misinterpretation of what I might have said I need to say a word about Dolos in particular. There is no doubt that it is a good armour unit and perhaps because it is superior in many respects to others in using the properties of a solid almost to the limit that we must use it with care. Until we understand all its properties we should

not exploit them to the full. I have used Dolosse in this lecture because more work has been done on this unit than any other and believing that they typify the family of blocks that interlock at least qualitatively.

Need for co-operation and further research

Apart from the few painstaking and excellent pieces of work that I have already referred to good designs have been produced based on careful tests but for one reason or another they are not consistent with others in the field and the results are then more or less lost to the science. We must do more experiments where we keep some of the variables constant while varying others.

It seems to be opportune that we should get down to some fundamental research preferably organised on a world wide basis and not rely

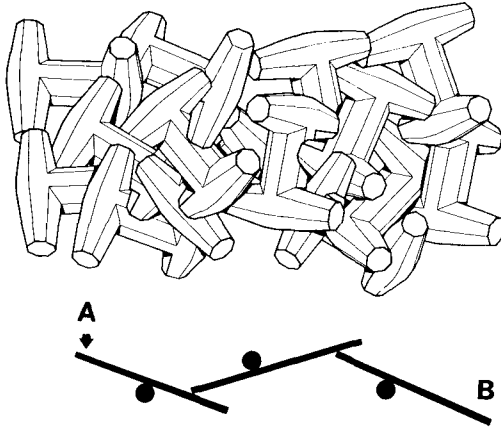

Fig.25 TRANSFER OF LOADS - INTERLOCKING BLOCKS

almost entirely on laboratory testing of specific schemes for insight to the problem. I was glad to hear at the Conference Professor Edge describe plans that ASCE have in this direction.

When writing about armour blocks nearly 30 years ago Pierre Danel, the inventor of the Tetrapod, said this -

"Engineers have too few opportunities for examining an overall problem in a sufficiently disinterested way and for a sufficient length of time. Each one is bound by his specialized field and naturally has a tendency to only consider solutions which entirely satisfy his own particular requirement".

It might sound a small point but if we could only agree about what we mean by certain percentages of damage and failure this would be a considerable step forward.

If we continue to test with the object of getting a stability factor alone we will lose the feel for the subject and our designs will suffer. The improvement of armour blocks has meant that their behaviour has become more and more detached from the supporting theory. One serious consequence is that data obtained from one situation cannot be applied to others. In my view we need to make advances quickly.

ACKNOWLEDGEMENTS

This lecture was given with the permission of the Director of the Hydraulics Research Station, Wallingford. I would particularly like to thank Mr A F Whillock whose ideas are incorporated in the section on breakwaters, Professor Emeritus Jack Allen for his comments and the loan of early slides and many of the staff at HRS for their instructive remarks. To others too numerous to mention I would like to say "Thank You".

The drawings by Leonardo da Vinci are published by permission of the Royal Library, Windsor Castle.

WELCOMING ADDRESS

Dr.-Ing. Karl-Eduard Naumann
President of the Hafenbautechnische Gesellschaft
and
Chairman, Organizing Committee, 16th ICCE

Excellencies, distinguished guests, dear colleagues and friends,
ladies and gentlemen:

On behalf of the Organizing Committee for this 16th International Conference on Coastal Engineering, it is my special privilege as its Chairman to welcome you all very heartily here in the Congress-Center Hamburg to inaugurate a week of lectures and discussions on the manifold problems of Coastal Engineering. The Organizing Committee is very happy about the large number of participants being 621 up to now coming from 41 countries all over the world.

Especially I should like to welcome Mrs. Helga Elstner, second Burgomaster, who is representing the Senate of this Free and Hanseatic City of Hamburg, the host-city for our conference this week. Thank you, Mrs. Burgomaster, for coming here and for your kind readiness to speak to us. In addition, we must give our respectful thanks for the generous sponsorship which the Senate has provided for organizing this conference.

Another special welcome is to Dr. Volker Hauff, Federal Minister for Research and Technology, who has come from Bonn to join this opening ceremony and to speak to us about the viewpoints of the German Federal Government concerning Coastal Engineering, especially the efforts made to defend the low German coast, which, because of its nature is very sensitive to the attacks of the sea. Thank you, Dr. Hauff, for coming and for the assistance and sponsoring your Ministry gave us when we were preparing this conference.

In addition to the Senate of Hamburg and the Federal Ministry for Research and Technology, there are three other sponsors of our conference. First the "Kuratorium für Forschung im Küsteningenieurwesen" which could be translated as the "Committee for Coastal Engineering Research". It is a coordinating and collaboration body of the Federal Republic and four coastal states. The KFKI is supporting our conference by publishing a special issue of the periodical "Die Küste" (the coast), which you all have in your conference-portfolio; it is written both in English and German and gives extensive information about the history and present problem of the German coast as well as pinpointing some features of the relevant research in this country. We are very grateful to the KFKI for this assistance.

The second sponsor is the "Hafenbautechnische Gesellschaft" (HTG), which may be translated as the "Association for Port and Coastal Engineering". This is a scientific association with the aim of studying scientific and practical problems of a technical and economical nature in the following fields:

- planning and constructing ports, port installations and traffic ways within ports;
- operating ports and port installations;
- planning, constructing and operating waterways;
- coastal research and coastal engineering.

This association is the local organizer of our Conference and bears the financial responsibility for it. The Organizing Committee is composed only of members of the HTG.

Last but not least I should gratefully mention the Coastal Engineering Research Council (CERC), borne by the American Society of Civil Engineers under the leadership of our "Grand Old Man" Dean O'Brien and his "Right Hand" Professor Johnson. Since the ICCEs came into existence in 1950, they all have been sponsored by the CERC at least by publishing the proceedings and thus providing the continuity of the respective literature as well as the exchange of the research results.

And now, ladies and gentlemen, let me welcome you all, the participants of this 16th ICCE in Hamburg. After a remarkably long row of conferences held in the past in different countries with different local conditions, the 16th ICCE has been convened to Hamburg, the biggest city of the Federal Republic of Germany, its most important seaport and industrial center. But we hope you will find that Hamburg is also a very beautiful city, worth visiting to enjoy its beautiful features, art treasures, opera and theaters, museums and other attractions. However, it is very difficult for Hamburg to compete with such wonderful settings as Vancouver, Copenhagen and Honolulu, to mention only the sites of the last three Conferences, which, moreover, were all favoured by excellent weather conditions. The Organizing Committee cross their fingers that similar favourable weather conditions will also be granted for this year's conference. After several summer-months spoiled by rain and terrible weather, we hope that now the celestial water reservoirs are empty and you will enjoy Hamburg generally in sunshine.

People in this country are disquieted by the increasing height and frequency of storm surges at our coast. Up to 1961 coastal and harbour engineers worked with a highest high water level, which dated back to 1825. No higher water levels had occurred up to February 1962, when the extreme water level of 1825 was exceeded by about half a meter. Then dikes were damaged heavily at many spots. But the frequency of storm surges continued to grow, and in January 1976 a new alarming water level was measured, which exceeds the peak of 1825 by

nearly one and a half meters. The reasons for this remarkable and disturbing development are contested up to now, as no scientifically founded answer is available on the question of why frequency and peak levels of storm surges at our coast have been growing so vehemently for about 25 years. We see a field of problems here, which will still take much effort to solve. Anyhow, you will understand that due to these facts the public interest in coastal engineering is very lively and widespread in this country. We hope that this conference will make a noteworthy contribution towards solving the problems.

Ladies and gentlemen, I should like to finish my welcoming speech by expressing our sincere thanks for the broad participation in this conference and wishing you all an agreeable and successful time in our country and in this Free and Hanseatic City of Hamburg.

I leave the desk first to Mrs. Burgomaster Helga Elstner, representing the Senate of Hamburg and then to Dr. Volker Hauff, Federal Minister for Research and Technology, representing the Federal Government. Thank you.

WELCOMING ADDRESS

Burgomaster Mrs. Helga Elstner
Senate of the Free and Hanseatic City of Hamburg

Ladies and Gentlemen. In the name of the Senate of the Free and Hanseatic City of Hamburg, and also personally, I welcome you most cordially here in our Congress Centre. We in Hamburg are happy that the International Conference on Coastal Engineering is being held in our city for the first time and that the "Hafenbautechnische Gesellschaft" has been entrusted with its organization.

We are pleased not only because this scientific event animates the diversity of the conference scene here in Hamburg, but also because the people and their representatives in this great seaport have an interest in the topic of coastal engineering which stems quite naturally from its geographical location. This interest in subjects of coastal research is as old as Hamburg itself and goes back almost a thousand years to Hamburg's beginnings as a centre of shipping and trade. Down the centuries they improved and enlarged the port, while the river Elbe, as its link with the sea, was regulated, deepened and protected. In the 14th century, our ancestors built an imposing defensive tower on a small island in the Elbe estuary to protect their shipping. Later on, upon the insecure ground of the shallow and hazardous coastal waters of the rough North Sea, they constructed sea marks, wooden beacons and flares, which had to be well secured against sea attack.

The construction of marks, regulating works along the Elbe as far as the estuary, dike building since the 16th century on the island of Neuwerk and on the coast at Cuxhaven--which belonged to Hamburg from the 14th century until 1937--also the experience and observations of tidal movement, currents, changes in the coastline and other natural phenomena which Hamburg seafarers and pilots collected and evaluated, are part of the knowledge which is now understood worldwide in research and teaching as "coastal engineering".

Stemming from its port interests, Hamburg has in the past made important contributions in this field. I will mention just two examples here. More than a century ago, Heinrich Hübbe, a hydraulics engineer with the authority responsible for the port and the Elbe waterway, and who later became its director, investigated the processes of sand movement in the tidal mudflats of the Elbe estuary and published the results in 1861 in a then epoch-making work. At about the same time Hugo Lentz, another engineer with the same authority, studied the tidal movements in the German Bight. After many years of careful gauge observations, he published the first tide tables for the southern and eastern North Sea coast. Even by our present state of knowledge these show a remarkably high standard of reliability.

But whatever Hamburg's pride in its long history, our attention is focussed very much on the needs of the present. In the field of coastal engineering we are engaged in two tasks which are of the greatest importance:

1. As a tidal harbour and as a city whose limits extend well into the Elbe marshland area, Hamburg is directly affected by the natural phenomena occurring in the North Sea and in the Elbe estuary. Our particular concern here is, of course, the storm tides, which advance in the tidal rivers far into the hinterland. After a long period of relative calm, a great storm tide occurred in 1962 and claimed the lives of many people as well as causing heavy material damage. Steps were immediately taken to make Hamburg safe against future storm tides, but hardly had work been completed before an even higher surge threatened us in 1976. Once again great flood damage was caused, this time particularly in the actual dockland area. These parts now are being well protected. This is a programme which includes not only the building of dikes, flood protection walls, storm barriers, etc., but also research into the problem of storm tides so as to be prepared for possible future developments and, especially, to develop reliable forecasting procedures by which precautions are possible for a good time in advance.
2. A further aspect of our coastal engineering activities is exemplified by a project directly on the North Sea coast. In 1962, following negotiations with the Land of Lower Saxony, Hamburg acquired an area of about 100 km² in the Wadden Sea of the Elbe estuary so as to prepare plans for a so-called outer port and to put these plans into effect when the time came. The location is unique on Germany's North Sea coast. The natural channel there is more than 20 m deep, so that--quite apart from the outer-port function--a harbour could be built for the largest bulk freighters which--because of the tidal conditions in the Elbe--could no longer reach Hamburg. This off-shore location is an area of complicated hydrodynamic and coastal morphologic processes and interrelations which called for extensive investigations, and a research unit was set up especially for this purpose in 1963. The concentrated and now largely completed research programme has, in addition to the immediate planning objectives, yielded valuable scientific information in the field of coastal engineering. These findings were published in the relevant technical literature and also featured in part at the coastal engineering conferences of recent years. But no doubt you all know this better than I do. My intention is merely to underline the fact that the interests of the seaport of Hamburg and your concern with coastal engineering are closely linked. Your field of interest has always been of particular importance for Hamburg as one of the world's leading ports, and it will continue to be so in the future. That is the reason for our particular pleasure in having you here as our guests.

I hope that, in spite of the demands of the Conference, you will find sufficient time to make the acquaintance of Hamburg, to enjoy its atmosphere, and to gain impressions which will remain with you when

you are back home in your own countries with which Hamburg maintains particular ties in peaceful international trade.

WELCOMING ADDRESS

Dr. Volker Hauff
Federal Minister for Research and Technology
Bonn

Ladies and Gentlemen. On behalf of the Government of the Federal Republic of Germany I would like to extend a cordial welcome to you, the participants of the 16th International Congress on Coastal Engineering in Hamburg.

We are especially pleased that you decided to hold your Congress this year near the North Sea after your last one took place on a very beautiful island in the Pacific. In general, these two places have very little in common. But for coastal engineers, both places--apart from providing a nice environment for meetings--have something to offer which is of professional interest to them: the problems of protection against extremely high water levels.

As you all know, the Federal Republic of Germany is a country with a relatively short coastline. Nevertheless, this shore line has always posed many problems to the population living near to it. Dikes have been constructed in Germany along the sea for roughly 1000 years because the coasts are generally flat, and they have to be protected against the impact of storm floods. One of the last most spectacular ones, the storm tide of 1962, caused heavy damage. The surges of 1973 and 1976 showed that the exceptional storm tide of 1962 was not an isolated incident and that even higher water levels may occur in the future--a prospect which leads to many lively discussions among experts and politicians as well as among the population. Of course, nobody knows exactly what the future has in store for us. But this problem must be regarded, as you will do during this Conference, from a scientific, an engineering and from an economic point of view.

Referring to the economic--and that means financial--aspect of coastal protection, I should like to give you a figure indicative of what the Federal Government is spending on improvements in coastal protection. In 1977 alone grants exceeding DM 120 million were provided and another DM 50 million were spent for this purpose by the Länder. But this is only one year under a long-range programme which is to secure the necessary construction work needed to protect the flat 10,000 square-kilometer near-coast areas. This figure gives you, I think, a good idea of the great importance which the government attaches to coastal protection.

There are also other coastal engineering aspects of concern to the Federal Government. In my country the extension and improvement of the navigable waterways is the task of the Federal Government. Shipping is very important for us: the importation of raw materials

and the exportation of industrial products call for safe and efficient ports. The traditional ports like Hamburg are situated on the large tidal rivers and at a distance of up to 100 km from the coast. The navigation channels from and to the harbours have to be developed for very large ships, and they have to be maintained in good condition in spite of the eternal problems of sediment transportation. Moreover, the development of new port facilities closer to the coast is under consideration by the competent authorities requiring careful planning based on a great number of environmental data.

It is obvious that all these practical aspects of coastal engineering must be supported by extensive research projects. Therefore, both the Federal and the Länder governments operate their own laboratories dealing mainly with project-oriented research, while the universities and their institutions primarily carry out basic engineering research. Cooperation between the various laboratories is of great importance because many of them are too small to handle complex projects which often require huge technical facilities and a substantial amount of support. This cooperation is ensured by the Coordinating Committee for Coastal Engineering (Kuratorium für Forschung im Küsteningenieurwesen).

As the Federal Minister responsible for research and technology, I deem it very important that there is always a continuous exchange and transfer of know-how among the institutions and disciplines involved in order to optimize the process of innovation which, in turn, is a prerequisite for progress in science and engineering. One example which illustrates these needs but also shows the possibilities in coastal engineering is the application of remote sensing techniques which permit collection of environmental data in coastal areas. Aircraft and satellites used as data collection platforms can be of considerable benefit to broaden the knowledge of actual coastal processes.

Furthermore, I should like to emphasize the role which coastal engineers can play in advising the developing countries in their needs to develop and manage their coastal areas. The advice in coastal engineering can be of considerable importance to those countries which want to make use of their natural resources, construct ports, control shore erosion or conserve the natural environment. Coastal engineers may also render advice with regard to problems related to the use of the renewable and unrenewable resources of the coastal area and problems of coastal urbanization. Many countries providing good training programmes in coastal engineering should consider the possibility of initiating training programmes for scientific and technical staff of developing countries in order to help them achieve a professional standard enabling them to manage their own coastal problems.

This International Congress provides--I trust--a good opportunity for advancement, continuation and expansion of international cooperation by the exchange of both theoretical results and experience gained in practical field work. Your programme which covers so wide a range of subjects and envisages papers by experts from so many countries will certainly stimulate discussions and will give new impulses to future research work. I therefore trust that you all will benefit

from your participation in this Congress, and I do hope that you will also enjoy your stay in this city and in this country.

Ladies and Gentlemen, I declare the 16th International Congress on Coastal Engineering open, and I sincerely wish you every success in your task.

WELCOMING ADDRESS

Dr. Hans-Werner Partenscky
Technical University of Hannover

Distinguished guests, dear colleagues and friends, ladies and gentlemen,

Dinner speeches are not very popular, neither for the speaker nor for the listeners. I nevertheless feel obliged to say a few words on this occasion.

First, I should like to extend our sincerest thanks to the American Society of Civil Engineers as well as to the Coastal Engineering Research Council, for the honour shown us in permitting the 16th International Conference on Coastal Engineering to be held in the Federal Republic of Germany here in Hamburg. Also, I should like to thank our guest speakers, Prof. Helge Lundgren from Denmark and Mr. Allan Price from the United Kingdom, for their excellent and stimulating speeches which they delivered to the audience during the Conference. Our thanks are equally extended to all authors for their presentations as well as to all those who participated actively in the scientific discussions. They all contributed in a very fine way to scientific progress in our field of Coastal Engineering.

Ladies and Gentlemen, all of you are certainly aware of the fact that Conferences of this kind are not possible without the moral and financial support of potential sponsors. I would therefore like to take this opportunity to address our sincere thanks to the Free and Hanseatic City of Hamburg and to the Federal Ministry for Research and Technology as well as to the numerous private associations, construction companies and consulting engineering firms--the list of all of them is too long to name them individually--for their generous support which helped us considerably to make possible this congress with its social events.

Ladies and Gentlemen, there is an old French saying which I have cited already on other occasions. It says:

"On ne peut pas aimer toutes les femmes du monde, mais on peut au moins essayer."

If I translate this into English, it goes like this:

"You can't be in love with all the women in the world, but you could at least try."

This is the way we felt in the German Organising Committee when we started with the first preparations for this Conference: "We

thought, we could at least try!" We did not know then what was ahead of us. It was only when we found out, that a considerable burden of our task could be delegated to the "German Convention Service", that we felt we would manage. I should therefore like to extend our sincere thanks at this occasion to Mrs. Lau-Thurner and her charming and effective young assistants for their help in preparing this conference. I should also like to mention the Secretary of our Organising Committee, Dr. Siefert, who was involved in many details of our preparations for almost two years. Thank you, Dr. Siefert, for all your efforts.

Gentlemen, there is one last, but very important thank-you, I have the privilege to extend in your name tonight. I would like to thank all ladies who have accompanied their husbands to this Conference and to this Banquet for being here with us and for being so especially beautiful tonight.

Our field of Coastal Engineering is still a relatively young science and more systematic research work is needed to cope with the impact of waves and storm surges against our coasts, and to develop better and more economical design criteria for coastal works. This is clear to us,--but not necessarily so evident to others. Therefore, when preparing this conference, I was often asked by "outsiders": "Why do we need Coastal Engineering?" The answer was of course easy for me. But being a professional, I felt that some more facts and data were needed to support my opinion on the importance of our field. So, I went deeper into the subject. I first investigated our situation in the Federal Republic of Germany by measuring the length of our coastline, the islands included. I then divided this figure by the population. The result was surprising: only a length of 1.9 m was available per person during the summer season.

Being a serious scientist, I assumed that only 30 percent of our population would be at our German beaches at the same time. The result was still unbelievable: only 6 cm of coastline per capita would then be available during the three summer months. No wonder, that it is so crowded at our German Beaches! To find out if this could have an effect on the stability of our shorelines, I consulted some experts of our German Coast Guard. The answer was astonishing: "The damage caused during the 3 month summer season by the tourists,--and especially by the nudists in the dunes,--is comparable to the damage of two average storm floods!

Now, everyone will understand why we need Coastal Engineering and Shore Protection in Germany. Going further into the subject, I found out that the situation with respect to the available length of shoreline per capita in other countries is not quite as critical as in the Federal Republic of Germany. For example, in the Netherlands we have 5 cm of shoreline per capita, in Japan 8 cm, in England 13 cm, in the USA 66 cm, Denmark 150 cm and Australia 180 cm per capita,--to name a few. However, I was informed that swimming at beaches is only allowed in restricted areas in most of these countries, i.e., the tourists are concentrated at certain spots, which certainly means that other countries need coastal engineering and "people management" too! We can be convinced, therefore, that our efforts of these last days

were not in vain and will certainly help to develop, maintain and protect our coasts all over the world.

Ladies and Gentlemen, our Conference comes to an end. We hope that the scientific program with its presentation of more than 200 contributions from 41 different countries will stimulate and help you in your own further research work and that we will all meet again in good health two years from now to the 17th International Conference on Coastal Engineering to be held in Sidney, Australia.

Let me thank all of you for coming to Hamburg. We all wish to those of you who will participate in one of the after-congress excursions much fun and good weather,—and to all of you a happy return to your home countries.

STRUGGLE OF PHYSICS AND MATHEMATICS
IN COASTAL ENGINEERING

H. Lundgren
Technical University of Denmark

ABSTRACT

This paper gives examples of the separate and combined efforts of Physics and Mathematics in coastal engineering with particular reference to the possibilities in the future. It points to the fact that physical thinking is necessary as an inspiration to mathematical and numerical work.

While there is relatively little duplication of work (among the various institutions) of a purely theoretical character, the same statement does not apply to numerical models. One may hope that the future will produce more coordination in this respect.

There are two disciplines where the establishment of high quality numerical models will require a particularly strong combination of basic research, numerical expertise and field work: three-dimensional mixing processes and sediment problems. It would seem that no single institution has available both the integrated expertise and the capital investment required. Hence, a close cooperation among several institutions is almost mandatory.

1. INTRODUCTION

A perfect Opening Ceremony has set the stage for

It is indeed a great honour to have been selected by the Organizing Committee to give an invited lecture at such occasion. In addition, it is a very difficult task: Let alone that more than 600 conference participants represent widespread scientific and practical interests within the various fields of coastal engineering; the lecture is also attended by the accompanying ladies.

The first play on this stage has THE CAST:

Mr. PHYSICUS, Master of the play
 Mrs. MATHEMATICA, Mr. Physicus' wife
 Miss NUMERICA, their daughter
 Mr. HARDWARE, Miss Numerica's boyfriend
 Miss SOFTWARE, young girl, often in troubles

Mathematica was married to Physicus at a quite mature age of his. As in all marriages there are both hours of happiness and hours of distress. The serious question about Numerica is: 'Is Physicus her true father or?' If not, very few coastal engineers will respect her. Miss Software is very interested in Mr. Hardware, always trying to get control of him but rarely succeeding!

Mr. PHYSICUS

Physicus was the first figure that entered the stage of Coastal Engineering, both in the sense that harbours and coasts were physical problems, and in the sense that scientific studies normally started with physical models.

Physicus' main disciplines are:

- a. Wave phenomena
- b. Tides, surges and currents
- c. Mixing phenomena
- d. Sediment problems
- e. Structures

2. WAVE PHENOMENA

Regular waves is one of the fields where Mathematica has had her greatest triumphs. She has always been very fond of closed (boundary) problems associated with Laplace' equation.

Before Physicus met her, he had made good progress with propagation considerations in shoaling and refraction by assuming that none of the energy flux was reflected from a gently sloping bed. Without improper interference from Mathematica, he should continue his propagation line of research, basing the description in each vertical of the slope on the time profile, i.e. the variation over the period T . Such approach should offer possibilities of treating the deformation of regular waves towards breaking, as well as broken waves (surf).

Mrs. MATHEMATICA

Naturally, when it comes to basic concepts, there is complete harmony between Physicus and Mathematica. For example, the latter originally derived the radiation stress for small sinusoidal waves in combination with a constant current. Physicus, on the other hand, is inclined to think of it as the wave thrust, $F_w = \bar{F}_m + \bar{F}_p$, where \bar{F}_m is the mean value over the wave period of the momentum force, and \bar{F}_p is the mean value of the pressure force. In establishing the equation of mean momentum, he considers the wave thrust as an analogy to the German 'reaction force' (Reaktionskraft), which was used around 1930 in the theory of steady state flow in hydraulic engineering (Wasserbau).

The wave thrust can be determined for any periodic flow, including breakers and surf. Physicus realizes, however, that the mean values, \bar{F}_m and \bar{F}_p , do not give any information about the variation of the momentum and pressure forces over the period. He knows that the equation of momentum is something much more universal than just its 'mean value over the period'. He likes to dream that the general equation of momentum may be used for studying important problems, such as wave deformation and breaking. Of course, the fact that F_p contains a first order term, where \bar{F}_p is of second order, presumably presents a serious difficulty.

In addition, Physicus recalls that the equation of moment of momentum has been used, in a qualitative manner, to explain the formation of sand bars on a coast as the result of water flowing along the sea bed towards the breaker line, where there is a particularly large part of the momentum force near the wave crest. Could it be that the moment of momentum could also be used to explain the skewness of waves on a slope because of the moment of the pressures exerted on the bed by a wave, the height of which increases as the depth decreases?

There is also complete agreement between Physicus and Mathematica with respect to the mean energy level, which is defined for any periodic potential flow. Physicus has difficulties, however, in seeing how the energy concept could be effectively used for the solution of general problems.

Attention should definitely be drawn to the fairly new concept, wave action, defined as E/ω_r , where E is the total energy of a periodic wave and ω_r its frequency relative to a current. For problems where regular waves are combined with currents it has been proved that the wave action flux and the conservation of wave action are concepts of a fundamental nature, analogous to the energy flux and the conservation of energy in the case of waves without currents.

Relative to the current the wave energy is propagated with the relative wave group velocity, c_{gr} , along the orthogonals. If c_{gr} is vectorially added to the current velocity, the absolute wave group velocity, c_{ga} , results. The direction of c_{ga} is called the wave ray.

For irregular waves the energy is distributed over the frequencies. Hence, it should be possible to apply the wave action concept also to the combination of currents and irregular waves, even with inclusion of the phase and direction information from the waves.

Wave description represents a field where Mathematica has long played a dominant rôle. Firstly, coastal engineers had to work with regular sinusoidal waves. Secondly, cnoidal waves came into the picture; because of the simplifying assumptions necessary, there is not one cnoidal theory but several with some secondary differences. Thirdly, Stokes waves of higher order, up to the fifth, appeared on the stage. In all these cases the waves were periodic and symmetric, even over sloping bed.

Simultaneously with this development, Mathematica transferred the concept 'energy spectrum' from a number of other physical sciences where it had served well since it was introduced in 1923 by Wiener in his 'generalized harmonic analysis'. She has used this tool unscrupulously - with a lot of success too - along our coasts for several decades in spite of two objections: (1) The spectrum is well fit only to a linear Gaussian stochastic process, i.e. a process consisting of

small sinusoidal components. (2) The spectrum throws away half the information (the phase relationships) available in a wave record.

Naturally, Physicus did not like being suppressed by his wife and, indeed, the consequences came about a decade ago when it was discovered that a model wave train with the correct spectrum did not produce one single shock force on a vertical face breakwater. Later on it was realized that the response of moored ships in models could differ much for two wave trains with the same spectrum. And, still worse, the stability of rubble mound breakwaters could be extremely different for two such wave trains.

Therefore, around 1970 Physicus went into action asking for natural wave trains in his models, also expressed as his desire for the correct wave grouping. The first successes of his action appeared immediately; however, he will have to work very hard together with Mathematica and Numerica before a really satisfactory result will be obtained.

To ask for natural wave trains in physical and numerical models is almost identical to a desire for a deterministic description of natural waves. In two dimensions (wave flumes) it is easy to give such a description under the (quite restrictive) assumption of linear superposition.

In three dimensions the matter is considerably more complicated. For more than a decade rough approximations to directional spectra have been determined by means of arrays of, say, three to five wave recorders. In this context, Mathematica has confined the data analysis to the determination of all the correlation coefficients that could be produced from the records.

Physicus is inclined to prefer a set of three recorders in one vertical (called Point 1): one recording the water surface elevation, η_1 , and two that record the horizontal orbital velocities, u_1 and v_1 . From

Fig. 1 Energy distribution between 0.2265 hz and 0.2535 hz

these three records it is possible, for each frequency interval, and under the assumption of linear superposition, to determine the directions, the amplitudes and the phases of the components.

From such a recording for a storm situation the components of energy in an interval centered around 0.240 hz have been plotted as the individual points shown in Fig. 1. The frequency interval chosen is the one with most energy. Each point represents a vector from the origin of the coordinate system.

With the knowledge of directions, amplitudes and phases at Point 1, the wave motion may be calculated at some other point, called Point 2. An example of this is illustrated by Fig. 2, where the calculated horizontal u_2 -component has been compared with the recorded one. As a first

Fig. 2 Horizontal velocity u_2 at point P_2

attempt the agreement is reasonably good. The discrepancies are probably mainly due to two circumstances: (1) The velocity meters were placed rather low, so their response to higher frequencies was strongly damped. (2) The nonlinear interaction of the wave components has not been taken into account. — In this connection it should be mentioned that the vector from Point 1 to Point 2 has a length of about $1.3 \bar{L}$, where \bar{L} is the mean wave length. The vector forms an angle of 22° with the mean direction of wave energy propagation.

With an embryo of a deterministic description available, Physicus suggests that F_m and F_p be investigated as stochastic processes with a view to a deterministic description of the long waves generated in harbours by the groups of short waves.

Recently this connection between long waves and the short wave groups has been demonstrated by two physical model tests with a moored ship in a harbour, as illustrated by Fig. 3. In the upper part of the figure the surge and sway of the ship, as well as the waves in the harbour, are shown with the irregular wave train $\eta(t)$ as input to the model. In the lower part the same quantities appear when the input is $\eta^2(t)$, smoothed as moving average over 30 s.

Until now the investigation of short wave disturbances in harbours, including motion of moored ships, has been a matter for

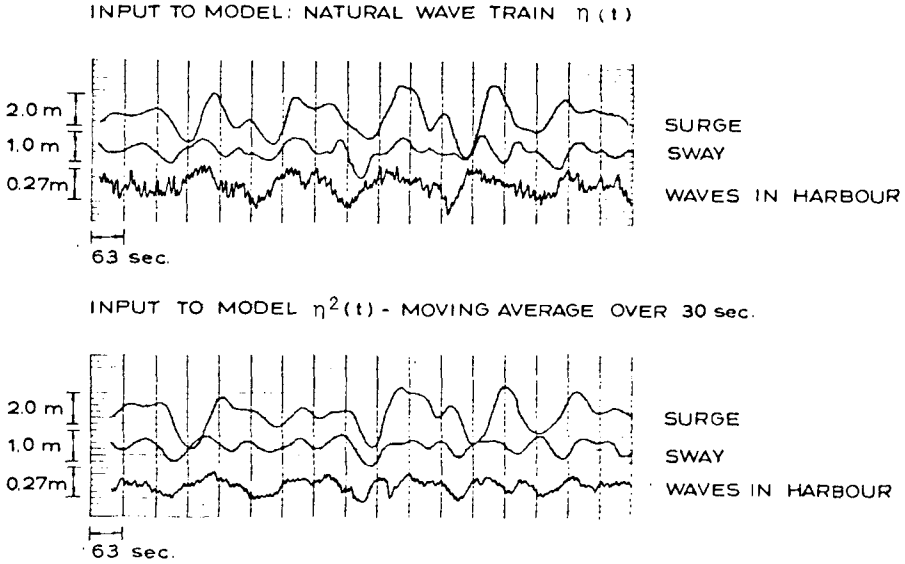

Fig. 3 Ship motions generated by irregular waves and by a simulation of drift forces

physical models exclusively. With Numerica's maturing, however, this field is now within her reach.

Miss SOFTWARE

Provided that the water depth is not too large compared with the essential wave lengths involved, the ordinary shallow water theory may be taken as the starting point. In this theory there are three dependent variables: the surface elevation η and the two horizontal fluxes (p, q) , all of them functions of $(x, y; t)$. Since the vertical accelerations must not be neglected in short waves, four Boussinesq-type terms have to be added to each of the two momentum equations. These terms are mixed derivatives of the third order, which have required special manipulations in order to make Numerica's difference schemes algorithmically efficient. Indeed, in order to handle problems of such complicated nature, Software needed many years of university education.

Fig. 4 shows a perspective plot of regular waves in a Danish harbour, as viewed from the harbour entrance.

Since Numerica handles the three difference equations by a time-step method, Software does not notice any difference whether the waves are regular or irregular. For irregular waves Fig. 5 shows the disturbance coefficients K along two wharfs in the same harbour as above, defined by $K = \bar{H}/\bar{H}_1$, where \bar{H} is the mean wave height at the wharf and \bar{H}_1 the mean height of the incoming wave at the entrance. The full curves present the results from a physical model, whereas the dotted curves are produced by Numerica.

Fig. 4 Regular waves in the outer harbour

Fig. 5 Mean wave height coefficients in the inner harbour

The above results provide convincing evidence that, on the whole, time-step methods are superior over other methods, particularly because of their ability to deal with nonlinear terms and their capacity for being extended to more general problems.

If an essential part of the energy pertains to wavelengths that are rather short in comparison with the depth, as is the case in ocean engineering, the Boussinesq-type equations are not sufficiently accurate. Then Numerica will probably have to handle computations in several layers. This may become economical some time in the future when Hardware is willing to work for a lower salary.

Hindcasting and forecasting of the wave weather is already an important field for Numerica's activity and, without any doubt, the future will show greatly increased activity of higher and higher quality.

As illustrated in Fig. 6, the input to a wind wave model may consist of a series of barometric pressure charts. Conveniently, the output may be a series of charts of significant wave heights.

Mr. HARDWARE

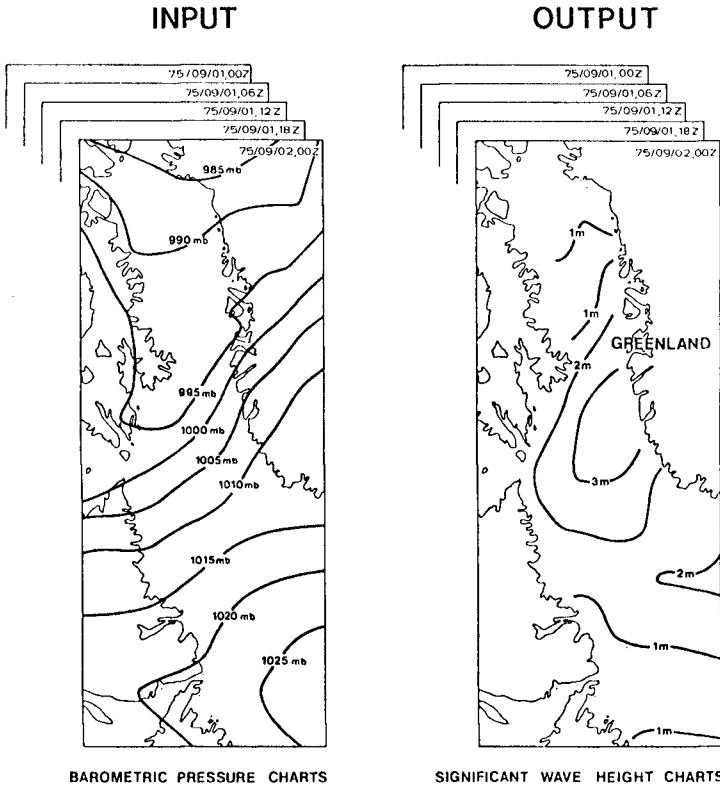

Fig. 6 Input to and output from wind wave model

In order to produce Fig. 6, Numerica discretized the sea surface in $10 \cdot 23 = 230$ grid points with a mesh of 150 km. At each grid point the wave energy was distributed over 12 directions and 10 frequencies, i.e. 120 values. The time step was 3 hours. In the energy transport equation she included both growth and decay terms.

Fig. 7 Variation of wave heights

For a check point near the centre of the area shown in Fig. 6, Fig. 7 gives the variation of the significant wave height during a storm, the full curve indicating the recorded values and the dotted curve the computed ones.

The recorded and computed spectra are compared in Fig. 8. At present the model has a tendency to give peak frequencies that are slightly on the low side. Numerica may remedy this tendency in the future.

Wave breaking has always been, and is still, the wave phenomenon in greatest need of rational treatment, particularly because of its paramount importance for most coastal sediment problems. Qualitative descriptions as spilling, plunging etc. are unsatisfactory. It is hoped that Physicus will soon come up with the combination of quantitative parameters that will characterize the initiation and development of the various breaking processes. Will his thoughts first of all go in the direction of momentum and moment of momentum?

3. TIDES, SURGES AND CURRENTS

In the field of tides and surges, Numerica has been very active in many institutions all over the world, producing a large number of two-dimensional, vertically integrated models. More international coordination at an early stage might have increased the efficiency of intellectual efforts.

Fig. 8 Spectra

In two different ways Numerica may assist Physicus:

(a) Numerica may treat a larger geographic area with Software designed to deliver data for boundary conditions as input to a smaller area physical model and, perhaps, also data for calibration of the physical model. This combination has been termed a 'hybrid model'.

(b) Numerica may study a larger number of alternatives, prior to the selection of a few for detailed studies in a physical model.

4. MIXING PHENOMENA

Numerica has initiated a large number of two-dimensional and some three-dimensional models of stratified flows of different types.

As she has grown up, one is sometimes inclined to think that she has become a member of Women's Lib, trampling upon Physicus, and believing that she could perpetuate life on this globe all by herself, for example by cloning. She could easily get into troubles, however; for example, in the following ways:

(a) By shipping Software as a package with deficiency in physical basis.

(b) By not observing that discretization can lead to scale effects, for instance, in the transport-dispersion equation where the diffusion coefficient D is dependent upon both its physical value and the grid size.

(c) By not noticing that an Eulerian solution of a Lagrangian process, e.g. transport, without special precautions will lead to a non-physical, numerical increase of the dispersion.

A large and important area for Numerica's future activity lies in the continued development of integrated hydrodynamic/water quality models.

5. SEDIMENT PROBLEMS

Because of all the scale effects inherent in physical sediment models, it has long been known that sediment problems will offer a particularly fertile ground for Numerica's activity.

In order to establish a high quality model, the cooperation of many scientists will be required, as illustrated by the following list:

- (a) Basic research on wave breaking.
- (b) Combination of waves and currents.
- (c) Basic research on sediment transport in waves and currents.
- (d) Expertise in constructing fast numerical algorithms.
- (e) Experience in organizing the various numerical modules with different scales in space and time, as illustrated by the scales of waves, currents and sedimentation.
- (f) Good field data for calibration.

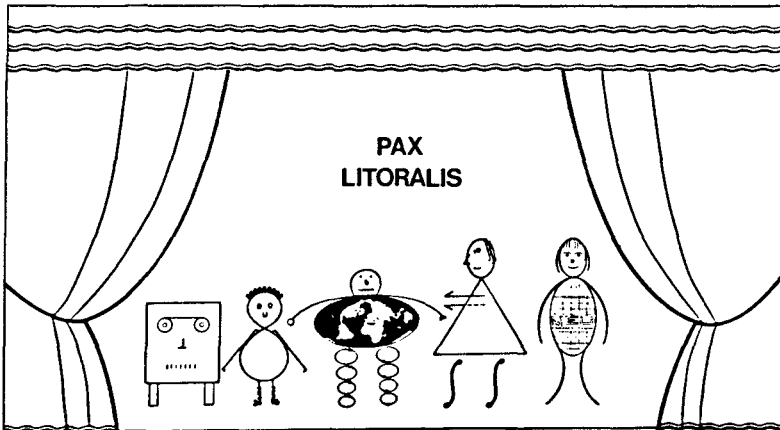

The computer capacity required is so large that Numerica might easily stress Hardware beyond his limits.

6. STRUCTURES

In many cases structures are entirely under Physicus' rule. An important exception is Morison's formula for cylinders. Here C_d has been assumed to be constant over the wave period, whereas Physicus would think that the separation points move and C_d changes with the pressure gradient. On the other hand, it is likely that the pressure gradient always imposes the value $C_m = 2$.

7. END

While the actors of this play thank the audience for their attention, they promise that they will cooperate in harmony in the future. They also express the hope that there will be extended coordination among the Coastal Engineering institutions around the world, and that there will be peace along our coasts.

ACKNOWLEDGEMENT: The author of this paper expresses his best thanks to the German Organizing Committee, as well as his sincere gratitude to all the colleagues who have contributed directly to parts of this paper or indirectly to its philosophy. He has chosen to give no reference, in accordance with the principle: Nobody named, nobody forgotten.

THEME SPEECH by W A PRICE

Senior Principal Scientific Officer
Head of Coastal and Port Engineering Division
Hydraulics Research Station, Wallingford, England

- (i) MODELS - CAN WE LEARN FROM THE PAST?
- (ii) SOME THOUGHTS ON THE DESIGN OF BREAKWATERS

I would like to deal with two quite different subjects. Firstly, the Hydraulic Modelling of Estuaries and Coasts and, secondly, Breakwaters.

MODELS - CAN WE LEARN FROM THE PAST?

Flow visualization

Leonardo da Vinci who lived some 500 years ago gave our profession a fitting motto which is especially applicable to those of us who deal with models. He is reported to have said "When dealing with water first experiment then use judgement". It is appropriate that his name be mentioned at one of our Conferences because he was one of the leading coastal engineers of his day and for part of his life planned and supervised the construction of canal and harbour works over a large part of Middle Italy. He was the first to describe a multiplicity of hydraulic phenomena - the velocity distribution in a vortex, the profiles of free jets, the formation of eddies at abrupt expansions, the propagation, interference and reflection of waves and the hydraulic jump. He was also an experimenter and suggested the technique often used today that internal currents could be observed by means of suspended particles in a glass walled tank, Ref.1. He thus spoke from experience.

One of his drawings showing water flowing past an obstruction is shown in Fig.1a. It records what he observed. However, as a working drawing he realized that it could be improved so that when he sketched

Fig.1 DRAWINGS BY LEONARDO DA VINCI

(a) Flow past an obstruction

water issuing from a rectangular hole in a dam (Fig.1b), he drew the flow like human hair; this was probably the first expression of the concept of flow in stream tubes. There are many other drawings like these which were used in connection with a project to canalise the River Arno in Italy, Ref.2.

(b) Flow from a hole in a dam

I have used these drawings to introduce and underline an important property of physical models - one that is sometimes neglected and played down - the ability to help us visualize the flow. One method of gaining this insight from models is to use floats as in Fig.2.

We have come a long way since Leonardo da Vinci. We now have good instrumentation, sophisticated control equipment, data can be acquired, logged and plotted by mini computer. These are all welcome developments so long as we remember that instruments cannot improve the quality of the processes we are trying to scale and are not a substitute for our eyes.

History of Estuary Models

River models appear to have been first used in France in 1875 when a model was constructed to investigate the suitability of certain river training schemes that had been proposed by a Monsieur Fague. It was Reynolds working about the same time in Manchester, England, who built a model of the estuary of the Mersey and introduced for the first time the general idea of dynamical similarity, Refs. 3, 4 & 5.

Broadly speaking during the history of the development of coastal and estuary models three very distinct ranges of scales have been used.

Fig.2 FLOAT TRACKS IN A MODEL

Reynolds and Vernon Harcourt at the end of the last century built to scales of about 1/30 000 to 1/40 000 although they did use others. Gibson and Allen in the 1920's, Ref.6, built to scales of about 1/3000 to 1/6000, Fig.3, and these days the major laboratories to scales of about 1/500 to 1/1000. Fig.4 shows the comparative sizes of a hypothetical estuary to these scales.

I would discard the 1/30 000 variety as being of little practical use but there are some who would disagree. I am particularly interested in the shift in scale by a factor of, say 6, that has taken place since the 1920's. Has this been entirely justified? Are we sure that it has

Fig.3 MERSEY, DEE AND LIVERPOOL BAY MODEL
Horizontal Scale 1:7040 Vertical Scale 1:190

Fig.4 AN ESTUARY TO DIFFERENT SCALES

Fig.5 SCALE OR SIZE ?

not come about partly because of larger resources and more space being available to the major laboratories?

Scale or size

I would like to pose three more questions. Have certain scales become fashionable? Do we confuse scale with size? Would the person on the right of Fig.5 build models many times larger than the person on the left? I think he might, but this would not be necessary. His house would have to be bigger because that is a question of size but not necessarily his models - that is a question of scale and the problems associated with the reproduction of physical processes. I stress that I would not deny that larger models are better than smaller ones but I would question whether we have the tools to help us decide with any confidence how much better one scale is than another.

I once took a visitor around a model I had built and he was so impressed that on leaving he asked me whether I thought the model was more accurate than the prototype. I thought for a moment and not to disappoint him I said "Yes"! Perhaps we all tend to believe that models are better than we think. What we need to know is how much does the situation improve if we move from one scale to another? My feeling is less than we think. How can we judge? There are methods.

Dimensional Analysis

Yalin has tried to provide a yardstick through the use of dimensionless analysis. The method has been the subject of considerable controversy but it is like any other mathematical tool - used correctly it is a useful device - used incorrectly it can be misleading. He has demonstrated that the theory works by building a model which for practical purposes is close to perfection, Refs. 7 & 8.

Fig.6a shows two flumes, one a 1/3 scale model of the other. From the identity of his dimensionless numbers he was able to choose the properties of the fluids and the bed materials almost exactly. By driving two pumps from a common variable speed drive he was able to obtain the necessary ratio between the model and prototype values of the flow. The bed forms were reproduced perfectly to scale, Fig.6b.

Fig. 6 YALIN'S SIMILARITY FLUMES

(a) General arrangement of flumes

(b) Enlargement of bed features

Again, while working at Wallingford, Yalin made further model/prototype comparisons in a tilting flume. Once more he had control of the variables but because it was a larger facility he was able to make more measurements. He calculated that the wave length of the "prototype" bed features should be 3.6 times greater than those in the model and Fig.7 shows that they were. The ratio of solids discharge should be 47 and that this was the case is illustrated in Fig.8.

Practical Difficulties

Yalin is the first to admit, however, that practical considerations make the criteria of similarity difficult to apply. The model and the prototype are on the same planet and hence subject to the same gravity and there are other physical reasons which make perfect similarity impossible. So of what use is the dimensional method? In the foreword to his book Yalin says "Whether applicable or not the exact solution should be determined and then when it proves impracticable used as a frame of reference to judge the degree of correctness of the adopted solution". That is, we have to compromise but in most cases we do not understand the rules.

Fig. 7 COMPARISON OF WAVE LENGTHS - MODEL AND PROTOTYPE

Fig. 8 COMPARISON OF SOLIDS DISCHARGE - MODEL AND PROTOTYPE

If we knew that the error involved in scaling a particular process was of the form shown in Fig.9 then we could choose an error which was acceptable in making our choice of scales. This hypothetical curve sums up what we need to find out and where some of our fundamental research should be directed. For example, when we relax certain parameters, like the dimensionless ones used by Yalin, what errors are involved?

It is interesting that when Reynolds had finished his studies on the Mersey estuary he set himself the task of learning more about scale by building movable bed models of hypothetical V-shaped estuaries to different scales. We could copy this example to advantage.

Until more fundamental work is carried out the choice of scales for estuary and coastal models will be based too much on practical arguments like these. (i) We need measurable tides and currents to make good measurements. (ii) To keep distortion to a minimum we need a large horizontal scale. There are other practical considerations and they are important but they should only be used as part of a total argument. The scaling of the physical processes and a greater knowledge of them is of fundamental importance.

Fig. 9 HYPOTHETICAL ERROR FUNCTION FOR A PARTICULAR PROCESS TO BE SCALED

Reynolds and Froude Numbers

Until we know more of the rules we must make the most of those we have. I sometimes think that we restrict ourselves unduly by interpreting some of them too rigidly. Take Reynold's Number as an example. The flow in the model needs to be turbulent for no other reason perhaps than that the head loss should be proportional to v^2 rather than v in the laminar case. To avoid laminar flow a limit is put on the Reynold's Number say of 1500. But is the size of this number an even approximate indicator of the level of turbulence in a tidal model? I would suggest that it is not. In this case the flow accelerates and decelerates, there are changes in geometry, there are the turns of the tide - all of which tend to induce and enhance turbulence. One could happily work at much lower Reynolds Numbers and if this is the case one argument that is used against smaller models would partly disappear. Reynolds said "For flow other than in parallel pipes the Reynold's Number at the critical velocity is of course different".

I do not think that we allow ourselves sufficient freedom with the Froude relationship either. Obviously there is little latitude if we are dealing with tidal propagation in a long estuary because the speed of propagation is proportional to $\sqrt{\text{depth}}$ or thereabouts. But there are cases where some relaxation is possible. HRS once built a model of Aberdeen Harbour, Hong Kong, Fig.10 in which we had the ability of increasing the discharges by a factor of 4 over what they would be on a Froude basis, Ref.9. You will see, Fig.11, that allowing for the change in the velocity scale the current velocities at Y, a critical

Fig. 10 MODEL OF ABERDEEN HARBOUR
- HONG KONG

Fig. 11 CURRENT VELOCITIES AT Y -
(FROUDE AND 4 X FROUDE)

A relaxation of both the Reynold's and Froude criteria allows greater freedom. The model is a tool or an analogue that we can manipulate by making sensible departures but the answer must be right for approximately the right reason. If it isn't then the results we obtain for any changes we make will be wrong. On the fly leaf of some works of fiction they put this phrase - "Any similarity between the characters in this book with those living or dead is purely imaginary". We want to avoid having to put at the beginning of our reports this transcription - "Any similarity between the model and prototype is purely coincidental".

position, are almost identical. I would suggest that this "distortion" in the Froudian velocity scales could be used to advantage in many studies. In sediment transport models it might be a valid way of getting over the problem of the initiation of movement of the sediment.

Instrumentation

What effect does the development of better instruments have on our attitude to model scales? With lasers we can now measure down to a velocity of zero and at a point and with no interference with the flow. This fact alone should encourage us to consider whether we dare go smaller or perhaps what is more important consider reducing vertical exaggeration.

Movable bed models

I would like to say a little more about mobile bed models because it is in this area that physical models of coasts and estuaries can border on the inadequate and where a great deal of interpretation is necessary.

We normally test the validity of a movable bed by running it for some time and then surveying it and making a comparison with nature or with changes that have taken place in nature over a given time. Provided the whole bed is mobile and the surveys agree we say that the sediment transport scale at all points over the mobile area is the same. However, we know even without measurement, that in many of our estuary models the distribution of sediment with depth is quite wrong as illustrated in Fig.12.

What we have at best is a 2 layer model and what we are assuming is that in nature a large proportion of the material is travelling in the bottom layers. It is only in exceptional circumstances, approaching the kind described earlier, that it is a true sediment transport model.

Neither is there any way around the problem of ripple formation which to scale bears no relation to features found in the prototype. In the 1950's claims were made that a material had been found which

Fig. 12 SKETCH OF SOLIDS CONCENTRATION

would move without rippling. The competition reached something of the intensity that in other periods of our history alchemists tried to turn base metals into gold. At least we know for ripples that the problem is insoluble.

Nevertheless provided we use the technique with care I feel that movable bed models are useful but I would prefer to look on the loose material as an indicator or as a tracer. When used to study changes in small areas they are invaluable, as for example in the study of the improvement that might be achieved over a bar at the entrance to a tidal inlet by a training wall. Here it is justified, in my view, to mould a small area of the model in mobile material as illustrated in Fig.13. In this way the approach flows to the area of interest are maintained by the solid bed - having made the assumption that the depths at the boundaries of the mobile material will remain relatively unaffected by any works that are introduced. Wave-cum-tidal models of this type are quite reliable and relatively easy to manipulate. Littoral drift is promoted by running waves from say two predominant directions. A feature like a bar will form in the right place when the scale of sediment transport under waves equals the scale of sediment transport under tidal currents. Returning to the point made about Froude scales this is under the operator's control to some extent. For example, suppose the bar is forming too close inshore then, in my view, one is justified in dispensing with Froudian tidal velocity scales by shortening the tidal period to push the bar out to sea or vice versa.

Fig. 13' TIDAL INLET MODEL

If the flow is canalised between banks as in the upper reaches of our major estuaries then loose material used as an indicator of bed deposition and erosion is a powerful technique.

I would not want to give the impression that the movable bed studies discussed so far are easy to carry out or to interpret but in my view they represent a realistic approach to these sorts of problems. Where we do strike extreme difficulty, however, is in the modelling of the wide approaches to our major estuaries with their multiplicity of banks and channels. Our inadequacies to scale sediment transport in this situation shows up most markedly.

If as I am suggesting we can model sediment transport only approximately, and at certain times hardly at all, then a small increase in the inaccuracy would be neither here nor there. In the 1920's there were movable bed models at scales of 1/3000 but their operators had one important practical advantage over us. If they didn't like the bed material they could change it overnight whereas we are reluctant to dig out 50m³ of expensive material. We tend to make the best of it.

I was in touch with Professor Jack Allen recently. He is a direct link with Reynolds through Gibson. In a letter to me he said this:-

"The reluctance of some researchers to use mobile beds or to experiment with different bed materials is partly their commitment to very large models in which the time required and the expense incurred in moulding, surveying and "proving" have encouraged them to be content in inferring, from observations of water movements alone over a fixed bed, what will happen to sand and silt in a natural estuary as a result of the construction of the proposed works. They, therefore, possibly fail to take sufficient account of the effect on the water movements of alterations to the bed created by the works themselves".

I will develop the theme later that mathematical models or computation are the eventual answers but I would not neglect the possibility that a small physical model and a mathematical model might be a good way to solve some of these problems in the future.

Sediment transport - fixed bed models

Another approach to the sediment transport problem is to build a fixed bed model, observe current velocities and integrate these with field observations of sediment flux, Fig.14.

Fig. 14 SEDIMENT FLUX FROM FIXED BED MODELS

We have tried this method at the Hydraulics Research Station but have certainly not exhausted its possibilities. For studies of large areas the difficulties at the moment certainly outweigh the advantages but for studies of small areas it has its merits. The crux of the problem is that the laws of continuity so far as water movements are concerned are certainly satisfied in a physical model but the difficulty is that they cannot be established by measurement with the accuracy required using conventional instruments. I can illustrate the problem as follows. The laws of sediment transport are a high power of the velocity - let us say V^5 for the sake of argument which means that if current velocities are in error by 5% the sediment flux will be out by approximately 25%. The consequences of such an error are obvious. Better current meters of the kind mentioned earlier make this method well worth pursuing.

Mathematical Models

When we talk about problems associated with tidal propagation, current velocities, salinity intrusion, there is a case for using either a physical or a mathematical approach. When it comes to sediment transport the solutions must lie eventually with mathematics, physics and computation. Considerable advances have been made in recent years but our knowledge is still so inadequate we are well advised, as far as possible, to use both techniques together.

The term Mathematical Model, is a misnomer because it belies the important characteristic of this technique - the ability to deal with physics processes full size. Provided we know the laws everything is possible but the problems involved in discovering these laws are formidable. For example, considerable effort has been expended to establish the laws of sediment transport and yet when faced with the problem of estimating maintenance dredging in a tidal cum wave environment we would be glad to get an answer which was accurate to a factor of less than 2.

To describe the way in which topographical features like banks and channels are formed and maintained means reproducing some very complicated secondary processes. The change in velocity, suspended solids, salinity with depth can be accommodated with a multi-layer approach - water and solids being exchanged between layers, but the flow round bends can only be described adequately by building in lateral influences.

I list these difficulties not to detract from the value of Mathematical Models but to remind ourselves that more sophistication means greater costs. What we are creating in building models, both in the physical and mathematical sense, are engineering tools not basic research facilities. A certain scheme to be constructed will only warrant a certain amount of money spent on investigation. The cost of physical model studies has increased considerably over the last 10 years in real terms. In the case of Mathematical Models - new developments hardly ever increase computing time by a factor of 2 - more often a factor of 8 or more. Unless the unit cost of computing comes down to match the extra sophistication they might become too expensive to use, except on some of the larger jobs.

Although I have dealt with the subject of Mathematical modelling rather "en passant" I believe there is a need to keep the advances in this technique and that of physical modelling constantly under review. This should be done in a way that illustrates the strengths and weaknesses of both techniques and where they can be used to advantage together. More contact should be encouraged between mathematical and physical modellers because the two subjects must go hand in hand. Hybrid models will go some way to bringing about a stronger link than exists at present. The possibility of interacting physical and mathematical models in real time has considerable potential for the future.

Summary

- (1) We should not undervalue physical models as visual aids. They give us a view of a situation that we can never get from the prototype.
- (2) We should work towards solving our problems by the smallest model for the job in hand but we do not yet have all the information to make the ultimate choice of scale.
- (3) We should question the way we use the Reynolds and Froude criteria.
- (4) Mathematical and physical models are powerful techniques which should not be seen to be in competition. They should be looked on as complementary to one another. We need both methods to improve the confidence we place on our advice.

SOME IDEAS ON BREAKWATERS

(Continuation of theme speech by W A Price)

Introduction

Many of us I am sure have realized that the science of the design of breakwaters has reached a crucial point in their development. A great deal of work is being done in many parts of the world on many important aspects of the problem and if I do no more than review some of the present day thinking and suggest some lines for further research, I will be well pleased. After producing the first draft of this lecture I read a paper by Magoon & Baird (not published at the time of writing) presented at a Symposium held at the British Hovercraft Corporation on the Isle of Wight, England, which expresses the need to put more science into the subject which is very much the theme of my lecture, Ref.10.

Fig. 15 ALDERNEY BREAKWATER - CHANNEL ISLANDS

History

It would be impossible to say who built the first breakwater. Ever since man realized that he could gain protection from the waves behind a headland he used this principle to protect his boats with stone breakwaters. Hence the beginning is in antiquity. Quite recently Jacques Cousteau in searching for the lost city of Atlantis discovered underwater remains of a Minoan breakwater 4000 years old, Ref.11. However, the first empirical formula for breakwater design did not appear until 1933.

Well known names are attached to the later chapters of the story - Carvalho, Vera Cruz, Irribarren, Epstein, Tyrell, Jackson, Hudson, Davidson and no review of the subject would be complete without acknowledging the excellent pioneering work carried out by the US Army Engineer Waterways Experimental Station, Vicksburg, Refs.12 - 21.

The Hudson Equation

I would like to start by looking at the form and basis of the now famous Hudson equation.

$$W = \frac{\rho_r H^3}{K_D (\rho_r / \rho_w - 1)^3 \cot \alpha}$$

H = Wave height

ρ_r = Specific weight of armouring

ρ_w = Specific weight of water

W = Height of armour unit

α = Slope of breakwater face

K_D = Coefficient of Stability

This is a surprisingly simple equation when you think about the complexity of the phenomena involved - wave breaking, penetration of flow into the bank, run up, interblock friction, hydraulic drag, interlocking and others. It is based on the assumption that regardless of the way in which the waves break the disturbing forces due to drag or lift from plunging or collapsing breakers are proportional to the square of the wave height and displacements will be resisted by the immersed weight of the blocks alone. This theoretical analysis was supported by a series of classical experiments.

Armour Units

Subsequent to the development of this equation there was a dramatic increase in the size of ships which meant that harbours had to be built in deeper water and usually at more exposed sites. Larger stones were required and at some sites these were not available in the necessary sizes or not available at all. It was these factors that led to the development of the multiplicity of armour units we know today.

Perhaps after cubes and other rectangular blocks the Tetrapod, designed by Pierre Danel was the first of these, Fig.16. It is half the weight of an equivalent stone to resist the same wave height. Whether to escape the patent on this block or to satisfy the basic need of engineers to innovate, many other designs have followed, Fig.19.

The designers of these blocks, to a larger or lesser degree, tried to achieve an open structure to provide a permeable assembly, a low centre of gravity and projections to form interlocks with neighbouring units and thus increase their resistance to removal by waves. A saving in the amount of concrete required to make the unit was of primary

Fig. 16 TETRAPOD

Fig. 17 TRIBAR

Fig. 18 DOLOS

Fig. 19 ARMOUR UNITS

importance. Interblock friction was brought into play as in the regularly placed Tribar, Fig.17

Merrifield and Zwanborn exploited interlocking in designing the Dolosse which are one fifth to one sixth the weight of a stone to resist the same wave height: a considerable achievement, Ref.22, Fig.18.

One of the simplest and most effective blocks, in my view, is the Tripod designed by Muir-Wood. It is half a cube. The neat thing about it is that being half a cube once you have built one you can reproduce others with very simple form work, Fig.20. The K_D value is about 7.

Need for new approach

Through all these developments the Hudson equation appeared to stand firm and has been used to describe the stability of all blocks. Hudson never claimed that it should, but perhaps he is paying the price of all philosophers in that they are often quoted but never read. He has in fact cautioned that his equation was applicable to quarry stone only. Subsequently, however, and in my view quite rightly, he used his theoretical approach to describe the stability of Tetrapods.

Fig. 20 TRIPOD - METHOD OF CONSTRUCTION

I will develop the thesis that all blocks are not alike - they exploit different qualities to achieve stability and these individual characteristics should be recognised more so than they are at present in any equation that describes their stability. Unless we do then we will not fully understand the behaviour of complicated blocks.

Let me use an analogy. Man has always been faced with the problem of spanning gaps. Through history he has tried to span larger and larger gaps and he has had to employ new methods from beams to arches, cantilevers and catenaries.

I want to use the analogy in two ways. The first is not in the mainstream of the argument but is important and it is this. In the early stages of design do we give enough attention to methods of construction other than rubble mound breakwaters like, for example, Lundgren's caissons? I suspect that we do not but this is a whole debate in itself so I will return to using the analogy in another way.

Bridges exploit the various properties of different materials like stone, concrete, steel, for their stability and this is analysed in different ways. Armour blocks too have various qualities that contribute to their stability. Some of the important ones are weight, interlocking, interblock friction, hydraulic drag, permeability of assembly etc. Qualitatively we can assess the blocks shown in Fig.21 like this

Fig. 21 ARMOUR UNITS - SCALED TO RESIST EQUAL WAVE HEIGHTS

- the stone and the cube rely on weight for their stability, the Tetrapod on weight and a small amount of interlocking, the Tribar on interblock friction and weight and the Dolos on a small amount of weight and a great deal of interlocking. They are certainly not different shaped bits of stone. Any advance on the Hudson equation must, therefore, recognise this and describe a block's stability in terms of these parameters.

[To digress slightly - interlocking is probably difficult to quantify although I would suggest it could perhaps be determined like this. Lay cover layers in the laboratory and determine the force required to remove units from the pack. Forces will vary from those equivalent to the weight of the unit to a force required to remove a block that is fully interlocked. We could express this variation in a dimensionless number of the form say -

$$I = \frac{\text{"Average" force required to remove block}}{\text{Weight of Armour Unit}}$$

This parameter expresses the way a particular block relies on the weight of neighbouring units for its stability.]

Types of failure

Another case for reappraisal is the very different way damage occurs for compact and open forms of block. With compact forms, like stones and Tetrapods, for which no friction or little interlocking is assumed a steady increase of damage is to be expected as the wave attack is extended in time, Fig.22, Ref.23. This pattern of damage is quite different for the blocks of open form with their properties of high interblock friction and interlocking. They exhibit a stiffness which resists damage over an initially large range of wave heights but once the applied forces are high enough to disturb the cover layer a rapid removal of units results and the margin of safety between acceptable damage and failure for closed forms becomes very small and could be well within the range of uncertainty of prediction of the design wave height. We need to take this fact into account in the design. The use of blocks that interlock puts a considerable premium on a good knowledge of the wave climate. I have heard Dean O'Brien call many times for more wave recording. I wholeheartedly agree with him. Highway engineers would not be prepared to design motorways with the lack of information Coastal Engineers are sometimes asked to design breakwaters.

Fig 22 HISTORY OF DAMAGE - STONES AND DOLOSSE

Fig.23 DOLOSSE - EFFECT OF WAVE PERIOD

The influence of wave period

Let me turn to the other side of the equation - the disturbing influence of the waves. Hudson found it quite sufficient to describe the sea in terms of a wave height. Whillock, working with Dolosse and the results have been confirmed by Burcharth, Zwamborn, & Bruun, Ref.26, showed that wave period was also important so far as this armour unit was concerned, Fig.23, Ref.24. Is there a discrepancy with the early Hudson results? I do not think there is. Within the scatter of his results for stone breakwaters there was probably a small period dependence but it was so small that he was justified in ignoring it.

The explanation probably lies partly in the fact that Dolosse with their limbs projecting through the cover layer are subject to much greater drag forces than stones which tend to protect one another in times of high surface currents. These currents are likely to be at their maximum when long period waves surge rather than break on the slope. Brebner shows that the Drag to Weight ratio for stones and Dolosse are almost the same, Ref.25. Quite recently experiments carried out at HRS confirms this fact. However, this does not mean that when they are in a pack that the effective drag to weight ratios are the same. Per Bruun has pointed out the importance of wave resonance and says that "elements that protrude should be avoided", Ref. 26. How dependent on wave period are other units? I do not know but I think we should find out.

Effect of angle of attack

Tests with stone breakwaters and tests done by SOTRAMER with Tetrapods show that their stability increases with angle of attack. This behaviour is quite different for Dolosse, Fig.24. The reason is again the production of high surface currents this time caused by waves running along the breakwater and setting up high drag forces on projecting limbs. The amplification of the wave height due to the Mach-Stem effect further complicates the issue.

Fig. 24 DOLOSSE - EFFECT OF ANGLE OF ATTACK

Every now and again one reads a paper containing an idea which one would have liked to have had oneself. Such a paper was presented at the Hamburg Conference by Brebner, Ref.25. He filled shallow boxes with stones and Dolosse and gradually tipped them about their bottom edge. The failure of the rock occurred at about 50° whereas the Dolosse had an

angle of repose of at least 80° and in one remarkable test 91° . He carried out tests where he layered Dolosse and stone in a tilting flume and ran water over them. The "wipe out" velocity was essentially the same for both the quarystone bed and the one constructed of Dolos. He concluded that "the effectiveness of the Dolos unit is not materially affected by the drag to weight ratio but to its high angle of repose". Interlocking can only be brought fully into play by using Dolosse on steep slopes. Brebner puts it this way - "one can also suggest that the steeper the breakwater slope ... when attacked by normal waves the better the Dolos unit appears to be". He points out that "this is the reason why the stability of Dolosse are affected by the angle of attack whereas stones are not", Ref.24.

Random Sea Testing

Random sea testing has become fairly commonplace in our laboratories although we still continue to argue how best they should be synthesised.

Johnson and Ploeg have questioned whether seas are necessarily random - the implication being that if they are not then the wave groupings will be different, Refs.27 & 28. Shuttler at HRS has measured the frequency of wave groups for a number of wave spectra (Moskowitz, Jonswap and a bimodal spectrum generated using the HRS synthesiser). These compare very favourably with published field data. I still think, however, there is still some debate about this question and more work needs to be done because it is an important one.

Burcharth and Ploeg have shown that coastal structures respond differently when exposed to various wave patterns that contain the same maximum waves: there is a significant influence of succession, Refs.29 & 30. They stress the importance of research into the occurrence and frequency of characteristic wave patterns in wave records so that the results can be incorporated in sea conditions used in model tests. Incidentally Boucherth proposes a new form of the Hudson equation for Dolosse pointing out that it would be appropriate to plot a Stability Number defined as

$$\frac{H}{\left(\frac{W}{\rho_r}\right)^{\frac{1}{3}} \left(\frac{\rho_r}{\rho_w} - 1\right)}$$

against a Surf Similarity parameter (Batjes), Ref.31.

This dimensionless parameter was designed by Batjes and its importance has probably not as yet been fully recognised. It is a convenient way of describing the way in which the wave breaks.

$$\zeta = T \left(\frac{g}{2\pi H}\right) \tan \alpha$$

where H = Wave height

W = Weight of Dolos

- ρ_r = Specific weight of blocks
 ρ_w = Specific weight of water
 T = Zero crossing wave period
 g = acceleration due to gravity
 α = angle of slope

Summary of the Important Parameters

Abernethy, as early as 1970, Ref.32, when carrying out an investigation to provide information for the design of Tribar armouring for a large reclamation project in Botany Bay, New South Wales, developed a similar theme to the one in this lecture when he suggested that any analysis of Tribars, and he could have included other armour units, based upon the Hudson formula must be considered suspect for many reasons. He suggested that the damage function Δ is dependent upon eleven dimensionless parameters. Taking these and adding others we could write a list of some of the more important variables affecting the damage function as follows:-

- | | | |
|--|---|-----------------------|
| (1) Weight of unit | } | Block Characteristics |
| (2) Density of material | | |
| (3) Interblock friction | | |
| (4) Packing Density | | |
| (5) Permeability of Assembly | | |
| (6) Height of Bank | | |
| (7) Hydraulic drag | | |
| (8) Wave Spectrum | } | Disturbing Influences |
| (9) Wave grouping | | |
| (10) Angle of attack | | |
| (11) Water depth | | |
| (12) Number of waves impinging
on slope | | |

The list is formidable and is not complete but it indicates the size of the problem.

Structural Damage

Vasco Costa, Baird, Lalevang, Magoon and Stickland have made major contributions to the subject and have highlighted among other things the problem of wear and the structural stability of the individual units. These are subjects which are worthy of further study. It occurs to me to wonder whether with blocks that interlock there is the possibility that impact loads could be transferred from block to block, and perhaps by chance the combination of forces caused by waves breaking out of phase with loads transferred from unit to unit could be one of the reasons blocks break, Fig.25.

Dolosse

To clear up any misinterpretation of what I might have said I need to say a word about Dolos in particular. There is no doubt that it is a good armour unit and perhaps because it is superior in many respects to others in using the properties of a solid almost to the limit that we must use it with care. Until we understand all its properties we should

not exploit them to the full. I have used Dolosse in this lecture because more work has been done on this unit than any other and believing that they typify the family of blocks that interlock at least qualitatively.

Need for co-operation and further research

Apart from the few painstaking and excellent pieces of work that I have already referred to good designs have been produced based on careful tests but for one reason or another they are not consistent with others in the field and the results are then more or less lost to the science. We must do more experiments where we keep some of the variables constant while varying others.

It seems to be opportune that we should get down to some fundamental research preferably organised on a world wide basis and not rely

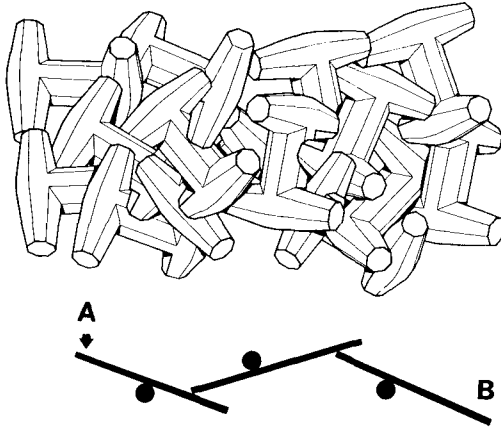

Fig.25 TRANSFER OF LOADS - INTERLOCKING BLOCKS

almost entirely on laboratory testing of specific schemes for insight to the problem. I was glad to hear at the Conference Professor Edge describe plans that ASCE have in this direction.

When writing about armour blocks nearly 30 years ago Pierre Danel, the inventor of the Tetrapod, said this -

"Engineers have too few opportunities for examining an overall problem in a sufficiently disinterested way and for a sufficient length of time. Each one is bound by his specialized field and naturally has a tendency to only consider solutions which entirely satisfy his own particular requirement".

It might sound a small point but if we could only agree about what we mean by certain percentages of damage and failure this would be a considerable step forward.

If we continue to test with the object of getting a stability factor alone we will lose the feel for the subject and our designs will suffer. The improvement of armour blocks has meant that their behaviour has become more and more detached from the supporting theory. One serious consequence is that data obtained from one situation cannot be applied to others. In my view we need to make advances quickly.

ACKNOWLEDGEMENTS

This lecture was given with the permission of the Director of the Hydraulics Research Station, Wallingford. I would particularly like to thank Mr A F Whillock whose ideas are incorporated in the section on breakwaters, Professor Emeritus Jack Allen for his comments and the loan of early slides and many of the staff at HRS for their instructive remarks. To others too numerous to mention I would like to say "Thank You".

The drawings by Leonardo da Vinci are published by permission of the Royal Library, Windsor Castle.

CHAPTER 1

A WORLD WAVE DATA CENTRE

by

Laurence Draper
Institute of Oceanographic Sciences
Wormley, Godalming, Surrey GU8 5UB, U.K.

ABSTRACT

There is a growing need for instrumentally-measured wave data, but it is not easy to discover what measurements, if any, may have been made in any particular area. To try to alleviate the situation the Institute of Oceanographic Sciences is establishing an international reference centre which will create and maintain an inventory of such data. It is appealing for volunteers world-wide to help in identifying locations where waves have been measured.

It will be operated through the U.K. Marine Information and Advisory Service at the Wormley Laboratory of the Institute.

The birth of wave recording can be assumed to have occurred during the Second World War, prompted by the need to land through surf on unfamiliar beaches and assisted by the developments in electronics which allowed the complexities of wave motion to be monitored at a distance. After peace returned, the applications of the new capability to coastal engineering were soon appreciated and instruments began to be deployed on many coasts of the world. The demand for data far exceeded the supply, and research laboratories, both engineering and oceanographic, found themselves being asked to advise on wave conditions, provide and interpret measured data and, where none existed, to predict wave conditions for both design and operational needs. Amongst the laboratories which responded to the need was the UK Institute of Oceanographic Sciences (known previously as the National Institute of Oceanography) which designed and built wave recording instruments, installed them around the UK and elsewhere, developed methods of analysis and data presentation and built up an index of sources of instrumentally-measured wave data. This index, along with the expertise built up within the Institute and elsewhere, meant that the Institute became a focus for questions on data

sources and advice on all aspects of waves, a large proportion of the questions coming from engineers working on coastal and also on offshore installations.

About ten years ago the Permanent International Association of Navigation Congresses (PIANC) established its International Waves Commission on which the author sat for a time as the UK Representative, under the Chairmanship of Professor J. Larras. It compiled a list containing brief but relevant details supplied by its members of instrumentally-measured wave data, and developed a system whereby the owners of such data could be identified through a network of area representatives. Each representative, on identifying a source of wave data, would obtain answers to a set of standard questions so that any potential additional user could quickly ascertain whether or not the measured wave data would be likely to be of value to him. It would also be possible to compare the characteristics of different data sources. It was originally intended that these completed questionnaire forms would then be sent to the Commission to allow the central inventory to be established and continually updated. Unfortunately, after devising the scheme, PIANC was unable to establish an on-going unit to operate it. Meanwhile, the amount of data being measured continued to increase as did the demand, but the potential value of wave data was being lost because the measurements were not known to later potential users, simply because there was no organization responsible for cataloguing even their existence, and wave conditions were needing to be re-measured unnecessarily.

The questionnaire form was developed further, under the chairmanship of Dr. J.R. Wilson, by the Task Team on Wave Data Management of the Intergovernmental Oceanographic Commission (IOC). The Institute of Oceanographic Sciences then made an offer to IOC to become a Responsible National Oceanographic Centre for Waves (RNODC(Waves)). The intention is that the Marine Information and Advisory Service will operate the PIANC scheme, and establish the RNODC(Waves) as an operational centre which will attempt to identify all sources of instrumentally-measured wave data through an international network of area representatives. The wave data questionnaire has evolved as a consequence of limited experimental use so far. It can form the basis of an Inventory to be used in satisfying the needs of a potential wave data user to identify suitable sources.

There is a demand for copies of this Wave Data Inventory but in its present form it is not practical to distribute it on account of its bulk. However, it is proposed to compile a Wave Data Catalogue in which the essential minimum information from the Inventory is condensed. This will constitute the working document within the RNODC (Waves). A number of people around the world, active in

RESPONSIBLE NATIONAL OCEANOGRAPHIC DATA CENTRE (WAVES)

Inventory form, first page.

the engineering aspects of waves and who have a direct interest in knowing of the existence, and quality, of instrumentally-measured wave data, have expressed a willingness to participate in the scheme as Area Representatives. The response to informal approaches has been encouraging, but more offers will be welcomed. It is proposed to leave the appointment of Area Representatives until after this conference, when a list of appointees will be compiled and published. An area representative will be a person active in this field who could obtain the backing of his establishment to run an effective search and identify mission, or even the establishment itself, provided that a dedicated individual would take responsibility for operations. It is a responsible and rewarding task, hopefully not too onerous, which will contribute significantly to engineering operations in the world. It does not seem that either the RNODC(Waves) or UNESCO will be able to provide funds externally for the running of the scheme, but it is planned that RNODC(Waves) will supply each Area Representative with questionnaire forms, a copy of the Catalogue and occasional up-date material. He will also maintain his own inventory of completed questionnaire forms relevant to his area. The four-page questionnaire form is illustrated in the figure. It consists of one sheet of paper folded to A4 size. The questions are arranged so that answers can be stored for computer retrieval. The RNODC(Waves) will provide anyone with advice on wave data measurements, analysis, interpretation and presentation, as well as reports on the data themselves if copies are available to the RNODC(Waves).

Although the early response to the appeal for Area Representatives has been excellent and the scheme is starting with good coverage, offers of participation will be welcomed at any time. In any one country it is likely that there will be a primary representative person or organization, so that additional participants will be asked to channel their completed forms through the primary representative for their areas. For example, it is likely that all U.S. participants will be asked to forward their forms to Mr. Wellington Waters of the USNODC in Washington for onward transmission to the RNODC(Waves).

It is hoped that the establishment of an effective RNODC(Waves) will be of appreciable communal benefit and will tidy up what is at present an active but only partially effective operation. It seems likely that it will be an on-going scheme dedicated to helping anyone working in an area affected by waves, whether in the building of structures intended to provide protection from them, the operation of vehicles through them, the abstraction of energy from them or in many other activities where waves have to be taken into account.

PART II : INVENTORY	
2.1 Report Title (if published).	
2.2 Description of Measurement Site.	2.3 Description of Measurements.
a) Sea Area	a) Type of instrument (e.g. waverider, resistance staff, pressure gauge, altimeter, etc.)
b) Latitude and Longitude (express as range if necessary)	b) Type of instrument mounting (e.g. ship, aircraft, tripod on sea bed, midwater mooring, etc.)
c) Mean Water depth	c) Digital sampling frequency (If applicable).
d) Mean Tidal Range Spring Neap	d) Duration of individual records.
e) Approximate maximum currents (if known).	e) Interval between starts of successive records.
2.4 Comment on presence of offshore bars, structures or obstructions, and whether or not their presence would make the data untypical of the area.	
2.5 Primary reason for measurements (brief statement)	
2.6 List any other observations made with the wave measurements	
2.7 Data available - state form and medium in which available (state NONE where none available) to other users.	
a) Original Data (e.g. chart records, analogue mag. tape records etc.)	
b) Processed Data (e.g. listings of Tucker-Draper statistics, spectral estimates on mag. tape, etc.)	
c) Analysis Presentations (e.g. exceedance diagrams, period histograms etc.)	

Inventory form, second page.

PART III : DATA DOCUMENTATION IIIA - INSTRUMENTATION	
3.1	Have you previously forwarded an inventory for this set of data? YES/NO.
3.2	Description of Instrument. <ul style="list-style-type: none"> a) Name of Instrument including Manufacturer and Model No. b) Pertinent physical characteristics (including modifications). c) Depth of sensors below, or height above, mean water level. <ul style="list-style-type: none"> Height of sensors above sea floor (if more appropriate). d) Recording Medium (e.g. strip chart, digital magnetic tape, analogue magnetic tape, etc.) e) Date and Method of calibrations (please state if not calibrated) and comment on stability of calibration. f) Steps taken to control biological fouling (if applicable).
3.3	Instrument Remarks (Specify operation failures during data collection, instrumental response characteristics, e.g. bandwidth and range, chart speed or other comments helpful in data interpretation).

Inventory form, third page.

PART III - continued. IIIB - DATA PROCESSING
3.4 a) Type of processing performed on data (e.g. spectral, Tucker-Draper, etc.) b) Main start and end dates of processed data.
3.5 Remarks on Data Reduction and Processing. (Include any comments pertinent to the interpretation of the data, e.g. description of methods used in deriving parameters, corrections applied to the data, filtering performed on the data, etc.)
3.6 a) Are the data checked and edited? Y/N. b) What criteria were used for the editing and quality assessment of the data?
3.7 General Remarks (Enter any other comments useful in interpretation and use of data reported).
3.8 If transmitting data for the first time in computer compatible form please append a detailed description of its format and a detailed definition of each data field including units.

Inventory form, fourth page

CHAPTER 2

ON LONG-TERM STATISTICS FOR OCEAN AND COASTAL WAVES

Michel K. Ochi*

ABSTRACT

This paper discusses the statistical properties of long-term ocean and coastal waves derived from analysis of available data. It was found from the results of the analysis that the statistical properties of wave height and period obey the bi-variate log-normal probability law. The method to determine the confidence domain for a specified confidence coefficient is presented so that reliable information in severe seas where data are always sparse can be obtained from a contingency table. Estimation of the extreme significant wave height expected in the long-term is also discussed.

INTRODUCTION

For the design of ocean and coastal structures, it is very important to obtain information on wave characteristics over a period of time sufficiently long to cover the lifetime of the structures. Collection of data on wave height and period has been made by several researchers through either visual observations or measurements, and their results are usually presented in tabular form [1][2][3][4][5]. Although considerable attention has been given to statistical information of long-term wave height, we have as yet little information on the combined properties of wave height and period for the long-term.

A statistical contingency table on wave height and period provides valuable information for the design of ocean and coastal structures. However, data for severe seas, which are indeed necessary for design, are unreliable since such data are, without exception, sparse. One way to solve this problem is to represent wave statistical data by a certain probability law which governs the data, and then obtain necessary information for design from the probability function.

The purpose of this paper is to provide solutions to the problems cited in the foregoing discussion. For this, the joint probability

*David W. Taylor Naval Ship Research and Development Center, Washington, D.C., U.S.A.

distribution of wave height and period for data accumulated over many years is derived, and a method to establish the confidence domain for a specified confidence coefficient is presented. A method for predicting the extreme value of significant wave height from the long-term accumulation of data is also discussed.

LONG-TERM WAVE STATISTICS

Long-term wave statistics as defined in this study is the statistical information of wave characteristics such as wave height and period accumulated over a sufficiently long period of time. In accumulating data for long-term wave statistics, wave observations are usually made for 20-30 minute intervals. Wave height and period are expressed in terms of significant wave height (or average wave height) and zero-crossing period (or average wave period), respectively, and the accumulated data are usually presented in tabular form known as a contingency table.

Examples of a contingency table for long-term wave statistics are shown in Tables 1 through 3. Table 1, taken from Reference [1], shows the tabulation of significant wave height and zero-crossing period, both analyzed from records obtained at Weather Station 1 (59°N, 19°W) in the North Atlantic. The numbers given in the contingency table are those per 1,000 observations. Table 2 shows an example of data on significant wave height and period observed during 20 months (from November 1961 to March 1964) at Port Hueneme, California, presented in Reference [2]. Table 3, taken from Reference [3], shows an example of a contingency table on significant wave height and modal period where the wave spectrum has a peak value. The table provides information based on a total of 2,304 measurements in one year (from March 1972 to February 1973) at Tiner Point, New Brunswick, Canada. There are many other examples of contingency tables similar to those shown in these tables, Reference [4] and [5] for example.

Needless to say all of these long-term wave statistics are extremely valuable in providing information for the design of ocean and coastal structures. However, a problem always exists in the use of this information for design. That is, data in severe seas are unreliable, since they are, without exception, sparse. For instance, information above 10 ft (3.05 m) significant wave height in the example shown in Table 3 are few; only 15 cases are observed in a total of 2,304 observations which is equivalent to about 0.7 percent. This implies that it is not appropriate to use the numbers given in this sort of table in practice.

One way to solve this problem is to apply the statistical inference concept and establish the confidence domains from the data, taking into account the correlation between significant wave height and period. For this, it is necessary to find the joint probability distribution which is applicable to significant wave height and period.

PROBABILITY DISTRIBUTION FOR LONG-TERM WAVE STATISTICS

In order to derive the combined statistical characteristics of the two random variables, significant wave height, H_s , and zero-crossing period, T_0 , we may first consider the marginal probability distribution of significant wave height. It is noted here that, although considerable attention has been given to statistical information of significant wave height, the probability function which is applicable to significant wave height is the focus of much criticism. Some claim that the log-normal distribution is appropriate [6][7][8], while others believe the data can be better fitted by the Weibull distribution [9][10]. The results of the present analysis, however, illustrate that significant wave height appears to follow the log-normal probability law over the range for the cumulative distribution up to 0.99. This conclusion appears to be valid for both ocean and coastal waves. To support this statement, the following discussion will be given:

Figure 1 shows the cumulative distribution function of significant wave height of ocean waves. The data are taken from the contingency table given in Table 1, and are plotted on log-normal probability paper. As can be seen in the figure, the data follow the log-normal distribution for the cumulative distribution up to 0.99. On the other hand, Figure 2 shows the same data plotted on Weibull probability paper. This figure shows that the data may also be represented by the Weibull probability distribution except for small significant wave height. Thus, one may have the impression that there is no significant difference in representing the statistical characteristics of significant wave height by the log-normal or Weibull probability law. However, if comparison is made between these two probability density functions and histograms, then the difference becomes pronounced.

Figure 3 shows a comparison between the histogram, log-normal and Weibull probability density functions. As can be seen in the figure, the log-normal probability density function agrees reasonably well with the histogram over the entire range of significant wave heights. On the other hand, the Weibull probability density function agrees well with the histogram for large significant wave height, but the agreement is rather poor for small significant wave height. This is the general trend observed in the analysis of the significant wave height data.

Examples of statistical analysis of significant wave height for coastal waves are shown in Figures 4 through 7. The cumulative distribution function of the significant wave height measured at Tiner Point, Canada [3] is plotted on log-normal probability paper (Figure 4) as well as on Weibull probability paper (Figure 5). On the other hand, comparison between the two probability density functions and the histogram is shown in Figure 6. As can be seen in these figures, the same conclusion derived from analysis of the significant wave height for ocean waves may also be applicable to the significant wave height for coastal waves.

As another example for coastal waves, Figure 7 shows a comparison between the histogram and the log-normal distribution of the significant wave height obtained at Port Hueneme, California [2]. Thus, it may safely be concluded that the log-normal probability distribution represents reasonably well the histogram over the entire range of significant wave height for ocean as well as coastal waves.

In regard to the marginal probability distribution of zero-crossing wave period (or modal wave period), it was found through the present study that the wave period appears to follow the log-normal probability law for both ocean and coastal waves. Although an attempt was made to represent the wave period data by the Weibull probability distribution, the representation was extremely poor for all examples. Figures 8 through 10 show examples of a comparison between histograms and the log-normal probability density functions. The figures pertain to comparisons made for data observed at Station 1 in the North Atlantic (Figure 8), at Tiner Point, Canada (Figure 9), and at Port Hueneme, California (Figure 10), respectively. As can be seen in these comparisons, wave period appears to be represented by the log-normal probability law.

From the foregoing discussion, it has been concluded that significant wave height follows the probability distribution given by,

$$f(H_s) \sim \Lambda(\mu_{HS}, \sigma_{HS}) \quad (1)$$

where, $\Lambda(\mu_{HS}, \sigma_{HS})$ is the log-normal probability density function with parameters μ_{HS} and σ_{HS} . Similarly, the zero-crossing wave period follows the probability distribution given by,

$$f(T_0) \sim \Lambda(\mu_{T_0}, \sigma_{T_0}) \quad (2)$$

The modal period also obeys the same distribution law as given in Equation (2) but with different parameters.

Then, from the properties of the log-normal probability distribution, it can be derived that the combined statistical properties of significant wave height and period follow the bi-variate log-normal probability law which may be written as,

$$f(H_s, T_0) \sim \Lambda(\mu_{HS}, \sigma_{HS}, \mu_{T_0}, \sigma_{T_0}, \rho) \quad (3)$$

where, ρ is a correlation coefficient between two random variables, H_s and T_0 , and its value can be determined from the data.

Various statistical properties of significant wave height and period can be derived based on Equation (3). First, it is possible

from Equation (3) to evaluate the confidence domain for a specified confidence coefficient which will provide reliable information for severe seas where data are always sparse in the contingency tables. Also, the statistical properties of the zero-crossing period (or modal period) for a specified significant wave height can be obtained as the conditional log-normal probability distribution given by,

$$f(T_s | H_s) \sim \Lambda \left(\mu_{T0} + \rho \frac{\sigma_{T0}}{\sigma_{HS}} (\ln H_s - \mu_{HS}), \sqrt{1-\rho^2} \sigma_{T0} \right) \quad (4)$$

DERIVATION OF CONFIDENCE DOMAIN

Derivation of the confidence domain for a specified confidence coefficient may be made around the modal value which represents that combination of significant wave height and zero-crossing (or modal) period most likely to occur. For the log-normal distributions given in Equations (1) and (2), the modal value (H_*, T_*) is given by,

$$(H_*, T_*) \sim (e^{\mu_H - \sigma_H^2}, e^{\mu_T - \sigma_T^2}) \quad (5)$$

Next, let us transform the joint probability density function given by Equation (3) into the following two new random variables, r and θ , shown in Figure 11.

$$\begin{cases} H_s = H_* + r \cos \theta \\ T_o = T_* + r \sin \theta \end{cases} \quad (6)$$

By carrying out the transformation of random variables given in Equation (6), the joint probability density function of r and θ , $f(r, \theta)$ becomes,

$$f(r, \theta) = \frac{r}{\sigma_1 \sigma_2 (2\pi) \sqrt{1-\rho^2} (H_o + r \cos \theta) (T_o + r \sin \theta)} \\ \times \exp \left\{ -\frac{1}{2(1-\rho^2)} \left[\left(\frac{\ln(H_o + r \cos \theta) - \mu_H}{\sigma_H} \right)^2 - 2\rho \left(\frac{\ln(H_o + r \cos \theta) - \mu_H}{\sigma_H} \right) \right] \right\}$$

$$x \left(\frac{\ln(T_o + r \sin \theta) - \mu_T}{\sigma_T} \right) + \left(\frac{\ln(T_o + r \sin \theta) - \mu_T}{\sigma_T} \right)^2 \quad (7)$$

In order to determine the confidence domain around the modal value (H_*, T_*), consider the conditional probability density function of r for a given θ . That is,

$$f(r|\theta) = \frac{f(r, \theta)}{\int_0^{\infty} f(r, \theta) dr} \quad (8)$$

Then, a point r , which yields a contour curve whose enclosed area is equal to a specified confidence coefficient, γ , can be determined from the following relationship:

$$\int_0^{r_i} f(r|\theta) dr = \gamma \quad (9)$$

Figure 12 shows an example of a thus derived confidence domain using Draper's data obtained in the North Atlantic [1]. The black circle in the figure represents the combination of significant wave height and zero-crossing period which is most likely to occur. The closed curves given in the figure outline the statistical confidence domains inside of which the probabilities of occurrence of the wave conditions are the specified values. The numbers in the figure refer to the number of observations given in Table 1. These numbers, however, for convenience sake, are regrouped and are divided by 1,000 so that the total number is equal to 1.

Figures 13 and 14 show two examples of such confidence domains derived using data on coastal waves. Confidence domains using the data obtained at Tiner Point, Canada, are given in Figure 13, while those using the data obtained at Port Hueneme, California, are given in Figure 14. The numbers in these figures refer to the frequencies of observations given in Tables 2 and 3, respectively. As can be seen in Figures 12 through 14, the domain for a confidence coefficient of 0.99 sufficiently covers the measured data. The significant benefit of drawing the confidence domains is that information in severe seas where data are always sparse can be clearly estimated from the overall data given in the contingency tables.

ESTIMATION OF EXTREME SIGNIFICANT WAVE HEIGHT

One of the most important pieces of information concerning long-term wave statistics is the largest value (extreme value) of significant wave height. The information is of particular importance for the design of ocean and coastal structures.

Although the significant wave height follows the log-normal probability law, this holds only for the cumulative probability distribution up to 0.99 as was discussed in the previous section. Therefore, it is not appropriate to estimate the extreme significant wave height based on the log-normal distribution, since the value of the cumulative probability distribution will be greater than 0.99 for the extreme value. Instead, it may be evaluated by applying the concept of asymptotic distribution of extreme values which is applicable for any probability distribution if certain conditions are met. For this purpose, let us assume that the cumulative distribution function can be expressed asymptotically in the following form:

$$F(x) = 1 - e^{-q(x)} \quad (10)$$

Then, it can be derived that the probable extreme value in n number of observations, denoted by \bar{Y}_n , satisfies the following condition when n is large:

$$e^{-q(\bar{Y}_n)} = \frac{1}{n} \quad (11)$$

This in turn, implies that the probable extreme value can be evaluated from,

$$\frac{1}{1 - F(\bar{Y}_n)} = n \quad (12)$$

As an example, Figure 15 shows the left-hand side of Equation (12) (often called the return period) in logarithmic form using the significant wave height data obtained at Tiner Point, Canada. Since a total of 2,300 observations of significant wave height were made in one year, the probable extreme significant wave height expected to occur in 20 years, for example, can be estimated from the figure as the wave height for which the ordinate is $\ln(2,300 \times 20) = 10.74$; namely, 18.0 ft (5.5 m).

Figure 16 shows the results of a similar analysis to that shown in Figure 15 but using data obtained at Port Hueneme, California. A

total of 3,400 observations of significant wave height were made in 20 months for this example; hence the probable extreme significant wave height expected to occur in 20 years can be estimated from the figure as the wave height for which the ordinate is 10.62; namely, 9.7 ft (2.96 m).

CONCLUSIONS

This paper discusses statistical properties of the long-term ocean and coastal waves derived from analysis of available data. In the analysis, correlation between wave height and period is taken into consideration, and data on ocean waves accumulated in the North Atlantic as well as data on coastal waves obtained at Tiner Point, Canada, and Port Hueneme, California, are analyzed.

It is found from the results of analysis that statistical properties of both wave height and period are approximately represented by the log-normal probability law, and that the joint probability of wave height and period obeys the bi-variate log-normal probability law. This conclusion appears to be valid for both ocean and coastal waves.

The confidence domain of wave height and period for a confidence coefficient of 0.99 sufficiently covers the measured data. A significant benefit of drawing the confidence domains lies in obtaining information in severe seas where the data are always sparse in the contingency table.

The estimation of the largest significant wave height (extreme value) expected to occur in a specified long period of time is discussed by applying the concept of asymptotic statistical distribution of extreme values.

CHAPTER 3

WIND WAVE FREQUENCIES IN A TROPICAL CYCLONE REGION

Rodney J. Sobey #

INTRODUCTION

Australia's Coral Sea coast from Bundaberg north to Cape York has a wind wave climate that is almost unique. The coastline is afforded unparalleled protection from the 1900 km Great Barrier Reef, yet it lies in a tropical cyclone region and must expect recurrent intense wind and wave conditions.

The Great Barrier Reef is a continuous chain of quite separate coral reef clusters located near the edge of the continental shelf. The separate reefs are often exposed at low tide, the inner fringe of the clusters ranges from 10 km offshore north of Cairns to 200 km offshore south of Rockhampton and the outer fringe is typically some 50 km further offshore, beyond which the ocean bed drops rapidly away. Incident wave energy from the Coral Sea is invariably dissipated on the outer edge of the Reef and wave conditions on the continental shelf can reasonably be considered due to local wind conditions. The Reef imposes an effective fetch limitations on wave generation over the continental shelf and there is, as a consequence, a moderately rapid response of wave conditions to changes in local wind conditions. A pronounced diurnal variation in the wind climate is reflected also in the wave climate and the stability of the region's tropical climate leads to frequent calm to slight sea conditions. This stability however is occasionally exploded by the generation and passage of a tropical cyclone in mid to late summer. Large waves can be generated by the intense winds of the tropical cyclone (hurricane or typhoon), often an order of magnitude greater than those in response to non-cyclonic events.

The rational design of coastal structures and the rational pursuit of coastal zone management requires appropriate estimates of the frequency of occurrence of waves of various heights. Ideally such information is obtained from an extreme value analysis of long term wave records at the particular site in question. Permanent wave recording programs unfortunately have only become common practice in the present decade and wave records, if they exist at all for a particular site, are rarely long enough to allow a satisfactory extreme value analysis. It is clear, in the Australian context at least, that historical wave data alone is not yet sufficient to derive satisfactory estimates of long term wave frequencies. The alternative is system modelling.

Wind is a major meteorological variable and its long term recording has been a standard meteorological practice now for over half a century.

Senior Lecturer, Department of Civil and Systems Engineering,
James Cook University, Townsville 4811, Australia.

Suitable data is normally available to estimate the statistical characteristics of a local wind climate. There is also now a developing confidence in wind wave forecasting techniques. Used together, it is possible to simulate several thousand years of statistically likely wind wave observations. A summary of these simulated observations will provide a reasonable estimate of long term wind wave frequencies for a particular site.

METHODOLOGY

Statistical simulation is now established as a basic technique in the study of a wide range of geophysical phenomena; earthquakes, precipitation, floods, wind, storm tides and wind waves have all been considered in this manner. The need for a stochastic approach stems from the recognised inadequacy of current deterministic models to make predictions beyond a few days. The present approach can be described as stochastic - deterministic; long term prediction of winds is essentially stochastic whereas the short term forecasting of the waves generated by a predicted wind field is deterministic. The approach involves a largely stochastic input (wind) to a deterministic system (wind-wave generation) yielding of course a stochastic output (wind waves). As pointed out by Nolte (7), the determination of wind wave statistics involves three important considerations: (i) desired end use, (ii) existing data base, and (iii) mathematical system model. All three should be defined and their compatibility established.

Desired End Use. - Essentially the objective is the estimation of the significant wave height - frequency relationship for a typical coastal site behind the Great Barrier Reef along Australia's Coral Sea coast. Reliable estimates of waves with average recurrence intervals in excess of 100 years are sought. It is recognised however that it is not always the maximum wave in any one year that causes the most damage. It may be that sustained attack from a more modest wave can be just as significant. The technique adopted should potentially allow the estimation of a wave height - duration - frequency relationship as well as the more common wave height - frequency relationship.

Existing Data Base. - Available data held by the (Australian) Bureau of Meteorology is far from perfect and the final result can be of course no better than the basic data. The adopted data base was drawn from Bureau records held in computer compatible form (1), specifically Card 7 "Hourly Surface Observations" and Card 13 "Tropical Cyclones and Tropical Disturbances". The Card 7 data includes three-hourly observations of mean wind speed and direction at coastal city airports. These sites are removed somewhat from the continental shelf but the quality of the data is good and the records are comprehensive. The wind speed observations are taken as wind speeds at the standard height of 10 m in the boundary layer. Card 13 data, while clearly the more important data source, is disappointing in terms of data quality. Notwithstanding some reservations they constitute the only historical data available for the estimation of long term wind fields, cyclonic and non-cyclonic, in the region.

SYSTEM MODEL

Even a brief consideration of the wind wave climate behind the Great Barrier Reef establishes the need to consider non-cyclonic as well as cyclonic conditions. While extreme wave conditions are invariably associated with a tropical cyclone, years pass without such an event in the immediate region. Even when a cyclone does influence the region it may not pass sufficiently close to affect the long term frequency of wind waves at the site. More often than not non-cyclonic winds will be responsible for the maximum wave conditions during any year and this fact must be included in the mathematical model.

Geophysical and especially hydrological time series $Z(t)$ are frequently postulated (5,8) as the summation of three separate components (see Fig. 1), such that

$$Z(t) = P(t) + C(t) + R(t). \quad (1)$$

$P(t)$ is a periodic component that is often possible to reconcile with known physical effects. Astronomical tide and, in the present context, diurnal and annual weather cycles are obvious examples. $C(t)$ is an infrequent catastrophic event such as an earthquake, a landslide and, in the present context again, a tropical cyclone. The residue $R(t)$ is a non-pure random series with a clear element of persistence. The component P is represented as a deterministic function of time whereas C and R are stochastic functions of time. Eq. 1 has been adopted as the basis of the mathematical system model.

The simulation methodology adopted is illustrated in Fig. 2. The cycle is initiated by determining the existence or otherwise of a tropical cyclone. Should one exist it must then be decided if it passes sufficiently close to the nominated site to influence the local wave climate. If it does not, this fact is recorded and the cycle is repeated. Should it influence the site the storm intensity and track are chosen and an estimate made of the maximum significant wave height at the site during the passage of the storm. This information is also recorded and the cycle repeated. When a tropical cyclone does not exist, and this is most of the time, non-cyclonic wind conditions are appropriate and the significant wave height at the site is predicted. Again this information is recorded and the cycle repeated. Details of this simulation cycle follow, firstly for non-cyclonic wind waves and then tropical cyclone wind waves.

Wave conditions throughout are represented solely in terms of significant wave height, with no consideration of directional spectra or even one-dimensional spectra. Further the Sverdrup-Munk-Bretschneider forecasting technique (13), deterministic and empirical, is adopted in the estimation of wind-generated waves under both cyclonic and non-cyclonic conditions.

CHARACTERISTICS OF NON-CYCLONIC WIND RECORDS

Following the adopted simulation methodology for non-cyclonic winds, the first step is the generation of a statistically equivalent wind record (magnitude and direction). A necessary preliminary step is an evaluation of the statistical characteristics of the wind climate, as represented by the Card 7 data, to assist in the selection of an appropriate synthetic

Fig. 1 GEOPHYSICAL TIME SERIES DECOMPOSITION

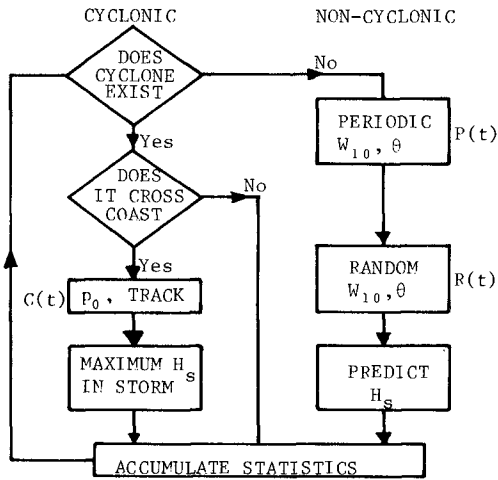

Fig. 2 WIND WAVE SIMULATION METHODOLOGY

generation technique. The available three-hourly wind records for two typical sites, Townsville and Rockhampton airports, were subjected to standard time series analysis techniques, namely spectral, correlation and probability analyses.

Spectral Analyses. - It was anticipated that the wind spectrum would cover a wide range of frequencies from seasonal effects around 0.003 cpd (cycles per day) to diurnal variations at 1 cpd to turbulence and gusts above 1000 cpd. Spectral resolution is bounded at the lower end by the time step Δt of the data series and at the upper end by the length of the data series, which is of course limited by computer storage. Using the FFT technique and a second data series formed from daily averages of the three-hourly records, a reasonable estimate of the wind magnitude and wind direction spectra can be obtained over the frequency range 0.000122 cpd to 4 cpd. The maximum frequency available is well below the range for gusts and turbulence which can not be discerned from the data available. This is no handicap however as such information is not required for the SMB wave forecasting technique.

Composite wind speed and wind direction power spectra for Townsville and Rockhampton airports are given elsewhere by Sobey, Rossow and McMonagle (11). All four spectra show the same trend, namely clear spectral peaks at frequencies of 1 cpd and around 0.0027 cpd, representing observable weather periodicities at periods of 1 day (diurnal) and 1 year (seasonal), together with a significant residual of essentially random noise throughout the spectrum.

Correlation Analyses. - Time domain analyses of the wind data in the form of auto and cross-correlation computations were undertaken in addition to the frequency domain analyses above. The base data only ($\Delta t = 3$ hr) was subjected to this analysis and a typical result (wind magnitude at Rockhampton airport) is shown in Fig. 3.

These results confirm the indications of the spectra. The diurnal periodicity is particularly clear and extension of the time-lag scale would also show the seasonal periodicity. The randomness of the residue is represented by the decay of the mean position to zero as the time-lag increases. The gradual exponential-like decay exhibits the characteristics of a Markov process in that substantial "memory" of preceding conditions is retained.

Probability Analyses. - Finally consideration was given to the amplitude domain characteristics. Figs. 4(a) and (b) show frequency histograms of wind magnitude and direction for Rockhampton airport. Davenport (3) considered the statistics of the total population of mean wind speeds and, assuming initially that the wind is isotropic and that there is no "prevailing" wind, showed that the mean wind followed the Rayleigh distribution. However prevailing wind conditions are normally experienced and Davenport has indicated that directional characteristics can reasonably be accommodated by the Weibull distribution, whose cumulative distribution function (CDF) is

$$F(W_{10}) = 1 - \exp\left[-\left(\frac{W_{10}}{c}\right)^k\right] \quad (2)$$

Additional flexibility is introduced by this two parameter distribution

Fig. 3 WIND SPEED CORRELOGRAM AT ROCKHAMPTON

Fig. 4 WIND FREQUENCY HISTOGRAMS AT ROCKHAMPTON

compared with the single parameter Rayleigh distribution (The Weibull distribution reduces to the Rayleigh distribution when $c = (2)^{1/2}\sigma$ and $k = 2$). It is apparent from the histogram in Fig. 4(a) that a Weibull distribution would be appropriate.

Calm Observations. - The wind records for both Townsville and Rockhampton contain a significant number of calm observations (approximately 30% of the record); this is a common characteristic of normally stable tropical conditions and appropriate consideration must be given to this situation. For analysis purposes it may be considered in terms of conditional probability - a Bernoulli distribution for calm or non-calm conditions and appropriate distributions for magnitude (Weibull) and direction (discrete), given that a wind exists.

This aim was implicitly achieved in the following manner. Calm observations were retained only in the wind direction records where they were entered as zeros, whereas the sixteen compass points from NNE through S to N were entered as integers 1 to 16. The left hand block of the histogram in Fig. 4(b) represents the calm observations. If zero is retained as a "direction", a simulated direction of zero represents a calm day.

WEATHER PERIODICITIES

A major feature of the non-cyclonic wind records is the diurnal weather cycle. An annual weather cycle is also apparent but less pronounced. On this evidence the periodic component $P(t)$ of Eq. 1 has been assumed to comprise only two Fourier components having angular speeds of $\omega = 2\pi$ rad/day and $\Omega = 2\pi/365.25$ rad/day respectively. The periodic component can be written as

$$P(t) = a \sin(\omega t + \phi) + A \sin(\Omega t + \Phi). \quad (3)$$

It is necessary however to consider both magnitude and direction of the wind; magnitude can be represented at $P_1(t)$, direction as $P_2(t)$ and Eq. 3 rewritten as

$$P_{1,i} = a_1 \sin(\omega t_i + \phi_1) + A_1 \sin(\Omega t_i + \Phi_1) \quad (4a)$$

$$P_{2,i} = a_2 \sin(\omega t_i + \phi_2) + A_2 \sin(\Omega t_i + \Phi_2). \quad (4b)$$

Separation of the periodicities (i.e. determination of $a_1, \phi_1 \dots A_2, \Phi_2$) is somewhat subjective. The initial approach was classical harmonic analysis, fitting Eq. 4 to the data by the method of least squares. Typically however the random component $R(t)$ is at least the same order of magnitude as the periodic component and, while harmonic analysis was numerically successful, the computed amplitudes did not match in magnitude the measured spectral peaks. As an alternative the spectral peaks themselves can be used in the estimation of $a_1, \phi_1 \dots$ etc.

From Parseval's theorem the amplitude of a single periodic component is related to the single-sided power spectrum $P(f)$ as

$$a^2 = 2 \int_0^N P(f) df, \quad (5)$$

from which it is possible to directly evaluate the amplitudes a_1, a_2, A_1, A_2 in Eq. 4 from the measured spectra. Estimation of the phase angles $\phi_1, \phi_2, \Phi_1, \Phi_2$ was much more subjective; it was based on visual estimates

from a number of sample records, three-hourly observations for ϕ_1 and ϕ_2 and monthly averaged observations for Φ_1 and Φ_2 . No doubt it is possible to improve this estimation but time did not permit pursuance of this point. The time datum throughout was taken as 00⁰⁰ hours 1 July 1950.

With the periodic signal $P(t)$ thus defined deterministically it may be subtracted from the complete record $Z(t)$ leaving theoretically (see Eq. 1) the components $C(t)$ and $R(t)$. Strictly it would be further possible to separate tropical cyclone winds $C(t)$ from this record. However the deletions from the record would be small in number and their retention would not unduly influence the population statistics of $R(t)$. They would of course have a significant influence on the extreme value statistics of $R(t)$ but the wind data has not been used for such a purpose.

RANDOM WIND COMPONENT

The auto-spectra for Townsville and Rockhampton indicate a substantial random-like residue that would remain after extraction of the ω and Ω periodicities; this is the component $R(t)$ of Eq. 1. The associated correlograms (Fig. 3 is typical) support this observation to some extent but also show a high level of persistence or memory. Physically this represents the observable tendency of high winds from a particular direction to follow high winds from much the same direction and alternatively for calm conditions to follow calm conditions. In time series analysis this persistence is measured by the auto-correlation function ρ_k which is a measure of the degree of linear dependence between observations separated by time $k\Delta t$, Δt being the time interval (3 hrs) of the observations.

Again both components of the residue must be considered, $R_1(t)$ representing wind speed magnitude and $R_2(t)$ representing wind direction, the two series being of course related. A multivariate Markovian generating process proposed by Matalas (6) for the synthetic generation of streamflow at two sites in the same river basin would appear to be an appropriate and relatively straightforward generating process in the present context. For two related series $x_1(t)$ and $x_2(t)$ that are Normally distributed, the Matalas algorithm preserves the sample estimates of:

μ_1, μ_2	- the means of x_1 and x_2
σ_1, σ_2	- the variances of x_1 and x_2
$\rho_{11}(1), \rho_{22}(1)$	- the lag-one auto-correlations
$\rho_{12}(0), \rho_{21}(0)$	- the lag-zero cross-correlations, and
$\rho_{12}(1), \rho_{21}(1)$	- the lag-one cross-correlations.

The multivariate generating process is

$$X_{i+1} = A X_i + B \epsilon_{i+1} \quad (6)$$

where

$$X_i = \begin{bmatrix} x_{1,i} - \hat{\mu}_1 \\ x_{2,i} - \hat{\mu}_2 \end{bmatrix}$$

ϵ_{i+1} is a vector of independent $N(0,1)$ distributed sampling deviates and the matrices A and B are defined as

$$A = M_1 M_0^{-1} \quad (7)$$

$$\text{and } BB^T = M_0 - M_1 M_0^{-1} M_1^T$$

$$\text{where } M_1 = \begin{bmatrix} \hat{\beta}_{11}(1)\delta_1^2 & \hat{\beta}_{12}(1)\delta_1\delta_2 \\ \hat{\beta}_{21}(1)\delta_1\delta_2 & \hat{\beta}_{22}(1)\delta_2^2 \end{bmatrix}$$

$$\text{and } M_0 = \begin{bmatrix} \delta_1^2 & \hat{\beta}_{12}(0)\delta_1\delta_2 \\ \hat{\beta}_{21}(0)\delta_1\delta_2 & \delta_2^2 \end{bmatrix}$$

Young and Pisano (15) have shown that B is not unique and, with $C = BB^T$, suggest using the lower triangular form

$$B = \begin{bmatrix} \sqrt{C_{11}} & 0 \\ \frac{C_{12}}{\sqrt{C_{11}}} & \sqrt{C_{22} - \frac{C_{12}^2}{C_{11}}} \end{bmatrix} \quad (8)$$

There remains a problem in that the $x_1(t)$ and $x_2(t)$ series must be Normally distributed. As seen in Fig. 4 the distributions of the R_1 and R_2 series are clearly not Normal.

A preliminary step is the adoption of suitable distributions to describe the R_1 and R_2 series respectively. R_1 has been fitted to a Weibull distribution by the method of maximum likelihood. No attempt was made to fit any distribution to the R_2 series and it was retained in a discrete histogram form.

Young and Pisano discuss "minimum skewness" transformations of the base data series to yield series that more closely follow a Normal distribution, the minimum skewness referring to the fact that the Normal distribution has zero skewness. They mention logarithmic and square-root transformations in the context of streamflow simulation and adopt the former. In the present context the two related series are not physically the same, as for example in the dual site streamflow case, and it would seem unlikely that the same transformation would be equally satisfactory for both wind magnitude R_1 and wind direction R_2 .

The adopted approach is rather direct; each residual is transformed to another having the same mean and variance but nominally zero skewness by matching the cumulative probabilities of the residual and normal distributions. The residual distribution was chosen as Weibull for the R_1 series and discrete for R_2 . The $R_2 \rightarrow x_2$ transformation contains an additional step, the rotation of the direction datum so that the peak region is central to the record and the relocation of the calm observations (direction zero) to harmonise with this distribution. In both cases it was necessary to adopt truncated Normal distributions, omitting wind speeds less than zero and directions less than zero and greater than sixteen. This CDF transformation has proved moderately successful. The reverse transformation in both cases is equally straightforward.

The steps involved in preparation for the synthetic generation are -

1. Separate $R(t)$ from data files $Z(t)$
2. Calculate $\hat{\mu}_1, \hat{\sigma}_1$ from $R_{1,i}$ and $\hat{\mu}_2, \hat{\sigma}_2$ from $R_{2,i}$
3. Fit Weibull distribution to $R_{1,i}$
4. CDF transformations on residual series
 $R_{1,i} \rightarrow x_{1,i}$ and $R_{2,i} \rightarrow x_{2,i}$
5. Calculate $\hat{\rho}_{11}(1), \hat{\rho}_{22}(1), \hat{\rho}_{12}(0), \hat{\rho}_{21}(0), \hat{\rho}_{12}(1)$ and $\hat{\rho}_{21}(1)$ from $x_{1,i}$ and $x_{2,i}$

The steps involved in the actual synthetic generation are -

1. Generate synthetic $x_{1,i}$ and $x_{2,i}$ series from Matalas algorithm
2. Inverse CDF transformation to synthetic $R_{1,i}$ and $R_{2,i}$ series:
 $x_{1,i} \rightarrow R_{1,i}$ and $x_{2,i} \rightarrow R_{2,i}$

Questions remain concerning the adequacy of the first-order Markov generating process in modelling long term persistence, for example the Hurst phenomenon. According to O'Connell (8), the retention of only lag-zero and lag-one correlations leads to the reproduction of only high frequency behaviour and cannot capture long term persistence. Several alternate generating processes have been proposed in the hydrology literature but there does not seem as yet to be any general agreement even in the case of streamflow. The Matalas algorithm certainly reproduces many of the observable features of geophysical time series and is just as certainly not the weak link in the present methodology.

NON-CYCLONIC WIND WAVE PREDICTION

At time t_i during non-cyclonic wind simulation the wind speed is

$$W_{10} = P_{1,i} + R_{1,i} \quad (9)$$

and the wind direction is

$$\theta = P_{2,i} + R_{2,i} \quad (10)$$

Wind conditions are simulated every 3 hours. This wind is assumed active in direction θ for sufficient time that the generated sea condition is fetch-limited. This would certainly not always be true but becomes an increasingly better assumption for higher wind speeds where interest is of course centred; it will always be conservative. Adopted fetches along radiating lines, corresponding to the sixteen compass points, from the nominated site to the coast or the inner edge of the Great Barrier Reef are taken direct from appropriate navigation charts.

Assuming deep water conditions wind waves have been predicted directly from the empirical equations (13) to the Sverdrup-Munk-Bretschneider forecasting method:

$$\frac{gH}{W_{10}^2} = 0.283 \tanh\left[0.0125 \left(\frac{gF}{W_{10}^2}\right)^{0.42}\right] \quad (11)$$

$$\frac{C}{W_{10}} = 1.20 \tanh\left[0.077 \left(\frac{gF}{W_{10}^2}\right)^{0.25}\right] \quad (12)$$

$$\frac{gt_D}{W_{10}} = K \exp \sqrt{A \ln^2 \frac{gF}{W_{10}^2} - B \ln \frac{gF}{W_{10}} + C_* + D \ln \frac{gF}{W_{10}}} \quad (13)$$

where K, A, B, C_* and D are constants, H is the significant wave height, C the wave celerity, F the fetch length and t_D the wind duration. Again the assumption of deep water conditions is conservative. Eq. 11 has been used directly to estimate wave height at time t_i corresponding to the wind magnitude and direction indicated by Eqs. 9 and 10.

TROPICAL CYCLONE OCCURRENCES

The advent of a tropical cyclone is an infrequent event and has been considered as a completely separate influence on the local wind and wave climates. The basic steps of the non-cyclonic wind wave simulation described above, namely simulate the wind field, then predict the resulting wave field, are repeated in principle for tropical cyclone wind waves with the details of course much altered. These steps however must be preceded by the simulation of the existence of a tropical cyclone, a step that has no parallel in the previous section. Given that a cyclone occurs, the methodology proceeds implicitly to the simulation of a moving wind field system and thence to the prediction of wind waves that would be generated at the nominated site by the moving wind field.

The stochastic modelling of tropical cyclone or hurricane occurrences in a particular region has been considered in detail by Russell (9), the approach adopted herein differing in detail but not in spirit. A suitable stochastic model should permit predicting multiple occurrence or none at all during the cyclone season. Within each southern hemisphere season, taken as mid-December to mid-April (a total of 121 days or 122 in a leap year), it should permit prediction of the time of occurrence of any events. Storm occurrences are assumed to follow a uniform Poisson process, which describes independent incidents occurring along a continuous time axis with a constant average rate of occurrence of λ per season. The distribution of storm occurrence time at particular time t_i then follows a Poisson distribution with parameter λt_i . The distribution of inter-arrival time τ between separate storms is more relevant in the present context however and, for a Poisson process, τ has an exponential distribution with parameter λ :

$$f(\tau) = \lambda e^{-\lambda\tau} \quad \text{for } \tau > 0. \quad (14)$$

No detailed analysis of the appropriateness of the Poisson process assumption has been undertaken, there being no reason to doubt its applicability in these circumstances.

TROPICAL CYCLONE WIND FIELD

The meteorological characteristics of a tropical cyclone and Australian data on the statistics of the various cyclone parameters are discussed in detail in Ref. 10. The tropical cyclone is essentially an atmospheric phenomenon, developing over tropical seas in mid to late summer. Extremely low central pressures (< 960 mb at M.S.L.), high vortex winds (> 40 m/s) and the presence of an eye are the dominant features of the atmospheric flow structure. The aerodynamics of the

tropical cyclone and the hydrodynamics of the underlying water body are coupled at the water surface by the atmospheric pressure and wind shear stress. The M.S.L. pressure and sustained wind both change significantly with distance from the eye, which itself moves forward, typically in a south-westerly direction in the Coral Sea. The hydrodynamic response is complex and transient and comprises both long waves (surge) and the short waves (wind waves), the latter being of interest in the present context.

According to current wind wave generation theories it is the near surface spectrum of the turbulent pressure fluctuations that is directly responsible for wind wave generation. Information on this aspect of tropical cyclones is just not available although the mean flow pressure structure can be predicted with some confidence. Existing tropical cyclone wind wave theories tend to relate wave generation to the near surface mean flow wind structure, specifically in the SMB approach to W_{10} . The spatial distribution of W_{10} within a moving storm is still the matter of some debate and the parameterised wind field adopted in Ref. 10 will also be adopted here. This is basically the N.H.R.P. tropical cyclone model (4); in Ref. 10 this model has been mathematically formalised and suitably modified to describe a Coral Sea tropical cyclone. The basic storm parameters number four:

- (1) Central pressure p_0 at Mean Sea Level
 - (2) Maximum sustained wind W_{10} at a height of 10 m above M.S.L.
 - (3) Radius to maximum wind R
 - (4) Speed V_E and direction of eye (i.e. track or path)
- and moving wind fields are built up in terms of these parameters. A sample wind field is given in Ref. 11.

Following Russell, the next step is to assign, from the historical data or otherwise, suitable probability distributions to these four parameters. The adopted procedure to some extent follows Sobey, Harper and Stark (10) and Stark (12) and is closely related to the available historical data.

Central Pressure. - The Card 13 meteorological data was searched by computer to extract all tropical cyclones passing within 200 n miles of the nominated site. As the Card 13 data does not distinguish between tropical cyclones and tropical disturbances only those "hits" less than or equal to 990 mb have been retained and termed tropical cyclones for the purpose of this study, the less intense disturbances being implicitly considered as non-cyclonic events. It was assumed that the partial duration series so formed followed a Gumbel or Extreme Value Type I distribution, using smallest value criteria: the probability density function (PDF) is

$$f(p_0) = \alpha \exp[\alpha(p_0 - u) - e^{\alpha(p_0 - u)}], \quad (15)$$

where α is the dispersion and u the mode of the Gumbel distribution. These distribution parameters are estimated from the partial duration series by the method of maximum likelihood. Also calculated was the Kolmogorov-Smirnov goodness-of-fit statistic, which measures the suitability of the assumed CDF in describing the observed cumulative frequency histogram. The K-S statistics indicate that the Gumbel distribution is by no means a perfect representation of the historical data. This however

is considered more as a measure of the unsatisfactory nature of the data than a condemnation of the Gumbel distribution. Certainly other extreme value distributions could have been adopted but this would not improve the quality of the data.

Maximum Sustained Wind. - The modified N.H.R.P. model relates V_{10} directly to the central pressure as:

$$V_{10} = K \sqrt{\frac{P_{\infty} - P_0}{\rho_a e}} \quad (16)$$

No probabilistic interpretation is introduced into this choice. The M.S.L. ambient pressure p_{∞} has been taken as 1013 mb, the wind coefficient K has been set at unity (Ref. 10) and ρ_a is the mass density of air.

Radius to Maximum Wind. - Russell adopts a log-normal distribution for R from U.S. data for the Gulf of Mexico but equivalent Australian data is not available. Card 13 data has an entry for distance from storm centre to position of maximum *reported* mean wind in the area influenced by the tropical cyclone. This is of course unlikely to be the radius of maximum winds, as the data recording network together with additional ship reports provide only a very sparse coverage in northern Australia. In many cases also this entry has been left blank, in implicit recognition of this problem. The feasibility of relating R to central pressure and latitude is discussed in Ref. 10, but not adopted. It was concluded that a subjective decision on R must be made, which was to set it at 30 km for all Coral Sea tropical cyclones with no regional variation. This approach was also adopted herein.

Storm Track. - The Card 13 data is somewhat more helpful on this aspect although it is still not entirely adequate. Russell, for the Gulf of Mexico, adopted a Normal distribution for storm speed V_g , a uniform distribution for coast crossing position and a linear relationship between coast crossing heading and position; the Australian data is insufficient to allow such a detailed description of storm movements but it is possible to make some reasonable assumptions.

The data is entered as position co-ordinates (latitude and longitude) at various times throughout the life of the tropical cyclone, one such entry per card. The time spacing between cards is a minimum of 3 hrs but is often much longer. In the case of storm speed the data that can be extracted is rather scattered but an average value of 28 km/hr was established in Ref. 10 and is also adopted here. The data was considered too scattered to attempt the adoption of a distribution about this mean.

Data on coast crossings was also too sparse and too scattered to draw any conclusions. Russell's data was apparently not too much better and he found it necessary to assume a uniform distribution for coast crossing position for landfalling storms. This assumption is quite reasonable and is adopted for landfalling storms herein.

In formal terms the probability of a landfalling tropical cyclone crossing the coast a distance y from a nominated coastal site with

equal probability over a length of coast extending a distance L both sides of the site is described by the PDF

$$f(y) = \begin{cases} \frac{1}{2L} & \text{for } -L \leq y \leq L \\ 0 & \text{elsewhere.} \end{cases} \quad (17)$$

The remaining decision concerns storm direction and here some very subjective assumptions are necessary as the Card 13 data is very inconclusive (10). It has been assumed that only one-half of all tropical cyclones passing within 200 n miles of the site actually cross the coast in this region and that these storms cross essentially at right angles to the general line of coastline; the remaining storms are assumed to move away from the site and not to unduly influence the coastal wave climate. In formal terms again the probability of a land-falling tropical cyclone, given that the storm exists, is described by the Bernoulli distribution: the probability mass function (PMF) is

$$p = \begin{cases} 0.5 & \text{for a landfalling storm} \\ 0.5 & \text{for a non-landfalling storm,} \end{cases} \quad (18)$$

TROPICAL CYCLONE WIND WAVES

Existing wind wave generation theories attempt to describe a process of gradual energy transfer to the sea across the air-sea interface, in which both wave height and wave celerity gradually increase under a steady wind towards some plateau level determined by the physical characteristics of the atmospheric boundary layer (represented by W_{10} alone in the SMB approach). The time scale of the energy transfer process is measured in hours and the atmospheric forcing must be maintained for the wave to continue to grow as it propagates across the sea. Should the wave impinge on a shoreline (a fetch limitation) or should the atmospheric forcing not be sustained (a duration limitation), then the wave may cease to grow before it reaches the plateau level, termed a fully arisen sea. Sustained forcing beyond the stage where there is sufficient time and sufficient fetch to attain the plateau level will not further increase the height or celerity of the wave. In physical terms the waves have been built up to a limiting steepness beyond which further energy transfer is dissipated in wave breaking.

Wave decay in deep water however is an even more gradual process. Swell waves behave almost as an ideal fluid and may propagate over hundreds of kilometres of ocean without appreciable decay. An opposing wind would of course hasten decay.

Wave generation within a tropical cyclone is clearly a very complicated process. Field observations are very sparse and rarely amount to more than water level versus time traces at a handful of sites. The spatial structure of the storm largely determines the distribution of wind waves and although peak waves do not necessarily coincide with peak wind velocities, it is implicit that there is a gradual decay away from the region of maximum waves. In deep water well beyond the edge of the continental shelf the spatial distribution of wind waves about the storm eye is thought to be broadly axi-symmetric, except for the forward motion of the storm, in a similar manner to the spatial

distribution of sustained wind within the tropical cyclone. Fetch limitations imposed by the coastline as the storm crosses the continental shelf would have a substantial influence on this structure; the Great Barrier Reef introduces further fetch limitations and further complications. The spatial distribution of wind waves over the continental shelf will certainly be different from the offshore situation. A numerical model developed by Cardone, Pierson and Ward (2) to predict the directional spectra of hurricane-generated waves largely confirms this general description.

MODIFIED WILSON MODEL

The Cardone et al model is based on the numerical integration of the wave energy balance or radiative transfer equation. A much less time consuming though certainly less satisfactory approach is to represent the developing sea conditions in terms of just significant wave height rather than directional spectra. Such an approach can be based on the SMB empirical forecasting equations, rather than wind wave generation theories. This was in essence the approach adopted for non-cyclonic conditions.

Wilson (14) has proposed a numerical technique, based on the SMB equations, for estimating deep water wave generation by a wind system that varies in both space and time. Waves are implicitly assumed to propagate along a *straight line* path in co-ordinate direction s , along which the wind W_{10} varies with both position s and time t . The method also assumes that local wave conditions are uniquely described by the significant wave height H . The method adopted herein is essentially Wilson's except that due consideration has been given to the mathematical formulation of the problem and the consequent numerical integration.

In mathematical terms the wave generation process is assumed to be described in deep water by two simultaneous functional relationship of the form

$$H = H(t, W_{10}) \quad (19a)$$

and

$$C = C(t, W_{10}) \quad (19b)$$

where $W_{10} = W_{10}(s, t)$. When W_{10} is a constant, Eqs. 19 are identical to the SMB Eqs. 11 to 13. When W_{10} is not a constant the rate of change of H and C with time is

$$\frac{dH}{dt} = \frac{\partial H}{\partial t} + \frac{\partial H}{\partial W_{10}} \cdot \frac{dW_{10}}{dt} \quad (20)$$

and

$$\frac{dC}{dt} = \frac{\partial C}{\partial t} + \frac{\partial C}{\partial W_{10}} \cdot \frac{dW_{10}}{dt} \quad (21)$$

At a particular position s , W_{10} is a function of t only:

$$\frac{dW_{10}}{dt} = f(s, t) \quad (22)$$

where the function $f(s, t)$ is specified uniquely by the adopted moving wind system. The wave being generated travels at the instantaneous group velocity C_g ($=\frac{1}{2} C$ in deep water):

$$\frac{ds}{dt} = C_g \quad (23)$$

Eqs. 20 to 23 form a system of four simultaneous ordinary differential equations that can be integrated numerically in time by the Runge-Kutta method. Following Wilson in spirit but not in detail the partial derivatives on the right hand sides of Eqs. 20 and 21 can be estimated from the deep water SMB equations. The details can be found in Ref. 11.

There is some difficulty with the SMB equations when the wind opposes the direction of wave propagation for a period of time. The SMB equations themselves are strictly inapplicable but numerical integration remains continuous - $\frac{dH}{dt}$ and $\frac{dC}{dt}$ become negative, H and C both decrease and eventually a negative wave height is predicted. Physically of course this would not happen but there would be some attenuation. A conservative approach to this difficulty is adopted by setting the right hand sides of Eqs. 20 and 21 to zero whenever a negative value is computed.

The remaining problem in the mathematical formulation is the specification of suitable initial conditions at $t = 0$. It is assumed in general that the wave is initiated in still water, i.e.

$$H = C = s = 0 \text{ and } W_{10}(0,0) \text{ at } t = 0.$$

MAXIMUM SIGNIFICANT WAVE AT NOMINATED SITE IN A TROPICAL CYCLONE

The application of the above mathematical model to the estimation of tropical cyclone wind waves on the continental shelf is relatively straight-forward. Given the storm central pressure and track, a moving wind system is predicted. According to the Wilson model any straight line drawn across the continental shelf will represent a fetch along which a wave will propagate. It is a simple exercise in trigonometry to determine at any time from the moving wind field the wind speed component directed along the adopted fetch line; this becomes the local $W_{10}(s,t)$. Interest is largely centred on coastal sites and all waves arriving at such sites are assumed to have been initiated at the inner fringe of the Great Barrier Reef; no wave energy is assumed to penetrate beyond the Reef from the Coral Sea. To avoid the necessity to consider shoaling and refraction in the wave model the nominated coastal site is assumed to be a near shore deep water site typically 10 km offshore such that shallow water effects need not be considered; wave routing shoreward from this point would need to consider shoaling, refraction and wave breaking to arrive at a site design wave.

For a particular near shore site a number of radiating straight-line "fetches" can be drawn towards the Reef and waves can be computed along each of these fetches in turn. Under the complicated forcing resulting from the passage of a tropical cyclone, wave energy can reach a site from potentially all points of the compass, contributing to the local directional spectrum at that time. The significant wave height at that particular time is an integral measure of the directional spectrum. The wave model predicts significant waves arriving at the coastal site at a number of different times from a number of different

directions; what to take as *the* maximum significant wave at the site is not particularly clear. The adopted procedure outlined below attempts to take some account of the development of the directional spectrum in the adoption of the maximum significant wave:

1. Radiating fetch lines are drawn from the coastal site towards the Great Barrier Reef at 15° spacings.
2. Waves are initiated at the Reef end of these fetch lines every half-hour during the passage of a tropical cyclone.
3. The two waves reaching the coastal site respectively before and after each integral hour along each fetch are interpolated to estimate the wave height for that fetch at that hour. Interpreting the radiating fetches as the contributions to the directional spectrum at the site at that time, an appropriate estimate of the wave height at the site at that integral hour is the root mean square value of the respective fetch contributions.
4. The maximum significant wave height for the particular site and storm track is taken as the highest value computed in 3 above; it typically occurs at one hour before storm landfall.

A computer program was developed for this purpose and could be used in the wave simulation procedure. However it was rather time consuming and it was decided instead to develop a somewhat simplified model of the situation in the form of a "universal" maximum significant wave profile that would obviate the need for such an extreme computational exercise.

COASTAL PROFILE OF MAXIMUM SIGNIFICANT WAVE

The steps adopted in the construction of a coastal profile of maximum significant wave height during the passage of a landfalling tropical cyclone were as follows:

1. The appropriate region of continental shelf between the Queensland coast and the Great Barrier Reef is idealised to a straightline coast and a straightline Reef perhaps angled to the coast and at a distance offshore from the site. The water over the continental shelf is assumed deep in the sense of the SMB forecasting equations.
2. Passage of a landfalling tropical cyclone across the continental shelf is assumed to be satisfactorily represented by storm movement at right angles to the straightline coast from sea to land.
3. A number of nearshore deep water coastal sites 10 km offshore are considered at 25 km spacings for distances N and S of landfall.
4. The maximum significant wave height was estimated at each of these coastal sites for storms with central pressures of 990 mb, 960 mb and 930 mb respectively. A typical result, for Cleveland Bay at Townsville, is shown in Fig. 5. The shape of these profiles was physically expected and is somewhat analogous to the storm surge profile that is forced by the same tropical cyclone. The waves peak approximately a radius of maximum winds to the south of the landfall position. In the range of central pressure considered there appeared to be an approximate linear relationship between increase in wave height at a particular position and decrease in central pressure.

TROPICAL CYCLONE WAVE SIMULATION

The steps involved in the tropical cyclone wind wave simulation can be summarised as follows:

1. Simulate the occurrence of the next tropical cyclone from the exponential distribution (Eq. 14) by the Monte Carlo procedure.
2. Simulate storm central pressure from the Cumbel distribution (Eq. 15) below 990 mb by the Monte Carlo procedure.
3. Simulate the storm track from the Bernoulli distribution (Eq. 18) by the Monte Carlo procedure. If not a landfalling storm return to the simulation of non-cyclonic conditions. If a landfalling storm simulate the coast crossing position from the uniform distribution (Eq. 17) by the Monte Carlo procedure.
4. For a landfalling storm predict the maximum significant wave height at the site from Fig. 5 or its equivalent for another site.

TYPICAL RESULTS

Some 5000 years of statistically likely wind wave records, nominally from 2001 AD to 7000 AD, can be simulated following the methodology described above. Typical results can be found in Ref. 11. While tropical cyclones are clearly responsible for the majority of the very high waves, non-cyclonic conditions make a dominant contribution to the long term statistics in the moderate wave height range.

The resulting significant wave height - average recurrence interval curve for Cleveland Bay at Townsville is shown in Fig. 6. The tendency towards a bi-modal character again illustrates the separate contributions to the long term statistics from cyclonic and non-cyclonic conditions. Such a curve would be appropriate for design purposes.

The procedures adopted for the wind wave simulation methodology will nominally estimate also the wave period associated with the predicted wave height at any given time. This would considerably increase the computational effort and was not attempted. However if the assumption is made that a fully arisen sea condition exists then a wave period appropriate to a nominated wave height may be estimated from the universal one-dimensional wave spectrum of Pierson and Moskowitz (13). Assuming the distribution of wave heights within the particular storm follows the accepted Rayleigh distribution, the significant wave height can be related to the total spectral energy and hence to the peak frequency or wave period of the Pierson-Moskowitz spectrum as

$$T_p = \pi \left(\frac{5}{\alpha}\right)^{1/4} \left(\frac{H}{g}\right)^{1/2} \quad (24a)$$

where the Phillips constant α is 0.0081. Evaluating the constant term, Eq. 24a becomes

$$T_p = 15.66 \left(\frac{H}{g}\right)^{1/2} \quad (24b)$$

The assumption of a fully arisen sea will not always be valid, in which case Eq. 24 will overestimate the wave period.

CONCLUSIONS

In a general sense mathematical system modelling has been confirmed as a realistic alternative to historical wave data in the prediction of long term wind wave frequencies in a tropical cyclone region. In the vast majority of cases where historical wave data is either not available or covers only a few years, system modelling is clearly a superior approach when maximum advantage is taken of historical wind and tropical cyclone records, as in the present model.

In a tropical cyclone region the importance of non-cyclonic conditions for short and medium term recurrence intervals has been established. The resulting frequency distribution is clearly bi-modal representing the separate influences of cyclonic and non-cyclonic conditions.

More specifically for Australia's Coral Sea coast, the Great Barrier Reef effectively prevents wave penetration on to the continental shelf from further offshore and provides a significant fetch limitations on locally generated wind waves.

COMPARISON OF SHIPBORNE WAVE RECORDER AND WAVERIDER BUOY DATA
USED TO GENERATE DESIGN AND OPERATIONAL PLANNING CRITERIA

by

C.G. Graham¹, G.Verboom² and C.J.Shaw²

ABSTRACT

This paper presents the results of recent investigations at three sites where waves have been monitored simultaneously by two commonly used deep-water wave recorders, over a total period of 16 sensor-years. The study confirms earlier statements that there are relative differences between the wave parameters and statistical values calculated from the measurements of the two instruments. However, the large amount of data has enabled the authors to quantify the results in engineering terms and to assess the implications for extreme value analysis, spectral analysis and wave climate operational planning.

INTRODUCTION

A considerable proportion of the instrumental wave recordings collected in Northwest European Waters has been obtained using either shipborne wave recorders (SBWR) or wave-rider buoys (WRB). The offshore engineer, who needs to establish operational and design wave criteria for a particular site, will draw upon the nearest reliable set of wave data, which may have been collected by either or both instruments.

Where a relative accuracy (in terms of gain and offset) of $\pm 10\%$ is acceptable, then the sensor used to collect the measurements is probably immaterial (provided of course it has been properly maintained and calibrated). However, in the situation where a higher degree of accuracy is required then the 'absolute' accuracy of the instrument(s) used becomes a prime consideration.

A number of workers, for example Draper (*ref. 9*) and Van Aken (*ref. 18*) have reported the results of field and laboratory investigations into both the 'absolute' and relative accuracies of the SBWR and WRB. This paper is intended to complement this work, not by comparing a small sample of data, but by presenting the results of an overall examination of simultaneous measurements collected over a total period of 16 sensor-years. It is hoped that these results will provide a useful guide to interpreting SBWR and WRB data, especially where they both appear in the same data set.

PURPOSE OF THE INVESTIGATION

The last 10 years have seen a rapid expansion in hydrocarbon exploration and production activities in the waters of the Northwest European Continental Shelf. In order to carry out these activities as safely, efficiently and economically as possible, a considerable amount of information about the environment is needed. Ten years ago very little measured data were available for the Continental Shelf areas away from the coast (water depths 50m to 200m).

Today, with five to eight years of data from particular sites (though the data return has often only been in the order of 60 to 70%), our knowledge has increased significantly, but it must be realised that the amount of data is, statistically speaking, still limited. To provide the environmental operational and design criteria statistics required by the offshore oil and gas industries to the accuracy and confidence levels often quoted would, from a mathematical point of view, need many more years of data. Since it is totally unrealistic to wait such a length of time, theoretical methods (such as hindcasting and correcting for relative severity) have been developed which compensate for the limited amount of data. It is essential that the accuracy of the measurements themselves should be considered if these methods are to have any significant meaning.

What accuracy levels are required? For most offshore operations carried out by the oil industry a wave height accuracy, in the field and at the planning stage, in the order of $\pm 4\%$ is probably acceptable. However, what is unlikely to be acceptable is an offset or difference in gain between two measuring instruments — particularly at low wave heights — which would create an unwelcome bias to the results of any analysis work. For this situation, it is important to quantify the relative difference between the two instruments.

¹ Environmental Consultancy Section, Marex, Cowes, England. (also Dept. of Civil Eng., University of Southampton, England.)

² Oceanographic Dept., Shell Internationale Petroleum Maatschappij B.V., Den Haag, Netherlands.

The 'absolute' accuracy of wave heights is important for structural design, however, in particular for extreme value analysis. In the formulation of extreme wave height criteria, an accuracy of $\pm 2\%$ is sometimes quoted (e.g. Draper, *ref. 9*). While this degree of accuracy is certainly attainable with individual components in the measurement system, it is doubtful if the system itself is capable of such 'absolute' accuracy. Indeed in high sea states the problem is compounded since the sea surface itself becomes difficult to define.

This apparent need for such high degrees of accuracy is understandable when it is realised that an extra 0.3 metre on the design wave height for an offshore structure (approximately +1% in the Northern North Sea) could increase the cost of the project by as much as \$2 million. While the industry certainly has no wish to under-design, neither does it wish to over-build since this is a waste of both money and scarce resources.

In some respects, all design work is empirical, so that the 'absolute' accuracy of an instrument might be regarded as academic if the data measured by one particular instrument (when fully calibrated) are generally accepted as the standard and are used as a basis for all design work. Measurements from the WRB (manufactured by Datawell) tend to be viewed in this light by some engineers.

When a relative difference appears consistently between two instruments — such as seen between the SBWR and WRB — then there is a real need to quantify the difference and this is the purpose of this paper.

BASIC DESCRIPTION OF THE SBWR AND WRB

The shipborne wave recorder was developed by the UK Institute of Oceanographic Sciences and has been described in detail by Tucker (*ref. 16*). It comprises two pairs of accelerometer and pressure units, one each side of the ship, approximately on the pitch axis. The accelerometers sense the heave of the ship which is itself a measure of the ship's response to waves of wavelength rather longer than the vessel's length, whilst the pressure units sense the short wavelength waves within the length of the ship. The output from the four sensors is combined to produce a wave signal which needs to be corrected for depth attenuation and instrumental response. As described by Van Aken (*ref. 18*), the SBWR has an advantage over the other wave measuring systems in that it is relatively easy to install (although dry-docking is usually necessary). It does have a drawback in terms of accurate calibration, originating from the fact that the wave signal is obtained synthetically from the ship's movement and the water pressure on the vessel's hull.

Details on calibrating and establishing the frequency response of the SBWR may be found in papers by Cartwright (*ref. 1*), Ewing (*ref. 10*), Darbyshire (*ref. 2*) and Van Aken (*ref. 18*).

A new integrated circuit version of the SBWR has recently been designed by I.O.S. and has been tested in service.

In 1965, the Datawell accelerometer Waverider buoy became available. This buoy is spherical, has a diameter of 0.7m (standard size) and produces a wave displacement signal by integrating twice the vertical accelerations of the buoy under the influence of wave action. This signal is then used to modulate a radio transmitter whose transmission can be received up to about 25 km away. The buoy accelerometer is kept in a vertical position by means of a cardanic suspension in a glass sphere filled with fluid.

The buoy itself can be moored in a number of different ways but the most common utilises 15 metres of rubber cord beneath the buoy, connected to a weighted mooring line leading to an anchor weight on the sea bed.

The response characteristics of the WRB are almost constant for wave frequencies between 0.065 Hz (15.4 sec) and 0.50 Hz (2 sec) being within 3% amplitude error, but for higher frequencies this response first increases due to resonance then tails off rapidly (*ref. 3*).

The WRB is not truly 'wave following' since it is not a fixed point reference. It tends to rotate in the horizontal plane with the passing of each wave and in short-crested seas may have a tendency to 'roll off' the wave crests.

DATA SOURCES

The input wave data for this comparison study were collected by the UKOOA Oceanographic Committee over a total period of nearly 16 wave sensor-years using weatherships at three stations on the UK Continental Shelf, as shown in *Figure 1*.

	Position	Water Depth	Data Measured	
			from	to
Stevenson Station	61°20'N., 0°00'E East of Shetlands	159 metres	Feb. '73	Feb. '76
Fitzroy Station	60°00'N., 4°00'W West of Shetlands	122	Dec. '73	May '76
Boyle Station	50°40'N., 7°30'W Celtic Sea	107	May '74	May '77

The following weatherships were used:

Vessel	Length Overall
	<i>metres</i>
m/v Edelstein (<i>later renamed Silver Pit</i>)	41.9
m/v Famita	41.9
m/v Ami	41.8
m/v Jomi	40.9
m/v Skagerak	46.9

Each ship used was fitted with a SBWR and maintained station within 2 miles of a moored WRB. The output from both instruments was recorded simultaneously on paper chart rolls as 15 minute samples every three hours. As an additional data recording method, the wave traces were also recorded continuously on FM analogue magnetic tape.

Both SBWR and WRB instrument sets were subject to regular maintenance and calibration checks. The SBWR transducer depths on the five ships ranged from 1.0 to 1.9 metres below the water line.

DATA PROCESSING

The SBWR and WRB chart roll records were processed on-shore according to the standard Tucker-Draper H₁, H₂ method of hand chart analysis.

A full description of this method is described in Tucker (*ref. 17*) and Draper (*ref. 6*).

From each 15-minute sample, the following wave parameters were computed:—

- H_s Significant Wave Height, the average height of the highest one third of the waves in the sample. H_s is related to the root mean square wave height and the square root of the sea surface energy. In more simple terms, it is approximately the same as the average wave height reported by an experienced observer through visual estimation.
- H_{max} (3 hrs) The highest wave height computed to occur within the 3-hour recording interval by the Tucker-Draper method.
- T_z The Mean Zero Up-crossing Period. This is obtained by dividing the duration of the record (in seconds) by the number of times the wave trace passes through the mean water level in an upward direction.

For the SBWR, a correction is required in the calculations to compensate for depth attenuation and instrumental response. This correction is defined by the equation (*ref. 14*):—

$$K_{SBWR} = 0.83 [1 + (8.8\mu)^{-2}]^{3/2} \exp (\beta\mu^2 d/g) \dots \dots \dots (1)$$

where $\mu = \frac{2\pi}{T_z}$ radians/sec

$\beta = 2.5$ (a dimensionless constant)

$g = 9.81$ m/sec²

$d =$ depth of pressure unit below waterline in metres.

Figure 1 – U.K.O.O.A. Weather Ship Stations

For the WRB, K usually equals 1.0 depending upon the instrument calibration, since the instrument response is generally regarded as constant for the majority of wave frequencies (*ref. 3*).

The following points are worth noting about the data processing method:--

1. If an H_s value is computed using the Tucker-Draper method from each of a series of wave records taken under the same stationary wave conditions, then the H_s values obtained will be found to vary from record to record in a random manner. The value required is the average of the large number of records measured at the same time in the same sea state but since only one reading is usually available in practice, it is important to realise that there is random error associated with each data value computed. The error has been quoted by Draper (*ref. 6*) to be in the order of $\pm 10\%$ (one standard error). The overall effect of this random error, when dealing with many data samples, is smoothed out, so that the long-term wave height distribution of H_s is unlikely to be affected except at the tail of the distribution containing values for the single event samples at the peak of the largest storm.

The implication of this for comparing WRB and SBWR H_s values, computed by the Tucker-Draper method, is that the comparison is 'clouded' by the random error effects which produce appreciable scatter in the H_s data points derived from the two instruments. However, it is expected that a realistic smoothed out relationship between the two instruments can be derived.

2. In the Tucker-Draper method, the computation of H_s is related to the T_z value. Thus any differences in the T_z values computed from the records of the two instruments will also be reflected in the H_s values computed. However, by examining Table 1 of Draper (*ref. 6*) it will be seen that differences in T_z would need to be quite large to affect the value of H_s , so this factor will have only minor influence.
3. In equation (1) above a single coefficient 'K' is derived to correct the SBWR records for the effects of depth attenuation and instrumental response. It can be seen that K is dependent upon values input for β (a constant), d (the transducer depth) and T_z . Their relative influence on 'K' — and hence on the SBWR H_s values computed — is clearly demonstrated in *Figures 2 and 3*.

Figure 2 is for a transducer depth of 1.0 metre below the water line, while *Figure 3* is for 1.75 metre depth. Obviously at the greater depth a larger correction is needed and therefore the value of 'K' used is greater. Curves are also presented in the figures for the range of β values sometimes applied (for these data $\beta = 2.5$ was used). Finally on each graph has been presented a curve for $\beta = 2.5$ and T_z multiplied by 1.25. This curve has been presented to demonstrate that for mean wave periods below about 9.0 seconds, the value of 'K' is very dependent upon any changes in T_z . For example, for $d = 1.0\text{m}$, $\beta = 2.5$ and a T_z of 5 seconds, 'K' = 1.26. However, if a period of 6.25 seconds had been used, then 'K' would only equal 1.09.

4. Since both the Tucker-Draper H_s and SBWR K values are related to T_z , it should be emphasised that the SBWR/WRB comparison study results presented here are generally only true for the particular size of weathership used, the depths of SBWR pressure sensors and the particular wave climatic conditions experienced at the three weather-station locations.

Figure 3 — SBWR Correction Curve — Transducer Depth 1.75m

STATISTICAL METHODS USED TO COMPARE THE SBWR AND WRB PROCESSED DATA

The following statistical procedures were employed to compare the SBWR and WRB simultaneous H_s and T_z values:—

1. STANDARD LINEAR REGRESSION ANALYSIS

This analysis establishes how well a straight line defines the relationship between the two variables 'Y' and 'X'. The 'Y' on 'X' regression analysis computes the equation for a straight line by a least-squares fit parallel to the 'Y' axis, through the data points. The 'X' on 'Y' regression analysis, on the other hand, computes a similar straight line but by a least-squares fit parallel to the 'X' axis.

The degree of scatter and 'goodness of fit' of a linear relationship between 'Y' and 'X' can be defined in terms of the dimensionless linear correlation coefficient, r . When $r = 1$, this indicates a perfect correlation, while $r = 0$ signifies no correlation at all.

Also computed in this analysis is the 'standard error of estimate' which has properties analogous to the standard deviation. For example, in the 'Y' on 'X' regression analysis, the standard error of estimate, S_{yx} , is computed. If we were to construct lines parallel to the regression line of 'Y' on 'X' at respective vertical distances S_{yx} , $2S_{yx}$ and $3S_{yx}$ from it, we should find with sufficient data samples, that there would be included between these lines about 68%, 95% and 99.7% of the sample points.

In the 'X' on 'Y' regression, a similar standard error of estimate is computed parallel to the horizontal axis.

2. MAJOR AXIS LEAST-SQUARES REGRESSION ANALYSIS

In the standard linear regression analysis, two 'best lines' are fitted to the data, the first by minimising the error parallel to the vertical axis and the second by minimising parallel to the horizontal axis. However, in most cases, and in particular for this study, the co-ordinates of the sample data points are in error parallel to both axes together. Therefore, neither of the standard regression analysis 'best lines' is appropriate by itself and even if an arithmetic mean line is computed between them, the result is rather unsatisfactory.

An improved method is to find a line such that the sum of the squares of the perpendicular distances of the points from this line is a minimum. This line is termed the Major Axis line and is described by York (*ref. 20*).

3. MAJOR AXIS ANALYSIS, LINE CONSTRAINED TO PASS THROUGH ORIGIN

For this, the major axis computations are adapted to produce a line constrained to pass through the origin. In this way the relationship between the 'Y' and 'X' data points can be simply defined in terms of the slope of this line. Such an analysis becomes particularly appropriate when more than two variables are compared together, as illustrated by the comparison of three wave sensors in Pitt *et al.* (*ref. 15*).

4. GROUPED CLASS INTERVAL ANALYSIS

The fourth method employed is described as 'Grouped Class Interval Analysis' and was applied in an attempt to see how any differences between 'Y' and 'X' varied from class interval to class interval.

The 'X'-axis is split up into equal intervals. For each of these intervals the mean 'X' and mean 'Y' are calculated together with the standard deviation of 'Y'. Unfortunately this analysis method suffers from the same limitations as the standard 'Y' on 'X' linear regression analysis method in that only scatter parallel to the vertical axis is examined, while the scatter parallel to the horizontal axis is ignored.

5. EQUI-PROBABILITY ANALYSIS

If there are a series of N values of 'X' and N values of 'Y', then these two data sets may be arranged in ascending order:—

$$X_1, X_2 \dots\dots\dots X_m \dots\dots\dots X_n \quad \text{and}$$

$$Y_1, Y_2 \dots\dots\dots Y_m \dots\dots\dots Y_n$$

such that $Q(X_m)$ and $Q(Y_m)$ are the respective cumulative probabilities of X and Y exceeding X_m and Y_m .

If $Q(X)$ is set equal to $Q(Y)$ then an equi-probability analysis can be carried out to determine the relationship between Y and X over the whole of the cumulative probability distribution.

This form of analysis is particularly appropriate since the H_s wave height cumulative probability distribution is often used directly by the offshore engineer in both the planning and design function.

6. EXTREME VALUE ANALYSIS

One method of extreme value analysis is to extrapolate cumulative probability distributions (all data points included) in order to estimate the values for extreme events with return periods of 1, 10, 50 or 100 years. (N.B. by themselves, 5 years or so of wave data are inadequate for this process without some form of mathematical correction for the relative severity of the particular 5 years covered by the measurements.)

For a comparison of SBWR and WRB data it is therefore important to assess the effect of any differences on the results of the extreme value analysis.

The extreme value analysis itself is based on the best fit of the cumulative probability distribution to a particular mathematical equation. In graphical terms, this best fit is reflected in how well the data points making up the distribution plot out as a straight line on the relevant cumulative probability graph paper.

For wave height data a number of different distribution equations are commonly applied. These include the Weibull, log-normal, Gumbel's Third Asymptote and Gumbel's First Asymptote. For this study, the Weibull scale distribution (*ref. 17*) was chosen on the basis of Jenkinson (*ref. 14*).

The SBWR and WRB H_s cumulative probability distribution data points were plotted out on the Weibull scale and a least-squares criterion was used to establish the two 'best fit' lines. These lines were then extrapolated up to the probability levels associated with return periods of 1, 10, 50 and 100 years, making it possible to compare the extreme event H_s values predicted by the SBWR and WRB distributions.

Out of these six comparison methods it was found that the Major Axis Line Through the Origin and the Equi-probability Analyses produced the most meaningful results.

PRESENTATION AND DISCUSSION OF STUDY RESULTS

The statistical methods described were applied in turn to the SBWR and WRB processed H_s and T_z values. Initially each monthly set of data was examined, before carrying out an overall analysis for each of three weathering stations and all three stations combined. The characteristics displayed in the overall analyses were reflected in the monthly data. Though fluctuations were noted from month to month, no significant trend was evident — except of course for a natural bias in the summer months towards lower wave heights compared with the winter months. A sample month of simultaneous H_s and T_z data is presented in *Figures 4 and 5*.

COMPARISON OF SBWR AND WRB SIGNIFICANT WAVE HEIGHTS

Table 1 below presents the results of the linear regression and major axis analyses:

Statistic	Station A	Station B	Station C	All Stations
No. of data point pairs	4273	3350	3860	11,483
Linear correlation coefficient 'r'	0.952	0.942	0.943	0.949
Y on X Linear Regression Analysis				
Slope (M_{YX})	0.975	1.016	1.013	1.002
Intercept (C_{YX})	+0.334m	+0.206m	+0.145m	+0.225m
Standard Error of Estimate (S_{YX})	0.507m	0.539m	0.403m	0.487m
X on Y Linear Regression Analysis				
Slope (M_{XY})	0.929	0.874	0.878	0.899
Intercept (C_{XY})	-0.042m	+0.146m	+0.123m	+0.063m
Standard Error of Estimate (S_{XY})	0.495m	0.500m	0.375m	0.461m
Major Axis Line (Y on X)				
Slope (b)	1.025	1.084	1.079	1.059
Intercept (a)	+0.190m	+0.010m	-0.004m	+0.073m
Standard Deviation of Slope σ_b	0.005	0.007	0.006	0.003
Standard Deviation of Intercept σ_a	0.758m	0.855m	0.703m	0.759m
Major Axis constrained to pass through origin				
Slope (b)	1.077	1.086	1.078	1.080
Standard Error of Estimate	0.364m	0.372m	0.279m	0.340m

Table 1 — Results of Linear Regression and Major Axis Analysis — SBWR/WRB H_s Comparison

The linear regression analysis results presented above reflect the scatter associated with the Tucker-Draper method, quoted earlier at $\pm 10\%$ for the computation of H_s . Some variations in the results from the three stations are noted, in particular with the 'Station A' ordinary major axis analysis. However, the final analysis of the major axis line constrained to pass through the origin produced virtually identical results for all three weather ship locations in that *on average*:

$$H_s\text{SBWR} = 1.08 H_s\text{WRB}$$

Further analyses were applied to see if this relationship varied with wave height; the most meaningful results were obtained from the equi-probability and extreme value analyses. The results for each threshold wave height are set out for each station in Table 2 below:

WRB H _s Threshold Wave Height	Percentage Increase H _s SBWR over WRB			
	Station A	Station B	Station C	All Stations
<i>metres</i>	%	%	%	%
1.0	+18.0	+17.0	+10.0	+14.0
1.5	+17.3	+11.3	+4.7	+10.0
2.0	+11.0	+10.5	+7.5	+10.0
2.5	+11.2	+8.0	+6.8	+8.0
3.0	+9.3	+8.3	+9.0	+7.3
3.5	+8.6	+7.1	+8.6	+7.1
4.0	+7.5	+8.0	+7.5	+8.3
4.5	+6.9	+7.1	+11.3	+8.9
5.0	+6.2	+6.0	+10.0	+6.0
5.5	+5.6	+7.3	+9.1	+5.5
6.0	+3.5	+8.3	+8.3	+8.3
6.5	+4.6	+9.2	+4.6	+6.2
7.0	+6.3	+7.1	+1.4	+7.1
7.5	+3.7	+5.3	-1.3	+5.3

*Insufficient data points for computation

Table 2 — Results of Equi-probability and Extreme Value Analyses

The results for all stations combined are presented in *Figure 6*, the left-hand ordinate is scaled in terms of the SBWR threshold wave heights, while the right-hand ordinate is scaled in terms of the percentage increase of the SBWR H_s over the WRB.

The equi-probability analyses do exhibit a fairly constant percentage increase of the SBWR H_s over the WRB for the central band of wave heights. However, at higher wave heights this percentage appears to reduce, particularly at Station C, though the effect is less at Station A and B. The extreme value analysis goes on to confirm the tendency but it must be borne in mind that this latter exercise is bound by two limitations:

Figure 6 — Results of H₅ Equi-probability and Extreme Value Analyses — All Stations

Figure 7 — Results of Tz Equi-probability Analysis — All Stations

1. The data have been constrained to follow the equation of the Weibull cumulative probability distribution
2. The extrapolation process is very dependent upon the scatter in the data points and the 'best fit' line computed.

It would therefore be dangerous to conclude too much from these results but they do, nevertheless, demonstrate the practical implications when interpreting or extrapolating data sets from the two sensors.

The apparent convergence between the SBWR and WRB H_s values as the wave height increases is probably explained by the operation of the SBWR instrument itself. At wavelengths longer than the length of the weathership (which are usually associated with high wave heights), the SBWR accelerometer components predominate (the ship effectively becomes a waverider) while the pressure transducers contribute very little. For seas shorter than the length of the ship (and therefore lower wave heights) the situation is reversed. In other words, from the analysis viewpoint, at high wave heights, the value of 'K' in equation (1), used to correct the SBWR data for instrument response, is approximately equal to 1.0. At lower wave heights, when the wave periods tend to be shorter, the value of 'K' needs to be greater than 1.0 to correct for the now influential pressure transducers.

Further analyses such as comparing wave heights in particular wave period bands were considered but are outside the scope of this particular study.

COMPARISON OF SBWR AND WRB MEAN ZERO UP-CROSSING PERIODS

Table 3 below presents the results of the linear regression and major axis analyses:

Statistic	Station A	Station B	Station C	All Stations
No. of data point pairs	4273	3350	3860	11,483
Linear Correlation Coefficient — 'r'	0.753	0.755	0.814	0.780
Y on X Regression Analysis				
Slope (M_{yx})	0.713	0.706	0.691	0.710
Intercept (C_{yx})	+2.324 sec	+2.630 sec	+2.656 sec	+2.471 sec
Standard Error of Estimate (S_{yx})	0.926 sec	0.889 sec	0.794 sec	0.879 sec
X on Y Regression Analysis				
Slope (M_{xy})	1.611	0.807	0.959	0.856
Intercept (C_{xy})	+0.796 sec	+1.530 sec	+0.112 sec	+1.063 sec
Standard Error of Estimate (S_{xy})	0.978 sec	0.951 sec	0.936 sec	0.965 sec
Major Axis Line (Y on x)				
Slope (b)	0.930	0.915	0.818	0.888
Intercept (a)	+0.591	+0.853	+1.656	+1.035
Standard Deviation of Slope (σb)	0.012 sec	0.014 sec	0.009 sec	0.007 sec
Standard Deviation of Intercept (σa)	2.496 sec	2.500 sec	1.832 sec	2.228 sec
Major Axis constrained to pass through origin				
Slope	1.002	1.014	1.022	1.012
Standard Error of Estimate	0.721 sec	0.699 sec	0.670 sec	0.699 sec.

Table 3 — Results of Linear Regression and Major Axis Analysis — SBWR/WRB T_z Comparison

The linear regression analysis results — in particular the correlation coefficients in the order of only 0.75 — reflect a considerable scatter in the T_z calculated from the records of the two instruments. Significantly, for all three stations, each major axis line constrained to pass through the origin has a slope of approximately 1.0, thus indicating that *on average* the mean zero up-crossing periods from the two instruments are equal. This apparent equality should be judged only in the context of the associated scatter.

The relatively larger intercept values and slopes less than 1.0 in the equations of the ordinary major axis lines might suggest that the SBWR tends to give longer wave periods. This aspect was investigated further and the most realistic results were produced by the equi-probability analysis. It was found that for all three weatherships, the SBWR and WRB Tz cumulative probability distributions were virtually the same. However, a slight tendency was noted for the SBWR wave periods to be longer than the WRB at low periods, while at high periods the opposite was found. This tendency can be seen in the Tz equi-probability results presented in *Figure 7*.

In effect, all the analyses showed that, *on average*, the SBWR and WRB Tz's are nearly the same, while for individual wave samples, considerable scatter can be expected. This scatter is probably caused by one or more of the following factors acting together:—

1. The SBWR and WRB are not measuring the same waves. Though sample times are simultaneous, the two instruments are separated by anything up to 2 miles.
2. The response characteristics of the weathership in different sea states and combinations of wind-waves and swell will vary and thus might affect the recordings.
3. Ship's heading relative to the sea.
4. The inherently different noise characteristics of the two instruments.

SUPPLEMENTARY ANALYSIS – WAVE SPECTRA

A comparison of simultaneous SBWR and WRB data in the frequency domain is presently under study and has yet to be completed.

It is expected that this work will produce different comparison results from those presented above. It is felt that the prime reason for this will be that in the frequency domain, it is possible to correct for the SBWR instrument response at each frequency component, while in the time domain analysis, the correction is dictated solely by the Tz count.

Figure 8(a) shows an example of simultaneous SBWR and WRB spectra which happen to compare rather favourably while *Figure 8(b)* is an example of a not so favourable comparison.

SUMMARY OF CONCLUSIONS

1. On average, the SBWR was found to record significant wave heights 8% higher than the WRB. This percentage difference was greater at low wave heights and less at high wave heights.
2. For most planning and design work it is recommended that this relative difference should be taken into account, especially in the situation where a data set contains a mixture of H_s values from the two instruments.
3. The convergence of the SBWR and WRB data as the wave height increases has important implications for extreme value analysis. The convergence is carried through into the extrapolations and into any extreme values thereby derived. This effect should be considered in the evaluation process to establish design wave height values.
4. On average, it was found that mean zero up-crossing periods from the two instruments were the same. However, appreciable scatter about the average was noted in the results.
5. Care should be exercised in applying the results of this study to significantly different SBWR systems (in terms of vessel length and transducer depth).
6. This study has highlighted the obvious benefit of having two sensors measuring the same parameter. Equipment faults and sensor drifts which did not show up initially often become very apparent when data from the SBWR and WRB were processed and then compared.

ACKNOWLEDGEMENTS

The authors wish to thank the Oceanographic Committee of the United Kingdom Offshore Operators Association for permission to utilize their proprietary wave records in the preparation of this study.

CHAPTER 5

WAVE CLIMATE IN SOME ZONES OFF THE BRAZILIAN COAST

Alberto Homsí¹

INTRODUCTION

METEOROLOGICAL FEATURES - The Brazilian coast could be considered a calm area not affected by violent tropical storms. The major meteorological factor in Brazil is the South Atlantic anticyclone, almost permanent, which causes periodical northward heading of cold fronts. A slightly reduced energy and frequency of storms could be observed going up from South coast toward North and could reach the major part of Northeast region.

As a general condition the average monthly frequency of cold fronts passing along the Brazilian coast is higher during the winter - five per month with an average duration of 3 days, decreasing to 2 per month during summer with an average duration of 5 days. During winter high waves could occur between Santos and Macaé caused by a depression near the Rio de Janeiro as the cold front stays at North, before the cold front goes down to South. Fig.1 shows the average flow pattern across Brazil for summer and winter periods and a six days cold front advancing toward North, going into as far as to tropical latitudes during winter time. The daily tracks of the winter cyclones appear on this figure; they do not get beyond latitudes of 40° South.

WAVE MEASUREMENTS - CHARACTERISTICS AND CHRONOLOGY - Instrumental observations of waves in Brazil were initiated in 1962 with one year wave measurements and direction observations in Tramandaí, at the very South of the Brazilian coast. After the occasion thirteen other wave recording stations have seldom been installed simultaneously along the near-shore coastline (See Fig. 2), to collect wave data for some limited period on an ad-hoc basis. These limitations unfortunately occur because wave measurements are intrinsically difficult and normally expensive, restricting in quality the required data. As it could be observed from Fig. 4, only from 1973 the wave measurements have occasionally been taken on a simultaneous basis for two or few more locations. The information so obtained (See Fig. 3), could generally have application for the planning, design, construction and operation of local coastal engineering structures, but could not provide a reliable picture covering all the coast, and could not be used for the research of wave generation.

A NEED FOR A COMPREHENSIVE WAVE MEASUREMENT PROGRAM - Reliable information on waves along the Brazilian coast can only be obtained by installing, at suitable locations, and for sufficient time length (from three to five years, for example), wave recording stations being part of a system to carry out a comprehensive program of obser-

vations of wave direction and also instrumental measurement of wave heights and periods, to detect annual and seasonal changes taking place in the characteristics parameters of the wave conditions. The more reliable the resulting information on waves, the better a coastal or an offshore structure could be properly and economically designed.

The increasing demand from 1975, for studies of coastal and offshore engineering problems, has led the INPH to undertake an evaluation of how the available wave record observations, specifically made for the design of a coastal engineering work, could be of a possible and reasonable use in adjacent areas; and what kind of overall wave measurement and analysis program would be needed for the entire Brazilian coast, in order to get more accurate wave data to be mainly used in studies with simulation of random sea states, and in the research of wave generation (four random wave generators are going to be installed in the INPH in the beginning of 79, with the cooperation of the Danish Hydraulic Institute).

With this evaluation it was possible to reach a diagnosis of the present state of understanding of the wave climate for the various wave recording locations, as well as an assessment of its usefulness. Experience gained with this evaluation formed the basis for the laying down of basic criteria, methodology and specifications (See Fig. 2) for the Brazilian Wave Measurement Project (BRAZWAVE) in order to derive the wave climatology by means of measurements and calculations. As waves information heavily affect the ultimate cost of a coastal or an offshore project, the cost of the wave information to be obtained with the BRAZWAVE are warranted by: the economy in capital cost of overdesigned structures, the economy in operational costs, major repair costs and costs of total reconstruction of underdesigned structures.

WAVE STATISTICS AND ANALYSIS METHODOLOGY

The wave statistics results presented in this paper are based in the analysis results of about seventeen thousands stripchart wave records of about fifteen minutes, obtained by means of fifteen wave record stations. With the exception of two or three stations where the significant wave heights were calculated by the average of the highest one-third wave, all records were processed according to Tucker-Draper's simplified method. In the case of Natal, the wave records have been processed also by spectral analysis.

WAVE CONDITIONS ALONG THE COAST

SHALLOW WATER WAVE HEIGHT TRENDS - Fig. 5 shows the general wave height trends along the Brazilian coast for H_s max - the maximum significant wave height recorded during the observation period, for NE, E, SE and S directions, for the various seasons and for all seasons - all directions. The highest H_s max being 4,90m, occurred off Tramandaí for E and SE direction during the autumn. In Macaé the highest H_s max, also higher than 4,00m, occurred for S direction du

ring the spring.

As a general feature, from Rio Doce to Natal and for NE direction, the wave heights are less than 2,00m. For the other places, NE waves were not observed as a result of local shore configurations.

Because of the heavy local refraction the waves undergo (caused by the sea bottom topography) no E direction waves were recorded at Santos, Angra dos Reis, Macaé and Tubarão; for the other places, with the exception of Tramandaí and Natal where the waves are higher, the Hs max trend assumes values around 2,00m. SE direction waves have been observed all along the coast. At Tramandaí they range from 4,00 to 5,00m; at Tubarão and Maceió, they stay less than 2,00m, and for all the other places between 2,00 and 4,00m.

Only for Natal and Recife, S direction waves were not observed. For Tramandaí, S.F. Sul, Paranaguá, Portocel, Maceió and Suape the wave heights lie between 1,00 and 2,00m; for Aracaju, Rio Doce, Angra dos Reis and Santos between 3,00 and 4,00m; and for Macaé they stay, between 4,00 and 5,00m.

During the spring at Macaé and Natal, the trends stays around 3,00 and 4,00m; for the other places around 2,00 and 3,00m.

During summer Hs max assumes values between 1,00 and 3,00m. In the autumn for all the places, exception made for Tramandaí, Hs max lies between 1,50 and 3,00m. In winter season all along the coast, the trend lies between 2,00 and 3,00m with the exception of Tubarão where it is about 3,50m. Considering all seasons all directions trend, Hs max values smaller than 2,00 were not observed.

DEEP WATER WAVE HEIGHT TRENDS - Fig. 6 shows the equivalent deep water wave height trends derived after the wave rays have been back tracked from shallow water waves directions. The trends show themselves more irregular than in shallow water. The highest Hs max deep water wave is found off Tramandaí with about 6,50m for E and SE direction during the autumn. Offshore Santos an Hs max of about 5,40m was found for SE direction. In the case of S direction, waves of about 5,50 to 6,00m could be found off Angra dos Reis, Macaé and Portocel, during winter and spring seasons.

As a general feature the Hs max waves become smaller the more northern the place is. An exception is made to S direction waves which pass through a maximum at about Angra dos Reis and Portocel, to decrease towards the north. The shallow water wave trends and mainly the deep water wave trends results should be taken with precaution due to the restrictions imposed by the near-shore method of observation of wave directions. (Visual).

WAVE CLIMATE ALONG THE COAST

The wave statistics presented herein for each location represent a seasonal and or annual reduction for publication, of the monthly results obtained in the whole analysis involved in this paper for the wave parameters: Hs, Hm (maximum wave height of the wave records), Tz, Tc, E (spectral width) and D (wave direction), of the joint-distribution of Tz x Hs, Hs x Tz and Hs x D, the Life-Time-Wave-Distri

bution of H_s and H_m and the exceedance distributions of H_s .

TRAMANDAÍ - Fig. 7 presents some statistics information about the wave climate off Tramandaí coast. The field observations and a first simplified analysis were done by the "Instituto de Pesquisas Hidráulicas" of the Federal University of Rio Grande do Sul for PETROBRÁS (the Brazilian State Oil Company) for the purposes of the hydraulic model studies of the Tramandaí bar.

A range of T_z periods from 5 to 13,5 seconds, not varying for the various seasons were recorded, presenting a slightly asymmetric distribution, with a maximum at about 7,5 seconds. The maximum occurrence for $T_z \times D$ joint distribution is for 7,5 seconds and 105° N. For $T_z \times H_s$ it is 8,5 seconds and 1,5m. The H_s wave heights do show significant variations, tending to be higher in the autumn. Larger H_s wave heights of about 4 to 5m are associated with periods of about 13,5 seconds and larger, and with the SE direction. The H_s wave for a 30 year return period is 6,0m.

PARANAGUÁ - The wave measurements were done by the INPH to give support to the studies of disposal areas for the dredging materials of the new channel entrance of Paranaguá Port.

Fig. 8 shows information about the Paranaguá wave climate. The $H_s \times T_z$ distribution has a maximum percentage of occurrence - 20%, for 1,00m and 5,5 seconds. For $H_s \times D$ the maximum is also 20% for 1,0m and 135° N. From Life-Time-Wave Log-Normal Distribution an H_s of 4,20m was predicted for a return period of 30 years. T_z periods do show a significant variation being longer in autumn with periods up to about 12 seconds.

SANTOS - For Santos the INPH made recordings of sea waves at two points simultaneously. P_2 point at -15,00m and P_1 Point at -10,00m, as a part of a large coastal measurements project for the hydraulic studies of the Port of Santos Expansion Program. The P_2 record station had been in operation only during the winter and spring, what restricts the comparisons which could be made between the wave characteristic parameters distributions of P_2 and P_1 . During the winter the H_s distribution for P_1 and P_2 shows the same range while a larger frequency of occurrence of low H_s could be noted in the case of P_1 . In the case of spring the range of H_s for P_2 station is wider and with larger H_s wave heights.

A comparison between the Life-Time-Wave Log-Normal Distribution of H_m for P_1 and of H_s for P_2 shows that they are almost coincident; anyway, one must be aware that for P_2 point the measurements of summer and autumn were not included and in the case they were, this coincidence should not occur.

The maximum value for H_s was 3,5m at P_2 and 2,40m at P_1 .

The T_z period distribution ranges are about the same, at P_1 and P_2 , during winter, spring and for all seasons.

In the case of P_1 , the most common situation for $T_z \times D$ joint distribution is 12 seconds and 170° N; for $H_s \times T_z$ it is 1,0m and 12 seconds, and for $H_s \times D$, 1,0m and 170° N. At P_2 there is a tendency to associate larger T_z period with 165° wave direction, and larger H_s

FIG. 7

FIG. 8

with southern wave direction and with 12 to 13 seconds T_z periods.

ANGRA DOS REIS - Two years of wave measurements have been made and processed by "FURNAS - Centrais Elétricas S/A" for the purposes of the hydraulics studies of the water intake protection works for the Angra dos Reis Nuclear Power Station. Fig. 10 presents the wave climate based on the first year of measurements.

During the winter and summer no H_s waves higher than 2,00 were observed, while in spring and autumn the waves respectively go up to 2,5 and 3,00m. A prediction of $H_s = 4,00$ m could be observed for 30 years return period.

The range of the T_z distributions become wider going from spring to winter. The most common situation for $H_s \times D$ distribution is a frequency of 45% for the binary 0.5/1,0m and 165° N.

MACAÉ - The INPH was charged by PETROBRÁS (The Brazilian Oil State Company) to develop the hydraulics studies of the Maritime Terminal of Macaé. This terminal, now under construction, should provide 12 sheltered berths for the supply boats of the Campos Oil Field. As a part of the field measurements, wave have been recorded since June 1977. The first year of measurements has been analysed (See Fig. 11). The H_s distribution do show larger waves in the spring with heights of more than 4,00m. During the winter the H_s highest wave is less than 2,00m. Summer and autumn seasons show maximum H_s waves of about 3,00m. With the exception of the spring, when the T_z period distributions range from 4 to 10 seconds, for the other seasons the range is wider, going from 4 to about 14 seconds.

Due mainly to diffractions around nearby islands, the range of wave directions distribution obtained at the site is narrow going from 135° N to 170° N. Because of this, a second wave measurement station is now in operation to get information of waves coming from NE and E direction. The most common situation of the $T_z \times D$ joint distribution was for 8 seconds and 150° N; for the $H_s \times T_z$ it was 1,50m and 8 seconds, and for the $H_s \times D$, 1,5m and 150° N. There is a strong association with higher waves heights and the direction 150° N.

TUBARÃO - CVRD (Tubarão Iron Ore Terminal) made a wave survey during 71/72 and the data were analysed by the CTH (Centro Tecnológico de Hidráulica). Fig. 12 shows the statistics obtained based on the processed CTH data. It is during winter and spring that occur the highest H_s waves being more severe during winter ranging from 0,0 to 4,00m and from 0,5 to less than 4,00m for the spring. Summer is the most calm season. The T_z period distributions range for the various seasons from 6 to 15 seconds. Higher wave heights are associated with 180° N direction and with 10,5 seconds periods.

PORTOCEL - The specialized Terminal of Portocel situated at about 65 Km north of CVRD Tubarão Iron Ore Terminal is now in operation. The wave observations carried out during the period 73/74 were analysed by the Danish Hydraulic Institute (DHI) and those of the period 76/77 by the INPH. Fig. 13 shows some statistics results obtain

FIG. 9

FIG. 10

FIG. 9

FIG. 10

FIG. 11

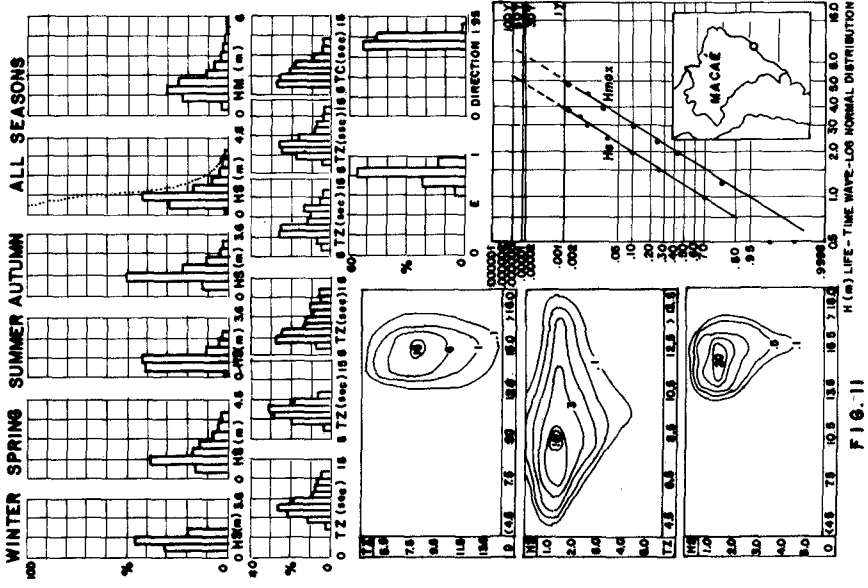

FIG. 12

ed for the period of 76/77, which did not include observation of wave directions.

During the spring and autumn the Hs wave distribution ranges from 0,00 to 2,50m. During the winter the conditions are a little more severe, ranging from 0,00 to 3,00m. In the summer, from 0,0 to 1,20m. With the exception of autumn when the Tz period distribution ranges from 5,5 to 10 seconds, for all the seasons it varies from 4,5 to about 12 seconds. The highest frequency (25%) is associated with the binary 1,0m and 7,5 seconds for the joint distribution Hs x Tz. According to Time-Life Log-Normal Distribution, a significant wave of about 4,40m is predicted for a return period of 50 years.

RIO DOCE - The CTH (Centro Tecnológico de Hidráulica) made wave recordings off Rio Doce at PETROBRÁS P₁ and P₃ oil survey platforms, in the period 72/73, and processed the resulted 189 strip-charts records. Fig. 14 presents some wave statistics information based on the CTH calculations. It is important to note that the observation period was less than one year and it did not include the winter. The most severe conditions were found in the autumn with Hs waves going as high as 3,00m and HM as high as 4,50m. The Tz period distributions ranges from 3 to 8 seconds for the spring, 5 to 13 seconds for the summer, and 5 to 11 seconds for the autumn. The most common situation for the Hs x Tz joint distribution is 1,50m and 6,5 seconds with a frequency of 15%. The direction distribution show gaps due probably to an exaggerated simplification on the wave direction method of observation.

ARACAJU - The wave measurements off Aracaju were made by the IPH of the Federal University of Rio Grande do Sul (Motta, V. F-1966), for the studies of the Off-Shore Terminal (TECARMO) of PETROBRÁS. During the autumn (See Fig. 15) the significant waves went up to 2,50m while during spring, summer and winter less than 2,00m. A maximum wave height of 4,00m were observed during the autumn.

As regard of Ts (Significant Period) the range of the respective distributions become wider going from spring to summer and autumn, narrowing in the winter. Only during the autumn Ts values of about 14 seconds were found. A high frequency of 15% was found for the binary 8 seconds and 120° N; for Hs x Ts the most common binary was 1,50m and 7 seconds with a frequency of 20%. The 30 year return period Hs wave assume a value of about 3,50m.

MACEIÓ - The Danish Hydraulic Institute has carried out the hydraulic studies of the SALGEMA Terminal at Maceió. Fig. 16 presents some wave statistics based on the results of those studies.

The most severe conditions occur during the spring when Hs waves go up to about 2,20m. During autumn and winter the significant waves do not get nearer than 2,00m. In the summer the maximum waves lie at about 1,50m.

The most common situation for the joint distribution of Hs x D is 1,00m and 120° N, with a frequency of 20%.

The Life-TimeWave Log-Normal Distribution of Hs was constructed by

FIG. 13 H (m) Life-Time Wave - Log Normal Distribution

FIG. 14 H (m) Life-Time Wave - Log Normal Distribution

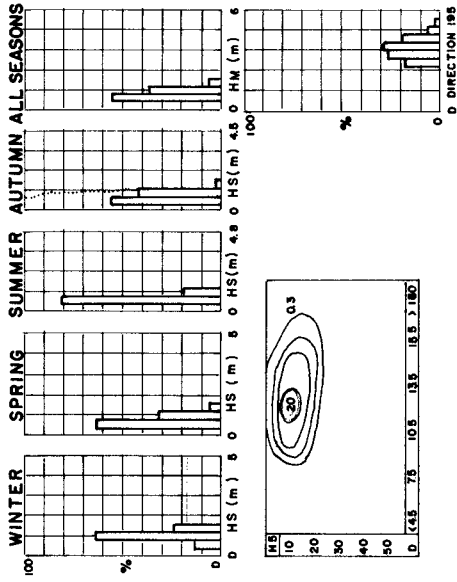

FIG. 15

FIG. 16

using the daily H_s highest waves observed. For a return period of 30 years a prediction is made for an $H_s = 2,40m$. For 100 years, $H_s = 2,70m$.

SUAPE - The INPH was charged by the Government of the State of Pernambuco to develop extensive hydraulic studies comprising field measurements, stability and agitation models including mooring forces, by using irregular waves generators, and movable bed model including the coast and the estuary at Suape.

The wave measurements were made by the IPR (Radioactive Research Institute of NUCLEBRÁS) by means of an accelerometer buoy of Datawell. Fig. 167 shows the wave statistics analysis made by the INPH for the first year of measurements. During the autumn and winter the wave conditions are slightly more severe than during summer and spring. The highest H_s wave was about 3,00m and the highest maximum recorded wave about 4,50m.

A maximum T_z period of 10 seconds with a high concentration around 6,5 seconds was observed. The joint distribution show a concentration of 14% for the binary 6,5 seconds and $105^\circ N$; a slight tendency to associate large periods with northern wave directions could be observed. A high concentration of 35% for the binary 1,50m and 6,50 seconds occur, in the case of the $H_s \times T_z$ joint distribution. For the $H_s \times D$ distribution the most common frequency was for the binary 1,50m and $105^\circ N$. A slight association is observed between the highest waves and $135^\circ/150^\circ N$ wave direction. The Life-Time-wave Distribution provides a prediction of a significant wave of 3,90m which might occur over a return period of 30 years.

RECIFE - The INPH made recordings of sea waves at a point off Recife Port and used the Tucker-Draper's method of analysis. In Fig. 18 some wave statistics results obtained may be observed. The significant wave height exceeded 1,00m for 81% of the year. The variation in height for spring, summer and autumn is not significant; only during the winter the conditions are more severe with H_s waves up to 2,50m.

The scatter diagram $T_z \times D$ shows a tendency of wave with NE direction to be associated with periods of 6,5 seconds and waves of SE direction to be associated with periods from 10 to 12 seconds; the most frequent combination was when T_z period was about 6,5 seconds and the wave direction $120^\circ N$. For the $H_s \times T_z$ and $H_s \times D$ distributions the most frequent situations were respectively 1,5m and 6,5 seconds, and 1,50m $110^\circ N$.

The Life-Time-Wave Distribution predicts a significant wave of 3,40m which might occur over a period of time of 30 years.

NATAL - The INPH is developing a comprehensive hydraulic study of the coast of Rio Grande do Norte around Natal and of the estuary of the Potengi river where the port of Natal is situated. The expansion plans include the increasing of the depth of the entrance channel to -12,00m. The wave measurements started at April/77 and is going to continue until April/79.

Fig. 19 include the statistic analysis made by the INPH by using the

FIG. 21

Tucker-Draper's simplified method. The highest Hs wave was 3,00m and the highest maximum measured wave, 5,00m. During the autumn occur Tz periods of more than 13 seconds while in the other seasons the maximum is 9 seconds. The Hs x Tz distribution shows that there is a tendency to associate small wave heights with high periods; the highest frequency of occurrence is 25% for the binary 1,50m and 7,5 seconds. In the case of Tz x D distribution the most common frequency (35%) is for 7,5 seconds and 105° N. For Hs x D the most common frequency has a very high percentage (40%) for the binary 1,50m and 105° N. An Hs wave of about 3,40m is probable to occur in a return period of 30 years. Fig. 20 presents a comparison of the periods obtained from the analysis of four daily strip-chart records by applying Spectral Analysis: Tp and Tc; and the Tz(.....) periods obtained by the Tucker-Draper method. In this figure the average of the four daily results were plotted. It could be observed that the zero-crossing period obtained by the simplified method has higher values than the obtained by spectral analysis. The trends of the peak period and the zero-crossing (Tucker-Draper) period compare well for the months of January, May, June, July and October, and reasonable well for August, September and November. The relation Tz/Tc for all seasons show values between 1,00 and 2,00 for the case of Tucker-Draper's analysis method, there being about 1% between 1,00/1,20 and 71% between 1,20/1,40. For the case of spectral analysis the relation Tz/Tc shows a range between 1,00/1,60 with 88% between 1,0/1,20 and 11% between 1,20/1,40m.

In the case of Tp/Tz (Tz of the S-A method) relation the values range from a little less than one (6.5%) to a little more than 2,00m (2%). The maximum occurrence is for 1,0/1,20 (45%) and 1,20/1,40 (40%). It is for the lowest value of the periods Tz and Tc that the relation Tz/Tc nearest to 1,00 are observed (due to filter effect of the pressure recorder). This characteristic is more accentuated in the case of the Tz/Tc Tucker-Draper's relation.

Fig. 21 shows the actual spectra for 24 days with significant wave height and zero-crossing period obtained from each strip-chart spectrum. The peak periods generally vary between 7,5 and 9,0 seconds.

THE PROBABLE WAVE INCOMING ENERGY

The wave action and the correspondent total energy at a location vary from season to season and, for each season from year to year. The actual situation is an irregular seasonal and yearly wave action. The information on this variability is important mainly for the cases of littoral process studies and work construction programs. The monthly, seasonal and annual wave energy could be obtained by considering the frequencies f_i of the distribution of the significant waves (Hs), calculating $\sum_i H_s^2 \times f_i$ for each month, each season, each year and for each location.

Fig. 22 shows the relative energy loads for the seasons, and for the year by taking as denominator the average of the annual expected wave energy of each location. The highest annual wave energy load occurred for Tramandaí (1.94) followed by Santos (1.53 for P₂ point) and Macaé (1.36).

In the case of the seasons, the highest seasonal wave energy load for each location occurred, for Tramandaí, in the spring (2.13) followed by Macaé also in the spring (1.98), Tubarão in the autumn (1.72); Suape in the winter (1.67) and Santos in the spring (1.60 for P₂ point).

CHAPTER 6

WAVE CLIMATE STUDY In THE REGION OF THE EAST FRISIAN ISLANDS AND COAST

by Hanz Dieter Niemeyer ¹⁾

1. The investigation area and research aims

The East Frisian Islands and Coast - located at the southern border of the North-Sea - are significantly characterized by a chain of off-shore islands which are separated from the mainland by wide spread tidal flats (FIG.1). Between the islands there are small and deep tidal inlets with strong currents, through which the tidal volume covering the flats is streaming in and out, with a tidal range of about 2,5 m.

Fig. 1: The East Frisian Islands and Coast

Seaward the tidal inlets are enclosed by an arched chain of separated shoals ranging from the eastern part of one island to the northwestern one of the other island. During the occurrence of high wave conditions these chains have the effect of closed bars where an intensive wave energy dissipation is forced by limited water depth.

Compelled by economic reasons the special research area was restricted to the zone around the tidal inlet Norderneyer Seegat (FIG.2) which significantly represents the

¹⁾ Dipl.-Ing., Head of Hydrographic Branch, Forschungsstelle für Insel- und Küstenschutz (Research Station for Island and Coast Protection), D 2982 Norderney, Germany F.R.

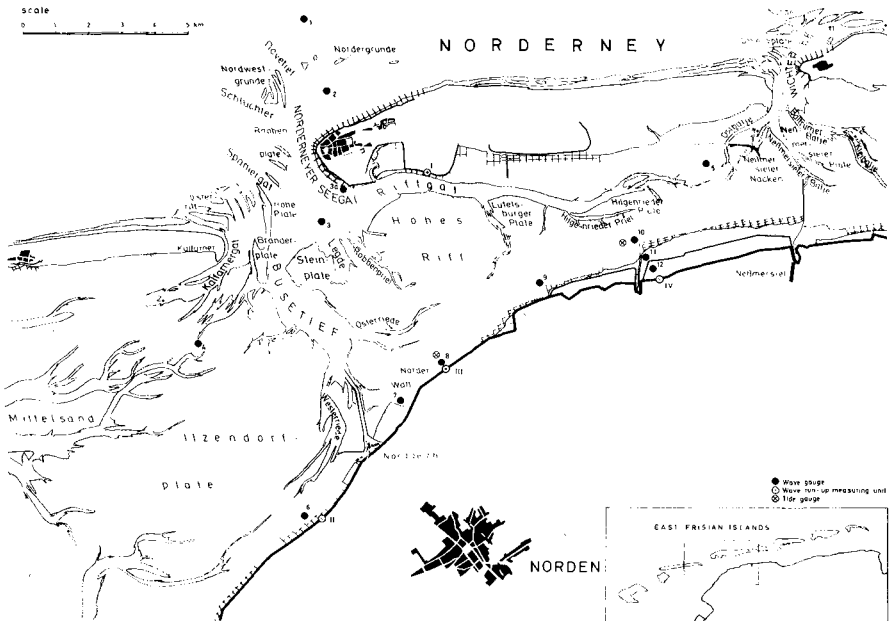

Fig. 2: Research Area and Measuring Net

main hydrographic and morphological features of the whole region of the East Frisian Islands and Coast.

There a measuring net of 13 wave measurement stations and also four wave run-up gauges inserted on sea dykes was erected (FIG.2). The spatial distribution of the wave measurement stations allows to record the changes in wave climate from the open sea to the mainland coast. The conception of the measuring net has therefore been orientated at the morphological features of the region in order to obtain data of their influences on waves propagating from the open sea to the mainland coast (LUCK + NIEMEYER 1977).

The main research aims of the wave measurement program are:

1. Derivation of a computable relationship, allowing the estimation of wave action in the seaward region of the East Frisian Islands and Coast as a function of wind conditions
2. Analysis of wave energy dissipation due to wave breaking on the bar
3. Determination of wave damping on the tidal flats
4. Establishment of design parameters for protection structures in function of wave action and wave loads in respect of the morphological and structural boundary conditions

In the on hand paper the first results of the study are presented, mainly referring to the changes of the heights of waves travelling from the open sea to the mainland coast.

2. Wave generation factors

The range of wind directions being most important for wave generation with respect to the research area extends from W to NNE (FIG.3). The length of fetch is great enough in consideration of the restricted water depth to establish a fully arisen sea within a few hours. Waves generated by winds from these directions are the only important for design conditions.

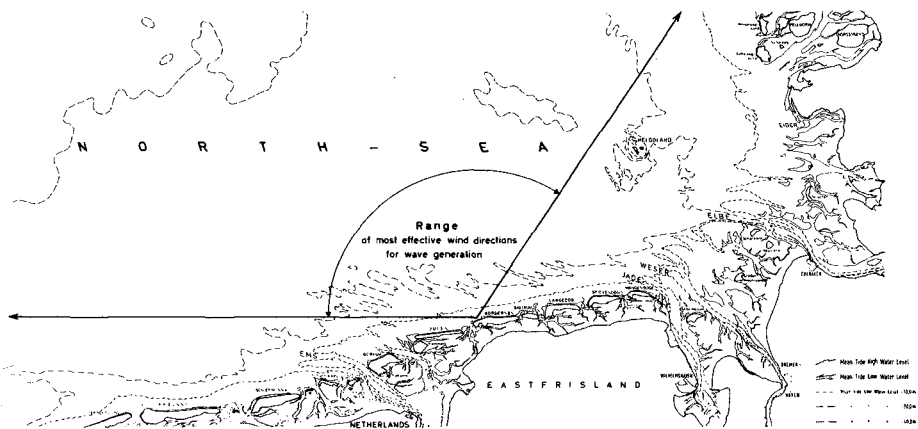

Fig. 3: Wave Generating Area

The hydrographical features of the generation area led to the conclusion that waves generated by normal high wind speeds within this range of directions should not differ in their order of magnitude.

The first investigations therefore were carried out in order to get a quantitative description of the interaction between wind velocity and wave height.

Linear regression analysis clearly shows that there is a rather high correlation between the significant wave height and the mean wind speed prevailing the last six hours before starting the wave measurements (FIG.4). In order to get dimensionally correct equations the significant wave height is plotted versus the ratio of chosen wind speed squared and gravitational acceleration.

But field data better meet a power curve fit for the same parameters than linear regression (FIG.5). The best accom-

Fig. 4: Linear Regression of $H_{1/3}$ and $\frac{\bar{U}^2(\bar{6h})}{g}$

Fig. 5: Power Curve Fit for $H_{1/3}$ and $\frac{\bar{U}^2(\bar{6h})}{g}$

odation of data and the computed equation could be reached for a power curve fit using the mean wind velocity for the last three hours before starting the wave measurements (FIG.6). Exactly as for the significant wave height there is a high correlation between maximum wave height and mean wind speed on the same boundary conditions (FIG.7).

Fig. 6: Power Curve Fit for $H_{1/3}$ and $\frac{\bar{U}^2}{g}$

These results show that the last three hours of the prevailing wind speed are the most important for the height of the occurring waves in the investigation area.

When comparing these results with the investigations of SCHÜTTRUMPF (1973) for the southern North Sea which are based on the hindcasting method of BRETSCHNEIDER (1954, 1957) it seems to be that for higher wind speeds than those measured during this research period a longer wind duration must be taken into consideration. Equally the influence of the distinct wind directions from W to NNE could increase on those conditions because then with the growing fetch length needed for the occurrence of a fully arisen sea even small differences in the hydrographical features become more important for wave generation.

But the obtained results meet well enough the requirements for the estimation of wave conditions in the seaward region of the research area by forecasting or hindcasting techniques.

Fig. 7: Power Curve Fit for H_{\max} and $\frac{\bar{U}^2}{g}$

3. Wave energy dissipation due to wave breaking on the bar

The incoming waves reach the bar seaward of the tidal inlet Norderneyer Seegat and the northwestern shore of the island of Norderney. There the limited water depth induces the breaking of the higher waves. During high wave conditions the bar could be distinguished as a ring of white foam on which nearly all waves are broken ranging from the eastern end of the island of Juist around the tidal inlet Norderneyer Seegat and the northwestern shore of the island of Norderney.

It can be seen on aerial photographs that there is a significant difference between the western and the eastern part of the bar in respect of the height and areal extension of the shoals (FIG.8).

The analysis of data verifies that these different morphological features condition a distinct form of surf processes leading to a locally diverse form of wave energy dissipation in a quantitative und qualitative manner: The

Fig. 8: Aerial Photograph of the Bar Enclosing the Tidal Inlet Norderneyer Seegat and the Northwestern Shore of the Island of Norderney

waves which pass the bar in front of the northwestern shore of the island of Norderney are higher than those passing the part in front of the tidal inlet Norderneyer Seegat.

In the eastern part the water depth of the bar has a great influence on the height of waves recorded landward of the bar. There is a rather satisfactory correlation between significant wave height measured at station 2 and water depth (FIG.9). But the correlation coefficient is not high enough to believe that there is not any other important influence, because the graph indicates that waves of a different height can occur in the same water depth.

In order to describe wave energy dissipation on the bar it is useful to take into account not only the wave heights recorded seaward of the bar but also the water depth on the bar itself. As it is very difficult to define a concrete water depth on the bar it is replaced by the actual mean height of tide water level occurring during a measuring period.

Fig. 9: Relation of Significant Wave Height and Water Depth at Station 2

In the eastern part of the bar in front of the north-western shore of the island of Norderney wave energy dissipation can be described by the ratio of wave heights landward and seaward of the bar. It is dependent on the wave heights seawardly recorded in relation to the height of the tide water level:

$$\frac{H_{II}}{H_I} = f \left(\frac{H_I}{W_{PN}} \right) \quad (1)$$

Explanatory in figures 10 and 11 wave energy dissipation is shown for the significant and maximum wave height. Data are best met by an exponential curve fit which is well proved by the high correlation coefficients (FIG.10 and 11).

This result allows the determination of wave heights in front of the northwestern shore of the island of Norderney for a certain tide water level and wave heights seaward of the bar which can be easily estimated by the developed forecasting formulas.

Fig. 10: Damping of Significant Wave Height on the Eastern Part of the Bar

These findings furthermore indicate the important protective function of the bar for the northwestern shore of the island. As the wave heights increase more considerably than the tide water levels during the occurrence of storm tides, wave energy dissipation increases as well.

On the western part of the bar seawardly enclosing the tidal inlet Norderneyer Seegat the water depth in respect of incoming wave heights is much smaller than in the eastern part. As additionally the areal extension of the shoals is much larger than in the eastern part the important influences for surf processes and the connected wave energy dissipation differ as well.

Wave height damping on this part of the bar is only dependent on the incoming wave heights but not on the changing water depths on the bar.

There is a linear relationship between the wave heights seaward of the bar and the difference to those landward of the bar which could be proved by regression analysis for the significant and maximum wave height. The data fit the

Fig. 11: Damping of Maximum Wave Height on the Eastern Part of the Bar

computed equation nearly precisely which is as well proved by the very high correlation coefficients (FIG.12 and 13).

The decrease of wave energy in front of the tidal inlet is of great importance for the wave conditions on the tidal flats and the wave loads on the dykes on the mainland coast. In this respect the part of the bar enclosing the tidal inlet has an essential protective function for the mainland coast.

The intensive wave energy dissipation on the bar is easily demonstrated by the ratio of maximum wave height to water depth recordered at the two stations landward of the bar. Its value is always much smaller than that necessary for shallow water wave breaking

$$H_b = h_b \quad (2)$$

which has been established by FÜHRBÖTER (1974) and SIEFERT (1974) by field measurements in shallow water regions. In this case the orders of magnitude are as follows:

$$H_{\max II} \leq 0,57 h \quad (3)$$

$$H_{\max III} \leq 0,39 h \quad (4)$$

Fig. 12: Damping of Significant Wave Height on the Western Part of the Bar

Fig. 13: Damping of Maximum Wave Height on the Western Part of the Bar

Landward of the bar wave breaking due to limited water depth cannot therefore occur before the new generated waves reach the shore of the island or the dykes on the mainland coast (FIG.14).

Fig. 14: Wave Breaking on the Bar in front of the Northwestern Shore of the Island of Norderney

4. Wave height damping on the tidal flats

While the waves passing the eastern part of the bar attack the northwestern shore of the island of Norderney, those which are generated after breaking on the eastern part spread out over the tidal flats. Though they are not high enough to be broken because of the limited water depth a certain wave damping on the tidal flats could be observed. It must be explained as a combined superposing effect of bottom friction, refraction, diffraction and shoaling.

The damping of maximum wave height from the inner part of the tidal inlet can be described as a function of itself in relation to the water depth at the end of the travel distance (FIG.15). One gets a more complicated expression for the damping of the significant wave height (FIG.15), but the influence of water depth can be distinguished too.

The intensity of wave height damping on the tidal flats can be described by another example:

Fig. 15: Wave Height Damping on the Tidal Flats

The comparison between the ratio of maximum wave height and water depth at the two stations with a different distance to the tidal inlet shows that there is a nearly continuous damping of maximum wave height with respect to water depth and travel distance (FIG.16). Considering the growing heights of flats with increasing distance from the tidal inlet in connection with the constant ratio of wave height and water depth it is possible to come to the conclusion that there is a well-balanced dynamic equilibrium between the morphological configuration of the flats and the local wave climate.

But this result includes another important fact, because one wave measuring station is situated in front of a dyke without foreland the other on a dyke foreland. The obtained ratio of wave height and water depth is significant for flats without any wave breaking according to the investigation of SIEFERT (1974) in the southwestern region of the Elbe estuary. Regarding both results the up to now generally accepted theory of an intensive wave damping due to wave breaking on dyke forelands must be abandoned.

Regarding the topography of the research area it seems to be that the existence of dyke forelands is even a consequence of the local low wave energy.

Fig. 16: Relation of Maximum Wave Height and Water Depth at the two Stations (8 + 12) on the Mainland Coast

5. Investigations on wave run-up

These investigations on wave climate are combined with those on wave run-up on sea dykes. Therefore four wave run-up gauges were meanwhile placed on sea dykes. But undisturbed wave run-up measurements can only be carried out at the occurrence of very high storm tide water levels. As such an event has not yet happened since the start of the measurements with the run-up gauges, there are not until now any measurements leading to new results.

But the influence of wave parameters on wave run-up has already been analysed by the investigations of HUNT (1959) on monochromatic waves as well as by those of VAN OORSCHOT and D'ANGREMOND (1968) on wave spectra.

Their commonly accepted results show that the height of wave run-up in respect of the occurring spectrum is dependent on the wave period and the square root of wave height. Accordingly wave run-up is here described as wave run-up potential only considering wave parameters and neglecting all other influences (NIEMEYER 1977b).

The data of 17 wave records of field measurements which include about 1800 waves are used for computing wave run-up potential with respect to the higher and longer waves of the spectrum. Important for the highest five per cent of wave run-up potential are the highest and longest ten per cent of waves. But the maximum wave run-up potential for every record is caused by its highest and longest waves. In figure 17 computations of wave run-up potential for all 17 records are shown for comparison (FIG.17):

Fig. 17: Comparison of Several Computed Wave Run-Up Potentials by Using Wave Data of Field Measurements

1. wave run-up potential R_{Tmax} of the longest wave with period T_{max} and height H_{Tmax}
2. wave run-up potential R_{Hmax} of the highest wave with height H_{max} and period T_{Hmax}
3. wave run-up potential $R_{T1/10}$ of a wave with the mean period $T_{1/10}$ and the mean height $H_{T1/10}$ of the longest ten per cent of waves
4. wave run-up potential $R_{H1/10}$ of a wave with the mean height $H_{1/10}$ and the mean period $T_{H1/10}$ of the highest ten per cent of waves

Mostly the highest computed wave run-up potential is caused by the longest wave of the considered records. Comparing all computed wave run-up potentials the following relations are gained:

$$R_{T1/10} = 0,82 R_{Tmax} \quad (5)$$

$$R_{Hmax} = 0,78 R_{Tmax} \quad (6)$$

$$R_{H1/10} = 0,72 R_{Tmax} \quad (7)$$

$$R_{H1/10} = 0,92 R_{Hmax} \quad (8)$$

6. Summary

The Research Station for Island and Coast Protection Nordeney has been operating the wave measurement program East Frisian Island and Coast for two years. The first results of this study can be summarized in the following manner:

1. There is a high correlation between the wind speed prevailing the last three hours and the heights of local waves subsequently occurring.
2. Wave energy dissipation on the bar enclosing the tidal inlet and the northwestern shore of the island situated westward of the inlet can be described in a quantitative manner in respect of the different morphological features of the bar.
3. The intensive wave energy dissipation on the bar prevents the breaking of waves spreading out over the tidal flats due to limited water depth, which indicates in spite of that a wave height damping in a certain order of magnitude.
4. The continuous wave damping on the tidal flats leads to such a decrease of heights that there cannot occur any wave breaking due to restricted water depth during the duration of high storm tide water levels.
5. It seemed to be that not the highest, but mainly the longer waves induce the highest wave run-up on sea dykes.

7. Acknowledgements

The wave measurement program East Frisian Islands and Coast is supported by the German Federal Ministry for Research and Technology (BMFT) through the German Committee on Coastal Engineering Research (KFKI).

CHAPTER 7

AN EVALUATION OF EXTREME WAVE CLIMATE AT KEAHOLE POINT, HAWAII

by

Charles L. Bretschneider¹ and Richard E. Rocheleau²

INTRODUCTION AND SUMMARY

An evaluation of extreme wave climate was made for Keahole Point, Hawaii. This evaluation was based on three separate sources of wave data and five methods of statistical evaluations. The three sources of data include (1) wave hindcasts data of 10 severe storms between 1947-1961 by Marine Advisors (1963), (2) wave hindcast data of 11 severe storms between 1947-1965 by U.S. Army Corps of Engineers, Honolulu District, and (3) shipboard wave observations of the U.S. Navy reports. Figure 5 shows SSMO area No. 1 for south and southwest of the islands and SSMO areas Nos. 2 and 3 for north of the islands.

The five methods of statistical extrapolations for extreme events include: (1) Gumbel's (1958) first asymptotic distribution, (2) Weibull distribution (1961), and (3,4,&5) semilog, log normal and normal distributions. The three most widely used distribution functions are: (1) Gumbel's (1958), (2) log normal (see Jasper, 1956), and (3) Weibull (1961), given in order as to the author's preference. The statistical extrapolations for Keahole Point, Hawaii, are given in Table 9 and Figure 9. Only Gumbel's (1958) distribution was applied to the north shore as shown in Table 8.

Based on Gumbel's distribution function, the results of the wave hindcasts statistics on the average (50 year recurrence interval) indicate that (1) the Marine Advisors (1963) wave hindcasts are about 25 percent higher than the U.S. Army Corps of Engineers wave hindcasts and (2) the U.S. Navy SSMO observations and the U.S. Army Corps of Engineers wave hindcasts are in closest agreement.

Shipboard wave observations have always been subjected to questions. However, various authors have correlated instrumentally measured and observed wave observations. A summary of these correlations are given in Table 6. No correction was made to the statistical analysis of the SSMO data.

Explanations are in order for the discrepancies between the three sources of data: (1) Both the U.S. Army Corps of Engineers and Marine Advisors have many years of experience in wave forecasting and hence their data should be reliable, (2) ship captains tend to avoid the worst of any storm, and also they are usually too occupied to make accurate observations

² Ph.D. Graduate Student at University of Delaware, formerly M.S. Graduate Student, University of Hawaii.

during heavy seas, and thus the extreme wave conditions are never experienced in the summaries of SSMO data, (3) it might be assumed that the Corps of Engineers hindcasts are somewhat low because they are in near agreement with the SSMO data which are assumed to be low. Perhaps one might use an average of the two sets of hindcast data, and (4) wave forecasting (and wave hindcasting) by experienced oceanographers is more accurate than visual wave observations. There are a number of experienced oceanographers who can make very accurate wave forecasts. The U.S. Navy Fleet Numerical Weather Central at Monterey, California, has a very excellent computer program that can produce wave forecasts more accurately than shipboard wave observations. There are other commercial computer programs equally calibrated to give the same accuracy.

The usefulness of the wave statistics of Hogben and Lumb (1966) and the U.S. Navy SSMO data should be limited to the similar conditions of ship routes under which the wave observations were taken. These data should never be used for the determination of extremes, since the extreme conditions have been absent. A very good case for the above statement can be made for Cape Horn, South America. Cape Horn is one of the most severe storm areas of the world, and yet the wave statistics of Hogben and Lumb (1966) would indicate the area to be relatively calm when we know from history that this is not true. The point here is that the ships avoid going around the Horn, and instead go either through the Magellan Straits or the Panama Canal. Perhaps an exception to the above is the area in the North Sea, where there is heavy ship traffic and many ships can hardly avoid extreme storm wave conditions in the North Sea.

The problem, of course, is how one can use the visual wave observations since these are very plentiful. First, the visual wave observations are excellent for ships avoiding extreme storm wave conditions. Insofar as obtaining reliable wave statistics from visual wave observations, somebody should determine a correlation between regular enroute shipboard wave observations and the extreme wave conditions that were avoided by the ships captain. Such a correlation is far more important than the correlation equations given in Table 6.

In view of the above discussions, it is concluded that: (1) at present wave hindcasting (now very accurate) is the best method for obtaining extreme wave statistics, since one can go back to 50 or more years of weather maps, and it is the only method that gives both the duration of the storms and simultaneous occurrences of swell from distant storms; (2) presently offshore and coastal engineering structures at Keahole Point should be designed on the basis of Marine Advisors' wave statistics as summarized in Figure 9 and Table 9; (3) a refinement of wave statistics for extremes at Keahole Point can only be obtained by wave hindcasts of severe storms prior to 1947 and after 1965; and, (4) there are available a number of calibrated computer programs for wave forecasting and hindcasting. The University of Hawaii does not yet have a computer program for wave hindcasting, but instead should use one of those already available.

WAVE CLIMATE IN HAWAIIAN WATERS

Waves affecting waters around the Hawaiian islands result from storms in all parts of the Pacific Basin and even in parts of the Indian Ocean. The superposition of distant and locally generated waves together with the influence of the islands result in a complex wave climate. The wave climate for the islands has been classified into four general types characterized by wave height, wave period, and direction of approach. Figure 1, from Moberly and Chamberlain (1964), shows the direction of approach of the four main wave types. Figure 2 shows the generating areas from which waves may approach Keahole Point, Hawaii. A fifth type of waves are those associated with hurricanes. Although hurricanes are less frequent than ordinary storms, hurricane generated waves must be considered for design purposes.

The above types of wave climate are discussed briefly:

- (1) Northeast tradewind waves. Northeast tradewind waves are present a large percentage of the time, but dominate from April to November when the tradewinds are present 90 to 95 percent of the time. The tradewinds blow 12 to 15 knots per hour about 50 percent of the time generating waves from 4 to 11 feet in height with periods of 5 to 9 seconds due to the long uninterrupted fetches. These waves approach the island between the north and northeast.
- (2) Southern swell. Southern swell approaches from between the southeast and the southwest. It is most frequent from April through October, resulting from severe winter storms in the southern hemisphere. Due to the decay over the distances, these waves usually arrive as low, long-period swell, typically 1 to 6 feet high with periods of 14 to 22 seconds. However, swell substantially larger than 6 feet has been observed along the southern boundary of the islands.
- (3) Kona storm waves. These waves approach the islands infrequently with the passage of kona storms which are generally cold-core, low-pressure systems of large radius. During the passage of such systems the tradewinds are replaced by south or southwesterly winds generating waves which arrive from the southeast to west. Although infrequent, the severity of kona storms varies from a light breeze to gale strength. The associated wave climate varies over a wide range. Waves of 10 to 15 feet with periods of 8 to 10 seconds are not uncommon.
- (4) North Pacific swell. North Pacific swells, having been generated by severe storms near the Western Aleutians or from mid-latitude low pressure systems, approach the islands from the north. These waves are most frequent from October through May and are responsible for the large surf observed in many areas.
- (5) Hurricane waves. Although not included in many discussions of Hawaiian waves, a fifth type of wave is important for design considerations. Large waves produced by passing hurricanes may affect many island locations. These tropical cyclones are characterized by a warm low-pressure core with sustained wind speeds substantially higher than those

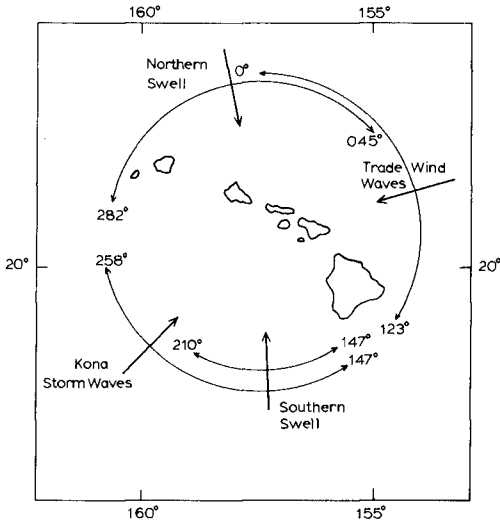

FIG. 1 APPROACH DIRECTION OF FREQUENTLY OCCURRING WAVES IN HAWAIIAN WATERS
After Moberly and Chamberlain (1964)

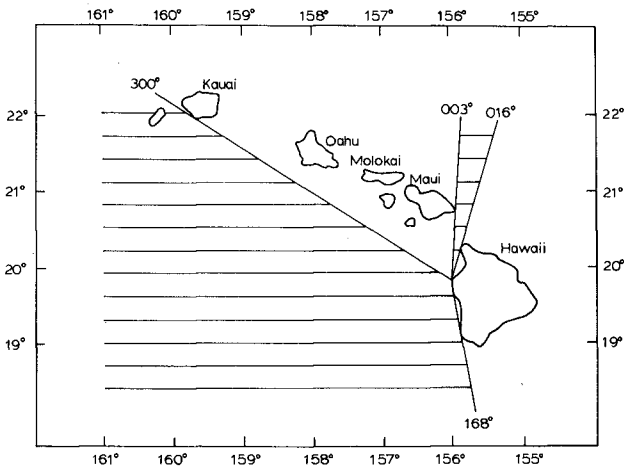

FIG. 2 GENERATION AREAS FROM WHICH WAVES MAY APPROACH KEAHOLE POINT

associated with tropical (kona) storms. Hurricane waves are important for design considerations and are based on the model hurricane for Hawaii as determined by Bretschneider and Tamaye (1976).

SOURCES OF WAVE DATA

Three sources of data have been analyzed to determine long-term wave heights. These are described below.

(1) Marine Advisers: Severe Storm Wave Characteristics in the Hawaiian Islands (1963). The report presents the results of a hindcasting program to determine the wave conditions produced by the 10 most severe storms of the 15-year period from 1947 through 1961 for all Hawaiian waters. These hindcasts were specific for waves approaching either the west coast of Lanai or the west coast of Molokai. Certainly not all the storms analyzed would have affected Keahole Point and even those which did may have had considerably altered wave characteristics at that location. However, these 10 most severe storms, without regard to sheltering effects or direction, were analyzed to provide an upper limit on the severity of the deepwater wave climate expected to occur. The direction of wave approach to the islands is shown in Figure 3. A complete discussion of the storm systems involved may be found in the Marine Advisers' (1963) report. Table 1 gives a summary of these wave hindcasts.

(2) Corps of Engineers: Hindcasts for Harbor Planning (1968). The U.S. Army Corps of Engineers, Honolulu District made hindcasts of 17 storms affecting the Hawaiian Islands from 1947 through 1965. Seven of these which resulted in severe waves at Honokohau Bay are applicable to Keahole Point. In addition, four storms north of the islands which generated large swell from a direction possibly affecting Keahole Point have been included. The inclusion of these storms is based on the location of the generation area relative to the window between Maui and Hawaii rather than on actual observations. Table 2 summarizes these hindcast results specific to Keahole Point. The approach directions of the waves from the 11 storms are presented in Figure 4. Six of the storms shown in Table 2 are also given in Table 1.

(3) U.S. Navy Hydrographic Office: Summary Synoptic Meteorological Observations (SSMO). Figure 5 shows 3 SSMO areas. Area No. 1 is for the windward or north and east areas of the Hawaiian Islands; Area 2 is for the leeward or south and west areas of the Hawaiian Islands; and Area 3 is for the north and west areas of the island of Kauai. SSMO provide monthly and annual summaries of many individual shipboard wave observations over the 8-year period from 1963 to 1971. The waves are classified by observed wave height and wave period, but not by direction. Table 19 of the SSMO reports for the annual summaries are reproduced in Tables 3, 4 and 5 for SSMO areas 1, 2 and 3, respectively. Table 6 represents various equations or relations between measured significant wave heights and shipboard wave observations. It appears that the overall best equation would be equation (d) of Table 6 to convert shipboard wave observations to significant wave height. The observed wave period is essentially the significant wave period, but the relationships given in Table 7 are used to determine f_0^{-1} and \bar{T} of the wave spectrum where

(b) $\bar{T} = 5.19 + 0.37 T_{ob}$	1.12	
(c) $\bar{T} = 4.945 + 0.345 T_{ob}^{**}$	--	
$f_0^{-1} = 4.1 + 0.76 T_{ob}$	2.15	
BEST LINE THRU ORIGIN		
(a) $\bar{T} = 0.73 T_{ob}$	1.20	0.50
(b) $\bar{T} = 0.86 T_{ob}$	1.40	0.48
(c) $\bar{T} = 0.795 T_{ob}^{**}$	--	
$f_0^{-1} = 1.12 T_{ob}$	2.23	0.50

* Hogben and Lumb use the notation \bar{T} for our \bar{T} and T_0 for our f_0^{-1} .
We use T_{ob} for T_{oms} .

** Equations (c) are the corresponding averages of (a) and (b).

f_0^{-1} is the model period or period of maximum energy density of the frequency spectrum and T is the zero crossing wave period. Figure 2 shows the possible approach directions for Keahole Point. The direction of wave approach is normally essential to determine the affected locations. Figure 5 shows the boundaries of SSMO Area 2, and it has been assumed that any sea state observed in the area could have affected Keahole Point. Similarly, all waves which affect the Point would propagate through the observation area. Unfortunately, there are no data which actually show the observations in SSMO Area 2 to be representative of Keahole Point. However, the SSMO data does give a means by which to make relative comparisons between the various SSMO areas.

STATISTICAL METHODS FOR EXTRAPOLATION TO FUTURE EVENTS

Except for data tabulated as a maximum series there is no widely applicable theoretical basis for determining the underlying probability distribution function or a suitable method of plotting the probabilities of exceedance calculated from the data. The criteria generally used is that data accurately fit by the chosen curve may be extrapolated. It is obviously best if the data are fit by a straight line. Several methods which have yielded such results in the past for wind and wave data and their application are discussed below.

(1) Gumbel's First Asymptotic Distribution. The first asymptote is described by the distribution function

$$F(x) = \exp \{-\exp[-\alpha(x-\mu)]\} \quad (1)$$

where

x = the variable of interest

α, μ = parameters of the extreme distribution.

A linear reduction is made by introducing the reduced variate

$$y = \alpha(x-\mu) \quad (2)$$

Substitution of y into equation 1 yields

$$y = -\ln \{-\ln F(x)\} \quad (3)$$

Gumbel has shown that the reduced variate (y) and return period (T) are related by

$$y = -\ln \ln \left(\frac{T}{T-1} \right) \quad (4)$$

where

T = the return period in same time interval as the maximum series. For large T , this reduces to

$$y = \ln T - 1/2 T \quad (5)$$

which has an error of only $\pm .7\%$ for $T \geq 7$.

Solving equation 5 for T

$$T = \exp(y) + 1/2 \quad (6)$$

$$\approx \exp(y) \text{ for large } T. \quad (7)$$

Substituting $y = \ln T$ into equation 2 yields $x = \ln T/\alpha + \mu$ which lends validity to the use of the semi-logarithmic plot for extreme data with an underlying exponential distribution for return periods greater than seven. Conversely, if the data were fit well by the logarithm of the return period vs x , it should be possible to use Gumbel's first asymptotic distribution for the analysis of these data.

Many techniques have been proposed for the proper selection of the parameters α , μ of the extreme distribution. These often were proposed for calculational convenience. With the proliferation of computers, one of the simplest methods is the use of least squares analysis. The line so determined represents the expected maxima at each return period. The actual values will be dispersed around these expected values.

One significant advantage of the extreme value model is the applicability of confidence bands around the line of expected values. Two sets of confidence bands may be calculated. The first is a function of the reduced variate and slope and is used to determine the goodness of fit of the assumed distribution. The second is a function of the slope only and is used to predict confidence levels of the extreme values.

(2) Weibull Distribution. Weibull in 1961 proposed a simple distribution which has been used for various civil engineering problems. The application of this distribution to the description of wind wave short-term statistics was suggested by Bretschneider (1965). Several sets of wave data, for example, Flatseth and Pederson (1970) and Battjes (1972), have been found to be described by the Weibull distribution. The Weibull distribution function is given by

$$F(x) = 1 - \exp \left\{ - \left[\frac{x-A}{B} \right]^C \right\} \quad (8)$$

where

A = the lower limit of the variable x

B = the scale factor

C = the shape factor

When the lower limit A is zero, this is known as a Frechet distribution. Rearranging the terms in equation 8 and taking the logarithm twice yields

$$\ln \ln(1-F(x))^{-1} = C \ln x - C \ln B \quad (9)$$

The appropriate values of B and C are determined from the slope and intercept of the straight line, using the statistical least squares technique.

(3) Semi-log Plot. Another technique which has been used by many authors involves plotting $\log \{1-F(X)\}^{-1}$ versus x . If a linear relationship is obtained, extrapolation beyond the observed data should yield an acceptable estimate of the expected wave height for the design return period.

(4) Log Normal Distribution. Following the work of Jasper (1956) and Darbyshire (1956), Draper (1963) concluded that the height and period of the design wave can best be estimated from a Gaussian distribution of the logarithm of the height or period. This technique may be applied to whichever wave height parameter is required (i.e. mean wave height, significant wave height, etc.) However, the data does curve off at the upper limits in some cases.

(5) Normal Distribution. One of the simplest methods of analysis first used in hydraulic studies and later extended for design hurricanes and waves is the method of Beard (1952), which assumes a Gaussian distribution. In this analysis, the cumulative probability and recurrence interval are defined by:

$$P(X \leq x_m) = F(x_m) = 1 - \frac{m+a}{M+B} \quad (10)$$

$$T_m = [1 - F(x_m)]^{-1}/n \quad (11)$$

where $F(x_m)$ = the assigned value of the probability distribution function of event m

m = rank of the observed value when ordered by increasing magnitude

M = total number of observed events

T_m = return period in years of event x_m

a, b = arbitrary constants to assure $0 < F(x) < 1$

n = number of observations/year

The method of Beard (1952) is to plot $F(x_m)$ versus x_m on normal probability paper. The points are then connected by a smooth curve which is extrapolated beyond the region of the observed data. For any return period of interest, the value of the probability distribution function is calculated and the expected value read from the plot.

Design Life and Risk Factors. In the design of an ocean structure the engineer needs to determine the risks involved in using a chosen design wave. The calculated return period is the average expected duration between events of a given magnitude, however, this value provides no indication of when the event may occur. Court (1952) and others have related design life, design return period, and risk in simple probabilistic terms to aid the design engineer. The argument presented is summarized here.

Assuming the annual maxima to be independent, the probability that x_m will not be exceeded in N years is given by

$$[P'(x \leq x_m)]^N \tag{12}$$

The probability of at least one more exceedance in N years is

$$P(X_{\max} > x_m) = 1 - [P'(X \leq x_m)]^N \tag{13}$$

The return period based on the work of Langbein (1949) and used by Rocheleau (1977) is given by

$$T_y = \{1 - [F(x_m)]^n\}^{-1} \tag{14}$$

Substituting T_y from equation 14 yields

$$P(X_{\max} > x_m) = 1 - (1 - 1/T_y)^N \tag{15}$$

N may be considered as the design life with a probability of failure given by $P(X_{\max} > x_m)$ for the event with a return period T_y . For convenience the design life is defined in terms of return period by

$$N = T_y/U \tag{16}$$

where

$U =$ a positive value ≥ 1 .

For design calculations, the value $P(X_{\max} > x_m)$ is considered as the risk (R). Substituting into equation 15 yields

$$R = 1 - (1 - 1/T_y)^{T_y/U} \tag{17}$$

For large T_y this becomes

$$R = 1 - e^{-1/U} \tag{18}$$

Solving for the factor U in equation 18,

$$U = -1/\ln(1-R) \tag{19}$$

Substituting equation 19 into equation 16, yields

$$N = -T_y (\ln(1-R)) \tag{20}$$

Thus for a chosen design life and risk factor, the necessary design return period may be calculated.

SUMMARY OF ANALYSIS

1. Keahole Point, South Shore and SSMO Area 2: Figure 5 will be discussed first, inasmuch as we have available two sets of wave hindcast data for locations around Keahole Point, and also the SSMO data for Area 2. Figures 6 and 7, based on Gumbel's distribution, show the results using the Marine Advisers (1963) wave hindcasts and the U.S. Corps of Engineers (1964) wave hindcast data, respectively. Figure 8 is based on the SSMO data for Area 2, where H, shipboard wave observations, have not been corrected to significant wave height.

Figure 9 shows the comparisons of expected wave heights from various methods of statistical extrapolations for the above three sources of data used in Figures 6, 7 and 8. It is seen that the various methods of statistical analysis give quite a wide variation in results based on the three sources (Figures 9a, 9b, and 9c). Figure 9d shows the variations of the three sets of data for the Gumbel distribution of wave heights.

Table 9 gives the results of statistical evaluations of wave height data (based on Figure 9) for Keahole Point, Hawaii.

2. North Shore of Oahu and SSMO Areas 1 and 3: Wave hindcast data of severe storms (similar to Tables 1 and 2) are not available for the north shores of Hawaii and hence we consider only shipboard wave observations for SSMO Areas 1 and 3. Figures 10 and 11 are the corresponding results based on the Gumbel distribution. We are also interested in the statistics for extreme waves for the north shore of the island of Oahu. SSMO Area 1 is mostly for the island of Hawaii and SSMO Area 3 is mostly for the island of Kauai. Therefore, we have averaged to two sets of data and assumed that this would be generally applicable halfway between Areas 1 and 3, or the north shore of the island of Oahu. Figure 12 shows the results of this averaging.

Table 8 gives a summary of the statistical analysis of the three SSMO areas. Based on shipboard wave observations, it is surprisingly interesting that the statistical analysis results give essentially the same extreme wave heights for all three SSMO areas for corresponding recurrence intervals. The explanation for this can be made, in view of the large SSMO areas surrounding Hawaii (see Figure 5). It would appear that the islands have little effect on the waves over large sections of the SSMO areas where the ship observations are made, because there can be large fetch lengths in any direction away from the islands. Evidently, the southern swells off the south shore of Hawaii either pass around or through the islands from SSMO Area 2 to SSMO Areas 1 and 3. This is probably not completely true, as it is also likely that the southern swell is not important in determining the extremes, and in some cases may even be absent from SSMO reports, particularly when tradewind waves are predominant.

CHAPTER 8

THE USE OF IMAGING RADAR IN STUDYING OCEAN WAVES

by

M. G. Mattie¹ and D. Lee Harris²

INTRODUCTION

Imaging radar can be used to provide information about the two-dimensional character of the wave field. This is especially important near shore where the effects of refraction and shoaling interfere with the simple interpretation of a directional spectrum based on records from a network of gages.

Imaging radar has the advantages of providing full two-dimensional information of the type provided by aerial photography and of being available continuously, including night time and during storms.

Imaging radar, of course, also has some disadvantages when compared to other data gathering systems. Specifically, the imaging radar does not provide a measure of wave height. It does not provide as much resolution as aerial photography and the shorter waves of interest may be missed. The most important disadvantage is that short ripples are essential to the detection of long waves, hence swell is not detected outside the breaker zone when the wind is calm or the high frequency waves are inhibited by oil slicks.

Several characteristics of the radar images of waves, as compared to aerial photography, are illustrated in Figure 1. Note the similarity of the wave patterns in the radar image and the aerial photograph. The image does not show any features of the land. The location of the radar is shown on the aerial photography by an "X".

Ijima et al (1964) and Wright (1965) appear to have been among the first to report the use of radar for imaging ocean waves. Oudshoorn (1960), Wills and Beaumont (1971), Evmenov et al (1973) and others have published photographs of a radar scope showing waves. This report differs from earlier papers on this topic by providing a discussion of practical procedures for overcoming some of the more mundane technical difficulties associated with routine data collection.

Landward of the bar wave breaking due to limited water depth cannot therefore occur before the new generated waves reach the shore of the island or the dykes on the mainland coast (FIG.14).

Fig. 14: Wave Breaking on the Bar in front of the Northwestern Shore of the Island of Norderney

4. Wave height damping on the tidal flats

While the waves passing the eastern part of the bar attack the northwestern shore of the island of Norderney, those which are generated after breaking on the eastern part spread out over the tidal flats. Though they are not high enough to be broken because of the limited water depth a certain wave damping on the tidal flats could be observed. It must be explained as a combined superposing effect of bottom friction, refraction, diffraction and shoaling.

The damping of maximum wave height from the inner part of the tidal inlet can be described as a function of itself in relation to the water depth at the end of the travel distance (FIG.15). One gets a more complicated expression for the damping of the significant wave height (FIG.15), but the influence of water depth can be distinguished too.

The intensity of wave height damping on the tidal flats can be described by another example:

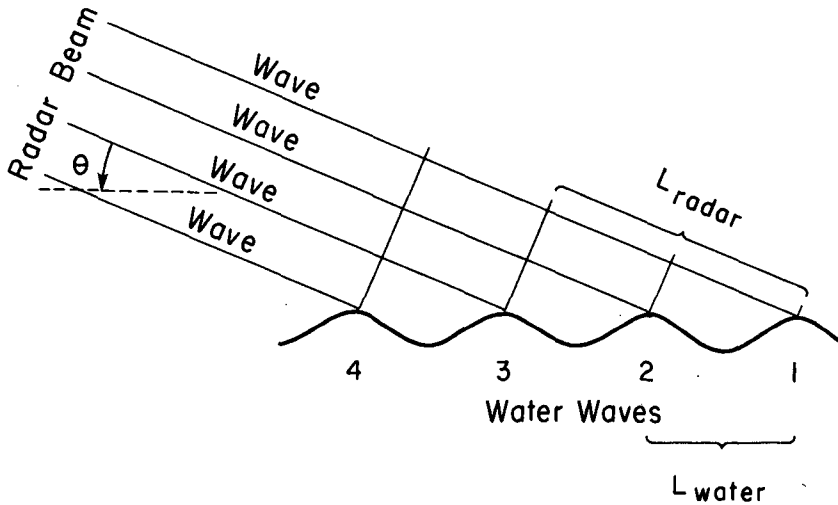

Figure 2. Illustration of first order Bragg Scattering. Each wave acts as a reflector. Reflection from several waves must be in phase for a significant return signal.

are nearly always in equilibrium with the wind. Thus if the wind is calm and the water surface glassy, the swell waves which may exist will not be detected seaward of the surf zone.

At least three processes have been recognized by which the long waves modulate the radar return from the short waves (Lynch and Wagner, 1970 Valenzuela, 1978). It has been known for many years that the convergence zone on the front face of the traveling waves tends to increase the height and decrease the length of the capillary waves and that the divergence zone on the back face of the waves has the opposite effect (Phillips, 1966). This process has been investigated in greater detail and with specific reference to the radar cross section by Keller and Wright (1975), Valenzuela and Wright (1976), Wright (1978), Reece (1978) and many others. This process is illustrated in Figure 3.

The strength of the radar return (generally called the radar cross section) from the sea is a function of the grazing angles, as shown by Skolnik (1970). The slope of the water surface for a distance of many radar wavelengths, varies with the phase of the long waves as shown in Figure 4. The angle is greater for the face of the wave facing the radar than for the opposite face. This process has been investigated extensively by Valenzuela (1970).

When the grazing angle is low the crest of one wave may prevent irradiation of the following trough, producing a shadow zone between successive wave crests as illustrated in Figure 5. This situation produces a maximum contrast in the return from different phases of the

Figure 3. Modulation of short waves by long waves

Figure 4. Modulation of the incident angle of the radar beam by the long waves.

Figure 5. Illustration of the shadowing of a portion of one wave, by a wave nearer to the radar.

wave. When the wave heights are variable, as they usually are, and the grazing angle is small, the crest of a large wave may shadow at least part of the crest of a following lower wave, so that at least parts of some wave crests are missing in the return signals from the longer useable ranges.

The smallest spot which can be distinguished on the radar scope is determined by the duration of the transmitted energy pulse and the ratio of the radar wavelength to the effective length of the radar antenna as shown in Figure 6. The factor of $1/2$ in the equation for ΔR occurs because the radar beam must travel across the spot once in each direction to permit detection. The smallest available pulse length in many radar systems is too long to permit the recognition of water waves. Some commercial marine navigation radars, however, do provide pulse lengths as short as 50 nanoseconds, (50×10^{-9} seconds) for ranges of 5.5 kilometers or less. This pulse length is short enough for the detection of 4-second waves in deep water. Shorter pulses could be used to permit the detection of shorter waves. This would involve a reduction in power and maximum range. Shorter pulses are not generally available in commercial radar systems.

The angular resolution is proportional to the ratio of the radar wavelength to the effective length of the radar antenna. Commercial marine radar manufacturers often provide several optional antenna systems. The shortest, and most widely used, provides an angular resolution of about 2.0 degrees. The longest gives a resolution of about 0.6 degrees. Obviously the longest antenna is preferable for imaging waves.

Figure 6. Resolution cell for the radar image. R is the range, ΔR resolution along the radar beam. $\Delta R = c\Delta T/2$, where c is the speed of light and Δt is the duration of a radar pulse. $\Delta\theta$ is the azimuthal resolution.

The intensity of the radiated energy decreases with the square of the distance from the antenna. The intensity of the back scattered energy likewise decreases with the square of the distance from the target. Thus the power returned to the antenna, decreases with the fourth power of the distance between antenna and the reflecting surface.

If the signal is strong enough to reveal distant targets, the scope may be saturated by nearby targets, so that no details are revealed. When the signal level is low enough to reveal details near the center of the scope, distant targets may escape detection. Some improvement may be made by using circuits which provide increased amplification at increased distances.

PRACTICAL CONSIDERATIONS

The optimum settings of the controls on the radar, for imaging waves, depend on ambient conditions and can be found for any given conditions by a little experimentation with the controls. Most wave data collection systems, however, are unattended and the need for frequent adjustment to the radar controls to obtain optimum performance has been a handicap in the exploitation of microwave, ground based radar for the collection of wave data.

A solution to this problem may be obtained by combining a control system which will vary the controls during each observation according to a preset schedule. An off-the-shelf 3 cm (X-band) marine radar has been combined with a control system which turns the radar on at preset times. After a brief warm up period, a series of 1-9 sweeps of the radar over the sea at each of several console settings is photographed. Photographs of the radar scope displaying sea conditions as shown for four range settings are presented in Figure 7. Note that the clearest image of this wave field is found at a range of 1.2 kilometers with 14-15 individual waves being discernable. We find that the clearest images are generally obtained with a range setting between ten and twenty wavelengths. Note also that the radar scope tends to be saturated near the center with faint images near the maximum range.

Figure 8. Development of the wave field as revealed by radar

Because of the effects of modulation of the ripples and surface slope on the radar return, it has been seen that longer and steeper waves can be detected at a greater range than short or flat waves. Thus the optimum range setting is seen to be a function of wavelength and wave steepness. This cannot be known in advance. Therefore the system is programmed to take a sequence of pictures at several ranges at a pulse length near 50 nanoseconds as a part of each observation. At present only one level of intensity is provided, but it appears that the addition of two intensity levels to the system would be an improvement. Only the most satisfactory photograph of the set is routinely analyzed.

One might expect the curvature of the earth to be a factor in determining the optimum antenna elevation, but this does not turn out to be the case. When commercial radar is used, the range is restricted to the order of 5.5 kilometers by the weak power return for longer ranges.

At this range an elevation of two meters is sufficient for the radar signal to illuminate the surface at maximum range, even in a vacuum. Refraction by the atmosphere causes radar beams to bend in the direction of the earth. On the average the radar waves propagate along a spherical surface whose radius is $4/3$ the radius of the earth. Refraction of the radar beam is greatest when the temperature of the air increases and the humidity decreases with elevation. Propagation parallel to the earth's surface is occasionally observed. The optimum elevation of the radar antenna is a function of the ambient wave conditions. As previously stated, the greatest contrast between wave crest and trough is obtained when the crest of one wave shadows the following trough but does not shadow the following crest. Variation of the antenna elevation to satisfy ambient conditions, however, cannot be accomplished very easily and it is not always possible to obtain an optimum value. Our most successful operations have been obtained with elevations between 20 and 40 meters.

ADDITIONAL EXAMPLES OF RADAR WAVE DATA

Figure 8 shows the development of a wave field near Cape Cod, Massachusetts. All views were obtained with a maximum range of 925 meters. One can easily follow the gradual change in wave direction from SE to E and the increase in wavelength from midnight to 0900. The wind had been blowing from the SE at 15 m/sec for three hours before the first photographs and varied between 14 and 17 m/sec until noon. The wind had shifted to NE by 1324. Wave refraction near shore can be seen in the first two photographs.

Figure 9 shows even stronger evidence of refraction and the presence of at least two distinct wave trains. Two or more distinct wave trains can be identified in a large fraction of our radar photographs of the wave field.

Figure 9. Two wave trains and refraction shown on the Radar Scope.
Coast Guard Radar, Cape Cod, Mass., Jan. 8, 1976.

It is obvious that wavelength could be measured in many of the radar pictures and that the wavelength decreases as the shore is approached. By following a single wave train such as that indicated by the arrow in the two pictures shown in Figure 10, it is also possible to measure the phase speed of a wave. The straight vertical line on the image is an offshore breakwater. The elapsed time between these two pictures is 5.46 seconds. Two intermediate frames have been omitted.

One of the remarkable features noted in many of the radar photographs is the persistence of individual waves. It is often possible to identify a single wave crest from the time it appears at the edge of the scope until it breaks against the shore. The wave patterns are very consistent from frame to frame. There appear to be perturbations in intensity and direction along many wave fronts, but the wave pattern, taken as a whole, gives the appearance of continuity for the full distance over which the waves can be followed.

Figure 10. Two views of the radar scope separated by 5.46 seconds illustrating technique for measuring the phase speed of water waves from photographs of the radar scope. CERC radar Channel Islands Harbor, CA, April 29, 1977.

ANALYSES OF THE PHOTOGRAPHS

The device which we have found to be most convenient for analyzing small quantities of radar film is shown in Figure 11. A 16 mm analytical projector is mounted to the left of the viewing screen. This projector can advance the film frame by frame, or automatically, at various speeds between 1 and 24 frames per second. A mirror is used to extend the light path and to form the image by rear projection on a ground glass screen. This arrangement permits the operator to review the film rapidly and select the best frame from each observation for evaluation. The protractor and ruler mounted over the display screen permits rapid determination of the direction of selected waves. When the only information wanted is the direction of the prominent wave trains at a selected point, evaluation of each observation requires only about a minute. In general, however, the radar record shows systematic variation of wave direction with location. A few frames may be selected for enlargement to reveal perspective about the wave field that is not provided by a network of wave sensors within a small area.

Figure 11. Device used for the analysis of radar film.

VALIDATION

In order to illustrate the agreement between data obtained with this radar and by other techniques, a few samples of radar images coincident with other independent wave measurements are presented in Table 1. The data were obtained during the West Coast Experiment which was a preflight test in preparation for SEASAT. The aerial photographs were obtained by NASA. Copies are available from U. S. Geological Survey EROS Data Center, Sioux Falls, South Dakota. The SAR images were provided by JPL. The procedure employed for analysis of SAR data has been described by Elachi (1978).

In interpreting the data in Table 1, it should be noted that the observations are not exactly synoptic and that the data appearing in any of the aerial photographs were collected within a few milliseconds.

A more extensive comparison of wave direction as determined by the CERC radar and a pressure gage array is in preparation. Publication by Mattie, Hsiao and Evans in the Journal of Geophysical Research sometime in 1979 is planned.

Table 1. Comparison of Information From CERC Radar Images With That Obtained With Other Direction Measuring Devices.

Date (1977)	Time	Wave Direction at NUC	Wave Length	Wave Period (Sec)	Wave Direction	Wave Length	Wave Period (Sec)			
CERC RADAR										
March 14	11:30	$283^\circ \pm 4^\circ$	$84 \pm 11m$	$8.6 \pm .9$	$284^\circ \pm 2^\circ$	$80 \pm 16m$	$7.6 \pm .9$			
		$261^\circ \pm 4^\circ$	$168 \pm 22m$	15.5 ± 2	$264^\circ \pm 3^\circ$	$120 \pm 16m$	10.2 ± 1			
March 29	11:00	$282^\circ \pm 4^\circ$	$107 \pm 21m$	9.2 ± 1.4	$288^\circ \pm 2^\circ$	$89 \pm 16m$	$8.1 \pm .9$			
		$256^\circ \pm 4^\circ$	$160 \pm 22m$	14.7 ± 2.2	$257^\circ \pm 3^\circ$	$109 \pm 16m$	9.4 ± 1			
U2 AERIAL PHOTO										
					$316^\circ \pm 2^\circ$	$40 \pm 16m$	$5.1 \pm .5$			
					$320^\circ \pm 2^\circ$	$30 \pm 16m$	4.4 ± 1			
SAR										
March 28	18:00	$285^\circ \pm 4^\circ$	$136 \pm 22m$	10.8 ± 1.5	286	Direction Refracted to NUC	Wave Length			
		$261^\circ \pm 4^\circ$	$105 \pm 22m$	9.9 ± 1.4				283°	138m	$9.4 \pm .1$
		$242^\circ \pm 4^\circ$	$182 \pm 22m$	15.2 ± 1.5				262°	208m	$11.5 \pm .2$

1. Photographs of the radar scope and the corresponding portion of the aerial photograph are shown in Figure 1.
2. The CERC radar images and the U2 photos for March 14 and 29 were taken within a 10 minute period on each day. The CERC radar measurement at 18:00 hours on March 28 is an average of three images taken within \pm 30 minutes of the SAR data. The 285° direction wave train appeared on all three images. The 261° and 242 direction trains each appear on only two of the three images used in the average.
3. Wave direction and period for SAR data were obtained from direction plots generated from the fourier transform. These were provided by JPL.
4. Periods estimates were obtained from wave length and depth through airy wave theory.
5. Wave length measurements were not all made at the same depth.

SUMMARY AND RECOMMENDATIONS

It has been shown by means of examples that it is often possible to obtain useful images of the nearshore ocean wave field with X-band based radar. The physical principles involved in the use of radar to image the wave field have been simply described. A comparison of wave direction, wavelength and period estimates obtained with the surface based radar and similar data obtained by other more expensive means shows that the information obtained with radar is comparable in quality with similar data obtained by other means. The surface based radar does not provide wave height information. This paper is a summary of a longer report on this topic by Mattie and Harris (1979).

It is recommended that if only a single wave sensor is to be used at any location, a good gage whose record permits the computation of one dimensional energy spectra should be used. If two or more sensors can be utilized, the second should be an imaging radar which can provide direct information about the two-dimensional nature of the wave field most of the time.

ACKNOWLEDGEMENTS

Data presented in this paper, unless otherwise noted, were obtained from research conducted by the United States Army Coastal Engineering Research Center under the Civil Works research and development program of the United States Army Corps of Engineers. Permission to publish this information is appreciated. The findings of this paper are not to be construed as official Department of the Army position unless so designated by other authorized documents.

CHAPTER 9

HF SKYWAVE RADAR MEASUREMENT OF HURRICANE WINDS AND WAVES

Joseph W. Maresca, Jr. and Christopher T. Carlson*

I. INTRODUCTION

We measured significant wave height, and surface wind speed and direction for the first two Gulf of Mexico hurricanes of the 1977 season using a high frequency (HF) skywave radar. The radar measurements were made from California by using the SRI-operated Wide Aperture Research Facility (WARF). We recorded sea backscatter for hurricanes Anita and Babe, at distances more than 3000 km from the WARF, by means of single F-layer ionospheric reflection. We compiled real-time maps of the surface wind direction field within a radial distance of 200 km of the storm center, then estimated the hurricane position from these radar wind maps, and developed a track for Anita over a 4 day period between 30 August and 2 September 1977 as the storm moved westward across the Gulf of Mexico. The radar track was computed from 17 independent position estimates made before Anita crossed the Mexican coast, and was subsequently compared to the official track produced by National Hurricane Center (NHC). Agreement between the WARF position estimates and coincident temporal positions on the NHC smooth track was ± 19 km. At approximately 0000Z on 1 September 1977, Anita passed within 50 km of the National Data Buoy Office (NDBO) open ocean moored buoy EB-71, and provided us with the opportunity to compare WARF estimates of the significant wave height, and surface wind speed and direction in all four quadrants of the storm with those made at the buoy. Agreement between the WARF and EB-71 measurements was within 10%.

Two days after Anita crossed land, tropical storm Babe--a weaker, short-lived storm--developed. WARF estimates of the significant wave height, and surface wind speed and direction were made for selected regions of the storm.¹ No in situ wave measurements were available for comparison to the WARF measurements. WARF estimates of the wind speed were compared to wind speed measurements made at nearby oil platforms, and surface wind speeds computed from flight level winds (305 m) measured by a NOAA reconnaissance aircraft. Agreement was again within 10%. The purpose of this paper is to describe the capability of remotely monitoring hurricanes and other open ocean storms by using an HF skywave radar. We will describe the important aspects of the WARF skywave radar, the sea echo Doppler spectra, the method of analysis used to estimate the wave and wind parameters, and the accuracy of these radar-derived quantities.

* SRI International, Menlo Park, California 94025.

II. WARF SKYWAVE RADAR

The Wide Aperture Research Facility (WARF)² is a high-resolution experimental high frequency skywave radar located in central California. The radar is bistatic and operates in the HF band between 6 and 30 MHz. Ocean areas are illuminated by a 20-kW swept-frequency continuous-wave (SFCW) signal from a transmitter site located at Lost Hills, California. The energy reflected from the surface beam is received 185 km to the north at Los Banos, California. The receiving antenna array is 2.5-km long and consists of a double linear array of 256 whip antennas producing a nominal $1/2^\circ$ azimuthal beamwidth at 15 MHz. The signal propagates to and from remote ocean patches by means of one or more ionospheric "reflections."

The coverage area is shown in Figure 1. The radar can be directed either east or west, and can be electronically steered in azimuth $\pm 32^\circ$ from boresight anywhere within the coverage area in $1/4^\circ$ increments. Position accuracy is a function of midpath ionospheric height estimates where uncertainty in the midpath height results in a nominal position accuracy of approximately 20 km. At any one location, the accuracy between consecutive measurements in range and azimuth is an order of magnitude better. WARF has multiple-beam capability, and sea backscatter is usually received simultaneously at four adjacent ocean areas from four different beams separated by $1/4^\circ$. The size of the ocean scattering patch is a function of the beamwidth, the range, the range cell separation, and the number of range cells averaged together. The size of the minimum scattering patch at a range of approximately 2000 km is 3 km in range by 15 km in cross range.

III. IONOSPHERIC PROPAGATION

The ionosphere consists of ions produced in the earth's atmosphere, primarily by solar radiation. Radio-wave propagation by means of ionospheric reflection occurs primarily between elevations of 100 km and 500 km. A graph of electron density as a function of height may show peaks in the ionospheric profile. These peaks are defined as layers and are designated by E_s (sporadic-E), E, F1, and F2. They correspond to peak electron densities located at about 110, 120, 200, and 300 km above the earth, respectively. Ionospheric conditions are transient in time and space and depend on the stability and strength of the electron density profile.³

The minimum radar range for one hop ionospheric propagation is approximately 1000 km; the maximum radar range is approximately 3000 km. The ionosphere will support propagation to a specific range over a limited frequency band. The achievable range is dependent on time of day, geographical region, and ionospheric height. We use two different types of real-time ionospheric soundings at WARF to manage the ionospheric propagation. An oblique-incidence sounding shown in Figure 2 is primarily used to determine: the relative signal strength; the radio

FIGURE 1 COVERAGE AREA OF THE WARF HF SKYWAVE RADAR. All Anita measurements were made west of 88° W in the Gulf of Mexico.

FIGURE 2 OBLIQUE-INCIDENCE SOUNDING TAKEN AT WARF. The oblique-incidence sounding is a plot of energy received for a given frequency at a given range.

FIGURE 3 VERTICAL-INCIDENCE IONOSPHERIC SOUNDING TAKEN AT WARF. The vertical-incidence sounding is a plot of overhead energy for different frequencies.

frequencies that will propagate to a particular range; and certain types of ionospheric disturbances such as traveling waves, and focusing or defocusing of energy. A vertical-incidence sounding shown in Figure 3 taken between the WARF transmitting and receiving arrays is primarily used to measure the overhead ionospheric mode structure and height of each ionospheric layer. A frequency surveillance spectrum analyzer is used to select interference-free frequency bands.

IV. SEA ECHO DOPPLER SPECTRUM

The sea backscatter received at the WARF is coherently processed in range and Doppler to produce a sea echo Doppler spectrum. We usually process 21 independent Doppler spectra spaced at 3-km range intervals. These spectra are obtained simultaneously at each of four adjacent radar beams. A total of 84 independent Doppler spectra are obtained for each coherent time period. We compute an average spectrum from a subset of these Doppler spectra, depending on the type of measurement and the time and space scales associated with the ocean surface features. An example of a mean sea echo Doppler spectrum produced by averaging 112 spectra obtained from four consecutive 102.4 s coherent time periods, over a scattering patch consisting of 21 range cells and 3 adjacent beams is shown in Figure 4.

The sea echo Doppler spectrum shown in Figure 4 is characterized by two dominant first-order echoes surrounded by a second-order continuum. Crombie⁴ interpreted the first-order echoes in terms of simple Bragg scattering that represented a resonant response between radio waves of wave number k_0 and ocean waves of wave number $k = 2 k_0$. The radar measures the relative power and Doppler of the ocean waves traveling radially toward or away from the radar. The power ratio of the two first-order echoes are indicative of the wave direction of the waves of wave number k . Because k is usually large ($k > 0.5$), it is assumed that the wind direction is identical to the direction of these waves.

The wave height spectrum is derived from the second-order structure surrounding the first-order echoes. For hurricanes, the power in the second-order echoes is large. As the total wave energy increases, the amplitude of the second-order echoes increases as illustrated in Figure 5. Barrick^{5,6} derived theoretical expressions that accurately model the HF scattering process to second order. For a specific directional wave spectrum, the model computes the Doppler spectrum. The effects of the wind direction, wave directionality and the wave frequency spectrum on the modeled Doppler spectrum have been extensively studied by the use of this model.

V. HURRICANE DATA SAMPLING

Data sampling during a hurricane is divided into two tasks to optimize the sampling time and the data quality. The spectral resolution,

FIGURE 4 AVERAGE SEA ECHO DOPPLER SPECTRUM RECORDED WITHIN 35 km OF THE CENTER OF HURRICANE ANITA AT 2343Z ON 31 AUGUST 1977.

FIGURE 5 Example of Two Synthetic Doppler Spectra (b) Produced from Two Input Wave Spectra (a) With the same Directional Distribution and Radar-to-Wind Direction, but Different Total Wave Energy (0.02 Hz Resolution).

directly related to the coherent integration time, can be much coarser for first-order measurements than for second-order measurements. Wind direction estimates are computed from the first-order echoes, and can be computed considerably more rapidly than wave height and wind speed estimates, which are computed from the second-order echoes. Usually, the longer the coherent integration time, the greater the influence the ionosphere has on the quality of the data.

The quality of the recorded sea backscatter depends on the ionospheric conditions over short periods on the order of minutes. High-quality sea backscatter is obtained if the radio waves propagate by means of a strong, single, stable, coherent ionospheric layer. Sometimes the signals may be received at the same time from two or more different paths (multipath). In this case, the second or succeeding signals will be reflected from different parts of the ocean and different parts of the ionosphere, and will contaminate the sea echo received from the first path. If the ionosphere is changing in time or space during the coherent radar dwell (time period), further degradation of the data will occur. The ability to predict the ionospheric conditions would enable the radar operator to minimize the contaminating effects of the ionosphere, improve the quality of sea backscatter, and reduce the sampling time. The ionospheric soundings provide some data quality information. The vertical and oblique incidence soundings are taken every 10 minutes; a complete sounding requires approximately 3 minutes. The coherent radar measurements made at WARF require between 10 and 100 seconds to complete. Because the time it takes to complete a sounding is greater than the time required to record the sea backscatter data, assessment of the data quality is difficult for rapidly changing ionospheres. Therefore, real-time output of the data from the WARF site minicomputer is used to verify data quality.

The wind direction measurement is not extremely sensitive to ionospheric contamination caused by multipath or smearing because only the amplitude of the two strong first-order echoes must be measured. Coherent integration times of 12.8 seconds (0.078-Hz resolution) are sufficient to resolve the peaks of the first-order echoes. We can map the wind-direction field in a hurricane by scanning in range and azimuth. It is possible to routinely map the surface-wind-direction field of a hurricane and this can be accomplished in about 10 minutes. Once the surface-wind-direction map is made, the storm center can be identified for tracking purposes, and regions of interest can be selected for more extensive monitoring of wind speed and wave height anywhere within the storm.

The significant wave height and wind speed measurements are sensitive to ionospheric contamination. This contamination is the largest source of error in these measurements. A coherent integration time of 102.4 seconds (0.01-Hz resolution) is required to resolve the second-order echoes. The ionosphere does not generally support coherent integration time periods of this length. Multipath and ionospheric smearing can seriously degrade the weaker second-order echoes. Because of this

contamination, we are not able to routinely estimate wave height for each 102.4-second time period as we were able to calculate wind direction for each 12.8-second time period. A sampling strategy that combines careful propagation management through selection of frequencies, which result in a stable, coherent, single propagation path, and signal processing that minimizes the contaminating effects of the ionosphere are used to obtain a data set suitable for analysis. Recent work by SRI and NOAA⁷ has resulted in improved methods of collecting high quality data by sorting the data according to a spectral sharpness index. The effect of ionospheric contamination, however, is less severe for data recorded during large waves generated during a hurricane. The amplitude of the second-order echoes containing the wave height information may be stronger than the contamination effects, and thus, wave height can be calculated despite the contamination.

For the Anita and Babe wind direction measurements, we divided the data into 16 groups and analyzed three consecutive 12.8-second coherent radar dwells. Each wind direction estimate was calculated from a minimum of 15 Doppler spectra. At a range of 3000 km, the size of each scattering patch is 15 km × 25 km. It would be desirable to compute wave height and wind speed from a similar data set, but this is not generally possible. Longer coherent time periods and more independent samples of the spectra are required to obtain a high quality sample. We could collect the data over a small scattering patch by averaging over a long time, or we could increase the scattering patch size and average in space. Averaging in space is preferable because it reduces the total time required to obtain a mean Doppler spectrum. For the Anita and Babe wave height and wind speed measurements, we analyzed the data from three of the adjacent azimuth cells and 21 contiguous range cells. The total scattering patch is 63 km × 50 km. Several consecutive integration periods are required to record the data.

VI. WIND DIRECTION MEASUREMENT

HF skywave radar has been used to map the surface-wind fields associated with large weather systems⁸ and tropical storms.⁹ The radar measured surface-wind directions are derived from the predominant direction of ocean gravity waves, approximately 10-m long. The waves satisfying the first-order Bragg scattering condition, $k = 2k_0$, are assumed to be tightly coupled to the wind for time scales on the order of tens of minutes. This assumption is reasonable for the high wind speed conditions associated with hurricanes. Available directional wave spectra measurements¹⁰⁻¹² indicate that the dominant wave direction is representative of the predominant wind direction. For open ocean conditions, agreement between the WARF radar and shipboard anemometer measurements of wind direction is $\pm 16^\circ$ ¹³. For hurricane winds, the agreement between coincident wind direction measurements made by the NOAA National Data Buoy Office (NDBO) data buoys and the WARF radar is better than 10° ^{1,9}.

The radar measures the relative power between the approaching and receding waves that satisfies the Bragg scattering condition. If a cosine directional distribution¹⁰

$$G(\theta) = \cos^s \theta / 2 \quad (1)$$

is assumed, then the relative power of the approaching and receding waves measured by the radar is sufficient to estimate θ with an ambiguity about the beam direction. This left-right ambiguity is resolved by the predictable cyclonic surface circulation within the hurricane. The shape of $G(\theta)$ is controlled by the spreading parameter, s , where θ is the angle between the radar beam and the wind direction. For open ocean conditions, we have estimated s from several models.^{11,13} For the maximum hurricane winds, the values of s estimated from these models are too low. Based upon previous hurricane analyses and spot measurements of wind direction at NDBO data buoys, we used values of s between 1.0 and 2.0. No attempts were made to account for variations in s as a function of location within the hurricane.

VII. SIGNIFICANT WAVE HEIGHT

Barrick⁶ derived an integral expression that predicts the Doppler spectrum for a specific directional wave spectrum input. Recent efforts have succeeded in inverting this integral expression to compute the input rms wave height,^{14,15} one-dimensional wave frequency spectrum,¹⁶⁻¹⁹ and the directional distribution.¹⁷⁻¹⁹ Barrick's^{14,16} expressions have been used to analyze skywave radar data recorded for a Pacific Ocean storm¹⁵ and tropical storms.^{1,20}

We used a power law derived from simulated data by Maresca and Georges¹⁵ to compute rms wave height by relating the ratio of the total second-order and first-order power to the rms wave height:

$$k_0 h = a R_2^b \quad (2)$$

where $0.2 \leq k_0 h \leq 1.0$, h is the rms wave height; k_0 is the radar wave number; R_2 is the ratio of the total second- to total first-order power; and $a = 0.8$ and $b = 0.6$ are constants. This average expression was derived from theoretical simulations of the Doppler spectra for different radar-to-wind directions, directional distributions, functional forms of the wave frequency spectrum, and operating radar frequencies. Equation (2) is accurate to within 10%. Discussion of the errors can be found in Maresca and Carlson,¹ and Maresca and Georges.¹⁵

VIII. WIND SPEED

Historically, wave models have been developed to predict wave height and the wave spectrum from an input wind field. The accuracy of these models is dependent upon the accuracy of the input winds. Hasselmann et al.²¹ proposed a one-dimensional parametric wind-wave model for fetch limited growing wind-sea conditions. Ross and Cardone²²⁻²⁵ empirically derived a power law expression for hurricanes based on the form proposed by Hasselmann that relates the nondimensional wave energy, \tilde{E} , by using wind, wave and fetch measured during hurricanes Ava, Camille, and Eloise. For hurricanes,

$$\tilde{E} = 2.5 \times 10^{-5} \tilde{R}^{0.45} \quad (3)$$

where $\tilde{E} = E g^2 / W^4$; $\tilde{R} = r g / W^2$; $E = h^2$; and $H_s = 4h$. In \tilde{E} and \tilde{R} , E is the total wave energy; h is the rms wave height; H_s is the significant wave height; r is the radial distance from the eye to the measurement point that accounts for fetch; g is the gravitational acceleration; and W is the wind speed. Solving for wind speed in Eq. (3), we obtain

$$W = \left(\frac{h^2 g^2}{2.5 \times 10^{-5} (r g)^{.45}} \right)^{0.323} \quad (4)$$

The wind-wave model used to derive Eq. (4) is applicable for slow moving storms in which $W > 15$ m/s and $\tilde{R} < 3 \times 10^4$. For the unusual cases where the storms move very fast or very slow, Ross and Cardone²⁴ showed that significant differences in the modeled and measured wave heights occur.

We used Eq. (4) to calculate wind speed for both Anita and Babe and compared our results with the wind speeds measured at NDBO buoys, oil platforms, and by reconnaissance aircraft. The radial fetch (r) was measured from the WARF-derived wind maps, and the wave height (h) was computed using Eq. (2). The radar-derived W is not an instantaneous wind speed estimate; it is a smooth temporal and spatial average of the winds. Our radar-derived W was compared to the 15-minute wind speed averages made at NDBO moored data buoys.

IX. ANITA MEASUREMENTS

Hurricane Anita formed as a tropical depression in the Gulf of Mexico at about 1200Z on 29 August 1977. Anita developed into a tropical storm at approximately 0600Z on 30 August 1977, and about 12 hours later intensified into the first Gulf of Mexico hurricane of the 1977 season. As Anita moved west across the Gulf, winds in excess of 75 m/s were recorded. Five days of skywave data beginning on 29 August 1977 were recorded prior to Anita's landfall on 2 September 1977 approximately 48 km south of Brownsville, Texas. Twenty-one radar wind maps were compiled at WARF. The first 4 wind maps were not used in the

radar-derived track presented here because the radar showed two distinct centers during this early period. On 30 August 1977, the storm intensified and developed one center. The wind maps were updated 3 to 5 times per day during both daytime and nighttime periods and were used to develop the WARF-derived track. Figure 6 shows the radar-derived positions in relation to the official NHC smooth track produced from reconnaissance aircraft measurements, visible and infrared satellite cloud photographs, and shore-based microwave Doppler radar. The relative agreement between the WARF position estimates and the interpolated temporal position estimates along the smooth track is ± 19 km.

There are two principal errors associated with the WARF hurricane position fixes: the absolute position error of the radar and the errors associated with locating the storm center from the radar wind direction measurements. We estimate the range errors of the radar caused by errors in determining the ionospheric height at midpath to be 20 km. If a coastal scan is included as part of collecting the wind map data, the land echo can be used as a reference to more accurately determine the ionospheric height, and therefore, reduce this error. We estimate the error in azimuth caused by ionospheric tilting to be 20 km. These range and azimuth errors can be reduced significantly by installing an HF repeater along the coast which receives our signal and transmits it back with a known frequency shift. Assuming similar mean ionospheric conditions within 200 km of the storm center, the entire wind map can be translated in azimuth and range to correct for the absolute position error. The location of the wind direction measurement with respect to the storm center is generally not affected by these position errors. We estimate the error associated with determining the storm center from the radar maps to be 20 km. The error is caused by the left/right ambiguity in the wind direction measurement. We can expect a maximum error of about 40 km from these two sources of error. In comparing the WARF position fixes to the NHC track we found relative differences of between 5 and 50 km. We attribute these relative differences to the above sources of error.

Anita passed 50 km south of NDBO buoy EB-71 at about 0000Z on 1 September 1977. Two WARF-derived wind maps were made at 2140Z on 30 August 1977 and 0120Z on 1 September 1977 that bracket this time period. One of these wind maps is shown in Figure 7. Also shown on Figure 7 are surface wind direction fields derived from data recorded by NDBO buoy EB-71. These buoy-measured wind directions were recorded at 2-hour intervals during the period ± 18 hours of Anita's passing EB-71. The buoy-derived wind field was computed by a time-space conversion that assumed uniform wind direction and lateral storm motion during this period. We compared the buoy-derived wind directions to the WARF-derived wind directions; agreement was within 19° . Agreement between the WARF-derived wind direction estimate coincident in time and space with the buoy wind direction estimate was 1° .

Between 2314Z on 31 August 1977 and 0020Z on 1 September 1977, WARF measurements were made at five locations surrounding the center of the

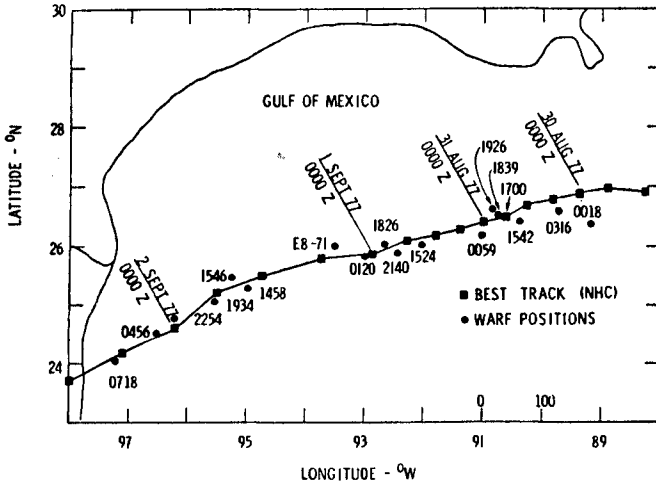

FIGURE 6 WARF-Measured Track of Hurricane Anita produced from the Radar Wind Maps

FIGURE 7 WARF-Derived Wind Direction Map made for Anita at 2140Z on 31 August 1977.

storm. The location of each measurement relative to the storm center was interpolated from the two wind maps. We computed the wind direction by using Eq. (1), wind speed by using Eq. (4), and wave height by using Eq. (2) at each location (see Table 1), and compared these measurements to a buoy-derived wind and wave field. The maps of the spatial distribution of the wind direction, wind speed, and wave height were compiled from NDBO EB-71 data buoy measurements. Each parameter was plotted in relation to the storm center and is shown in Figures 8, 9, and 10. We assumed that Anita moved uniformly with no change in the meteorological conditions during the period 18 hours before and 18 hours after passing the buoy.

The significant wave height shown in Figure 8 was measured at the buoy every 3 hours; the wind direction and wind speed shown in Figures 9 and 10, were measured at the buoy every 2 hours. During this 36-hour period, Anita began to intensify, and the validity of the buoy-derived wind and wave fields are suspect. Exact comparison of the EB-71 and WARF measurements are difficult because of the differences in the time, location, and area of ocean monitored. On Figure 8 we also included the wave hindcast for significant wave height computed by Cardone et al.²⁵ for comparison.

The WARF estimates made at Point B (26.3°N, 92.1°W) are in close proximity to the buoy-derived estimates located at (26.2°N, 92.1°W). The remaining WARF wind and wave height estimates are too far away from the buoy-derived quantities for direct comparison, but the agreement between the WARF- and buoy-derived wind and wave fields is reasonable.

FIGURE 8 Comparison of the WARP-Derived Significant Wave Height (m) measured between 2342Z on 31 August 1977 and 0020Z on 1 September 1977. The wave height contours are reproduced from Figure 9 of Reference 25. The letter designations are given on Figure 9.

FIGURE 9 Comparison of the WARP-Derived Wind Directions (→) made between 2342Z on 31 August 1977 and 0020Z on 1 September 1977 and the EB-71-Derived Wind Directions (→) made between 0600Z on 31 August 1977 and 1800Z on 1 September 1977.

FIGURE 10 Comparison of the WARP-Derived Wind Speed (m/s) measured between 2342Z on 31 August 1977 and 0020Z on 1 September 1977 and the EB-71-Derived Wind Speeds (m/s) measured between 0600Z on 31 August 1977 and 1800Z on 1 September 1977.

The wave hindcast was compared to both the buoy- and WARF-derived wave heights. We find good agreement between the hindcast, buoy and WARF estimates of wave height along the 4.6-m contour east of the hurricane. The buoy estimate west of the hurricane along the 4.6-m contour line suggests the radius of this contour line is too large. WARF estimates of wave height at Points B and C, located at the extremes of the hindcast region of highest waves, are lower than the hindcast. The good agreement of Point B with the nearby buoy estimate, and the consistency of the WARF estimates at Point B and C suggest that the 7.6-m contour should be smaller. The WARF estimates of wave height at Points A and D are located between the 6.1-m contours. Again the buoy- and WARF-derived wave heights suggest that the 6.1-m contour line is too large. We should also note that any contamination of the sea echo Doppler spectra by the ionosphere would result in radar wave-height estimates that would be too high. The composite of wave height data obtained from the hindcast and EB-71 buoy indicate the validity of the WARF wave height estimates.

The agreement between the WARF-derived estimates of wind speed and the buoy-derived estimates of wind speed is good. There are three principal errors associated with the WARF wind speed estimate: error in estimating the radial fetch, error in estimating the rms wave height and error in the parametrics model. We computed the error in calculating wind speed for a ± 0.5 m error in estimating wave height for a significant wave height of 5.5 m (9.1% error) for radial fetches of 30, 50, 70 and 100 km. The errors were less than 1.6 m/s. We also computed the error in calculating wind speed for a ± 20 km error in estimating the radial fetch for a significant wave height of 5.5 m and radial fetches of 30, 50, 70, and 100 km. For radial fetches greater than 30 km, a +20 km error causes an error of less than 2 m/s in wind speed. For radial fetches greater than 50 km, a -20 km error causes an error of less than 2 m/s in wind speed. This represents less than an 8% error. These errors are typical of the WARF estimates of the significant wave height and radial fetch measurements. The errors associated with the model are discussed in Ross and Cardone.²⁴ For Anita, the mean and rms differences between the Cardone et al.²⁵ parametric model forecast and measured wave heights at EB-71 is 0.21 ± 0.83 m. This includes errors in measuring wave height at the buoy and radial fetch from the conventional position fixes. We also calculated the wind speed using Eq. (4) for some of the buoy-measured wave heights shown in Figure 8, and compared the calculated wind speed measurements to wind speeds measured at the buoy (Table 2). The data is indicative of the accuracy we could expect from the WARF estimates of wind speed using Eq. (4). For these data, we believe the largest sources of error in the comparison are the uncertainty in the radial distance to each point caused by compiling the map over a 36-hour period, and the assumption of a symmetrical distribution of the winds.

W_m = Measured Wind Speed

X. BABE DATA

We recorded skywave data for Babe from 2000Z on 4 September 1977 until landfall on 5 September 1977. Wind direction maps were made at 2253Z on 4 September 1977 and 1507Z on 5 September 1977. Babe was already onshore before the second map was made. We analyzed a sea echo Doppler spectrum near the peak winds for wind speed. This spectrum was recorded at a radius of 50 km from the hurricane center (27.9°N, 91.6°W). The WARF estimate of significant wave height was 3.6 m. The wind speed was computed by using Eq. (4) and was compared to wind speeds measured at several offshore oil platforms at 2100Z and from aircraft reconnaissance at 1800Z. Winds measured from aircraft at an altitude of 305 m were reduced to the equivalent 10 m wind for comparison to the radar data. We reduced the aircraft winds to the surface using a simple ratio relating upper level gradient wind to the surface wind, indicated by Elsberry et al.²⁶ calculations. Using the two layer Cardone²⁷ marine boundary layer model, Elsberry et al.²⁶ computed the ratio of the wind at the top of the upper layer to the wind at the top of the surface layer for different regions of the hurricane, different surface roughness and different ratios of heat conductivity to eddy viscosity. For moderate to high wind speeds, the top of the surface layer is approximately 20 m. This wind ratio ranges from about 0.5 to 0.85. The lower value represents regions near the peak winds. We assumed the 305 m aircraft wind was representative of the wind at the top of the upper layer and reduced it to 20 m using a ratio of 0.6. The corrected 20 m wind is 18.5 m/s. We realize the error associated with this calculation can

be large. We computed the 19.5 m WARF wind speed for comparison by assuming a logarithmic profile in the surface boundary layer of the form

$$W(z) = \frac{W_*}{k} \ln \left(\frac{z}{z_0} \right) \quad (5)$$

where $W(z)$ is the wind speed at a height of z , $W_* = C_D W^2$ is the friction velocity, C_D is the drag coefficient, $k \approx 0.4$ is Von Karman's constant, and z_0 is the surface roughness. We estimated $z_0 = 0.00392$ m for hurricane conditions using the wind speeds measured during Eloise²⁸ at NDBO buoy EB-10 at 10 m, and a constant drag coefficient of 0.0026 proposed by Wu²⁹ for high wind speeds to calculate W_* . We found good agreement between our 19.5 m computed wind speed using Eq. (5) for Eloise and the 19.5 m Eloise wind speed computed by Ross and Cardone.²⁴ Using $z_0 = 0.00392$ m and $C_D = 0.0026$ m we computed the 19.5 m WARF Babe wind speed to be 18.3 m/s. We also computed the maximum wind speed, W_{\max} , and the maximum sustained wind speed, W_s , for a storm moving at 5.1 m/s from the following expressions³⁰ relating the central pressure and radius of the storm to wind speed at 10 m:

$$W_{\max} = 0.868 [6.45(P_n - P_o)^{1/2} - 0.296 \text{ rf}] \quad (6)$$

and

$$W_s = 0.865 W_{\max} + 0.5 V_F \quad (7)$$

where W_{\max} and W_s are in m/s, P_n is the normal pressure of 1013 mb, P_o is the central pressure in mb, r is the radius in km, f is the coriolis parameter in radians/hour, and V_F is the forward motion of the storm in m/s. The maximum wind recorded from the aircraft at 1800Z were located approximately 60 km from the center and the central pressure was reported as 1000 mb. We calculated $W_{\max} = 16.4$ m/s and $W_s = 16.8$ m/s. We summarize these wind speed estimates in Table 3. Because none of the wind speed estimates are coincident in time or space with the WARF estimate and the assumptions inherent in deriving these quantities we can only compare the results qualitatively. The WARF wind speed estimate is reasonable.

XI. SUMMARY

Spatially-averaged hurricane wind speed, wind direction, and wave height estimates made at the WARF for Anita and Babe were compared to point measurements made at NDBO buoys and oil platforms and by reconnaissance aircraft. Agreement was within the nominal measurement accuracy of all the sensors. The WARF data set is not limited to the results presented in this paper. Other analyses of the radar data that were not obtained in the vicinity of the buoy are also available. These

experiments indicate that during a hurricane, HF skywave radar can provide operational surface data that are as accurate as the more recognized in situ measurements. The supportive surface data supplied by the WARF radar would prove particularly useful for tracking during early formative stages of hurricanes when multiple centers may be observed or when cirrus shielding may obscure visual location by satellite cloud photography. The high resolution, large coverage area, real-time steering and continuous monitoring capabilities are unique to skywave radar. The hurricane data obtained from skywave radar complements data obtained from satellites, aircraft, and buoys.

Table 3
BABE WIND SPEED ESTIMATES MADE ON 4 SEPTEMBER 1977

Sensor	Observation (GMT)	Bearing From Hurricane Center (°N)	Radial Distance From Hurricane Center (km)	Wind Speed (m/s)
WARF (10 m)	2253	340	60	18.2
WARF (19.5 m)	2253	340	60	18.3
Aircraft (305 m)	1800	25	60	30.8
Aircraft (19.5 m)	1800	25	60	18.5
Oil Platform (19.5 m)	2100	320	100	15.4
Oil Platform (19.5 m)	2100	0	35	11.3

CHAPTER 10

RADAR OBSERVATIONS OF HURRICANE WAVE DIRECTIONS

by

D. B. King¹ and O. H. Shemdin²

ABSTRACT

This paper presents an analysis of data collected in a hurricane wave research program. The data were collected with a synthetic aperture radar (SAR) during five aircraft flights into hurricanes in August and September, 1976. These data are the first collected on the directional distributions of waves throughout the region of active generation.

The wave patterns in all of the storms are similar and show a marked radially asymmetry. The dominant waves propagate ahead of the storm in a broad arc that has an apparent center in a region of confused sea to the right and rear of the hurricane eye. The asymmetry in the wave patterns is attributed to the forward motion of the storms. The wave directions throughout the storms do not show a sensitive dependence on the forward speed of the storms or on their maximum wavespeeds. However, there is an increase in peak wavelength with increasing windspeed and forward velocity.

Introduction

Hurricane waves play a controlling factor in the design of permanent structures along the Gulf and East Coasts of the United States and in other parts of the world. In spite of their importance, they are poorly understood and often not adequately predicted. This lack of understanding is due partially to the difficulty of data collection and partially to the fact that the wave generation process is not completely understood, even for the case of simple windfields.

Some of the first research on hurricane waves was conducted by Tannehill (1936). He, along with Arakawa (1954) and Pore (1957) compiled information on hurricane wave heights and directions collected from shipboard observations. This technique has not been followed up by other researchers because the frequency and the nature of the observations rendered them inadequate for an understanding of the processes involved.

Few other measurements were collected until recently, when two large programs were initiated. The first, in the late 60's and early 70's, involved the instrumentation of offshore oil platforms in the Gulf of Mexico (See Ward (1974)). The second is a continuing project by the NOAA Data Buoy Office in which deep water environmental buoys have been moored at various offshore locations along the U.S. coasts. These buoys have recently encountered several hurricanes (See Withee and Johnson (1975), Johnson and Speer (1978) and Johnson and Renwick (1978)). Most of the reported wave height measurements are in the form of time histories of significant wave heights and dominant periods showing variations during periods when storms pass by or over the measurement sites. More recently, data revealing the directional nature of waves were analyzed and directional wave height spectra were reported (See Forristall et al (1978)). However, these results are restricted to only one site. The data do not reveal the directional distributions of wave fields over the entire region of hurricane influence.

The Aircraft Hurricane Program

In August and September 1976, and again in October 1977, the Jet Propulsion Laboratory (JPL) participated in a hurricane research program with a number of other NASA research centers and with the NOAA — National Hurricane and Environmental Meteorological Laboratory. JPL collected information on the directional properties of hurricane waves using a Synthetic Aperture Radar (SAR) onboard a NASA CV-990 research aircraft. The 1976 flights were made into Tropical Storm Emmy on August 24 (designated as Emmy 1 in this paper), Hurricane Emmy on August 25 (Emmy 2), Hurricane Frances on August 31 (Frances), Tropical Storm Gloria on September 28 (Gloria 1), and Hurricane Gloria on September 30 (Gloria 2). These storms were all in the western Atlantic. The flight tracks and storm paths are shown in Figure 1. Approximately 700 minutes of data was collected in these five storms. Table 1 lists the important parameters associated with each storm.

On October 5, 1977, the JPL-SAR collected data in Typhoon Heather in the eastern Pacific. Images have also been obtained with the Seasat-1 SAR from Typhoon Fico on July 15, 1978. Data from these two storms are not included in this paper but preliminary analysis shows that their wave patterns are in good agreement with the data presented here.

The Synthetic Aperture Radar (SAR)

The data presented in this paper represent the first extensive collection of directional wave data throughout the region of hurricane influence. The data were obtained with the SAR, a sensor that provides all weather images of the sea surface topography during day or night. The images are similar in appearance to photographs of the sea surface. The SAR transmits a microwave pulse in the L-band region (23.0 cm wavelength) and records the intensity and phase history of the signal returned from the sea surface. This information is then converted

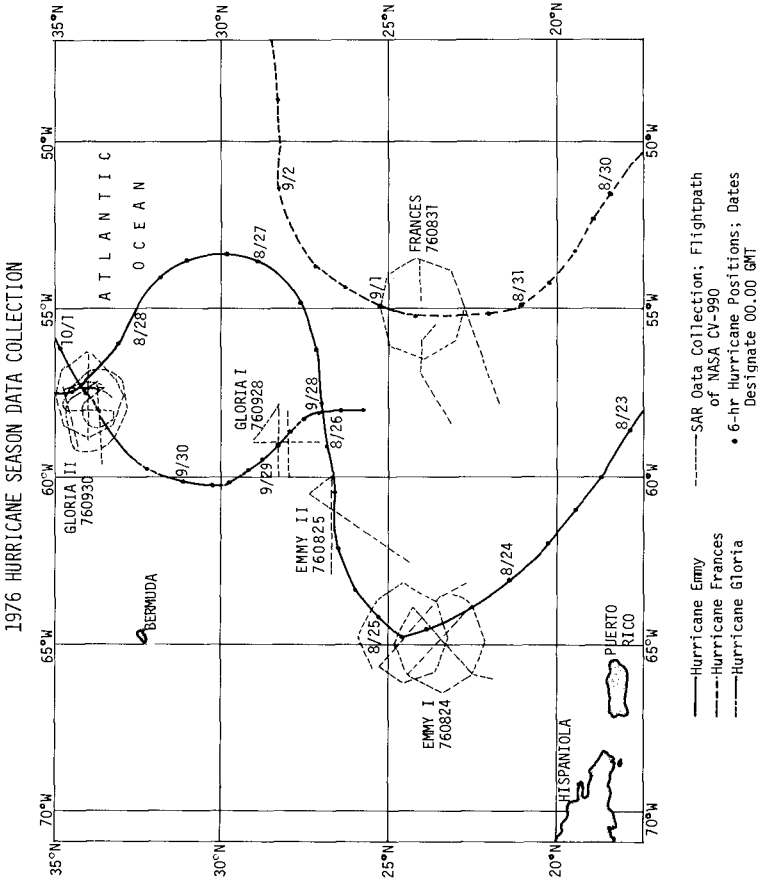

Figure 1. Flight paths of hurricanes Emmy, Frances and Gloria in 1976. The flight patterns and locations of hurricane interceptions are also shown.

Table 1. Important hurricane parameters associated with hurricanes Emmy 1 and 2, Frances and Gloria 1 and 2. The parameters are representative for the periods from 18 hours before SAR data collection to 6 hours after SAR data collection.

Hurricane	Emmy 1	Emmy 2	Frances	Gloria 1	Gloria 2
Date	Aug. 24	Aug. 25	Aug. 31	Sept. 28	Sept. 30
Time of Collection (GMT)	15:34-19:23	15:20-16:48	15:13-18:24	16:46-17:45	15:58-20:14
Max Winds (kn)	60	65-70	75-85	60-65	85-95
Min Pressure (mb)	995	990	975-963	992-988	980
Forward Speed (kph)	14-20	24-27	20-22	10-12	27-28
Heading	Turn NW-NE	E	N	NW	NE
Radius of Gale Force Winds (nm)	225	225	225	175	250

through the use of an optical correlator to an image of the sea surface. Figure 2(a) is an example of an image showing surface waves.

The SAR has many advantages over optical photography. Operating at L-Band it can penetrate cloud cover and, being an active system, it is independent of solar illumination. The image can be further processed to yield the wave phase-speed and to resolve the 180° ambiguity in the direction of wave propagation. The imaging characteristics of the SAR and its application to oceanography has been the subject of intensive investigations recently (See for example Shemdin et al (1978)).

A two-dimensional spectral transform of the SAR image provides a convenient representation of the wavelengths and corresponding directions that appear in a wave image. The Fourier transform of the image shown in Figure 2(a) is given in Figure 2(b). The center of the transform represents an infinite wave length (or zero wave number). The wave direction is determined by the azimuthal angle of the two spectral peaks which are symmetrically aligned with respect to the origin.

Observed Directional Wave Patterns in Hurricanes

Figure 3 shows processed SAR wave imagery at selected locations throughout Gloria 2. Each wave image is enlarged ten times relative to the hurricane scale. The direction of hurricane forward motion is to the top of the figure. For comparison, all the hurricane flights were oriented in this manner, regardless of the direction of true north. These images are placed in their proper location relative to the moving eye of the hurricane. Fourier transforms of each of the wave images in Figure 3 are shown in Figure 4. The transform scale is shown in the lower right hand corner of Figure 4. The innermost circle designates 300 meter waves, the next innermost designates 250 meter waves, then 200, 150, and 100 meter waves. The outside edges of the transforms are at 75 meter waves.

The striking feature of Figures 3 and 4 is the pronounced asymmetry in the wave field. There is an arc of waves which extends from the right front quadrant through the left front and into the left rear quadrant. The waves along the arc are propagating outward from the storm center. The hurricane winds are blowing in a counterclockwise spiral and thus the dominant waves in much of the storm are traveling at 90° or more with respect to the local wind direction. This is shown in Figure 5. The arc appears to have its center in the right rear quadrant but there is no distinct origin. Instead, the wave patterns in this area suggest a confused sea. The Fourier transforms show multiple dominant peaks which are traveling in different directions.

The pronounced asymmetry in the wave field is caused primarily by the forward motion of the hurricane. The counter-clockwise winds (for northern hemisphere storms) blow faster on the right hand side of a

moving hurricane than on the left due to the added speed of the storm. This causes larger waves to be generated in this area. However, more importantly, these waves tend to travel with the storm and so stay in the generation region much longer. These dominant waves then propagate throughout most of the storm depending on the group velocities and directions of propagation.

In comparing the wave patterns in different storms, it is necessary to know how the meteorological parameters vary in different storms. A comparison of wind speeds, central pressures, forward speeds, headings and radii of gale force winds are given in Table 1 for the five 1976 flights. The maximum wind speeds and hurricane forward speeds are likely to play important roles in the wave generation processes. A spread in these two parameters for the hurricanes shown would have been desirable. Unfortunately, this was not the case. All of the storms were of weak to moderate intensity (max winds of 60 to 90 knots) and of a moderate to medium forward speed (11 to 28 kph). Also, the slower storms had lower windspeeds and the faster storms had higher windspeeds, making it impossible to determine the relative importance of these two parameters. However, the wavefields show variations which can be related to these two parameters. Gloria 1 was the slowest moving storm. The next slowest was Emmy 1 whose wave pattern was complicated by the fact that she was in a 90° right turn during the time of data collection. Then in ascending order were Frances, Emmy 2 and Gloria 2. The maximum wind speed follows the same ascending order with the exception of Frances and Emmy 1 which are reversed.

Figures 6, 7, and 8 show spectral transforms from the five flights taken in the left-front, the right-front, and the right-rear quadrants, respectively. The transforms were taken in areas that appeared interesting and in which data from most of the storms were in close proximity. Table 2 summarizes the information in Figures 6, 7 and 8.

The left-front quadrant (Figure 6 and Table 2) is a typical example of the waves that propagate outward ahead of the storms. The directions of wave propagation in all of the transforms are in close agreement and within the uncertainty limit of determining the true heading of each storm. The peak wavelengths vary in close agreement with variations in intensity and forward speed of storms, the more intense and faster moving storms have longer wavelengths. The one anomalous point is Emmy 1, which may be due to the fact that Emmy 1 was in a turn.

The transforms in the right-front quadrant (Figure 7 and Table 2) exhibit the longest dominant waves compared to other regions of the storm. In this quadrant the wave propagation directions are in good agreement. Some variation is observed but is attributed to the spatial separations of the areas analyzed. As in the left front quadrant, the peak wavelengths again vary with the forward speed of the hurricane and its maximum wind speed.

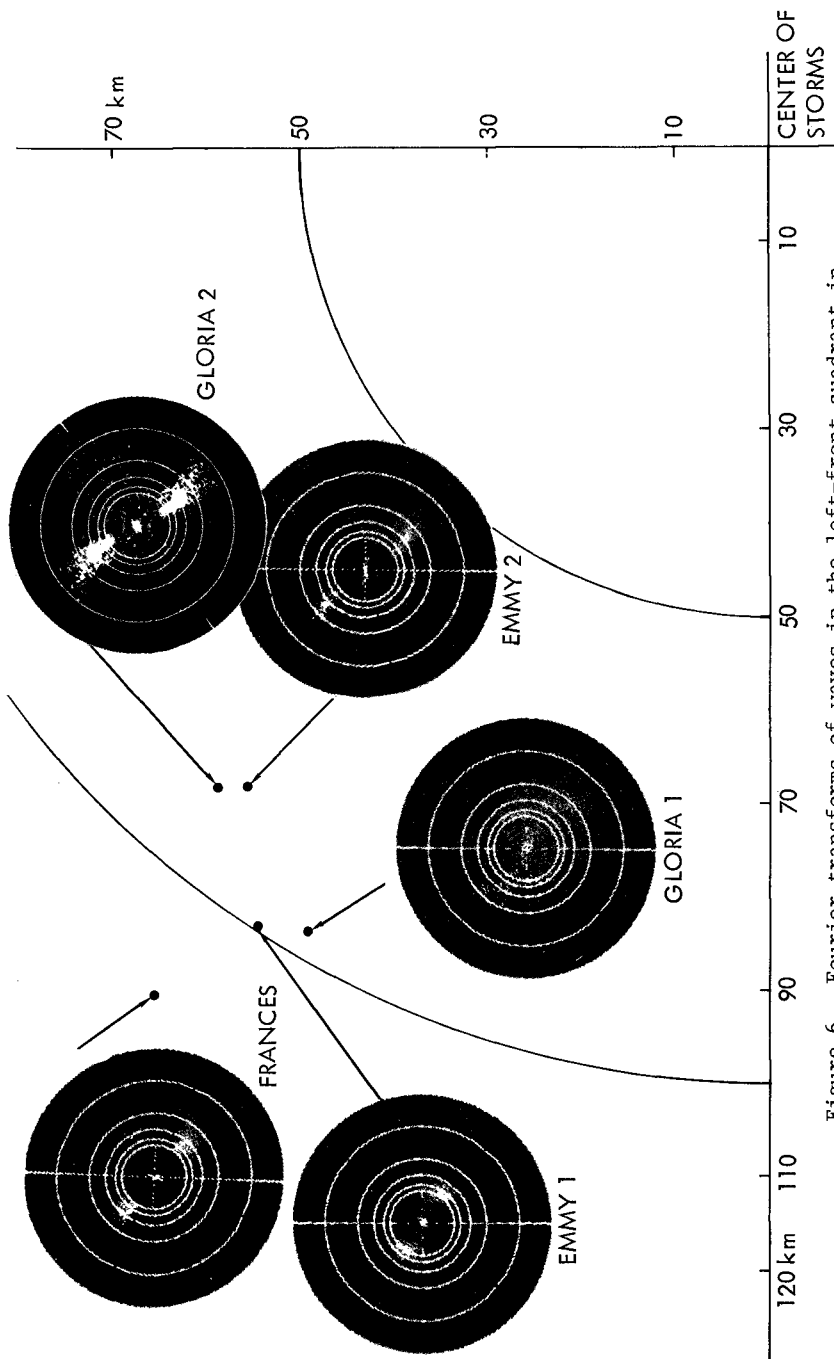

Figure 6. Fourier transforms of waves in the left-front quadrant in five hurricanes.

Figure 8. Fourier transforms of waves in the right-rear quadrant in five hurricanes.

Table 2. Dominant wave lengths and wave directions measured for five hurricanes in left-front, right-front, and right-rear quadrants.

	<u>Peak Wavelength (in meters)</u>	<u>Direction (+20°)</u>
LEFT FRONT QUADRANT		
Near 100 km, 315° from storm center		
Emmy 1	275	300°
Emmy 2	190	320°
Frances	230	310°
Gloria 1	160*	315°
Gloria 2	275	320°
RIGHT FRONT QUADRANT		
Near 40 km, 80° from storm center		
Emmy 1	250	5°
Frances	300 275	345° 320°
Gloria 1	125*	325°
Gloria 2	275	350°
RIGHT REAR QUADRANT		
Near 60 km, 140° from storm center		
Emmy 1	160	335°
Frances	250 210	5° 120°
Gloria 1	100	10°
Gloria 2	280 120	80° 30°

*Poor quality images; wave lengths inferred.

The right-rear quadrant (Figure 8 and Table 2) has different properties because it shows little agreement among different hurricanes in wave direction, in contrast to the other two regions examined. It is difficult to determine the causes of the diversity observed. However, it is reasonable to conclude that this region deserves special attention in future modeling efforts and in future data collection missions. Nevertheless, in spite of the apparent confusion in the wave directions in this quadrant, the dominant wavelengths tend to vary with the maximum wind speed and forward speed parameters.

Thus based on dominant wavelengths in three different quadrants the hurricanes under study fall into the following ascending order: Gloria 1, Emmy 1, Frances, Emmy 2, and Gloria 2. There are two exceptions. Emmy 1 is out of this order in the left-front quadrant and Frances and Gloria 2 are reversed in the right-front quadrant.

The correlation between increasing wind speed and dominant wavelength is straightforward and in agreement with known wave generation theories. The argument for an observed correlation between increasing forward storm speed and wave length is more subtle. As waves are generated in the right-hand side of the storm, those that are correctly aligned will travel in the same direction as the storm. These waves are generated over a spectrum of wavelengths and, as such, have a spectrum of group velocities, some slower and some faster than the storm. The generated waves will either lag the storm forward motion and increase in height to saturation through breaking or travel faster than the storm and appear as waves ahead of the storm. The dominant waves, however, are likely to be those waves which extract maximum energy from the wind through elongated residency in the region of intense wave generation. The latter is determined by the difference between the wave group velocity and forward speed of the hurricane. Also, nonlinear interaction plays an important role in affecting energy transfers across a wave spectrum. In an active generation region the frequency of the spectral peak shifts continuously to lower frequencies. The processes of atmospheric transfer, dissipation and nonlinear transfer must all be correctly simulated in a moving circular storm pattern in order to predict the observed directional wave patterns. It is clear that this type of analysis must now follow. However, it is possible to infer that the dominant waves are likely to have wave lengths longer than those which are resonant with the hurricane forward speed. Such inference is consistent with Figure 9 and Table 2 which indicate that the dominant waves are considerably longer than those which are resonant with the hurricane forward motion.

Summary and Conclusions

In summary, this paper presents a unique data set on the directional distribution of wave fields in hurricanes, and as such it provides an insight into the configurations associated with such wind fields. However, it also opens the question of why these wave fields are as they appear. The paper introduces in a qualitative manner certain hypotheses on the generation processes in hurricanes. It also

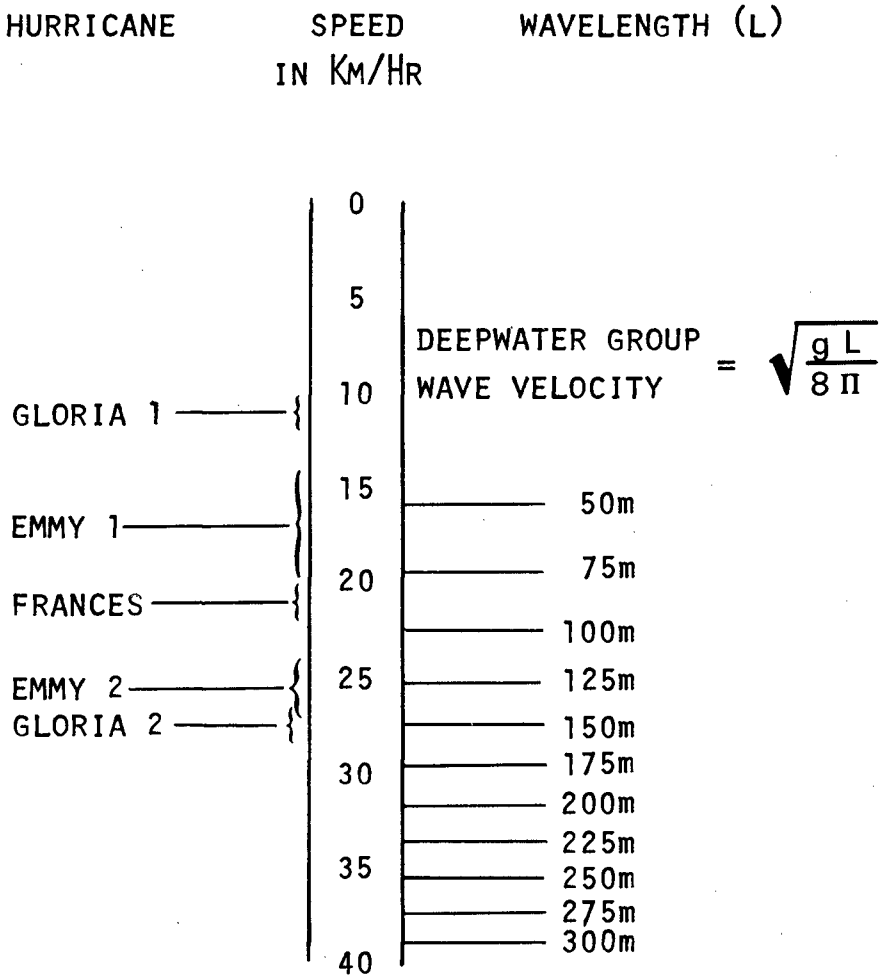

Figure 9. Comparison of hurricane forward speeds and equivalent wave lengths having equal group velocities.

lay the ground for a logical follow-on analytical effort, namely that of modeling the generation processes through the use of numerical techniques.

ACKNOWLEDGEMENT

This research was supported by the Severe Weather Program of the NASA-Office of Applications. The authors acknowledge the valuable support of Dr. R. Sheets of the NOAA-National Hurricane and Environmental Meteorological Laboratory. Mr. W. Stromberg assisted in digitizing the images and calculating the Fourier transforms. Mr. E. McMillan participated in collecting the data with the SAR.

CHAPTER 11

THE OBSERVED JOINT DISTRIBUTION OF PERIODS AND HEIGHTS OF SEA WAVES

Yoshimi Goda

Marine Hydrodynamics Division, Port and Harbour Research Institute
Ministry of Transport, Nagase, Yokosuka, Japan

ABSTRACT

Analysis is made of 89 records of surface waves for the joint distribution of the heights and periods of zero up-crossing waves. Records are classified into five groups according to the rank of the correlation coefficient between individual wave heights and periods, and the data of the joint distribution are presented for five groups separately. In comparison with the present data, the theory of Longuet-Higgins for a narrow band spectrum can describe the joint distribution in its upper portion with high waves when the spectral width parameter is fitted to the marginal distribution for wave periods, although the joint distribution in the lower portion with low waves shows deviation from the theory. Another theory by a group of C.N.E.X.O. based on the distribution of positive maxima can describe the general pattern of observed distribution better than the former theory, but the agreement remains qualitative. The present data also suggests that the joint distribution of wave periods and heights may be parameterized with the correlation coefficient between wave heights and periods.

INTRODUCTION

In the analysis of sea waves, the relationships between characteristic wave periods such as the highest, significant, and mean wave periods are often discussed, as there exists a growing demand for such information in the design of coastal and offshore structures. The problem is one aspect of the joint distribution of wave heights and periods. When the problems of irregular wave runups, overtopping, and wave forces are analyzed by the wave-by-wave method, the information of the joint distribution becomes vital for solving these problems.

The theory of the joint distribution of wave heights and periods was given by Longuet-Higgins [1] in 1975 in a closed form under the assumption of a narrow band spectrum. It was recapitulation of his previous work [2] on the statistical properties of random, moving surface. The theoretical distribution is characterized by having the axis of symmetry at $T = \bar{T}$ as demonstrated in Fig. 1, while sea waves generally demonstrate asymmetric distribution with respect to wave periods as exhibited by Chakrabarti and Cooley [3]. A measure of asymmetry is the correlation coefficient between wave heights and periods, which sometimes amounts to more than 0.7 among sea waves, while the theoretical distribution of Longuet-Higgins yields zero correlation.

The asymmetric pattern of the joint distribution of wave heights and periods was incorporated in the theory by Ahran, Cavanié, Ezraty,

and Laurent, i.e., a group of C.N.E.X.O. [4,5,6]. They formulated the joint distribution of the amplitudes and quasi-periods of positive maxima on the basis of Cartwright and Longuet-Higgins [7]. The quasi-periods of positive maxima were estimated from the second derivatives of surface elevations at the maxima by fitting a sinusoidal wave profile. They further presumed that it could be applicable to the joint distribution of the heights and periods of zero up-crossing waves by replacing the amplitude of positive maximum with one-half wave height and the quasi-period of positive maximum with the zero crossing wave period. The theory was found to agree with the ocean wave data except for the region of large nondimensional wave periods where the theory tends to overestimate the probability density.

Sea waves are known to exhibit large variability in their statistical parameters such as the correlation coefficient and spectral width parameters. It is readily conceived that the characteristics of the joint distribution of wave heights and periods could be examined in detail by making a rankwise analysis according to the magnitude of statistical parameters. Following this concept, reanalysis of the available surface wave records was made for the joint distribution of wave heights and periods after classifying the data according to the rank of the correlation coefficient of individual wave heights and periods. The analysis has yielded several findings on the characteristics of the joint distribution as it will be seen in the subsequent chapters.

Note: Throughout the present paper a wave is defined by the zero up-crossing method, and no reference is made of a wave defined by the crest-to-trough method except for the number of maxima in a wave record.

FORMULAE OF JOINT PROBABILITY DENSITY

The joint probability density of wave heights and periods by the theory of Longuet-Higgins can be written as in the following form after normalizing wave heights and periods with their mean values, or \bar{H} and \bar{T} , respectively:

$$p(x, \tau) = \frac{\pi x^2}{4\nu} \exp\left\{-\frac{\pi}{4}x^2\left[1 + \frac{(\tau-1)^2}{\nu^2}\right]\right\}, \quad (1)$$

where,

$$x = H/\bar{H} \quad \text{and} \quad \tau = T/\bar{T}.$$

The parameter ν is a measure of spectral bandwidth defined by

$$\nu = [m_0 m_2 / m_1^2 - 1]^{1/2} \equiv \nu_S, \quad (2)$$

where,

$$m_n = \int_0^\infty f^n S(f) df. \quad (3)$$

An example of the joint probability density is shown in Fig. 1 for the case of $\nu = 0.26$.

The marginal distribution of wave heights is shown to be the Rayleigh, by integrating Eq. 1 with respect to τ from $-\infty$ to ∞ .

The marginal distribution of wave periods is similarly derived as

$$p(\tau) = \int_0^{\infty} p(x, \tau) dx = \frac{v^2}{2[v^2 + (\tau-1)^2]^{3/2}} \quad (4)$$

The distribution has a tail in the region of $\tau < 0$ which is unrealistic, but the assumption of narrow band spectrum with the condition $v \ll 1$ yields the probability of $\tau < 0$ practically nil.

As the distribution is symmetric with respect to $\tau = 1$, the mean of heightwise ranked period remains at $\bar{\tau}_H = 1$. The standard deviation of heightwise ranked period is calculated from the conditional joint probability density as

$$\sigma_H(\tau) = \frac{v}{\sqrt{\pi/2} x} \quad (5)$$

Because this diverges as x goes to zero, the overall standard deviation of wave periods cannot be defined. As an alternative measure of the dispersion of wave periods, Longuet-Higgins [1] introduced the interquartile range of the marginal distribution of nondimensional wave periods and correlated it with the spectral width parameter v . Alternatively, v can be estimated from the interquartile range of nondimensional wave period as

$$v = \frac{\sqrt{3}}{2} \text{IQR}(\tau) \equiv v_T \quad (6)$$

In order to avoid confusion, v_T estimated by Eq. 6 is henceforth called the period bandwidth parameter.

The applicability of Longuet-Higgins' theory to waves with a narrow band spectrum can be proved, for example, with the data of numerically simulated random wave profiles [8]. The upper limit of v may be taken at about 0.1 if it is to be estimated from the spectrum [9]. It will be later shown however that the theory can be partially applied to sea waves with broad band spectra as well if v is estimated from the bandwidth of period distribution by Eq. 6.

The joint probability density of wave heights and periods by the group of C.N.E.X.O. has the following form:

$$p(\xi, \zeta) = \frac{\alpha^3 \xi^2}{4\sqrt{2\pi}\epsilon(1-\epsilon^2)\zeta^5} \exp\left\{-\frac{\xi^2}{8\epsilon^2\zeta^4}[(\zeta^2-\alpha^2)^2 + \alpha^4 a^2]\right\}, \quad (7)$$

where,

$$\xi = H/\sqrt{m_0}, \quad \zeta = \bar{\zeta}\tau = \bar{\zeta}T/\bar{T}, \quad \alpha = \frac{1}{2}(1 + \sqrt{1-\epsilon^2}), \quad \text{and} \quad a = \epsilon/\sqrt{1-\epsilon^2}. \quad (8)$$

Though Battjes [10] recommends to introduce the relationship between the mean interval of positive maxima and that of zero up-crossings into the term of ζ so as to have theoretical consistency, the original form is employed in the subsequent calculation as it produces fairer agreement with observation data.

The parameter ϵ is a measure of spectral bandwidth introduced by Cartwright and Longuet-Higgins [7] as

$$\epsilon = [1 - m_2^2/m_0m_4]^{1/2} \equiv \epsilon_S \quad (9)$$

This parameter is very sensitive to the Nyquist frequency of spectral

analysis relative to the frequency of spectral peak when applied to sea waves [11,12]. The group of C.N.E.X.O. recommends the use of the following parameter for ϵ :

$$\epsilon = [1 - N_0^2/N_c^2]^{1/2} \equiv \epsilon_T, \quad (10)$$

in which N_0 and N_c denote the numbers of zero up-crossings and maxima within a wave record, respectively. Though ϵ_S and ϵ_T should give the same value from theoretical point of view, sea waves usually produce ϵ_T less than ϵ_S without a definite interrelation. In this sense, ϵ_T estimated by Eq. 10 should be treated separately from ϵ_S estimated by Eq. 9, and it is henceforth called the apparent spectral width parameter.

The marginal distribution of wave heights derived from Eq. 7 is nearly the Rayleighian when ϵ is not large. The marginal distribution of wave periods is obtained as

$$p(\zeta) = \frac{\alpha^3 a^2 \zeta}{[(\zeta^2 - \alpha^2)^2 + \alpha^4 a^2]^{3/2}}. \quad (11)$$

The mean value of ζ which is estimated by numerically integrating Eq. 11 remains close to 1.0 for the range of $0 < \epsilon < 0.95$. The period bandwidth parameter ν_T can also be estimated numerically from Eq. 11. It is interesting to note that there exists an approximate relation of

$$\nu_T \approx 0.5\epsilon_T + 0.023\epsilon_T^2 \quad ; \quad 0 < \epsilon_T < 0.85, \quad (12)$$

which nearly coincides the relation of $\nu = \frac{1}{2}\epsilon$ derived by Longuet-Higgins [1] for a very narrow band spectrum.

After evaluating $\bar{\xi}$ and $\bar{\zeta}$, the joint probability density can be expressed in terms of the mean wave height and period, \bar{H} and \bar{T} . An example of the joint probability density is shown in Fig. 2, which corresponds to the parameter of $\epsilon_T = 0.51$ and $\nu_T = 0.26$. Asymmetric pattern of the probability density curves is observable even at this level of apparent spectral width parameter.

For comparison with these theoretical joint probability density, a result of compilation of correlation tables of observed sea waves is exhibited in Fig. 3, which represents the data of a group of sea waves with the correlation coefficient $r(H,T)$ between individual wave heights and periods being in the rank of -0.25 to 0.19; the definition of $r(H,T)$ is as follows:

$$r(H,T) = \frac{1}{\sigma_H \sigma_T N_0} \sum_{i=1}^{N_0} (H_i - \bar{H})(T_i - \bar{T}) \quad (13)$$

where σ_H and σ_T denotes the standard deviations of wave heights and periods, respectively, and N_0 is the number of zero up-crossing waves. The groups of 13 wave records in this rank of correlation coefficient had the mean of $\nu_T = 0.26$ for the period bandwidth parameter. The observed density is close to the theory of Longuet-Higgins rather than that of C.N.E.X.O. except for the range of $x = H/\bar{H} < 0.4$.

PRESENTATION OF SEA WAVE DATA

In order to investigate the applicability of the above theories to sea waves, an examination of various wave records was undertaken. The data were taken from the same source with the author's previous analysis of statistical properties [11,12]. Among 171 records analyzed, 89 records were selected under the conditions that each record exhibits a clearly defined single spectral peak and the significant wave height does not exceed about 0.4 times the water depth. The latter condition was introduced to exclude the influence of random wave breaking upon the statistical properties of observed wave records [13]. In total, 10,584 zero up-crossing waves were counted in 89 records.

The stations of wave observations and other data are listed in Table 1 and their locations are shown in Fig. 4. The data at Nagoya were recorded inside and outside a long mole, and they represent deep-water wind waves generated in a short fetch. The other data were recorded at coastal stations, and they mostly represent shallow water waves generated in medium to long fetches; some of them are wind waves and others are young swell.

All the data were recorded on the charts of servo-balanced type pen-writing recorders and were digitized with the aid of a manually operating X-Y digitizer with a magnifier. The digitized wave records were analyzed for their statistical properties as well as spectral characteristics by a computer program. Examples of wave spectra are shown in Fig. 5, where the spectrum is normalized by means of the frequency at the spectral peak, f_p , and the zeroth moment of spectrum, m_0 . The waves observed at Nagoya Port usually show sharp peaks and a few humps at high frequency range, while most of coastal waves have the spectral slope at high frequency range milder than -5. In general, however, the Pierson-Moskowitz type or the Bretschneider-Mitsuyasu type spectral form provides a fair approximation to the spectra of observed waves.

The analysis of the joint distribution of observed wave heights and periods was proceeded first by classifying 89 records into five groups according to the magnitudes of the correlation coefficient $r(H,T)$, because $r(H,T)$ is considered to represent the pattern of joint distribution best. Table 2 lists the numbers of wave data in five groups of $r(H,T)$ as well as the numbers of wave data in ranked groups of v_T . The data of Nagoya Port is characterized with low values of $r(H,T)$ and v_T though its cause is not clarified. There is a possibility that short fetched wind waves may exhibit such characteristics as there is such indication in the data compiled by Bretschneider [13]. The parameters of v_S and ϵ_T as listed in Table 1 do not show marked difference between Nagoya data and coastal wave data. Various statistical properties of the data analyzed are listed in groupwise in Table 3 with the mean values and the standard deviations. The correlation coefficient $r_{1/3}(H,T)$ is the one calculated for the highest one-third waves, which is a measure of correlation among high waves, and Q_p is the spectral peakedness parameter defined as [8]

$$Q_p = \frac{2}{m_0} \int_0^{\infty} f S^2(f) df \quad (14)$$

RESULTS OF DATA ANALYSIS

Marginal Distribution of Wave Heights

As reported by many researchers, the marginal distribution of wave heights does not show any significant deviation from the Rayleigh. An indication is the mean values of three height ratios listed in Table 3, which are close to the theoretical values of the Rayleigh distribution. The chi-square test for the goodness-of-fitness to the Rayleigh was made for the present data with 14 classes of wave heights. The probability that the total data has come from the population of the Rayleigh distribution is calculated as about 0.30, and the probability that the data in the rank of $r(H,T) = 0.70 \sim 0.81$ has come from the Rayleigh distribution is about 0.10. Thus the hypothesis of the Rayleigh distribution cannot be discarded for the present data.

Marginal Distribution of Wave Periods

Figure 6 shows the marginal distribution of observed wave periods normalized by the mean wave period of respective wave records. For the data with $r(H,T)$ less than 0.4, both of the theoretical distributions of Eqs. 4 and 7 provide good approximation so long as the period bandwidth parameter obtained from the data is employed in theoretical estimation. The two theories do not yield much difference for small values of v_T . As v_T increases, the observed marginal distribution deviates gradually from the theoretical ones, which become unapplicable for $r(H,T) \gtrsim 0.6$. It should be noted that the maximum value of $r(H,T)$ and v_T predicted by the theory of C.N.E.X.O. is about 0.69 and 0.55, respectively, both of which correspond to the case of $\epsilon = 0.99$.

Joint Distribution of Wave Heights and Periods

The joint distribution of wave heights and periods were analyzed with the rank of $\Delta H/\bar{H} = \Delta T/\bar{T} = 0.2$ after having been normalized with \bar{H} and \bar{T} . The correlation table with the curves of probability density for the group of $r(H,T) = -0.25$ to 0.19 has been presented as Fig. 3 for comparison with theoretical ones. The correlation tables for the other four groups of $r(H,T)$ are shown in Fig. 7. As $r(H,T)$ increases, the asymmetry of joint distribution becomes conspicuous and the position of maximum probability density moves toward the origin. The change of the pattern is qualitatively in accordance with the theory of C.N.E.X.O.

Characteristics of Heightwise Ranked Wave Periods

One feature of Fig. 3 and Fig. 7 is that the center of wave periods at each level of wave height does not vary in the upper portion of correlation table and the distribution is symmetric there. This feature is clearly shown in Fig. 8, where the mean of heightwise ranked wave periods is plotted against the wave height level. The ranked mean \bar{T}_H of high waves relative \bar{T} shifts toward large values as $r(H,T)$ increases, but it holds a common value among high waves as seen in Fig. 8(a). The shift of \bar{T}_H is an apparent phenomenon, however, as demonstrated in Fig. 8(b), where the ranked mean of wave period is normalized with the period corresponding to the spectral peak, T_p . Figure 8(b) shows that \bar{T}_H of high waves remains in the range of $(0.87 \sim 0.98)T_p$ irrespective of $r(H,T)$. The mean of wave periods with $H > 1.4\bar{H}$, for example, is calculated to be $(0.91 \sim 0.97)T_p$. The figure also indicates that the increase

$$(1) r(H, T) = -0.25 \sim 0.19$$

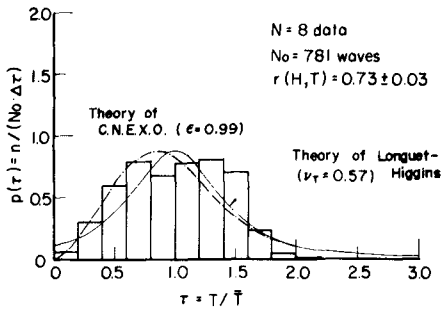

$$(2) r(H, T) = 0.20 \sim 0.39$$

$$(3) r(H, T) = 0.40 \sim 0.59$$

$$(4) r(H, T) = 0.60 \sim 0.69$$

$$(5) r(H, T) = 0.70 \sim 0.81$$

Fig. 8 Mean Period of Heightwise Ranked Waves

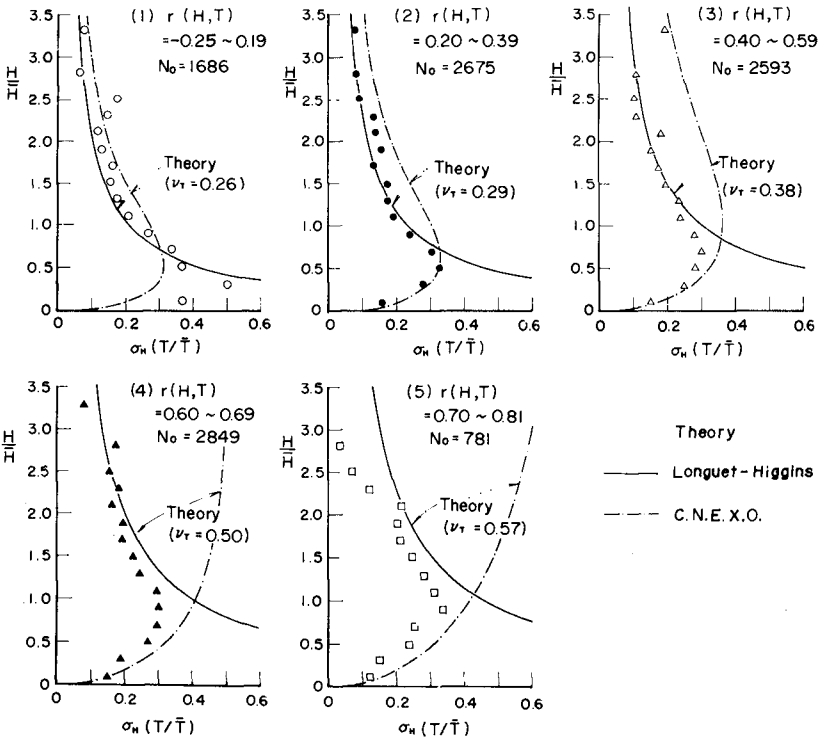

Fig. 9 Standard Deviation of Heightwise Ranked Wave Periods

of $r(H,T)$ is owing to the appearance of small waves with very short periods.

The constancy of mean ranked wave periods is inherent in the theory of Longuet-Higgins although its shift with respect to \bar{T} cannot be dealt with. The theory of C.N.E.X.O., on the other hand, can yield the increase of mean wave periods of high waves with the increase of ϵ , but the mean wave period steadily elongates itself as the level of wave height rises.

The spread of wave periods in a particular rank of wave height can be represented with their standard deviation. Figure 9 shows the results of the calculation of standard deviations of heightwise ranked wave periods for five groups of wave data classified by the rank of $r(H,T)$. The theory of Longuet-Higgins is seen to predict the spread of wave periods of high waves when the mean period bandwidth parameter of respective wave group is employed in calculation of Eq. 5, although the decrease of standard deviations in the region of small waves cannot be predicted. The theory of C.N.E.X.O., on the other hand, can present the standard deviation decreasing in the lower portion of wave heights, but it yields the deviation much larger than the observed ones in the upper portion of wave heights especially for groups with high correlation coefficients.

DISCUSSIONS ON THE GOVERNING PARAMETERS OF JOINT DISTRIBUTION

It has been demonstrated that the joint distribution of the heights and periods of sea waves exhibit quite large variations. One of the questions may be what the parameter is governing the joint distribution. There are two spectral width parameters of ν_S and ϵ_S defined by Eqs. 2 and 9, respectively. Statistical analysis of wave records yields the apparent spectral width parameter of ϵ_T by Eq. 10, the period bandwidth parameter of ν_T by Eq. 6, and the correlation coefficient between individual wave heights and periods by Eq. 13. Among these parameters, ϵ_S is not qualified for describing the statistical properties of sea waves, because ϵ_S is essentially 1.0 for wind-generated water waves and becomes less than 1.0 owing to incompetence in the high frequency response of a wave recorder [11,12]. The parameter ν_S may need further examination, but the present data at least reject the effectiveness of ν_S because of large scatter of ν_S without associating itself with the statistical properties of waves analyzed.

The question is thus focussed on the selection among three parameters of ϵ_T , ν_T , and $r(H,T)$. The relationships among them are first examined as shown in Figs. 10 to 12. The relationship between ν_T and $r(H,T)$ is most conspicuous with the correlation coefficient between them amounting to 0.80. If one makes a polynomial regression analysis instead of linear regression, a much higher correlation will be obtained. Among the whole data, those in the range of $r(H,T) \gtrsim 0.4$ closely follow the trend of the theory of C.N.E.X.O. as well as the result of numerically simulated wave analysis [8], even though both the theory and the simulation data cannot explain the existence of data with $r(H,T) > 0.7$ or $\nu_T > 0.55$. The relationship between ν_T and ϵ_T is obscure although the means of rankwise data indicate the existence of interrelation, which is close to the data of simulation study. The correlation coef-

Fig. 10 Correlation between v_T and $R(H,T)$

Fig. 11 Correlation between $r(H,T)$ and ϵ_T

Fig. 12 Correlation between v_T and ϵ_T

ficient between v_T and ϵ_T is calculated as 0.72. The third set of relationship, that is the one between $r(H,T)$ and ϵ_T , is clouded with the presence of the data with $r(H,T) \lesssim 0.3$, which come from the Nagoya Port data. The correlation coefficient between $r(H,T)$ and ϵ_T nevertheless has the value of 0.66 for the present data.

A criterion for the selection of governing parameter will be a high level of correlation with statistical properties of the joint distribution of wave heights and periods. One of the appropriate properties is the ratio of significant to mean wave period, $T_{1/3}/\bar{T}$, as employed by the group of C.N.E.X.O. for demonstration of the influence of ϵ_T . Figure 13 is the result of comparison of the influence of three parameters upon $T_{1/3}/\bar{T}$. Data are shown in the form of ranked mean and standard deviations with the number of records in respective ranks. The wave period ratio, $T_{1/3}/\bar{T}$, is seen to be closely related with the three parameters. The relationships are also close to those derived by the theory of C.N.E.X.O. and the simulation data. Among three parameters, their correlations with $T_{1/3}/\bar{T}$ is lowest for ϵ_T with the correlation coefficient of 0.72, while v_T and $r(H,T)$ show the coefficient of 0.92 and 0.94, respectively.

The degree of correlation between $T_{1/3}/\bar{T}$ and ϵ_T of the present data is about the same with the data presented by the group of C.N.E.X.O., as judged from the magnitude of standard deviations of $T_{1/3}/\bar{T}$. In this sense, ϵ_T seems inferior to the other two parameters. Between the remaining two, $r(H,T)$ is slightly superior to v_T on the basis of the former's high correlation coefficient. In the application of the theory of Longuet-Higgins, however, the information of period bandwidth parameter is required, and from this point of view v_T may be more convenient than $r(H,T)$. The final selection between $r(H,T)$ and v_T cannot be made at this stage yet, and it will necessitate the analysis of many more data of sea waves.

A remaining question is the correlation of these parameters with spectral characteristics. Though v and ϵ have originally been derived from spectral moments, v_T and ϵ_T are the parameters estimated from the statistical analysis of wave profiles; their relationships with v_S and ϵ_S cannot be well established at least for the present data. The definition of correlation coefficient $r(H,T)$ is independent of wave spectrum and it has not been related to a wave spectrum (variance) except for a numerical simulation study [8]: the spectrum proposed by Bretschneider [13] with $r(H,T)$ as a parameter is an apparent one and not the variance spectrum analyzed by the spectral theory. As indicated in Figs. 10 to 12, these parameters vary over quite large ranges. A spectral characteristics which seems to be related to these parameters to some extent is the spectral peakedness parameter defined by Eq. 14. As shown in Fig. 14, the period bandwidth parameter v_T of the present data does indicate an interrelation with Q_p ; the correlation coefficient between them is -0.65. The correlations of other two parameters ϵ_T and $r(H,T)$ with Q_p are not so prominent, however.

Another factor which may affect the parameter of the joint distribution of wave heights and periods is the sampling interval of wave profile relative to the spectral peak period, or $\Delta t/T_p$. The present data shows the relationship between v_T and $\Delta t/T_p$ as in Fig. 15.

(1) influence of ϵ_T on $T_{1/3}/\bar{T}$

(2) influence of ν_T on $T_{1/3}/\bar{T}$

(3) influence of $r(H,T)$ on $T_{1/3}/\bar{T}$

Fig. 13 Comparison of the Parameters of ϵ_T , ν_T , and $r(H,T)$ for Their Influences upon the Wave Period Ratio of $T_{1/3}/\bar{T}$

Fig. 14 Correlation between ν_T and Q_p

Fig. 15 Correlation between ν_T and $\Delta t / T_p$

A negative correlation between them is somewhat expected, though the quantitative analysis should await the accumulation of a greater number of sea wave data.

SUMMARY

The joint distribution of wave heights and periods exhibits statistical variability greater than the marginal distributions of wave heights and periods. Any analysis of the joint distribution should have a sufficiently large number of wave records as the data base. The present analysis based on 89 records cannot be claimed to be very reliable, it nevertheless covers a variety of wave conditions from short-fetched wind waves to young swell in shallow water. Findings made in this analysis can be summarized as follows:

1. The joint distribution of wave heights and periods of sea waves is characterized with no correlation among high waves and a strong correlation among low waves.
2. The mean period of waves higher than a certain level is independent of the wave height, and it remains at a value slightly less than the period corresponding to the spectral peak.
3. The theory of Longuet-Higgins can explain the characteristics of the joint distribution in its upper portion with high waves if the spectral width parameter is so selected to fit the marginal distribution of wave periods, even though the theory disagrees with the observed joint distribution in its lower portion with low waves.
4. The theory by the group of C.N.E.X.O. can qualitatively predict the change of the joint distribution with the increase of spectral width parameter, but the quantitative agreement is only partial.
5. The parameter governing the joint distribution seems to be the correlation coefficient between individual wave heights and periods and/or the period bandwidth parameter. The apparent spectral width parameter is less influential than the formers.

LIST OF MAJOR SYMBOLS

H_{\max}	: height of highest wave
$H_{1/10}$: mean height of highest one-tenth waves
$H_{1/3}$: mean height of highest one-third waves
\bar{H}	: mean wave height
Q_p	: spectral peakedness parameter defined by Eq. 14
$r(H, T)$: correlation coefficient between individual wave heights and periods
$r_{13}(H, T)$: correlation coefficient among highest one-third waves
T_p	: wave period corresponding to spectral peak frequency
T_{\max}	: period of highest wave
$T_{1/10}$: mean period of highest one-tenth waves
$T_{1/3}$: mean period of highest one-third waves
\bar{T}	: mean wave period
$x = H/\bar{H}$: nondimensional wave height
Δt	: time interval between successive sampling of surface elevation
ϵ_S	: spectral width parameter defined by Eq. 9
ϵ_T	: apparent spectral width parameter defined by Eq. 10
$\zeta = \bar{\zeta}\tau$: nondimensional wave period
ν_S	: spectral width parameter defined by Eq. 2
ν_T	: period bandwidth parameter defined by Eq. 6
$\xi = H/\sqrt{m_0}$: nondimensional wave height
$\tau = T/\bar{T}$: nondimensional wave period

ANOMALOUS DISPERSION OF FOURIER COMPONENTS OF SURFACE GRAVITY WAVES IN THE NEAR SHORE AREA

by

Fritz Büsching ¹⁾

ABSTRACT

Water level deflections $\eta(t)$ have been measured synchronously at some positions in a beach profile on the isle of SYLT / North Sea during severe storm surge conditions as well as at attenuating wave action.

A steadily increasing wave period \bar{T}_z in the upbeach direction, turning out from strip chart evaluations, is in accordance with the result of FOURIER syntheses. Near shore wave deformation is explained by ANOMALOUS dispersion of the frequency components.

1. INTRODUCTION

Because of the well known restrictions of model investigations on surf zone processes (FÜHRBÖTER 1970 and 1971) since 1971 comprehensive field investigations have been performed by members of the LEICHTWEISS-INSTITUT on the west coast of the isle of SYLT / North Sea.

Especially the energy transformation on the beach was considered by FÜHRBÖTER (1974) based on strip chart evaluations and on a linear analysis.

Later on in this respect the spectrum analysis was used by the author (BÜSCHING, 1974, 1975, 1976).

The present study refers to both partly previously presented data sets analyzed by means of the zero-up-crossing evaluation method and by spectral functions respectively. In the first part of this study the description of the wave deformation in the upbeach direction is based on strip chart evaluations, whereas the second part consists of an attempt to explain these deformation processes by spectral methods.

2. WAVE PARAMETERS IN THE NEAR SHORE ZONE

In a conservative treatment of the transformation of shoaling waves into breaking and finally into broken waves the wave period is assumed to be a constant, whereas wave heights, lengths and celerities change. In addition to this it is well known that real gravity waves continuously change form as they proceed into shallower water.

This, however, is not only represented by the different asymmetries previously defined (BIESEL, 1951 ; PATRICK and WIEGEL, 1956 ; ABEYMO, 1968 ; IWAGAKI, SAKAI and KAWASHIMA, 1973 ; FÜHRBÖTER, 1974) but also by the so-called decomposition of the initial wave into two or more waves (solitons) (MULTER and GALVIN, 1967 ; MADSEN and MEI, 1969 ; ZABUSKY and GALVIN, 1971 ; GALVIN, 1972).

Applying the zero-up-crossing evaluation method on strip chart records of water level deflexions which are deformed in such a way, this method turns out to be somewhat questionable, as in the present case the result is a steadily increasing mean wave period \bar{T}_z in the upbeach direction.

This can be seen from Fig. 1 containing the variation of some wave parameters in the coast perpendicular measuring profile on the isle of SYLT for synchronous measurements at fixed positions on March 18th and April 3rd, 1973 respectively.

The shown parameters (mean wave heights \bar{H}_z and mean wave periods \bar{T}_z) refer to synchronously measured water level deflexions taken by echo sounders at the offshore positions at 225 m, 570 m, 940 m and 1280 m and by pressure type wave meters at the beach positions 40,50, 60, 70, 80, 90 and 100 m.

The details of the wave measuring instrumentation used are given by FÜHRBÖTER and BÜSCHING (1974). Because of the lack of space in the following it shall only be considered here the measurements on the beach face, where in addition to the above mentioned parameters the wave propagation velocities could be determined from the phase differences between the respective synchronously taken wave traces.

Additional interpretation of the more offshore measurements and the influence of the long shore bar (ridge) on the wave deformation will be given in

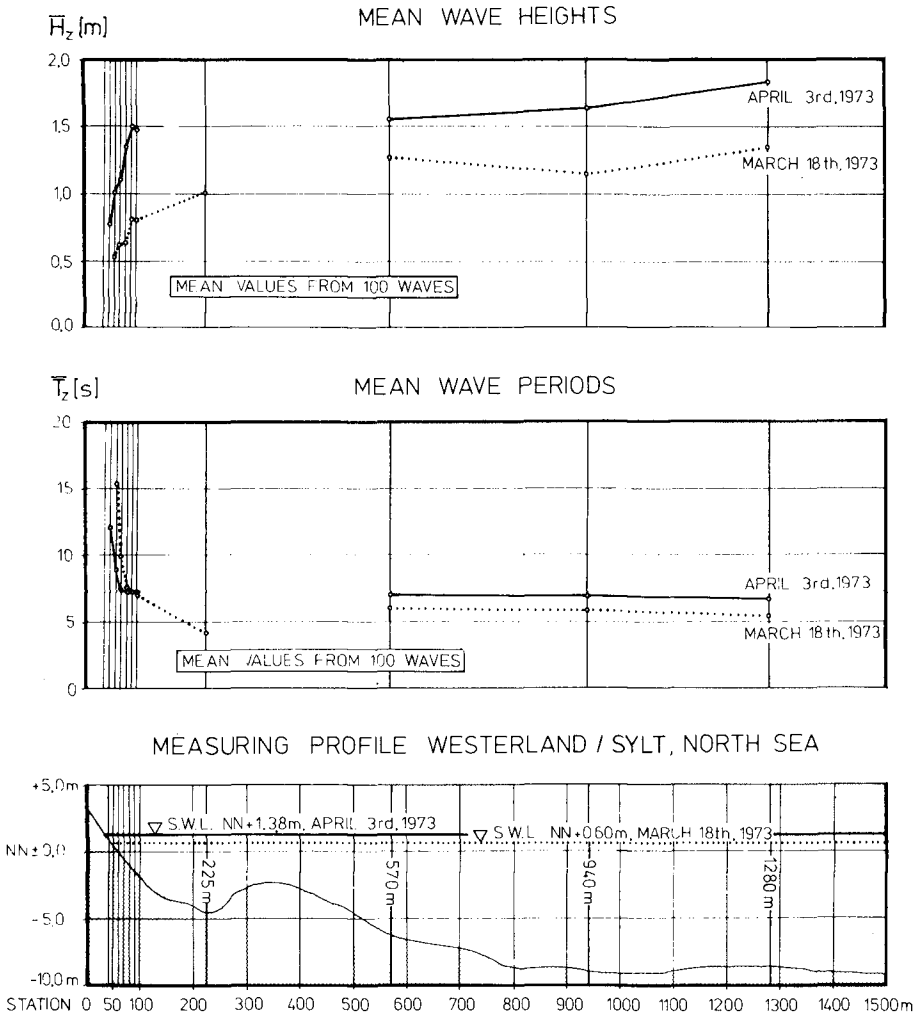

Fig. 1 : Mean wave heights and periods in the measuring profile on the isle of SYLT / North Sea

another paper (BÜSCHING, 1978) with reference to the measurements of RAMAN (1976) and WANG and YANG (1976) in the same area.

As regards energy dissipation treatments based on the present measurements, they are contained in FÜHRBÖTER (1974).

The complete strip chart data are plotted in Fig. 2 with reference to the beach measuring positions. With the known wave propagation velocity the mean wave

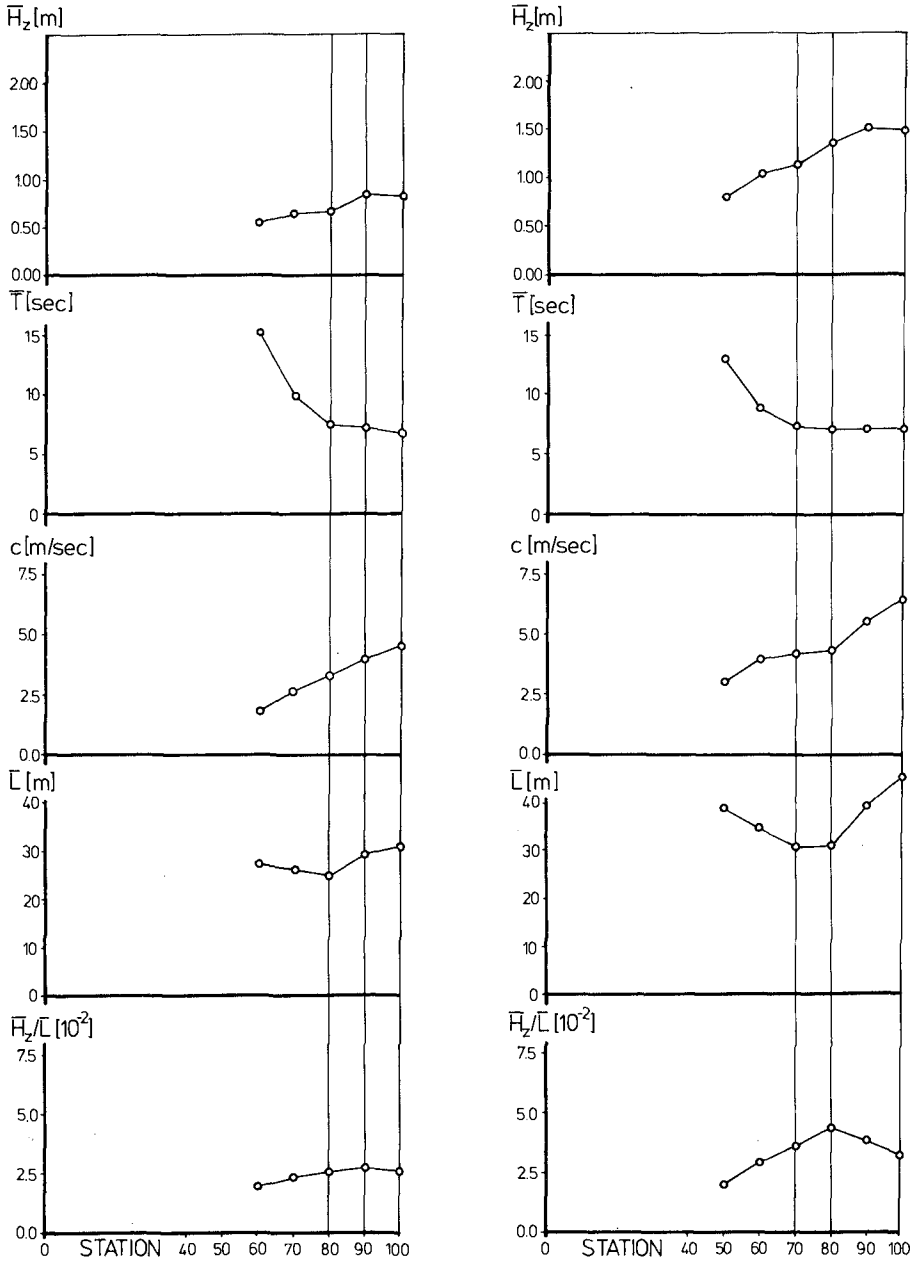

Fig. 2 : Variation of wave parameters on the beach during measurements on March 18th and April 3rd, 1973 respectively

length \bar{L}_z and mean steepness \bar{H}_z/\bar{L}_z can be calculated.

As to be seen from Fig. 2 the overall impression is that mean wave lengths decrease until the maximum steepness is reached and from that moment on the wave length again increases along with decreasing wave steepness.

It is worth mentioning here that the maximum steepness values $\bar{H}_z/\bar{L}_z = 0.028$ and $\bar{H}_z/\bar{L}_z = 0.044$ respectively are both in reasonable agreement with MICHE's formula for the breaker steepness

$$H_b/L_b = 0.140 \tanh [2 \pi d_b / L_b]$$

The magnitude of underprediction by this formula is minimal and can as well be interpreted as errors in the local water depth measurements of the order of only 5 and 10 cm respectively.

In order to demonstrate the variation of wave heights (\bar{H}_z), wave lengths (\bar{L}_z) and horizontal wave asymmetries ($\alpha = \Delta L/L$ as defined by FÜHRBÖTER (1974)) in an overall view the average wave deformation is plotted for both measurements in Fig. 3.

Fig. 3: Average wave deformation based on the variation of wave height \bar{H}_z , wave length \bar{L}_z and horizontal wave asymmetry α only

Constructing these sets of curves mass conservation. In both cases is preserved in such a way that the initial volumes of the water mass under the waves at position 100 m were placed beneath each deformed wave contour. Thus with the wave shapes changing in the upbeach direction the water level increases.

As the construction of each wave contour is based on three points only, this procedure, however, can only deliver a crude estimate of the wave set up, which is obviously underpredicted because especially the indicated convex front faces significantly deviate from the real shapes of steep, breaking and broken waves. Further interpretation of these measurements will be given in the above mentioned additional paper.

3. SPECTRAL FUNCTIONS

As mentioned before analyses based on the zero-up-crossing or similar methods applied to strip chart records of near shore water level deflexions are valuable only to a certain extent, because deformations like the decomposition into solitons are not considered herein.

This is supposed to be the reason why the author previously was not able to establish a correlation of some quality between the significant wave period $T_z^{1/3}$ (of the zero-up-crossing-method) and the spectral peak period determined in different ways. (BÜSCHING, 1974 ; also HARRIS, 1972).

As the above demonstrated variation of wave parameters in the upbeach direction is difficult to explain in the time domain, in the following an attempt of explanation in the frequency domain is presented by means of the storm surge data of December 13th to 14th, 1973 and measurements at attenuating wave action.

This was formerly started with the investigation of synchronously measured energy spectra taken in the beach profile of Fig. 1 at positions 100 m and 85 m distant from the shoreline respectively.

The present study consists, however, in an analysis of the TRANSFER FUNCTIONS and COHERENCE FUNCTIONS based on cross power spectrum analysis. Because of the lack of space here it is not possible to go into the details of the spectrum analysis. The basic parameters, however, in this respect are equal to those mentioned in the author's previous work (BÜSCHING, 1975 and 1976).

As is well known the complex transfer function measures the relationship between any two signals at specific frequencies by relative PHASE and MAGNITUDE. In the present case the signals represent the water level deflexions $\eta_{100}(t)$ and $\eta_{85}(t)$ at positions 100 m and 85 m respectively. Hence the transfer function is defined as

$$H_{\eta_{85} \eta_{100}}(f) = \frac{S_{\eta_{100}, \eta_{85}}}{S_{\eta_{85}, \eta_{85}}}$$

with

$S_{\eta_{100} \eta_{85}}(f)$ = CROSS POWER SPECTRUM from the water level deflexions at positions 100 and 85 m.

and

$S_{\eta_{85} \eta_{85}}(f)$ = AUTO POWER SPECTRUM at position 85 m.

The coherence function is constructed to detect the presence of noise (or nonlinear distortion) in the transfer functions. If the transfer system is linear (and noise-free) the input to output coherence must be 1 (BENDAT and PIER-SOL, 1968).

Because of the shape of the coherence functions in the present case the frequency range 0 to 0.36 Hz was selected for evaluation only.

As an example in Fig. 4 the total set of interesting spectral functions is plotted belonging to the measuring interval at the highest storm tide water level (mean record water depth $z_3 = 3.1$ m).

In the upper part of the graph the respective energy spectra are shown, whereas the coherence function and the transfer function subdivided into magnitude and phase are plotted below.

For instance at the spectral peak at a frequency $f = 0.073$ Hz the coherence is a maximum and the magnitude of the transfer function is greater than 1. This means in the present case that - as expected - at this frequency the amplitude of the respective FOURIER COMPONENT at position 100 m is greater than that at position 85 m and on the other hand the phase difference is about 80 degrees, which can be seen from the $\vartheta(f)$ -curve plotted below.

As the distance of the measuring devices x [m] is known, the phase information $\vartheta(f)$ [degrees] of the transfer function can easily be converted into a PHASE VELOCITY plot $c(f)$ [m/sec]:

$$\left. \begin{aligned} \frac{\vartheta}{360^\circ} &= \frac{x}{L} \\ c &= \frac{L}{T} = L \cdot f \end{aligned} \right\} c = \frac{x \cdot 360^\circ}{\vartheta} \cdot f \text{ [m / sec]}$$

$f = \frac{1}{T}$ = frequency of FOURIER component

L = length of the component wave

T = period of the component wave

This curve is also shown in the lower part of Fig. 4.

In this connexion it has to be mentioned here that the transformation of the phase information $\vartheta(f)$ - presented in the range $-180^\circ \leq \vartheta \leq +180^\circ$ only - is based on the assumption that the magnitude of the phase velocity of dominant

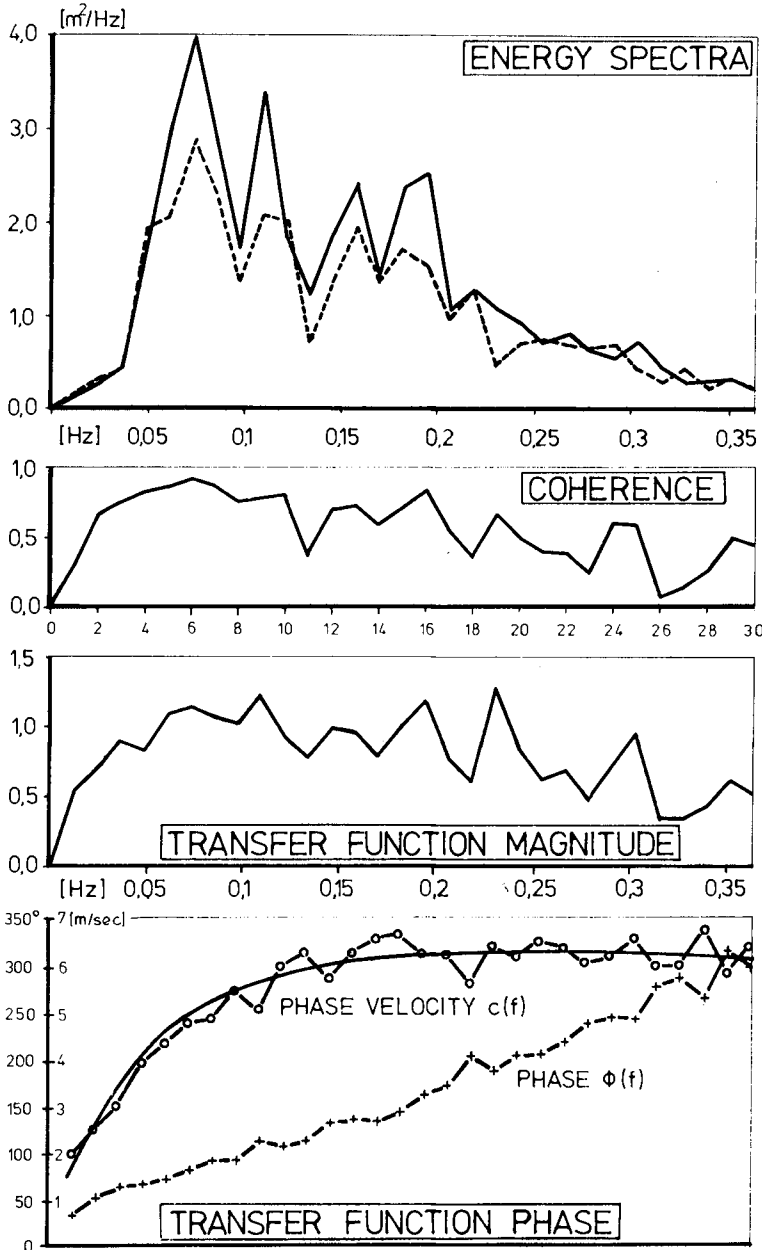

Fig. 4 : Spectral functions from water-level-deflection-measurements on December 12th, 1973, 3.46 a.m.

FOURIER components (near the spectral peak) roughly corresponds to that predicted by the dispersion formula or the shallow water relation. If alternatively phase angles $\theta \pm 360^\circ$ were considered for the transformation quite unrealistic phase velocities would turn out in the present case.

During the storm surge period of about 30 hours in total at 16 measuring intervals samples were analyzed as illustrated in Fig. 4.

The results of these measurements in the form of MEAN VALUES of coherence, transfer function magnitude and phase velocity are plotted in Fig. 5 along with the storm tide curve.

The mean values are related to the frequency ranges as listed in the inset. In case the smallest frequency range only containing the lowest frequency FOURIER components

$$(7) \quad 0 < f \leq 0.06 \text{ Hz}$$

is disregarded, because the confidence of the FOURIER ANALYSIS is not sufficient at low frequencies, the overall impression is that mean values of coherence $\bar{\gamma}^2$ and transfer function magnitude decrease with an increasing number of contributing frequency components (say from curves (6) to curves (2')), whereas the mean values of the phase velocities increase from curve (6) to curve (2').

This means that a linear relationship would rather exist at lower frequency FOURIER components and especially at high water levels, which should be expected.

By contrast an average the higher frequency components are faster than the longer ones.

The later phenomenon is analyzed more detailed in the following, whereas some remarks regarding the transfer function magnitude are contained in BÜSCHING (1978).

Fig. 6 contains two different sets of curves in the respective frequency band up to 0.36 Hz :

1. A more regular set of curves representing a presentation of the well known DISPERSION FORMULA for the wave propagation

$$c = \frac{L}{T} = L \cdot f = \left(\frac{g \cdot L}{2 \pi} \tanh \frac{2 \pi d}{L} \right)^{1/2}$$

The respective phase velocity curves $c(f)$ are marked by the parameter of the water depth d [m] at the left hand side ; and

2. The set of phase velocity curves $c(f)$, resulting from the storm surge measurements smoothed by non-linear regressions.

As is well known the above dispersion relationship describes a so-called NORMAL DISPERSION : Lower frequency components travel faster than the higher ones ; only in very shallow water all components travel with nearly the same speed. By contrast this does not come out of the storm surge measurements in the near shore area. Here a so-called ANOMALOUS DISPERSION turns out

Fig. 5 : Mean values of COHERENCE, TRANSFER FUNCTION MAGNITUDE and PHASE VELOCITY of the measurements on December 13th and 14th, 1973

Fig. 6 : Predicted and measured dispersion of phase velocities

in the shown frequency band. Even if in the example of Fig. 4 the range of highest coherence, say greater than $\bar{\gamma}^2 \geq 0,8$ in between 0.05 and 0.08 Hz is regarded as reliable only, the statement remains true: In very shallow water the higher frequency components travel faster than the longer ones (in the shown frequency band). In addition it is remarkable that the frequency points of the phase-velocity-plots $c(f)$ form smooth curves wherever the coherence shows appreciable values.

Hence, those components can possibly be regarded as anyhow coupled components of predominating wave systems approaching the beach more or less perpendicularly, whereas especially at very low frequencies (right next to $f = 0$) and at higher frequencies the rate of scatter in the frequency points of the phase information gradually increases with the water depth decreasing. Because of the low coherence in those frequency ranges it is, however, not worthwhile to try an analysis.

According to similar measurements on a platform, standing in a water depth of about $d = 30$ m even at that position about 100 km offshore exists a distinct deviation from the conventional dispersion relationship. As to be seen from Fig. 7 representing a swell measurement on November 22nd, 1975 ($2,0 \leq H \leq 2,5$ m) a distinct normal dispersion exists only on the right hand side of the spectral peak at a frequency $f = 0.12$ Hz, which corresponds to a coherence of $\bar{\gamma}^2 > 0.94$. On the left hand side, however, the tendency for an ANOMALOUS DISPERSION exists, which is at least reliable at high coherence values as indicated in the graph. At lower frequencies again there is a remarkable scatter in the frequency points accompanied by decreasing coherence and phase angles uncertain to determine from the respective plot. In the case of very large phase velocities resulting from very small phase angles at low frequencies it can, however, be supposed that here the phase angle must be changed to $\vartheta + 360^\circ$, see dotted line in Fig. 7.

Comparing this plot to the dispersion formula it turns out that only the phase velocity very near to the spectral peak roughly corresponds to that predicted by the formula. On the right hand side there are higher values to be seen, whereas phase velocities are less on the left hand side.

If high enough frequency components can be regarded as deep water components, which are unaffected by the bottom and the influence of the water depth is regarded to be the dominant parameter for a certain critical frequency $f_{crit.}$ at which NORMAL dispersion changes into ANOMALOUS dispersion, it can be stated from this graph that this critical frequency is considerably less than that determined by the condition $d = L/2$ according to linear theory. In the present case

$$f_{crit.} = 0.11 < f_{(d = L/2)} = 0.16 \text{ Hz}$$

With the above findings in mind in the following the behaviour of the FOURIER components in the near shore area are considered again. In order to simplify in the lower part of Fig. 8 the storm surge measurements are represented by 3 smoothed curves only, belonging to water depth $Z_3 = 3.1$ m, $Z_3 = 1.65$ m, $Z_3 = 1.40$ m respectively. As concerns the nearly horizontal portion of the phase velocity curve, corresponding to the maximum water depth $Z_3 = 3.1$ m, this indicates nearly complete non-dispersiveness at frequencies $f \geq 0.2$ Hz.

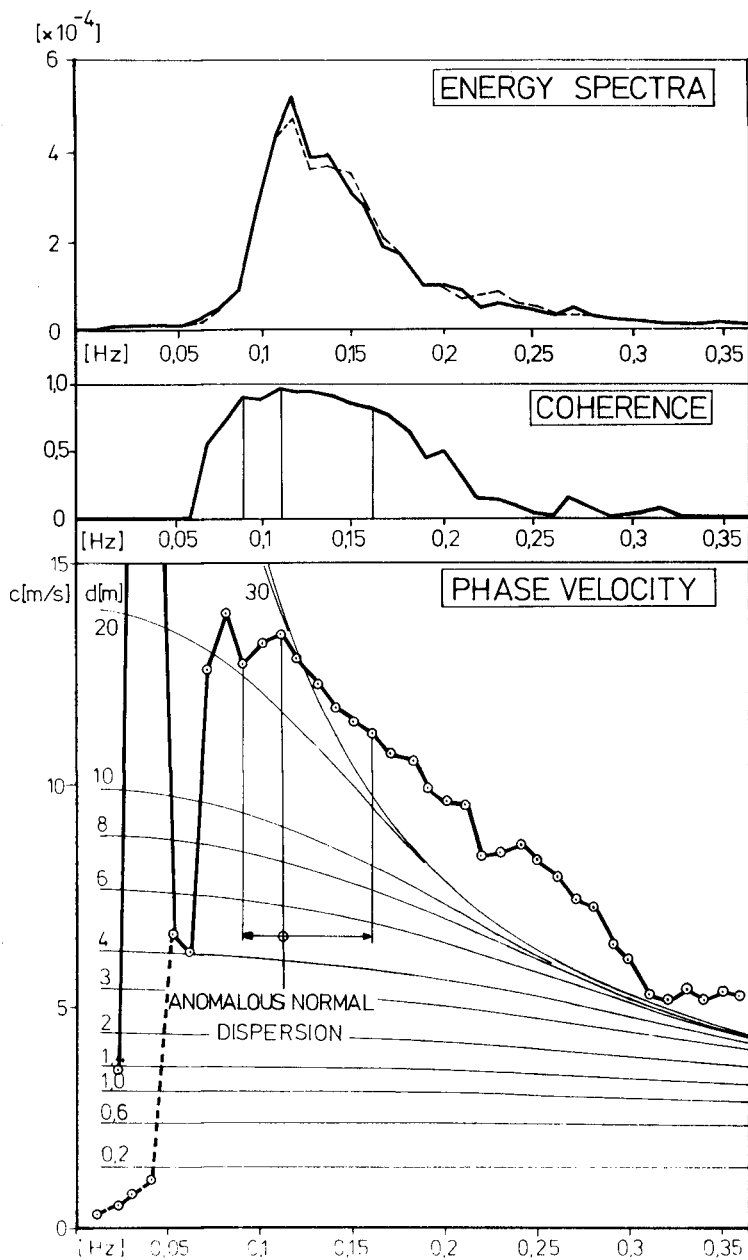

Fig. 7 : Spectral functions of a swell-measurement in a water depth $d \approx 30$ m on November 22nd, 1975

Fig. 9 : Weak anomalous dispersion of phase velocities at attenuating wave action, January 20th, 1974

Fig. 8 : Normal and anomalous dispersion of phase velocities

This, however, can also be interpreted as the frequency range where normal dispersion changes to anomalous dispersion. The respective critical frequency f_{crit} is still to be found in the shown frequency band, whereas that of the condition $d = L/2$ according to linear theory is not :

$$0.25 < f_{crit} < 0.30 \text{ Hz} < f_{(d = L/2)} = 0.5 \text{ Hz}$$

In accordance with the even higher critical frequencies ($f_{(d = L/2)} = 0.69 \text{ Hz}$ and $f_{(d = L/2)} = 0.75 \text{ Hz}$ for deep water components at the lower water depth $Z_2 = 1.65 \text{ m}$ and $Z_3 = 1.40 \text{ m}$ respectively, the curves are steeper in the shown frequency band. Hence, the ANOMALOUS DISPERSION in this frequency band gets even more distinct with the water depth decreasing.

This tendency also turns out from the dotted lines representing the respective ranges of maximum coherence values only.

On the other hand it can as well be presumed from this plot a position just seaward of the breakers where the non-dispersive property is even more distinct than at the water depth $Z_3 = 3.1 \text{ m}$. Presumably such a position depends on the actual ratio H/d .

Actually this kind of PHASE COUPLING comes out of the measurements of THORNTON, GALVIN, BUB and RICHARDSON (1976) and this condition is almost included in the profile measurement on January 20th, 1974 carried out at attenuating wave action, see Fig. 9.

The three curves shown result from synchronous measurements at positions 128 m, 120 m, and 100 m with reference to position 85 m. Hence, the curves can be attributed to positions 106.5 m, 102.5 m and 92.5 m respectively.

Compared to the storm surge measurements the dispersion in this case is minimal in the total frequency range at position 106.5 m and with the water depth decreasing the weak dispersive property is preserved at frequencies $f > 0.1 \text{ Hz}$, where in the present case appreciable values of energy density are to be found in the respective energy spectra, see BÜSCHING, 1976.

In order to demonstrate the so-called ANOMALOUS DISPERSION with its effect on the deformation of the waves, Fig. 10 refers to the above mentioned profile measurement of January 20th, 1974 with the weak anomalous dispersive property only.

Assumed that at a certain position outside the shown profile all components are in phase and from that moment on propagate with their own singular phase speeds, one can perform a FOURIER SYNTHESIS after a certain time of propagation, which is 10 sec in the present case. In order to clarify this in Fig. 10 the 0.1 Hz-FOURIER-component is to be seen fixed at the three positions mentioned above.

Additionally only the 0.3 Hz-component is plotted. It is obvious that already at the position 106.5 m the 0.3 Hz-component leads the 0.1 Hz-component and the relative position of the 0.3 Hz-component is shifted in the upbeach direction (with the water depth decreasing). The total FOURIER synthesis consisting of the superimposition of 30 components representing the frequency range

Fig. 10 : Relative behaviour of the frequency components 0.1 Hz and 0.3 Hz at decreasing water depth on January 20th, 1974

$0 < f \leq 0.36$ Hz delivers the average wave deformation in the time domain, see middle part of Fig. 11.

The total set of varying wave parameters is to be seen on the right and left hand side of this figure respectively.

Wave heights and periods are taken from the graph as indicated, whereas the variation of the average wave propagation velocity is assumed to be equal to the phase velocity of the peak frequency component.

Hence, the wave length and steepness could also be calculated.

JANUARY 20, 1974

Fig. 11 : Average wave deformation resulting from a FOURIER synthesis considering anomalous dispersion of frequency components

4. CONCLUSION

Comparing the results from the time domain wave analysis of the measurements on March 18th and April 3rd, 1973 (Figure 2 and 3) with the results from the FOURIER synthesis considering anomalous dispersion (from the measurements of January 20th, 1974, see Fig. 11) it can be stated that both treatments qualitatively deliver similar variations of the wave parameters.

With the water depth decreasing in the upbeach direction

- a) the wave height \bar{H} at first increases and then continuously decreases,
- b) the wave period \bar{T} increases,
- c) the wave velocity \bar{c} decreases,
- d) the wave length \bar{L} at first decreases and after wave breaking increases and as a result of a) and d)
- e) the steepness \bar{H} / \bar{L} at first increases and then decreases.

The findings according to a), c) and e) are in agreement with the conservative treatment of near shore processes, whereas the increase of the wave period with the consequence of the shown behaviour of the wave length is not. In the following this discrepancy is tried to be explained in terms of a spectral treatment :

Assumed that at idealized conditions there exists a swell in deep water propagating towards the shore (with a normal dispersion), its content of higher order harmonics decreases the more it travels away from its origin.

With the water depth decreasing the swell is increasingly affected by the bottom in such a way that at first only the longer components decrease in phase velocity. As the higher frequency components, being deep water components, keep their phase velocities they recover the more the longer components slow down. At a certain position possibly more or less all of the components travel with approximately the same speed, which means nondispersiveness.

The above described behaviour, which is qualitatively in accordance with the conventional dispersion relationship, at first represents increasingly shortening waves and finally the non-dispersive property leads to high and steep (shoaling) waves, which would not change form very much, if the bottom would be plane at this position.

With the water depth, however, further decreasing the higher frequency components pass the longer ones and thus in a superimposition once again longer waves are produced.

As regards the breaking process the differences between the phase velocities of higher and longer components are such that a regular wave shape can no longer be preserved. The kinetic energy of the continuously slowed down longer components possibly is gradually transferred into potential energy causing a water level increase (wave set up), whereas at breaking that part of kinetic energy associated with the unaffected higher frequencies leaves the former wave shape producing foamlines.

An explanation like this would be in accordance with the author's previous finding of increasing energy densities at higher frequencies at the expense of the energy densities associated with lower frequencies (BÜSCHING, 1976).

In addition, with respect to Fig. 11 it is obvious that the FOURIER synthesis can better describe the deformation of shoaling waves than at least by means of parameters derived from the zero-up-crossing method as to be seen from Fig. 3.

It clearly turns out that the maximum steepness does not occur together with the maximum asymmetry, which is indicated (in this case) by a continuously steepening front face (Fig. 11). Furthermore finally there exists a saddle on the rear face of the wave, which can be compared very well to the formation of solitons.

In this connection it shall be mentioned here that an anomalous dispersion does not necessarily contradict GALVIN's (1972) wave tank observations stating that in shallow water initially sinusoidal waves decompose into two or more waves (solitons) which travel at different speeds in such a way that the bigger travel faster than the smaller and the crest elevation and the height of the bigger increases.

In this respect a definition is needed between "bigger" and "smaller" waves in terms of a spectral treatment, as it can very well be possible that the longer frequency components are associated with the smaller resultant water level deflection if the respective energy densities are less at those frequencies.

Hence, being able to reconstruct significant features of the input water level deflections, this may be an indication that the respective result (ANOMALOUS DISPERSION) obtained by a linear analysis might not be that bad.

Finally some important consequences of an anomalous dispersion associated with energy dissipation, being a very common phenomenon in physics, shall be pointed out :

- 1) As is well known from capillary waves the group velocity of anomalously propagating waves exceeds the phase velocity and thus the energy propagates faster than the singular FOURIER components of a wave system. As concerns gravity waves this may be an indication why the wave energy is transmitted so rapidly, - especially in plunging breakers. Possibly this process can be compared on the one hand with the strong attenuation of capillary waves and on the other hand with the absorption of electromagnetic waves, although the mechanisms - except anomalous dispersion - are completely different.
- 2) In a dispersive system small nonlinear disturbances travel with different velocities and thus an accumulation is more or less prevented. (LIGHT-HILL, 1978). So, at least, the question is open about the rates of contribution on wave deformation by nonlinear and dispersive properties.

5. ACKNOWLEDGEMENTS

This paper is still an outcome of the research program "ENERGIEUMWANDLUNG IN BRANDUNGSZONEN" sponsored by the DEUTSCHE FORSCHUNGSGEMEINSCHAFT (GERMAN RESEARCH FOUNDATION).

The author is indebted to a. Prof. Dr.-Ing. A. Führbäter, Head of the LEICHTWEISS-INSTITUT, for making this work possible, to Prof. K. Harikawa, University of Tokyo, for fruitful discussions and to Dipl. math. F. Wolpers for performing comprehensive computations.

CHAPTER 13

Infragravity Waves in Storm Conditions

R. A. Holman, D. A. Huntley, and A. J. Bowen*

ABSTRACT

Nearshore sediment is actively reworked during major storms, often significantly altering the nearshore morphology. It has been suggested that infragravity waves with wave periods 30-300 seconds are very important in the formation of major nearshore features.

A field study to further understand the nature of infragravity waves was carried out in Martinique Beach, Nova Scotia. Velocity measurements were taken using three electromagnetic flowmeters. Incident conditions varied from calm to swell and wind waves generated by hurricane Belle. Spectral analysis of the low tides revealed a sharp increase in the infragravity band energy associated with the storm. Throughout the storm the spectra of all three instruments were dominated by a strong 100 second peak which remained constant in frequency despite significant changes in the incident wave field. This peak is found to satisfy edge wave theory. A frequency selection mechanism based on longshore topographic trapping of edge waves is suggested.

INTRODUCTION

Surf beat, low frequency motion with wave periods of 30 to 300 seconds usually associated with shoaling waves, was first observed and christened by Munk (1949) and Tucker (1950). Their observations were relatively low amplitude (approximately 1/10 of the incident swell), which they explained as a modulation of a beating incident wave field with no longshore variability.

Gallagher (1971) modelled surf beat as edge waves with energy transfer from the incident waves through a non-linear mechanism. Huntley (1976) showed field evidence of a series of discrete, energetic infragravity (surf beat) peaks which he proved were edge waves.

Bowen and Inman (1971) suggest that natural, crescentic bars could theoretically be caused by edge waves. Reversing the logic, they then use the existence of crescentic bars to predict that narrow low frequency peaks of significant edge wave energy should exist on natural beaches. Suhayda (1974a, 1974b) presents field evidence which appears to confirm that standing infragravity waves generated perpendicular to the beach can lead to the formation of straight longshore bars.

* Department of Oceanography
Dalhousie University
Halifax, Nova Scotia, Canada

Coupling this latter hypothesis that low frequency waves are closely related to major features with the common observation that these features undergo significant change under storm conditions (Schalk, 1963, Short, 1975) leads to the conclusion that surf beat probably forms an important part of the nearshore wave climate, especially during storms when one would expect to see narrow, strong peaks of low frequency energy. It is the purpose of this paper to present a field study of surf beat activity during incident conditions varying from calm to hurricane generated swell. Interestingly, a narrow 100 second peak is found to dominate the spectrum during storm conditions.

EDGE WAVES

Edge waves are normal modes of oscillation on a sloping beach. Eckart (1951) solved the shallow water equations for a plane beach of slope $\tan \beta$ to find the velocity potential ϕ , where

$$\phi = \frac{a_n g}{\sigma} f_n(x) \cos(ky - \sigma t) \quad \text{for a progressive edge wave} \tag{1}$$

and $\phi = \frac{a_n g}{\sigma} f_n(x) \cos ky \cos \sigma t$ for a standing edge wave.

Here a_n is the shoreline amplitude of the edge wave of modal number n , g is the gravitational acceleration, σ is the angular frequency, k the longshore wavenumber and t is time. x , y , and z are a right-handed Cartesian co-ordinate set with x positive to seaward from the still water shoreline and z positive upwards from mean sea level. The off-shore behaviour is given by

$$f_n(x) = e^{-kx} L_n(2kx) \tag{2}$$

where L_n is the Laquerre polynomial of order n , having n zero crossings. Figure 1 is a plot of $f_n(x)$ against the non-dimensional offshore distance $\chi = \sigma^2 x / (g\beta)$ for the first four modes. The offshore profile of a standing incident wave is included for comparison. Edge waves must satisfy the dispersion relation

$$\sigma^2 = gk (2n+1) \tan \beta. \tag{3}$$

The onshore velocity u , longshore velocity v , and edge wave elevation η are given by

$$u = \frac{\partial}{\partial x} \phi, \quad v = \frac{\partial}{\partial y} \phi, \quad \eta = -\frac{1}{g} \frac{\partial}{\partial t} \phi \tag{4}$$

For a progressive wave at the shoreline, the ratio of u and v is simply

$$\frac{u}{v} = 2n+1$$

showing the dominance of u for higher modes.

Fig. 1 Offshore dependence $f_n(x)$ for edge wave modes 0, 1, 2, and 3, and or normally incident reflected wave.

EXPERIMENTAL

The site chosen for the field experiment was Martinique Beach, about eighty kilometers east of Halifax, Nova Scotia. Martinique has a fairly simple topography with an almost linear offshore profile of beach slope $\beta = 0.02$. The slightly concave shoreline is terminated at one end by a headland and at the other by a reef which extends 250 m offshore (figure 2). A second reef divides the length of the beach in the ratio 2:1. The beach has an open exposure to the Atlantic.

An array of sensors was set up along two ranges approximately 700 m from the west end of the beach (figure 3). The west range consisted of two Marsh-McBirney electromagnetic flowmeters labelled MMB1 and MMB2. One hundred meters to the east was a Cushing, spartype electromagnetic flowmeter labelled Cush. Sensors were mounted 50 cm above the sea bed.

All data was digitized at a 1/3 second interval prior to spectral analysis. Spectra presented will have two degrees of smoothing. A half filter width of 30 (HF=30), with a bandwidth of .0142 hz, was used to give a broad spectral picture (95% confidence limits are 0.75 and 1.4). For higher resolution a half width of 10 (HF=10), with a bandwidth of .0044 hz and confidence limits of 0.6 and 1.9, was used.

Four fifty minute data runs, centered at high, low, and both mid-tides, were usually taken per tidal cycle. Data was collected from the 6th to the 12th of August, 1976.

Fig. 2

Martinique beach.

Fig. 3 Placement of sensors.

An overall summary of the visually observed wind and wave climate is shown in figure 4. Individual runs are indicated by stars with every fifth one numbered. Weather conditions changed through the week from four days of relative calm with low regular swell to winds of over 20 m/sec and accompanying high wave activity associated with the tail end of hurricane Belle which passed to the west (figure 5). Local winds were almost directly onshore at the height of the storm, shifting to the west during the decay. Rough visual estimates of significant wave height and significant wave period (figure 4) also reflect the presence of the storm, although the latter tends to underestimate the period of the spectral swell peak.

Figure 6 shows the mean run-up and visually estimated breakpoint for each run. Randomness of the incident waves and lack of an offshore length scale made breakpoint estimation difficult and introduced some scatter.

Beach profiles, taken at the beginning and end of the week, show a significant movement of sand during the storm (figure 7). This was also demonstrated by the partial burial of the two flowmeters in the west range.

Fig. 4 Summary of the week of the experiment. Runs are indicated by stars with every fifth one numbered. The storm started in run 21, and peaked in run 26.

Fig. 6 Mean runup (numbers) and break point (short horizontal lines) for each run. Long vertical lines are then the surf zone width. There is no data for runs 1-6.

Fig. 7 Beach profiles before and after storm for both ranges. MMB2 was buried by the storm.

RESULTS AND DATA ANALYSIS

Edge wave amplitudes dies away relatively rapidly offshore. Therefore, only the low tide runs, when the instruments are closest to the shore, will be considered in this paper.

Figure 8 shows the mean currents for each run. On/offshore currents are generally weak until run 21. MMB1 and MMB2 then jump to approximately 20 cm/sec offshore drift, staying offshore until the end of the experiment. The longshore currents change from a general westward drift during calm conditions to an eastward drift, the direction of travel of the storm waves, during the storm. Run 21 shows a longshore current divergence, with eastward flow at the east flowmeter and westward flow at the west range. This is consistent with a rip cell with rip heads slightly west of the west range and a larger distance east of the east flowmeter. Visual observations made by a diver during the run confirm this, reporting a rip current of approximately 50 cm/sec 15 m to the west of the west range.

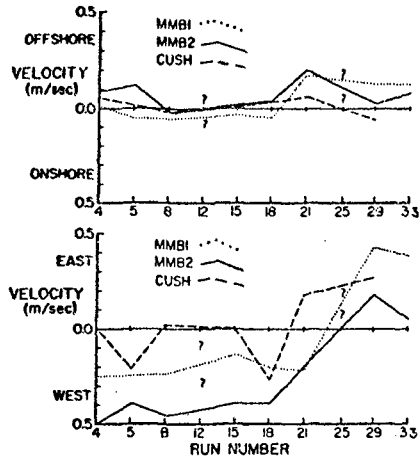

Fig. 8. Mean currents for the three instruments. Question marks indicate missing data.

Figure 9 shows a partial time series from run 29 just after the height of the storm. The longshore currents show substantial low frequency energy at a variety of time scales. The onshore currents show 100 second period activity particularly between 36 and 42 minutes. Evidence of shoaling can be seen from comparison of the on/offshore components of MMB1 and MMB2. MMB1 shows more of the variance contained in the higher frequencies (wind waves and swell), while the MMB2 shows relatively more variance in low frequencies. There is also some evidence of bore-bore capture, for instance at 42 minutes.

Figure 10 shows two spectra from the onshore channel of MMB2; run 12 is typical of calm conditions, while run 25 is at the height of the storm. The instrument is in the surf zone in both cases. Both spectra are fairly featureless with run 12 much flatter and of lower energy. The spectrum from run 25 is red up to a well-defined 100 second peak. Huntley and Bowen (1975) remark on the flatness of surf zone spectra when plotted on a log-linear scale. They are able to empirically parameterize the exponential decay coefficient, p , as a function of

local water depth h and wave amplitude at breaking a_b , as

$$p \propto h^{5/2} a_b^{-2}$$

Contrary to their result, this data shows p to vary as a positive exponent of a_b and a possibly negative component of h .

Fig. 9 Example time series for the three instruments. Run 29 is near the height of the storm.

Fig. 10 Example onshore velocity spectra from calm conditions (run 12) and from storm conditions (run 25).

An estimate of the importance of the low frequency energy can be made by splitting the spectrum into a high frequency part consisting of swell, wind waves and higher frequencies, and a second part containing the lower frequencies. For run 29, the small dip in the spectrum at 0.075 hz is consistent with the low frequency side of the swell peak from the deeper MMB1 and is used as the division point. The low frequencies are found to account for 84% of the total energy for this run.

Picking a division point for run 12 is more difficult. Even using a relatively high value of .09 hz, the low frequencies account for only 41% of the total energy. Table 1 shows numerical comparisons between the calm run 12 and the stormy run 25. The mean square velocities were taken from the spectra in figure 10.

Table I. Comparison between calm and storm conditions.

Run ID	12 (calm)	25 (storm)
wind speed (m/sec)	1.5	21.2
significant wave height (m)	0.3	1.0+1.5
significant wave period (sec)	7.0	11.0
mean longshore current (m/sec)	-0.45	no data
Mean Square Velocities - MMB2X (all in m^2/sec^2)		
low frequency	$1.2. \times 10^{-2}$	1.86×10^{-1}
high frequency	1.77×10^{-2}	0.349×10^{-1}
total	2.98×10^{-2}	2.195×10^{-1}
% low frequency of total	41%	84%

Figure 11 shows time series of the spectra for the onshore and longshore components of the three flowmeters. Each heavy line represents an individual spectrum, from the first low tide, run 3, on the lower left of each plot, through to the last low tide, run 33, on the upper right. Each run is labelled above its y axis.

An obvious feature in the spectra is the presence of very low frequency energy in all longshore and many onshore spectra. Reduced smoothing fails to improve the detail of the energy. Because resolution is limited by run length, it can only be said that the low frequency hills are made up of energy from wave periods between about 3 and 200 minutes. Detrending largely removes periods longer than 200 minutes. Cross-spectral analysis between different channels of the

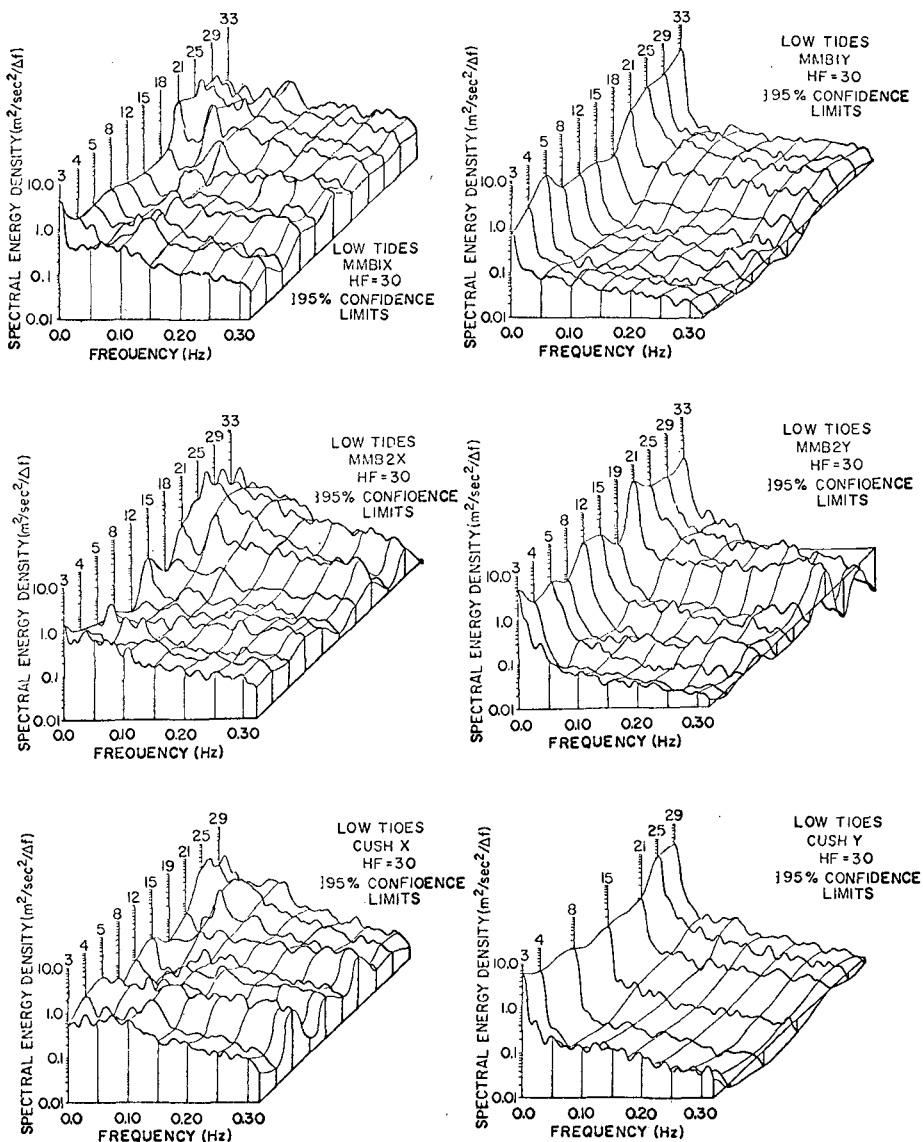

Fig. 11 Spectral time series for onshore and longshore velocities of all instruments. Each bold line is an individual spectrum with run numbers above the y-axis.

same instrument and between the same channels of different instruments reveals no pattern; coherences are usually insignificant. This implies a forced flow, not a free wave. One possibility is that the very low frequency energy may represent movements of the longshore current relative to the instrument.

The general trend of the week can be seen clearly from the spectral time series. The long calm period for the first half of the week is reflected by the low energies of the first seven spectra. The onshore component of MMB2, the shallowest instrument is, on average, featureless, while for MMB1 and Cush, a weak, unsteady wind wave peak is seen.

The forerunners of hurricane Belle appear in the onshore spectra of all three instruments on run 21 as an energetic swell peak of period 16 seconds and RMS velocity 14 cm/sec. This peak is then lost in the overall high energies of the shallow MMB2, but is seen to slowly shift to higher frequencies for MMB1 and Cush in agreement with expected wave dispersion.

Following the appearance of the storm forerunners in run 21 is a sudden, order of magnitude, increase in low frequency energy in the onshore velocity components of all instruments. In particular, for run 25, the spectra from all three instruments is dominated by a narrow, strong, 100 second peak. Throughout the rest of the storm, this peak continued to dominate the MMB2x and Cushx and stayed constant in frequency for all three instruments even though incident conditions changed significantly. (The peak seems to disappear for MMB1x. However, rerunning the spectra with decreased smoothing shows it to be present). For the MMB2x on run 25, the 100 second peak has a corresponding RMS velocity of 30 cm/sec.

Edge wave energy shows an offshore decay described by $[\frac{\partial}{\partial x} f_n(\lambda x)]^2$ for the onshore velocity component. Since the instruments MMB1 and MMB2 were at different offshore distances on the same range, the ratio of the energies of the 100 second peaks could be compared to the theoretical ratio for edge waves of various modes. The observed ratios of 0.56 for run 25 and 0.36 for run 29 compare reasonably with the theoretical values for a mode 1 edge wave of 0.61 and 0.53 respectively, considering the difficulty involved in estimating a velocity from a spectrum. As can be seen from figure 1, the offshore energy decay for higher mode edge waves is quite similar to that of mode 1 for the small values of χ involved ($\chi \approx 1.5$).

Cross spectra between the onshore components of the different instruments were run with reduced smoothing. A peak which is highly coherent over the distance between instruments usually indicates a wave motion, while a peak which has only a low coherence is probably just a forced flow. Figure 12a shows spectra from the three instruments for run 29. The peaks at 100 seconds are quite narrow and consist in frequency from instrument to instrument. Figure 12b shows the

coherence and phase between the onshore velocity components of MMB2 and Cush. The 100 second peak shows up clearly with a coherence of 0.88 and a phase of 0±11 degrees. Cross spectra between other parts of onshore velocity components give similar results.

Fig. 12a Onshore velocity spectra for run 29 for the three instruments. Higher resolution is achieved by reducing the smoothing. The 100 second peaks stand out clearly in all three spectra.

Fig. 12b Coherence and phase between the onshore velocities of the MMB2 and Cush for run 29. The 100 second peaks in figure 12a are seen to be highly coherent with a phase of 0°.

The corresponding 100 second peak is not present in the longshore spectra of MMB1 and Cush (figure 11) and only weakly present in that of MMB2, even with reduced smoothing to eliminate contamination from the very low frequency redness. Similarly, u-v cross-spectra fail to show significant coherence at 100 seconds. A possible explanation for this is shown in figure 13 which plots the offshore profile of the longshore velocity for 100 second mode 0, 1, and 2 edge waves (higher mode edge waves and standing incident waves are similar to mode 2). The positions of the flowmeters for runs 25 and 29 are superimposed on the figure. It is unfortunate that the zero crossing of longshore current for modes greater than 0 lies so close to the position of MMB1 and Cush. Even for run 25, a lower low tide, the longshore velocity at Cush is only 25% of the shoreline value, hence only 6% of the shoreline energy would be seen. The shallower MMB2 would see somewhat more energy, about 30% for run 25 and 10% for run 29. This may explain why MMB2 is the only channel on which the 100 second peak is seen.

For comparison, the onshore velocity component for a mode 1 edge wave is also plotted figure 13. The first zero crossing for this mode is well away from the instrument position. Coupled with this is the fact that the ratio of onshore velocity to longshore velocity at the shoreline goes as $(2n+1)$ for progressive edge waves and $(2n+1) \tan ky$ for standing edge waves. Thus, even for the worst case, MMB2 on run 25, the ratio of the onshore to longshore velocities for a mode 1 edge wave, as seen by the instrument, should be about 4:1 and the ratio of the spectral energies 16:1. For higher modes the ratio would be higher. This explains why the onshore peak can be so strong and the longshore peak so weak, and still be consistent with edge wave motion.

Fig. 13 Offshore behaviour of longshore current for a 100 second edge wave of mode 0, 1 and 2. The instrument positions for runs 25, 29 are included and are very close to the first node. This is not true for onshore velocity as seen from the mode 1 profile.

FREQUENCY SELECTION

The presence of energetic, low frequency waves, steady in frequency through a variety of hurricane-generated incident conditions, is important to the coastal engineer for the understanding of the growth of large beach features. However, there must be some underlying mechanism which provides the frequency selection either through forcing, damping, topographic constraints, or a combination of these.

The forcing mechanisms proposed by Longuett-Higgins and Stewart (1964) and Gallagher (1971) depend on beating in the incident wave field. This was tested directly by comparing the time series of the low-passed velocity and the incident envelope (the square of the high-pass record which is then smoothed). The correlation was not significant for the several time series tested, suggesting a broad banded forcing. However, it should be remembered that the time series tested were from within the surf zone where the strong non-linearities associated with breaking could have easily obscured the low frequency forcing.

If surf zone sampling is assumed to be dominant, then Guza and Bowen (1976) suggest that edge waves are most likely to survive if their offshore length scales are large compared to the width of the surf zone. This simply favours low frequencies and high mode numbers but does not provide a selection mechanism for a particular frequency.

Ball (1967) suggested that particular offshore beach topographies can select favoured edge wave modes, the cut-off modes. Huntley (1976) finds field evidence for cut-off modes from Hell's Mouth Bay. However, this cut-off requires the beach profile to flatten in water which is not "deep" for the edge wave, a requirement not met by Martinique with its approximately plane profile. For the large longshore wavelengths inferred for these low frequencies, the longshore beach topography provides the most significant constraint on possible length scales and hence edge wave frequencies. The headland and reef at the beach ends, and the second reef two thirds of the distance along the beach suggests $b=953m$ as a fundamental longshore length scale for the beach (figure 2). As free waves reflected between end walls on a sloping beach are necessarily edge waves, an obvious model to consider is one based on the superposition of standing edge waves. Requiring that an integral number m of half-wavelengths fit into b , and using equation 3, we find

$$f = \left(\frac{g \tan \beta}{4\pi b} \right)^{\frac{1}{2}} (m(2n+1))^{\frac{1}{2}}$$

$$= 4.04 \times 10^{-3} (m(2n+1))^{\frac{1}{2}}$$

The combination of $m=2$, $n=1$ provides an excellent fit, predicting a frequency of .0099 hz compared to the observed frequency of .01 hz. However, it should be noted that equation (5) describes a whole suite of possible edge waves which could fit the beach. Addition of surf zone damping constraints as described previously and forcing as discussed by Gallagher (1971) and extended by Bowen and Guza (1978) does not alter the picture significantly enough to produce the narrow 100 second peak observed. So the present theoretical picture is one of a fairly broad-banded spectrum with the only features being "valleys" at frequencies where the non-dimensional offshore distance of the instrument $\chi_1 = \sigma^2 x_1 / g\beta$ corresponds to an edge node (see figure 1).

Further evidence that topographic constraints are basic to the frequency selection is provided by data taken at approximately the same location on Martinique Beach in July of the previous year when the beach was steeper, with $\beta=0.05$. On that day, a narrow, energetic peak centered at 62 seconds was observed (figure 14). If the same length scale is responsible for both the 62 and the 100 second peaks, then, using equation (3), the ratio of edge wave periods for a change in beach slope should be

$$\frac{T_1}{T_2} = \left(\frac{\beta_2}{\beta_1} \right)^{\frac{1}{2}} = 0.63$$

This ratio is almost exactly satisfied for the two peaks indicating that in the face of different incident conditions and a different offshore profile, the edge wave adjusts to give the same wavelength, presumably because of longshore topographic trapping.

Fig. 14

Onshore velocity spectrum taken from the same location on 4 July 1975. Note the strong 62 second peak.

CONCLUSIONS:

A field experiment recording wave velocities during both calm and storm conditions showed a dramatic jump in infragravity (0.003-0.03 Hz) energy during the storm. At the height of the storm, infragravity waves accounted for 84% of all spectral energy. This low frequency dominance sheds doubt on the relevance of the simple, visually-observed, wave statistics in understanding surf zone dynamics.

A strong 100 second peak appeared in the onshore velocity spectra of all flowmeters near the beginning of the storm. This peak remained dominant and consistent in frequency through two further tides despite significant changes in the incident wave climate. Longshore topographic constraints are probably important in providing the lengthscale necessary for frequency selection, although the addition of forcing and damping constraints to the topographic model produces a fairly broad-banded theoretical spectrum, not the narrow 100 second peak observed.

CHAPTER 14

EXTREMAL PREDICTION OF SIGNIFICANT WAVE HEIGHT Enrique Copeiro*

The most generally used procedure for estimating the extremal distribution of geophysical variates consists in obtaining a sample of extreme values (for instance a number of annual maxima) and fitting to them a distribution function. One of the main problems involved in this procedure is the choice of the type of distribution adequate in each case. No general agreement exists, to date, for any geophysical variate. This means a serious trouble because of the wide range of extrapolations which can usually be obtained by using different functions. Some of the authors who have tackled this problem have adopted a strictly empirical point of view, going as far in it as to advise to make a choice for each particular case, according to the goodness-of-fit obtained when several types of distribution functions are fitted to the sample. Others have instead tried to base the choices on some theoretical foundation, placing less emphasis in the goodness of the fits and generally suggesting the use of one or other of the three well known Asymptotic Extremal Distributions.

In actual practice, the casuistic choice of function from each extremal sample -- does not provide a reliable solution to this problem as a general criterion. The methodology in use today for estimating distributions from extremal samples (or, in general, from samples of independent values) of a random variate suffers from ambiguity in several respects (1). Because of that, it is often uncertain to determine how much of the differences observed between goodness of fits is due to the methodology itself or to the different degree of adequacy of the functions which are being tried. This reduces the meaning of the differences between fits, particularly when they are small. Minor differences between fits can not be considered relevant in the choices. This is unfortunate because in most real cases the extremal sample available is not too large and usually some different functions can be used which give only minor differences between its goodness-of-fits but which diverge considerably in extrapolations. The variate significant wave height (H_s) is a good example, its extremal samples being obtained by hindcasting (or visual estimates) and resulting not only of small size generally but also of moderate (or low) accuracy. In Figs.(2) to (6) two published extremal samples of H_s (2) hindcasted for Cabo Machichaco (Bay of Biscay, Spain) and Valencia (Spain) have been fitted, with minor differences between fits, by distribution functions Asymptote-I, Asymptote-II, Asymptote-III, Weibull and Log-Normal. All of these functions have been recommended for general use (Asymptote-I, (2); Asymptote-II, (3); Asymptote-III, (4), or used in some published cases, for the variate H_s . The dispersion of extrapolations is broad (Fig.(1)): For T=100 years the maximum difference between results is 3 m. at Valencia and 7 m. at Cabo Machichaco. These differences would have large repercussions in the design of maritime structures, and the differences between goodness-of-fits could not provide a reliable choice criterion in both cases. It can be proved (1) that the reliability of every extremal sample (or any set of observed probabilities obtained by random sampling) is not constant but varies along the values of the variate. The approximation to the true (population) probabilities is best at the center of the distribution function $F(x)=0,5$, and diminishes towards both tails. From this point of view, a non-ambiguous fitting criterion was developed (1). When using it, the upper and lower tails of the sample points are excluded from the fits because of their low reliability. Therefore it must be realized that the effective or useful size of the samples is quite smaller than their total size. The need for very long samples is thus emphasized, the others not being capable to yield reliable extrapolations in individual analysis.

The theoretical justifications stem from the basic extremal equation for a random variate X : $\Phi(x)=(F(x))^n$, where $\Phi(x)$ is the probability of x not to be exceeded in any of n random trials, and $F(x)$ is the distribution function of the variate or probability of x not being exceeded in a single trial. For x approaching 1 and n large enough, the extremal distribution converges asymptotically towards one of the so-called First, Second and Third Asymptotic Extremal distribution functions, when one of three types of conditions is fulfilled by the tail of interest of $F(x)$. Because these conditions are quite broad, covering a very wide spectrum of distribution functions, and n is supposed to be large for -- most geophysical variates along one year (the basic geophysical cycle), a great number of authors have assumed (notably after the fundamental work of E.Gumbel (5)) that the extremal distribution of any geophysical variate could be closely approximated by one or other of the three Asymptotes. References (5) and (1) mention a good number of published applications of the Asymptotes in extremal analysis of variates like temperature, wind speed, -- rainfall, river discharge, significant wave height, etc. In the justifications for the -- use of the Asymptotes it has generally been assumed that, for instance, a variate like -- the average discharge in 24 hours has in a year a value of $n=365$, a number which is fairly high and supposed to yield statistical independence at high levels of the variate (E.Gum-

(FIG. 4)

(FIG. 6)

(FIG. 5)

(FIG. 3)

(FIG. 2)

bel, (5)). This interpretation of the parameter \underline{n} is erroneous. Variates like temperature, whose evolution is not discrete but continuous with time, can not be said to "occur" a certain "number of times" along a year. The variate takes an infinitude of values within a finite time interval. Therefore, it is not possible to assign directly a value to \underline{n} . This, -- which is self-evident for an instantaneous variate like temperature, can be shown to be al so true for other variates. J.Battjes (6), commenting on an extremal analysis of H_s , showed that when parameter \underline{n} is given a value equal to the duration of the year divided by the duration of each H_s record, an absurd result is obtained. This author was the first, to the knowledge of the writer, to realize for a particular variate that such an assumption for \underline{n} is not correct (in spite of what, some further extremal analysis of H_s with the same erroneous criterion for \underline{n} have been published later). Actually the same \underline{s} applies to all geophysical variates which consist in averages or totals within a fixed time interval. These variates belong to a group whose evolution with time is continuous, to which most of the -- variates relevant in civil engineering belong: Rainfall in a time interval; Discharge in a time interval; Average wind speed in a time interval; Significant wave height; etc. The average discharge in 24 hours does not take on 365 values in a year, but an infinitude. -- The fact that just 365 of them are juxtaposed in time is not particularly relevant. It can be shown (1) that an assumption like $n=365$ leads to an absurd result in the extremal analysis of this variate too, and so for all the variates of the same type. It will be shown later on that, for that type of variates, \underline{n} is not a constant value but a function of the variate. From this follows that the derivation of the Asymptotes, which was done with the implicit assumption $\underline{n=constant}$ (see, for instance, (5)), is not valid for the continuous-evolution variates. Therefore the extensive use which has been done of the Asymptotes for -- those variates does not have any theoretical justification as yet. The writer (7) presented a model by which the extremal equation can be applied to continuous variates:

1.- EXTREMAL EQUATION FOR CONTINUOUS EVOLUTION VARIATES

The extremal equation $\Phi(x)=(F(x))^{\underline{n}}$ was stated on a discrete basis for the occurrence of the variate. In order to apply this equation to a continuous-evolution variate, the variate itself must be prepared for a discrete analysis. This can be done when, instead of the individual values taken by the variate, the undulations described by the variate in -- its evolution along time are taken into consideration. The undulations can be said to have individual physical entity with finite dimensions and can therefore give support to a discrete analysis. Each entire undulation can not be assigned a certain duration. Instead, only a fixed level \underline{x} of the variate will be considered. Cutting the continuous curve at -- the level \underline{x} , a number of isolated undulations (what will be called "curves of exceedance of \underline{x} " or more simply "x-exceedances") remain above the cut. Now a dichotomy can be established at each level \underline{x} : The probability of occurrence of a x-exceedance, or of its non occurrence. This entails to change the continuous axis "time" into a discrete "number of times" (or statistical trials) in which an event (x-exceedance) might happen or not. For that, -- the "duration" of each statistical trial is taken as the average duration $t(x)$ of the x-exceedances. The "number of trials" at the level \underline{x} is, in an average year of duration T_y :

$$n(x) = \frac{T_y}{t(x)} . \text{ Being } n_x \text{ the average number of x-exceedances in a year or } n_x = \frac{\sum t x_i}{t(x)}$$

the probability that in a single "trial" a x-exceedance does not occur is $1 - \frac{n_x}{n(x)} = 1 - \frac{\sum t x_i}{T_y}$.

This is the expression for the distribution function $F(x)$ of the former continuous-evolution variate X. Therefore, the probability that in the $n(x)$ trials of the average year no x-exceedance will appear, or extremal distribution function, is:

$$\Phi(x) = [F(x)]^{n(x)}$$

The resulting expression is similar to the extremal equation for a discrete evolution variate except for the exponent, which now is not constant but a function of the variate. The type of function corresponding to $\Phi(x)$ will be determined once the types of functions $F(x)$ and $n(x)$ are found. This will be done in the following for some variates, chiefly H_s . An empirical determination of the form of $F(x)$ and $n(x)$ from several samples is far more reliable than the same direct estimate for $\Phi(x)$, due to the incomparably higher number, length and accuracy of the samples of $F(x)$ and $n(x)$ than of $\Phi(x)$. The extremal samples can best be used as control checks for the predictions made with the extremal equation. This was done in (1) for a few cases.

2.- FUNCTION $n(x)$

It will be first indicated which is the kind of relationship existing between the values of $n(x)$ corresponding to the whole population and the estimates of this parameter - obtained from a limited sample or observation period. For each sample, estimates of $n(x)$ are obtained from the observed average durations $t(x)$ of the exceedances.

- The higher the number of exceedances, the more reliable (close to the population) the estimate of $t(x)$ and thus of $n(x)$. In every single observation period that number varies along the range of values of X (Fig. 48), having a sharp maximum at a certain level - (very close to the center of the distribution function, $F(x)=0,5$, (1), and steadily diminishing towards both tails. The reliability varies in the same way too.

- Assuming that along a certain "central" stretch of values of X the $n(x)$ estimates are correct or acceptable, the estimates belonging to the adjacent zones in both directions will show a random deviation from the population values due to their low reliability.

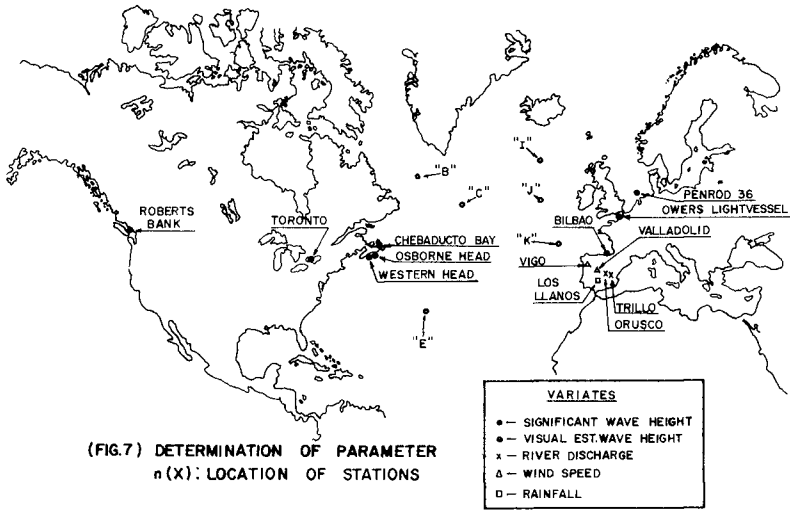

- The variate may be in general unlimited in both directions, but each sample will instead be necessarily limited by a maximum and a minimum values. The observed values of $n(x)$ will show, at both ends, systematic deviations: Towards $n(x)=0$ at the minimum observed value of X , and towards $n(x)=\infty$ at the maximum. Most geophysical variates, such as H_s , have a natural lower limit at $x=0$, and then only the upper systematic deviation exists.

TABLE-7

These conditions were satisfied by the linear relationship $n(x)=A(x-B)$, in the analysis of 13 sets of data (see Table 1) belonging to the following continuous evolution variates: Instrumentally recorded significant wave height (8 cases); average wind speed in - 24 hours (2 cases); average river discharge in 24 hours (2 cases); and total rainfall in - 30 days (1 case). In Fig. 7 the location of all observation stations is shown. Figs. 8 to 20 show the linear fits. In this figures, the points for whose computation less than 10 exceedances were available have been excluded. That has limited considerably the deviations which could be seen. The fact that in the cases analyzed the upper deviation next to the central stretch starts more often towards large $n(x)$ values than towards small ones, goes in well with the skewness which was appreciated in the distributions of the durations at each level of X . The skewness indicates a higher frequency of durations below the average than above it. The proper fit of the function $n(x)$ to the data calls for the use of "accuracy intervals" as defined in (1). However, visual fits are acceptable for extremal analysis provided that the "central" stretch of reliable estimate is long enough. Later on some interesting results concerning H_s are obtained.

In Figs. 21 to 26 six long duration sets of visually estimated wave height are analyzed. These are not intended to be a check of the linear function, since the reliability of the visual estimates is as yet less clear than should be. However, they have been included here because of the practical importance of visual wave observations. The central and lower points lie in a peculiar sinuous pattern, which only becomes straight on a log-log paper (1). This seem to give support to the power relationship between H_s and H_v sugges-

ted by Nordstrom (9). But the log-log plots yield a quick systematic deviation of the upper tail, which might indicate that the power relationship is not applicable to the higher waves. It is possible that no single simple relationship is valid for the whole range of wave heights. This point still needs clarification, and in the mean time the linear fits of Figs. 21 to 26 will be used (in following sections) as an approximation which probably (in view of the acceptable behaviour of the upper points) is reasonably accurate for extrapolations.

3.- FUNCTION F(x)

Only the variate significant wave height will be tackled in this section. The 8 sets of instrumental data used in the preceding section (Table 1) will be analyzed, together with other 12 sets selected from the technical literature (Table 2). The aim of the selection was to choose the longest possible durations (and complete annual series when duration consists in a small number of years) and waters not too shallow at the site. The result is a compromise which seems acceptable as a whole. Fig. 28 shows the location of the 20 stations.

A comparison has been done between the distribution functions Exponential, Log-Normal, Weibull and Double Exponential (Asymptote-I) which are the most widely used today for H_s . No general agreement exists today in this respect, what is unfortunate because of the large differences which can be obtained in the extrapolations when one or another of those functions are used. The comparative study is set up under the initial hypothesis that for any geophysical variate a single type of distribution is valid, at least within each type of homogeneous climate which can be discriminated in the behaviour of that variate. The results obtained prove that the hypothesis works in the case of H_s . The relative amount of swell existing within the waves recorded at each site has been chosen as an operative criterion to discriminate between different "wave climates". The situation of the stations relative to prevailing winds, size and limitations of available fetches and local shelters, and tables of coincidence wave height-wave period, have been evaluated in order to assign each station to a certain group. According to this, four different groups have been defined: In both extremes are the groups denominated "Very low swell" (Toronto, Roberts Bay, Morecambe Bay, Mersey Bar, Nice, Benghazi, Chausey Sud, Dunkerque), and "Heavy swell" (important relative weight of swell reaching relatively high values of the variate: Sevenstones, Bilbao, Cattlewash, Camp Pendleton). As intermediate groups, "Low swell" (Chebaducto Bay, St. John-Deep, Smith's Knoll) and "Moderate swell" (Osborne Head, Western Head, Penrod 36, Varne, Owers Lightvessel). It must be admitted that the border between the two intermediate groups is not altogether clear, but that is not a serious trouble in the comparative study.

TABLE-2

Similarly to what was done for parameter $n(x)$, it will be indicated which kind of relationship exists between the values of $F(x)$ corresponding to the population of the variate and the values observed in a sample of limited size (observed distribution):

SAMPLE OF INDEPENDENT OBSERVATIONS: In a sample of N independent observations of a random event, the probability of the observed probability of success being $\frac{m}{N}$ can be computed from the binomial distribution, $P(m)_N = \binom{N}{m} p^m (1-p)^{N-m}$ where p is the true (population) probability of success in a single trial. Now, the event "success" is the occurrence of a value higher than x in each observation of a random variate X with a distribution function $F(x)$. The probability that in N independent observations the observed probability at the level x (the observed frequency of x being exceeded) is $\frac{m}{N}$, can be computed as: $P(x, m)_N = \binom{N}{m} q(x)^m (1-q(x))^{N-m}$ where $q(x) = (1-F(x))$. The reliability of a sample estimate of $q(x)$ can be measured as the probability of the observed probability $\frac{m}{N}$ to fall inside a certain (arbitrary) interval around the true probability $q(x)$: $((1-k)q(x) < \frac{m}{N} < (1+k)q(x))$. It can be shown (1) that: a) The convenient intervals ("accuracy intervals") should be defined in relative terms with respect to $q(x)$, so that k is a certain percentage of $q(x)$ to be deter-

(FIG. 27).— OBSERVED DISTRIBUTION CURVES: CHARACTERISTIC REGIONS.

(FIG. 28).— DETERMINATION OF $F(H_0)$: LOCATION OF STATIONS

mined accordingly to the accuracy required by the user; b) the appropriate "true" probability to be used as reference for these intervals is $q(x)$ for the upper half of the distribution function ($q(x) < 0,5$) and $F(x)$ for its lower half ($F(x) < 0,5$). The use of the binomial distribution as indicated above shows that, for any fixed width of the accuracy intervals (any constant value of k), the reliability of the observed probability (probability of that probability to fall inside the intervals) is maximum at the center of the distribution function $F(x)=q(x)=0,5$, and diminishes towards both tails of the distribution. Thus, for any sample of independent values of a random variate X , provided it is large enough, two characteristic regions can be discriminated in the set of observed probability points:

- A central region of good estimate, where the observed probabilities are close to the true (population) probabilities.

- Regions of poor estimates at both tails, where the observed probabilities are expected to show wide random deviations from the population probabilities. Limits between both regions can be set by use of accuracy intervals, as discussed in (1) (Accuracy intervals can be defined in terms of the probability or of the value of the variate, and different procedures for estimating their values from the sample itself can be used).

SAMPLE OF CONTINUOUS OBSERVATIONS: If a continuous-evolution variate is observed systematically with short time intervals between records (for instance H_s , with typical observation intervals of 2-3-4 hours), statistical independence between observations can not be assumed. The high density of observations allows the whole curve of evolution of the variate to be drawn, and from it a complete observed distribution (with probabilities from 0 to 1) can be obtained. It can be shown (1) that also for these samples the observed probabilities have a maximum reliability at the center of the distribution function and lower reliability towards both tails. For a sampling period long enough, three characteristic regions can be distinguished in the observed distribution curve: Two of them are the same as indicated above for independent observations, and the third is a final systematic deviation of the uppermost and lowermost tails, which converge asymptotically towards cumulative probabilities $\underline{1}$ and $\underline{0}$ at the maximum and minimum values of the variate observed in the sampling period. This is a natural consequence of any finite sample having a maximum and a minimum observed values, in contrast with the population whose values are in general unlimited. In Fig. (27) the three characteristic regions of an observed distribution of H_s are shown. The lower systematic deviation does not appear, since this variate has a natural lower bound at $H_s=0$. When estimating the distribution function of the population from one of such observed distributions, only the central region of expected good estimate should be considered for the fit.

Comparative studies published in previous years have adopted the criterion of choosing the function which would give the best fit to the whole set of sample points, and specially to its upper tail if extrapolation is the final goal. Such a criterion is erroneous, particularly for continuous or almost-continuous observations, as Fig. 27 makes it evident. The aim of fitting the complete observed distribution and the aim of estimating from it the distribution of the population are not only two different purposes but in fact incompatible. In particular, to place the emphasis of the fit in following the uppermost tail of the observed distributions means to follow the points with the poorest reliability, belonging to the region of expected random deviation or, worse, to the final systematic deviation. This can only lead us away from the expected behaviour of the population, in extrapolations.

In order to compare the behaviour of the 4 functions, it will be checked whether the deviations of the observed values in the regions of "random deviation" are actually random in the set of fits, or whether they are systematic. This criterion suffices to solve satisfactorily the comparison. Although the strictly correct method would be a simultaneous use of accuracy intervals to make the fits and confidence intervals to evaluate the deviations quantitatively, such laborious procedure does not prove necessary in this case. The Exponential and Log-Normal functions will be compared first and later on the Weibull and Double Exponential which are closely related to the Exponential.

EXPONENTIAL - LOG-NORMAL. - In Figs. 29, 30, 31, 32, the fits corresponding to the group "very low swell" can be seen. The Exponential fits are uniformly satisfactory, with deviations which are not systematic and start at reasonable levels of the probability. -- The longer the observation period, the longer is the central region of good fit (Nice, Dunkerque, Chausey Sud). Instead, the Log-Normal fits are uniformly poor. The upper tails show systematic deviation towards low values of the variate, deviation which begins to show very quickly. In Figs. 33, 35, the group "heavy swell" is fitted, showing quite a different behaviour. The Log-Normal fits are good from the lower region to high levels of --

(FIG. 29)

(FIG. 30)

(FIG. 31)

(FIG. 32)

the probability. The Exponential function behaves well in the upper region, but shows a -- sharp systematic deviation in the lower tail. The number of stations included in this group is small, but the inspection of the two remaining groups will clarify the behaviour of both functions. In Figs. 34, 36, 37, 38, the "low swell" and "moderate swell" groups are plotted. The fits show characteristics which are intermediate between those seen in the former groups. As a rule the Log-Normal behaves better in the lower part of the central region, but in the upper zone shows a quick, systematic deviation. At Penrod 36, Owers L., Varne and - Smith's Knoll, the deviations start at probabilities from 0,8 to 0,9, which means a total exceedance time of 73 to 36 days (their observation period is 1 year). This is certainly - excessive, since a good number of exceedances are included in that time for those levels - of H. Even if only the upper part of the central region is fitted, neglecting the lower - part^s (discontinuous lines in the figures), the Log-Normal still deviates systematically in its upper tail. Therefore this function should be rejected for extrapolations. The Exponen - tial law shows for this two groups a systematic deviation at its lower tail. This deviation starts at low values of H_s for low levels of swell, and at higher points for high levels - of swell. At the upper half of the distributions, the Exponential function behaves uniform - ly well for both groups and hence for all the 4 groups. Therefore this function appears - to be in principle acceptable for extrapolations and, thus, for extremal analysis, although its lower tail can not be used when swell has any relative importance.

EXPONENTIAL - WEIBULL.- Exponential: $F(x)=1-e^{-\frac{x-A}{B}}$; Weibull: $F(x)=1-e^{-\frac{(x-A)^C}{B}}$

The difference between both expressions is only the exponent C which appears in the Weibull function. The aim of this comparison is thus to investigate whether the inclusion of that third parameter in the Exponential function leads to better fits. The individual fits of - the 20 stations are not shown here because of space limitations (they can be seen in (1)), but in the following table the values obtained for A and C in the fits are listed. Its -- three parameters give to the Weibull function a higher flexibility, but also a higher degree of indetermination for estimating the values of the parameters themselves. This is -- specially true for observations of not long duration, whose central region of good estimate is short. As an example, in Fig. 39 the fit corresponding to Osborne Head is shown: -- When parameter A is increased in 0,2 feet (\approx 6 cms.), parameter C (which is a certain measure of the slope of the line) changes from 0,97 to 0,87. Should the data of this station belong to a short observation period, there would be no clear way to make a choice between both fits. Due to its high sensitivity to small changes in A (parameter which arranges the points for the fit), the parti - cular values obtained for C must be understood with some am - plitude. In the evaluation of the table, the really meaning - ful values are those corresponding to the stations with rela - tively long observation periods (Osborne Head, Chausey Sud , Nice, Bilbao, Camp Pendleton, Western Head, Dunkerque, Roberts Bank). Their central region of good estimate is the longest, and thus the influence of the upper and lower sample peculiarities in the fit is reduced. In all these stations the C va - lues are very close to 1. According to what was indicated -- above about the accuracy of C estimates, it can be assumed - $C=1$ for all, in practice. Therefore it has not been found jus - tified to include this third parameter and the choice is -- still the 2-parameters Exponential function. In the table, - the cases in which C takes on values not close to 1 belong to samples with the shortest durations (1 year), where it can be supposed that the peculiar flexibility of the Weibull function leads the one who performs the fit to follow to some extent - the deviations of the tails since the central region of good estimate is too short for an unequivocal choice of A. The Wei - bull function has, in Exponential paper, a curvature concave upwards for $C<1$ and concave downwards for $C>1$, but not always that flexibility allows it to fit the deviations of both tails simultaneously in short samples: In Figs. 49, 50, 51 three cases are shown where the fit of the lower tail leads to an ill behaviour of the rest of - the distribution (compare with Figs. 39, 40, 41, where the lower tail was not fitted. In - these kind of fits, the values given to A makes the lower points "disappear" from the probability paper, giving an outward look of perfect fit throughout).

Other 3-parameter functions do also have a high flexibility. For instance, in Figs. 42, 43 the group of stations "very low swell" has been fitted with Asymptote-III functions. The Log-Normal function may include a third parameter too (change $H_s = H_s' \cdot A$): see in Figs. 44, 45, how in this way the fits obtained in Figs. 29, 30 with two parameters are improved with 3.

(FIG. 44)

(FIG. 45)

(FIG. 46)

(FIG. 47)

(FIG. 49)

(FIG. 48)

(FIG. 50)

(FIG. 51)

Even more flexibility would be attained with 4 parameters (Log-Normal with the change $H_s = \frac{H_s - A}{B - H_s}$), and so on. But, as it has been shown, the proper use of functions with a high number parameters would only be feasible had we a better knowledge of the statistical properties - of geophysical variates, than is available today. Otherwise their flexibility is more of a trouble than an advantage. More detailed statistical studies including large numbers of samples are needed. In the mean time we have to be content with the usual simple functions which, if proved well-behaved (like the Exponential herein), are able to give reasonable approximations.

EXPONENTIAL - DOUBLE EXPONENTIAL.- Both functions converge quite quickly for large probabilities:

$$\text{Exponential: } F(x) = 1 - e^{-\frac{x-A}{B}} \quad \text{Convergence: } F(x) \xrightarrow{F(x) \rightarrow 1} e^{-(F(x)-1) \frac{x-A}{B}} = e^{-\frac{x-A}{B}} \quad (\text{Double Exponential}).$$

The speed of the convergence can be visually appreciated by comparing both probability papers. The difference between their probability scales is that, for the lower probabilities, the Double Exponential scale is "stretched" with respect to the other. However this feature is not able to improve, in general, the fits in the lower part of the distributions (which were found to be unsatisfactory with the Exponential). Some of the fits can be seen in Figs. 46, 47 (the rest can be seen in (1)) showing a systematic deviation, this time upwards instead of downwards: The "stretching" of the scale was excessive. Therefore the use of this function is not advisable.

CONCLUSIONS.- None of the 4 functions tried is adequate for the whole extent of the distributions in all the stations studied. The Exponential function has been found to behave satisfactorily in the upper part of the distributions, and thus apt for extrapolations. In the lower part its fits are good when swell is negligible, but as the importance of swell reaches higher levels of H_s so grows a lower region with a systematic deviation. Log-Normal function behaves reciprocally: its fits are good in the lower region, reaching higher levels of H_s as the importance of swell also reaches higher H_s values. In the upper region, the fits show a systematic deviation. This result suggests that the statistical heterogeneity found in each station corresponds with different physical properties of swell -- and sea, each of which is predominant within a certain range of H_s values (with a region of overlapping). The Exponential function could then describe statistically the growth of the sea caused by wind fields reaching the observation site, originated by differential pressure centers (typically low pressure centers). The highest waves are almost everywhere -- formed in this way; thus the adequacy of the Exponential law for extrapolations. On the other hand, the Log-Normal law seems to fit correctly the region where waves are a mixture, in space and time, of a good proportion of swell, low waves formed by the local microclimate, and sea that is being generated by larger wind fields. It is curious to notice that -- the Log-Normal distribution is theoretically correct for natural variates formed by a high number of random factors which join their individual effects in a multiplicative way (V. - Chow, 1955). In (1) further speculations along the same line are indicated to reason this hypothesis, which is able to explain why the deviation of the observed points in the lower tail of the Exponential fits takes place in the form of a quite sudden drop. Summing up, at every single station a discrimination between different wave "climates" can be made, according to the different relative importance of swell along the H_s levels. This discrimination has proved effective in selecting distribution functions with general applicability.

EXTREMAL DISTRIBUTION $\Phi(H_s)$

From the results obtained before for $n(H_s)$ and $F(H_s)$, the following expression is reached for $\Phi(H_s)$:

$$\text{Convergence: } \Phi(H_s) = (F(H_s))^{n(H_s)} \xrightarrow{F(H_s) \rightarrow 1} e^{-(1-F(H_s))n(H_s)}; \quad F(H_s) = 1 - e^{-\frac{H_s - k_1}{k_2}};$$

$$n(H_s) = k_3(H_s - k_4); \quad \Phi(H_s) \rightarrow e^{-(H_s - C)e^{-\left(\frac{H_s - A}{B}\right)}}$$

It is a 3-parameters distribution function. Should $n(H_s)$ have an exponential form, the expression for $\Phi(H_s)$ would be the double exponential or Asymptote-I. With a linear growth for $n(H_s)$, $\Phi(H_s)$ has a quicker growth than the Asymptote-I has. In Figs. 52, 53, 54, - 55, the extremal distributions computed for the 14 wave observation stations listed in Table 1 have been plotted in Asymptote-I paper. From the curvature of the distributions it turns out that the use of Asymptote-I for fitting extremal samples of H_s consistently overestimates the real values in the extrapolations. However the overestimations are small, -

(FIG. 52)

(FIG. 53)

(FIG. 54)

(FIG. 55)

(FIG. 56)

(FIG. 57)

and acceptable for most applications, within the range of return periods usual in practice. Instead, the Asymptote-II would cause large (unacceptable) overestimates.

The good performance showed by the linear and exponential functions with the sets of data analyzed in the two previous sections makes one confident that this simple laws will yield sufficiently accurate results for the extremal analysis of H_s . In some meaningful cases, a good correspondence between both functions has been noticed. In station Bilbao, for instance, where exceptionally rough winters took place within the observation period, the sharp deviation of the sample points above the exponential fit for $F(H_s)$ (Fig. 33) starts almost exactly at the same point where the (also sharp) deviation appears above the linear fit for $n(H_s)$ (Fig. 15). This kind of correspondence is to be expected only in case of very exceptional winter seasons (abnormally rough or mild), since not only the durations but also the number of exceedances play a role in $F(H_s)$.

Some aspects of the use of the extremal equation for significant wave height predictions will be commented in the following sections.

5.- STATISTICAL INDEPENDENCE

One of the basic hypothesis on which the extremal model that is being used here was built, is the independence between "statistical trials". This means randomness in the presentation of exceedances. The practical adequacy of this hypothesis must be inquired.

When the crest of an exceedance is long, it usually follows a sinuous pattern rather than a smooth curve (Fig. 56, case B). These secondary peaks are obviously interdependent. Should this feature be dominant along the entire range of values of the variate, the use of the model would become rather difficult. Fortunately the crests of the exceedances which reach high levels of the variate are typically pointed, leaving little room for secondary oscillations. In order to check in a real case the quantitative influence of this effect, one year of H_s observations in Bilbao (April 1976-April 1977) has been used to compute 3 different estimates of $n(H_s)$: a) using the entire H_s -course unmodified (analyzed by computer); b) using the H_s -course where secondary peaks have been suppressed by a slight smoothing (hand made) of the exceedances; c) deep smoothing of the exceedances. The result (Fig. 57) are three straight lines which run quite parallel. Thus the relative difference between the three estimates steadily diminishes with increasing levels of the variate. At H_s levels relevant for extremal predictions, the predictions calculated with any of these $n(H_s)$ estimates are practically identical.

The distinction between these secondary peaks and proper exceedance curves is not always neat. Sometimes (Fig. 56, case A) crests with good sizes lie close to each other in a way that suggests some kind of inter-dependence. In this respect, it can be remembered that P. Rijkooort and J. Hemelrijk (1957) found proof of statistical dependence between storms in the North Sea. Again it can be argued that this dependence loses importance with increasing levels of the variate. At medium and long return periods the exceedances appear typically as isolated, well-spaced peaks. This seems to be the general behaviour of geophysical variates. In (1) some real records are shown which illustrate his statement, and two comparisons between extremal predictions and extremal samples for the variates average wind speed and total rainfall in an interval show good agreement even for low return periods. It is unfortunate that accurate (instrumental) extremal samples of H_s are not available with enough length to make similar checks, but in principle there are no reasons to assume a too different behaviour for this variate.

6.- HYPERANNUAL CYCLICITY

The extremal distribution has been stated here on a yearly basis (probability of not-exceedance in the average year). The use of this probability in terms of return periods implies the assumption of randomness in the intensity of the variate in different years. The adequacy of this hypothesis should be questioned.

Numerous authors have found significant evidences of some kind of periodicity (more properly called "pulsations") in several geophysical variates. These pulsations are generally thought of as being connected with the 11-years cycles found in the solar activity. Pulsations of about 11 (or 22) years in the maxima of the variate should not appreciably influence the practical use of predictions made on an average-year basis, since usual design return periods have an order of magnitude of hundreds of years. However, it can still be questioned whether the estimates of $n(x)$ and $F(x)$ (with which the extremal prediction is calculated) are random from year to year. Should they be subject to pulsations, a minimum

(FIG. 58)

(FIG. 59)

(FIG. 67)

(FIG. 69)

(FIG. 68)

(FIG. 70)

observation period of those 11 or 22 years would be needed for a proper characterization of the "average year". Long duration instrumental records are still missing, but the visual observations of wave height in the Weather Ships (more than 20 years) will be used to get some information. In Fig. 63, the wave height corresponding to probability $F(H_s) = 0,5$ in the distribution observed each year (October-October) are plotted for six Weather -- Ships. Clear grouping of higher and lower heights appears in most of them, with semi-periods curiously near -- to the 11 years above mentioned. Extremal distributions were computed for the six W.S. with each yearly estimate of $F(H_s)$, $n(H_s)$ (1). In Figs. 64, 65, the points corresponding to $T=100$ years in each prediction are -- plotted, showing that in some Ships there is no trace of grouping and where grouping may seem to be detected it does not keep in correspondence with the groupings observed in Fig. 63. Although the quantitative value of -- these estimates does not seem to be high (next section), the qualitative pattern obtained suggests that cycli city does not have a significant influence in the extremal predictions of H_s .

7.- SUFFICIENT ESTIMATES OF $n(H_s)$ AND $F(H_s)$

Even assuming that the hypothesis of annual randomness is reasonable in practice, still remains the problem of determining which is the minimum observation time necessary to obtain acceptably accurate estimates of the extremal distribution, i.e. how many years are enough to get a good estimate of $n(H_s)$. Recent works assume that one single year of observation is enough to yield the average year in terms of $F(H_s)$. However this -- hypothesis has never been sufficiently checked, and the main reason to keep it is probably the tight time li mits which are customary in actual projects. In Figs. 58, 60, the observed distributions for each year in Osborne Head (5 years) and Bilbao (2 years) are compared with the distributions fitted to the complete sets of observations. In Figs. 59 and 61 the same comparison is carried out with the parameter $n(H_s)$. In Fig. 62 the extremal predictions computed from each 1-year estimates are plotted. For $T=500$ years (10% risk of exceedance in 50 years), the difference between the higher and lower predictions is 1,3 m. at Osborne Head ($\pm 5,72$ of the intermediate value), and 3,7 m. at Bilbao ($\pm 13,62$). Although the number of years worked out is too small for stating general conclusions, the results might be indicative of two wave climates with different degrees of -- homogeneity. Anyway the dispersion of results obtained for Bilbao represents a heavy influence on the design of maritime structures and shows the need for wider comparative studies of this kind in various ocean areas.

The comparisons made for Bilbao and Osborne Head show reasonable agreement between the yearly estima tes of $n(H_s)$. The differences obtained in the extremal predictions are almost exclusively due to the different yearly estimates of $F(H_s)$. Furthermore, it can be easily showed (1) that $\Phi(x)$ is far more sensitive to varia tions of $F(x)$ than of $n(x)$.

Figs. 64, 65 show a large variability of the yearly estimates of $\Phi(H_s)$, much in excess than what was observed in Fig. 62. Moreover the yearly estimates of $n(H_s)$ (showed in (1)) also show a high dispersion, in -- contrast with the behaviour of Figs. 59, 61. This suggests a deficiency in the visual observations of wave -- height. It seems that a higher number of $n(H_s)$ values than a year includes is necessary to get an acceptable approximation of $n(H_s)$, and that a higher number of observations of H_s is needed than what is usually performed in a year, in order to get an acceptable estimate of $F(H_s)$, in that year (aside from the variability of -- both parameters from year to year). It can be concluded that 1-year of visual observations do not suffice to obtain useful extremal predictions of wave height.

With the aim of reducing as much as possible the time of observation, some published works use only a "winter season" (often the roughest 6 months of the year) of measurements in order to estimate the upper ta il of $F(H_s)$. In Figs. 66, 67, 69, estimates of $F(H_s)$ and $n(H_s)$ in the "winter season" (October-March) and "sum mer season" (April-September) during one year in Owers Lightvessel and 2 years in Bilbao, are compared with -- the estimates obtained with complete years. Both stations were selected for the completeness of their observa tions. The resulting extremal predictions are compared in Fig. 70: The "winterly" predictions are higher (for $T=500+1,8$ m. at Bilbao and 0,5 m. at Owers L.). This is a natural consequence of having used the same distribu tion (Exponential) for the "winterly" and "yearly" estimates: since not all the H_s values of the "winter sea son" are higher than the values of the "summer season", the slope of the exponential line for the winterly es timate is steeper than for the whole year estimate. "Winterly" predictions are bound to stay systematically -- higher than yearly ones, unless distribution functions are used which can be made to converge in their upper tails (different functions, or maybe variable-parameters functions). This possibility is above our present kno wledge of the behaviour of geophysical variates. It must be indicated that the use of more flexible functions may worsen the situation: when the Weibull distribution was used instead of the Exponential, the difference be tween predictions was 2,0 m. for Owers Lightvessel.

The different $n(H_s)$ estimates did not appreciably account for the variability in extremal predictions. However, the "winterly" points form a peculiar double arch above (higher durations) the complete-year line. The same pattern can be seen in Fig. 68 corresponding to 6 "winterly seasons" recorded by rescue ship "Famita" -- (North Sea). These points do not show the linear trend which was clear in the complete-year estimates.

ACKNOWLEDGEMENTS

This paper is a resume of a part of the Doctoral Thesis presented by the author to the Faculty of Civil Engineering at Santander (Spain). The study, published in (1), was carried out at the Laboratorio de Puertos -- "Ramón Iribarren" within a research program on wave climate. The author wishes to thank the kind help of W. Bar ird and D. Birrell (Mar. Direct., (Canada), L. Draper (I.O.S., U.K.), L. Bows (K.N.M.I., Netherlands), E. Cirujeda (C.E.H., Spain), H. Allen (L.N.H.C., France) and L. Tejedor (Thalassa, Spain) in the acquisition of data; V. Fernán dez Dupuy for providing free use of the excellent computer facilities of Intessa (Madrid); J. Conde and A. Arcilla (Lab. de Puertos) for their critical reading of the manuscript. The necessary computer programs were com pletely done by staff of Intessa.

CHAPTER 15

DEEPWATER DIRECTION FROM AN INTENSITY ARRAY

Alan L. Higgins*
Richard J. Seymour**

I. INTRODUCTION

Knowledge of the distribution of wave intensity along a shoreline can be used to infer deepwater directional information for non-locally generated waves. Measurement of this energy distribution may be accomplished using a network of widely spaced nearshore wave gages known as an intensity array. Analysis for intensity array data uses the principle that deepwater swell of a given frequency produces varying patterns of nearshore wave intensity, which depend on the unrefracted directional energy distribution for that frequency. Assuming linear wave propagation to the measurement sites, this dependence may be inverted and applies at all frequencies. Energy spectra measured at the intensity array may be used in this manner to estimate the deepwater directional spectrum. In Part II, details of the relationship between deepwater directional spectrum and nearshore energy spectra are discussed. In Part III, intensity array data are applied to detection of waves incident within a narrow directional interval. Part IV describes the application of an intensity array to detection of long period southern swell in San Diego, California. Comments regarding the relative merits of the method follow in Part V.

II. THEORY

From measured bathymetry offshore of the array, refraction diagrams may be prepared for all frequencies and directions of interest, using linear wave theory. For each such diagram and at each gage site, the ratio of energy at the gage site to deepwater energy is determined. These amplification factors may be calculated from ray spacings or by analytic means.

Consider an intensity array whose gages are located at x_i ($i = 1, 2, \dots, N$). For each frequency f , a directional distribution will be calculated at a discrete set of directions, θ_j ($j = 1, 2, \dots, M$). Denote the amplification factors $a_{ij}(f)$ and suppose a deepwater directional spectrum $d_j(f)$ produces measured nearshore energy spectra $e_i(f)$, where i and j are position and direction indices, respectively. Since the propagation is linear,

$$e_i(f) = \sum_j a_{ij}(f) d_j(f)$$

In matrix form,

*Scripps Institution of Oceanography, UCSD, La Jolla, California

**California Dept. of Navigation and Ocean Development, Scripps
Institution of Oceanography, UCSD, La Jolla, California

$$\begin{bmatrix} e_1(f) \\ e_2(f) \\ \vdots \\ e_N(f) \end{bmatrix} = \begin{bmatrix} a_{11}(f) & a_{1M}(f) \\ \vdots & \vdots \\ a_{N1}(f) & a_{NM}(f) \end{bmatrix} \begin{bmatrix} d_1(f) \\ d_2(f) \\ \vdots \\ d_M(f) \end{bmatrix} \quad \text{or } \underline{e} = \underline{A} \underline{d}$$

For an array of fixed size ($N = \text{const}$), the choice of M is a compromise between angular resolution and smoothing which may be required for stability of the directional distributions. For the case $N = M$, no smoothing is employed. The matrix $\underline{A} = \{a_{ij}\}$ may be inverted to solve for \underline{d} ,

$$\underline{d} = \underline{A}^{-1} \underline{e}. \quad \text{equ. 1}$$

For $N > M$, the linear equations $\underline{e} = \underline{A} \underline{d}$ are overdetermined. One must then seek a solution \underline{d} which approximately satisfies all equations. Define an error vector $\underline{\epsilon}$ by

$$\underline{\epsilon} = \underline{A} \underline{d} - \underline{e}.$$

Minimization of the sum squared error $\underline{\epsilon}^T \underline{\epsilon}$ (see Claerbout, 1976) results in the least squares estimate

$$\underline{d} = (\underline{A}^T \underline{A})^{-1} \underline{A}^T \underline{e}. \quad \text{equ. 2}$$

For each frequency at which this computation is repeated, goodness-of-fit is measured by

$$\underline{\epsilon}^T \underline{\epsilon} = \underline{e}^T \underline{e} - \underline{e}^T \underline{A} \underline{d}.$$

III. UNIDIRECTIONAL WAVES

The assumption that directional distributions are unimodal and narrow makes it possible to estimate incidence angles with an intensity array containing only a few gages. Theoretical proportions of energy at the set of measurement sites are calculated from refraction diagrams as described in Section II. For a given frequency, these proportions vary as a function of the assumed deepwater direction. An estimated direction is chosen for which the theoretical proportions are in closest agreement with measured proportions.

As a measure of agreement, various correlation coefficients are available. The standard product moment coefficient is given by

$$\phi^2 = \frac{\sum_{i=1}^N (m_i - \bar{m})(t_i - \bar{t})^2}{\sum_{i=1}^N (m_i - \bar{m})^2 \cdot \sum_{i=1}^N (t_i - \bar{t})^2}$$

where m and t denote measured and theoretical energies, respectively, and overscoring indicates quantities averaged over all gages. The use of this coefficient emphasizes the relationship of energy proportions which differ greatly from the mean.

When the amplification factors provided by linear refraction theory are of questionable quality, it is desirable to employ a correlation measure which is relatively insensitive to parameter errors. One nonparametric measure having this robust property is Spearman's rank-difference coefficient. For its application, the gage sites are ranked both in order of measured energies and theoretical energies. Spearman's coefficient is based entirely on the difference in ranking and is not severely effected by wild observations or erroneous parameters.

IV. APPLICATION

A four-gage intensity array presently exists in the county of San Diego, California under the operation of the California Coastal Engineering Data Network (Seymour and Sessions, 1976). Data from this array were applied to detection of swell produced by equatorial storms or by storms in the South Pacific. Ships observations of meteorological data for these areas are sparse and as a result, hindcasts are not available. This study was supported by the California Coastal Commission to provide wave climate data for development of engineering structures on south-facing coastline segments.

The array spans 37 miles, with gages at Imperial Beach, Ocean Beach, La Jolla and Oceanside. Bathymetric charts for this region were used by the Los Angeles District of the Army Corps of Engineers to prepare refraction diagrams. Approach azimuths were considered from 180° to 230° in 10° increments. Periods mapped were 14, 16, 18 and 20 seconds. From these diagrams, 96 ($4 \times 4 \times 6$) amplification factors were estimated by graphical means. In this process, a weighted average of ray separations around the gage sites was used, discarding those rays which produce crossings.

The diagrams were generated by the Delaware-Dobson method and do not take account of such non-linear effects as dissipation and diffraction. Therefore, behavior of waves travelling near islands or other types of aberrant bathymetry or over long shallow shelves is not accurately described.

The technique of Section III was applied to obtain product-moment and rank-difference correlation coefficients for long period swell from the southwestern quadrant. An event was defined as exceedance of an arbitrary threshold of 0.90 by both coefficients. Given an event, the amplification factors are assumed to be known and the deepwater energy can be estimated. For each gage,

$$a_i d = e_i, \quad i = 1, N.$$

Minimization of the sum squared error

$$\sum_i (e_i - a_i d)^2$$

gives the least squares estimate of d as a weighted average.

$$d = \frac{\sum_i a_i e_i}{\sum_i a_i^2}$$

Evaluation of the array performance is difficult in the absence of ground truth measurements. Some concurrent data do exist from a five-element linear array operated by the Shore Processes Laboratory at Scripps Institution of Oceanography (Pawka, et al., 1976). The location of this array is not ideal since it is sheltered from southern swell by Point La Jolla. Also, spectral instability associated with limited record length produces large directional ambiguity, particularly in the southwestern quadrant. Comparison for one simultaneous run is shown in Figure 1. Southern swell is refracted offshore of Point La Jolla and again enters deep water over La Jolla Canyon before reaching the linear array. Directions on the abscissa of Figure 1 account for only the latter refraction and should not be compared directly with azimuths listed for the intensity array. However, the general trend can be seen.

Directional spectra for the entire year of 1973 is available from a similar four-element linear array. Peaks of these spectra corresponding to southern swell were picked out. The number of these peaks is compared month-by-month in Figure 2 with events detected in 1977 by the intensity array. Entries on this graph are total events per month divided by the number of days per month in which equipment was operational.

V. CONCLUSION

Records from the individual gages of an intensity array have the intrinsic value of providing local wave climate data at a number of locations. Data processing for the array, as described in Section III, is much simpler and results directly in a deepwater directional spectrum. An additional advantage over coherent arrays is that intensity array estimates appear to exhibit greater directional stability for short periods.

The intensity array method is ad hoc in the sense that confidence intervals are not available. Erroneous amplification factors bias the directional estimates in a data dependent manner. Computation by the method of Section III suffers the obvious difficulty of being invalid for non-narrow directional distributions.

Site selection for intensity array gages is both important and difficult. One objective is to choose a set of unique locations for which the matrices of amplification factors, A in Equation 1 or $A^T A$ in Equation 2, are non-singular and well-conditioned. On the other hand, restriction must be made to sites at which wave propagation is practically linear.

CHAPTER 16

NATURAL WAVE TRAINS: DESCRIPTION AND REPRODUCTION

H. Lundgren¹ and S. E. Sand²

ABSTRACT

In many applications there is a great need for a correct description of the natural, irregular three-dimensional sea and its reproduction in physical and numerical models. Because of the tremendous difficulties inherent in the nonlinearities, the science of coastal engineering is still very far from this ultimate goal.

Indeed, the scope of this paper is comparatively very modest: To describe and reproduce natural, irregular two-dimensional waves, i.e. waves propagating in one direction in a flume. In addition, this scope is fulfilled only by assuming linear superposition of Fourier terms.

As opposed to the usual spectral description, the deterministic description presented here does not eliminate the phase information in the wave train recorded. Because of the nonlinearities, however, the linear deterministic description invariably degenerates with the distance travelled by the waves. It appears though from the present paper that the degeneration is fairly slow even for rather steep waves.

1. INTRODUCTION

Traditionally, irregular waves are represented by their spectra. For a number of applications, however, the main interest lies in the lengths of groups of higher waves and in the wave shapes. This is certainly true for the stability of rubble mounds, shock forces, rolling and pitching of ships, wave drift forces, and generation of long waves. Hence, for the last decade the Danish Hydraulic Institute has emphasized the reproduction of natural wave trains (Ref. 4).

As a consequence of this philosophy, it is desirable in some cases to use a deterministic description instead of the stochastic one, with a view also to a deterministic reproduction.

2. DETERMINISTIC DESCRIPTION

In principle, when progressive waves in a flume are recorded at one point, the time series of all other quantities (such as eleva-

¹Professor of Marine Civil Engineering, Institute of Hydrodynamics and Hydraulic Engineering (ISVA), Technical University of Denmark, DK-2800 Lyngby. - Consultant, Danish Hydraulic Institute.

²Ph.D.-student, ISVA, Technical University of Denmark.

tions, orbital velocities and pressures) are defined down along the flume. The present theory is based upon a linearized decomposition in a Fourier series, so that each component propagates independently.

Let the waves $\eta(x,t)$ be recorded at $x = 0$ as the wave train $\eta(0,t)$. It is desired, for example, to calculate the time series $p_b^+(x,t)$ of the bed pressure (in excess of hydrostatic pressure) at a fixed distance x from the wave recorder. p_b^+ may be expressed as

$$p_b^+(x,t) = \gamma \sum_{n=1}^{\infty} \frac{a_n \cos(nft - k_n x) + b_n \sin(nft - k_n x)}{\cosh k_n h} \quad (1)$$

where a_n, b_n are the Fourier coefficients belonging to a finite interval, $|t| < t_0$, of the recorded wave $\eta(0,t)$, $f = \pi/t_0$, h is the water depth, and k_n is the wave number corresponding to the circular frequency nf .

a_n, b_n may be found from the usual integral expressions

$$a_n = \frac{1}{t_0} \int_{-t_0}^{t_0} \eta(0,\tau) \cos n f \tau \, d\tau \quad (2a)$$

$$b_n = \frac{1}{t_0} \int_{-t_0}^{t_0} \eta(0,\tau) \sin n f \tau \, d\tau \quad (2b)$$

which, inserted in Eq. (1), give

$$p_b^+(x,t) = \gamma \sum_{n=1}^{\infty} \frac{f}{\pi} \int_{-t_0}^{t_0} \frac{\eta(0,\tau) \cos(nf\tau - nft + k_n x)}{\cosh k_n h} \, d\tau \quad (3)$$

Here, the order of integration and summation is inverted. If, in addition, $t_0 \rightarrow \infty$, the basic frequency f may be replaced by $d\omega$ and nf may be written $nf = \omega$, leading to the convolution integral

$$p_b^+(x,t) = \gamma \sqrt{g/h} \int_{-\infty}^{+\infty} P(\tau-t, x) \eta(0,\tau) \, d\tau \quad (4)$$

where

$$P(\tau-t, x) = \frac{1}{\pi} \sqrt{h/g} \int_0^{+\infty} \frac{\cos[(\tau-t)\omega + k_\omega x]}{\cosh k_\omega h} \, d\omega \quad (5)$$

and k_ω is the wave number corresponding to ω and h .

For $x = 0$ Eqs. (4+5) give the bed pressures at the point, where η is recorded. $P(\tau-t, 0)$ is shown as a function of $(t-\tau)\sqrt{g/h}$ in Fig. 1.

The curve gives a clear impression of how the bed pressures $p_b^+(0,t)$ are influenced by the elevations $\eta(0,\tau)$, and, as could be expected, the weighting of $\eta(0,\tau)$ is such that $\tau = t$ has the maximum influence on the bed pressure at time t .

Using the same procedure as above, formulae for all other quantities along the flume, such as elevations, orbital velocities etc., may be derived. Each quantity can be expressed as an integral

$$\left(\frac{g}{h}\right)^\alpha \int_{-\infty}^{+\infty} (\text{influence function}) \cdot \eta(0,\tau) \, d\tau \quad (6)$$

Fig. 1. Dimensionless influence function $P(\tau-t, 0)$

Some dimensionless influence functions are given below:

For water surface elevations:

$$E(\tau-t, x) = \frac{1}{\pi} \sqrt{h/g} \int_0^{\infty} \cos [(\tau-t)\omega + k_{\omega}x] d\omega \quad \alpha = \frac{1}{2} \quad (7)$$

For bed velocities:

$$U(\tau-t, x) = \frac{1}{\pi} \frac{h}{g} \int_0^{\infty} \frac{\omega \cos [(\tau-t)\omega + k_{\omega}x]}{\sinh k_{\omega}h} d\omega \quad \alpha = 1 \quad (8)$$

For bed pressures:

See Eq. (5).

$P(\tau-t, x)$ is shown as a function of $(t-\tau)\sqrt{g/h}$ in Fig. 2 for two values of x/h .

Fig. 2 shows that the main loop of P is shifted to the right when x is increased. Hence it follows from Eq. (4) that the main influence of $\eta(0, \tau)$ on the pressure $p_b^+(x, 0)$ for $t = 0$ originates from increasing negative values of τ when x increases, i.e. for increasing x the useful information is found earlier in the time series $\eta(0, \tau)$.

Fig. 2 also illustrates how far back in time it is needed to know η in order to obtain a certain accuracy. For larger values of x the oscillations of P have longer 'wave lengths' and decrease more slowly, due to the influence of the higher frequencies.

Fig. 2 Dimensionless influence function $P(\tau-t, x)$

In Fig. 3 the influence function, $E(\tau-t, x)$, for surface elevations will be seen as a function of $(t-\tau)\sqrt{g/h}$ for two values of x/h . As compared with the P-function in Fig. 2, the E-function decreases much more slowly with large values of $t-\tau$. This slow decrease is due to the higher frequencies (for which the bed pressures are strongly damped). At the same time the 'wave lengths' of the E-function decrease so rapidly that it is not too essential to extend the integration in the convolution integral for $\eta(x,t)$ very far in the direction of negative τ .

Fig. 3 Dimensionless influence function $E(\tau-t, x)$

3. TESTS ON DETERMINISTIC DESCRIPTION

The theory of deterministic description was tested in a flume ($h = 0.40$ m) with the input wave gauge at $x = 0$ and pressure cells mounted in the bottom of the flume at $x = 0$, $x = 4.5$ m and $x = 8.98$ m. The wave trains used for the tests had mean periods of 0.84 s, 1.02 s and 1.72 s, respectively, i.e. mean wave lengths of 1.09 m, 1.58 m and 3.4 m. The maximum steepness ranged from 2% to 8%.

The record $\eta(0, \tau)$ was used as input in Eq. (4) together with one of the influence functions in Fig. 2. Fig. 4 demonstrates that the calculated output $p_b^+(x, t)$ agreed reasonably well with the recorded one for $x = 8.98$ m.

Fig. 4 Calculated and measured bed pressures at $x = 8.98$ m

Fig. 5 Calculated and measured elevations at $x = 8.98$ m

Also the elevations along the flume were tested at $x = 4.5$ m and $x = 8.98$ m. Again, the record $\eta(0, \tau)$ was used as input in Eq. (6) which, together with one of the influence functions in Fig. 3 gave $\eta(x, t)$. Fig. 5 shows the elevations for $x = 8.98$ m.

At a given position the agreement between measured and calculated elevations was the same for all tests. It was found, however, that the deviations increased with x , due to nonlinear interactions.

4. DETERMINISTIC REPRODUCTION

For the generation of small, regular waves the exact transfer function was in essence derived in 1929 by Havelock (Ref. 5) and presented to the engineering world in 1951 by Biésel (Ref. 1) in the following form

$$H = \frac{2 \sinh^2 kh}{\sinh kh \cdot \cosh kh + kh} \cdot 2e = \frac{2 \tanh kh}{1 + G} \cdot 2e \tag{9}$$

where $2e$ is the stroke of the piston.

For the generation of waves with a given spectrum Eq. (9) has been directly applied (Refs. 2-3).

For the generation of natural waves in fairly shallow water an approximate transfer function was applied by the senior author (cf. Ref. 4) with the specific purpose of reproducing, in a short flume, shock forces on vertical face breakwaters.

The scope of the deterministic reproduction has been to generate a given natural wave train in arbitrary depth in a flume at a distance x_0 from the piston. This has been achieved by means of Eq. (9) in combination with the theory of deterministic description presented above, x being equal to $-x_0$ for calculation backwards to the paddle.

From the Fourier series of the recorded natural wave train $\eta(x_0, t)$, the amplitude and phase for each frequency is, by means of Eq. (9), transformed into a contribution to the piston position.

Thereafter, the procedure is completely analogous to the one described in Sec. 2, resulting in the following convolution integral for the piston position

$$x_p(t) = \sqrt{g/h} \int_{-\infty}^{+\infty} X(t-\tau, x_0) \eta(x_0, \tau) d\tau \tag{10}$$

where the influence function is

$$X(t-\tau, x_0) = \frac{1}{2\pi} \sqrt{h/g} \int_0^{\infty} \frac{1 + G}{\tanh kh} \sin [(t-\tau) \omega + k x_0] d\omega \tag{11}$$

with $k = k(\omega)$. The X -function is shown in Fig. 6 for $x_0/h = 5.56$ and may be interpreted in a way similar to Fig. 3.

Fig. 6 Dimensionless influence function $X(t-\tau, x_0)$

5. TESTS ON DETERMINISTIC REPRODUCTION

The theory of deterministic reproduction was tested in a flume ($h = 0.36$ m) with a wave gauge mounted $x_0 = 2$ m from the piston. At this position it was attempted to reproduce various wave trains from Hanstholm, Denmark.

In addition, the piston positions were recorded as a feed back signal to be used as the basis for a calculation of expected elevations at point x_0 in the flume. For the latter purpose Eqs. (10) - (11) are easily inverted, yielding the surface elevations with the piston motion as input. As stated by Biéssel (Ref. 1) one must be aware of the local disturbances at the generator. The local oscillations at the piston are, however, already reduced to one percent at a distance of three water depths from the piston.

Hence, the test procedure was:

- (a) calculate the piston positions x_p on the basis of a natural wave record,
- (b) by means of the feed back signal calculate the expected elevations at x_0 .

Fig. 7 illustrates the close agreement between the values $\eta(x_0, t)$ actually reproduced in the flume and the values calculated from the actual piston motion x_p . (The latter deviated slightly from the desired piston motion because of the imperfect control of the hydraulic power system.)

Fig. 7 Calculated and measured elevations at $x_0 = 2$ m

6. FUTURE DEVELOPMENTS

The encouraging results obtained with the linear two-dimensional theory makes it attractive to extend the theory to nonlinear terms and to three dimensions.

CHAPTER 17

WAVE LENGTH, WAVE VELOCITY AND SHOALING CHARACTERISTICS OF RANDOM WAVES

Akira Kimura* and Yuichi Iwagaki**

ABSTRACT

Fundamental properties of random waves determined by the zero-up-cross method are discussed. Firstly, the wave length and the wave velocity are treated. Experiments are carried out with some supplemental definitions such as the spatial zero-up-cross method in a laboratory wave tank. Average values of K (= a ratio of measured wave length to theoretical one L_e/L_{th}) and R (= a ratio of measured wave velocity to theoretical one C_e/C_{th}) are very close to unity though data are considerably scattered. But the relations between $L_e \sim T_e$ and $C_e \sim T_e$ are slightly different from the theoretical ones where T_e is the measured wave period. Secondaly, breaking characteristics on sloping beaches are treated. The wave height H_b , the wave length L_b and the water depth h_b are measured at a breaking point. Breaking characteristics of random waves are considerably different from those of periodic waves. The measured wave height-water depth ratio H_b/h_b is plotted against the water depth-wave length ratio h_b/L_0 about 30 ~ 40% below the breaker inception curve for periodic waves.

INTRODUCTION

There are two method of analysis for random sea waves. One is a wave spectrum analysis and the other is an analysis by the wave statistics. The zero-up-cross method is the most general one to treat the wave statistics. It has been considered that the method of wave spectrum analysis is supported by the small amplitude wave theory, but analysis by the zero-up-cross method are convenient to some extent. But recently the authers showed that the spectrum analysis method is not theoretically supported for random waves in a shallow-water region [Iwagaki and Kimura (1977)]. And the spectrum analysis method is not applicable also for discontinuous phenomena such as wave breaking, overtopping and etc. On the other hand, the analysis by the zero-up-cross method seems to be empirically usefull for treating these discontinuous phenomena. But this method does not have analytical bases and very few studies have examined the validity of this method. Then fundamental studies on properties of zero-up-crossing waves are desired to know the effectiveness of this method of analysis

WAVE LENGTH

It is very difficult to measure the random wave length because no apparent scale or level line for measurement is available in the real sea condition. Some times oceanographers measured intervals of successive wave crests on ship sides. This definition of wave length is intuitive and uncertain. Pierson(1954) studied the following theoretical relation between the mean wave length and the mean wave period which are determined by the crest-to-crest method:

$$L_m = K \frac{gT_m^2}{2\pi} \quad (1)$$

and concluded that $K=2/3$ for a uni-directional Neumann spectrum, where g is the acceleration of gravity, L_m and T_m are the mean wave length and the mean wave period of crest-to-crest wave. He assumed that wave length of component waves are equal to those by the small amplitude wave theory. Ewing(1969) studied the theoretical relation between the mean wave length and the mean wave period of crest-to-crest waves for Pierson-Moskowitz spectrum. He introduced directional spectra and concluded that K in Eq.(1) changes from $1/3$ to $3/4$ according to an increase of truncation frequencies in a high frequency region of the power spectrum. But the crest-to-crest method is not natural to determine the wave length, because there are many maxima on the surface of random waves as seen in Fig.1 if the spectrum width is not narrow [Longuet-Higgins(1957)]. The zero-up-cross method seems preferable for a definition of the wave length. In this section, wave lengths determined by the zero-up-cross method are treated.

DEFINITION OF WAVE LENGTH

Generally the wave period is determined from a record measured with a wave gauge at a fixed point. On the other hand, the wave length is usually determined from a photograph. Then it is difficult to treat the wave length and the wave period as properties of the same wave by the difference of definitions, because the random wave profile changes gradually with propagation. Changes of the wave profile is very slight and wave propagation can be easily followed if the distance of propagation is short. Fig.2 shows wave records measured by three wave gauges installed 1m apart in the wave tank. It can be seen that changes of wave records are very small. Then the wave length and wave period of random waves can be determined as those for periodic waves in case when the travelling interval is very short. But as a nature of random waves, wave profiles change gradually. Then following two supplemental definitions are made to determine the wave length and the wave period.

- (1) The wave period is determined from a record measured with the No.2 wave gauge shown in Fig.2 by the zero-up-cross method.
- (2) The wave length is determined from a photograph taken at an instance when the water surface crosses the still water level downward at the No.2 wave gauge.

Fig.1 Definition of wave length

Fig.2 Definition of wave period and wave velocity

Fig.3 Equipments for photographing

EXPERIMENTS

A random wave generator of electro-hydraulic type is installed at one end of a 27m long, 50cm wide and 75cm deep glass sided wave tank. Measurements were carried out in a 4m long interval apart 12m from the wave generator. On the surface of fore-side glass, a 3mm wide black tape was marked to show a still water level and scale marks were placed with the same black tape. Fig.3 shows illustration of the equipment for photographing. Tracing papers were used to make scattered light. Rest part of the glass was covered with black papers to prevent a camera from direct light of lamps. Random waves were generated with a random wave simulation system [Kimura and Iwagaki(1976)]. Fig.4 shows power spectra of random waves used in this study. A photograph was taken at the instant when the water surface crossed the black tape downward at the No. 2 wave gauge. This instant was automatically marked on a chart of the pen-oscillograph which was connected with a flash terminal socket of the camera. Photo-1 shows an example of the wave profile. Wave lengths were analyzed from these photographs by using a film motion analyzer.

EXPERIMENTAL RESULTS

Typical values of the mean wave height H_m , the mean wave period T_m , the significant wave height $H_{1/3}$ and the significant wave period $T_{1/3}$ are shown in Table 1. f_p is the peak frequency of the power spectrum. Measured wave lengths are plotted in Fig.5 (a) ~ (d). Chain lines in these figures mean the theoretical relation between the wave length and the waveperiod by the small amplitude wave theory. About 250 data are plotted in each figure. Data are considerably scattered but tendencies of data seem in average to agree fairly well with the theoretical curves in every cases. And the value of \bar{K} which makes D minimum in the following equation is very close to unity as shown in Table 1:

$$D = \sum [L_e - \bar{K} L_{th}]^2 \quad (2)$$

in which L_{th} is the theoretical wave length by the small amplitude wave theory under the condition that the water depth is 50cm. Then it is known that the wave length and the wave period satisfy the theoretical relation approximately if the discussion is confined only on the mean value. But it can be seen from these four figures that there are little difference between the mean tendency and the theoretical curve if data are examined carefully in detail. The mean tendency of data has slightly mild inclination compared with the theoretical curve. In fig.6 (a) ~ (d), relations of L_e/L_{th} versus T_e of measured data are plotted in each case. Values of L_e/L_{th} decrease gently with increase of T_e in every figures. Fig.7 shows a results of best fit curves with the 3rd order polynomial expression. The approximated curve in each case has slightly mild inclination compared with the theoretical curve. And it is very interesting that each curve does not coincide but shifts upward as f_p decreases.

I-2	1/10	1.0	12
I-3	1/10	1.2	13
II-1	1/20	0.8	21
II-2	1/20	1.0	21
II-3	1/20	1/2	19

Then the wave length of random waves cannot be determined only by the water depth, but f_p or the mean wave period is needed in addition to them. T_c in Table 1 shows the period of intersection between the best fit curve and the theoretical curve.

WAVE VELOCITY

It has already explained that the profile of a random wave is conserved with very small change if the distance of propagation is very short. Then the wave velocity can also be determined by measuring the time spent for a wave crest or a zero-crossing point to propagate a fixed interval. In this section, the velocity of zero-down-crossing point is determined as the wave velocity C_e . The wave gauge interval from the No.1 wave gauge to the No.3 wave gauge divided by $t_A + t_B$ is determined as the wave velocity in this study, in which t_A and t_B are the times spent for the zero-down-cross point to propagate the wave gauge No.1 to No.2 and No.2 to No.3 respectively. The wave period T_e was determined by the zero-up-cross method with the No.2 wave gauge record as before. Same waves as used to measure the wave length were selected to determine the wave velocities. Experimental data are plotted in Fig.8 (a) ~ (d). Data are considerably scattered, but agree fairly well with theoretical curve shown by the chaine line. And R which makes E in the following equation minimum is very close to unity as shown in Table 1:

$$E = \sum [C_e - \bar{R} C_{th}]^2 \quad (3)$$

where C_{th} is the theoretical wave velocity calculated with the wave period T_e by the small amplitude wave theory. Then if discussions are confined only on the mean value, the relation between the wave velocity and the wave period satisfies approximately the theoretical relation by the small amplitude wave theory. But it can be seen from these figures that many of the data are plotted above the theoretical curve in the region where the wave period is small. Fig.9 shows the best fit curves for the plotted data with the 3rd order polynomial expression. The best fit curve is plotted above the theoretical curve in the region where the wave period is small and gradually approaches to the theoretical curve as T_e increases. It is interesting that each curve does not coincide when T_e is small, but shifts slightly upward with increase of f_p . f_p or the mean wave period is needed in addition to the wave period and the water depth to calculate the wave velocity when T_e is small. But when T_e is greater than $1.1T_m$, the wave velocity can be calculated approximately by the water depth and the wave period.

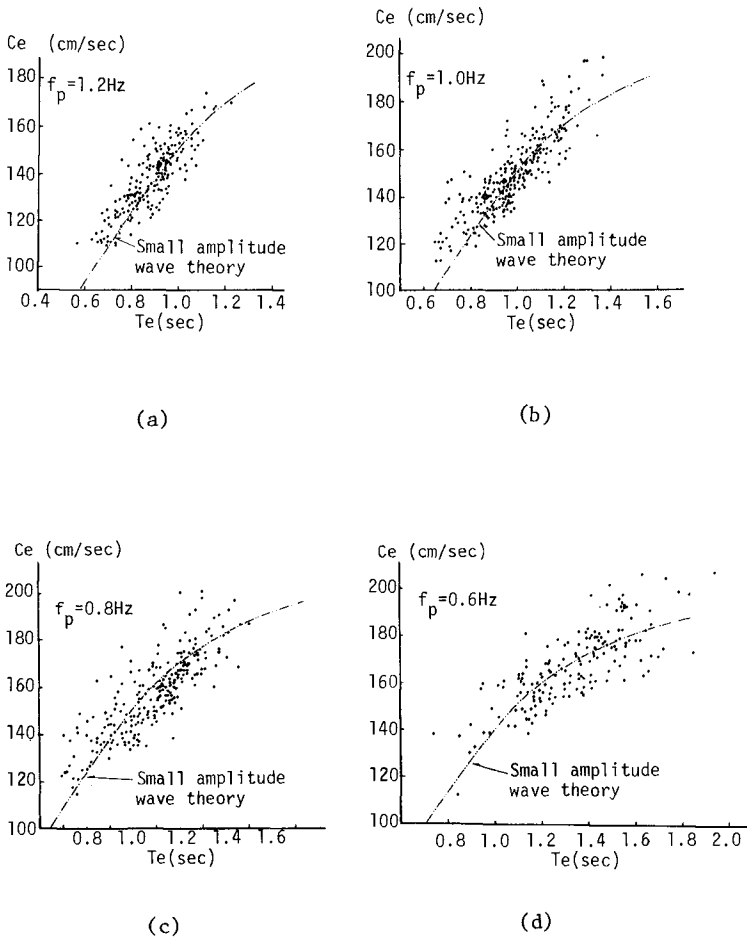

Fig.8 Relations between wave velocity and wave period for random waves

Fig.9 Best fit curves of wave velocity \sim wave period relations for measured data

Fig.10 Wave velocity and group velocity over long distance

Fig.11 Experimental equipments for wave breaking

The results so far are for the wave velocities which are measured in the short distance. Fig.10 shows the records measured with 6 wave gauges installed 2m apart in the wave tank. It can be seen that wave profiles change gradually with propagation, but clear crests are easily followable. Then mean velocities of random waves over a long distance can be also determined. The solid lines show the theoretical wave velocities which are calculated with the mean periods of the wave groups marked as A,B and C above the W-1 wave gauge record. Each line starts from a clear trough at the middle part of the wave group in the W-1 wave gauge record. The solid lines connect the same wave troughs, then wave velocities over the short distance are very close to the theoretical wave velocities. But each line go over gradually the wave group among propagation. The theoretical wave velocities are a little faster than the velocities of wave groups. Broken lines show the group velocities calculated with the same wave periods as those of the solid lines. These broken lines always pass through middle part of the wave groups. Then over the long distance the wave velocity seems to be equal to the group velocity.

BREAKING CHARACTERISTICS OF RANDOM WAVES

Breaking characteristics of periodic waves have been studied theoretically and experimentally for many years. Many significant results were obtained from these studies. And breaking characteristics of random waves have been treated by Collins(1970), Battjes(1972), Kuo et al(1972), Nath et al(1974) and Goda(1975). They discussed changes of mean and significant wave heights or deformation of probability distribution of the wave height by wave breaking under the assumption that breaking characteristics of the zero-up-crossing waves are equal to those of regular waves. Collins used the breaking criterion by Le Méhauté and Koh.

$$H_b/H_0 = 0.76 \lambda^{1/7} (H_0/L_0)^{-1/4} \quad (4)$$

where H is the wave height, L the wave length and λ the slope of the beach, suffix b means the value at the breaking point and suffix 0 in deep water. Battjes used the following theoretical relation by Miche and Hamada:

$$H_b/L_b = 0.142 \tanh(2\pi h_b/L_b) \quad (5)$$

where h_b is the water depth at the breaking point. Kuo et al recommended the following criterion obtained from field observations:

$$H_b/h_b = 0.63 \quad (6)$$

Nath et al used the following equation proposed by Dean:

$$H_b = 0.278 T_b^2 \quad (\text{m-sec}) \quad (7)$$

Goda used the approximate expression of breaker inception proposed by himself for regular waves:

$$H_b/L_0 = A [1.0 - \exp\{-1.5\pi(h_b/L_0)(1.0 - 1.5\epsilon^{4/3})\}] \quad (8)$$

where $A=0.17$.

But the common problem to these studies is the fundamental assumption that breaking characteristics of zero-up-crossing waves are same as those of regular waves. In this section, breaking characteristics of zero-up-crossing waves on a sloping beach are examined experimentally to make clear the above assumption.

EXPERIMENTS

The same wave tank and the random wave generator were used in the experiments. Sloping beaches of 1/10(Case-I) and 1/20(Case-II) were installed in the wave tank and 6 wave gauges(Case-I) or 12 wave gauges(Case-II) were provided with 1m interval on the slope as shown in Fig.11. The water depth at each wave gauge point is shown in Table 2. Measurements were carried out in the interval of 3m long around the breaking point. The water depth changes from 40cm to 10cm in Case-I and from 25cm to 10cm in Case-II in this interval. Same equipments for photographing are provided as shown in Fig.3. A camera and a 16mm movie camera were set 3m apart from the wave tank. Photographs were analyzed and several properties of breaking waves were determined by the following definitions:

- (1) The wave height H_b and the wave length L_b at the breaking point are determined from the photograph taken at the instance of breaking as shown in Fig.12. But the water depth h_b at the breaking instant is determined from the 16mm movie film.
- (2) The period of breaking wave is determined from a record measured by the nearest offshore wave gauge.

These definitions are different somewhat from those for regular waves, but very close values to those by the usual method were obtained at the preliminary experiments. Fig.13 shows the power spectra used in the experiments of which f_p are (1) 0.8Hz, (2) 1.0Hz and (3) 1.2Hz. Hereafter the case number will be expressed as I-1, which means that the experiment was carried with 1/10 slope and random waves of the peak frequency 0.8Hz.

REPRESENTATION OF EXPERIMENTAL RESULTS

The mean water depth of wave breaking measured in each case is

Fig.12 Definition sketch of breaking wave height H_b , wave length L_b and water depth h_b

Fig.13 Power spectra of experimental waves for wave breaking and shoaling

Fig.14 Transformation of power spectrum on 1/10 slope

Fig.15 L_b/L_{th} of regular waves

shown in Table-3. There were very few waves which break in the region where $h > 25\text{cm}$ in Case-I. Most of waves break in the region between the water depth of 25cm and 15cm in Case-II. In both cases very small waves and reproduced waves after breaking break generally in the region where the water depth is less than 5cm. These waves in such shallow region were excluded because they seem to be affected by surf beat phenomena. Breaking type of most waves was of plunging breaker. Spilling type breaking was observed sometimes in the region where $h > 30\text{cm}$. Fig.14 shows an example of transformation of the power spectrum. The water depth changes from 50cm to 10cm in this figure. Where the water depth is larger than 30cm there is no apparent change in the shape of power spectrum. But in the region where h is less than 20cm, the energy of power spectrum around the peak frequency decreases and increases in the regions where $f < 0.4\text{Hz}$ and $f > 1.0\text{Hz}$. This means that sudden changes happened on the water surface in this shallow region.

WAVE LENGTH AT BREAKING POINT

Breaking characteristics of regular waves on 1/10 and 1/20 slopes were examined in the experiments. The breaking wave length L_b is compared with the theoretical one L_{th} in Fig.15. White circles show experimental data on 1/10 slope and black circles show those on 1/20 slope. It can be seen in this figure that the ratio of measured wave length to theoretical one L_b/L_{th} on 1/20 slope are very close to unity but the data on 1/10 slope are plotted considerably above unity. This is because the water depth to calculate the theoretical wave length is determined at the crest phase of the wave as shown in Fig.12. White squares (1/10) and black squares (1/20) show the modified values of L_b/L_{th} , where L_{th} is calculated with the water depth at the center of the wave profile. The data are corrected to some extent. Figs.16(a) and (b) show the experimental results of L_b/L_{th} for random waves in Cases I and II respectively. L_{th} in these figures were calculated with the water depth at the wave crest phase. Many data in Case-I are plotted above the line of unity L_b/L_{th} , but in Case-II many data are plotted below this line as seen in Fig.15. And with respect to the mean tendency of plotted data, L_b/L_{th} decreases as T_b increases in both cases and mean line for each case shifts rightward as f_p decreases. Such tendencies have been observed in Fig.5.

BREAKING CHARACTERISTICS OF RANDOM WAVES

Miche and Hamada gave the breaking criterion for periodic waves shown by Eq.(5). Experimental results of regular waves on 1/10 and 1/20 slopes are compared with Eq.(5) which is shown by the solid line in Fig. 17. The data on 1/20 slope are plotted below the theoretical curve, but the data on 1/10 slope agree fairly well with this equation. The relation between H_b/L_b and h_b/L_b for random waves is plotted in Figs.18(a) for

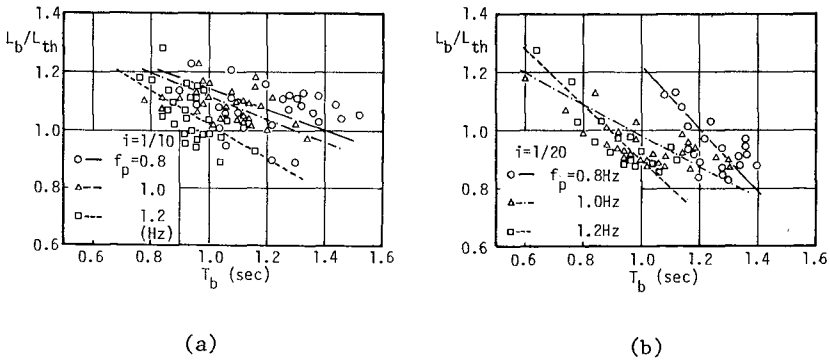

Fig.16 L_b/L_{th} of random waves

Fig.17 Relations between H_b/L_b and h_b/L_b for regular waves

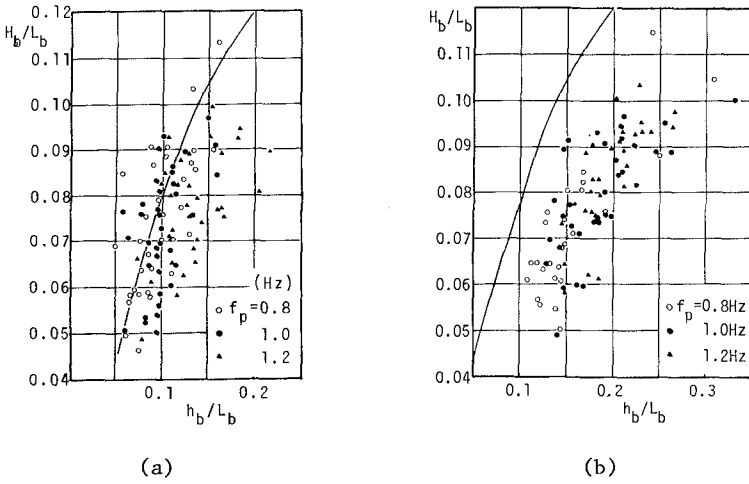

Fig.18 Relations between H_b/L_b and h_b/L_b for random waves

Fig.19 Relations between H_b/h_b and h_b/L_0 for regular waves

1/10 slope, and (b) for 1/20 slope respectively. Mean tendency of data agrees fairly well with the theoretical curve in Case-I, but in Case-II the data are plotted about 30% below the theoretical curve. Then the difference of slope affects largely breaking characteristics of random waves. To estimate the influence of slope, these data are compared with the breaker inception curve by Goda [Eq.(8)]. Firstly, experimental data of regular waves are compared with the breaker inception in Fig.19, in which solid line is for 1/10 slope and the break line is for 1/20 slope. Data are plotted below the lines in both cases. Then experimental results for random waves are plotted in Figs.20(a) and (b). In these figures L_0 is the wave length in deep water calculated with the measured wave period T_b . It is found from both figures that H_b/h_b decreases as h_b/L_0 increases, so that the breaking criterion such that $H_b/h_b = \text{constant}$ for cnoidal waves or solitary wave is not available in this region ($0.03 < h_b/L_b < 0.4$).

Then the effect of slope must be considered for breaking characteristics of random waves as seen in Eq.(8) or Eq.(4). The data are compared with Eq.(8) in Fig.20, in which the data are plotted about 30~40% below the curves in both cases of 1/10 and 1/20 slopes. Then it can be concluded that random wave break easily compared with regular waves. Dotted lines in these figures are modified breaker inception curves with changing A in Eq.(8) from 0.11 to 0.13. It is known that $A=0.12$ for Case-I and $A=0.11$ for Case-II are adequate.

Goda pointed out that changes of the water depth by surf beat affect largely breaking characteristics of random waves. Fig.21 shows the wave records obtained in Case II-1, in which dotted lines express what is called surf beat obtained by cutting off the higher frequency components than 0.35Hz. The mean amplitude decreases as the water depth increases. Apparent surf beat phenomenon cannot be observed at $h=25\text{cm}$. The mean breaking depth of water measured in Case II-1 is 21cm as shown in Table 3, so that the change of water depth by surf beat phenomenon seems to be negligible in this case and also in other cases.

Some other factors will be considered which affect the phenomena of random wave breakings such as unsteady back wash, variation of mean water level due to non-stationary radiation stress and etc. But it is very difficult to estimate the influence of these phenomena because they have not been made clear yet.

CONCLUSION

Fundamental properties of random waves defined by the zero-up-cross method are examined experimentally in a laboratory wave tank, and the following conclusions could be obtained:

The properties such as the wave length and the wave velocity are very close to those of regular waves, but certain properties in wave breaking are considerably different though random waves have their own inherent characteristics. Then it can be finally concluded that the analysis by using the zero-up-cross method is not a conventional method for random waves but an effective method to analyze dynamic properties of random waves. However it is worth mentioning that certain dynamic

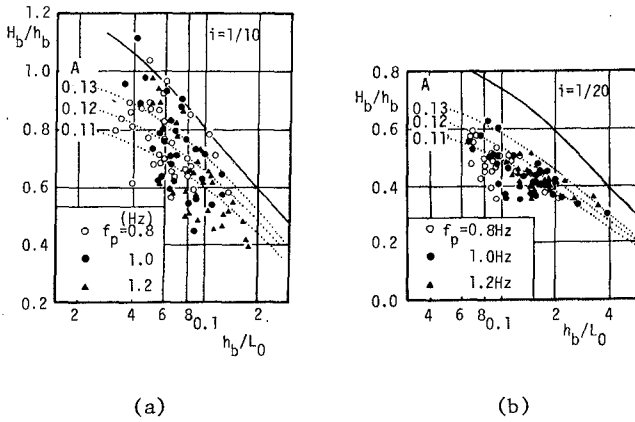

Fig.20 Relations between H_b/h_b and h_b/L_0 for random waves

Fig.21 Surf beats at various water depth

properties of zero-up-crossing waves are considerably different from those of regular waves.

ACKNOWLEDGEMENT

The authors wish to acknowledge to Mr. N.Kishida for his assistant throughout the experiments.

CHAPTER 18

PERIODIC THEORY VELOCITY PREDICTION IN RANDOM WAVE

by John H. Nath¹, F. ASCE and Koji Kobune²

Abstract

Large waves in a series of random ocean waves are considered in the design of ocean structures. When random structural vibrations can be ignored, periodic wave theories are used to predict the water particle kinematics for a design wave even though the real wave is irregular. This paper presents the authors' first attempt to quantify the validity of using periodic wave theory for random waves. Measurements of maximum horizontal and vertical velocities were made in laboratory generated periodic and random waves. They compared favorably with predictions from periodic wave theories (even with Airy theory) particularly for the large waves in a series. Since the design wave concept is applied to the largest waves, the conclusion is that periodic wave theory may be adequate, providing an appropriate factor of safety is used to account for the differences between the actual maximum wave kinematics in nature and those in the predictive theory.

1.0 INTRODUCTION

Presented herein is a part of a continuing program of study at Oregon State University to determine the wave kinematics and dynamics in a closed system wave flume with experimentation and theory. Mass transport is also being studied and a first report on that subject is included in (8). For example, it is known that in wave flumes circulation patterns of mass transport must occur, the configurations of which are time dependent. How much these circulations affect the waves, and thus the experiments which depend on them, is not yet known. However, in the region in which measurements were made for this study, it is felt that the influence of circulation within the flume was small. Therefore, it was assumed to be negligible.

1.1 Purpose and Scope

The purpose of the work was to make measurements of water particle kinematics in individual random waves and to compare the results with predictions from periodic wave theory. The scope of the work included measurements of the maximum horizontal velocities under the crests and troughs of periodic and random waves and the vertical velocities at approximately the nodes. These measurements are compared with theoretical predictions and the errors are examined statistically. We estimate that the random waves in the laboratory have characteristics that are close enough to real ocean waves that the results can be applied to design conditions.

At least two methods have been developed to represent random ocean waves for the prediction of wave forces on marine structures. One is the conventional method which uses the design wave concept designated by

¹Professor and Director of Environmental Fluid Dynamics Laboratory, Oregon State University, Corvallis, Oregon 97331, USA.

²Chief, Storm Surge and Tsunami Laboratory, Hydraulic Eng. Division, Port and Harbour Research Institute, Japan.

height (H_D) and period (T_D) and direction. The other utilizes the mean square spectral density of the water surface fluctuation which is herein called the wave spectrum. The latter method is important for the dynamic analysis of marine structures, such as relatively flexible offshore oil facilities. Short, stiff offshore oil facilities and massive structures, such as sea walls and breakwaters, are not very dynamically responsive to the waves and can, therefore, be treated with the design wave approach. The dynamic stability and fatigue characteristics of relatively flexible structures should be examined against the continuous random wave action. However, stiff structures can be designed as if the maximum wave loads are applied in a static manner.

The design wave technique includes considerations for the water depth, h , the wave height, H , and the period, T , which are determined on the basis of a statistical study. Wave records, hindcasting, experience and judgment are utilized. The design wave height is usually a large, rare value, and is sometimes specified as the "one hundred year wave" or something analogous thereto. The design wave should be defined as the largest wave to which the structure is likely to be subjected in its lifetime. On the other hand, the probability distribution of wave magnitudes can be estimated for a site for the lifetime of the structure and the design decision is focused on selecting a probability level beyond which the chances of having a higher wave are very small. The wave size at this probability level then becomes the design wave.

The water kinematics within such a wave are estimated by fitting a periodic wave to the profile and using an appropriate periodic wave theory. However, the design wave in nature will have an irregular profile and the kinematics may be different from those for a periodic wave.

Thus, the purpose of this study can be restated to be to examine the validity of using periodic wave theory for the design wave method, by estimating the error to be expected when a periodic wave theory is used to predict the water kinematics within a particular random wave.

1.2 Literature Review

Because of the difficulty of making Eulerian measurements of water particle velocities, few experimental studies on water kinematics of *random* waves have been reported.

Iwagaki, et. al., (4) measured water particle velocities of random waves utilizing a sonic doppler current meter. They found that Reid's numerical filter (9), i.e. superposition of many sinusoidal component waves, provided a fairly good estimate of the time series of water kinematics for a given time series of water surface elevation. Their velocity measurements showed that the horizontal velocity variation closely followed the water surface elevation, where the maxima and minima appeared at the wave crests and troughs, respectively, even in random waves. The vertical velocity was related to the slope of the water surface, and the peak vertical velocity occurred when the water surface crossed the still water level. The frequency response function for velocities was computed. The measured response functions turned out to be larger than the predicted response function for the high frequency range. They commented that such a difference was partly caused by the noise from the sonic doppler current meter.

Tsuchiya and Yamaguchi (10) measured the velocity of wind generated waves in a recirculation wave tank utilizing the sonic doppler current meter. They also noted the contamination of their record by the noise from the current meter.

The discussion about the water particle velocities of discrete waves in random waves is seen in the study by Grace and Rocheleu (2). They measured the near bottom velocities with a propeller meter beneath the wave crests and troughs of long period waves (from 14 to 20 seconds) simultaneously with the dynamic pressure at Waikiki Shore, Hawaii. For this wave period range and water depth (10.6 m), there was almost a constant ratio of the horizontal velocity beneath a wave crest, u_+ , to the wave height deduced from Airy theory, H_p . The wave heights were defined as the average of the trough to crest height fore and aft the crest. Thus, their definition is different from the zero upcrossing wave height. The residuals between measured and predicted velocities were examined. The distribution turned out to be normal with a mean of -0.18 cm/sec and the standard deviation of 7.25 cm/sec. From the above discussion, they concluded that Airy theory provided an excellent prediction of the velocity beneath the wave crests.

Lee, et. al., (7) recently tested laser doppler anemometers in random wave action and they reported that it was a highly suitable instrument for laboratory study of waves. A full discussion about the kinematics, however, was not given in the paper.

2.0 METHOD

The methods used to meet the objectives are briefly presented, beginning with a condensed review of error sources.

2.1 Errors

In an experimental study of this kind, there are many sources of error between predictions and actual forces experienced by the structure. Some very important sources are:

1. Antiseptic conditions in the laboratory are considerably different than the conditions in the ocean. Wind driven ocean waves can be short crested and generally variable in many respects. The waves in this study were strictly two-dimensional. Wave theories assumed the waves are long crested and it is helpful to have laboratory waves modeling such conditions in order to corroborate the predictions.

2. Experimental errors can be minimized with proper calibration procedures. The natural frequencies of the measurement systems should be much higher than the frequencies of the items being measured. This study increased the reliability of the measurements by using two different instruments, a hot film anemometer and a small propeller meter. In addition, the signal to noise ratio should be on the order of 10:1 for precise measurements.

3. Innate errors in the wave theories contribute to overall errors. Since perfect measurements are not possible, it can only be said that results from the laboratory reflect the differences between theory and measurements as determined within the accuracy limits of the measurements. Often errors in theory are increased because theories are used in regions between the wave trough and wave crest even though boundary conditions

are established at the still water surface. It is not possible to find absolute errors in such cases.

4. Reflections from the beach can modify results, particularly for random waves. In order to get representative samples of waves, long periods of time are used. For this study the wave absorber was a concrete beach with a 1:12 slope which fairly well dissipated the wave energy. From previous experience, reflection coefficients range from 3% to 12% for wave periods of 1 to 5 secs. In addition, for long periods of testing, certain mass transport circulations must be established in the flume as previously mentioned. Such mass transport circulations cannot be adequately evaluated at this time.

2.2 Wave Theories

Three wave theories are employed to predict the maximum and minimum velocities -- Airy theory, which is simple and widely used for design of marine facilities; Stokes' fifth order theory; and Dean's Stream Function theory. Dean (1) showed that Stokes' fifth order theory is accurate for deep and near deep water wave conditions, and that Dean's Stream Function theory covers deep, intermediate and near shallow water wave conditions. The comparison was based on how well the theory predicted the kinematic and dynamic free surface boundary conditions. Mostly, deep water waves were tested for this work and there is no real difference between the predictions from Stokes' fifth order theory and those from Dean's Stream Function theory.

2.3 Laboratory Arrangement and Procedures

2.3.1 Facilities and instruments

The experiments were conducted in the Wave Research Facility at Oregon State University which is shown in Fig. 1. The wave tank is 104 m long, 3.7 m wide and 4.6 m deep. The wave absorber is a concrete beach with a slope of one on twelve. The wave generator has a flap-type wave board. The wave board is driven by a hydraulic piston which is controlled by an electric input, which can be either a sinusoidal or random signal. Additional information can be found in (3,8).

Fig. 1 Elevated View of OSU Wave Research Facility

The water surface elevation was measured with a Sonic System Model 86 sonic wave profiler. The velocities were measured with a Nover Nixon Streamflo Probe 403 propeller current meter and a Thermo Systems, Inc. (TSI) 1240-60W X-type cylindrical hot film anemometer, which are shown in Figs. 2 and 3.

Fig. 3 Hot Film Anemometer Probe

The hot film probe was coupled with TSI model 1050 constant temperature anemometer and model 1052 linearizers. These probes were installed on the side walls of the wave tank as shown in Fig. 4.

Fig. 4 Probe Set-up Looking North

The propeller probe has a diameter of 1.2 cm and is composed of five blades. When the propeller revolves, the passage of a blade past a gold wire tip, contained in the head of the slim support of the propeller, generates an electric pulse. The hot film probe has an orthogonal pair of quartz coated cylindrical hot film sensors with diameter of 0.15 mm and sensing length of 2.0 mm. The sensors were operated at a low overheating ratio of 1.03 throughout the measurements, in order to avoid the generation of air bubbles on the sensor surface, which reduces the sensitivity. It was oriented in the waves as shown in Fig. 5.

Fig. 5 Hot Film Anemometer Orientation

The hot film output voltage was linearized with a device which approximates the relation between the nonlinear output voltage, E_B , and the flow speed, V , by a fourth order polynomial. Thus, the relation of the linearized output voltage, E , to the flow speed, V , is expressed by the following equation:

$$E = A(\theta) V \quad (1)$$

where $A(\theta)$ is the directional function for the linearized output voltage, which is determined through calibration; and it takes a maximum when the yaw angle θ is zero, i.e., when the flow direction is perpendicular to the sensor axis and decreases according to the increase of θ , up to 90° . As shown in Fig. 5, Sensor 1 was most sensitive to the horizontal velocity component, while Sensor 2 was most sensitive to the vertical velocity component. For data reduction, the maximum value in the time variation of the linearized output was processed using the calibration coefficient $A(0)$.

2.3.2 Calibration procedure

Calibration procedures are described in detail in (6) and reviewed briefly here. The primary calibration was conducted by swinging each probe in still water at the bottom of a long pendulum, which generated a damped free oscillation. Figure 6 illustrates the pendulum and Fig. 7 shows a typical output from the propeller meter. The hot film output was equally accurate, but continuous. The pendulum motion was monitored with a sonic sensor turned sideways and beamed to the reflector shown in Fig. 6. The range of the period of the pendulum motion was set from two to three seconds. The significant wave periods of the test random waves fall into this range.

The number of impulses per second from the propeller meter was calibrated from the pendulum motion for what is herein termed the low speed range. For speeds greater than about 9 cm/sec. the calibration curve fell on a straight line as shown in Fig. 8, where V_{max} is taken from the maxima of the pendulum velocities. It was also calibrated from a hand oscillated carriage, the motion of which was carefully monitored with the sonic sensor. The results are shown in Fig. 9 with the best fit straight line from Fig. 8 superimposed. The effects from non-alignment of the axis with the water flow direction was also examined

and found to be appreciable (6). Thus, only the horizontal wave velocities at the crests and troughs were considered with the propeller meter, as well as vertical velocities at the zero crossings.

Fig. 7 Response of Propeller Current Meter

Fig. 6 Pendulum Calibration for Hot Film Anemometer

Fig. 8 Calibration of Propeller Current Meter for Low Speed Range

Fig. 9 Calibration of Propeller Current Meter for High Speed Range

The sensitivity of the hot film sensor is easily affected by dirt and fluid temperature. Therefore, the hot film anemometer was calibrated at the beginning and the end of each series of runs. In the case that these two calibrations were different, but not too different, the first half of the run was processed using the result of the calibration at the beginning, while the latter half was processed using the result at the end. A calibration example is shown in Fig. 10 where the plotted gage readings are for the velocity maxima, as with the propeller gage.

Fig. 10 Calibration for Periodic Wave Tests (Series I)

2.4 Test Schedule

Testing was first performed on periodic waves in order to compare laboratory measurement with the theories that are felt to be most applicable. Measurements were made simultaneously with the propeller meter and the hot film anemometer in order to also compare results between these two measurement methods. The test schedule was then organized into the topics of instrument calibration, comparison between instruments, comparison between measurements and periodic wave mathematical predictions, and comparisons between measurements in random waves and predictions from periodic wave theory. The tests were intended to sample a wide range of wave height and period as indicated in Table 1. Some measurements were made by Jensen (5) using the propeller meter only. These measurements concentrated in the area between the wave trough and the wave crest.

Table 1 Wave Conditions for Periodic Waves Tested

Wave height H (cm)	Wave period T (sec)	Ursell number U	Index in ref. (1)	Probe Position z (cm)		
				Series I	Series II	Series III
110.0	2.50	1.89		-122.0	-61.0	-30.5
83.5	2.50	0.72		--	--	-30.5
38.4	2.50	0.65		-122.0	-61.0	--
82.6	2.07	0.78	8-C	-122.0	-61.0	-30.5
28.7	2.07	0.18	8-A	-122.0	-61.0	--
40.5	1.47	0.10	9-C	-122.0	-61.0	--
14.3	1.47	0.024	9-A	-122.0	-61.0	--
61.3	4.61	5.4	6-A	-122.0	-61.0	--
52.4	3.28	1.72	7-A	-122.0	-61.0	--
104.9	3.28	4.02	7-B	-122.0	-61.0	--

*Note Series I and II were repeated twice for two propeller orientations: horizontal and vertical. In Series III, hot film only was operated. Another series was tested by Jensen with the propeller meter at several vertical positions between the wave trough and crest.

Two wave spectra were used for the random wave tests, wherein the water velocity measurements were made primarily with the hot film anemometer. The spectra are shown in Figs. 11 and 12.

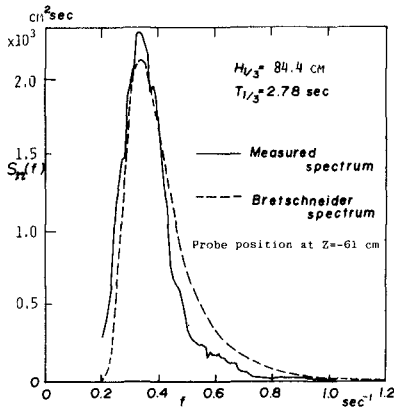

Fig. 11 Experimental Wave Spectrum I

Fig. 12 Experimental Wave Spectrum II

On the figures the random wave parameters were obtained from the direct reduction of zero upcrossing wave heights and periods. The wave trains were approximately 160 secs. long and they contained approximately 60 zero upcrossing waves each. The range of parameters for the individual waves in spectrum I are shown in Fig. 13. The periodic wave conditions are shown with triangles on Fig. 13 and the random waves are solid dots. Figure 14 gives the parametric variations for spectrum II.

Fig. 13 Range of Periodic Waves, Δ , Individual Random waves, \bullet , for Spectrum I.

Fig. 14 Range of Individual Random Waves for Spectrum II.

2.5 Data Analysis

The accuracies of all experimental studies are particularly dependent on the care taken and the methods used to analyze the data. The intent of this section is to explain the methods used herein and to point out problem features.

The hot film anemometer turned out to be a versatile and excellent instrument for this study. However, we did not realize until after the study that the entire velocity vector, as a function of time, at a point, can be measured with it as reviewed in (12) and clarified in (6). It is suggested that for future experimental studies dealing with wave theory verification that the entire vector be thus determined. However, wake problems are still bothersome wherein one sensor can shield the other, or the mounting itself might shield both sensors, as seems to have been the case in (12) for some flow directions. Anyway, the maximum horizontal and vertical velocities are very important in design and they are featured in this study.

The propeller meter output is sometimes difficult to read if the impulses are too close. The recording media must be run at sufficient

speed for adequate resolution. As previously stated, the propeller meter is very sensitive to flow direction and for this study only, the data were utilized where it was felt the flow direction was parallel with the propeller axis.

2.5.1 Periodic waves

A sample record for periodic waves is shown in Fig. 15, which is a photocopy of the actual visicorder recording. The record shows, from the top, water surface elevation, nonlinear outputs from Sensors 1 and 2, linearized outputs from Sensors 1 and 2, and the output from the propeller, the orientation of which is horizontal for this record.

Fig. 15 Sample Record of Periodic Wave

It is seen that the pulses from the propeller are dense at a wave crest and trough. The maximum frequency, n , of the pulses was determined as the mean frequency over a period of from 0.3 to 0.2 seconds under the wave crests and troughs. The maximum velocities were reduced with the conversion relation given on Fig. 8. The linearized output from Sensor 1 shows maxima at wave crests and troughs, while that from Sensor 2 shows minima. In the same way, the output from Sensor 2 shows maxima at wave nodes approximately, while that from the other sensor shows minima. Thus, variations of the output from Sensors 1 and 2 correspond to those of the magnitude of the theoretical horizontal and vertical velocity component, respectively. However, it should be noted that the minimum voltage is not zero, while wave theories predict that the minimum magnitude of each velocity component is zero. This is caused by the effect of the parallel velocity component. Each cylindrical film sensor output voltage is due to both the normal and transverse velocity components with respect to the sensor axis. When the normal velocity component is a minimum there can still be a sizable parallel component that will create a voltage reading. From the records, the following maximum velocities were reduced from the maximum output voltage using the corresponding calibration curves for each sensor.

- u_+ : the horizontal velocity beneath a wave crest
 u_- : the horizontal velocity beneath a wave trough
 w_+ : the vertical velocity when the water surface crosses the still water level upward
 w_- : the vertical velocity when the water surface crosses the still water level downward

2.5.2 Random waves

A typical record for the random wave tests is shown in Fig. 16. Generally, the maxima of the output voltage from Sensor 1 appear beneath the wave crests and troughs where the output from Sensor 2 shows its minima. The maxima of Sensor 2 appear at the wave nodes while the output from Sensor 1 shows the minima. These aspects are clearly seen for large waves and have the same general characteristics as observed in the periodic wave tests. Hence, the maximum values of horizontal and vertical velocity components in a random wave train were processed in the same way that was used for the periodic wave tests.

Fig. 16 Sample Record of Random Wave Test (Spectrum II, $Z = -61$ cm)

3.0 RESULTS

This section will first compare the results from the hot film anemometer to those from the propeller meter. Periodic wave theory predictions will then be compared to measurements in periodic waves, followed by measurements in random waves.

The measurements made with the hot film anemometer compared very favorably with the propeller meter. Correlation curves were obtained and the coefficients calculated for various wave conditions. The results are displayed in Table 2.

Table 2 Correlation Coefficients between propeller meter and hot film anemometer for various conditions

Wave Type	Probe Position (cm)	Velocity Measured	Correlation Coefficient
Periodic	-61	$u_{+,-}$	0.993
"	-61	$w_{+,-}$	0.974
"	-122	$u_{+,-}$	0.991
"	-122	$w_{+,-}$	0.947
Spectrum I	-61	$u_{+,-}$	0.983
"	-61	$w_{+,-}$	0.976
Spectrum II	-61	$u_{+,-}$	0.952
"	-61	$w_{+,-}$	0.970

For comparing predictions vs. measurements for velocities, the error is defined as

$$r = \frac{(u)_{\text{measured}} - (u)_{\text{predicted}}}{(u)_{\text{predicted}}} \quad (2)$$

where u stands for $u_{+,-}$ or $w_{+,-}$.

In order to compare linear theory to measurements of fairly high finite amplitude waves, it is necessary to use a fictitious water depth so that the wave crests and troughs for linear theory will occur at the same elevations as the measurements. This condition is shown in Fig. 17. An example of a few measurements vs. theory, for an intermediate water depth wave, is shown in the usually accepted way in Fig. 18. All of the errors for the periodic wave tests were calculated according to Eq. 2 for each of the theories and they are summarized in Table 3. Wave steepness A, B and C refer to the Dean classification with $H_A = 1/4 H_b$ and $H_c = 3/4 H_b$, etc.

The means of the relative error show that the horizontal velocity beneath the wave crests are three to four percent smaller and those beneath the wave troughs are 10 to 20 percent larger than those predicted from the theories. On the other hand, the measured vertical velocities, in general, are smaller than the theoretical predictions for both w_+ and w_- . The standard deviations vary from 0.1 to 0.2 at the level of -122 cm and they are about 0.1 at the level of -61 cm. According to the mean and standard deviations listed, there was no significant difference for the wave theory used; higher order wave theories or Airy theory. Hence, for the convenience of the remainder of the computation herein, Airy theory is used to predict the velocities of each discrete wave in a random wave train. This conclusion was also reached in (4).

The results from measurements vs. predictions for the two random waves were quite encouraging for the continued use of the Airy theory, even above the wave troughs. For both spectra tested, the individual zero upcrossing wave height distributions were closely approximated by the Rayleigh distribution as shown in Fig. 19. In addition, the maximum horizontal velocities under the wave crests were closely approximated by the Rayleigh distribution as shown in Fig. 20.

Fig. 19 Random Wave Height Distribution

Fig. 20 Probability Distribution of Horizontal Velocities Beneath the Wave Crests.

The comparison between Airy theory and measurements for the horizontal velocities is shown in Fig. 21 for the vertical velocities, for $z = -61 \text{ cm}$. The scatter appears to be reasonable and was treated statistically as will be explained. For vertical velocities, the correlation was 0.934 for w_- and 0.638 for w_+ , with the plots looking much like Fig. 21.

Samples of how the errors were plotted on normal probability paper are shown in Figs. 22 and 23. The figures show that as the sample size is reduced by focusing on the smaller number of larger waves (i.e. $H_{1/10}$ vs. $H_{1/3}$) the standard deviation of the errors is reduced! This means that the factor of safety can be made smaller for calculating the kinematics for the larger waves, as will be shown. The total sample sizes were from 60 to 70 waves.

Fig. 21 Comparison Between Predicted and Observed Horizontal Velocities for Random Waves

Fig. 22 Probability Distribution of Relative Errors for Horizontal Velocities Under Wave Crests

Fig. 23 Probability Distribution of Relative Errors for Vertical Velocities

The normal distribution hypothesis was checked with the chi square test and it was found that almost all populations passed the test at a significance level of 95%. The populations of $H_{1/10}$ were not checked because they were quite small. In this manner, the mean and standard deviations of the errors between the measurements and Airy theory were compared for various fractions of the wave height populations for sensor position below the wave troughs. The results are shown in Table 4. It is seen that the standard deviations of the errors clearly reduced markedly as the height of the samples were restricted to ever increasing wave heights. The data between wave troughs and crests were treated similarly, with similar trends resulting. However, the means were closer to zero and the standard deviations were even smaller, as reviewed in the next section.

4.0 DISCUSSION

The comparisons between the measurements made with the hot film anemometer and the propeller meter were very good. From this it can be concluded that the laboratory and experimental techniques concerning the instruments were excellent. Experimentation in periodic waves showed fairly good agreement between measurements and periodic wave theory. This was done in order to compare with the work of others and as another

step in verifying the laboratory method for measuring wave velocities. Since the agreement between measurements and predictions was quite good it is felt that the measurements then made within random waves would be quite reliable.

The laboratory data indicate that the large random waves have the smaller standard deviations of errors between theoretical predictions and measurements. In addition, the variation of the means and the standard deviations are about the same whether one utilizes finite amplitude wave theories or the Airy wave theory. The hot film anemometer is reliable and relatively handy to use *providing* proper calibration techniques are utilized. There is still a wake problem which can be minimized with the proper orientation of the hot film anemometer.

Thus, according to the measurements made for this study, it is reasonable to use periodic wave theory to predict the particle kinematics in large waves, given that a complete dynamic analysis of the structure is not necessary. Thus, the designer may be interested in predicting *maximum* values (e.g. maximum horizontal velocity) *given* the design wave. The errors in this work were distributed normally so that two standard deviations added to the mean will include 97.7% of the population and three standard deviations will include 99.9%. Considering the errors between laboratory random waves and actual storm waves, it would seem to be prudent to use the 3σ level.

Now consider Eq. 2 for error definition and let r_{u+} be the error under the crest for the maximum horizontal velocity. In the field, the actual maximum horizontal velocity under the crest for the *design* wave (given that it occurs) will also be in error with design predictions. Let this occurrence be designated as

$$\epsilon_{u+} = \frac{u_a - u_p}{u_p} \quad (3)$$

where u_a is the actual maximum horizontal velocity. Now, let $u_a = u_d$, the design value for the maximum horizontal velocity, and solve for it from Eq. 2

$$u_d = u_p (1 + \epsilon_{u+}) \quad \text{or} \quad (4)$$

$$u_d = u_p \cdot FS \quad (5)$$

where u_p , again, is the value predicted from Airy theory and FS is the factor of safety. The error value must now be estimated. We propose

$$\epsilon_{u+} = \overline{r_{u+}} + 3\sigma \quad (6)$$

where the overbar indicates the average value, and the values of FS determined therefrom are displayed in Fig. 24. The factors of safety for the spectrum conditions were calculated for the $H_{1/10}$ conditions.

Since the larger waves in the random series have the smallest standard deviation for the errors and a relatively small variation in the means, it is concluded that it is reasonable to use periodic theory (in

Fig. 24 Factor of Safety for u_+ for Airy Theory

fact Airy wave theory) to predict the conditions in large waves at sea providing an appropriate factor of safety is used. An example is shown here for u_+ . Similar safety factors can be developed for other wave parameters at the discretion of the designer.

5.0 ACKNOWLEDGEMENTS

Some of the work in this research was supported by the National Science Foundation Grant No. ENG76-16423, on the section regarding wave kinematics and circulation in a closed system wave flume. Dr. Tokuo Yamamoto provided valuable comments at the beginning of the work. The authors are indebted to Prof. C. K. Sollitt and Mr. Robert Jensen for use of the data on horizontal velocity measurements above the trough, which were collected from Mr. Jensen's M. S. Thesis.

CHAPTER 19

HIGHER ORDER WAVE SPECTRA¹

By Paul C. Liu², M. ASCE and Albert W. Green³

1. INTRODUCTION

As part of an effort aimed at examining the empirical aspects of nonlinear processes of wind-generated waves, this paper presents calculations and examples of bispectra and trispectra and indicates applications of these results to the study of wave growth processes.

Recent publications on wave studies have indicated that the growth process of wind waves is primarily associated with the nonlinear energy flux due to wave-wave interactions. While most of these studies are conjectures from theoretical considerations, it is of interest to explore the nonlinear studies empirically. From available wave data largely recorded at a single station, a first step is to perform bispectral and trispectral analyses of the data. Since the unispectrum provides information on the energy content of the frequency components, the bispectrum and trispectrum generally provide information on the interactive relations between two and three frequency components, respectively. These higher order interactive relations can thus be considered as estimates or characterizations of nonlinear interactions.

Hasselmann, Munk, and McDonald (1962), perhaps the first to use bispectral analysis, demonstrated that calculations of observed bispectra of ocean waves correlate reasonably well with theoretically derived bispectra. Other ocean wave bispectra were presented by Garrett (1970) and Houmb (1974). Trispectral analysis has not yet been attempted in practical problems.

2. CALCULATION PROCEDURES

By definition, a bispectrum is the two-dimensional Fourier transform of the third-order covariance function of the data; a trispectrum is the three-dimensional Fourier transform of the fourth-order covariance function of the data. A two- or three-dimensional Fourier transform of the corresponding covariance function is generally cumbersome

¹GLERL Contribution No. 160.

²Physical Scientist, Physical Limnology and Meteorology Group, Great Lakes Environmental Research Laboratory, National Oceanic and Atmospheric Administration, 2300 Washtenaw Avenue, Ann Arbor, Michigan 48104.

³Chief, Physical Oceanography Branch, Oceanography Division, Naval Oceanographic Research and Development Activity, Code 331, NSTL Station, Mississippi 39529.

to calculate. However, following procedures discussed by Haubrich (1965) and Hinch and Clay (1968), which use fast Fourier transform directly on the data, the bispectrum and trispectrum can be feasibly calculated.

For a given discrete series of ℓ data points at a sampling interval Δt , $\zeta(\ell\Delta t)$, with $\ell = 1, 2, \dots, L$, subdividing the series into P non-overlapping subseries, each of length K , such that $p = 0, 1, \dots, p - 1$ and $k = 1, 2, \dots, K$ yield

$$\zeta_p(k\Delta t) = \zeta[(pK + k)\Delta t],$$

and the K complex Fourier coefficients for each group are given by

$$X_p(\omega) = \left(\frac{\Delta t}{2\pi K}\right)^{1/2} \sum_{j=1}^K \zeta_p(j\Delta t) e^{i2\pi kj/K}, \quad k = 1, 2, \dots, K. \quad (1)$$

Then the unispectrum, the bispectrum, and the trispectrum can be estimated by

$$S_2(\omega) = \frac{1}{P} \sum_{p=1}^P X_p(\omega) X_p^*(\omega), \quad (2)$$

$$S_3(\omega_1, \omega_2) = \frac{1}{P} \sum_{p=1}^P X_p(\omega_1) X_p(\omega_2) X_p^*(\omega_1 + \omega_2), \quad (3)$$

and

$$S_4(\omega_1, \omega_2, \omega_3) = \frac{1}{P} \sum_{p=1}^P X_p(\omega_1) X_p(\omega_2) X_p(\omega_3) X_p^*(\omega_1 + \omega_2 + \omega_3), \quad (4)$$

respectively. The asterisks in equations (2)-(4) indicate complex conjugates. In the actual computations $P = 30$ is used for each 20-min data segment of $L = 1800$ and $\Delta t = 2/3$ s to obtain smoothed spectral estimates with 60 degrees of freedom.

Because of the symmetric relations in the definitions of higher order spectra, spectral estimates are needed only within a fundamental region. The fundamental region for $S_2(\omega)$ is the line segment $0 \leq \omega \leq \omega_N$; for $S_3(\omega, \omega_1)$ the triangle defined by $0 \leq \omega \leq \omega_1$ and $0 \leq \omega_1 \leq \omega_N$; and for $S_4(\omega, \omega_1, \omega_2)$ the tetrahedron defined by $0 \leq \omega \leq \omega_1$, $0 \leq \omega_1 \leq \omega_2$, and $0 \leq \omega_2 \leq \omega_N$, with $\omega_N = 2\pi/(2\Delta t)$ representing the Nyquist frequency. A detailed discussion of these procedures and their theoretical backgrounds is given in Liu (1977a).

3. HIGHER ORDER SPECTRA OF KNOWN FUNCTIONS

In order to understand and interpret the higher order spectral behavior of actual wave data, unispectra, bispectra, and trispectra of three known functions are first calculated as examples. Figures 1, 2,

and 3 show the results for a synthesized sinusoidal record with three frequency components, a Gaussian white noise, and a second-order autoregressive process, respectively. All calculations are based on 1800 generated data points at 2/3-s sampling intervals.

In the figures, logarithms of unispectral density are plotted versus frequency; the bispectra show the contours of the logarithms of bispectral amplitude plotted in the triangular fundamental region. The increasing contour levels are represented by the increasing darkness in the shaded areas. For the trispectra, a tetrahedral fundamental region is represented by cutting discrete layers along one frequency axis parallel to the plane formed by the other two frequency axes. In each trispectral layer, the number on the corner represents the third frequency. The logarithms of trispectral amplitude are again contoured, with increasing level represented by increasing darkness in the shaded areas.

Figure 1 shows the sinusoidal wave with three frequency components of 0.1 Hz, 0.2 Hz, and 0.3 Hz. There are three delta functions at the three components in the unispectrum. Its bispectrum has strong interactions at components (0.1, 0.1), (0.2, 0.2), (0.3, 0.3), as well as (0.1, 0.2), (0.1, 0.3), and (0.2, 0.3). Its trispectrum is characterized by the strong interactions between the various second-order interactions shown in the bispectrum and other frequency components, with the strongest interaction at (0.1, 0.1, 0.1), (0.2, 0.2, 0.2), and (0.3, 0.3, 0.3).

Figure 2 shows the results for the computer-generated Gaussian white noise. Its bispectrum is practically zero and its trispectrum is characterized by random patterns without specifically stronger interactions. Figure 3 shows the second-order autoregressive process X_t defined by

$$X_t = X_{t-1} - 0.5X_{t-2} + Z_t ,$$

where Z_t is the Gaussian white noise generated for Figure 2. Its unispectrum, bispectrum, and trispectrum are all characterized by higher interactions at the low frequency range and a gradual decrease in magnitude toward the higher frequencies.

It is clearly shown by these results that bispectral and trispectral densities are directly related to and dependent on unispectral characteristics, which is what would be expected from theoretical analysis (Hasselmann, 1962). It seems reasonable to infer that the higher order interactions presented in this paper are estimates of nonlinear interactions.

As the basic assumption for higher order spectral analysis is stationarity while the growth process of surface waves is clearly nonstationary, a modified assumption of local stationarity in which the

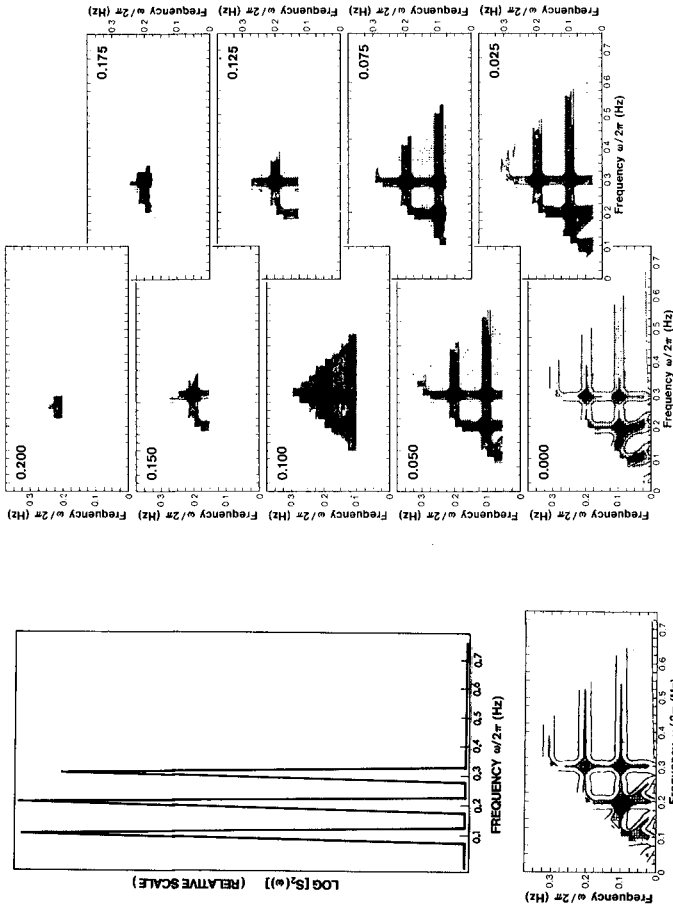

Figure 1 Spectra for a sinusoidal wave with three frequency components.

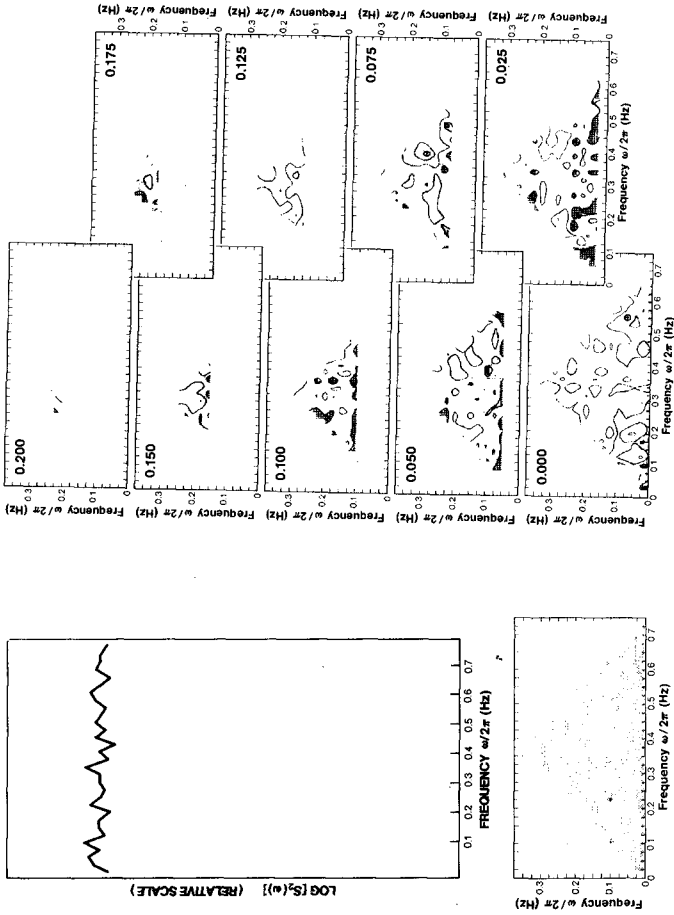

Figure 2 Spectra for a Gaussian white noise.

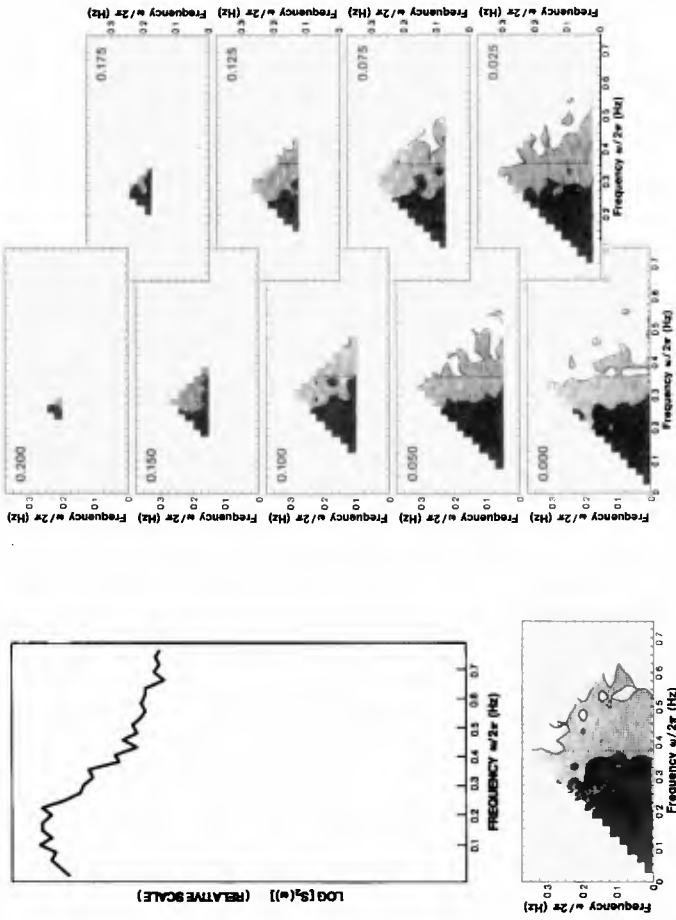

Figure 3 Spectra for a second-order autoregressive process.

process is considered to be stationary only within a local time interval can be used. A previous study (Liu, 1977b) indicated that the local stationarity assumption is statistically acceptable in actual applications.

4. HIGHER ORDER SPECTRA OF WAVE DATA

The calculations using equations (1)-(4) have been applied to an episode of recorded wave data. The episode was recorded continuously on 9 August 1972 in Lake Ontario approximately 35-km offshore of Oswego, New York, with a Waverider deployed in 150 m of water. Figure 4 shows the wind conditions during the episode, which started at a wind speed of 8 m s^{-1} and increased to over 11 m s^{-1} in 3 hours. The westerly wind direction provided fairly constant and long fetches during the episode. The group of short straight lines plotted on the figure indicates the locations in time of 64 overlapping segments of wave data analyzed for the episode. Each segment is 20-min long and has a 17.5-min overlap with the next segment. Figure 5 shows the computed unispectral density versus frequency versus time. The three-dimensional perspective figure presents a clear overview of spectral growth during the episode. Figure 6 presents six bispectra from the episode at 30-min intervals as representative of the whole process. As the temporal variations are gradual, the figures clearly show that the magnitude of the bispectral amplitude increases and the hills and ridges migrate toward lower frequencies during wave growth. Figure 7 presents three representative trispectra at 1-hour intervals. The trispectrum on the left is 2.5 min from the beginning of the episode; the one in the middle is 1-hour later, with the trispectral interactions increasing and migrating toward lower frequencies; the one on the right is 2 hours from the first during the intensive wave growth stage. The intensity of trispectral density has increased significantly as shown by the very dark contour areas.

These results give only qualitative features of the higher order spectra during wave growth. In order to use these results for quantitative study, efforts must be made to examine the relative growth behavior of the individual higher order spectral components. Liu (1977a) has pursued this approach and found that, during the intensive stage of wave growth, the interaction between the components of peak-energy frequency and the next lower frequency grows consistently stronger than its interaction with the next higher frequency. Thus, the peak-energy frequency transfers more energy to the lower frequency components than to the higher ones, confirming the well-known fact that unispectral peaks shift progressively toward lower frequencies during wave growth.

5. CONCLUDING REMARKS

This paper has presented results of higher order wave spectra calculations with an intent to study nonlinear processes of wave growth by examining these higher order interactions. While the higher order spectra can be feasibly calculated from given wave data, it is only

Figure 4 Wind conditions for the 9 August 1972 episode in eastern Lake Ontario.

Figure 5 Perspective view of unispectra versus time during the 9 August 1972 episode.

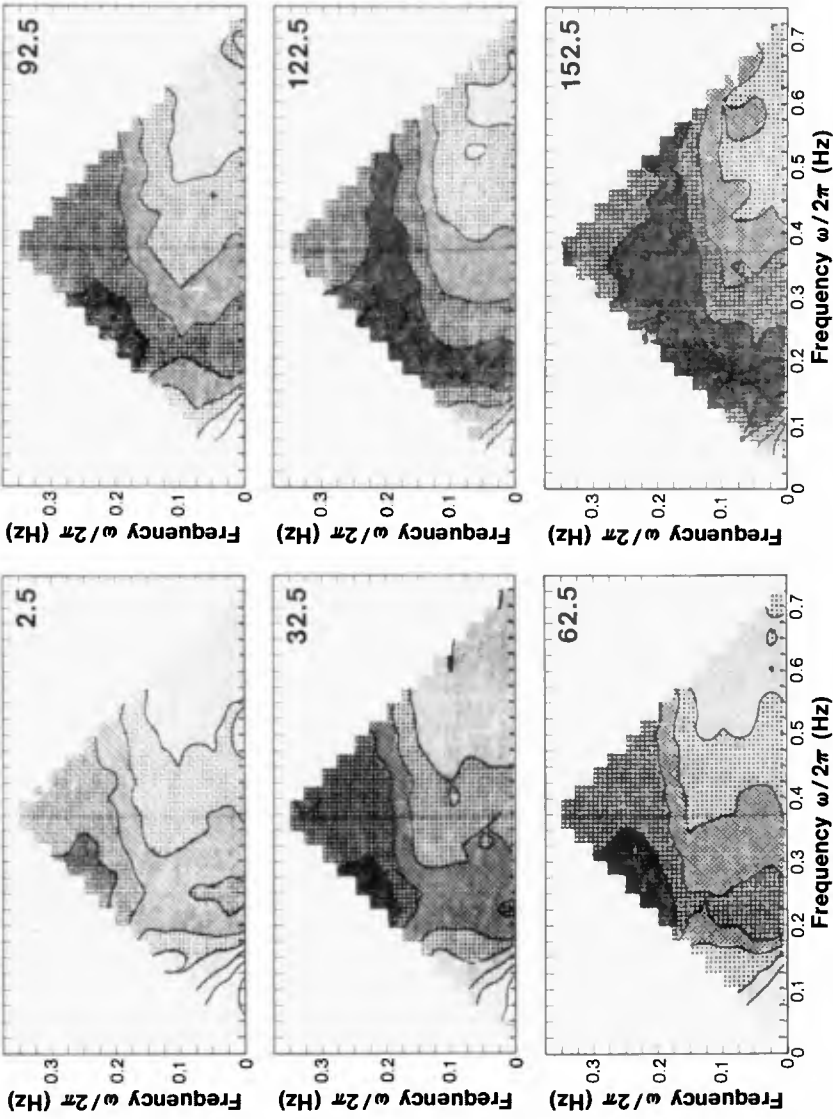

Figure 6 Bispectra during the 9 August 1972 episode. The numbers 2.5, 32.5, . . . , and 152.5 represent minutes from beginning of the episode.

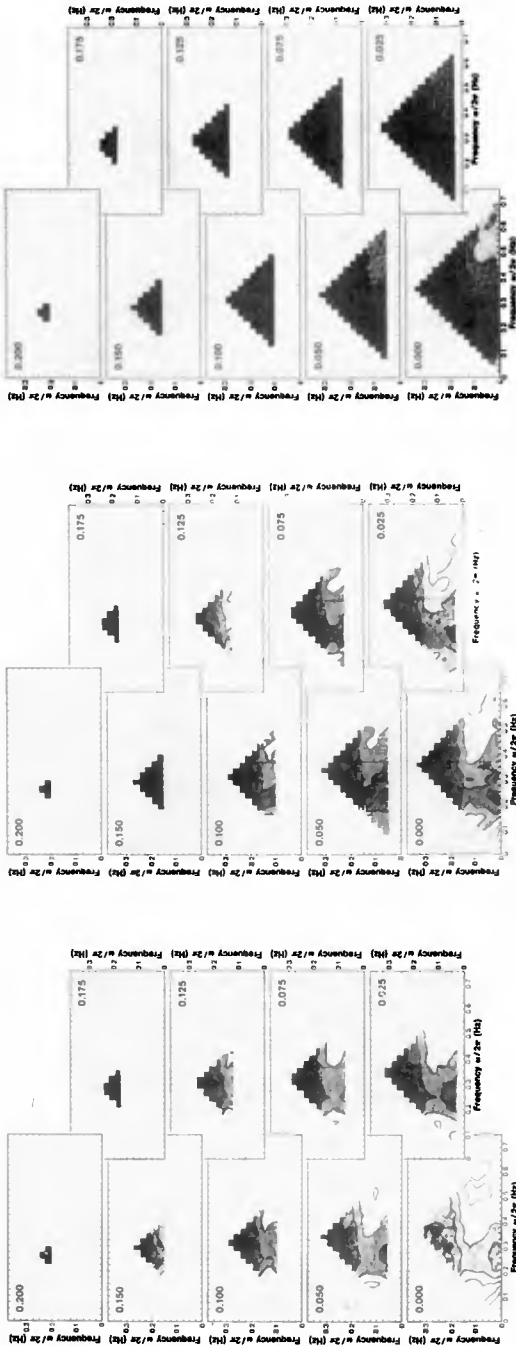

Figure 7 Trispectra during the 9 August 1972 episode at 1 hour interval from left.

inferred that these spectra are estimates of nonlinear interactions. At present, nonlinear processes have only been studied theoretically; it is hoped that an empirical effort presented in this paper will serve to indicate another approach to greater understanding of the processes. Efforts to further interpret and use these results will be continued.

ABSTRACT

The theoretical dimensionless frequency response functions for the wavemaker stroke spectrum, $Q_S(\omega)$, and for the wavemaker dynamic pressure moment spectrum, $Q_M(\omega)$, were verified experimentally in the Oregon State University-Wave Research Facility (OSU-WRF) from random waves which were simulated from two types of two-parameter theoretical design wave spectra. The random motions of the wavemaker were first digitally simulated by a unique inverse stacked FFT algorithm which were then used to drive the wavemaker through digital-to-analog converters (DAC). The dimensionless frequency response function for the hydrodynamic pressure moment spectrum was not measured directly but was computed from the dynamic covariance equations for a hinged wavemaker of variable-draft by linear combinations of related dimensionless frequency response functions and cross-spectral estimates. The measured estimates were found to agree reasonably well with the analytical approximations, and these measured stochastic hydrodynamic pressure moment estimates on a hinged wavemaker of variable-draft are believed to be unique.

INTRODUCTION

The elaborate design curves for hinged wavemakers presented by Gilbert, *et al* (1971) have been extended in a minor way (for the case of deterministic waves only) to variable-draft hinged wavemakers by Hudspeth and Chen (1978). Experimental comparisons of these theoretical design curves with deterministic waves which were approximately 25% of the theoretical breaking limit were reported by Hudspeth and Leonard (1978a) for measured data which span one decade of dimensionless relative wave frequency. The squared modulus of the dimensionless wavemaker gain function, S/H , in which S = the wavemaker stroke and H = the wave height, for deterministic waves may be shown to be equivalent to the squared modulus of the dimensionless frequency response function for the wavemaker stroke spectrum; *viz*,

$$\left| \frac{S}{H} \right|^2 = |Q_S(\omega)|^2 = \frac{S(\omega)}{S(\omega)} \frac{SS}{\eta\eta} \quad (1)$$

and the squared modulus of the dimensionless wavemaker hydrodynamic pressure moment about the wavemaker hinge, M , may be shown to be equivalent to the squared modulus of the dimensionless frequency response function for the wavemaker hydrodynamic pressure moment spectrum; *viz*,

$$|Q_M(\omega)|^2 = \frac{S(\omega)}{W^2 S(\omega)} \frac{MM}{\eta\eta} \quad (2a)$$

in which

$$W = \rho g B h (h - \Delta) \quad (2b)$$

in which ρ = density of fluid; g = gravitational constant; B = width of waveboard; and the dimensions h and Δ are defined in Fig. 1. These theoretical dimensionless frequency response functions for the stochastic design of hinged wavemakers of variable-draft were verified experimentally in the Oregon State University-Wave Research Facility (OSU-WRF) for two types of two-parameter theoretical spectra; *viz*, the relatively narrow-banded Scott spectrum and the relatively broad-banded Bretschneider-Pierson-Moskowitz spectrum.

We shall first give the analytical expressions for the dimensionless frequency response functions required for the stochastic design of hinged wavemakers which were experimentally verified in the OSU-WRF. A brief description will be presented next. Finally, graphical comparisons will be given between the theoretical and experimental dimensionless frequency response functions. The experimental values were computed from measured time series that were synthesized from the two-parameter theoretical design wave spectra. These theoretical dimensionless frequency response functions should be useful for the stochastic design of hinged wavemakers of variable-draft in wave flumes which have water on one side only of the wavemaker.

FREQUENCY RESPONSE FUNCTIONS

From the dynamic covariance equations for a hinged wavemaker of variable-draft in the wave flume shown in Figure 1, it may be shown [cf. Hudspeth and Leonard (1978b)] that the real-valued dimensionless theoretical frequency response function for radial frequency $\omega = 2\pi f$ is given by

$$Q_S(\omega) = \frac{KH}{4 \sinh Kh} \Gamma(\kappa, K) \left[\frac{2Kh + \sinh 2Kh}{K(h-\delta) \sinh Kh - \cosh Kh + \cosh K\delta} \right] \quad (3a)$$

in which

$$\Gamma^2(\kappa, K) = \left[\frac{K}{\kappa} \right] \left\{ \frac{1 + \frac{2\kappa(h-\Delta)}{\sinh 2\kappa(h-\Delta)}}{1 + \frac{2Kh}{\sinh 2Kh}} \right\} \quad (3b)$$

provided that the propagating wave number in the constant depth domain immediately adjacent to the wavemaker of depth, h , is determined from

$$\omega^2 = gK \tanh Kh \quad (3c)$$

and provided that the wave number in the constant depth test section domain of depth, $h-\Delta$, is determined from

$$\omega^2 = g\kappa \tanh \kappa(h-\Delta) \quad (3d)$$

The dimensionless complex-valued frequency response function for the hydrodynamic pressure moment on the wavemaker may be computed from the dimensionless complex-valued moment amplitude given by Hudspeth and Chen (1978) according to

$$Q_M(\omega) = M_p'(\omega) + i M_e'(\omega) \quad (4)$$

in which the dimensionless moment due to the *propagating* mode is given by

$$M_p'(\omega) = \Omega \frac{\{K(h-\delta) \sinh Kh - \cosh Kh + \cosh K\delta\}}{Kh \cdot K(h-\Delta) \cdot K(h-\delta) \sinh Kh} \Gamma(\kappa, K) \quad (5a)$$

and the dimensionless moment due to the *evanescent* modes is given by

$$M_e'(\omega) = \Omega \frac{(Kh)^3 \{2Kh + \sinh 2Kh\}}{K(h-\Delta) \cdot K(h-\delta) \sinh Kh \{K(h-\delta) \sinh Kh - \cosh Kh + \cosh K\delta\}} \Gamma(\kappa, K) \sum_{n=2}^{\infty} \frac{\{K_n(h-\delta) \sin K_n h + \cos K_n h - \cos K_n \delta\}^2}{(K_n h)^4 \{2K_n h + \sin 2K_n h\}} \quad (5b)$$

in which

$$\Omega = (h-\Delta) \frac{\omega^2}{g} \quad (5c)$$

and the evanescent eigenvalues, K_n , are computed from

Fig. 1 Definition sketch for wave flume geometry with a hinged wavemaker of variable draft

Fig. 2 Schematic representation of hydraulic piston and hinged wavemaker dynamic system in OSU-WRF

NOT TO SCALE

PLAN

Fig. 3 Schematic representation of OSU-WRF geometry

$$\omega^2 = -g K_n \tan K_n h; n > 1 \quad (5d)$$

The dynamic equation of motion for the translational motion of the wavemaker hydraulic piston displacement, $S(t)$, shown schematically in Figure 2, is given by [cf. Hudspeth and Leonard (1978a)]

$$P(t) = \frac{M(t)}{H} - N(t) + A\ddot{S}(t) + B\dot{S}(t) \quad (6)$$

in which $P(t)$ = hydraulic piston pressure force; $M(t)$ = hydrodynamic pressure moment on the waveboard about the wavemaker hinge; H = hydrodynamic pressure force moment arm about the wavemaker hinge; $N(t)$ = dynamic nitrogen gas pressure force and the coupled translational mass of the hydraulic piston, m , and the rotational inertia of the hinged wavemaker, I/H^2 , is given by

$$A = m + \frac{I}{H^2} \quad (7a)$$

and the coupled translational viscous resistance of the hydraulic piston, μ , and the rotational viscous resistance of the hinged wavemaker, ν/H^2 , is given by

$$B = \mu + \frac{\nu}{H^2} \quad (7b)$$

The time dependent nitrogen gas pressure term, $N(t)$, was not recorded directly in the OSU-WRF and had to be estimated from the measured piston displacement, $S(t)$. The nitrogen gas system in the MTS designed OSU-WRF is used to backpressure the wavemaker piston in order to compensate for the static column of fluid on the wave flume side only of the hinged wavemaker [*vide* Fig. 2]. The time varying nitrogen gas pressure is a result of the small volume changes induced by the motion of the wavemaker piston. The total nitrogen gas pressure on the wavemaker piston may, therefore, be approximated by a static plus a time varying component according to the real gas equation:

$$N = N_s + N(t) = \frac{nZRTA_N}{V_N + A_N S(t)} \quad (8)$$

in which n = mass of the nitrogen gas; Z = the compressibility coefficient for a real gas; R = gas constant for nitrogen; T = temperature; V_N = static volume of nitrogen gas; and A_N = surface area of the terminal end of the wavemaker ram normal to the wavemaker stroke. For the experimental verifications in the OSU-WRF, the ratio of $A_N S(t)/V_N \ll 1.0$; and we may expand Eq. 8 by the binomial theorem to obtain, approximately,

$$N_s + N(t) = \frac{nZR^T A_N}{V_N} \left\{ 1 - \frac{A_N S(t)}{V_N} + 0 \left(\frac{A_N S(t)}{V_N} \right)^2 \right\} \quad (9)$$

in which the static nitrogen gas pressure component exactly balances the hydrostatic moment on the wavemaker flap while the dynamic nitrogen gas pressure component acts like a stiffness element in opposing positive displacements of the piston.

Consequently, the experimental dimensionless frequency response functions were estimated by replacing the exact dynamic nitrogen gas pressure force in Eq. 6 with an equivalent linear spring element approximated by

$$N(t) = -KS(t) \quad (10)$$

in which the equivalent spring constant, K , is determined from a static moment balance between the hydrostatic pressure moment on the wavemaker flap and the static nitrogen gas pressure force according to

$$K = nZR^T \left(\frac{A_N}{V_N} \right)^2 = \frac{\rho g h^3 B A_N}{6H V_N} \quad (11)$$

in which B = width of the hinged wavemaker flap in Fig. 2. Substituting Eq. 10 into Eq. 6 and evaluating the equivalent nitrogen gas spring constant, K , from the static water depth in the wave flume at the time of experimental testing according to Eq. 11, the coupled dynamic equation of motion for the hinged wavemaker system becomes

$$P(t) = \frac{M(t)}{H} + KS(t) + A\ddot{S}(t) + B\dot{S}(t) \quad (12)$$

The covariance function for a stationary stochastic process such as that described by Eq. 12 may be defined by [cf. Papoulis (1965)]

$$C(\tau) = E\{X(t) \cdot X^*(t+\tau)\} \quad (13)$$

in which $E\{\cdot\}$ = expectation operator and the superscript asterisk $*$ = the complex conjugate value for a stochastic process $X(t)$. The Fourier transform of the covariance function yields the frequency spectrum [cf. Papoulis (1965)]. Solving Eq. 12 for the hydrodynamic pressure moment on the wavemaker, $M(t)$, and forming the covariance function according to Eq. 13, the following dynamic covariance equation is obtained for a variable draft hinged wavemaker [cf. Hudspeth and Leonard (1978b)]:

$$C_{MM}(\tau) = H^2 \{ C_{PP}(\tau) + |Q(\omega)|^2 C_{SS}(\tau) - Q(\omega) C_{PS}(\tau) - Q^*(\omega) C_{SP}(\tau) \} \quad (14)$$

in which the complex-valued frequency response function for the wavemaker is given by

$$Q(\omega) = \frac{Q(\omega)}{I} + i \frac{Q(\omega)}{V} \quad (15a)$$

$$= (K - \omega^2 A) + i(\omega B) \quad (15b)$$

and $C_{PS}(\tau)$ = cross-covariance function between the hydraulic oil piston pressure, $P(t)$, and the wavemaker stroke, $S(t)$. We note that our definition for the complex-valued frequency response function is the reciprocal of the usual structural definition for the response receptance of a single-degree-of-freedom oscillator [cf. Robson (1963)]. Dividing the Fourier transform of Eq. 14 by the spectrum of the water surface elevation, $S_{nn}(\omega)$, and a non-dimensional factor defined by Eq. 2b, we obtain the following dimensionless frequency response function for the hydrodynamic pressure moment on the hinged wavemaker:

$$|Q_M(\omega)|^2 = \frac{S(\omega)}{W^2 S_{nn}(\omega)} \quad (16a)$$

$$= \left\{ \frac{H}{W} \right\}^2 \left\{ Q_P^2(\omega) + |Q_W(\omega)|^2 Q_S^2(\omega) - 2Q(\omega) \frac{PS}{I S(\omega)} - 2Q(\omega) \frac{PS}{V S(\omega)} \right\} \quad (16b)$$

in which $C_{PS}(\omega)$ and $Q_{PS}(\omega)$ = the co- and quad- spectrum, respectively, for the cross-spectrum between the hydraulic piston pressure and the wavemaker stroke. Graphically, we may now compute the dimensionless frequency response function for the hydrodynamic pressure moment on a hinged wavemaker of variable draft from a linear combination of individual frequency response functions with cross-spectral components. We remark that this method for verifying the dimensionless frequency response functions for the stochastic design of variable-draft hinged wavemakers from the dynamic covariance equations using measured realizations of the hydraulic piston pressure and the piston motion must be considered as an approximation in contrast to the direct measurement of the hydrodynamic pressure moment on the wavemaker. However, for the purpose of verifying the stochastic design method via the dynamic covariance equation, this approximation should be adequate.

OSU-WRF DESCRIPTION

The experimental verification of the theoretical dimensionless frequency response function for the wavemaker gain function, $Q_S(\omega)$, and for the hydrodynamic pressure moment on the wavemaker, $Q_M(\omega)$, were conducted in the Oregon State University-Wave Research Facility (OSU-WRF) shown schematically in Fig. 3. The wave flume is 104.27 m long, 3.66 m wide,

and has a relocatable bottom in the test section. Experimental data were obtained for a test section depth of $h-\Delta = 3.51$ m.

The hinged wavemaker in the OSU-WRF is sealed under pressure along both vertical sides and the horizontal hinged bottom so that water is not allowed in the dry well behind the wavemaker. This dry well reduces the power requirements for the wavemaker and also eliminates the need to place any wave dissipating material behind the wavemaker. The hinged wavemaker is controlled by a 112 kW, 24 MPa hydraulic pump through a hydraulic servo-mechanism mounted 3.05 m above the wavemaker hinge. The forced motion of the wavemaker may be either periodic or random and may be activated by either an electronic function generator or a digital time sequence synthesized on a PDP 11 E10 digital minicomputer through digital-to-analog converters (DAC). A description of a unique inverse finite Fourier transform algorithm (FFT) developed at the OSU-WRF to generate either periodic or random waves of the periodic-random type through a minicomputer is described by Hudspeth and Borgman (1978). The random motions of the hinged wavemaker in the OSU-WRF which were used to verify the linear wave theory dimensionless wavemaker frequency response functions for random waves were synthesized from a stacked FFT digital computer algorithm using the theoretical dimensionless wavemaker frequency response function, $Q_S(\omega)$, and two types of theoretical two-parameter wave spectra. A comparison of two methods used to digitally filter Gaussian white noise to generate random wave spectra in the OSU-WRF is described by Hudspeth and Nath (1978). Similar digital random wave simulations have been described by Weber and Christian (1974), Funke (1974), van Oorschot and Koopmans (1976), and Kimura and Iwagaki (1976). Additional information on the OSU-WRF is presented in Nath (1978) and in Nath and Kobune (1978).

The two types of two-parameter theoretical wave spectra selected to synthesize the random waves used to verify the dimensionless frequency response functions are listed in Table 1. The Pierson-Moskowitz spectrum may be seen from Table 1 to be equivalent to the Bretschneider spectrum when the two parameters of m_0 and ω_0 are employed. The two parameters required to synthesize the wavemaker motion from these spectra are: 1) the peak spectral frequency, ω_0 , and 2) the total area under the spectrum which may be computed from

$$m_0 = \int_0^{\infty} \frac{S(\omega)}{\eta} d\omega \quad (17)$$

for one-sided spectral density functions.

SPECTRAL RESPONSE FUNCTIONS FOR HINGED WAVEMAKERS

The dimensionless frequency response function for the wavemaker stroke spectrum, $Q_S(\omega)$, was estimated from measurements of the wavemaker stroke, $S(t)$, and the instantaneous water surface elevation, $\eta(t)$. The measured wavemaker stroke was recorded through an LVDT mounted just above the wavemaker hinge in the dry well behind the wavemaker [*vide*, Fig. 3]. This LVDT signal was calibrated by rotating the wavemaker through a discrete set of arcs measured at the height of the wavemaker piston and by then correlating the LVDT signal with these measured rotations. The instantaneous water surface elevation was recorded in the test section of the wave flume by a Sonic System Model 86 sonic wave profiler. The sonic wave profiler was calibrated by displacing the sonic transducer through a discrete sequence of vertical distances measured above the still water level in the absence of waves and by correlating the sonic transducer output with these measured displacements.

The two-sided spectral densities for the two data records which are required in order to estimate the dimensionless frequency response function by Eq. 1 were estimated from an integer Finite Fourier Transform (FFT) algorithm which is intrinsic to the SPARTA function library of the Laboratory Peripheral System written by DEC for the OSU-WRF PDP 11 E10 mini-computer. A total of 8192 discrete time values were digitized at even

time intervals $\Delta t = 0.06$ seconds for each of the three realizations synthesized from each of the two theoretical design wave spectra listed in Table 1. The measured data signals were digitized through analog-to-digital converters (ADC) simultaneously with the activation of the motion of the wavemaker piston by the FFT-synthesized wavemaker signal through digital-to-analog converters (DAC). This digital activation of the wavemaker piston motion through a digital signal required a small sending rate time interval, Δt , in order to avoid overdriving the servo-mechanism and results in the small sampling rate for the simultaneous digital recording of the multichannel data signals. The two-sided spectral densities required in the analyses were computed from the discrete complex-valued FFT coefficients, $X(m)$, by the following:

$$S(\omega) = \frac{X(m) \cdot X^*(m)}{d\omega} \quad (18a)$$

in which

$$d\omega = 2\pi df = \frac{2\pi}{(LX) \cdot \Delta t} = \frac{2\pi}{(8192)(0.06)} \quad (18b)$$

Figures 4 and 5 compare the theoretical target wave spectra with a typical smoothed measured wave spectra for the Scott spectra and for the Bretschneider-Pierson-Moskowitz spectra, respectively, which were used in the experimental verifications. Each measured spectrum was smoothed by a box-car filter using 13 discrete spectral estimates which give 26 degrees-of-freedom for discrete spectral estimates computed from FFT coefficients.

Figure 6 compares the squared modulus of the theoretical dimensionless frequency response function for the wavemaker stroke spectrum computed from Eq. 3a with the measured dimensionless frequency response function estimated from the spectral estimates according to Eq. 1.

Figure 7 compares the square modulus of the theoretical dimensionless frequency response function for the wavemaker hydrodynamic pressure moment computed from Eq. 4 with measured frequency response functions which were approximated from spectral estimates of the measured data according to Eq. 16b.

CONCLUSIONS

A minor extension of the elaborate stochastic design curves for hinged wavemakers developed by Gilbert, *et al* (1971) were experimentally verified in the Oregon State University-Wave Research Facility (OSU-WRF) using two types of theoretical two-parameter design wave spectra. The analytical expressions for the dimensionless frequency response functions for the wavemaker stroke spectrum, $Q_S(\omega)$, and for the hydrodynamic pressure moment spectrum, $Q_M(\omega)$, were shown to give quite good agreement with

FIG. 4 TYPICAL SCOTT SPECTRA FOR WATER SURFACE ELEVATION, η WAVEMAKER STROKE, S , AND HYDRAULIC OIL PRESSURE, P [$f_0 = 0.2857 \text{ sec}^{-1}$ AND SUPERSCRIPIT PRIMES ' INDICATE NONDIMENSIONAL QUANTITIES]

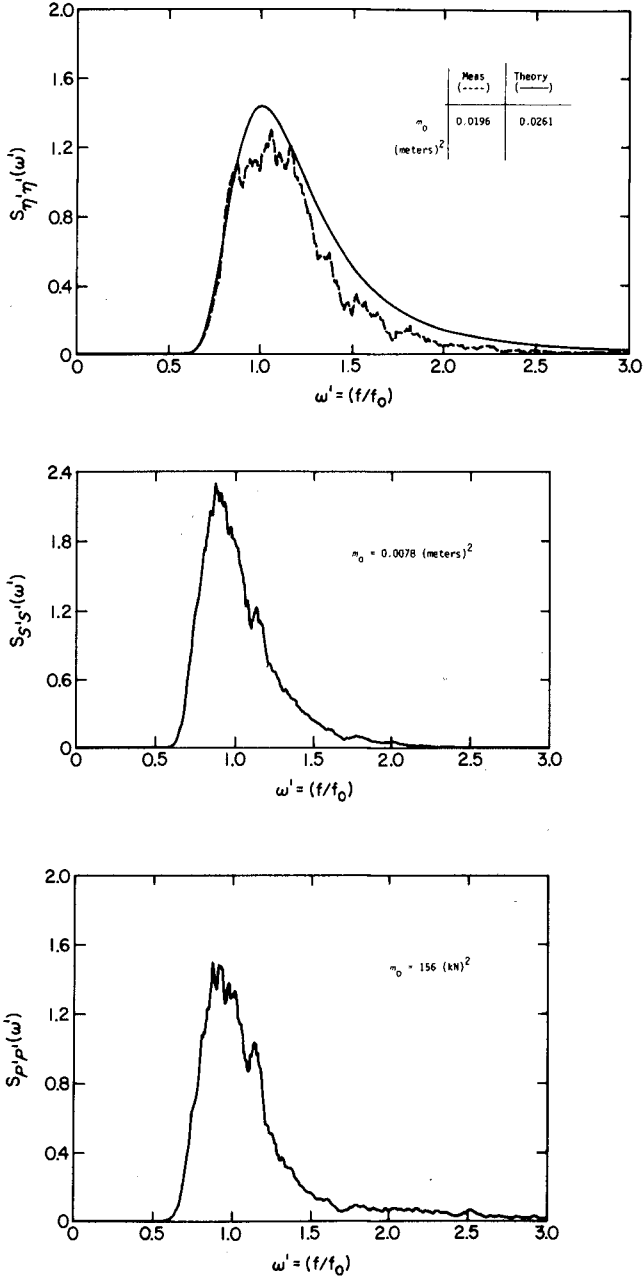

FIG. 5 TYPICAL BRETSCHNEIDER-PIERSON-MOSKOWITZ SPECTRA FOR WATER SURFACE ELEVATION, η , WAVEMAKER STROKE, S , AND HYDRAULIC OIL PRESSURE, P . [$f_0 = 0.3333 \text{ sec}^{-1}$ AND SUPERSCRIPIT PRIMES INDICATE NONDIMENSIONAL QUANTITIES]

the spectral estimates from the measured data. The dimensionless frequency response function for the hydrodynamic pressure moment spectrum was not measured directly but was estimated from the dynamic covariance equation for a hinged wavemaker using a linear combination of related dimensionless frequency response functions and cross-spectral estimates. The dynamic component of the nitrogen gas pressure force in the MTS designed wavemaker was found to be well approximated by an equivalent linear spring in which the spring constant was estimated by a static moment balance between the static nitrogen gas pressure force on the wavemaker flap and the static column of water in the wave flume. The use of the analytical expressions for these dimensionless frequency response functions in the stochastic design of large scale hinged wavemakers of variable-draft appears to be experimentally justified by these stochastic hydrodynamic pressure moment measurements which are believed to be unique.

CHAPTER 21

AN INCLINED-PLATE WAVE GENERATOR

by Fredric Raichlen¹ and Jiin-Jen Lee²

ABSTRACT

A numerical method for determining the characteristics of waves generated by a hinged inclined-plate wave generator operating in a constant depth channel is discussed. The analysis is in reasonably good agreement with experimental results. The results indicate the sloping generator operating under certain conditions is completely inefficient, i.e., for a given stroke and depth-to-wave-length ratio, very small waves are produced; for other wave periods for the same conditions significantly larger waves are generated.

INTRODUCTION

The inclined-plate wave generator discussed herein consists of a plate with one edge hinged and attached to the bottom and mounted, in its at-rest position, at a given angle in a constant depth wave tank; the plate is moved about this position with a periodic motion. The purpose of this investigation was to determine, theoretically and experimentally, the characteristics of such a wave-maker.

Two different problems served as incentives for this study. An understanding of the characteristics of such a generator may be important in predicting waves which could arise from the impulsive movement of a sloping nearshore region due to an earthquake. This is a transient problem, but an understanding of the characteristics of an inclined wave generator, i.e., the transfer function, would assist in the solution of this type of problem. (Linear aspects of the generation of impulsive waves have been explored and presented by Hammack (1973) and the interested reader is referred to that publication.) The steady state problem is related to a proposed offshore mobile breakwater constructed from a group of moored partly sunk barges. By mooring each barge in an inclined position with one end resting on the bottom and the other end near the free surface pointing in the direction of wave incidence, a temporarily protected site may be created. An understanding of the waves generated by an inclined wave-generator is important to the understanding of the transmission characteristics associated with this type of breakwater.

Numerous investigators have studied analytically the wave generating characteristics of vertical wave generators, among these are Havelock (1929), Biesel and Suquet (1951), Ursell *et al.* (1960), Madsen (1970), and Gilbert *et al.* (1971). Several of these investigators have conducted experiments or used experimental data of others to compare to

¹Prof. of Civil Engrng., W. M. Keck Lab. of Hydr. & Water Res., Calif. Inst. of Tech., Pasadena, CA, USA.

²Assoc. Prof. of Civil Engrng., Univ. of So. Calif., Los Angeles, CA, USA.

their theory. Gilbert *et al.* (1971) and Hammack (1973) studied the behavior of more unusual generators; the former investigating the characteristics of a moving wedge and the latter studying the waves generated by the motion of a section of the bottom of a constant depth tank. In addition to these, theoretical studies have been conducted by Tuck and Hwang (1972) relating to the impulsive generation of long waves by the movement of a continuously sloping beach. These studies provide insight into the general problem of wave generation, and suggest certain differences which might be realized for the inclined-plate generator.

THEORETICAL CONSIDERATIONS

For the analysis of waves generated by the periodic oscillations of an inclined plate hinged at the bottom, the fluid is assumed inviscid and the flow irrotational. The velocity potential, ϕ , is expressed in a separable manner as:

$$\phi(x,y;t) = \phi(x,y)e^{-i\sigma t} \quad (1)$$

where x is in the horizontal direction and y represents the depthwise direction as shown in the definition sketch, Fig. 1, $i = \sqrt{-1}$, and σ is the circular wave frequency defined as $2\pi/T$ where T is the wave period. The spatial variation of the velocity potential, $\phi(x,y)$, must satisfy the two-dimensional Laplace's equation:

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = 0 \quad (2)$$

with the following boundary conditions:

$$(i) \quad \frac{\partial \phi}{\partial y} = 0 \quad \text{at the bottom, } y = 0 \quad (3a)$$

$$(ii) \quad \frac{\partial \phi}{\partial n} = -i\sigma\xi\varepsilon \quad \text{on the surface of the inclined plate (The } n\text{-direction is normal to the boundary, } \xi \text{ is the distance from the hinge point to the position } (x,y) \text{ at the plate surface, and } \varepsilon \text{ is the maximum angular displacement of the plate.)} \quad (3b)$$

$$(iii) \quad \frac{\partial \phi}{\partial n} = \frac{\sigma^2}{g} \phi \quad \text{on the free surface, } y = h \quad (3c)$$

(This is a linearized free surface condition; thus, small amplitude wave motion is assumed.)

$$(iv) \quad \frac{\partial \phi}{\partial n} = ik\phi \quad \text{at } x = x_{01}, \text{ to approximately represent the radiation condition. (This condition for Region II at } x = x_{02} \text{ is shown also in Fig. 1.)} \quad (3d)$$

Figure 1 Definition Sketch for Theoretical Analysis.

Since the two regions cannot be represented by a separable coordinate system, it is advantageous to seek the solution of Eq. 2 by the boundary integral method. (A description of this method can be found in a number of texts on partial differential equations, e.g. Carrier and Pearson (1976).) Thus, the velocity potential can be expressed as:

$$\phi(\vec{x}) = \frac{1}{2\pi} \int_C \left[\ln\left(\frac{1}{r}\right) \frac{\partial\phi}{\partial n} - \phi \frac{\partial}{\partial n} \ln\left(\frac{1}{r}\right) \right] ds \quad (4)$$

where r represents the distance between the field point \vec{x} and the boundary points, and ds is a differential length along the boundary. The boundary integration is to be performed in a counter-clockwise direction, and the position vector \vec{x} of a field point is in the interior of the region to be considered. Eq. 4 implies that if one knows both ϕ and $\frac{\partial\phi}{\partial n}$ at the boundary of the region, the solution ϕ at the interior can be found readily. However, as indicated in the boundary conditions (Eqs. 3), the value of ϕ along the boundary needs to be determined before the value of the velocity potential in the interior of the fluid can be obtained. For this purpose, the following integral equation is obtained from Eq. 4 by allowing the field point \vec{x} to approach the boundary point \vec{x}_j :

$$\phi(\vec{x}_j) = \frac{1}{\pi} \int \left[\phi \frac{\partial}{\partial n} (\ln r) - \ln(r) \frac{\partial\phi}{\partial n} \right] ds \quad (5)$$

An approximate solution of ϕ in Eq. 5 is obtained numerically by dividing the boundary into a finite number of segments, N . In this manner Eq. 5 can be written in the following discrete form:

$$\phi(\vec{x}_j) = \frac{1}{\pi} \sum_{i=1}^N \left[\phi(\vec{x}_i) \frac{\partial}{\partial n} \ln(r_{ij}) - \ln(r_{ij}) \frac{\partial\phi}{\partial n}(\vec{x}_i) \right] \Delta s_i \quad (6)$$

where Δs_i represents the boundary segment length and r_{ij} is the distance between the i^{th} and the j^{th} segment. Eq. (6) can be expressed as a matrix equation as:

$$\begin{bmatrix} \phi(\vec{x}_1) \\ \vdots \\ \phi(\vec{x}_N) \end{bmatrix} = \frac{1}{\pi} \begin{bmatrix} (G_n)_{ij} \end{bmatrix} \begin{bmatrix} \phi(\vec{x}_1) \\ \vdots \\ \phi(\vec{x}_N) \end{bmatrix} - \frac{1}{\pi} \begin{bmatrix} (G)_{ij} \end{bmatrix} \begin{bmatrix} \frac{\partial\phi}{\partial n}(\vec{x}_1) \\ \vdots \\ \frac{\partial\phi}{\partial n}(\vec{x}_N) \end{bmatrix} \quad (7)$$

The elements in matrices G_n and G are defined as:

$$(G_n)_{ij} = \frac{1}{r_{ij}} \left[-\frac{(x_i - x_j)}{r_{ij}} \left(\frac{\Delta y}{\Delta s} \right)_j + \frac{(y_i - y_j)}{r_{ij}} \left(\frac{\Delta x}{\Delta s} \right)_j \right] \Delta s_j \quad (i \neq j)$$

$$(G_n)_{ij} = \left[\frac{(-x_{ss}y_s + x_s y_{ss})_i}{2} \right] \Delta s_i$$

$$(G)_{ij} = \left[\ln(r_{ij}) \right] \Delta s_j$$

(i ≠ j)

$$(G)_{ii} = \left[\ln\left(\frac{1}{2} \Delta s_i\right) - 1 \right] \Delta s_i$$

The vector $\frac{\partial \phi}{\partial n}(\vec{x}_i)$ in Eq. 7 involves the plate velocity, the bottom boundary condition, the radiation condition at either x_{01} or x_{02} and the free surface boundary condition and is given by:

$$\frac{\partial \phi}{\partial n}(\vec{x}_i) = \left[\underbrace{\frac{\partial \phi}{\partial n}(\vec{x}_1) \dots \frac{\partial \phi}{\partial n}(\vec{x}_p)}_{\text{"p" elements on the plate}}, \underbrace{0 \dots 0}_{\text{elements at bottom}}, \underbrace{ik\phi(\vec{x}_\ell) \dots ik\phi(\vec{x}_m)}_{\text{elements at the radiation boundary}}, \underbrace{\frac{\sigma^2}{g} \phi(\vec{x}_n) \dots \frac{\sigma^2}{g} \phi(\vec{x}_q)}_{\text{elements at the free surface}} \right]$$

It is clear that the vector $\frac{\partial \phi}{\partial n}(\vec{x}_i)$ contains values of the velocity potential along both the radiation boundary and the free surface which are to be evaluated in the solution. Therefore, to obtain a solution, the vector $\frac{\partial \phi}{\partial n}(\vec{x}_i)$ is represented by the linear superposition of vectors involving the known values of the velocity of the plate and the unknown velocity potentials on the boundaries. After some manipulation Eq. 7 can be rearranged into a form which can be solved readily:

$$\left\{ \begin{matrix} \left[\frac{1}{\pi} (G_n)_{ij} - I \right] \\ - \frac{1}{\pi} \begin{bmatrix} 0 \cdot (G_{ij}) \\ \dots \\ ik(G_{ij}) \\ \dots \\ \frac{\sigma^2}{g} (G)_{ij} \end{bmatrix} \end{matrix} \right\} \begin{bmatrix} \phi(\vec{x}_1) \\ \phi(\vec{x}_2) \\ \vdots \\ \vdots \\ \phi(\vec{x}_N) \end{bmatrix} = \frac{1}{\pi} G_{ij} \begin{bmatrix} \frac{\partial \phi}{\partial n}(\vec{x}_1) \\ \vdots \\ \frac{\partial \phi}{\partial n}(\vec{x}_p) \\ 0 \\ \vdots \\ 0 \end{bmatrix} \quad (8)$$

(A)
(B)
(D)
(E)

and from Eq. 8 one can obtain the following matrix expression for the velocity potential at the boundary $\phi(\vec{x}_i)$:

$$\begin{aligned}\phi(\vec{x}_t) &= (A - B)^{-1} \cdot D \cdot \underline{f} \\ &= M\underline{f}\end{aligned}\quad (9)$$

From the linearized dynamic free surface condition the wave amplitude at the free surface is given as:

$$\eta = -\frac{1}{g} \frac{\partial \phi}{\partial t} \Big|_{y=h} \quad (10)$$

In obtaining the numerical solutions described by Eqs. 6, 7, 8, two aspects of the problem should be mentioned. The first deals with the distribution of the elements on the boundary. The basic requirement is that the length of a boundary-element must be small compared to the wave length. Such requirement is particularly important in regions near the plate where the water depth is changing.

For the experimental conditions of $h = 15.24$ cm and $\alpha = 21.8^\circ$ the entire boundary of Region I was divided into 85 segments which include 20 segments on the wave-generating plate and 20 segments for the portion of the free surface which is located directly above the inclined plate; the remaining segments were distributed around the rest of the boundary. It should be noted the segments are not of equal length but are considerably smaller in the region over the plate on the free surface compared to the free surface in the constant depth region. The segment length was determined from numerical experiments. Numerical experiments were also conducted with the "radiative" boundary (at $x_{01} = 1.22$ m for the experimental arrangement) extended to $1.5 x_{01}$ and $2.0 x_{01}$. It was found that the results from these extended regions were nearly identical to those when the "radiative" boundary was set at 1.22 m. In other words, progressive waves of the same amplitude were found at $x_{01} = 1.22$ m, 1.83 m, or even at 2.44 m, i.e., for 8, 12, or 16 depths from the toe, respectively.

The second aspect of the numerical solution which must be given special attention is the treatment of the "corner point" above the plate where the water depth goes to zero. To avoid difficulty in this region the "corner" point was eliminated in the computation and it was replaced with a very small vertical segment. The numerical solution indicated that without such an approximation the results would be very sensitive to the distribution of the boundary elements. However, if a small portion of the "tip" of the fluid volume above the plate was eliminated, the solution was quite stable and the results tended to converge. The ratio of the length of the portion which was eliminated to the length of the inclined plate varied from 0.5% to 4%. The numerical results presented in the following section are obtained by eliminating a portion which is approximately 1% of the length of the plate. (Of course, a more sophisticated treatment of the region where the water depth tends to zero would be a welcome addition to the theoretical treatment of the problem.)

EXPERIMENTAL EQUIPMENT AND PROCEDURES

The experiments were conducted in a wave tank which is 18.3 m long, 84 cm wide, and 30 cm deep. The wave machine is located at one end of the tank and a rock-covered beach was placed at the opposite end for purposes of wave dissipation thereby substantially reducing the amplitude of reflected waves.

The wave generator could be inclined in the at-rest position at a specified angle and consisted of an inclined plate with a hinge at one end which was attached to the bottom of the wave tank. The top of the plate was restrained to be in contact with two horizontal arms which were connected at their opposite ends to a carriage which was mounted to horizontal rails by linear ball bushings. Ball bearings were attached to the end of each arm at the point of contact between the arm and the wave plate. Thus, as the carriage moved the hinged plate was forced to undergo a periodic motion with a maximum angular excursion, ϵ . A rod approximately 1.8 m long connected the carriage to an eccentric mounted to the output shaft of a variable speed motor; hence, varying the eccentricity varied the stroke. In this manner the inclined plate was forced to move with minimum modification to existing wave generating equipment.

The wave plate was constructed of plywood with a very small clearance (less than 1 mm) where it was hinged at the bottom. Along each sidewall of the wave tank the clearance was approximately 1.5 mm. Only waves were measured for the region for which the included angle between the wave machine and the bottom was an obtuse angle (Region I in Fig. 1). Various methods were used to measure both the angle of the plate and the stroke of the wave machine to ensure accuracy; both of these measurements were important in the comparison of the experimental results to the theory.

Mounted directly to the output shaft of the motor was a circular disk with 150 holes uniformly spaced near its circumference. A photocell and a light source were independently mounted on either side of the disk and aligned with the holes so as it rotated the interrupted light generated a pulsed voltage output. The frequency of these pulses was determined using an electronic counter; hence, the rotational speed of the motor could be accurately set and measured. In this manner the wave period could be determined to within less than 0.1 per cent.

The waves were measured approximately 6 m from the toe of the inclined-plate ($x = 6$ m); for the experiments conducted, this corresponds to 24 to 38 depths away from the generation region. All measurements were made using conventional parallel-wire-resistance wave gages which were calibrated before and after each experiment. The wave heights were measured before any reflections from the beach could return to the wave gage. Thus, a reasonably accurate determination of the incident wave could be obtained.

RESULTS AND DISCUSSION OF RESULTS

In this section the results that have been obtained from the theory and the experiments are presented and discussed. In Figure 2 the

Figure 2 Theoretical Results for the Waves Generated by an Oscillating Inclined-Plate.

theoretical results are presented for the wave-maker theory described previously in the two regions: Region I where the region is bounded by the wave machine making an obtuse angle with the bottom, and Region II whose upstream limit is where the wave machine makes an acute angle with the bottom. (These two regions are shown in the insets in Figure 2.) The ordinate is the ratio of the wave height to the total stroke of the wave machine and the abscissa is the ratio of the depth to the wave length in the constant depth region. The stroke is the maximum excursion of the plate measured perpendicular to the plate at the plate-water-surface intersection with the generator in its at-rest-position. The wave length used is determined from small amplitude water wave theory for the given depth in the constant depth region and the measured wave period.

Attention is first directed to the lower portion of Figure 2 where the generation curves are shown for Region II for five different angles of inclination of the wave machine. A comparison is shown between the results using a series expansion for a perpendicular wave machine, i.e., $\alpha = 90^\circ$, and the results from the integral equation technique developed in this study. (The results of the analysis using a series expansion can be found in several references, e.g., Biesel and Suquet (1951)). Reasonable agreement between the two theories is seen with the disagreement attributed to certain approximations which are inherent in the present numerical approach.

It is noted that only a limited portion of the theoretical curves are shown, although the range in the ratio of depth to wave length extends from shallow water wave to nearly deep water wave conditions. Figure 2 shows, for a given ratio of depth to wave length, as the angle α decreases, the ratio of wave height to stroke increases, and the increase is approximately proportional to $(1/\sin\alpha)$. This is because the wetted length of the wave maker relative to the perpendicular plate increases in that ratio. It is recalled, the value of H/S for a perpendicular generator for large h/L is two; hence, for the inclined cases one would expect the height-to-stroke ratio to approach a limit of $(2/\sin\alpha)$.

The wave generation characteristics of the inclined plate in Region I are quite different from those just shown in Region II. Theoretical curves of the variation of the ratio of wave height to wave machine stroke with the ratio of depth-to-wave-length are shown in the upper portion of Figure 2 for plates with five angles of inclination. Again, for reference, the theoretical curves are presented for the hinged wave generator which is perpendicular to the water surface in its at-rest position ($\alpha = 90^\circ$) for both theories mentioned. The appearance of the other curves is interesting in that for a given wave stroke as the ratio of the depth to the wave length increases the wave height reaches a maximum and then decreases. (For small values of h/L the curves shown are nearly the same as the corresponding curves in Region II.) For the smallest angle investigated ($\alpha = 21.8^\circ$) the maximum wave height generated for a given stroke is about 0.8 and occurs at a ratio of depth-to-wave length of approximately 0.1; a minimum of nearly zero is realized for a depth-to-wave length ratio of about 0.3.

The reason for this variation is that waves are generated along this sloping face and propagate to the constant depth region. As waves

propagate past the hinge point into Region I, a portion is reflected back into the triangular region above the wave plate. For certain ranges of h/L the reflection is more than for others. This action essentially describes a resonant condition which can lead to maximum and minimum efficiencies of wave generation. This does not take place when waves are generated in Region II, since there is not a free surface above the wave generator for that case.

In Figure 3 experimental results are presented in addition to the theory for wave generators with four different angles: $\alpha = 21.8^\circ$, 33.85° , 45° , and 90° . In general, it appears that the theory agrees reasonably well with the experimental results. There is some disagreement which can be noted, and the reasons for this are: the effect of dissipation on the wave heights measured 24 to 38 depths from the wave generator, energy leakage around the sides of the wave generator, and, of course, the approximate nature of numerical theories. With the leakage less than 1% of the wetted area one would not expect as large a difference as observed for the case of $\alpha = 45^\circ$ (see Madsen, 1970).

CONCLUSIONS

In general, it can be concluded the numerical method developed provides a reasonable means of predicting the characteristics of the inclined plate wave generator. Two regions of generation are apparent with the response of the generator in these two regions distinctly different except for small ratios of depth-to-wave length. For certain at-rest angles of inclination and ratios of depth-to-wave length the generator could be described as being totally inefficient.

ACKNOWLEDGMENT

This study was supported in part by Grants ENV77-20499 and ENV77-01599 of the National Science Foundation and from support of the U.S. Navy Civil Engineering Laboratory. Certain of the experiments were conducted by Ella Wong.

CHAPTER 22

CHANGES IN HEIGHT OF SHORT WAVES ON LONG WAVES

by Michio Sato* and Kazuo Nakamura**

ABSTRACT

In this paper we describe an experimental study on changes in height of short gravity waves on long waves.

Experiments were conducted by making mechanically generated long waves superpose on mechanically generated short waves in a wave flume of 30m long and 1m wide.

Exact solution by Longuet-Higgins and Stewart explained our experimental results, but approximate expression $a' = a_1(1+P)$ which is widely accepted seemed to be inadequate to explain our results.

INTRODUCTION

It has been considered that, when gravity waves of short wavelength ride upon the surface of longer waves, the short waves become shorter and higher at the crests of longer waves, and they become longer and lower in the troughs. Unna(1) estimated the changes in amplitude and wavelength of short waves. Later his estimation on the change in amplitude was corrected by Longuet-Higgins and Stewart(2). They calculated it by taking into account the non-linear interactions between the two wave trains. According to their theory by using the perturbation method, the surface elevation of short waves is given by

$$\zeta = a_1(1+P)\sin \psi_1 + a_1 Q \cos \psi_2 \quad (1)$$

where a is amplitude, ψ is phase and subscript 1 denotes quantities of short waves. P and Q are expressed by somewhat complicated expressions when waves are in water of finite depth, but in the case of deep water, they are given by

$$P = a_2 k_2 \sin \psi_2 \quad Q = - a_2 k_1 \cos \psi_2 \quad (2)$$

where k is wave number and subscript 2 denotes quantities of the longer waves. Longuet-Higgins and Stewart described that, if P and Q are any small quantities, the expression (1) represents a wave of slightly modified amplitude

$$a' = a_1(1+P) \quad (3)$$

* Assistant Professor of Marine Civil Engineering, Kagoshima University, Kagoshima, Japan

** Technical Official of Marine Civil Engineering, Kagoshima University, Kagoshima, Japan

They also showed that equation (3) could be obtained in some cases from the physical point of view in terms of a radiation stress. From equation (3), the amplitude of short waves is predicted to become larger at the crests of longer waves and smaller in the troughs. Longuet-Higgins (3) discussed a mechanism in the generation of sea waves on the basis of equation (3). Phillips (4) obtained expressions for the change of short waves similar to equations (1) and (3) under the influence of wind, and discussed the attenuation of long waves passing through a local wind-generated sea. In equation (1), it is true that P is small. But Q is not always small, because $a_2 k_1$ is equal to $a_2 k_2 (k_1/k_2)$ and k_1/k_2 is able to become large. Therefore, $a_2 k_1$ is much larger than $a_2 k_2$. For example, if waves with period of 1 second ride on longer waves with period of 10 seconds and a_2 is 2.48m in deep water, then ζ is given by

$$\zeta = a_1(1+0.1\sin\Psi_2)\sin\Psi_1 - a_1(10\cos\Psi_2)\cos\Psi_1$$

This indicates that the change of ζ is dominated by Q rather than $(1+P)$. The change of ζ is shown in figure 1. The short waves become higher not at crests of longer waves, but at phases where surface elevation of longer waves is near the still water level.

Can we analyse the actual phenomena on the basis of equation (1)? Can equation (3) explain the actual phenomena? This is the reason why we made the present experiments on this phenomena.

EXPERIMENTAL EQUIPMENT AND PROCEDURE

Experimental studies on the interaction between wind generated short waves and mechanically generated long waves were performed by Mitsuyasu(5), Phillips & Banner(6) and Lee(7). But these were not designed to test directly the validity of the results of Longuet-Higgins and Stewart.

The presence of wind would probably prevent such experiments or field measurements testing the validity of the theory through problems such as interaction among waves, wind and a wind-induced current field which are not completely understood. So we attempted to superimpose mechanically generated long waves on mechanically generated short waves. The experiments were carried out in a wave flume, 30 m long and 1 m wide (Figure 2). A flap type wave generator driven by a servo-controlled DC motor was installed at one end of the flume. The long waves were superposed on the short waves in the following way.

We generated short waves first, and long waves subsequently to make the long waves run after the short waves and catch up with them. Capacitance type wave gauges were used to measure the water surface elevation. The experimental procedures

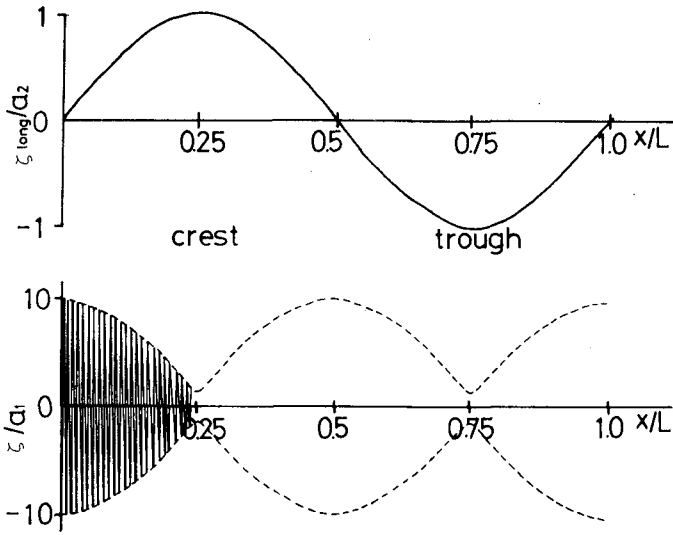

Figure 1. Change in amplitude of short waves calculated on the basis of equation (1)

Figure 2. Experimental apparatus

Table 1. Wave characteristics used in experiment

h (water depth)	40,60,80 cm
T (wave period)	3~7 sec (long waves) 0.5~0.9 sec (short waves)
H (wave height)	1~13 cm (long waves) 0.6~4 cm (short waves)
Reflection coefficient	5~10 % (short waves) 10~20 % (long waves)

are summarized in figure 3.

In the early stage of our experiments, we used an electric highpass filter to pick up only the surface elevations due to the short waves. But the highpass filter was inadequate to be used in our experiments, because the error caused by phase shift due to the highpass filter lead us to wrong conclusions. Therefore, instead of the filter, we selected a frequency analyser with stored program system to process the measured signals. Wave characteristics used in our experiments are shown in table 1.

EXPERIMENTAL RESULTS AND DISCUSSIONS

On the basis of the records measured in the way as described above, we calculated power spectra of surface elevation by using the analyser through the fast Fourier transform method. One of examples of calculated spectra is shown in figure 4. In this figure, (a) shows the power when short waves and long waves were superposed, (c) and (d) are the power of the long waves only, and that of the short waves only, respectively, when they were generated solely. A quadruple enlarged scales are used as the axis of the ordinates in (b) and (d). f_1 and f_2 mean the frequency of the short waves and that of the long waves respectively. Only the relative values of powers among the components included in the records could be obtained by the reason of the program which was provided in the analyser.

Two components with frequencies f_1-f_2 and f_1+f_2 are produced by the second order nonlinear interaction between the long waves and the short waves, and they do not appear in (c) and (d). When both of the two wave trains are superposed, the f_1 component decreases its power comparing with the power of short waves contained before both waves were superposed. In our experiments waves of rather small steepness (especially in long waves) were used because of capacity of the wave generator. Therefore, components produced by the third order interaction were very small. This seems to be convenient to examine the theory based on second order interaction.

It has been shown that the components with frequency $f_1 \pm f_2$ will be produced through the second order interaction in the exact solution obtained by Longuet-Higgins and Stewart by using the perturbation method. contribution of the second order interaction to the elevation of free surface is given by

$$\zeta^{(2)} = \frac{1}{2g} a_1 a_2 [C \cos(\Psi_1 - \Psi_2) - D \cos(\Psi_1 + \Psi_2)] \quad (4)$$

where

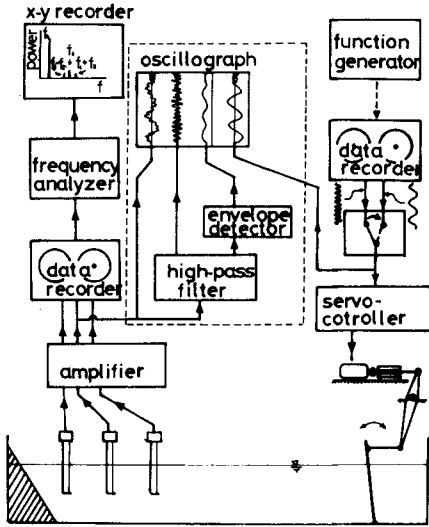

Figure 3. Experimental procedure

Figure 4. Example of power spectrum

$$C = \frac{[2\sigma_1\sigma_2(\sigma_1 - \sigma_2)(1 + \alpha_1\alpha_2) + \sigma_1^3(\alpha_1^2 - 1) - \sigma_2^3(\alpha_1^2 - 1)](\sigma_1 - \sigma_2)(\alpha_1\alpha_2 - 1)}{\sigma_1^2(\alpha_1^2 - 1) - 2\sigma_1\sigma_2(\alpha_1\alpha_2 - 1) + \sigma_1^2(\alpha_1^2 - 1) + (\sigma_1^2 + \sigma_2^2) - \sigma_1\sigma_2(\alpha_1\alpha_2 + 1)} \quad (5)$$

and D is given by a similar expression with the signs of α_2 , σ_2 reversed. σ denotes angular frequency, α is equal to $\coth kh$. Equation (1) is derived by combining the first approximation for the surface elevation of short waves, i.e. $a_1 \sin \psi_1$, with equation (4). Now, we put $a_1 a_2 C / 2g$ as $a_{f_1 - f_2}$, $a_1 a_2 D / 2g$ as $a_{f_1 + f_2}$ and a_1 as a_{f_1} . Then, we compare the experimental values of ratios $a_{f_1 - f_2}$ and $a_{f_1 + f_2}$ to a_{f_1} with theoretical values. Figure 5-(1)~(3) show the results. A full line and a broken line represent theoretical values of $|a_{f_1 - f_2} / a_{f_1}|$ and that of $|a_{f_1 + f_2} / a_{f_1}|$, respectively. In figure 5-(1), the wave steepness and the relative depth of long waves were kept constant and the ratio of frequency of short waves to that of long waves was changed. In figure 5-(2), the steepness of long waves was changed, and in figure 5-(3), the relative depth was changed. Experimental values agree with the theoretical curves. In figure 6, the wave profile ① within the part enclosed by solid line is one of examples of surface elevation when the short waves ride on the long waves. Powers of components included in this wave profile are given in the same figure, too. The wave profile ② was obtained by the following way. We calculated the Fourier transform of wave profile ① first and made the Fourier coefficients of components with frequencies in the range ② equal to zeros. Then, we calculated the inverse Fourier transform of the results. The wave profile ① can be regarded as the profile of the long waves. By the same procedure, we obtained the wave profile ② from the components with frequencies in the range ②. This can be regarded as the short waves on the long waves and this should correspond to ζ given by equation (1). Figure 7 is another examples whose power is shown in figure 4. Figure 7-(a) is the profile of long waves and (b), (c) and (d) are that of component with frequency $f_1 + f_2$, f_1 and $f_1 - f_2$, respectively. Adding up these three wave profiles, we get the wave profile (e). In these examples, the short waves become higher twice in one cycle of the long waves and not at the crests of long waves but at the phases that the surface elevation of long waves is near the still water level. Other results with frequency ratio σ_1 / σ_2 greater than 7 of our experiments show a similar tendency. As the frequency ratio σ_1 / σ_2 becomes small, the changes of amplitude of short waves become to correspond with the surface elevation due to the long waves. An example of such cases is shown in figure 9. In this case, the amplitude of short waves becomes large not at the crest of the long waves at the back faces.

Figure 9. Profile of short waves when σ_1/σ_2 is small

Figure 10. Effect of components with frequency $f_1 \pm 2f_2$ on modulation of short wave

Figure 8-(1)~(3) show how much the amplitude of short waves become larger relative to the amplitude of component with frequency f . Equation (1) can be written as follows

$$\zeta = a' \sin[\Psi_1 + \tan^{-1}(Q/(1+P))] \quad (6)$$

Then, modulated amplitude a' is given by

$$a' = a_1 \sqrt{(1+P)^2 + Q^2} \quad (7)$$

In figure 8, experimental results are compared with the predicted values by equation (3) and equation (7).

White circles show the experimental results, a full line shows the calculated one on the basis of equation (7), and a broken line shows calculated one on the basis of equation (3). Experimental results agree approximately with the predicted values by equation (7).

From the results above mentioned, we may conclude that the exact solution on the changes in height of short gravity waves on long waves by Longuet-Higgins and Stewart can sufficiently explain our experimental results.

But the approximate expression (3) which is widely accepted seems to be inadequate to explain the actual phenomena.

In our experiments long waves were restricted to small steepness. However, as the steepness become large, higher order interaction will become to play the important part of the change. This is suggested in some of our experimental results. In figure 10, (a) shows the wave profile with frequency of $f_1 - f_2 \sim f_1 + f_2$, and (b) shows that with frequency of $f_1 - 2f_2 \sim f_1 + 2f_2$. Components with frequency $f_1 \pm 2f_2$ modify the aspect of change in amplitude of short waves.

In figure 11, (a) is the wave profile with frequency of $f_1 - 2f_2 \sim f_1 + 2f_2$, and, in this example, not only amplitude of short waves but also frequency is modulated.

Though we didn't investigate systematically about these problems, these examples seem to suggest that the actual phenomena in nature is more complicated than the second order theory will predict.

CONCLUSION

Changes in height of short gravity waves on long waves were investigated experimentally by making mechanically generated long waves superimpose on mechanically generated short waves. The experimental results were compared with theoretical results by Longuet-Higgins and Stewart.

It becomes clear that the exact solution by them can sufficiently explain our experimental results. But approximate expression (3) seems to be inadequate to explain our results.

Figure 11. Example of experimental results in which not only amplitude but also frequency of short wave is modulated

CHAPTER 23

COMPUTATIONS OF SHORT WAVES IN SHALLOW WATER

M.B. Abbott¹, H.M. Petersen² and O. Skovgaard³

ABSTRACT

The simulation of short wave propagation, including refraction, diffraction, partial reflection and all other such features, is made possible by a new version of the System 21, Jupiter. The System-generated models can describe any bathymetry and topography with any time-varying mean flow, correctly accounting for wave and current interactions, wave-thrusts or radiation stresses, longshore currents and other "second order" effects. The models work with irregular waves just as well as with regular waves. Radiation boundary modules are also provided so that models can be cut-out in any desired region and new features introduced without invalidating the field-study-determined boundary data. As models are system-generated, they can be constructed and run in a few hours, starting from charts, a lay-out of the proposed engineering works and the available boundary data. The development and testing of the System is briefly described, followed by an account of its applications in coastal engineering practice.

1. INTRODUCTION AND BACKGROUND

The modelling system used to compute short waves in shallow water that is the subject of this work constitutes the eight version of the System 21 "Jupiter" (Abbott, Damsgaard and Rodenhuis, 1973). This system was originally conceived for nearly-horizontal flow (negligible vertical acceleration) computations in two dimensions in plane and for vertically homogeneous (unstratified) waters. It was constructed in a system form capable of generating and running models when provided with only an elementary description of the area to be modelled, the boundary and other auxiliary conditions (e.g. barometric pressure fields or geostrophic wind fields) and resistance and similar parameters. (The difference between a model and a modelling system can be compared with the difference between a product and a factory to build products. Each

product can be made individually more cheaply than the factory, but once the investment in the factory is made, the factory-produced products can be made more cheaply than the individually-made or "one-off" products. Thus although a modelling system costs roughly an order of magnitude more in money and time, as compared with a single one-off model, once built it can produce models at a fraction of the cost and in a fraction of the time required for one-off models). The System 21 was based upon various one-off models developed between 1960 and 1968 (e.g. Abbott, 1963; Sobey, 1970). It was started in 1969 but was only strongly backed from mid 1970. The first prototype was field tested in late 1971, pre-production versions ran in 1972 on two engineering contracts (Karachi harbour seiche analysis and Penang causeway connection) and the first production version, the Mark 5, came into use in 1973. This version used a four-stage difference scheme and was stable over a sufficiently wide range of Courant numbers and bathymetric configurations to provide a practical engineering instrument. On the basis of the success of this version, it was possible, from 1974 onwards, to design and develop an improved version, the Mark 6. This was field tested in 1975 and took-over as the main production version from 1976 onwards. These two versions have been the most widely used of all modelling systems in hydraulic and coastal engineering practice, accounting for 44 contracts in 13 countries, providing modelling services for engineering works the construction cost of which exceeds U.S.\$ 10,000,000,000.

This work on nearly-horizontal flow modelling took place in the environment of institutes well known for their pioneering work in short wave theory and practice. The Danish Hydraulic Institute had pioneered the use of irregular wave generators, essential for wave disturbance testing with ships, and together with the Technical University of Denmark had engaged in much basic research on short wave phenomena. On the other hand, the numerical tools available for short wave modelling were, more or less, the usual ones of linear-harmonic analysis and geometric-optical analogy, and these appeared increasingly incongruous in this environment.

Accordingly, it was decided to produce an instrument compatible with physical modelling over the widest possible range of applications and one that would be more satisfactory from the standpoint of modern wave theory. This instrument would be a logical development of the System 21, extending it to provide the simplest description of vertical accelerations with a sufficient range of validity, corresponding to the theory and equation formulations of Boussinesq (1877).

Now it was well known from earlier work (e.g. Abbott and Rodenhuis, 1972) that solutions of the equations of Boussinesq were exceedingly sensitive to errors. On the other hand, if any such instrument were to be of practical value, it would have to work with only a small number of descriptive points per wave length (as little as 6) in order that computing costs should remain acceptable. The main problem was then to produce a numerical scheme that was of such a high accuracy that worthwhile results could be obtained with very coarse descriptions.

At first sight, the task of designing a scheme of sufficient accuracy appeared quite overwhelming, apparently involving the

balancing-out of well over 100 terms in the truncation error, one against the other, each balancing necessitating the use of substitutions of formidable complexity. However, earlier work (Peregrine 1974; Abbott and Rodenhuis, 1972) had already indicated a possible simplification and on this basis of this work and its later elaborations (e.g. Bona & Smith, 1976) it was possible to develop satisfactory methodology of error elimination.

2. CONTINUUM AND DISCRETE DESCRIPTION

The present system solves difference equations that are consistent with the following differential equations

$$n \frac{\partial \zeta}{\partial t} + \frac{\partial p}{\partial x} + \frac{\partial q}{\partial y} = 0 \quad (1)$$

$$\begin{aligned} n \frac{\partial p}{\partial t} + \frac{\partial}{\partial x} \left(\frac{p^2}{h} \right) + \frac{\partial}{\partial y} \left(\frac{pq}{h} \right) + n^2 gh \frac{\partial \zeta}{\partial x} \\ = n \frac{Dh}{2} \left[\frac{\partial^3}{\partial x^2 \partial t} \left(\frac{Dp}{h} \right) + \frac{\partial^3}{\partial x \partial y \partial t} \left(\frac{Dq}{h} \right) \right] \\ - n \frac{D^2 h}{6} \left[\frac{\partial^3}{\partial x^2 \partial t} \left(\frac{p}{h} \right) + \frac{\partial^3}{\partial x \partial y \partial t} \left(\frac{q}{h} \right) \right] \\ - (1-n)^3 \frac{\alpha v}{d^2} p - \frac{(1-n)}{n} \frac{\beta}{d} p \sqrt{\left(\frac{p}{h} \right)^2 + \left(\frac{q}{h} \right)^2} \end{aligned} \quad (2)$$

$$\begin{aligned} n \frac{\partial q}{\partial t} + \frac{\partial}{\partial y} \left(\frac{q^2}{h} \right) + \frac{\partial}{\partial x} \left(\frac{pq}{h} \right) + n^2 gh \frac{\partial \zeta}{\partial y} \\ = n \frac{Dh}{2} \left[\frac{\partial^3}{\partial y^2 \partial t} \left(\frac{Dq}{h} \right) + \frac{\partial^3}{\partial x \partial y \partial t} \left(\frac{Dp}{h} \right) \right] \\ - n \frac{D^2 h}{6} \left[\frac{\partial^3}{\partial y^2 \partial t} \left(\frac{q}{h} \right) + \frac{\partial^3}{\partial x \partial y \partial t} \left(\frac{p}{h} \right) \right] \\ - (1-n)^3 \frac{\alpha v}{d^2} q - \frac{(1-n)}{n} \frac{\beta}{d} q \sqrt{\left(\frac{p}{h} \right)^2 + \left(\frac{q}{h} \right)^2} \end{aligned} \quad (3)$$

In open water the pore volume n is set to 1 while in permeable breakwater and similar porous structures is it set to the prevolume.

The equations are solved using a difference scheme that is brought to third order accuracy in all its essential terms, by use of the elimination method described by Abbott, Petersen and Skovgaard (1978). The range of application of the equation system (1, 2, 3) is also given in that work, together with experimentally derived phase portraits and other more theoretical information.

3. FIELD TESTS AND APPLICATIONS

In order to prove the System, simulations were first made of one-dimensional situations. Fig. 1 shows results of a simulation of shoaling cnoidal waves, the computed results being compared with the experiments of Madsen and Mei (1969). The agreement is seen to be very satisfactory. Another simulation is that of wave reflection and transmission at a permeable breakwater. In this case, illustrated in fig. 2, comparisons were made with experimental results reported with Keulegan (1973). In this case it is shown that by setting n to its physical value, values of the laminar and turbulent resistance parameters α and β can be found such that the experimental results are recovered to an acceptable accuracy. It should be added that the α and β values so found were entirely reasonable on physical grounds.

Results of a two dimensional simulation with small-amplitude periodic waves is shown in fig. 3 together with the results of the corresponding classical Sommerfeld diffraction theory. The agreement is again striking. Fig. 4 shows a perspective plot of the wave pattern of fig. 3, providing a more visually familiar picture.

Field testing of the Mark 8 was rounded-off by simulations of regular and irregular wave behaviour in Hanstholm harbour, Denmark. The prototype is illustrated in fig. 5 while fig. 6 shows the physical model that provided the results used for the comparison. Fig. 7 shows the Hanstholm physical model bathymetry(a) and how well this bathymetry is resolved in the numerical model(b). A perspective plot of fig. 7b is provided in fig. 8, for comparison with the photographs.

The first stages in a simulation, when a model is "cold started", are pictured by contours in fig. 9 for periodic waves. The first diffractions and refractions are clearly seen. Fig. 10 shows how steady a state can be attained with periodic waves after a suitable number of time steps have been run (here about 300-400 are necessary). The corresponding comparison between physical model and numerical model results for periodic waves is shown in fig. 11. The agreement is satisfactory taking account of the over-sensitivity of periodic wave amplification factors to measuring station positions and periods (Sørensen, 1973; Abbott, Petersen and Skovgaard, 1978). The reproducibility of phenomena with irregular waves, exemplified in plan in fig. 12, is generally more satisfactory and the comparison between physical model and numerical model results (fig. 13) is correspondingly much better. By way of visual verification, fig. 14 shows a perspective plot of waves in the outer harbour of Hanstholm.

When preparing a system model it is usual to set the charts of the region on a plotting table and follow contours with the plotter follower. The sequence of positions of the follower are translated by

suitable software into a digital description of the region and from this the grid points of a model of any size, orientation and degree of resolution can be generated. The results usually contain a considerable amount of 'noise' (2-4 points per resolved wave length), as illustrated by the bathymetry contours of a model resulting from this process, shown in Fig. 15a. Since this 'noise' is irrelevant to the essential behaviour of the model and it is improperly resolved in the model, it is usual to filter the bathymetry during the grid-generating process. By way of contrast with Fig. 15a, a very heavily smoothed model bathymetry is shown in Fig. 15b. Considerably less smoothing is used in System 21 models.

This process of automatic model generation and model operation allows the use of many different model areas in a single job. Fig. 16 illustrate the use of this facility in a study of a large harbour in the Persian Gulf. The objective here was to determine wave agitation in the area at different stages of the harbour construction. Fig. 17 shows the irregular wave train used as input while Fig. 18 shows (with a greatly exaggerated vertical-horizontal scale) a perspective plot of wave action around a 200 m long obstruction placed in the area. Fig. 19 shows the corresponding isolines of significant wave heights. (Figs. 16-19 courtesy Stevin Dredging B.V.).

Fig. 13. Comparison between amplification factors obtained in the first inner harbour in the physical model with those computed using the System model, for tests with irregular, field-measured waves, applied at the harbour entrance.

Fig. 14. A perspective plot of regular waves in the outer harbour (view from the harbour entrance).

Another application is illustrated by the contours of a Mediterranean harbour in Fig. 20. Fig. 21 shows 10s waves penetrating the harbour as viewed from two different elevations. Fig. 22 shows 14s waves, the upper picture corresponding to 143 time steps (200 sec simulation), and the bottom picture to 200 time steps (280 sec simulation) after starting from cold. The time step here was 1.4s. A corresponding chart of amplification factors is shown in Fig. 23.

It is possible to include ship motions simultaneously with wave motions in a new version of the system. At each time step the pressure field around the ship is computed simultaneously with the wave field, the resultant force and thence motion of the ship is determined, the ship moved into the corresponding new position. Then at the next time step this process is repeated.

A typical resulting movement in pure (heave) of a dredger is illustrated in Fig. 24.

4. ECONOMIC FEASIBILITY

The results obtained with this latest version of the System 21 show that it is capable of solving a wide range of short wave problems of engineering interest. Models can be constructed from charts and run under

BATHYMETRY : BINTULU

 smoothing are requested.

a wide range of incident wave climates in a few hours, or at most days and a large number of alternative engineering solutions can be investigated. The results are compatible with the input data used to steer irregular wave generators for physical model tests, so that a working interaction between numerical and physical models is practical.

However, it must be accepted that short wave modelling is more demanding in the level of resolution required, as compared with the now established nearly-horizontal flow modelling of tides, storm surges, seiches and similar "long-period" phenomena. This need for a much finer resolution implies the use of many more grid points in both space and time in a model and although the operational speed of the code is but little reduced by the higher accuracy and vertical acceleration resolving capacity, the cost of running a model for a given physical time becomes important. This cost must, of course, be acceptable to engineering practice if the work is to have any other than an academic interest. For example, the cost of running the simulation shown in Fig. 22 is about U.S. \$ 24 per physical minute simulation of the 3 km² harbour. It is considered necessary, however, that this price be reduced to U.S. \$ 6

per physical minute by mid 1979 in order that the system may have a satisfactory range of practical applications. It is expected that this objective will be met. This new System 21 version obviously has a wide range of applications, to ship motions, sediment transport and other problems, as outlined by Abbott, Petersen and Skovgaard (1978).

BOTTOM DISSIPATION IN FINITE-DEPTH WATER WAVES

By

S. V. Hsiao¹ and O. H. Shemdin²

ABSTRACT

The dissipation of wave energy by various bottom mechanisms plays an important role in the spectral transformation of waves as they propagate from deep to shallow water. Three bottom dissipation mechanisms are discussed. The bottom friction mechanism is investigated in detail and a method for calculating the friction coefficient is proposed. The method is tested by comparison with field measurements. Dissipation due to percolation and bottom motion are also discussed. The magnitude of dissipation rates induced by the different mechanisms are compared under various wave and bottom conditions.

1. Introduction

The dissipation due to bottom friction is the work done by the wave orbital velocity against the bottom turbulent shear stress. The latter is usually expressed as

$$\vec{\tau} = \rho C_f |\vec{u}| \vec{u} \quad , \quad (1)$$

where $\vec{\tau}$ is the turbulent shear stress, ρ is the density of water, C_f is the friction coefficient, and \vec{u} is the velocity immediately outside the bottom boundary layer. Previous studies by Bretschneider and Reid (1954) and Hasselmann and Collins (1968) had indicated that the friction coefficient is of order 10^{-2} . Consequently, this value has been widely used. More recently, the friction coefficient has been observed to vary significantly above and below this value depending on the sand grain diameter and whether bottom ripples are present. This paper reviews the mechanisms responsible for generating bottom ripples and a method is proposed for estimating bottom friction coefficients under various bottom configurations.

The dissipation due to percolation is caused by viscous damping of energy induced by water seeping through the pores of the sandy bottom. Waves propagating above soft muddy bottoms can have their energy transferred at a rapid rate to the bottom mud layer where it is dissipated by the viscous motion induced in the bottom mud. The magnitude of such energy dissipation can be one to two orders of magnitude greater than that due to bottom friction or percolation. The rates of energy dissipation due to these three mechanisms are compared at corresponding water depths

in the last section of this paper.

II. Review of Bottom Friction Studies

Bottom friction was first investigated by Putnam and Johnson (1949). They used the quadratic friction law, $\vec{\tau} = \rho C_f |\vec{u}| \vec{u}$, and found the dissipation rate for sinusoidal waves to be

$$\frac{1}{E} \frac{dE}{dt} = -\frac{4}{3} \frac{C_f \omega^3 H}{g \sinh^3 kh}, \quad (2)$$

where E is wave energy, t is time, ω is wave frequency, H is wave height, k is wave number, and h is water depth. Bretschneider and Reid (1954) applied Putnam and Johnson's equation and found $C_f = 0.01$ for the sandy bottoms of the Gulf of Mexico. Hasselmann and Collins (1968) assumed the wave field to be Gaussian. They derived the following equation to compute the rate of energy dissipation in a random sea

$$\frac{1}{F(\vec{k})} \frac{dF(\vec{k})}{dt} = -\frac{g C_f k_i k_j}{\omega^2 \cosh^2 kh} (\delta_{ij} \langle |\vec{u}| \rangle + \langle \frac{u_i u_j}{|\vec{u}|} \rangle), \quad (3)$$

where $F(\vec{k})$ is the wave energy density at wave number \vec{k} , $\langle \rangle$ denotes the ensemble average, $i, j = 1, 2$, u_1 and u_2 are the two orthogonal components of \vec{u} , k_1 and k_2 are the two corresponding wave number components of \vec{k} . They found C_f to be 0.015 using the wave spectra measured offshore of Panama City, Florida. Based on these two studies C_f values of the order 10^{-2} have been widely used (see for example Collins (1972) and U.S. Army Coastal Engineering Research Center (1973)). More recently, much higher values have been reported. Van Ieperen (1975) computed the friction coefficients for wave data obtained offshore of Melkbosstrand, South Africa to be in the range 0.06 - 0.10.

Laboratory and semi-theoretical studies by Jonsson (1965) indicate that C_f is a function of both the wave Reynolds number defined, $R = a U_m / \nu$, and the relative roughness defined, a/k_s , where a is one half of the horizontal orbital excursion above the bed, U_m is the maximum wave orbital velocity outside the bottom boundary layer, ν is the kinematic viscosity of water, and k_s is the bottom roughness. A friction factor diagram showing the relationship between the friction coefficient, the wave Reynolds number, and the relative roughness was first proposed by Jonsson (1965) based on very little data. Expanding the data base through a series of laboratory tests, Kamphuis (1975) presented his friction coefficient diagram shown in Figure 1 which shows that the friction coefficient can easily vary by one order of magnitude either above or below the widely used value of 10^{-2} depending on bottom roughness.

When sand ripples are formed on a sandy bottom, the bottom dissipation is enhanced due to form drag. Additional energy dissipation occurs in the vortices formed above the ripple troughs. The formation

Figure 1. Friction factor diagrams (after Kamphuis, 1975).

of ripples has been investigated extensively in the laboratory, and to a lesser extent in the field. A review of these studies was reported by Dingler (1975) who also formulated a relationship for the prediction of bottom sand movement under wave action. The condition for the onset of sand motion suggested by Dingler (1975) has the form

$$\frac{\gamma_s T^2}{\rho D_s} = 240 \left(\frac{2a}{D_s} \right)^{4/3} \left(\frac{\rho \gamma_s D_s^3}{\mu^2} \right)^{-1/9} \quad (4)$$

where $\gamma_s = (\rho_s - \rho) g$, ρ_s is the density of sand, T is wave period, D_s is the mean sand diameter, and μ is the viscosity of water. If this condition is satisfied, bottom ripples can be expected. The ripple slopes, ζ/λ_s , were found to have a functional dependence on a dimensionless stress parameter, θ_s , defined in terms of wave orbital velocity and bottom sediment properties as follows:

$$\theta_s = \rho \frac{U_m^2}{\gamma_s D_s} \quad (5)$$

(see Figure 2). The ripples were found to vanish for $\theta \geq 2.5 \times 10^2$.

A different characterization of ripple properties was reported by Nielsen (1977) who found the dimensionless ratio, λ_s/a , to be functionally dependent on U_m/w , where w is the fall velocity of sand. The experimental results supporting such a relationship are shown in Figure 3. From the results of Dingler and Nielsen, it is possible to determine whether ripples are present, and then to predict the lengths and heights of such ripples. The only necessary inputs are the properties of prevailing waves and bottom sediment. As will be shown in the following sections, the ripple heights determine the bottom roughness and consequently the magnitude of the friction coefficient.

III. A Proposed Method for Estimating the Bottom Friction Coefficient

From the discussion in section II, it is clear that a constant C_f value of 10^{-2} cannot be expected to be universally valid. In this section, a method for determining C_f is proposed.

In analogy with friction losses over rigid boundaries, the use of a friction diagram such as shown in Figure 1 is necessary to estimate C_f . For given wave and depth conditions, it is possible to determine the Reynolds number $R = U_m a/\nu$ and the orbital amplitude, a . Still, the roughness height, k_s , must be estimated before C_f is determined.

For a flat bottom, the roughness height, k_s , is assumed to be equal to the sediment diameter, D_s . Therefore, under conditions when Equation (4) can not be satisfied or $\theta \geq 2.5 \times 10^2$ the value of k_s is determined directly from D_s . Then C_f is defined from known value of (a/k_s) and R using Figure 1.

When the wave and bottom sediment conditions satisfy Equation (4), bottom ripples form. Their heights, ζ , and lengths, λ_s , are then determined in the manner discussed in section II. In the presence of ripples Tunstall and Inman (1975) found that the experimental results of Bagnold (1946), Inman and Bowen (1963), Jonsson (1966), Carstens et al (1969), and Reidel et al (1972) all supported an inverse dependence of

Figure 2. Ripple steepness vs. relative stress (after Dingler, 1975).

Figure 3. λ_s/a vs. U_m/w (after Nielsen, 1977).

C_f on (a/k_s) provided that $k_s = 4\zeta$. The friction coefficient diagram shown in Figure 1 is in fact constructed to provide the correct C_f value for a given R value. As ripples form, the k_s value increases in proportion to the ripple height, ζ , so that the ratio of (a/k_s) decreases. The latter increases C_f . In the following section the validity of this procedure is tested against new field data not used in deriving the friction diagram.

IV. Friction Coefficients Computed from Field Measurements

Two sets of wave data were available to compute the friction coefficients in order to verify the method described in section III. One is the wave spectra obtained offshore of Panama City, Florida on September 9, 1965 (Breeding, 1972). The waves were measured by two pressure sensor arrays located at 31.7 m and 19.2 m water depths. The other is the spectra obtained offshore of Marineland, Florida on December 14, 1975 (Shemdin et al, 1975). A Geodolite laser sensor was used to measure the waves at 31 m water depth and a pitch-and-roll buoy was used at 8.5 m water depth.

The C_f values were computed from spectra at two different depths using a method similar to that of Hasselmann and Collins (1968). For the Panama City case the C_f values were found to be in the range 0.035-0.05. A sample predicted shallow water spectrum is compared with the measured shallow water spectrum in Figure 4. The C_f value in this particular calculation is 0.04.

Using the method described in section III, the estimated C_f value is 0.03. It is also found to be approximately a constant between the two measuring stations based on wave and sediment conditions at both stations. A summary of wave and sediment conditions needed to calculate C_f is shown in Table 1. The agreement between the proposed procedure for calculating C_f and the values obtained from shoaling spectra is of order 25%. The agreement is considered reasonable.

For the Marineland data the computations are somewhat more complicated by the fact that conditions vary sufficiently between the two stations to warrant different bed forms and C_f values. From the measured wave spectra, a constant C_f value of 0.008 is computed. The procedure outlined in section III provide C_f estimates which vary from 0.05 at 30 m water depth to 0.002 at 8.5 m water depth. A summary of wave and sediment parameters is shown in Table 1. In order to test the validity of the procedure outlined in section III, predicted shallow water spectra are compared with measured shallow water spectra in Figure 5. The predicted spectra are based on (a) fixed $C_f = 0.008$, and (b) variable C_f from 0.05 in deep water to 0.002 in shallow water. At high frequencies the fixed and variable C_f values give similar results. At low frequencies the variable C_f value procedure gives better agreement with the measured values in shallow water. The Marineland data set serves to demonstrate that predicting shallow water waves may not be as simple as defining a representative value for the entire shoaling region and that more detailed measurements are needed to verify the procedure outlined in section III.

Figure 4. Comparison between measured and computed Panama City spectra. — measured, -- computed at Stage II.

Table 1. Estimation of Friction Coefficients from Wave and Sand Parameters

Variable	Marineland		Panama City	South Africa (TBO 37)
h	30	8,5	19,2 - 31.7	10.6 - 32
T_m	8	8	12	13.7
$H_{1/3}$	1.7	1.5	1,9 - 3,7	2.3 - 2,8
d_o	0,49	1,68	1.9 - 2.9	2.6 - 4.5
D_s	$(0,1 \times 10^{-3})$		$(0,4 \times 10^{-3})$	$(1,5 \times 10^{-3})$
λ	0.070	0.032	0.24	0.9
θ	24 - 290		33 - 82	15 - 45
ζ	0.012	0	0.024	0.15
k_s	0.048	0.0001	0,096	0.60
C_f	0.05	0.002	0.03	0.10

h	= water depth (m)	λ_s	= ripple wave length (m)
T_m	= peak period (sec)	θ_s	= nondimensional relative stress
$H_{1/3}$	= significant wave height (m)	ζ	= ripple wave height (m)
d_o	= horizontal excursion (m)	k_s	= roughness height (m) (4ζ as was suggested by Jonsson, 1966)
D_s	= median sand diameter (m)	C_f	= friction coefficient

Finally, the procedure proposed in section III is tested by using it to estimate a C_f value for the waves measured offshore of Melkbosstrand, South Africa. The bottom sediment properties in that region were not reported. A value of $C_f = 0.1$, in agreement with that calculated from shoaling spectra, could only be predicted if the bottom material was composed of coarse sand with $D_s = 1.5$ mm. Under such conditions bottom ripples can form and the high reported C_f values can be explained. A summary of wave and assumed sediment conditions for Melkbosstrand is also included in Table 1.

Figure 5. Comparison between measured and computed Marineland wave spectra.

V. Percolation Dissipation

Putnam (1949) was the first to compute the wave energy dissipation rate due to percolation in an isotropic permeable sandy bottom. However, he overestimated the dissipation rate by a factor of four due to an arithmetic error. Later, Bretschneider and Reid (1954) applied Putman's equation to study the wave height modification and consequently overestimated the percolation damping. A more general equation to compute the percolation dissipation rate was given by Shemdin et al (1977) as

$$\frac{1}{E} \frac{dE}{dt} = -k \sqrt{\alpha\beta} \frac{\tanh \sqrt{\frac{\alpha}{\beta}} kd}{\cosh^2 kh}, \quad (5)$$

where α and β are the horizontal and vertical coefficients of permeability, respectively, and d is the thickness of the sand layer. Using this equation and the magnitude of permeability coefficients determined by Sleath (1970) they computed the dissipation rates at different water depths. The results are compared with corresponding friction dissipations in Figure 6. These results demonstrate that percolation dissipation can be more important than friction dissipation for coarse sand in deeper water.

VI. Bottom Motion Dissipation

Excessive attenuation of wave energy in the Mississippi Delta area was reported by Bea (1974) and Tubman and Suhayda (1976). The attenuation cannot be reasonably explained by refraction, shoaling, bottom friction, nor bottom percolation. It is believed that the excessive attenuation is due to the effect of the wave-induced motion in the soft muddy bottom. Gade (1958, 1959) studied the wave energy dissipation effects of a non-rigid bottom in shallow water. His results are restricted to only shallow water waves. (i.e., $kh < 0.1\pi$) and cannot be applied to intermediate waver waves. Mallard and Dalrymple (1977) studied the effects of an ideal elastic bottom on water waves. Their computations, which neglected viscosity in the mud, show no wave energy loss. Hsiao and Shemdin (1978) assumed a viscoelastic bottom and obtained the following dispersion equation

$$k = \frac{\omega^2}{g} \frac{1 + \tanh kh \Omega}{\tanh kh + \Omega} \quad (6)$$

where Ω is a function of wave and bottom properties and k is the complex wave number in which the imaginary part is a measure of energy dissipation. The dissipation rates predicted by Equation (6) can explain the wave decay rates reported by Tubman and Suhayda (1976). Some computed dissipation rates using Equation (6) are shown in Figure 6 for comparison with dissipation rates due to friction and percolation. It can be clearly seen that the dissipation rate due to bottom motion can be one to two orders of magnitude greater than those due to friction and/or percolation.

Figure 6. Comparison between dissipation mechanisms. ν_m = kinematic viscosity of mud, G = shear modulus of mud, ρ_m = density of mud (after Shemdin et al, 1977).

VII. Conclusions

It is shown that any of the three dissipation mechanisms discussed in this paper, namely friction, percolation, and bottom motion can be dominant in dissipating wave energy in shallow water depending on wave properties and bottom sediment properties. None can be arbitrarily neglected. Information on bottom sediment is considered of critical importance to properly identify the prevailing mechanism. Such information is not routinely obtained when measuring shoaling waves.

The friction coefficient is found to vary considerably above or below the widely used 10^{-2} value. A method for estimating the friction coefficient is suggested and found to give acceptable values over a broad range of conditions.

ACKNOWLEDGEMENT

Financial support for this study was provided by ONR-Geography Program, Contract No. N00014-76-MP60029, and by NATO Special Grant No. SRG 14. The Marineland data were gathered under NASA-Office of Applications. The wave spectra at Marineland were provided by W. McLeish of NOAA-AOML. The Panama City data were provided by J.E. Breeding, Jr. of Naval Coastal Systems Laboratory.

CHAPTER 25

EXCITATION OF LOW FREQUENCY TRAPPED WAVES

by

ROBERT KING* & RONALD SMITH**

Weak nonlinear interactions in water of non-constant depth between an incident wave, a side-band incident wave and a relatively low frequency trapped wave are shown to lead to the generation of the trapped wave. Three situations are considered in detail: edge waves in a wide rectangular basin, progressive edge waves on a straight beach, and standing waves in a narrow wave tank.

1. Introduction

The formation of crescent-shaped sand-bars along laboratory beaches was shown by Bowen and Inman (1971) to be due to the presence of standing edge waves. For their explanation to be relevant to naturally occurring crescentic bars it would be necessary for the edge waves to have periods of between 30 and 60 seconds. It is thus of interest to consider how such standing edge waves are generated. A possible mechanism would be via resonant interactions between two edge waves and an incident untrapped wave (Guza and Davis, 1974). However, for this to produce edge waves of the required period the necessary periods of the incident waves would be between 15 and 30 seconds, but, typically, there is not much surface wave energy at such long periods (Sonu, 1972).

In this paper we consider a wavefield consisting of a relatively short scale incident wave, the dominant Fourier component of which is characterised by (ω, k) , and a long scale trapped wave characterised by (σ, κ) . The wavelength of the long scale motion is taken to be much greater than that of the short scale motion, i.e. $|k| \gg |\kappa|$. This means that, except in the immediate vicinity of the shoreline, we can assume the water to be "deep" with respect to (ω, k) and "shallow" with respect to (σ, κ) . Since the system is non-linear, weakly non-linear interactions give rise to the harmonics $(\omega \pm \sigma, k \pm \kappa)$ being present.

* Irrigation and Drainage Consultant, Brick Kiln Lane, Thorrington N.E. Essex.

** C.E.G.B. Research Fellow, Department of Applied Mathematics and Theoretical Physics, University of Cambridge.

Now, if $\omega \gg \sigma$, then the harmonics $(\omega + \sigma, k + \kappa)$ are very close to (ω, k) and therefore almost satisfy the dispersion relation for incident waves. Thus, there is an almost-resonant triad consisting of the short scale wave (ω, k) , one of the side-band waves $(\omega + \sigma, k + \kappa)$ and the long scale wave (σ, κ) . Indeed, if the strong inequalities are relaxed then there can be exact resonance between two incident and one trapped wave (Gallagher, 1971). The existence of such a triad of waves makes it feasible for there to be a significant energy transfer from (ω, k) to (σ, κ) (Phillips, 1974). Numerical estimates made in §2.4 suggests that edge waves in the sea can be generated by the side-band mechanism.

As has been pointed out by Phillips (1974), resonant interactions between waves of different length scales can be interpreted as short waves propagating on a non-uniform current. It was shown by Longuet-Higgins and Stewart (1961) that there is not a partition between wave energy and stream energy. However, in the absence of dissipation there is a conserved property of the short waves - wave action - which can be identified with wave energy when there is no current (Bretherton and Garrett, 1968). In the present problem the current is of limited extent and from wave action considerations it can be concluded that, in the absence of dissipation, there is no net energy transfer from the short waves to the trapped waves. Specifically, the energy feed from the incident wavetrain is exactly negated by the energy extracted by the reflected waves. Through ignoring the presence of any reflected waves, the mechanism being studied in this paper relies crucially upon there being dissipation, particularly near the shoreline.

Although the generation of standing edge waves is the primary concern of this paper, the side-band mechanism need not be restricted to standing waves nor to edge waves. In §§3 and 4 respectively, we briefly consider the generation of progressive edge waves on an open beach and the generation of longitudinal standing waves in a narrow wave tank. It is hoped that this latter situation might permit laboratory testing of the side-band mechanism using apparatus of modest dimensions.

2. The generation of standing edge waves

2.1 Equations of motion

Consider a body of water, the free surface of which is at rest, $z=0$, where z is measured vertically upwards. The equations for small amplitude oscillations of an ideal fluid can be written in the form

$$\nabla^2 \phi + \phi_{zz} = 0,$$

$$\phi_{tt} + g\phi_z = R \quad \text{at } z = 0,$$

$$\phi_z + \nabla h \cdot \nabla \phi = 0 \quad \text{at } z = -h(\underline{x}),$$

where ϕ denotes the velocity potential, $h(\underline{x})$ the depth, ∇ the horizontal gradient operator and R represents complicated nonlinear terms which are, correct to second order in the wave amplitude,

$$R = -\nabla \cdot (\phi_t \nabla \phi) - \partial_t \left[\frac{1}{2} (\nabla \phi)^2 + \frac{1}{2} \phi_z^2 + g^{-2} \phi_t \phi_{ttt} \right].$$

If $W(\underline{x}, z; \sigma)$ represents a free standing wave mode of the undamped linear system with frequency σ , then W satisfies the equations

$$\nabla^2 W + W_{zz} = 0, \quad -\sigma^2 W + g W_z = 0 \text{ at } z = 0, \quad W_z + \nabla h \cdot \nabla W = 0 \text{ at } z = -h(\underline{x}).$$

For each eigenfunction W an application of Green's Theorem leads to the evolution equation

$$\left(\frac{d^2}{dt^2} + \sigma^2 \right) \int_{\Omega} [W\phi]_{z=0} + g \int_{\partial\Omega} \int_{-h}^0 \left(\phi \frac{\partial W}{\partial n} - W \frac{\partial \phi}{\partial n} \right) = \int_{\Omega} [RW]_{z=0} \quad (2.1)$$

where Ω denotes the water surface, $\partial\Omega$ the boundary of Ω and $\partial/\partial n$ denotes differentiation along the outward normal to $\partial\Omega$. If Ω is of infinite extent, then, to assure the convergence of the integrals, it may be necessary to take W to be that leaky trapped wave which decays exponentially at infinity (Longuet-Higgins, 1967). Equation (2.1) enables us to determine the effect of the nonlinearity upon the evolution of the standing waves without the necessity of explicitly evaluating the correction terms due to the nonlinearity. It corresponds to the non-secularity or integrability condition which arises in a direct solution of the governing differential equations (Bretherton and Garrett, 1968).

Let $w(z; \omega, h)$ be a local solution to the progressive wave eigenvalue problem for waves of frequency ω :

$$-(\nabla\theta)^2 w + w_{zz} = 0,$$

$$w = 1 \text{ and } w_z = \omega^2/g \text{ at } z = 0,$$

$$w_z = 0 \text{ at } z = -h(x),$$

where $|\nabla\theta|$ is the local wave-number (eigenvalue). The equation which enables us to focus our attention on the effect of nonlinearity on the ω -component of the wavefield is

$$(\partial_t^2 + \omega^2)\phi_{z=0} - g \int_{-h}^0 w(\nabla^2 + (\nabla\theta)^2)\phi dz - g\nabla h \cdot [\nabla w \nabla \phi]_{z=-h} = R. \quad (2.2)$$

Just as it is not essential to explicitly evaluate the nonlinear

corrections to Φ , in both equations (2.1) and (2.2) the vertical structure of Φ need not be represented exactly. This fact will be used subsequently when $w(z; \omega \pm \sigma, h)$ are approximated firstly by $w(z; \omega, h)$ and then by $w(z; \omega, \infty)$.

The model equations presented above are inadequate to describe the complicated structure of the surf zone. This problem is most easily overcome by making the following assumptions: (a) The incident short waves are not reflected at the beach, yet the trapped waves are totally reflected. (b) The wavelength of the incident waves does not change as they shoal. The consequence of these assumptions is that our approximation for Φ , and more particularly R , is grossly in error in the immediate vicinity of the shoreline. As can be seen from equation (2.1), a local error in R need not greatly effect our estimate of the growth rate of the standing wave. In the calculations given below, assumption (a) is made at the onset but the use of assumption (b) is delayed.

The assumptions (a) and (b) were also made by Gallagher (1971). For his analysis it is extremely difficult to provide a justification because there is not a marked disparity in length scales between the incident and trapped waves. Guza and Davis (1974) chose the opposite extreme of perfect reflection of the incident waves. The no-reflection boundary condition is also appropriate to situations where there is no coastal boundary, such as in the excitation of ducted waves on an under-sea ridge (Buchwald, 1969).

On vertical sections of the boundary we impose the normal velocity conditions

$$\partial W / \partial n = 0, \quad \partial \Phi / \partial n = Q,$$

where Q is non-zero on those sections of the boundary which are being used (or interpreted) as being wavemakers for the generation of the incident waves.

2.2 Side-band representation

For the interaction mechanism under consideration, the wavefield is dominated by the incident wave of frequency ω and the standing trapped wave of frequency σ . A vitally important role is also played by the side-band incident waves of frequencies $\omega \pm \sigma$. Accordingly, we write the velocity potential as

$$\begin{aligned} \Phi = \exp(i\omega t - i\theta(\underline{x})) & \left[\Phi_0(\underline{x}, t)w(z; \omega, h) + \Phi_+(\underline{x}, t)w(z; \omega + \sigma, h)e^{i\sigma t} \right. \\ & \left. + \Phi_-(\underline{x}, t)w(z; \omega - \sigma, h)e^{-i\sigma t} \right] + W(\underline{x}, z; \sigma)\eta(t)e^{i\sigma t} + * + \Phi'. \end{aligned} \quad (2.3)$$

Here Φ_0 , Φ_+ and η are the slowly-varying amplitudes of the incident, side-band and the trapped waves respectively. All other contributions to the wavefield are assumed to play no significant role in the generation of the trapped waves, and are collectively represented by Φ' . The

formally largest of such neglected terms are virtual modes with frequencies 2ω , 2σ and the wave set-up which has zero frequency. Reflections on the vertical sections of the boundary $\partial\Omega$ could be represented by permitting ϕ_0 , ϕ_{\pm} and θ to be multiple-valued.

Substituting for ϕ in (2.2) and equating $\exp(i\omega t - i\theta)$ terms gives

$$2i\omega\phi_{0t} + \phi_{0tt} + ig \int_{-h}^0 w\{2\nabla\theta \cdot \nabla(w\phi_0) + W\phi_0 \nabla^2\theta\} dz - \int_{-h}^0 w\nabla^2(w\phi_0) dz - g\nabla h \cdot [\nabla w(\phi_0 w)]_{z=-h} = R_0,$$

where w stands for $w(z; \omega, h)$ and R_0 is the $\exp(i\omega t - i\theta)$ term in the side-band representation for the nonlinear terms. For the side-band amplitudes ϕ_{\pm} similar equations involving $w(z; \omega, \sigma, h)$ are obtained. We

note that even though we shall only represent R correct to quadratic terms, the explicit representation for R_0 in terms of ϕ_{\pm} , η is quite unwieldy.

We now make the following simplifying assumptions

$$\omega \gg \sigma, \quad |\nabla\theta|L \gg 1, \quad \omega/(L|\nabla\theta|) \gg \eta_L/\eta,$$

where L is a length scale appropriate to either the topographic variations or to the trapped waves. Physically the assumptions mean that the incident wave is very short and that an individual wave packet is "unaware" that the standing wave is growing in amplitude. Mathematically the assumptions mean that in the expression for R_0 , and the corresponding expressions in the equation for the side-bands, derivatives of the short wave exponent $(\omega t - \theta(x))$ dominate derivatives either of the wave amplitude ϕ_0 , ϕ_{\pm} , η or of the mode shapes w , W . Also, we can justify approximating $w(\bar{z}; \omega \pm \sigma, h)$ by $w(z; \omega, h)$. Retaining only the largest real and imaginary terms, we can simplify the equations for the progressive waves to

$$\begin{aligned} \zeta \cdot \nabla \phi_0 + (\nu + \frac{1}{2} \nabla \cdot \zeta) \phi_0 &= \left[W \frac{\omega^2 \sigma^2}{g^2} + i \nabla \theta \cdot \nabla W \right] (\eta^* \phi_+ + \eta \phi_-) \\ &+ \left[\frac{\omega^4}{g^2} - (\nabla \theta)^2 \right] \frac{\sigma W}{2\omega} (\eta^* \phi_+ - \eta \phi_-), \end{aligned} \tag{2.4a}$$

$$\begin{aligned} \underline{c} \cdot \nabla \phi_+ + i\sigma \phi_+ + (v + \frac{1}{2} \nabla \cdot \underline{c}) \phi_+ &= \left[W \frac{\omega^2 \sigma^2}{g^2} + i\nabla \theta \cdot \nabla W \right] \eta \phi_0 \\ &- \left[\frac{\omega^4}{g^2} - (\nabla \theta)^2 \right] \frac{\sigma W}{2\omega} \eta \phi, \end{aligned} \quad (2.4b)$$

$$\begin{aligned} \underline{c} \cdot \nabla \phi_- - i\sigma \phi_- + (v + \frac{1}{2} \nabla \cdot \underline{c}) \phi_- &= \left[W \frac{\omega^2 \sigma^2}{g^2} + i\nabla \theta \cdot \nabla W \right] \eta^* \phi_0 \\ &+ \left[\frac{\omega^4}{g^2} - (\nabla \theta)^2 \right] \frac{\sigma W}{2\omega} \eta^* \phi_0, \end{aligned} \quad (2.4c)$$

where \underline{c} is the group velocity of the incident waves of frequency ω , and the v terms are an empirical representation of the damping. The left-hand side terms could have been anticipated from the fact that in the absence of currents and damping, the wave energy of the short waves propagates at the group velocity.

If the low frequency component of the wavemaker motion is neglected and if W is normalised:

$$\int_{\Omega} [W^2]_{z=0} = \ell^{-2},$$

then substituting (2.3) into (2.1), and equating coefficients of $e^{i\sigma t}$, we obtain the following simplification of the standing wave equation

$$\begin{aligned} \eta_L + v' \eta &= \int_{\Omega_1} (\phi_0^* \phi_+ + \phi_0 \phi_-^*) \left[\frac{1}{2} W \left(\frac{\omega^4}{g^2} - (\nabla \theta)^2 \right) + \frac{i\omega}{\sigma} \nabla \theta \cdot \nabla W \right] \ell^2 \\ &- \frac{i\omega \ell^2}{\sigma} \int_{\partial \Omega_1} (\phi_0^* \phi_+ + \phi_0 \phi_-^*) \frac{\partial \theta}{\partial n} W \Big|_{z=0} \end{aligned}$$

$$+ \int_{\Omega_1} (\Phi_0^* \Phi_+ - \Phi_0 \Phi_+^*) 2 \frac{\omega^3 \sigma}{g^2} W \Big|_{z=0} \lambda^2 - \frac{i \lambda^2}{2\sigma} \int_{\Omega - \Omega_1} |RW|_{z=0} \quad (2.5)$$

Here, ν' is an empirical representation of damping, Ω_1 denotes that region of the water surface in which (2.3) is thought to be an adequate description of the waves, and in Ω_1 we have only retained the largest real and largest imaginary contributions to R . If θ were multiple-valued (due to there being reflections off vertical portions of $\partial\Omega$) then different branches of θ would contribute separately to the nonlinear terms.

To make further progress we must either give a description of the waves which is valid in the surf zone $\Omega - \Omega_1$ or we must be able to neglect the $\Omega - \Omega_1$ term in (2.5). Here we choose the latter alternative. It is reasonable to assume that the effects of both reflection and strong nonlinearities is to keep the interaction term R bounded. Thus to ignore the effect of the $\Omega - \Omega_1$ region it suffices that it has small extent relative to the interaction region. The previously assumed disparity of length scales between the incident and trapped waves adds credence to this further assumption.

We observe that all the retained quadratic terms in equations (2.4) and (2.5) involve derivatives of the short wave exponent $(\omega t - \theta)$. Thus of the formally largest neglected terms in (2.3) it is only the $2(\omega t - \theta)$ virtual modes which would lead to any change in equations (2.4) or (2.5). A calculation akin to that of Stokes (1849) leads to the extra terms

$$i\lambda\phi_0^2\phi_0^*, \quad i\lambda\phi_0^2\phi_-^*, \quad i\lambda\phi_0^2\phi_+^*$$

on the right-hand sides of equations (2.4a,b,c), where

$$\lambda = \frac{1}{8}\omega^3 k^2 g^{-2} (1 + \frac{1}{8} \text{Coth } 4 kh).$$

These terms play a very minor role in the energy transfer mechanism and for simplicity we continue to ignore them.

2.3 Onset of instability

To explain the onset of the instability we assume that the system is started from a state of near rest and we can thus regard the sidebands ϕ_{\pm} and the standing wave η as being of very small amplitude. Thus the incident wave amplitude ϕ_0 approximately satisfies the linear equation

$$\zeta \cdot \nabla \Phi_0 + (\nu + \frac{1}{2} \nabla \cdot \zeta) \Phi_0 = 0, \quad (2.6)$$

and the perturbation quantities Φ_+ , Φ_- , η satisfy couple linear equations. The form of equations (2.5) leads us to define the sum and difference terms:

$$\eta |\Phi_0|^2 S = \Phi_0^* \Phi_+ + \Phi_0 \Phi_-^*, \quad \eta |\Phi_0|^2 D = \Phi_0^* \Phi_+ - \Phi_0 \Phi_-^*,$$

where during the initial stages of the instability S and D satisfy the first order differential equations

$$\zeta \cdot \nabla S + i\sigma S = 2 \omega^2 \sigma^2 W|_{z=0}, \quad (2.7)$$

$$\zeta \cdot \nabla D + i\sigma D = 2i\nabla\theta \cdot \nabla W|_{z=0} - \left(\frac{\omega^4}{g^2} - (\nabla\theta)^2\right) \frac{\sigma}{\omega} W|_{z=0}$$

The boundary conditions for these equations are that $S = D = 0$ far away from the interaction region. It now follows from equation (2.5), with the $\Omega - \Omega_1$ term neglected, that η grows exponentially with time, the exponent being

$$-\nu' + \int_{\Omega_1} |\Phi_0|^2 S \left[\frac{1}{2} W \left(\frac{\omega^4}{g^2} - (\nabla\theta)^2 \right) + i \frac{\omega}{\sigma} \nabla\theta \cdot \nabla W \right]_{z=0} \ell^2 \quad (2.8)$$

$$+ \int_{\Omega_1} |\Phi_0|^2 D \left[2 \frac{\omega^3 \sigma}{g^2} W \right]_{z=0} \ell^2 - \int_{\partial\Omega_1} |\Phi_0|^2 \frac{i\omega}{\sigma} SW|_{z=0} \frac{\partial\theta}{\partial n} \ell^2.$$

The condition for there to be an instability is that the time exponent (2.8) should have a positive real part.

2.4 Uniformly sloping beach

In the representation (2.3) no account is taken of any reflection of the short waves. As a consequence, even if there is no wave-breaking the description is inappropriate near the shoreline and predicts spurious singularities. For our present purposes these singularities are particularly unfortunate in that the expression (2.8) is sensitive to our choice of Ω_1 . It is to avoid this dilemma that we invoke the assumption (b) referred to in §2.1. Thus we assume that the

beach angle is so steep that the deep water description for the incident waves is appropriate in a region Ω_1 which extends to within the order of one wavelength of the shoreline. Since the modified representation for Φ is free from singularities (though still not valid in $\Omega - \Omega_1$) we can also approximate Ω_1 by the entire water region Ω in the integrals (2.8).

The only geometry for which an exact solution for a linear trapped wave is known is a beach of constant slope in a channel with parallel vertical walls which are orthogonal to the beach. The exact solutions involve a superposition of exponentials (Ursell, 1952), the normalised solution for the lowest mode being

$$W = \left[2(\cos \alpha)^{\frac{1}{2}} \pi^{\frac{1}{2}} \right] \cos ly \exp(-lx \cos \alpha + lz \sin \alpha), \quad \sigma^2 = g l \sin \alpha,$$

where α is the beach angle and π/l is the distance between the vertical walls. If we are to retain the convenience of working only with exponential functions, then it is necessary that the coefficients c, v in equations (2.6-2.7) are constant. Fortunately, this is indeed the case when the beach angle is sufficiently steep (i.e. $(\sigma/\omega)^2 \ll \tan^2 \alpha$) that the deep water approximation (b) can be used. For incident waves normal to the beach the appropriate solutions to equations (2.6-2.8) for the lowest mode edge waves are

$$\Phi_0 = A \exp(vx/c) \quad \text{with} \quad \underline{c} = (-c, 0, 0),$$

$$S = \frac{2 \omega^2 l \sin \alpha W|_{z=0}}{g(c l \cos \alpha + i \sigma)} \quad D = \frac{i 2 \omega^2 l \cos \alpha W|_{z=0}}{g(c l \cos \alpha + i \sigma)}$$

$$\text{exponent} \doteq v' + |A|^2 \frac{2 \omega^5 l \cos \alpha}{g^3} \left[1 + i(c l \cos \alpha / \sigma) \right] \left[\frac{l \cos \alpha + 2(v/c)}{l \cos \alpha - (v/c)} \right]$$

Thus, if the wave steepness $\omega^3 |A| g^{-2}$ exceeds the critical value

$$\left[\frac{v' \omega}{2 g l \cos \alpha} \left\{ \frac{l \cos \alpha - (v/c)}{l \cos \alpha + 2(v/c)} \right\} \right]^{\frac{1}{2}} \quad (2.9)$$

then the edge wave will grow in amplitude.

As a numerical example of the estimate (2.9), to a moderately large laboratory size situation we specify the values

$$\alpha = \pi/6, \quad \ell = \pi m^{-1}, \quad \sigma \sim 4s^{-1}, \quad \omega \sim 20 s^{-1}, \quad \nu/c \sim 10^{-1} m^{-1}.$$

Although the value of ν/c corresponds to a dirty surface, we note that $(\nu c/\ell)$ is essentially negligible. Guza and Davis (1974) show that a laminar model of edge wave damping gives

$$\nu' = \bar{\nu}^{\frac{1}{2}} \ell \sigma^{\frac{1}{2}} \cot \alpha \quad 2^{-\frac{1}{2}},$$

where $\bar{\nu}$ is the kinematic viscosity. Thus we can estimate that $\nu' \sim 7 \times 10^{-3} s^{-1}$, critical steepness ~ 0.05 .

Hence the instability would appear to be realisable in a laboratory situation.

If we regard σ/ω , $\bar{\nu}$ as being fixed, then we can use the above results to determine the dependence of the critical steepness upon the beach angle α and wavenumber ℓ :

$$\text{critical steepness} \sim \ell^{\frac{3}{8}} \alpha^{\frac{1}{8}}.$$

Thus an increase of the length scale, i.e. a decrease of ℓ , lowers the critical steepness. Regrettably, the deep water approximation is not applicable to naturally occurring beaches where $(\tan \alpha)^2$ is typically 10^{-3} or less. In such cases there seems no alternative but to allow for shoaling. Within the framework of the present calculations, this would entail choosing Ω_1 as to avoid the spurious singularities. (The authors hope to present at a later date a more complicated calculation procedure which avoids the singularities).

3. Progressive edge waves.

For progressive trapped waves the longshore direction plays the role of a second time-coordinate. Although the mathematical consequences of this change of role are numerous, they are individually quite minor and we can follow the pattern of calculations developed in §2.

On the assumptions that the coastal curvature is small relative to the wavenumber of the trapped waves and that the seaward depth topography varies very slowly in the longshore y -direction, the local eigenvalue problem for trapped waves of frequency σ and longshore wavenumber ψ_y is

$$W_{xx} + W_{zz} - \psi_y^2 W = 0, \quad -\sigma^2 W + gW_z = 0 \text{ at } z = 0,$$

$$W_z + h \frac{W}{x} = 0 \text{ at } z = -h.$$

The corresponding integral form of the equations of motion is

$$(\partial_t^2 + \sigma^2) \int_0^\infty [W\Phi]_{z=0} dx - g \int_0^\infty \int_{-h}^\infty W(\partial_y^2 + \psi_y^2) \Phi dz dx + g \int_0^\infty h_y [W\Phi]_{z=-h} dx \tag{3.1}$$

$$+ \left[\int_{-h}^0 \left(\Phi \frac{\partial W}{\partial x} - W \frac{\partial \Phi}{\partial x} \right) dz \right]_0^\infty = \int_0^\infty [RW]_{z=0} dx.$$

For the progressive waves the eigenvalue problem and integral version of the nonlinear equations remain as in §2.1, but it is natural to regard the longshore dependence of the phase measurement θ as being imposed by conditions far from the shore.

The time-like character of the y-coordinate leads us to modify the side-band representation of the wavefield:

$$\begin{aligned} \Phi = e^{i(\omega t - \theta)} & \left[\Phi_0(x, y, t) w(z; \omega, h) + \Phi_+(x, y, t) w(z; \omega + \sigma, h) e^{i(\sigma t - \psi)} \right. \\ & \left. + \Phi_-(x, y, t) w(z; \omega - \sigma, h) e^{-i(\sigma t - \psi)} \right] + W(x, z; \sigma, y) \eta(y, t) e^{i(\sigma t - \psi)} \tag{3.2} \end{aligned}$$

Thus, the y-dependence on the length scale of ψ_y^{-1} is represented

explicitly by the ψ exponents, and possible very slow y-dependence associated with any instability is represented via the amplitude factors Φ_0, Φ_\pm, η . This representation is assumed to be accurate in a region $(a, \infty)^t$ which excludes the shoreline.

Making the same simplifying assumptions as in §2.2, i.e.

$$\omega \gg \sigma, \quad |\nabla\theta|L \gg 1, \quad \omega/(L|\nabla\theta|) \gg \eta_t/\eta,$$

we can simplify the equations for the incident waves to

$$c_1 \Phi_{0,x} + (\nu + \frac{1}{2} c_1) \Phi_0 = \left[W \frac{\omega^2 \sigma^2}{g^2} + i\theta \frac{W}{x} \right] (\eta^* \Phi_+ + \eta \Phi_-)$$

$$+ \left[\frac{\omega^4}{g^2} - (\nabla\theta)^2 \right] \frac{\sigma W}{2\omega} - \theta_y \psi_y W \left[\eta^* \phi_+ - \eta \phi_- \right], \quad (3.3a)$$

$$c_1 \phi_{+x} + i(\sigma - c_2 \psi_y) \phi_+ + (\nu + \frac{1}{2} c_1)_x \phi_+ = \left[W \frac{\omega^2 \sigma^2}{g^2} + i \theta_x W_x \right] \eta \phi_0 - \left[\left(\frac{\omega^4}{g^2} - (\nabla\theta)^2 \right) \frac{\sigma W}{2\omega} - \theta_y \psi_y W \right] \eta \phi_0, \quad (3.3b)$$

$$c_1 \phi_{-x} - i(\sigma - c_2 \psi_y) \phi_- + (\nu + \frac{1}{2} c_1)_x \phi_- = \left[W \frac{\omega^2 \sigma^2}{g^2} + i \theta_x W_x \right] \eta^* \phi_0 + \left[\left(\frac{\omega^4}{g^2} - (\nabla\theta)^2 \right) \frac{\sigma W}{2\omega} - \theta_y \psi_y W \right] \eta^* \phi_0, \quad (3.3c)$$

where $(c_1, c_2, 0)$ is the group velocity of the incident waves of frequency ω and the ν terms are an empirical allowance for the damping. The corresponding equation for the trapped wave is

$$\begin{aligned} \eta_t + c' \eta_y + (\nu' + \frac{1}{2} c'_y) \eta &= \frac{\sigma^2}{g} \int_a^\infty (\phi_0^* \phi_+ + \phi_0 \phi_-^*) \left[\frac{1}{2} W \left(\frac{\omega^4}{g^2} - (\nabla\theta)^2 \right) \right. \\ &+ i \frac{\omega \theta}{\sigma} \frac{W_x}{x} - \frac{\omega \theta}{\sigma} \frac{W \psi_y}{y} \left. \right] dx + \frac{\sigma^2}{g} \int_a^\infty (\phi_0^* \phi_+ - \phi_0 \phi_-^*) \frac{2\omega^3 \sigma}{g^2} \frac{W}{z=0} dx \\ &+ \frac{i\sigma\omega}{g} \left[(\phi_0^* \phi_+ + \phi_0 \phi_-^*) W \right]_{z=0} \theta_x - \frac{i\sigma}{g} \int_0^a [RW]_{z=0} dx. \end{aligned} \quad (3.4)$$

where c' is the longshore group velocity of the trapped waves and W is normalised:

$$\int_0^\infty |W^2|_{z=0} dx = g\sigma^{-2}$$

We shall assume that the representation (3.2) applies sufficiently close to the shore that the $(0,a)$ term in equation (3.4) can be neglected. As noted in §2.2 the particularly simple form of the left-hand-side terms is related to the fact that in the absence of interactions or damping the wave energy of the incident and trapped waves propagate at their respective group velocities.

In considering the onset of instability it is again convenient to introduce the sum and difference terms S and D . To determine the development of η it is convenient to use axes moving with the local group velocity c' . The evolution can be assumed to be exponential only if the topography and the incident wave amplitude Φ_0 are both independent of y . For the special case of edge waves on a uniformly sloping beach of large angle (i.e. $\tan^2\alpha \gg (\alpha/\omega)^2$) it is possible to obtain an analytic description of the onset condition

$$\text{critical steepness} = \left(1 - \frac{\ell c_2}{\sigma}\right)^{\frac{1}{2}} \left[\frac{v'\omega}{2g\ell\cos\alpha} \left\{ \frac{\ell\cos\alpha - v/c_1}{\ell\cos\alpha + 2v/c_1} \right\} \right]^{\frac{1}{2}} \quad (3.5)$$

The group velocity c_2 of the incident waves is less than the phase velocity σ/ℓ of the trapped wave. Thus, the extra factor in (3.5) as opposed to (2.9) does not make a substantial reduction in the numerical estimates.

4. Standing waves in a narrow tank

Laboratory experiments permit much more stringent testing of theories than field measurements, but edge wave experiments can make severe demands upon facilities due to the large area of water involved (Bowen and Inman, 1969). With this in mind, we now show the side-band theory can be used to predict the growth of a standing wave in a narrow channel. Numerical estimates of the onset conditions are obtained for the particular case of a tank with a sloping bottom and a plane wave-maker positioned at one end. As with §3, the pattern of calculations developed in §2 can again be followed with only a few minor alterations.

We consider here a tank of length L and breadth B such that $L \gg B$. Axes are chosen so that x is measured along the tank, y across the tank and z vertically upwards. In this case we have $w(y,z;\omega,h)$ as a local solution to the progressive wave eigenvalue problem:

$$-\theta^2 \frac{\partial^2 w}{\partial x^2} + w_{yy} + w_{zz} = 0, \quad w_z = \frac{\omega^2 w}{g} \quad \text{at } z = 0,$$

$$w_z = 0 \quad \text{at } z = -h(x), \quad w_y = 0 \quad \text{at } y = 0, B,$$

with the normalisation

$$\int_0^B [w^2]_{z=0} dz = B.$$

For each position x , the local energy transport equation for the progressive waves is

$$\begin{aligned} (\partial_t^2 + \omega^2) \int_0^B [w\Phi]_{z=0} dy - \int_{-h}^0 w(\partial_x^2 + \theta_x^2)\Phi dz dy - g \int_0^B [wh_x \Phi_x]_{z=-h} dy \\ = \int_0^B [wR]_{z=0} dy. \end{aligned} \tag{4.1}$$

Following §2.2, the side-band representation of the wavefield is written as

$$\begin{aligned} \Phi = \exp(i\omega t - i\theta(x)) \left[\Phi_0(x,t)w(y,z;\omega,h) + \Phi_+(x,t)w(y,z;\omega+\sigma,h) e^{i\sigma t} \right. \\ \left. + \Phi_-(x,t)w(y,z;\omega-\sigma,h) e^{-i\sigma t} \right] + W(x,z;\sigma)\eta(t) e^{i\sigma t + i\theta(x)}. \end{aligned} \tag{4.2}$$

We again make the assumptions

$$\omega \gg \sigma \quad |\theta_x|L \gg 1, \quad \omega \gg L|\theta_x|\eta_t/\eta.$$

The resulting equations for the progressive waves are

$$\begin{aligned} c\Phi_0 + (\nu + \frac{1}{2}c_x)\Phi_0 &= R_0, \\ c\Phi_+ + i\sigma\Phi_+ + (\nu + \frac{1}{2}c_x)\Phi_+ &= R_+, \\ c\Phi_- - i\sigma\Phi_- + (\nu + \frac{1}{2}c_x)\Phi_- &= R_-, \end{aligned}$$

where

$$\begin{aligned} R_0 = B^{-1} \int_0^B w \left[w \left(W \frac{\omega^2 \sigma^2}{g^2} + i\theta_{xx} W \right) (\eta^* \Phi_+ + \eta \Phi_-) \right. \\ \left. + \frac{\sigma W}{2\omega} \left(\frac{\omega^4 w}{g^2} - \theta_x^2 w + w_{yy} \right) (\eta^* \Phi_+ - \eta \Phi_-) \right]_{z=0} dy, \end{aligned}$$

$$R_+ = B^{-1} \int_0^B w \left[w \left(W \frac{\omega^2 \sigma^2}{g^2} + i \theta \frac{W}{x} \right) \eta \phi_0 - \frac{\sigma W}{2\omega} \left(\frac{\omega^4 w}{g^2} - \theta^2 w + w_{yy} \right) \right. \\ \left. \eta \phi_0 \right]_{z=0} dy,$$

$$R_- = B^{-1} \int_0^B w \left[w \left(W \frac{\omega^2 \sigma^2}{g^2} + i \theta \frac{W}{x} \right) \eta^* \phi_0 + \frac{\sigma W}{2\omega} \left(\frac{\omega^4 w}{g^2} - \theta^2 w + w_{yy} \right) \right. \\ \left. \eta^* \phi_0 \right]_{z=0} dy.$$

The corresponding equation for the standing wave is

$$\eta_t + \nu \eta = \ell B^{-1} \int_0^B \int_a^L \left[\frac{1}{2} W \left(\frac{\omega^4 w^2}{g^2} - \theta^2 w^2 + w^2 \right) \right. \\ \left. + \frac{i\omega}{\sigma} \theta \frac{W}{x} \right]_{z=0} (\phi_0^* \phi_+ + \phi_0 \phi_-^*) dx dy \\ + \ell B^{-1} \int_0^B \int_a^L \frac{2\omega^3 \sigma}{g^2} w^2 W \Big|_{z=0} (\phi_0^* \phi_+ - \phi_0 \phi_-^*) dx dy \\ + \ell B^{-1} \int_0^B \left[\frac{i\omega}{\sigma} \theta \frac{W}{x} \Big|_{z=0} w^2 (\phi_0^* \phi_+ + \phi_0 \phi_-^*) \right]_{x=a} dy - \frac{iB^{-1}}{2\sigma} \int_0^a [RW]_{z=0} dy,$$

where we have assumed the normalisation

$$\int_0^B \int_0^L [W^2]_{z=0} dx dy = B\ell^{-1}.$$

If the progressive and the standing waves are plane, i.e. w and W are independent of y , then the above equations reduce to a one-dimensional form of equations (2.4) and (2.5). Thus, provided we can neglect the effect of the nearshore region $(0,a)$, we can directly apply the analysis of §2.3.

For a shallow tank of depth αx an approximate normalised solution for the standing wave is

$$W = KJ_0(2\sqrt{\ell x}),$$

where

$$J'_0(2\sqrt{\ell L}) = 0, \quad \sigma^2 = \alpha g \ell, \quad K^2 = \frac{1}{\ell \int_a^L J_0^2(2\sqrt{\ell x}) dx}$$

Following the onset-of-instability calculation of §§2.3,2.4 we make the deep water assumption i.e. $(\sigma/\omega)^2 \ll \tan^2 \alpha$, and define the sum and difference terms to be

$$S = \frac{2\omega^2 \sigma^2}{cg^2} K e^{i\sigma x/c} \int_x^L J_0(2\sqrt{\ell x}) e^{-i\sigma x/c} dx,$$

$$D = -2i\frac{\theta_x}{c} K e^{i\sigma x/c} \int_x^L \ell^{\frac{1}{2}} x^{-\frac{1}{2}} J_1(2\sqrt{\ell x}) e^{-i\sigma x/c} dx,$$

where $\underline{c} = (-c, 0, 0)$. Hence an expression for the onset condition can be found, and the standing wave will grow if the steepness at the wavemaker exceeds the critical value

$$\left[\frac{\omega v' c \int_0^L J_0^2(2\sqrt{\ell x}) dx}{2\sigma g [I_1 + 2I_2 + I_3]} \right]^{\frac{1}{2}},$$

where the real integrals I_1, I_2, I_3 are defined:

$$I_1 = - \int_0^L \int_x^L \ell^{\frac{1}{2}} x^{-\frac{1}{2}} e^{-2\nu(L-x)/c} J_1(2\sqrt{\ell x}) J_0(2\sqrt{\ell x}) \sin(\sigma(\bar{x}-x)/c) d\bar{x} dx,$$

$$I_2 = - \int_0^L \int_x^L \ell^{\frac{1}{2}} x^{-\frac{1}{2}} e^{-2\nu(L-x)/c} J_1(2\sqrt{\ell x}) J_0(2\sqrt{\ell x}) \sin(\sigma(\bar{x}-x)/c) d\bar{x} dx,$$

$$I_3 = \int_0^L e^{-2\nu L/c} J_0(2\sqrt{\ell x}) \sin(\sigma x/c) dx.$$

If we consider a particular situation of a narrow tank of length 4m, with a beach of slope $\alpha = 0.1$, the numerical integration of the above expression leads to the graph (fig. 1) of the wave steepness at the wavemaker. The damping for the standing wave was taken to be constant $\nu = 0.01s^{-1}$, and the damping for the progressive waves was calculated using the formula

$$\nu = \frac{1}{2} \frac{\omega^2}{g^2} \left(\frac{\omega \times \text{viscosity}}{2} \right)^{\frac{1}{2}}, \text{ with viscosity} = 1.3 \times 10^{-6} m^2 s^{-1}.$$

This expression for ν corresponds to the "dirty water" limit of an inextensible surface film. Results for frequencies below $\omega = 20$ have not been presented because the results are dominated by the beach contribution I_3 , and it may not be justifiable to neglect the effects of shoaling and wave reflection. For example, at $\omega = 20.5$ the other two contributions are exactly cancelled out. However, by $\omega = 28$ the beach contribution is less than one percent. The narrowness of the frequency band in which the low frequency mode can be generated is due to the difficulties in simultaneously satisfying the requirements that the short waves penetrate far enough to be "aware" of the nonuniformity of the low frequency mode, and yet do not penetrate so far that there is significant cancelling of contributions from successive crests of the standing wave.

CHAPTER 26

VOCOIDAL THEORY FOR ALL NON-BREAKING WAVES

by D.H. Swart and C.C. Loubser¹⁾

ABSTRACT

The ideal theory for the prediction of wave-induced phenomena should be sufficiently accurate in all relative water depths, easy to apply and extensively tabulated. No available theory meets all these requirements. Vocoidal theory has been developed for application in all water depths. An extensive evaluation against experimental data proves that this theory meets the above requirements.

1. INTRODUCTION

During the past two decades great progress has been made in the development of new techniques for the prediction of wave-induced phenomena, such as the flow field in the vicinity of a coastal structure, longshore currents, forces on marine structures, ship motions, coastal sediment transport and combined wave diffraction and refraction. With the development of these more sophisticated techniques came the need for more accurate wave theories. Coastal sediment transport is an example of such a need.

Until about 10 years ago, the only way of predicting longshore sediment transport was to use an overall predictor [26], i.e. a formula yielding the total longshore sediment transport across the breaker zone. An example of such a theory is the well-known CERC-formula [22]. In 1967, Bijker published the first detail predictor [2], based on a uniform flow sediment transport formula. This method predicts the local longshore sediment transport rate. Subsequently, various researchers refined the Bijker technique, although the basic principle has remained the same. As the predictors become more sophisticated, the input required gets more extensive and it becomes more important to have accurate values for these input parameters. For example, because the transport is proportional to the longshore current raised to some power (between 3 and 6 [32]), a wrong prediction of the current by 10% will result in an error of 33% to 77% in the estimate of the transport. The longshore current, in turn, is determined from the balance between wave thrust (radiation stress) and dissipative forces (bed friction and lateral mixing). The Airy wave theory, which is the theory most frequently applied to water wave problems, can result in a radiation stress estimate at the breaker line up to 300% higher than the actual radiation stress. However, this does not imply that the longshore current will be overpredicted by the same amount, because the current velocity is linked to the radiation stress via an empirical roughness coefficient. It does, however, underline the importance of finding a more accurate description of the wave characteristics in shallow water.

Both for the prediction of erosional/depositional patterns in the vicinity of a coastal structure, by making use of a composite mathematical model, and for

1) National Research Institute for Oceanology, Stellenbosch, South Africa.

the computation of longshore sediment transport on a straight coast, accurate wave characteristics are required over the whole area of active transport. This zone can extend to depths of more than 50m [26], depending on the wave and sediment characteristics. For the prediction of erosional/depositional patterns wave characteristics and sediment transport computations are needed at numerous grid points. This requires large computer storage [8]. Both for this application and for the hand-computation of sediment transport rates, it must be possible to calculate the required wave characteristics easily. This can be done only if the wave theory under consideration either has simple algebraic expressions or is extensively tabulated.

A review was made of the available water wave theories [27] and the conclusion drawn that no existing theory meets all the above requirements. Vocoidal theory has therefore been developed in answer to these needs. The analytical and experimental validity of this theory is compared in Section 4 with that of other theories.

2. DERIVATION OF EXISTING WATER WAVE THEORIES

An insight into the techniques used for the derivation of the various existing theories is crucial for the understanding of the key differences between the results obtained. It is also the determining factor for the choice of a technique for the derivation of the new wave theory in Section 3.

2.1 Assumptions

The following well-known assumptions are common to all existing water wave theories and are therefore given below without any discussion, namely : (1) only non-breaking waves are considered; (2) the water movement is two-dimensional; (3) the water depth is constant, i.e. the bed is horizontal; (4) the flow is frictionless; (5) the fluid density is invariant; (6) surface tension effects are neglected; and (7) the wave motion is periodic and the waves propagate with constant velocity in water of constant depth.

2.2 Basic governing equations

The basic governing equations for the wave boundary value problem can be derived by making use of the above-mentioned assumptions. These governing equations are : (1) equation for the conservation of fluid mass, (2) equations of motion and (3) expression for the rotation of a fluid particle. These equations are given below without further explanation, as they can be found in numerous text books (e.g. [11] and [20]).

Conservation of mass (CM)

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0 \quad \dots (1)$$

where x and z are the horizontal and vertical coordinates and u and w are the horizontal and vertical orbital velocity components.

Equations of motion (EM)

In the x -direction :

$$\frac{1}{\rho} \frac{\partial p}{\partial x} + \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + w \frac{\partial u}{\partial z} = 0 \quad \dots (2)$$

In the z-direction :

$$g + \frac{1}{\rho} \frac{\partial p}{\partial z} + \frac{\partial w}{\partial t} + u \frac{\partial w}{\partial x} + w \frac{\partial w}{\partial z} = 0 \quad \dots (3)$$

where p is the pressure, g the gravitational acceleration, ρ the fluid density and t time.

Rotation of a fluid particle (RF)

The mean angular velocity R of an element of water is :

$$R = \frac{1}{2} \left(\frac{\partial w}{\partial x} - \frac{\partial u}{\partial z} \right) \quad \dots (4)$$

If R = 0 the flow is irrotational, otherwise it is rotational. For cases where R ≠ 0 Van Hijum [29] shows, by using the equations of motion, that

$$\frac{DR}{Dt} = \frac{\partial R}{\partial t} + u \frac{\partial R}{\partial x} + w \frac{\partial R}{\partial z} = 0 \quad \dots (5)$$

Equations (1) to (4) are the basic governing equations common to all solutions of the water wave problem.

2.3 Boundary conditions

All solutions to the system of equations (1) to (4) above should satisfy a number of boundary conditions, namely : (1) a *kinematic boundary condition* at both (a) the bed and (b) free surface, stating that no particle can pass through these boundaries (i.e. both bed and free surface are stream lines) and (2) a *dynamic boundary condition* which specifies that the pressure just inside the water mass should equal the atmospheric pressure.

re (1a) The *kinematic bed boundary condition (KBBC)* implies that

$$w = 0 \quad \text{at} \quad z = 0 \quad \dots (6)$$

re (1b) The *kinematic free surface boundary condition (KFSBC)* can be transformed to :

$$w = (u - c) \frac{\partial \eta}{\partial x} \quad \text{at} \quad z = d + \eta \quad \dots (7)$$

where η denotes the free surface wave profile, d the mean water depth and c the wave celerity

re (2) The *dynamic free surface boundary condition (DFSBC)* states simply that

$$p = 0 \quad \text{at} \quad z = d + \eta \quad \dots (8)$$

where p is the amount by which the pressure exceeds atmospheric pressure.

2.4 Solutions to the problem

The solutions found to date for the wave boundary value problem can be classified as follows : (1) irrotational theories, (2) rotational theories and (3) modified theories, which are discussed under these headings below. Discussions of these classes of theories can be found in numerous text books and original papers so that only those characteristics of the theories which are relevant to the present study are given in the following discussion. Table 5, in turn, is a summary of the discussion below.

Irrotational wave theories

When $R = 0$ in equation (5) it is possible to define a velocity potential ϕ (or stream function Ψ) which, in a reference system moving along with a celerity the same as that of the wave, is given by

$$u - c = - \frac{\partial \phi}{\partial x} = - \frac{\partial \Psi}{\partial z} \quad \dots (9)$$

$$w = - \frac{\partial \phi}{\partial z} = + \frac{\partial \Psi}{\partial x} \quad \dots (10)$$

With the aid of the above definition for ϕ , the equation for conservation of mass (equation (1)) is transformed into the well-known Laplace equation ($\nabla^2 \phi = 0$) and in addition the rotation is identically zero when equations (9) and (10) are substituted into equation (5). Similarly, when the stream function Ψ is used, the rotation R in equation (5) is transformed into the Laplace equation ($\nabla^2 \Psi = 0$) and the conservation of mass equation (equation (1)) is exactly satisfied when equations (9) and (10) are substituted into it. Therefore

$$\begin{aligned} \nabla^2 \phi &= 0 \\ \text{or} \quad \nabla^2 \Psi &= 0 \end{aligned} \quad \dots (11)$$

In all irrotational theories, the Laplace equation is used instead of equation (1) when solving the governing equations. The velocity potential ϕ (or stream function Ψ) is determined by the domain in which it exists, i.e. it is a function of η , which in turn specifies the free surface. It is, consequently, not possible to find a unique solution to equations (6), (7), (8) and (11) above. These equations must be simplified by means of approximations to linearize the problem in such a manner that the non-linear terms in the defining equations become small when compared with the linear terms. These approximations determine the specific form of the irrotational theory. Three main methods of solution are used, namely: (i) analytical perturbation of ϕ , η and c , as is performed in the Stokesian wave theories, which are valid for deep water, (ii) analytical perturbation of ϕ , leading to the cnoidal wave theories, which are valid for shallow water and (iii) numerical perturbation of ϕ or Ψ , which leads to the so-called numerical theories, valid for $H/d \leq 0.78$.

re (i) Stokesian wave theories

Taylor series expansions are assumed for ϕ , η and c . By assuming that $H/d \ll 1$ (where H is the wave height) and thus that the free surface boundary conditions (7) and (8) can be applied at the mean water level, i.e. at $z = d$, a first-order solution, called Stokes I, is found. A second-order solution is obtained by making use of the first-order solution, etc. The higher the order of the expansion, the greater the mathematical effort required to obtain a solution. Although higher-order Stokesian theories do exist, only Stokes I (Airy), II and V are used frequently. The first-order Stokes theory is valid for deep water only because of the assumption that $H/d \ll 1$. In addition, higher-order Stokesian theories become unstable in shallow water because of the magnitude of the expansion parameter.

Earlier comparisons with experimental data show that predictions given by Stokes I are good for deep water but get progressively poorer as the water depth decreases.

re (ii) Cnoidal wave theories

The assumption is made that both d/λ and H/d are $\ll 1$ where λ is the wave length, i.e. small-amplitude waves in shallow water are considered. The choice of an appropriate expansion parameter allows the expansion of ϕ into a Taylor series. The Laplace equation and kinematic bed boundary condition (equation (6)) are used to simplify this Taylor expansion to an equation in terms of the first-order term in ϕ . Only the terms necessary to obtain the first-order cnoidal theory are retained. Substitution of this expression for ϕ into the free-surface boundary conditions (equations (7) and (8)) yields the well-known long-wave equations, which are simplified to the Korteweg-de Vries equation and solved for η and c . Cnoidal theories can only be applied in shallow water, because of the assumptions made regarding the expansion parameter which yields imaginary wave celerities for $\lambda/d \lesssim 10$. However, comparison with measurements show that, provided the wave length is known, the cnoidal theory offers a good representation of the wave profile for deep to shallow water. This is not surprising since the cnoidal wave profile has as limiting cases a sinusoidal profile in deep water and a solitary wave profile in shallow water.

re (iii) Numerical wave theories

The rapid development of digital computers over the last three decades has opened up a new way of solving the defining equations (6) to (8) and (11) above by finding a solution, using direct numerical calculation. The best known numerical irrotational theories published to date are those of Chappellear [3], Dean [6], Von Schwind and Reid [31] and Cokelet [4]. The principle used is straightforward, namely: (1) find a Fourier series solution to the Laplace equation, and (2) optimize iteratively the coefficients in the Fourier series by means of the free-surface boundary conditions. The order of the Fourier series determines the accuracy to which the boundary conditions can be approximated. Each additional term of the Fourier series expansion added reduces the error in the free-surface boundary conditions. Dean used a variable number of terms in the Fourier expansion, and terminated the iterative procedure as soon as consecutive iterations (additions of further terms) resulted in small improvements in the error in the free-surface boundary conditions. The number of Fourier terms in Dean's solution varies between 2 (for deep water) and 19 (for shallow water). Dean showed that his stream function solution corresponds more closely to the free-surface boundary conditions than the theories of Chappellear and Von Schwind/Reid do. Cokelet raised the level of accuracy by using 110 Fourier terms. As a result, his solution to Laplace is more accurate than any other to date. However, the advantage of Dean's method over that of Cokelet is that Dean's results are tabulated more conveniently for engineering use. Furthermore, the resulting celerities for 24 arbitrarily chosen sets of initial conditions (T , d , H) as computed by using Dean's and Cokelet's theories differed by a maximum of 2.8%; the mean difference being 1.4%. In all cases Cokelet's theory yielded larger celerities. The conclusion is that the improvement obtained in the celerity by extending the Fourier series to the 110th order is not significant for engineering purposes. Furthermore, Cokelet's theory has not yet been tabulated to permit the prediction of time-dependent wave properties, such as the wave profile and orbital velocities.

Earlier comparisons with measurements have shown Dean's stream function theory to be in good agreement with data for all water depths within its tabulated range.

Rotational wave theories

The assumption of frictionless flow can normally be regarded as a good approximation over the greater portion of the water column. Frictionless flow implies irrotationality. It is possible to obtain an easy solution for the horizontal orbital velocity by making use of the conservation of mass equation (1). Because frictionless flow is also assumed for this approach, the resulting theory should be an irrotational theory. However, it is possible that due to approximations made in finding a solution, a finite value of R , as given by equation (4), remains. Such theories will be called rotational theories. The equation for conservation of mass (equation (1)) is integrated over the depth. After substitution of the kinematic boundary conditions (equations (6) and (7)) and assuming no net mass transport (which is valid as long as no set-up occurs) an equation is found for the mean horizontal orbital velocity u , namely :

$$\bar{u} = \frac{c\eta}{d+\eta} \quad \dots (12)$$

As no assumptions are made regarding rotationality, equation (12) is equally valid for irrotational wave theories and can, in fact, be used to check whether any given theory adheres to the original continuity equation (1) (see Table 5). Any expression for the instantaneous horizontal orbital velocity u which satisfies equation (12) therefore also satisfies equation (1). Expressions for the wave celerity c and wave profile η are found from the equations of motion, by making use of an assumed form of the orbital velocity u . Two recent examples of this approach are the rotational wave theories of Van Hijum [30] and Mejlhede [19].

To date no comparison has been made between actual measurements and predictions given by rotational theories.

Modified wave theories

As stated above, the simple-to-apply Airy wave theory yields predictions which become poorer as the water depth decreases. Various modifications have therefore been suggested to improve Airy theory's correspondence to wave characteristics in shallow water. The two most successful modifications are (1) Goda's empirical modification [9] of the Airy horizontal orbital velocity and (2) Hedges' theoretical modification [10][18] of the Airy wave celerity. Rather than modify Airy, another approach is to simplify the cnoidal solution, which is in any case applicable to shallow water conditions. In this manner, a good theory is obtained for shallow water which at the same time is easy to apply. The best example of such a simplified theory is Van Hijum's simplification [30] of the cnoidal wave profile, in which the cnoidal function is approximated by a cosine function raised to a variable power (depending on T , d , H).

Earlier comparisons with measured horizontal orbital velocities showed that Goda's approximation for the orbital velocity under the wave crest is superior to that predicted by Airy theory and is surpassed only by predictions for horizontal orbital velocity made with Dean's stream function theory.

2.5 Summary

The discussion above indicates that :

- (1) Numerical theories show the greatest overall adherence to boundary conditions.

- (2) None of the available theories agrees well with data for all water depths. The best theory which is still applicable in practice is Dean's numerical stream function theory.
- (3) No one analytical theory is clearly superior to any of the other analytical theories as far as experimental validity is concerned.

The derivation of a new theory is described in the next section. This theory incorporates the properties of the best contemporary theories and is easy to apply.

3. VOCOIDAL WATER WAVE THEORY

3.1 General

As indicated in Section 2 above, the theoretical derivation of a water wave theory involves the approximation of the free-surface boundary conditions. Depending upon these approximations, various classes of solutions are found. A different approach is used below, namely, (1) qualitative assumptions are made regarding the expressions for η , c and u in terms of unknown parameters (Section 3.2), (2) by substituting these qualitative expressions into the free-surface boundary conditions, three equations are found from which the above-mentioned parameters can be solved numerically (Sections 3.3 and 3.4) and (3) algebraic formulae for the parameters are determined by means of curve-fitting techniques (Section 3.5).

3.2 Qualitative assumptions

Wave profile η

A wave profile of the type given by the cnoidal theory provides the best fit to data, mainly because it has as theoretical limiting forms a sinusoidal wave in deep water and a solitary wave in extreme shallow water. Van Hijum [30] showed that the following expression has the same characteristics :

$$\frac{\eta}{H} = (\cos^2 \pi X)^P - \eta_{*t} \quad \dots (13)$$

where $X = x/\lambda$, η_{*t} is the dimensionless ($\pm H$) trough elevation and P is a parameter which depends on the wave conditions (H/d , λ/d). By expressing $(\cos^2 \pi X)^P$ as an infinite series, η_{*t} is found, after integration, to be :

$$\eta_{*t} = (\pi P)^{-\frac{1}{2}} \{ 1 - (8P)^{-1} + \frac{1}{2}(8P)^{-2} \} \quad \dots (14)$$

When $P = 1$ equation (13) represents a sinusoidal profile and when $P \gg 1$ the profile given by equation (13) tends towards a solitary profile. Equation (13) is used here to define the wave profile η .

A new function, which simplifies the representation of formulae in the new wave theory, namely the variable order cosine function, or *voc*-oidal function, is defined :

$$\text{voc}(P, X) = (\cos^2 \pi X)^P \quad \dots (15)$$

where P is the order of the function.

Wave celerity c

Hedges [10] has shown that when applying the free-surface boundary conditions

at some fixed "effective" level d_e the wave celerity is given by :

$$\frac{c^2}{gd} = \frac{1}{kd} \tanh Nkd \quad \dots (16)$$

where $N = d_e/d$. He shows that N tends to unity in deep water (same result as given by Stokes I) and to $1 + \eta_c/d$ in very shallow water ($\eta_c =$ crest elevation of wave - same result as given by solitary theory). Equation (16) is used here to define the wave celerity c . N remains to be determined in terms of the wave conditions (H/d , λ/d).

Orbital velocity u

The approach leading to equation (12) is used to define the horizontal orbital velocity u . Mejlhede [19] shows that the following expression for u satisfies equation (12) :

$$u = \frac{c\eta M(X)k \cosh [M(X)kz]}{\sinh [M(X)k(d+\eta)]} \quad \dots (17)$$

where $M(X)$ is a function of the wave conditions (H/d , λ/d) and also of X . Equation (17) is used to define the orbital velocity u in the new wave theory. Thus the new theory is not derived from the Laplace equation. It does not, however, necessarily imply that the theory is rotational, as will be seen in Section 3.3.1. Equation (17) represents an exact solution to the continuity equation which satisfies both kinematic boundary conditions.

3.3 Formulation of the governing equations

The wave boundary-value problem has now been reduced to a set of equations in which the unknowns are not η , c and u but the wave profile parameter P , the wave celerity parameter N and the orbital velocity parameter $M(X)$. An expression for $M(X)$ in terms of P is found below by using equation (4), after which optimum values of P and N are found by evaluating the pressure p from the equations of motion and equating it to the pressure in Bernoulli's equation.

3.3.1 A value for $M(X)$ in terms of P

Equation (5) specifies that any particle retains its rotation. For the free surface, which is a stream line, it is possible to write $R[z=d+\eta] =$ constant. An expression for R at the free surface is found by combining equations (4), (7) and (17) :

$$[R]_{z=d+\eta} = \frac{1}{2} \left[\frac{\partial}{\partial x} \left\{ (u-c) \frac{\partial \eta}{\partial x} \right\} - c\eta(M(X)k)^2 \right]_{z=d+\eta} \quad \dots (18)$$

which can be rewritten as

$$M(X)^2 = \left[\frac{\frac{\partial u}{\partial x} \frac{\partial \eta}{\partial x} + (u-c) \frac{\partial^2 \eta}{\partial x^2} - 2R}{c\eta k^2} \right]_{z=d+\eta} \quad \dots (19)$$

At the wave trough, that is at $X = 0.5$, equation (19) reduces to

$$M(0.5)^2 = \left[\frac{-2R}{c\eta_t k^2} \right]_{z=d+\eta} \quad \dots (20)$$

where subscript t denotes the wave trough.

$R [z=d+\eta] = 0$ (and consequently $M(0.5) = 0$) is a solution to equation (20). Therefore $R[z=d+\eta] = 0$ is used. At the wave trough, where $M(0.5) = 0$, equation (17) reduces to equation (12). Substitution of this equation (12) into equation (4) indicates that $R [X=0.5] = 0$ for all $0 \leq z \leq d + \eta$. As all stream lines in the flow field pass through $X = 0.5$, this implies that the flow will be irrotational, provided that $M(X)$ is determined exactly from equation (18). However, since small approximations have to be made to obtain a usable solution (see below) the flow will not be completely irrotational but will retain a small rotation, which can be neglected when secondary wave properties are derived.

Substitution of zero rotation into equation (19) and rearrangement yields :

$$M(X)^2 = \left[\frac{\frac{\partial(u/c)}{\partial X} \frac{\partial(\eta/H)}{\partial X} + (u/c - 1) \frac{\partial^2(\eta/H)}{\partial X^2}}{4\pi^2(\eta/H)} \right]_{z=d+\eta} \dots (21)$$

Equation (21) provides an implicit equation for $M(X)$ in terms of P and X .

3.3.2 Optimum values of P and N

Integration of equation (3) to z and substitution into the resulting equation of the dynamic free-surface boundary condition results in an expression for the pressure p , which at the bed ($z=0$) becomes :

$$\left[\frac{p}{\rho} \right]_{z=0} = g(d+\eta) + \left[\frac{u^2 + w^2}{2} - uc \right]_0^{d+\eta} \dots (22)$$

Since the bed is a stream line, the pressure at the bed should also satisfy Bernoulli's equation, that is

$$\left[\frac{p}{\rho} \right]_{z=0} = \left[gd - \frac{(u-c)^2}{2} \right]_{z=0} + k_1 \dots (23)$$

where k_1 is a constant.

The pressure can be eliminated from equations (22) and (23) to yield, after substituting the kinematic bed boundary condition into the resulting equation, an expression for c^2/gd :

$$\frac{c^2}{gd} = \left[\frac{\eta/d}{(u/c) - \frac{1}{2} \{ (u/c)^2 + (w/c)^2 - (w_0/c)^2 \}} \right]_{z=d+\eta} \dots (24)$$

where $w_0 = -c \frac{\partial \eta}{\partial x} \Big|_{\eta=0, z=d+\eta}$, that is, w_0 is the value of w at the free surface when $\eta=0$.

Because of assumption (7) in Section 2.1 above, the wave celerity defined by equation (24) must be a constant, that is

$$\frac{\partial}{\partial X} \left[\frac{c^2}{gd} \right] = 0 \quad \text{for } 0 \leq X \leq 0.5 \dots (25)$$

Equations (21), (24) and (25) are the governing equations used to find solutions for P , N and $M(X)$.

3.4 Solving the governing equations

The solution is determined in two phases, namely (1) a first-order solution is found by assuming $u/c \ll 1$, and (2) a second-order correction is applied to compensate for the fact that u/c is not negligible with respect to unity. This two-phase approach is necessary because $M(X)$ cannot be determined at wave breaking.

The exact solution to equations (21), (24) and (25) above can only be obtained numerically for $u/c < 1$. The following wave conditions (H/d , λ/d) are used :

$$\begin{array}{ll} 0.01 \leq H/d \leq 0.8 & 1 \leq \lambda/d \leq 75 \\ 0.01, 0.02, 0.05, 0.1(0.1)0.8 & 1, 2, 5, 8(2) 20, 20(10) 50, 75 \end{array}$$

Equation (25) is satisfied by computing c^2/gd from equation (24) at 1000 discrete intervals in the area $0 \leq X \leq 0.5$ and choosing that combination of P and N for which the relative standard deviation of the computed c^2/gd -values is the least.

Although the maximum theoretical breaker index H/d is about 0.78, experimental data indicate that H/d -values as high as 1.3 can occur. To ensure that the theory developed herein is applicable in this area the numerical solution of equations (21), (24) and (25) is repeated with the assumption that $u/c \ll 1$ for an extended H/d range $0.01 \leq H/d \leq 1.3$. The following ratios are computed for those wave conditions at which an exact solution was found above.

$$\begin{aligned} R_P &= P/P_1 \\ R_N &= N/N_1 \end{aligned} \quad \dots (26)$$

$$\text{and } R_M = M(0)/M_1(0)$$

where subscript 1 denotes the solution with the small-amplitude assumption (that is $u/c \ll 1$) and P , N and $M(0)$ denote the "exact" solution, that is the solution in which no assumption is made regarding the value of u/c .

The results obtained for the above-mentioned wave conditions indicate the following :

- (1) It is possible to find solutions for P_1 , N_1 and $M_1(0)$ for all wave conditions listed ($H/d \leq 1.3$).
- (2) The values of R_M and R_N vary systematically with H/d for all λ/d -values.
- (3) For any given λ/d -value N tends to $1 + \eta_c/d$ for large H/d .
- (4) For any given λ/d -value $M(0)$ tends asymptotically towards a constant value with varying H/d . For all practical purposes $M(0)$ is constant for $H/d \geq 0.7$.
- (5) R_P varies systematically with λ/d for all H/d -values. The variation of R_P with H/d is analogous to the variation of P_1 with H/d at large λ/d -values (say $\lambda/d = 50$).

The above observations imply that it is possible to use the small-amplitude solution to extend the range of the "exact" solution.

3.5 Algebraic expressions for P, N and M(X)

The values determined as described above for P, N, M₁(0), R_P, R_N and R_M are correlated to the wave conditions (H/d, λ/d) and algebraic expressions are determined by curve-fitting. The resulting algebraic expressions are listed below.

Wave profile parameter P

$$(1) \quad P_1 = \begin{cases} 1.03 F_s + 9 + 3.33 \exp(-0.109(11 + F_s)) & \text{for } F_s > -11 \\ 1 & \text{for } F_s \leq -11 \end{cases} \quad \dots (27)$$

where $F_s = \frac{U_r - U_{r0}}{\theta} \quad \dots (28)$

$$U_r = (H/d)(\lambda/d)^2 = \text{Ursell parameter}$$

$$U_{r0} = 63 + 90 (H/d)^{1.48} \quad \dots (29)$$

$$\theta = \begin{cases} 1.01 \exp(3.31(H/d)) & \text{for } H/d \geq 0.505 \\ 5.38 & \text{for } H/d < 0.505 \end{cases} \quad \dots (30)$$

$$(2) \quad R_P = R_{P1} - (R_{P1} - 1) \exp(b \lambda/d) \quad \dots (31)$$

where $R_{P1} = 1 + 0.0021 (P_{1i} - 1) + 6.09 \times 10^{-7} (P_{1i} - 1)^{2.56} \quad \dots (32)$

$$b = -0.0916 + 2.718 \times 10^{-4} P_{1i} \quad \dots (33)$$

$$P_{1i} = P_1\text{-value for } \lambda/d = 50$$

$$(3) \quad P = R_P P_1 \quad \dots (34)$$

Wave celerity parameter N

$$(4) \quad N_1 = \begin{cases} 1 + 0.19 F_N^{1.5} & \text{for } F_N < 0.72 \\ 0.6 + 0.72 F_N & \text{for } F_N \geq 0.72 \end{cases} \quad \dots (35)$$

$$\text{where } F_{RN} = (H/d)(\lambda/d)^{0.1} \quad \dots (36)$$

$$(5) \quad R_N = \begin{cases} 1 & \text{for } F_{RN} < 0.093 \\ 0.67 F_{RN} + 0.938 & \text{for } F_{RN} \geq 0.093 \end{cases} \quad \dots (37)$$

$$\text{where } F_{RN} = (H/d)(\lambda/d)^{-1} \quad \dots (38)$$

$$(6) \quad N = R_N N_1 \quad \dots (39)$$

Orbital velocity parameter M(X)

(7) For any given wave condition (H/d, λ/d) equation (19) can be used to obtain numerical values of M(X) for $0 \leq X \leq 0.5$. These M(X)-values vary systematically from M_p at X = 0 to zero at X = 0.5. It is shown in [27] that M(X) can be closely approximated by

$$M(X) = \begin{cases} (M_p - M_t) \cos \pi X + M_t & \text{for } r_1 P_1 < 0.5 \\ M_p \text{ voc}(r_1 P_1, X) & \text{for } r_1 P_1 \geq 0.5 \end{cases} \quad \dots (40)$$

M_t is defined in (8) to (10) below and M_p in (11) below and where r_1 as determined by curve-fitting equals :

$$r_1 = 0.4 \{1 - P_1^{-0.9}\} \quad \dots (41)$$

Maximum value M_p of orbital velocity parameter M(X)

(8) The maximum value M_t of M(X) as determined by equation (19) is always found at X = 0. An expression^p for $M_t(0)$ is determined analytically from equation (19) by setting X = 0 and rearrangement :

$$M_t(0) = \left(\frac{P_1}{2\eta_{*c1}} \right)^{\frac{1}{2}} \quad \dots (42)$$

where $\eta_{*c1} = 1 - \eta_{*t1}$ and subscript 1 refers to the first-order approximation.

$$(9) \quad R_M = \begin{cases} \frac{0.54}{1+6.7(H/d)^4} + 0.46 & \text{for } H/d \leq 0.7 \\ 0.667 & \text{for } H/d > 0.7 \end{cases} \quad \dots (43)$$

$$(10) \quad M_p = M(0) = \begin{cases} R_M M_{p1} & \text{for } H/d \leq 0.7 \\ (R_M M_{p1})_{H/d=0.7} & \text{for } H/d > 0.7 \end{cases} \quad \dots (44)$$

Minimum value M_t of orbital velocity parameter $M(X)$

(11) The solution to equation (20) indicates that $M_t = M(0.5) = 0$. However, when $P_1=1$, that is, for very deep water, $r_1 = 0$, thereby indicating a constant $M(X)$ -value for $0 \leq X < 0.5$. The resulting discontinuity at $X = 0.5$ is unrealistic. To a lesser extent the same phenomenon occurs for $1 \leq P_1 \leq 2$. To prevent the discontinuity from occurring, the following approximations are made: (i) $M(X)$ -values in the area $0.45 \leq X \leq 0.49$ are extrapolated to $X = 0.5$ and the value thus found is used as a minimum value M_t for $M(X)$ where

$$M_t = R_M \exp \{ - 4.2 (P_1 - 1) \} \quad \dots (45)$$

and (ii) the X -variation of $M(X)$ is determined by equation (40a) rather than by equation (40b). It is shown in [27] that the effect of the approximations on the predicted horizontal orbital velocity amounts to less than 2% of the actual velocity for any location within the fluid.

Because $M(X)$ as determined from equation (40) is an approximate solution to equation (19), the flow will not be irrotational. However, computations covering the same wave conditions used in Section 3.4 above indicate that \bar{K} never exceeds a few per cent of $(2\pi/T)$ and can for practical purposes be assumed equal to zero. This implies that although the flow is, as a result of the approximation of $M(X)$, rotational, the rotation is negligible.

3.6 Presentation of other wave properties

As stated in Section 1, the aim of the study is the derivation of a simple-to-apply wave theory in which wave characteristics can be computed from algebraic expressions. For this reason, algebraic expressions were also derived in [27] for the following primary wave characteristics, namely, vertical orbital velocity, horizontal and vertical orbital excursions, mass transport velocity, group velocity, wave energy/unit surface area and the pressure within the wave. Where necessary, further parameters were introduced and expressions determined for them by curve-fitting techniques, in a similar manner as in Section 3.5 above.

A quantitative knowledge of secondary wave-induced phenomena, such as shoaling of water waves, wave refraction, diffraction and breaking, principal radiation stresses, wave set-up, generation of longshore breaker-zone currents, shear stresses exerted on the bed due to combined current and wave action, wave-induced bed-form generation, sediment entrainment and sediment suspension, is essential for the prediction of the effect of waves on the coastal environment. These aspects will be studied in follow-up reports to [27].

3.7 Tabulation of parameters

To facilitate the easy use of the theory, it is essential to tabulate the main parameters in terms of the wave conditions (H/d , λ/d), in a way similar to that for linear wave theory. It is intended to publish such a book of tables in 1979. However, abridged tables are included here as Tables 1 to 4.

4. VERIFICATION OF WATER WAVE THEORIES

4.1 Evaluation

The various theories mentioned in Section 2 are evaluated in this section (see Table 6). The data sets used in the evaluation are summarized in Table 7. There are various methods for the verification of wave theories. Dean [7] mentions two methods, namely (1) an analytical verification, that is, the adherence of each

theory to the free-surface boundary conditions, and (2) an experimental verification, based on the adherence of each theory to observed data. Another possibility exists, namely, (3) a comparison of each theory with an exact solution to the governing equations, such as Cokelet's numerical theory. Possibilities (1) and (3) test the extent to which any given theory adheres to the governing equations and boundary conditions, but do not necessarily indicate the correlation with observed data. The reason for this is that the governing equations are in themselves approximations; they do not include the effects of, for example, surface tension and the bed slope, both of which are important near wave breaking. Provided that observations can be made with sufficient accuracy under controlled conditions, i.e. when errors due to both measuring equipment (techniques) and the generation of waves in too shallow water are minimized, experimental verification is the most reliable of the above methods. However, the available data are frequently contaminated, especially by secondary waves because of the method of generation used. Because of the large number of data sets used (see Table 7) errors due to both generation and measuring techniques are to some degree averaged out.

Dean's computations [7] regarding the adherence of various theories to the free-surface boundary conditions indicate that this measure (analytical verification) is not always a true reflection of the relative validity of the various theories. For example, the Stokes I (Airy) theory (derived for deep water) has a smaller dynamic free surface boundary condition error than the cnoidal theory (derived for shallow water) under shallow water conditions ($H/H_b = 1$ where b denotes breaking waves, $d/\lambda_0 < 0.195$) (Dean [7]). Therefore, the analytical verification, in the way defined by Dean [7], is not discussed further in this paper. However, an extensive analysis of the analytical verification of the above 13 theories will be contained in a follow-up to [27], which is being prepared at present.

A practical comparison with Cokelet's theory is not yet possible, because the tabulation of parameters in Cokelet's theory permits only the calculation of wave characteristics which are independent of time. However, the comparison between the theories of Dean and Cokelet, mentioned in Section 2.4 above, indicates that Dean's theory can, for engineering purposes, be assumed to be an "exact" solution to the "approximate" governing equations.

The following procedure has been adopted to establish experimental validity :

- (1) The relative error E_r for each wave characteristic W is given by :

$$E_r = \left| \frac{W_p - W_m}{W_m} \right| \quad \dots (46)$$

where subscripts p and m denote predicted and measured values, respectively.

- (2) Relative errors for the orbital velocity u under the wave crest, wave length λ and wave profile η are computed by applying each theory to all data sets for which relevant data are available.
- (3) To assist the evaluation of the application range of the various wave theories, an Ursell-like parameter which depends solely on the wave conditions T , d and H , is defined, namely,

$$F_c = (H/d)^{\frac{1}{2}} T_c^{2\frac{1}{2}} \quad \dots (47)$$

$$\text{where } T_c = T (g/d)^{\frac{1}{2}} = (2\pi)^{\frac{1}{2}} (\lambda_0/d)^{\frac{1}{2}} \quad \dots (48)$$

A wave with a height $H = 1\text{m}$ and period $T = 8\text{s}$ has F_c -values of 0.3, 17, 934 and 3143 in water depths of 200m, 20m, 2m and 1m respectively, that

is, F_c varies from zero in very deep water to a few thousand in very shallow water. The values of F_c for shallow water are limited by wave breaking.

- (4) For each wave characteristic and wave theory the mean and standard deviation of the absolute values of all relative errors are computed for each of the following F_c -groups (0-50, 50-100, 100-200, 200-500, 500-1000 and > 1000). Those theories which do not differ at a 5% significance level from the theory with the smallest mean relative error in each of the above-mentioned F_c -groups are singled out as being the best theories for the prediction of the specific wave characteristic in that F_c -group. A theory is considered to fall within its validity area if it passes this statistical test.
- (5) The resulting validity areas of the various theories for the prediction of u , λ and η are shown in Figures 1 to 3. Also shown in each F_c -group is the average of the mean relative errors of the equivalent good theories.
- (6) Figure 4 indicates the overall validity areas of the evaluated theories and, as such represents a generalized experimental validity, which is not bound to a specific wave characteristic. The theories listed in this figure are those with a higher than average occurrence in any given F_c -group (that is those appearing two or three times in the specific F_c -group on Figures 1 to 3).

4.2 Results

- (1) According to Figure 4 only two wave theories are valid for all F_c -groups, namely, Dean's stream function theory and Vocoidal theory, that is, only these two theories are suggested for application in all relative water depths (theory numbers are listed in Table 6).
- (2) However, Dean's tabulated range restricts the application of his theory at both high and low H/d values.
- (3) In the restricted range of Dean's tables there is no significant difference between Dean's results and those obtained by Vocoidal theory. It can therefore be concluded that Vocoidal theory is equivalent at a 5% significance level to Dean's theory, which in turn was shown, for engineering purposes, to be an "exact" solution to the governing equations.
- (4) The wave profile predicted by Vocoidal theory for $F_c < 200$ is not statistically equivalent to the best theories in this range. The relative errors in the 0-50, 50-100 and 100-200 F_c -groups for Vocoidal theory are 6%, 7% and 8% respectively, as compared to 5%, 5% and 7% for the best theories.
- (5) Within its application range, i.e. for $(T\sqrt{g/d})^{-1} < 0.126$, Mejlhede's gravity cnoidal theory is statistically equivalent to Dean's stream function theory and Vocoidal theory. The same does not apply to the Keulegan/Patterson and Svendsen cnoidal theories [15], [25].
- (6) Stokes I, II and V are statistically equivalent to the better theories for $F_c \leq 200$, 100 and 200 respectively, which indicates that the use of Stokes II theory for anything but deep water is normally not advisable and that Stokes I is, generally speaking, equivalent to Stokes V.
- (7) Goda's theory is listed in the $500 \leq F_c \leq 1000$ column only because of its good adherence to orbital velocity data.
- (8) Mejlhede's rotational cnoidal theory is statistically equivalent to the better theories for $F_c \leq 200$. Beyond this range, it yields unrealistic horizontal orbital velocities under the wave crest, which tend to zero at the bed and to some extremely high value (far greater than the wave celerity) at the free surface.

FIGURE 1 BEST THEORIES FOR THE PREDICTION OF THE ORBITAL VELOCITY UNDER THE WAVE CREST

FIGURE 2 BEST THEORIES FOR THE PREDICTION OF THE WAVE LENGTH

FIGURE 3 BEST THEORIES FOR THE PREDICTION OF THE WAVE PROFILE

FIGURE 4 REGIONS OF OVERALL VALIDITY: VARIOUS WAVE THEORIES

- (9) The simple-to-apply Van Hijum-approximation to cnoidal theory is statistically equivalent to the better theories for $F_c \leq 200$. It should preferably not be used beyond this range because the predicted horizontal orbital velocity tends to a constant value over the full depth from bed to free surface.

5. SUMMARY AND CONCLUSIONS

1. There is a need for a water wave theory which is (i) sufficiently accurate in all relative water depths, (ii) expressed in terms of algebraic expressions, (iii) relatively easy to apply/require little computer time and (iv) well-tabulated. None of the available theories meets all these requirements.
2. Vocoidal theory has therefore been developed from first principles in answer to these needs. The theory is simple to apply and is expressed algebraically (see equations (13), (16) and (17)).
3. Frictionless flow was assumed in the derivation of Vocoidal theory, but because of an approximation made in the representation of the time-variation of the horizontal orbital velocity, the theory contains a small rotation, which can, for practical purposes, be neglected.
4. An extensive analysis of the experimental validity of thirteen different theories indicates that only two of the evaluated theories consistently yield good results in all relative water depths, namely, Vocoidal theory and Dean's stream function theory.
5. Dean's theory is only applicable in a restricted H/d-range (see - 11 - line in Figure 4), which can never be extended beyond $H/d = 0.78$.
6. Vocoidal theory is therefore recommended for general application for all relative water depths.

CHAPTER 27

FIELD STUDY OF BREAKING WAVE CHARACTERISTICS

LEE L. WEISHAR*
ROBERT J. BYRNE[†]

ABSTRACT

This study focuses upon four elements of breaking wave behavior:

- 1) Relative breaking depth criteria
- 2) Breaking wave classification
- 3) Evaluation of the plunge distance
- 4) Breaking wave height prediction

The data set is 116 waves filmed at Virginia Beach, Va., on the Atlantic U.S. coast. The cine-photographic observation technique permitted the viewer to freeze the free surface profile at successive time steps as the waves passed an upright plane grid placed perpendicular to the beach. The results indicate that:

- 1) While the average value of $H_b/d_b \approx 0.78$, there was a significant difference between plunging and non-plunging waves.
- 2) Neither the breaker classification of Galvin nor that of Battjes successfully discriminated between plunging and spilling breakers.
- 3) The distance travelled by the foreface of a plunging wave was found to be underestimated by the free fall trajectory model advanced by Galvin. The field observations show the weakness to be in the plunge time arising from neglect of the vertical velocity component.
- 4) The breaking wave height prediction formulation advanced by Komar and Gaughan adequately predicts the breaking wave height within the constraints of calculating deep water wave characteristics, neglecting wave refraction and frictional effects. The combined data set covers the breaker wave height between laboratory scale observations to greater than 3 m.

INTRODUCTION

The purpose of the study was to compare field observations of breaking wave characteristics with existing formulations, which for the most part have been derived from wave tank observations. Four elements of breaking wave behavior are addressed:

- 1) Relative breaking depth criteria
- 2) Breaking wave classification
- 3) Evaluation of the plunge distance
- 4) Breaking wave height prediction

METHODS. The field measurements were obtained from cine-photography of waves as they passed through an upright plane grid installed perpendicular to the beach. The field site was at Virginia Beach, Va. (Fig. 1), an ocean beach receiving waves generated in the North Atlantic Ocean. The observations were made in the summer when the wave climate is dominated by swell with characteristic average wave period of about 8 seconds generated by the Bermuda "high". Levelled rectangular grid sections, 3.3 m in length, were fixed to pipes jettied into the substrate. The square unit cell of the pipe grid was 61 cm (2 ft) on a side with each side further indexed to 30.5 cm (1 ft), (Fig. 2). The grids extended from the top of the foreshore to about 40 m offshore (Fig. 3).

Cine photography was achieved by mounting a motor-driven 16 mm Bolex camera with wide angle lens on the existing pier some 50 m from the grid (Fig. 4). Film advance rate was 12.53 frames/sec. Three film runs, obtained over a one hour period on 26 September 1968 constitute the data base for this report. The semi-diurnal tide has a mean range of 1.04 m. The observations were made about 2 hours after high water.

After each run the sediment surface was profiled relative to the grid. As no significant changes were observed between runs, a single profile was used in the analysis (Fig. 3). Mean water level relative to the grid was determined from a series of graduated transparent pipes (5 cm diameter) with constricted orifice (0.32 cm) which acted to filter high frequency fluctuations. The internal water level within the tubes was visually monitored.

The observation method allowed the viewer to freeze the free surface profile at successive time steps so the complete transformation of individual waves could be traced. Basic film data reduction was achieved using a Lafayette Analyst Time-Motion Projector with the image projected on a wide rear surface screen. Water surface elevation was estimated to 3 cm (0.1 ft) on the grid cell.

FIGURE 2. GRID IN PLACE.

FIGURE 3. GRID LAYOUT DURING EXPERIMENT.

FIGURE 4. AERIAL VIEW OF PIER USED AS CAMERA PLATFORM.

FIGURE 5. DEFINITION SKETCH FOR RELATIVE BREAKING DEPTH.

The observed waves were categorized according to breaker type. The criterion for breaking of "spilling" waves was the first appearance of foam cascading down the foreface. In the case of "plunging" waves, the criterion used was the position when initial overturning appeared with the formulation of a protruding lip or jet at the top of the near vertical foreface. While well-developed plunging waves and well-developed continuously spilling waves were distinct and easily separable, some breaker events were less clear. In some cases there was obvious interference between an incoming plunging wave and a strong backwash or cases when a wave was overtaking another while breaking. In a few cases the spilling crest would transform to a plunging crest. The 116 waves were distributed as follows: 70 well-developed plunging; 18 interference plunging; 21 well-developed spilling; and 7 spilling transformed to plunge.

For calculations involving breaker wave period, T_b , the observed period at a distance of 21 m from the mean water line was used. The period was considered to be the elapsed time between the passing of the wave in question and the passing of the prior wave. Wave celerity was considered to be the speed of travel over the 2 m distance prior to the inception of breaking. A data listing is given in Weishar (1976).

RELATIVE BREAKING DEPTH

The limiting wave height to depth ratio has been the subject of considerable study since the work of McCowan (1894). Galvin (1972) offers a complete review. McCowan derived a limiting value of $\eta/d_b = 0.78$ (see Fig. 5 for definition sketch) from solitary wave theory. The numerical value of 0.78 remains in common use although it is generally associated with the ratio, $\alpha = H_b/d_b$. Laboratory studies have demonstrated a dependency of α upon beach slope, m :

$$\frac{1}{\alpha} = 0.92 \quad \text{for } m \geq 0.07$$

$$= 1.40 - 6.85 m \quad \text{for } m \leq 0.07$$
Galvin (1969) (1)

$$\alpha = 0.724 + 5.6 m, \quad \text{Weggel (1972) (2)}$$

$$\alpha = 0.75 + 25 m - 112 m^2 + 3870 m^3, \quad \text{Camfield and Street (1969) (3)}$$

RESULTS. Three ratios, η/d_b , H_b/d_b , and H_b/d_t (Fig. 5) were examined with the data set of 116 waves, which were segregated into plunging and non-plunging. The results are shown in Table 1.

TABLE 1

SUMMARY OF WAVE HEIGHT TO WATER DEPTH RATIOS

Ratio	Total Sample (116)		Plunging Waves (70)		Non-plunging Waves (46)	
	Mean	Std. Dev.	Mean	Std. Dev.	Mean	Std. Dev.
η/d_b	0.69	0.31	0.73	0.27	0.67	0.32
H_b/d_b	0.79	0.36	0.87	0.33	0.68	0.37
H_b/d_t	0.89	0.46	1.03	0.53	0.69	0.31

Application of the Student "t" test indicates that the difference between the means of the plunging versus non-plunging waves is significant ($P < 0.01$) for the ratios H_b/d_b and H_b/d_t . In all cases the standard deviations are relatively large. It is of interest to note that the average value of H_b/d_b for the entire sample is very close to the value commonly used in engineering practice. The histograms for H_b/d_b are shown in Figure 6.

The observed values of H_b/d_b were also compared with the three relationships denoting slope dependency (Eqs. 1-3) using the local slope in the region of breaking. All the plots exhibited wide scatter as a result of the wide variation in H_b/d_b for a very small slope range. This data set is inappropriate to independently test for the effect of slope on relative breaking depth.

CLASSIFICATION OF BREAKER TYPE

Visual inspection of waves breaking in the nearshore or on the foreshore leaves even the casual observer with the impression that there are characteristic differences between the modes of breaking which range between a condition where the waves cascade foam down the foreface of the crest as they approach the foreshore to conditions where, on steeper slopes, the waves simply surge up the foreshore without "breaking". The qualitative dependence of wave breaker type on beach slope and wave steepness has been recognized for several decades. Perhaps the most important difference between breaker characteristics is the varying rates of wave energy dissipation as the wave interacts with the nearshore and beach morphology. Galvin (1968) formulated a quantitative classification of breaker type based upon laboratory studies which demonstrated a dependence upon beach slope, wave period, and deep water or breaking wave height. Battjes (1974), in the development of a general similarity parameter for breaking wave behavior, also presented a basis for breaker classification. Both authors formulated offshore and inshore parameters.

FIGURE 6. HISTOGRAMS OF H_b/d_b .

Offshore

$$\frac{H_0}{L_0 m^2} \quad , \quad \text{Galvin (1968)} \quad (4)$$

$$\xi_0 = \frac{m}{(H_0/L_0)^{1/2}} \quad , \quad \text{Battjes (1974)} \quad (5)$$

As noted by Battjes

$$\frac{H_0}{L_0 m^2} = \frac{1}{\xi_0^2}$$

Inshore

$$\frac{H_b}{gmT^2} \quad , \quad \text{Galvin (1968)} \quad (6)$$

$$\xi_b = \frac{m}{(H_b/L_0)^{1/2}} \quad , \quad \text{Battjes (1974)} \quad (7)$$

Galvin's results are shown in Figure 7. Battjes reexamined Galvin's data in terms of his classification parameters and suggested the following limits:

Offshore

surging	$\xi_0 > 3.3$
plunging	$0.5 < \xi < 3.3$
spilling	$\xi_0 < 0.5$

Inshore

surging	$\xi_b > 2.0$
plunging	$4.0 < \xi_b < 2.0$
spilling	$\xi_b < 0.4$

The purpose of this section is to test the criteria of Galvin and Battjes with the Virginia Beach data set.

FIGURE 7. BREAKER TYPE AS A FUNCTION OF OFFSHORE AND INSHORE PARAMETER AFTER GALVIN, 1968.

RESULTS. It is important to note that the criteria being tested were formulated under laboratory conditions with uniform slopes whereas the Virginia Beach data set represents conditions of small, but continuously variable slope. In the principal breaking region the average bottom slope was about 0.02 . The slope of the upper foreshore was 0.10 . The slope values entered in the parameter calculations were those of the local bottom slope at the breaker position. This procedure does not take into account the fact that the wave shape is conditioned by the slope conditions prior to the zone of breaking.

The results for the breaker type classification are shown in Figure 8. The most striking result is that the criteria do not separate plunging waves from spilling waves. Although the sample size for spilling waves is much smaller than that for plunging waves, the distribution of spilling waves does not favor the ranges of the parameters suggested by Galvin (1968) or Battjes (1974). On the other hand, most of the plunging waves do fall, or cluster, within the ranges found under laboratory conditions. Furthermore, it is to be noted that the data for plunging waves exhibit closer clustering on the basis of Battjes' criteria relative to those of Galvin. Finally, it may be noted that the "interference" plungers cluster with the "well-defined" plungers.

EVALUATION OF PLUNGE DISTANCE

As an aid in the design of coastal structures, Galvin (1969) presented results of laboratory experiments on the distance a plunging wave travels from the point of breaking to and including the splash region excited by the falling lip of the crest. Part of this distance is the plunge distance which is defined as the distance covered from the inception of breaking to the point where the falling, forward lip touches down in the preceding wave trough (Fig. 9). The results presented in this section offer a comparison of field observations with Galvin's laboratory study.

Galvin's analysis is based on the assumptions that the internal particle velocities are given by the solitary wave phase speed, and that the falling forward face of the plunging wave can be approximated by a free fall trajectory (ballistics) model.

Thus, P , the plunge distance is given by the product of the phase speed, C_b , at breaking, and, t_p , the plunge time. For the free fall parabolic path condition, the time of fall is given by

$$t_p = 1/4 (H_b)^{1/2} \quad (8)$$

FIGURE 8. VIRGINIA BEACH BREAKER TYPES COMPARED WITH CRITERION OF GALVIN (1968) AND BATTJES (1974).

FIGURE 9. DEFINITION SKETCH FOR PLUNGE DISTANCE.

FIGURE 10. COMPARISON BETWEEN CALCULATED AND OBSERVED PLUNGE DISTANCE AT VIRGINIA BEACH.

The wave speed at breaking, C_b , is assumed to be (Fig. 9)

$$C_b = \{g (H_b - G + d_b)\}^{1/2} \quad (9)$$

Taking as approximations, $G \approx 0.25 H_b$ and $d/H_b \approx 1.25$ substitution yields in units of feet per second

$$C_b \approx 8 (H_b)^{1/2} \quad (10)$$

Finally, combining Equations 8 and 10 yields

$$P/H_b \approx 2 \quad (11)$$

Galvin (1969) recognized that the crest foreface has an upward velocity component at breaking and he expected Equation 11 to underestimate the plunge distance. His laboratory measurements showed P to range up to 4.5 with $\bar{P} \approx 3$. Moreover, he found a dependency on bottom slope, P/H_b decreasing as slope increases. This dependency was attributed to the fact that on steeper slopes breaking occurs closer to the shore and the waves may have increasing interaction with the swash-backwash zone. From his averaged values on slopes of 0.05, 0.10 and 0.20, he found

$$P/H_b = 4.0 - 9.25 m \quad (12)$$

Thus, for a horizontal bottom the expected $P/H_b = 4$.

RESULTS. The comparison of expected versus observed values of P is shown in Figure 10. The average value of P/H_b was 5.9 with the range extending from 1 to 10. The poor correspondence between the observed and "expected" values is obvious. In order to investigate the source of error, the observed breaker celerity, C_b , was compared with the calculated celerity using Equation 9. The average error between observed and expected was 12%, with the calculated celerity underestimating the observed at higher values. However, comparison of the calculated t_p (Eq. 8) with the observed t_p indicated an average error of 64% (Fig. 11). The principal source of error is thus in the calculation of plunge time. In order to determine the validity of the equation for plunge distance, $P = C_b t_p$, the observed plunge distance was compared with product of the observed values of breaker celerity and plunge time. These results are shown in Figure 12, wherein a close correspondence is observed. The remaining scatter is attributed to errors in determining the exact breaker position and the observed parameters, breaker celerity and plunge time.

The observations and analysis indicate that the free fall trajectory assumption is an incomplete model as an estimator for the trajectory of the plunging wave. A more complete model would have to include the vertical velocity components at breaking. The results presented for conditions of small beach slope do approximate, on the

FIGURE 11. COMPARISON OF OBSERVED PLUNGE TIME WITH THAT EXPECTED FROM EQ.8.

FIGURE 13. OBSERVED BREAKER HEIGHT AS A FUNCTION OF EQ. 17. REGRESSION GIVES $K=0.36$.

average, the experimental results of Galvin (1969) for small slope. Further field research on steeper beaches should clarify whether the level of approximation is consistent with experimental results.

PREDICTION OF BREAKING WAVE HEIGHT

Many engineering applications entail the estimation of wave breaker height given the deep water wave characteristics. Komar and Gaughan (1972) tested three sets of laboratory data and one set of field data from the California coast (Scripps pier) against a formulation for breaker height prediction using linear wave theory combined with a similarity criterion for relative breaking depth, H_b/d_b . The resulting relationship, empirically fitted to the data, was found to be an adequate predictor for breaker height over the range from small laboratory waves to the field data set consisting of breaker heights ranging from 1.2 to 3.5 m. Since the wave heights observed at Virginia Beach fall in the range intermediate to those tested, an independent evaluation was considered worthwhile.

From Komar and Gaughan (1972), the conservation of energy flux is,

$$(E C_\eta)_b = (E C_\eta)_o \quad (13)$$

From linear wave theory,

$$E_b = 1/8 \rho g H_b^2 \quad (14)$$

$$\text{and } C_b = \sqrt{g d_b} \quad (15)$$

Substitution of deep water characteristics and Equations 14 and 15 in Equation 13 yields, with reduction,

$$H_b^2 (g d_b)^{1/2} = \frac{g}{4\pi} (TH_o^2) \quad (16)$$

Using $\alpha = H_b/d_b$ gives the results of Komar and Gaughan

$$H_b = K g^{1/5} (H_o^2 T)^{2/5} \quad (17)$$

where $K = \frac{\alpha}{5} (4\pi)^{2/5}$

A best fit comparison with the experimental data yielded $K = 0.39$. In passing, the predicted value of α for the combined data set of Komar and Gaughan is then 0.71.

Also, if

$$C_b = \{g (\eta + d_b)\}^{1/2}$$

from this study $\eta = 0.92 H_b$; $d_b = 1.26 H_b$

then the expected $K = 0.31$. Regression analysis of the Virginia Beach data yields $K = 0.36$ (Fig. 13).

The combined results of Komar and Gaughan, which compares the laboratory results of Komar and Simmons and Munk (1949), with the Virginia Beach data is shown in Figure 14. It appears that the relationship

$$H_b = 0.39 g^{1/5} (TH_0^2)^{2/5}$$

provides a reasonable estimation of breaker height as a function of wave period and deep water wave height. However, it is to be noted that the effects of wave refraction or frictional dissipation are not incorporated. In the laboratory results the deep water wave height is calculated from linear wave theory. In the case of the data from Scripps pier H_0 is an approximation as the shoaling coefficient varied between 0.99 and 1.44 . A more severe approximation applies for the Virginia Beach data set as the nearshore slope is slight and the effects of wave refraction and dissipation may be expected to be significant. Consequently, the fit to the deduced relationship should be viewed as a relationship between breaker height and the "apparent" deep water wave height with refraction and frictional effects ignored. The degree to which the relationship is an artifact borne of circular reasoning will await further testing which includes refraction and frictional effects. It should be further noted that calculation of the deep water parameters involved the use of the near breaking wave period which for individual waves bears an unknown, and perhaps indeterminate, relationship to deep water period for even "simple" wave trains.

CHAPTER 28

PROBABILITY DENSITY FUNCTIONS OF BREAKING WAVES

By

Edward B. Thornton¹ and George Schaeffer²

ABSTRACT

Waves in the surf zone are a highly nonlinear process which is evident by the appearance of secondary waves. The secondary waves appear as strong peaks in the period PDFs corresponding to the first harmonic of the peak of the wave spectrum. The strong first harmonic period peak is also reflected in the highly correlated height and velocity PDFs. Due to the high probability of the secondary waves, the mean wave period for breakers is a poor descriptor of the average period of the offshore incident waves.

The joint probability density functions for periods and heights of the breaking waves show high correlation (0.60-0.80) which says that greater wave periods are associated with larger breaker heights. The joint PDFs of period and particle velocity, and velocity and height, suggest that the maximum onshore particle velocities are correlated with both the wave periods and wave heights.

I. INTRODUCTION

Studies of the PDFs of period, height, and wave lengths have been conducted over the last 20 years. The majority of these studies have been mainly concerned with theoretical or deep water aspects of the problem.

The theoretical distribution of wave amplitudes for a narrow-banded Gaussian surface elevation in deep water, was shown by Longuet-Higgins (1952) to be a Rayleigh distribution. Tayfun (1977), in studying the transformation of deep water waves to shallow water waves, showed that the Rayleigh distribution for wave amplitude was generally applicable to all bandwidths.

¹Associate Professor, Naval Postgraduate School, Monterey, California, 93940

²Lieutenant, United States Navy

Longuet-Higgins (1975) extended his earlier work on narrow-banded Gaussian surface elevations in deep water and derived an expression for the joint distribution of wave periods and amplitudes

$$p(\xi, \eta) = \frac{\xi^2}{(2\pi)^{\frac{1}{2}}} \exp(-\xi^2(1+\eta^2)/2) \quad (1)$$

where ξ and η are the normalized amplitudes and periods as defined by,

$$\xi = a/\mu_0^{\frac{1}{2}} \quad (2)$$

and

$$\eta = (T - \langle T \rangle) / v \langle T \rangle \quad (3)$$

where $\langle T \rangle$ is the mean period and v is proportional to the spectral width where

$$v = (\mu_2/\mu_0)^{\frac{1}{2}} (\langle T \rangle / 2\pi) \quad (4)$$

and μ_0 and μ_2 are the zero and second moments of the energy spectrum. The wave periods are defined by their zero up-crosses. It is noted that the marginal distribution of wave periods in deep water is bell shaped (but not Gaussian). Longuet-Higgins (1975) compared this theoretical distribution of ocean waves to that of the deep water data obtained by Bretschneider (1959) and found good agreement. He found that for the marginal wave height distribution there is a slight excess of waves with heights near the middle of the range and a deficit at the two extremes. Since much of the high frequency portions of the wave records are filtered out by the pressure transducer, he suggests that the narrow-band approximation may not be as applicable for the unfiltered records. In shallow water with much steeper waves, the distribution can again be expected to be less applicable due to the non-linearities which become increasingly important.

Chakrabarti and Cooley (1977) compared the theoretical joint distribution of Longuet-Higgins (1975) with wave data recorded during a 1961 storm in the North Atlantic. The spectrum of these waves did not fall in the category of narrow-band. Through the comparison, it was found that there was a considerable agreement at the higher wave heights, but a definite trend away from the theoretical curve at the lower wave heights.

Bretschneider (1959) investigated the PDFs of wave heights, H , wave lengths, L , and wave periods, T . He concluded from his empirical study that in deep water wave systems, the PDFs of wave heights and lengths can be approximated by a Rayleigh distribution. Using the relationship, wave length proportional to period squared for deep water linear waves, he concluded that the PDF of periods squared is a Rayleigh distribution.

Assuming that the marginal PDFs are Rayleigh, Bretschneider (1959) examined the extreme cases of 0 and +1 correlation. For the case of zero correlation, the marginal Rayleigh PDFs are given by

$$p(\zeta) = \frac{\pi}{2} \eta \exp(-\pi\zeta^2/4) ; \quad \zeta = H/\bar{H} \quad (5)$$

$$p(\lambda) = \frac{\pi}{2} \lambda \exp(-\pi\lambda^2/4) ; \quad \lambda = L/\bar{L} \quad (6)$$

For zero correlation, i.e. total independence, the joint PDF of heights and lengths is given by

$$p(\zeta, \lambda) = \frac{\pi^2}{4} \zeta \exp(-\pi\zeta^2/4) \cdot \lambda \exp(-\pi\lambda^2/4) \quad (7)$$

In terms of heights and periods,

$$p(\zeta, \tau) = 1.35 \zeta \exp(-\pi\zeta^2/4) \cdot \tau^3 \exp(-0.675 \tau^4)$$

where $\tau = T/\bar{T}$. (8)

For the case of total dependence, the correlation coefficient is equal to one. For a correlation coefficient of one, all data points on a plot of joint Rayleigh PDFs fall on a 45 degree straight line passing through the origin.

Koele and de Bruyn (1964), Goda (1967), and Siefert (1970) have observed that the distribution of wave heights in shallow water does not correlate well with the Rayleigh distribution. Kuo and Kuo (1974) have suggested that this is due to: 1) the non-linear effects of wave interactions yielding more larger waves, 2) the effect of bottom friction yielding a reduction in the low frequency components, and 3) the effects of wave breaking, which would truncate the distribution and transfer some of the kinetic energy to the high frequency components. Therefore the PDFs of wave heights with a certain intensity, may be considered to approximate a conditional Rayleigh distribution truncated by the local breaking height.

A zero-up-cross analysis was conducted on waves measured on a reef by Black (1978), who then compared the observed distribution with the Rayleigh, truncated Rayleigh, and the Weibull distributions. He observed that the truncated Rayleigh distribution fit well for those waves in the breaker zone when the heights were depth limited. The truncated Rayleigh distribution did not fit well for those waves measured either inshore or offshore of the breaker zone. He has found that a Weibull distribution more closely approximated these measured distributions.

It would be expected that the Weibull distribution would yield the better fit. The Rayleigh distribution is a function of the variance of the data, whereas the Weibull distribution is a function

of higher moments about the mean. Neither theoretical distribution adequately describes observed distributions which are multi-modal.

Black's (1978) observations of wave periods show distributions which are skewed to the right. This does not fit well with the symmetrical Longuet-Higgins (1975) distribution. It was found that the period distribution more closely followed the Rayleigh distribution than the period square as proposed by Bretschneider (1959). It was found that the Weibull distribution most closely fit the empirical PDF, but there is considerable variation in the peakedness parameter. His attempts in relating the period statistics to the position on the reef were unsuccessful. He feels that this is due to the non-linearities of the waves in shallow water.

In this paper, the empirical data collected for breaking waves are compared with the Rayleigh distribution.

II. EXPERIMENT AND ANALYSIS

Three different California experimental sites were used to obtain data on the three types of breaking waves--plunging, spilling, and collapsing. Plunging and spilling waves were measured on Del Monte Beach, Monterey, California; collapsing breakers were measured on the Carmel River Beach, which is located approximately five miles south of Monterey, California. Due to the steepness of the beach and the rapidity of breaking of the shoaling waves, reflected waves are found to be present. Spilling breakers on a gently sloping beach were measured at Torrey Pines Beach, a site just north of La Jolla, California.

Capacitance type gauges were used to measure the change in the sea surface elevation. The velocity of the water particles was measured with Marsh-McBirney Model 721 and 722 Electromagnetic Current meters. The meters were calibrated in the laboratory prior to use in the field. The instruments were placed on towers in the surf zone at low tide at the expected point of breaking of the waves for the subsequent high tide. Each tower held a capacitance wave gauge and an electromagnetic flowmeter. The flowmeter was placed below the wave gauge, approximately 0.5 m from the bottom, to insure constant submergence. Data were collected within an hour or two on both the ebb and flow sides of high tide. Details of the experiments are given in Thornton *et al* (1976).

Record lengths of approximately 30 minutes from each data set were analyzed. It was desired to only examine the sea-swell band of frequencies lying between 0.03-1.0 Hz (30 sec-1 sec). Hence, the data were passed through both a high and low pass digital filter. The high pass filter had a cut-off frequency of 0.03 Hz (30 sec). The high pass filter used a Fast Fourier Transform (FFT) algorithm to obtain the Fourier spectrum of the entire 30 minute record. The Fourier coefficients corresponding to 0-0.03 Hz were then used to synthesize a low frequency time series which was subtracted from the wave record. The low pass filter was a 25 weight inverse transform

filter. A cut-off frequency of 1.2 Hz was used with a terminal frequency of 1.8 Hz. The mean and variance of sea surface elevations were calculated for each record as well as the mean and variance of the heights, periods and maximum velocities.

Wave heights were determined from the surface elevation record by means of the zero-up-cross method. The zero-up-cross technique defines a wave period as the interval between adjacent upcrosses. The maximum and minimum of the surface elevation within the interval defines the crest and trough of a wave. Maximum onshore particle velocities were calculated from the flowmeter records. Maximum onshore velocity was defined as the maximum velocity amplitude occurring between successive zero upcrossings as defined by the sea surface elevation record. Joint PDFs of wave height and period, wave height and maximum velocity, and maximum velocity and period were calculated from the analyses.

Heights and maximum velocities were normalized by dividing by their respective standard deviations of the surface elevations and particle velocities respectively. The periods were normalized by dividing by their mean period. Histograms were calculated for the normalized heights, periods, and maximum velocities. The histograms were transformed into PDFs by dividing the number of values over an interval by the total number of values in the array and by dividing by the interval width.

Joint probability density functions of periods versus heights, velocities versus heights and periods versus velocities were calculated in a similar fashion. A 15 by 15 grid was used to determine the frequency of values which simultaneously fill each joint interval.

The energy density spectrum (power spectrum) was obtained by means of a Fast Fourier Transform (FFT) algorithm. The energy density spectrum tells how the variance is distributed with respect to frequency. The spectral width parameter was calculated using the equation:

$$\epsilon = \sqrt{\frac{m_0 m_4 - m_2^2}{m_0 m_4}} \quad (9)$$

where m_0 , m_2 , and m_4 are the spectral moments (Cartwright and Longuet-Higgins, 1956). For $\epsilon = 0$ the waves have only one frequency and the energy spectrum would be represented by a spike. As $\epsilon \rightarrow 1$

the sea surface can be described as a broad-band process for which the distribution would be Gaussian and the spectrum would approach a horizontal line. Swell can therefore be described as a narrow-band process and seas as broad-band. Due to the appearance of secondary waves, a narrow-banded deepwater spectrum of waves broadens in the surf region.

The correlation coefficients of the joint values were calculated to obtain a measure of the amount of linear relationship of random pairs of values of periods and heights, velocities and heights, and periods and velocities.

III. DISCUSSION

Data measured on 16 March 1977 for the case of spilling breakers at Torrey Pines Beach is chosen for subsequent discussion. The off-shore waves on this date appeared as narrow-band swell. But spectral analysis of the surface elevation records in the surf zone yielded spectral width parameters ranging from 0.94-0.97, suggesting a broad-band spectrum in the surf zone. The broad spectral width can be attributed to the non-linear wave-wave interactions yielding harmonics in the breaking zone.

In order to determine the origin of the large spectral width parameter, ϵ was calculated in the ranges of 0-0.25 Hz, 0-0.50 Hz, 0-1.0 Hz and 0-nyquist frequency. The analysis revealed that large values of the spectral width parameter occurred in all cases. In the case of 0-0.25 Hz which contains the first three harmonics, ϵ was greater than 0.7, which was the case with the smallest ϵ . It is concluded that the change from a narrow deep water spectrum to a broad-band shoaling spectrum is primarily due to generation of secondary waves at harmonic frequencies.

Probability Density Functions of Period and Height

Bretschneider (1959) made the assumption that the wave lengths were Rayleigh distributed; using this assumption and the linear wave theory relationship

$$L = \frac{g}{2\pi} T^2 \quad (11)$$

the wave periods squared would be Rayleigh distributed in deep water. Bretschneider's analysis can be extended to the shallow water case using the shallow water approximation for wave length

$$L = \sqrt{gh} T \quad (12)$$

Assuming the wave lengths are Rayleigh distributed, the periods in shallow water would be expected to be Rayleigh distributed since period and wave length are directly proportional.

The period PDF is shown in Figure 1 and it is noted to have a definite skewness. The Rayleigh PDF has been superimposed on the period PDFs for comparison. The period PDFs only loosely follow the Rayleigh PDF. The Rayleigh PDF overpredicts the wave periods greater than the Rayleigh mode value, and underpredicts the observed periods less than the peak Rayleigh value. The observed period PDF has the mode lying close to the maximum of the superimposed Rayleigh PDF.

The mode of the breaking wave distribution is located at a period (7 sec) corresponding to the first harmonic of the offshore peak wave period (14 sec). A peak corresponding to the peak offshore wave period is absent. The waves periods as determined by a zero-up-cross of the surface elevation record for breaking conditions yields a poor indication of the peak of the energy spectrum which corresponds to the mean offshore wave period. The mean periods corresponded to the first harmonic periods or even to a valley between the primary and first harmonic periods. The appearance of strong peaks at one-half the offshore wave period is indicative of the importance of nonlinearities in the form of secondary waves in the surf zone.

The wave height PDF is shown plotted against the theoretical Rayleigh PDF at the top of Figure 1. The height PDF is loosely described by the Rayleigh PDF. The major height peak is centered at 2.2. The Rayleigh PDF overestimates the density of the small wave observations and tends to underestimate the density of the large waves. The heights are truncated at approximately six standard deviations. Since the wave gauge is stationary and therefore the depth of the water is essentially fixed, this truncation occurs due to the breaking of the large waves seaward of the wave gauge. The calculated mean height value on 16 March 1977 lies at 2.7, which actually corresponds to a dip in the PDF relative to the peak intervals on either side. The bimodality was very commonly observed and is attributed to the very narrow band incident wave system and the generation of secondary waves at the first harmonic.

The joint PDF of periods and heights is contoured in Figure 1. It is noted that the longest wave periods are associated with the greatest wave heights suggesting strong correlation between periods and heights. The correlation coefficient was calculated for all cases and varied between 0.60 and 0.80. The area of maximum joint density is found to be associated with the first harmonic of the offshore wave period, and the mode of the observed breaker heights.

Greater density was found at short periods and heights for all records than predicted by the Rayleigh PDF. A high frequency wave riding on a long period wave causes an additional zero crossing as the longer wave passes through zero. Most previous comparisons of heights or periods of waves have been done using pressure sensors which greatly filter the high frequencies due to hydrodynamic attenuation. Capacitance wave staffs and electromagnetic flowmeters have good response times and thus measure high frequencies. Therefore, even though the data were filtered at 1 Hz, all records showed peaks at the shortest periods and heights.

Figure 1. PDFs of Wave Heights and Periods, 16 March 1977

Joint Probability Density Functions of Velocities

The velocity PDFs were calculated as the maximum onshore velocities within the period segments determined by the zero-up-crosses of the surface elevation record shown in Figure 2. Using this technique can result in both positive and negative maximas for onshore particle velocities.

The theoretical Rayleigh PDF is superimposed on the same graphs for comparison and it is apparent that the velocity PDF is not adequately described by the Rayleigh PDF. The velocity PDF for spilling breakers appears to be symmetrical, with the mode value falling at the bin with center velocity of 1.5. There also appears to be a small peak value at 0.3.

The joint probability distributions of velocities and heights shown in Figure 2 show high correlation between velocities and heights. The high positive correlation (0.7) suggests that the larger maximum onshore velocities are correlated with the larger wave heights.

Figure 3 shows the joint PDF of periods and velocities in which the periods were determined from the zero-up-crosses of the wave gauge record and the coincident maximum onshore velocities are determined from the flowmeter record. The results are similar to the joint PDF of period and heights. The maximum spilling probability is found at the intersection of period 0.84 and velocity 1.5.

The negative values of the maximum velocity indicate that, during a wave period defined by the zero-up-crosses of the surface elevation, the maximum velocity can be negative. The joint PDF of wave height and velocity shows that the negative velocities are associated with the low wave heights. The joint PDF of velocity and period shows that small negative velocities are correlated with the short periods. Therefore, it is concluded the negative velocity maxima are associated with short periods and low wave heights. The secondary waves occur after the passage of the primary wave crest and have a peak near the trough of the primary wave; the velocities associated with the primary wave would be negative maximum in this region so that the measured velocity, which is a sum of the primary and secondary waves, can be small or negative.

IV. CONCLUSIONS

Waves in the surf zone are a highly non-linear process which is evidenced by the appearance of secondary waves. The secondary waves appeared in the PDFs at the first harmonic of the primary period.

The joint probability density functions of the breaking wave properties show high correlations. The correlation factor ranged between 0.60-0.80 for periods and heights and suggests that the greater the wave period, the higher the breaker height will be. High correlation between the periods and velocities and the heights

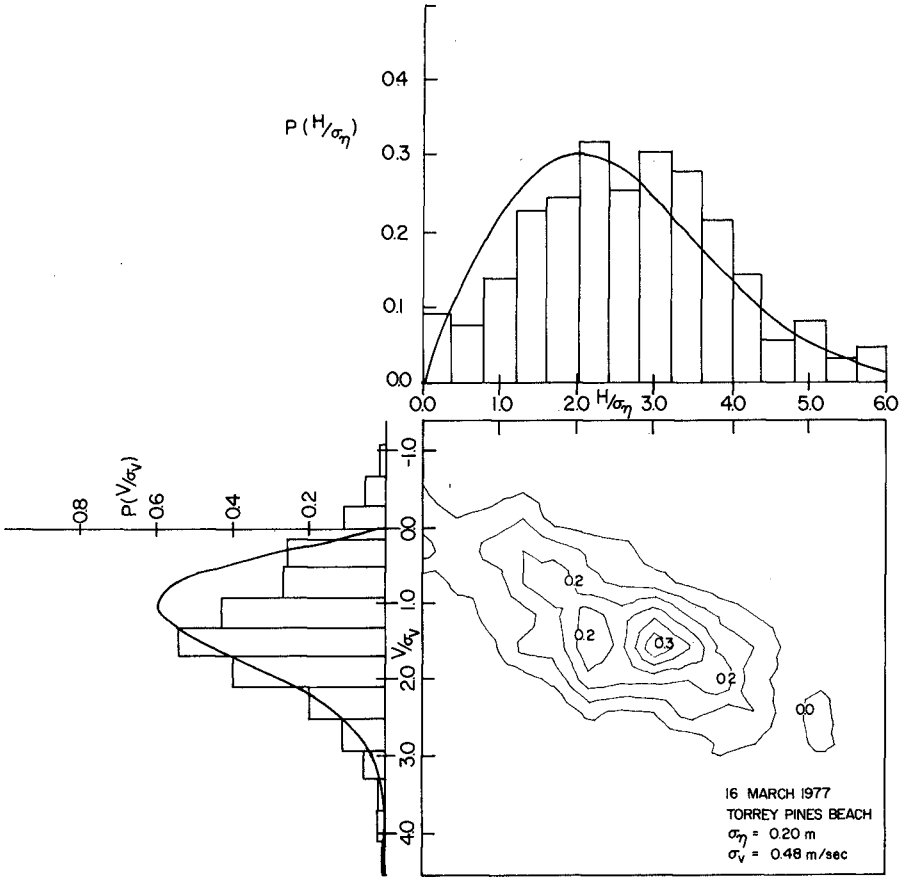

Figure 2. PDFs of Wave Heights and Velocities, 16 March 1977

Figure 3. PDFs of Velocities and Periods, 16 March 1977

and velocities suggests that the maximum onshore velocities are a function of wave periods and breaker heights.

A truncated Rayleigh PDF was found to loosely approximate the empirical period and the height PDFs of spilling breakers. This truncation seems to be the result of long period waves with their associated larger breaker heights breaking prior to the arrival at the wave gauge.

The velocities PDFs of breaking waves, where the velocity maxima are associated with the periods defined by the surface elevation, yields a symmetrical distribution with some negative onshore velocities present. Since the Rayleigh distribution is undefined for negative values, the resulting fit of observed data with the theoretical Rayleigh distribution is poor.

The mean wave period as obtained by the zero-up-cross method in the surf zone is a poor indicator of the mean offshore wave period. Spectral analysis of the breaking waves shows an energy peak corresponding to the primary offshore wave period, but the period PDFs of breaking waves have a strong peak at the first harmonic of the wave spectra peak. The joint PDF ($p(T,H)$) of breaker waves showed a maximum density at a wave period equal to one half the peak period of the wave energy density spectrum, i.e. the first harmonic. The corresponding velocities ($p(v,T)$) or heights ($p(H,T)$) likewise were found to have a peak density associated with the first harmonic wave period. The mean period of breaking waves therefore is a poor estimation of the mean period of the incident waves offshore.

ACKNOWLEDGEMENTS

The data collected at Torrey Pines Beach was measured in cooperation with Robert T. Guza and the Shore Processes Laboratory at Scripps Institution of Oceanography. This work was supported by the Office of Naval Research, Geography Branch, under contract NR 388-114.

CHAPTER 29

WAVE CHARACTERISTICS IN THE SURF ZONE

I.A. Svendsen¹ P.Å. Madsen² J. Buhr Hansen¹

ABSTRACT

The equations describing conservation of mass, momentum and energy in a turbulent free surface flow are derived for a controle volume extending over the whole depth. The effect of the turbulent surface oscillations are discussed but neglected in the following analysis, where the equations are applied to the energy balance in a surf zone wave motion. This leads to results for the wave height variation and the velocity of propagation. The results cannot be reconciled completely with measurements and the concluding discussion is aimed at revealing how the model can be improved.

1. INTRODUCTION

Wave breaking and wave development in the surf zone are topics that have given raise to numerous investigations in the past, and yet much remains to be done before a satisfactory understanding has been obtained and real prediction is possible.

The present paper describes a combined experimental and theoretical work. We concentrate on the development of the gross parameters of wave motion after breaking on a gently sloping beach, and first of all on the phase velocity c and the energy dissipation, i.e. the attenuation of the wave height.

From visual observation aided by photography in laboratory flumes and in the nature it appears that immediately after the wave has started to turn over from the breaking point a violent transition takes place over a horizontal distance of several times the water depth at the breaking point. In this region, which we term the outer breaking region, the motion still shows large scale patterns that are repeated with only small variations from wave to wave (in regular waves) though they of course differ radically with the type of breaking and hence also from wave to wave in an irregular train of waves as on a natural beach. This feature of the breaking process is most significant in a plunging breaker.

From this description it is natural to conjecture that the process is dominated almost entirely by the wave data at the breaking point, i.e. the water depth h_b and wave height H_b . In other words that for a wide range of wave parameters the horizontal scale for the development in this

¹Assoc. Professor, ²Ph.D.-student.

Institute of Hydrodynamics and Hydraulic Engineering (ISVA),
Technical University of Denmark, Building 115, DK-2800 Lyngby.

Fig. 1 Wave characteristics in the surf zone.

Fig. 2 Relative change in wave height right after breaking.

region is h_b . This is actually confirmed in Fig. 2 which shows the relative change in wave height H/H_b versus the distance from the breaking point measured in units of h_b .

The figure also includes data obtained by Horikawa & Kuo (1966) and by Nakamura et al (1966) on a similar slope (1 in 30 against ours 1 in 34) though the above mentioned conjecture implies that the effect of the slope is insignificant. It is worth noticing that the wide range of wave parameters in Fig. 2 means that the wave height variation is independent of the breaker type (spilling or plunging). Considering the actual differences in the motion one must question the adequacy of the notion "wave height" as a means of description.

As the wave propagates further the large scale deterministic flow breaks up into small scale details which gradually become of a random turbulent nature. During this process the front of the wave becomes

very similar to a moving bore or a hydraulic jump, and we may speak of a system of periodic bores. We term this the inner breaking region and it extends to the shoreline where the run-up starts.

It should perhaps be emphasized that if the wave breaks at or near the shoreline (as e.g. a collapsing or surging breaker) this region is absent and the outer region is immediately followed by the run-up. The description also fails to apply if the depth starts to increase shorewards so the breaking ceases.

One of the remarkable features of the inner region is that the waves or bores from a plunging breaker cannot be distinguished visually from those originating from a spilling breaker.

Thus the water motion at each depth seems to be strongly locally controlled in the sense that local depth and bed slope determines the characteristics of the flow and hence the energy dissipation, the shape of the wave including energy flux, and consequently the decrease in wave height. This hypothesis will find further support in the measurements reported in § 2, where we shall find that for a particular wave train the height to depth ratio H/h is only slowly decreasing and the shape is almost constant in the case of a constant slope.

The internal flow pattern has been studied by Peregrine and Svendsen (1978) who describe the resemblance with in particular hydraulic jumps and single bores occurring in front of a propagating change in water depth. Based on a new flow visualization method they concluded that the turbulence associated with a hydraulic jump or a bore is not limited to a surface roller. In fact there is nothing that separates the surface roller from the rest of a region of highly turbulent flow which originates from the toe of the roller. From there the turbulence develops, in the beginning much like in a turbulent mixing layer. The thickness of the turbulent region increases gradually with distance behind the toe of the roller but remains attached to the free surface. At some distance it reaches the bottom too. These conclusions are supported by the measurements made in a hydraulic jump by Resch et al. (1976).

It is the purpose of this paper to try to explain analytically the basic features phase velocity, energy dissipation rate and wave height attenuation. For this purpose we develop in § 3 the integrated forms of equations describing conservation of mass, momentum and energy and discuss the assumptions made, in particular with respect to the turbulent surface fluctuations.

§ 4 describes how the energy equation can be used to determine the wave height variation and the measurements are used as guidance in the choice of velocity and pressure profiles required in the computations. This also applies to the determination of the velocity of propagation c which turns out to be an important quantity in the description.

The conclusions are not satisfactory yet, and the analysis is succeeded by a discussion of the inaccuracies and possible improvements (§ 8).

2. EXPERIMENTAL RESULTS

The experiments were performed in one of ISVA's 60 cm wide wave flumes (length 32 m) with a water depth at the wave generator of 36 cm's. The waves were of the very regular type deprived of their free second harmonic components (Buhr-Hansen and Svendsen, 1974). The waves broke on a plane slope 1:34 (see Fig. 3) and the surface variations were measured

Fig. 3 Experimental set-up.

by resistance gauges (two goldplated silver wires, 0.17 mm diameter, 5 mm apart) and recorded digitally. Eight fixed wave gauges (denoted channel 0, ..., 7) were used, positioned as shown in Fig. 3. Only surface elevations were measured and the depth (excluding set-up) range from about 82 mm at channel 0 to about 13 mm at channel 7.

The following account of measurements is only a preliminary presentation. Results of a more detailed and systematical investigation will follow.

First it is worth mentioning that resistance wave gauges can not without further notice be used in water with air entrained as bubbles as we find it around the front of the broken waves. However, detailed investigations have been made in a vessel with controlled air entrainment. The results show that the gauges used to the accuracy required here measure solid water, i.e. measure the elevation we would have had if the air had been absent. Furthermore visual observations of the bubble-water mixture were compared with photos of the front of the waves indicating that the actual air content in the most densely entrained parts of the laboratory wave is only 2-4 per cent.

Thus the surface elevations reported in the following may be regarded as the elevation of water with normal density.

The digital registration makes it possible to identify data points separated an integral number of wave periods, and thus an ensemble average over many waves can be obtained for the profile at each measur-

ing point. Fig. 4 shows such profiles (η) and the standard deviation $\sigma(\eta)$. The results were obtained over 20 wave periods. As expected the

Fig. 4 Mean and standard deviation of measured profiles for experiment with $T = 1/7$ sec, $H_i = 100$ mm.

standard deviation is maximum (about $0.2H$, H being wave height) at the front and very small elsewhere. Notice that the variations at the front may well be fluctuations in the horizontal position interpreted as vertical fluctuations by the ensemble averaging procedure.

Fig. 5 shows wave height to mean water depth H/h_{MWS} versus still water depth h_{SWL} in the region considered. The experiments reported have deep water steepnesses H_0/L_0 between 0.0088 and 0.034. Thus the distance from the breaking point varies from test to test. The figure shows that H/h is decreasing slowly and that the value depends on H_0/L_0 . Yet the scattering for tests with similar data is considerable, so further investigations are obviously needed for a systematical understanding of this point.

Fig. 5 Variation of wave height to water depth ratio versus still water depth.

Fig. 6 Measured propagation velocity c .

The measurements of c reported in Fig. 6 were obtained from a trolley moving along the wave flume with two wave gauges 20 cm apart. This set-up measured the propagation time between the two gauges for a point of the wave with a fixed chosen elevation. Results for c versus mean water depth are shown in Fig. 6 with \sqrt{gh}^{MWS} as reference curve. It is tempting though - as we shall see - irrelevant to conclude that the linear shallow water result is a fair approximation (i.e. c/\sqrt{gh}^{MWS} is almost equal to unity).

For each of the 8 recording points (channel 0 through 7) the (ensemble) mean profiles have been determined in each test and Fig. 7 shows such profiles at 4 of the points for 4 different tests, and Fig. 8 shows a comparison of the profiles at the first and the last measuring point. Notice that the abscissa corresponds to increasing time at fixed x so that the wave profiles are "propagating towards the left". The vertical coordinate is scaled with the local wave height to make a direct comparison possible.

The striking feature of these figures is the remarkable similarity of the profiles, not only from point to point in a particular test, but also at the same point for different deep water data (Fig. 8). In fact the only significant development seems to be a decrease in the height of the crest and an increase in depth of the trough as the wave propagates shorewards. Since the surface elevation η is adjusted so that $\int_0^T \eta dt = 0$ (i.e. η is measured from the local MWS) these changes do of course correspond to a systematical change in shape. It may be noticed that this development goes in the direction of a linear variation of η between crest and trough.

In the following sections we try to understand the physical flow conditions behind these results on the basis of the fundamental equations of hydrodynamics.

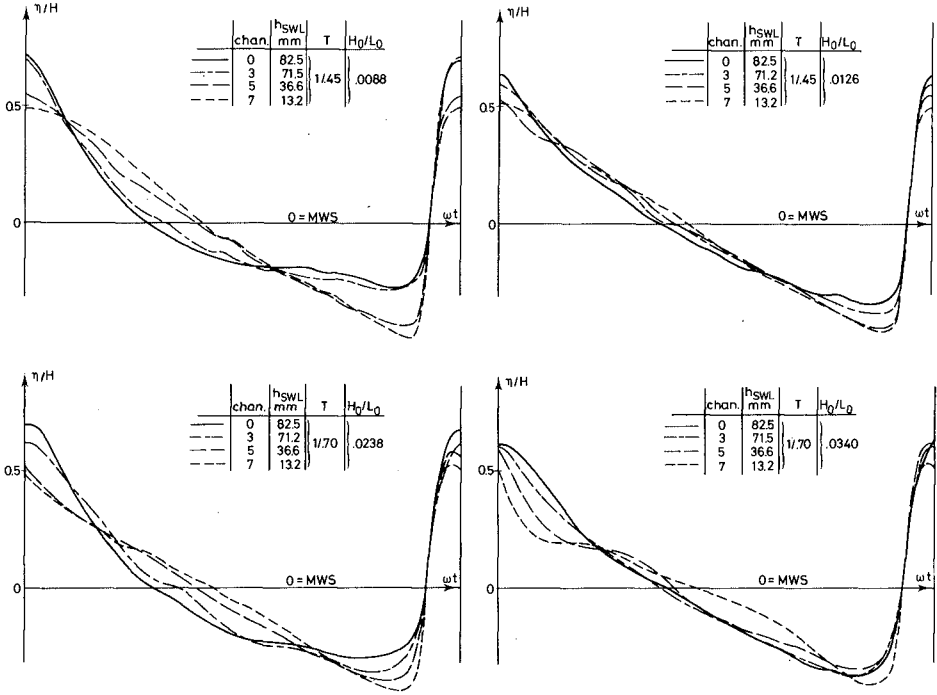

Fig. 7 Mean profiles at four different points.

3. THE INTEGRATED EQUATIONS

As described in the introduction the motion of the waves in the inner region of the surf zone resembles periodic bores or hydraulic jumps. Thus it is natural to start a theoretical analysis by applying the same methods as have been used with great success on particularly hydraulic jumps, i.e. using the integrated equations of mass and momentum to determine the velocity of propagation c and the integrated energy equation to find the dissipation.

Before doing so it is profitable to consider the form of these basic equations. In this context we briefly mention some effects at the free surface which are due to the turbulence, and which do not seem yet to be widely appreciated.

The coordinates and notation used in the following are shown in Fig. 9, which also indicates the type of problem considered.

Fig. 9 Definition sketch.

The integrated equations for conservation of mass, momentum and energy may be derived from the general formulation of these principles given by Jeffrey (1965) for volumes with boundaries moving arbitrarily relative to a fixed frame of reference.

For reference these equations are quoted in our notation and for our conditions, i.e. an incompressible fluid without interval energy (nuclear, chemical, etc.).

Equation of continuity

$$\frac{\partial}{\partial t} \int_{V(t)} \rho \, d\omega + \int_{S(t)} (\vec{u} - \vec{v}) \cdot d\vec{S} = 0 \quad (1)$$

Equation of momentum

$$\frac{\partial}{\partial t} \int_{\Omega(t)} \rho \vec{u} \, d\omega = - \int_{S(t)} p \, d\vec{S} - \int_{S(t)} \rho \vec{u} (\vec{u} - \vec{v}) \cdot d\vec{S} + \int_{\Omega(t)} \rho \vec{g} \, d\omega \quad (2)$$

Equation of energy

$$\begin{aligned} \frac{\partial}{\partial t} \int_{\Omega(t)} \rho \vec{u}^2 / 2 \, d\omega = & - \int_{S(t)} p \vec{u} \cdot d\vec{S} - \int_{S(t)} \rho u^2 / 2 (\vec{u} - \vec{v}) \cdot d\vec{S} \\ & + \int_{\Omega(t)} \rho \vec{u} \cdot \vec{g} \, d\omega - \int_{\Omega(t)} D_V \, d\omega \quad (3) \end{aligned}$$

Here $S(t)$ is the surface of the control volume $\Omega(t)$, \vec{u} is the fluid velocity and \vec{v} the velocity of the surface element dS (for a volume changing in time) positive along the outward normal. D_v is the energy dissipation per unit volume due to viscous forces. In the equation of momentum viscous stresses along the surface have been neglected in this formulation.

For waves on a sloping bottom it appears to be simplest to use a control volume (see Fig. 9) following the free surface but otherwise being fixed in space, at first of length dx , later on integrated over a finite horizontal distance. (Thus the first step corresponds to an integration over depth of the differential form of the three equations).

The continuity equation

From (1) the continuity equation becomes

$$\frac{\partial}{\partial t} \int_{-h}^{\eta} \rho dz + \frac{\partial}{\partial x} \int_{-h}^{\eta} \rho u dz = 0 \quad (4)$$

which results in the well known

$$\frac{\partial}{\partial x} \int_{-h}^{\eta} u dz = -\eta_t \quad (5)$$

In this equation we now extract the turbulent fluctuation denoted by $'$. Thus we in general introduce

$$(u, w, p, \eta) = (\bar{u}, \bar{w}, \bar{p}, \bar{\eta}) + (u', w', p', \eta') \quad (6)$$

where $\bar{\quad}$ means time mean value.

In (5) this yields after turbulent time averaging (i.e. disregarding the time variation of the mean values)

$$\frac{\partial}{\partial x} \int_{-h}^{\bar{\eta}} u dz = -\frac{\partial \bar{\eta}}{\partial t} - \frac{\partial}{\partial x} \int_{\bar{\eta}}^{\bar{\eta}+\eta'} u dz \quad (7)$$

The last term here actually corresponds to the extra term found by Hasselmann (1971) in the kinematic free boundary condition in a situation with wavelets superimposed on larger scale wave motions.

Notice that the result (7) is readily obtained by an integration over depth of the continuity equation $\nabla \cdot \vec{u} = 0$ if Hasselmann's kinematic boundary is used at the turbulent mean surface $\bar{\eta}$.

Obviously similar terms must occur in the equations of momentum and energy. Hasselmann also showed that the dynamic free surface condition at $z = \bar{\eta}$ is not $\bar{p}(\bar{\eta}) = 0$, but

$$p(\bar{\eta}) = -\rho \overline{w'^2} \quad (8)$$

a change which is again a result of the fluctuations at the turbulent mean water surface $\bar{\eta}$.

In all published investigations on bores and hydraulic jumps known to the authors (as e.g. Resch, Leutheusser and Coantin, 1976, Rouse, 1958, Tsubaki, 1950) the fluctuations in η seem to have been neglected, corresponding to omission of the last term in (7) and similar terms in the other equations. In an ordinary free surface turbulent flow these

terms are probably small, but this can hardly be expected to apply to the region with the surface roller in a hydraulic jump or a bore.

Thus being aware of the possible errors it may lead to, we shall in the present investigation allow ourselves to make the same approximation (i.e. neglect the effect of the surface fluctuations) in order to be able to pursue other ideas. We therefore assume that the continuity equation reads

$$\frac{\partial}{\partial x} \int_{-h}^{\bar{\eta}} \bar{u} dz = - \bar{\eta}_t \quad (9)$$

in which we may substitute the definition

$$U \equiv \frac{1}{d} \int_{-h}^{\bar{\eta}} \bar{u} dz \quad (10)$$

to get

$$\frac{\partial}{\partial x}(Ud) = - \bar{\eta}_t \quad (11)$$

The equation of momentum

From (2) we get

$$\frac{\partial}{\partial t} \int_{-h}^{\bar{\eta}} \rho dz = - \frac{\partial}{\partial x} \int_{-h}^{\bar{\eta}} (\rho u^2 + p) dz + h_x p(-h) - \tau_b \quad (12)$$

which is exact since $p(\eta)$ is zero. τ_b is the bottom shear stress. Introducing the turbulent description by substituting (6), and neglecting the fluctuations of the free surface yields after turbulent averaging

$$\frac{\partial}{\partial t} \int_{-h}^{\bar{\eta}} \bar{u} dz + \frac{\partial}{\partial x} \int_{-h}^{\bar{\eta}} (\bar{u}^2 + \overline{u'^2} + \bar{p}) dz - \frac{1}{\rho} h_x p(-h) + \tau_b = 0 \quad (13)$$

For further applications it is convenient to express the integrals in terms of coefficients, which we define as

$$\alpha = \frac{1}{d} \int_{-h}^{\bar{\eta}} (\bar{u}/U)^2 dz, \quad \alpha' = \frac{1}{d} \int_{-h}^{\bar{\eta}} \overline{u'^2}/U^2 dz \quad (14)$$

$$\kappa^+ = \frac{1}{\rho g d^2} \int_{-h}^{\bar{\eta}} p^+ dz \quad \text{where} \quad p^+ = \bar{p} + \rho g z \quad (15)$$

Thus (13) may be written

$$\rho \frac{\partial}{\partial t}(Ud) + \frac{\partial}{\partial x} [\rho(\alpha + \alpha')dU^2 + \rho g \kappa^+ d^2 - \frac{1}{2} \rho g \bar{\eta}^2] - h_x p^+(-h) + \tau_b = 0 \quad (16)$$

Here the $\partial/\partial t$ - term can not be integrated with respect to x without information or assumptions about the changing shape of the wave. This is discussed in the following paragraphs.

The energy equation

Here it is useful first to consider the \vec{g} - term in (3). This term

in fact represents the potential energy and may conveniently be re-written as follows

$$\int_{\Omega(t)} \rho \vec{u} \cdot \vec{g} d\omega = - \int_{\Omega(t)} \rho \vec{u} \cdot \nabla g z d\omega$$

which invoking the continuity equation $\nabla \cdot \vec{u} = 0$ becomes

$$= - \int_{\Omega(t)} (\nabla \cdot g z \vec{u}) d\omega = - \int_{S(t)} E_p \vec{u} \cdot d\vec{S} \quad (17)$$

$$\text{with } E_p \equiv g z \quad (18)$$

We further notice that the rate of change of potential energy inside the volume is

$$\frac{\partial}{\partial t} \int_{\Omega(t)} E_p d\omega = - \int_{\Omega(t)} \rho \vec{u} \cdot \vec{g} d\omega + \int_{S(t)} E_{pot} (\vec{v} - \vec{u}) \cdot d\vec{S} \quad (19)$$

where the minus sign of the first right hand term indicates that gravity has to do negative work to increase the potential energy. Combining (17) and (19) yields

$$\int_{\Omega(t)} \rho \vec{u} \cdot \vec{g} d\omega = - \frac{\partial}{\partial t} \int_{\Omega(t)} E_p d\omega + \int_{S(t)} E_p (\vec{v} - \vec{u}) \cdot d\vec{S} \quad (20)$$

When substituted into (3) this can be written

$$\begin{aligned} \frac{\partial}{\partial t} \int_{\Omega(t)} (E'_k + E_p) d\omega = & - \int_{S(t)} p \vec{u} \cdot d\vec{S} - \int_{S(t)} (E'_k + E_p) (\vec{u} - \vec{v}) \cdot d\vec{S} \\ & - \int_{\Omega(t)} D_v d\omega \end{aligned} \quad (21)$$

with

$$E'_k \equiv \frac{1}{2} \rho \vec{u}^2 \quad (22)$$

For the particular control volume considered here we get in the first step (length dx , see Fig. 9)

$$\rho \frac{\partial}{\partial t} \int_{-h}^{\eta} (E'_k + E_p) dz = - \frac{\partial}{\partial x} \int_{-h}^{\eta} (p + E'_k + E_p) u dz - \int_{-h}^{\eta} D dz \quad (23)$$

When we in (23) substitute the turbulent description (6) and average, a large number of turbulent fluctuation terms result. These, however, all belong to the category which we in this context include in the dissipation term D . Thus we concentrate our attention on the ordered mechanical energy only and therefore get

$$\frac{\partial}{\partial t} \int_{-h}^{\bar{\eta}} (E_k + E_p) dz = - \frac{\partial}{\partial x} \int_{-h}^{\bar{\eta}} (p + E_p + E_k) u dz - \int_{-h}^{\bar{\eta}} D_t dz \quad (24)$$

with

$$E_k \equiv \frac{1}{2} \rho (\bar{u}^2 + \bar{w}^2) \quad (25)$$

in which D_t now includes both viscous dissipation and turbulent energy

not yet dissipated, and we recognize the well known expression for the flux of ordered mechanical energy

$$E_f(t) = \int_{-h}^{\bar{\eta}} (\rho g z + \bar{p} + \frac{1}{2}\rho(\bar{u}^2 + \bar{w}^2))\bar{u} dz \quad (26)$$

Thus the energy equation may be written

$$\frac{\partial \mathcal{E}}{\partial t} = - \frac{\partial}{\partial x} E_f(t) - \mathcal{D} \quad (27)$$

with the definitions

$$\mathcal{E} = \int_{-h}^{\bar{\eta}} (E_k + E_p) dz ; \mathcal{D} = \int_{-h}^{\bar{\eta}} D_t dz \quad (28)$$

which simply states that the rate of change of energy inside the control volume is the difference between net flux over the boundary and the loss due to dissipation.

Again it is useful to express the integrals in terms of coefficients which we define as

$$\beta = \frac{1}{d} \int_d (\bar{u}^3 + \bar{w}^2 \bar{u})/U dz \quad (29)$$

$$\delta = \frac{1}{\rho g d^2} \int_d (\bar{u} - U)p^+/U dz \quad (30)$$

Then the energy flux $E_f(t)$ may be written

$$E_f(t) = \int_{-h}^{\bar{\eta}} (p^+ + \frac{1}{2}\rho(\bar{u}^2 + \bar{w}^2))\bar{u} dz = \rho g d^2 U(\delta + \kappa^+) + \rho \beta d U^3 \quad (31)$$

and the energy equation becomes

$$\frac{\partial \mathcal{E}}{\partial t} = - \frac{\partial}{\partial x} [\rho g d^2 U(\delta + \kappa^+) + \rho \beta d U^3] - \mathcal{D} \quad (32)$$

Thus it has been shown how the three fundamental equations integrated over depth can be expressed in terms of velocity and pressure profiles under the assumptions mentioned. In the following these equations are applied to waves.

4. AVERAGED ENERGY EQUATION

One of the important features in the surf zone is the wave height attenuation due to the turbulence generated by the breaking.

For this purpose we average (27) over a mean period (assuming periodicity in time) to get

$$\bar{\mathcal{D}} = - \frac{\partial \bar{E}_f}{\partial x} \quad (33)$$

where $\bar{\mathcal{D}}$ is the mean dissipation per m^2 of bottom and \bar{E}_f is the time mean of $E_f(t)$. We define a non dimensional energy flux B in analogy to ordinary wave theory and using (26) find

$$E_f = \frac{1}{T} \int_0^T \int_{-h}^{\bar{\eta}} (\bar{p}^+ + \frac{1}{2} \rho (\bar{u}^2 + \bar{w}^2)) \bar{u} dz dt \equiv \rho g c H^2 B \quad (34)$$

Similarly we define a nondimensional energy dissipation D and since we want to relate this quantity to the hydraulic jump or bore conditions it is convenient to let D represent the energy dissipation per wave length. Thus we write

$$\bar{D} \equiv \rho g \frac{c}{L} \frac{H^3}{4h} D \quad (35)$$

a form which is closely related to the expression for the hydraulic jump.

Substitution of (34) and (35) into (33) and rearrangement of the terms yield

$$\left(\frac{H}{h}\right)_X = - \left(\frac{h_X}{h} + \frac{c_X}{2c} + \frac{B_X}{2B}\right) \frac{H}{h} - \frac{h_0}{8L} \frac{D}{B} \left(\frac{H}{h}\right)^2 ; \quad X = \frac{x}{h_0} \quad (36)$$

which is a first order nonlinear differential equation in H/h . Notice that (36) itself is fairly general. It is only assumed that the motion is periodic and that D includes the turbulent energy. It also turns out to be a quite convenient basis for studying the effect of simplifying assumptions, also in the related expressions (31) and (34) for B . Solution, however, requires information of the coefficients, and this is the purpose of the following analysis.

The h_X/h term includes the wave set-up so that determination of this term requires integration of the averaged form of the equation of momentum (16). This is perfectly possible but is considered beyond the scope of the present paper. Since the set-up in most of the surf zone is only a small fraction of the still water depth we use an estimate of h_X/h based on the bottom slope and experimental results for the set-up.

The $c_X/2c$ and $B_X/2B$ are more interesting terms, and we first tackle the determination of c .

5. THE VELOCITY OF PROPAGATION

For simplicity the method by which c can be determined for a breaking wave is described for constant depth only. It should be mentioned, however, that it is fairly straightforward to show that the effect of a sloping bottom is negligible on c .

We also assume that the wave motion is of constant form to avoid the complications of defining a speed of propagation for a changing wave form and include the associated effects in the analysis. With a proper choice of c (speed for $\eta = 0$, say) the effect would again be negligible.

None of these assumptions in fact remove from the problem the effects we want to study, namely the influence of the velocity and pressure variation over the depth (i.e. the magnitude of α and κ and for the energy dissipation of β and δ).

Under these conditions it is convenient to change to a frame of reference moving with the wave, and in which the horizontal particle velocity is termed v . Thus

$$\begin{aligned}
 v &= u - c \quad ; \quad V = U - c \\
 \alpha^v &= \frac{1}{d} \int (v/v)^2 dz
 \end{aligned}
 \quad \left. \vphantom{\begin{aligned} v &= u - c \\ \alpha^v &= \frac{1}{d} \int (v/v)^2 dz \end{aligned}} \right\} (37)$$

In a wave of constant form we have

$$\int_d u dz = U d = c \bar{\eta} \quad (38)$$

if i) $\bar{\eta}$ is measured from the mean water level

ii) there is no net mass flux

(see Svendsen, 1974, p. 164 ff).

The continuity equation (11) yields

$$V d = \text{const} = (U - c)d = c \bar{\eta} - c d$$

or

$$V = -c h/d \quad (39)$$

h being the mean water depth.

The equation of momentum (16) becomes (neglecting the bottom friction)

$$\frac{\partial}{\partial t} (V d) + \frac{\partial}{\partial x} [(\alpha^v + \alpha') d V^2 + g \kappa^+ d^2 - \frac{1}{2} g \bar{\eta}^2] = 0 \quad (40)$$

in which the constant form assumption implies that $\partial/\partial t = 0$ so that the equation can be integrated from x_2 to x_1 (see Fig. 9) to yield

$$(\alpha^v + \alpha') d V^2 + g \kappa^+ d^2 - \frac{1}{2} g \bar{\eta}^2 \Big|_2^1 = 0 \quad (41)$$

or with V from (39)

$$c^2 h^2/d (\alpha^v + \alpha') + g \kappa^+ d^2 - \frac{1}{2} g \bar{\eta}^2 \Big|_2^1 = 0 \quad (42)$$

For a wave of constant form c is the same for any choice of x_1 and x_2 . Hence (42) is an equation from which c may be determined, the proper information given. (A check on a solitary wave, say, rapidly confirms this).

In numerical computations, however, the most accurate results are obtained when x_2 and x_1 are placed at the (instantaneous) position of the crest and trough, respectively (Fig. 9).

As a special case we first consider a periodic bore with static pressure and v uniform over the depth. Placing x_2 so far down the stream that there is no turbulence we have

$$\alpha^v = 1 \quad ; \quad \alpha' = 0 \quad ; \quad \kappa^+ = \eta/d \quad (43)$$

Solving for c we then get

$$\frac{c_{\text{bore}}^2}{gh} = \frac{1}{2} \frac{d_1 d_2}{h^3} (d_1 + d_2) \quad (44)$$

$$\text{or with } \zeta = d_2/d_1 \quad ; \quad \zeta_t = d_1/h \quad (45)$$

$$\frac{c_{\text{bore}}^2}{gh} = \frac{1}{2} \zeta_t^3 \zeta (\zeta + 1) \tag{46}$$

which transforms into the well known expression for a single bore if we choose $h = d_1$ (i.e. $\zeta_t = 1$).

In the more general case the direct solution of (42) yields

$$\frac{c^2}{c_{\text{bore}}^2} = A_1 \left[1 + 2 \frac{\kappa_2 \zeta - \kappa_1}{\zeta^2 - 1} \right] \tag{47}$$

where by definition

$$\kappa \equiv \kappa^+ - \bar{\eta}/d \quad ; \quad A_1 \equiv \frac{\zeta - 1}{(\alpha_1^V + \alpha_1') - (\alpha_2^V + \alpha_2')}$$

index $1, 2$ referring to x_1 and x_2 respectively and c_{bore} given by (46).

In (47) may now be introduced various assumptions for the α^V and κ coefficients and the outcome compared with the measurements reported in § 2. Fig. 10 shows the result of such computations. Here three different sets of coefficients have been used, and for reference \sqrt{gh} is shown too.

Fig. 10 Measured and computed values of c .

The results denoted c_{bore} correspond to (46). The values of $\bar{\eta}$ used in the computation were taken from the measured profiles and we see that the agreement is good, but of course this can not be taken as a proof of static pressure and uniform velocity.

The points denoted c_B have been obtained by assuming a deviation from static pressure corresponding to a Boussinesq approximation. Thus for \bar{u} we have used

$$\bar{u} = c \bar{\eta}/d + \frac{1}{2} \left(\frac{1}{3} - \left(\frac{z+h}{d} \right)^2 \right) h \bar{\eta}_{xx} \tag{48}$$

and for \bar{p}

$$\bar{p} = \rho g [(\bar{\eta} - z) + \frac{1}{2} (1 - (\frac{z+h}{d})^2) h \bar{\eta}_{xx}] \quad (49)$$

Again the values of $\bar{\eta}$ and $\bar{\eta}_{xx}$ have been determined from the measured mean profiles.

As Fig. 10 shows the resulting c -values are smaller than the bore velocity. In general a non uniform velocity profile under the wave crest (x_2) (as (48)) yields $\alpha^v > 1$, which tends to increase c , whereas a pressure lower than static ($\kappa < 0$) will reduce c . (In the trough (x_1) the value of $h\bar{\eta}_{xx}$ is too small to give significant contributions).

In c_{bore} and c_B the turbulence has been neglected by assuming $\alpha' = 0$.

The last set of points (denoted c_B^t) shows the effect of the turbulent velocity fluctuations. The value of α' has been chosen as 0.10, which is the approximate value one can derive from Rasch et al. (1976) who report results for u'^2 in a hydraulic jump.

The turbulent velocity fluctuations act as an additional momentum and hence increase c . In the figure α' has been applied to the case where α^v and κ were determined by a Boussinesq approximation (so c_B^t should be compared with c_B). In the classical sense this is inconsistent since the Boussinesq theory is usually based on potential theory. However, the formula (49) may also be derived simply by assuming a linear variation of the curvature of the mean stream lines, and (48) may be regarded as simply a parabolic approximation for u .

In general the effect of turbulence (i.e. α') on c can be extracted from (47) as

$$\frac{c^{\text{turb}}}{c^{\text{potential}}} = (1 - \frac{\alpha'}{\zeta - \alpha})^{-1/2} \quad (50)$$

It is emphasized here that $\alpha' = 0.10$ is not much more than an arbitrary guess used to illustrate the nature of the problem.

6. THE ENERGY FLUX

The non dimensional energy flux B can be determined from (34) using the same type of information required to find c . When (31) is substituted B is expressed in terms of the coefficients β, δ and κ^+ and by $U, c^2/g h$ and H , and the result can be tidied for waves of constant form using the continuity equation.

Here it suffices to mention that for sections (x_2, x_1) at crest and trough $\bar{w} \sim 0$, and if we introduce the linear shallow water assumptions

$$u \sim c \bar{\eta}/h \quad ; \quad p^+ \sim \rho g \bar{\eta} \quad (51)$$

we get as first approximation for B

$$B = \frac{1}{T} \int_0^T (\bar{\eta}/H)^2 dt \quad (52)$$

Let us for a moment consider improvements of this result using the

Boussinesq approximation introduced above. Then (52) is the first term in an expansion in η/H . Further analysis shows that the next term with $(\eta/H)^3$ yields contributions only a few percent of (52), for measured values of η .

Therefore in the following considerations it seems reasonable at the present stage to rely upon (52) for B.

7. WAVE HEIGHT VARIATION AND ENERGY DISSIPATION

The application of (36) to determine the wave height variation requires input for the energy dissipation described by D, and considering that c was found to be nearly equal to c_{bore} the first natural choice is also to use the bore result for the energy dissipation. For a periodic bore this corresponds to

$$D = h^2/d_1d_2 \tag{53}$$

Fig. 11 shows the resulting variation in the wave height compared with

Fig. 11 Measured and computed ratios of wave height to water depth H/h.

measured results. As input to the computations is used the wave height at the first measuring point (largest depth). The agreement is poor and obviously the energy dissipation can not be determined by simple bore relations.

To further illustrate this (36) has been reversed by solving with respect to the D-term which is then determined by using measured values of the other terms including $(H/h)_X$. We define

$$\begin{aligned} \Delta E_{\text{measured}} &\equiv \frac{h_0}{8L} \left(\frac{H}{h}\right)^2 \frac{D}{B} \\ &= -\left(\frac{H}{h}\right)_X - \frac{H}{h} \left(\frac{h}{c} \frac{X}{h} + \frac{c}{2c} + \frac{B}{2B} \frac{X}{h}\right) \end{aligned} \tag{54}$$

Fig. 12 shows a comparison between $\Delta E_{\text{measured}}$ and ΔE_{bore} which clearly confirms the conclusion above.

Fig. 12 Measured and computed values of ΔE defined by Eq. 54.

The actual energy dissipation may be determined from (32) for simplifying assumptions similar to those introduced to find (47) for c . And again these represent a good approximation locally. Thus neglecting the changing form of the wave and assuming a horizontal bottom $\partial \mathcal{E} / \partial t$ becomes equal to $-c \partial \mathcal{E} / \partial x$ and (32) integrates directly from x_2 to x_1 . The result represents an equation with the term $\int_{x_2}^{x_1} \mathcal{E} dx$ as unknown. This term represents the total energy dissipation between x_2 and x_1 . The solution can be written in terms of D introduced above as

$$\frac{D}{D_{\text{bore}}} = 1 + \frac{2}{(\zeta-1)^2} (\zeta^2 \kappa_2 + \kappa_1) + A_3 \left(\frac{\zeta+1}{\zeta-1} \right)^2 \left[1 + \frac{2}{\zeta^2-1} (\zeta^2 \kappa_2 - \kappa_1) \right] - 4 \frac{\zeta}{(\zeta-1)^3} (\zeta \delta_2^V - \delta_1^V) \quad (55)$$

where

$$A_3 = A_1 \frac{\zeta^2 \beta_1^V - \beta_2^V}{\zeta^2 - 1} - 1$$

with β^V and δ^V defined from (29) and (30) in analogy with (37), and κ and A_1 by (15) and (47) respectively.

In (55) a uniform velocity distribution corresponds to $\delta = 0$, $A_3 = 0$ and $A_1 = 1$, and static pressure implies $\kappa = 0$, $\delta = 0$.

8. DISCUSSION

Eqs. 47 and 55 have been evaluated for a variety of velocity and pressure conditions in order to obtain agreement with the measurements. This would require a D/D_{bore} value of 1.4 to 1.6 corresponding to the ratio between the two curves in Fig. 12, and at the same time c must be close to c_{bore} as indicated by Fig. 10.

In this context the physical picture of the process suggested by Peregrine and Svendsen (1978) (see description in § 1) has been invoked.

This model implies that at the bottom between x_2 and x_1 the flow is not influenced by the (surface) turbulence, so that the Bernoulli equation yields a simple relation between the bed velocities at x_2 and x_1 , (pressure specified). In all cases considered the conditions at the wave trough were fixed at static pressure and uniform horizontal velocity.

The following general properties may be extracted from these investigations:

- a) D/D_{bore} increases for increasing values of α_2^v . On the other hand any physically relevant velocity profile yields α^v not much larger than unity. The opposite applies to the pressure variation where pressures smaller than the static at x_2 reduce D/D_{bore} .
- b) In this respect D/D_{bore} follows c/c_{bore} . It also appears that the largest value of D/D_{bore} for a fixed value c/c_{bore} is obtained if $|\beta^v|$ is minimized for fixed α^v .
- c) None of the relevant velocity profiles and the associated pressure variations, however, lead to D/D_{bore} larger than about 1.2 as long as $\alpha' = 0$ (i.e. as long as the momentum of the turbulent velocity fluctuations are omitted).
- d) Notice that the energy dissipation (55) includes the turbulent energy generated between x_1 and x_2 and subsequently convected out of the volume through section 2 (see Fig. 9). But (55) does not include the energy lost by generation of turbulent energy behind section 2. This amount is difficult to estimate but may account for some of the deficit in energy dissipation.
- e) Finally it turns out that D/D_{bore} given by (55) increases rapidly with increasing α' , i.e. if the momentum of the turbulent fluctuations are included, even though we have seen that the velocity of propagation c is relatively insensitive to this factor.

Though a more detailed investigation of this is required it seems obvious that the significant deviations between measured and calculated energy dissipations shown in Fig. 12 are primarily associated with the momentum of the turbulent velocity fluctuations represented by α' . Further analysis, however, will also require that the effect of the free surface fluctuations are included.

Hydraulic Engineering (ISVA), Technical University of Denmark

Quasi-steady breaking waves

On gently sloping beaches, almost all water waves break. After the initial breaking the water motion usually appears quite chaotic. However, for a moderate time, for example two or three times the descent time of the "plunge" in a plunging breaker, the flow can be relatively well organised despite the superficial view which is largely of spray and bubbles. If waves continue to break the breaking motion, or "white water" soon becomes fully turbulent and the mean motions become quasi-steady.

A reasonable definition of a quasi-steady wave is one which changes little during the time a water particle takes to pass through it. We exclude water particles which may become trapped in a surface roller and surf along with the wave.

At this stage in its development a wave on a beach may be described as a spilling breaker or as a bore. In fact, there is a range of these waves from those with a little white water at the crest to examples where the whole front of the wave is fully turbulent. In investigating the properties of such waves it is desirable to start by looking at the whole range of related motions. The most obvious extension is to the hydraulic jump; since, in the simplest view, it is equivalent to a bore but in a frame of reference moving with the wave. It is also an example where the mean flow is steady rather than quasi-steady. It takes little further imagination to see that a range of steady and quasi-steady breaking flows is more or less as follows:

- spilling breakers in deep water
- spilling breakers in shallow water
- bores
- hydraulic jumps
- flow below sloping weirs
- waterfalls.

These are illustrated by sketches in figure 1. Within and between each example given there is a considerable variety of flows, not least, because of the differing physical sizes on which they may be realized, from a scale of a centimetre to a scale of ten metres. Other examples

(a) spilling breaker (deep water) (b) spilling breaker (finite depth of water)

(c) spilling breaker/bore (d) bore

(e) hydraulic jump

(g) waterfall

Figure 1. A spectrum of quasi-steady breaking waves.

may be found; for example the white water at the bows of a ship.

Our aim is to increase understanding of the fluid motions in these waves. The only theoretical work on spilling breakers we are aware of is that of Longuet-Higgins and Turner (1974). They focus attention on the aerated surface roller falling down the front face of the wave. We started with ideas based on this model but after observing experimental waves modified our views, as described below. There is rather more work on hydraulic jumps (including a review paper by Rajaratnam (1967), some of which is discussed below.

Experiments and flow visualization

We have studied the motion and surface configuration of breakers, bores and hydraulic jumps in flumes with transparent sides. Photography and direct visual observation have been used. As well as observing entrained air bubbles we observed the motion of buoyant particles on small scale hydraulic jumps. This latter example induced some doubts about the importance of the downward flow in the surface roller of a hydraulic jump since the mean motion down the surface roller appeared to be very slight compared with the random motions. The scale of the flow observed was such that the roller had a height of a few centimetres, surface tension was important and there was only a small amount of aeration.

A few drops of dye in the roller of the hydraulic jump were very rapidly diffused and showed the extent of the turbulent motion. An attempt to minimise the effect of surface tension led us to a technique of flow visualization which enabled us to see the extent of the turbulent motion in propagating breaking waves as well.

The flow visualization method involves forming a layer of tiny bubbles on the free surface of the water. Best results are obtained by a layer which is rather less than a monolayer of bubbles. The bubbles are formed by adding detergent, we found a few parts per million to be satisfactory, to the water in a closed circuit flume. The flume is then run with air entrainment into the pump. This forms many bubbles of a diameter much less than a millimetre. When the pump is stopped the bubbles very slowly rise to surface and form a layer with clear water beneath.

When a breaking wave propagates over such a layer the bubbles indicate the motion of the surface layer of water after it is engulfed by the toe of the surface roller. The bubbles are sufficiently small that their rate of rise under gravity is almost negligible compared with the turbulent velocities. They give an indication of the extent of the turbulence, though it should be remembered that in liquids momentum diffuses much more readily than matter so that the turbulence may spread a little further than the bubbles. However, the spread of turbulence is not a diffusive but a convective process.

Visual and photographic observation, see figures 2 and 3, shows that the strong turbulence rapidly mixes the surface layer into an increasing

Figure 2. Visualization of the turbulence in propagating breaking waves - distant view.

Figure 3. Visualization of the turbulence in propagating breaking waves - near view.

volume. This volume appears to commence from a point at the toe of the roller and forms a wedge which in an instantaneous view has "billows" on its under surface. For waves in moderate and shallow depths of water the turbulent region soon fills the whole depth. On the other hand, for deeper water, or for waves which are only just breaking, the breaking region is followed by a "wake" just below the free surface which only slowly thickens.

A model for the flow field

Our observations indicate that the surface roller does not play a dominant role in the dynamics of the wave. It is only a small part of the region of highly turbulent flow and is in no way separate from it. We consider that it acts as a trigger to initiate the turbulence. In many ways the initial volume of turbulent flow resembles a turbulent mixing layer.

A turbulent mixing layer occurs when two uniform parallel streams of velocities u_1 and u_2 are allowed to meet, for example by passing the end of a partition between them.

There have been numerous studies of turbulent mixing layers, some of which will be referred to shortly.

Consider the water motion in a frame of reference moving with the wave. The smooth water approaching the breaking wave has a velocity u_1 say. It means the toe of the surface roller which has a velocity u_2 which is not very different from zero. Mixing of the incoming water and the water already in the breaker ensues. The similarity to a mixing layer is enhanced by considering u_2 to be zero. There is then no need to have an upper fluid present except for that which is entrained into the mixing-layer. This small amount can be supplied by the reverse flow in the surface roller.

Alternatively, we note that for the toe of the surface roller u_2 is small and negative. In a true mixing layer u_2 is never quite as small as zero because there is always entrainment leading to a small adjustment of the velocity field. Thus if u_2 nominally equals zero

there is still some positive flow towards the mixing layer. In our imagination we can suppose u_2 to be nominally small and negative so that there is then no net flow towards the mixing-layer. This is the situation in a breaking wave.

A well documented property of turbulent mixing layers is that they spread linearly with distance in a wedge. The angle of spread depends largely on the velocity difference between the layers, however, for the case where u_2 is nominally zero there is a large scatter of recorded angles. See for example, Brown and Roshko (1974) which confirms the linear growth of mixing layers, and in figure 10 illustrates a scatter from 0.145 to 0.22 for one measure of the tangent of angle of spread with u_2 zero. The argument of the above paragraph indicates that for u_2 nominally equal zero, some small positive or negative values for u_2 might be more appropriate.

Another aspect of the flow in breakers which attracts attention is the air entrainment. This certainly leads to a lower mean density of fluid, but we consider this to be of secondary importance in the mechanics of the breaking wave. The eye, and camera, can only see one drop or bubble in any direction - vision beyond is obscured, thus it is very difficult to estimate the proportion of air and water. However, on the scale of 10 cm there is only a little air entrainment and yet breakers otherwise appear similar in structure to those on a much larger scale. Even with appreciable air entrainment the above mixing layer resemblance still holds. As Brown and Roshko (1974) show, by measuring mixing layers between helium and nitrogen, there are only quantitative differences when fluids of differing densities mix.

After the initiation of the turbulence it spreads until, at its upper boundary the effect of gravity becomes dominant towards the crest of the wave, and at its lower boundary interaction with the bottom becomes important. Exactly where these interaction regions are depends strongly on the type of breaking wave. Figure 4 is a sketch of these regions.

In the only case where there are measurements, the hydraulic jump, there is a considerable difference in the mean flow when a thick bottom boundary layer exists and when the flow is nearly uniform with depth, as is well shown by the work of Resch and Leutheusser, summarized in Resch et al (1976). This clearly indicates that these "interaction" regions can be important.

Behind the breaking region there is a long 'wake' in which the turbulence spreads, if the water is deep enough, and decays. The first part of this region is that which is most likely to be affected in a qualitative manner by entrained air.

Discussion

The model of flow in a quasi-steady breaker which is given above is not entirely new. We have found that Rajaratnam (1965) shows the

Figure 4. Model of quasi-steady breaking wave

similarity between a strong hydraulic jump and a wall jet, and that Ogris (1975) has likened the hydraulic jump to a succession of vortices and also used the term 'mixing zone' to describe our 'mixing region' and our 'interaction regions'.

In studying any turbulent flow it is very helpful if it can be shown to be similar to other well known flows. Here we have made a hypothesis that flow in a breaking wave is in part like a mixing layer and part may be like a wake. Clearly it is important to assess the accuracy of this hypothesis with actual flow measurements since if the hypothesis proves reasonable then it will be of value in many studies relating to wave breaking such as air/sea interaction, sediment motion and wave forces on structures.

It is possible that some pressure and velocity measurements taken below breakers are of a quality to show the turbulent 'wake' of a spilling breaker, but we are unaware of them. This model of the wake from a spilling breaker is however supported by a laboratory investigation of sediment transport under waves (Nielsen et al 1978, final section).

Measurements of mean flow and turbulent fluctuations in hydraulic jumps are reported by Resch and others in a sequence of papers. Unfortunately they only consider very strong jumps. However, one can examine their weakest example which is for a Froude number of 2.85, that is a depth ratio of 3.6. The only measurements which appear to be relevant to our mixing layer hypothesis are those for a potential inflow at a distance of approximately 7 times the entry depth from the toe of the roller. These are shown in figure 5. From the measures of $\sqrt{u'^2}$ it appears that interaction with the bottom boundary-layer has already commenced. However, the upper part of the mean velocity profile does have an almost constant gradient as one finds through the centre of a mixing layer profile (eg Brown & Roshko, 1974, Fig 9) and the maximum intensity of $\sqrt{u'^2}$ is $0.19U_0$, which is not very different from the values for a mixing layer of around $0.17U_0$, found by several experimenters (see Champagne et al, 1976, figure 5). Examination of Resch and Leutheusser's figures for $\sqrt{v'^2}$ shows one very extreme point, in this profile only, so that we do not consider it reliable for comparison.

We hope this paper will help to stimulate further measurements and would particularly like to point out that it is possible to have quasi-steady breaking waves without air entrainment. The scale simply needs to be small enough. If the breaking front is of a height 1 to 2cm then, depending on the water quality and the particular type of wave, there may be no air entrainment and yet there is a very turbulent flow with all the other qualitative characteristics of a breaking. Without air entrainment laser-doppler anemometer measurements should be straight forward and able to show how far the ideas of this paper can be exploited.

(a) mean velocity profile from Resch et al (1976), figure 8.

(b) intensity of turbulent velocities in the mean flow direction from Resch and Leutheusser (1972), figure 5.

Figure 5. Velocity measurements in a hydraulic jump of depth ratio 5.6. h_1 and U_1 are the depth and mean velocity of the approximately uniform undisturbed flow. The measurements are at a point $7.2h_1$ from the toe of the surface roller.

We suspect that order of magnitude estimates from this model may be quite useful in some circumstances. For example to estimate the strength and scale of turbulence reaching the bottom from a bore on a beach, one could use results corresponding to a mixing layer with u_1 =bore velocity, $u_2=0$ and thickness approximately equal to the total height of the bore (note, bores on a beach only rarely have a depth ratio as great as 2, eg see Svendsen et al, 1978). Alternatively if a spilling breaker is causing the turbulence, one might assume that at the wave crest the mixing layer had a width approximately equal to the height of the roller, then estimate the relative momentum deficit and patch this on to the corresponding wake flow, assuming the free surface represented a symmetric plane at the centre of the wake. When the wake half width equals the depth of water the turbulence affects the bottom.

The authors wish to acknowledge, with thanks, financial support from the U K Science Research Council, The British Council, and Institute of Hydrodynamics and Hydraulic Engineering, Denmark, which has enabled them to meet in order to discuss and experiment together.

CHAPTER 31

ESTIMATION OF WATER PARTICLE VELOCITY OF BREAKING WAVE

by

Tetsuo Sakai
Associate Professor

and
Yuichi Iwagaki
Professor

Department of Civil Engineering
Kyoto University, Kyoto, 606 Japan

ABSTRACT

A possibility to estimate the water particle velocity of breaking wave on beaches by giving only the values of the beach slope i and the deep-water wave steepness H_0/L_0 is investigated. The data of the water particle velocity and profile of breaking wave on the beaches measured by Iwagaki, Sakai, Tsukioka and Sawai(1974) are used for this purpose. A method of using empirical curves relating the coefficients of Dean's stream function to i and H_0/L_0 does not give good results. The relations between the asymmetric breaking wave profile, i and H_0/L_0 are examined. As well as the front face of the profile, the slope behind the crest above some level is found to become steep when H_0/L_0 becomes small. The breaking wave profiles are reproduced by using the empirical curves relating the parameters characterizing the breaking wave profile to i and H_0/L_0 . The velocity of Dean's stream function calculated from the reproduced profile explains the measured velocity better than that of Stokes waves. It is therefore possible to estimate the water particle velocity of breaking wave on beaches by giving only the values of i and H_0/L_0 .

INTRODUCTION

The water particle velocity of breaking wave on beaches is very important in discussing the wave forces on coastal structures and the sediment movement in surf zone. However, one can find few investigations on this subject(for example, Adeyemo(1970) and Thornton, Galvin, Bub and Richardson(1976)). This is because the measurement of the water particle velocity of breaking wave is very difficult.

Recently the horizontal water particle velocities of

breaking waves on the beaches with the slopes of 1/10, 1/20 and 1/30 were measured in a wave tank with a high speed camera (Iwagaki, Sakai, Tsukioka and Sawai (1974)). It was found that the existing small and finite amplitude wave theories can not explain the measured water particle velocities. The velocities of small amplitude waves agree roughly with the measured ones in average, but the vertical distributions of small amplitude waves were more uniform than those of the measured ones. The vertical distributions of the horizontal velocity under the crest phase of the breaking wave were found to be classified by the breaker types.

The water particle velocities of Dean's stream function (Dean (1965)) were calculated by giving the simultaneously measured asymmetric breaking wave profiles (the wave record at the breaking point) (Iwagaki and Sakai (1976)). Although Dean's stream function is based on the assumption of permanent type waves on the horizontal bottom, the calculated velocities of Dean's stream function explained the measured velocities better than the existing theories of symmetric wave profile. It was concluded that the asymmetric breaking wave profile dominates the water particle velocity field of the breaking wave on beaches.

From the view point of practical use, it is desirable that the water particle velocities of breaking waves on beaches can be estimated by giving only the values of parameters such as the beach slope and the deep-water wave steepness or Iribarren number (Battjes (1974)). This investigation is one approach to this problem.

RELATIONS BETWEEN COEFFICIENTS OF DEAN'S STREAM FUNCTION, BEACH SLOPE AND DEEP-WATER WAVE STEEPNESS

Dean's stream function represents the permanent waves on the horizontal bottom:

$$\psi = \frac{L}{T}z + \sum_{n=4,6,8,\dots}^{N-1} \frac{\sinh \frac{(n-2)\pi(h+z)}{L}}{L} x \times \left(X_n \cos \frac{(n-2)\pi x}{L} + X_{n+1} \sin \frac{(n-2)\pi x}{L} \right) \quad (1)$$

in the reference x-z moving with the waves, where L is the wave length, T the wave period, x-axis in the direction of wave propagation, z-axis vertically upward from the still water level, h the water depth, X_n the unknown coefficients. The sine terms in Eq. (1) are introduced so as to represent the asymmetric wave profile. At the water surface $z = \eta$, the value of the stream function $\psi(x, \eta)$ becomes constant (= X_3).

The wave profile η is therefore expressed as follows:

$$\eta = \frac{T}{L} X_3 - \frac{T}{L} \sum_{n=4,6,8,\dots}^{N-1} \frac{\sinh \frac{(n-2)\pi(h+\eta)}{L} x}{L} \times (X_n \cos \frac{(n-2)\pi x}{L} + X_{n+1} \sin \frac{(n-2)\pi x}{L}). \quad (2)$$

As seen from Eq.(2), the wave profile is determined by giving the unknown coefficients X_n . The relations between the coefficients and Iribarren number ξ_0 are examined at first.

The horizontal water particle velocity u is obtained by differentiating ψ with respect to z . The obtained horizontal water particle velocity in the fixed reference is expressed in non-dimensional form as follows:

$$\frac{u}{\sqrt{gh}} = -\frac{Y_2}{Y_1} \sum_{n=4,6,8,\dots}^{N-1} (n-2)\pi \cosh \left\{ (n-2)\pi Y_1 \frac{h+z}{h} \right\} \times (Y_n \cos \{ (n-2)\pi \theta \} + Y_{n+1} \sin \{ (n-2)\pi \theta \}), \quad (3)$$

where $Y_1 = h/L$, $Y_2 = H/L$, $Y_4 = X_4/LH\sqrt{g/h}$,, $Y_n = X_n/LH\sqrt{g/h}$,, $\theta = x/L - t/T$. Table 1 shows the experimental conditions of 39 cases in which the breaking wave profiles were measured by Iwagaki, Sakai, Tsukioka and Sawai(1974). In this table hb is the breaking depth and H_b is the breaking wave height. In 20 cases among them the measured horizontal water particle velocities were compared with the theoretical velocities. Dean's stream functions were already calculated for all 39 cases. Fig.1 shows two examples of the relations between the non-dimensional coefficients Y_n and Iribarren number ξ_0 for 39 cases. The quantity ξ_0 is defined as $i/\sqrt{H_0/L_0}$, where i is the beach slope and H_0/L_0 is the deep-water wave steepness.

As seen from Fig.1, the data scatter considerably as well as in the relations between the breaking depth, the breaking wave height and the deep-water wave steepness. On the other hand, it is clear that the non-dimensional coefficients of Dean's stream function are not determined by Iribarren number only. The data for the different beach slope have a different trend. Empirical curves were drawn through the plotted points for each beach slope. Using these curves for all non-dimensional coefficients and Eq.(3), the horizontal water particle velocities at crest phase were calculated for the same 20 cases by giving the values of the beach slope and the deep-water wave steepness in each case. Fig.2, (1), (7) and (12) show three examples of the compari-

sons between the measured horizontal water particle velocities at crest phase and the calculated velocities denoted by D' . In these figures are also shown several theoretical velocities as follows (Iwagaki and Sakai (1976)):

- S : Stokes waves with first definition of wave celerity
- S' : Stokes waves with second definition of wave celerity (Tsuchiya and Yamaguchi (1972))
- D : Dean's stream function with measured wave profile
- D' : Dean's stream function with determined coefficients
- D'' : Dean's stream function with reproduced wave profile (explained later)

Unfortunately the calculated velocities by using the empirical curves for the non-dimensional coefficients (D') are in general smaller than the measured ones. In Figs. 2, (1) and (12), the velocity near the water surface is rather smaller than that near the bottom. One reason is of course the scatter of the values of the non-dimensional coefficients. Furthermore, the term in the summation of Eq. (3) contains $(n-2)\pi \cosh\{(n-2)\pi Y_1(h+z)/h\}$. Therefore, even if the value and the scatter of Y_n of large n are small, the error of estimating the term of large n (the higher order term) becomes large as n becomes large. The contribution of the higher order term to the water particle velocity is confined near the water surface. This is why the slope of the vertical distribution is reversed near the water surface.

RELATIONS BETWEEN BREAKING WAVE PROFILE, BEACH SLOPE AND DEEP-WATER WAVE STEEPNESS

Considering that the water particle velocity field of the breaking wave is dominated by the asymmetric breaking wave profile, it is tried to relate the measured breaking wave profiles (the wave record at the breaking point) to the beach slope and the deep-water wave steepness. Adeyemo (1970) proposed four parameters on the wave profile asymmetry. They were the relative positions of the crest during one wave period, the crest height and the slope of wave profile. In order to represent the asymmetric wave profile exactly, such a rough parameterization is not sufficient. 39 measured breaking wave profiles were characterized with 25 parameters shown in Fig. 3. Two parameters t_a and η_a are respectively the phase and the level of the point on the profile behind the crest where the slope changes abruptly. Fig. 4 shows the relations between the representative 9 parameters, the beach slope and the deep-water wave steepness. Although the scatter

Fig. 3 25 parameters characterizing breaking wave profile

(1)

(2)

Fig. 4, (1), (2) Examples of relations between parameters of breaking wave profile, beach slope and deep-water wave steepness

of the data in each figure is considerable, empirical curves were drawn through the plotted points for each beach slope.

It is well known, from the classification of the breaker types, that the front face of the breaking wave profile becomes steep and the slope behind the crest becomes gentle as the beach slope becomes large and the deep-water wave steepness becomes small. This trend is seen in Figs.4,(1) (the phase of the front trough $|t_t/T|$), (3) (the phase of the front face at $z/H_b = -0.1$ $|t_f-0.1/T|$) and (7) (the phase of the profile behind the crest at $z/H_b = 0.0$ $t_r0.0/T$). The same trend is seen in all phases of the front face and the slope behind the crest below the level of $z/H_b = 0.0$.

In Fig.4,(4), however, the experimental results of the phase of the slope behind the crest at $z/H_b = 0.3$ $t_r0.3/T$ show a different trend. The phase at $z/H_b = 0.3$ slightly decreases as the deep-water wave steepness decreases. Also as for other phases of the profile behind the crest above $z/H_b = 0.3$, the same trend is seen. This fact means that the slope behind the crest above $z/H_b = 0.3$ becomes steep as well as the front face when the deep-water wave steepness becomes small. On the other hand, the relations between the beach slope and the phases of the slope behind the crest above $z/H_b = 0.3$ are not clear.

At $z/H_b = 0.2$, as shown in Fig.4,(5), only in the case of $1/10$ beach slope, the phase behind the crest becomes large as the deep-water wave steepness becomes small. At $z/H_b = 0.1$ (Fig.4,(6)), in two cases of $i = 1/10$ and $1/20$, the phase becomes large as the deep-water wave steepness becomes small. Thus, the beach slope has the effect on the level where the relation between the phase of the slope behind the crest and the deep-water wave steepness reverses. Fig.4,(9) on η_a/H_b explains the effects of the beach slope and the deep-water wave steepness on this level. The level (the value of η_a/H_b) becomes high as the beach slope becomes large and the deep-water wave steepness becomes small.

As seen from Fig.4,(8), the phase of the point of abrupt slope change t_a/T becomes small as the deep-water wave steepness becomes small. That is, the width of the base of the crest of the breaking wave profile becomes narrow as the deep-water wave steepness becomes small. The effect of the beach slope is not clear. The crest height η_c/H_b , as seen from Fig.4,(2), shows complicated trends.

REPRODUCTION OF BREAKING WAVE PROFILE

The empirical curves relating 25 parameters to the beach slope and the deep-water wave steepness in Fig.4 are used to

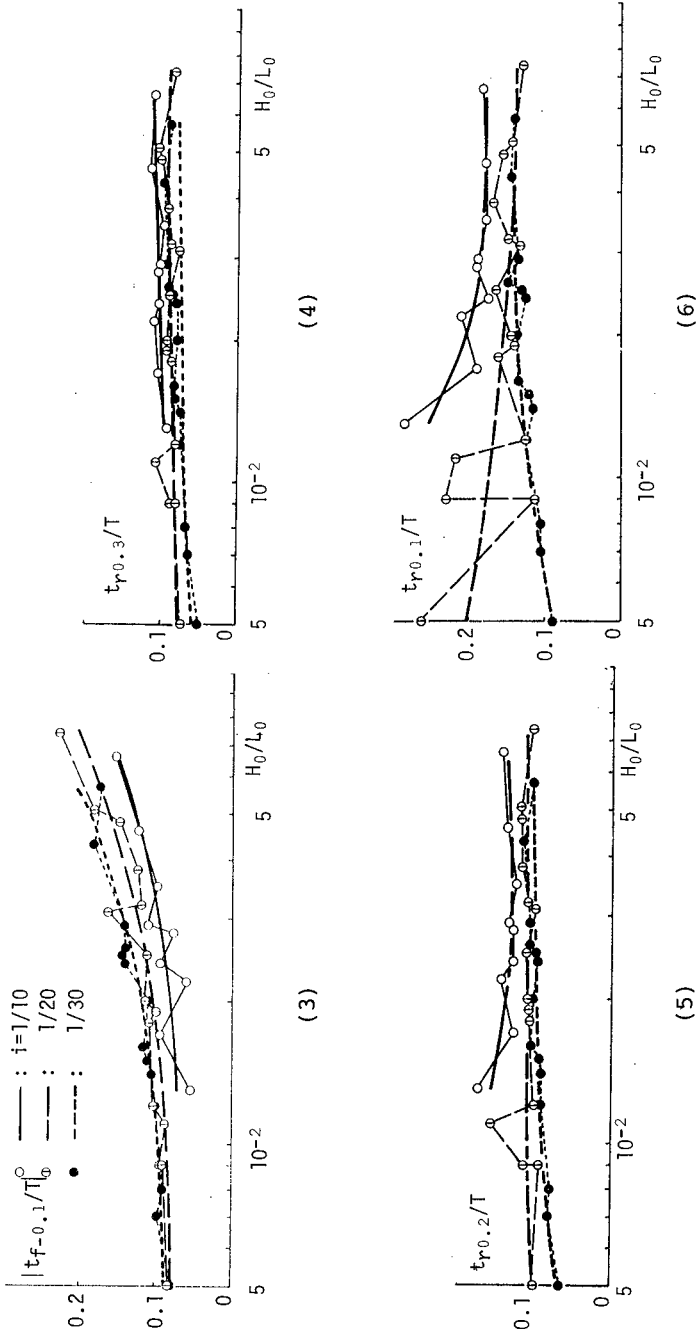

Fig. 4, (3)~(6) Examples of relations between parameters of breaking wave profile, beach slope and deep-water wave steepness

(7)

(8)

(9)

Fig. 4, (7) ~ (9) Examples of relations between parameters of breaking wave profile, beach slope and deep-water wave steepness

reproduce the breaking wave profiles by giving the values of the beach slope and the deep-water wave steepness. In some cases, the phases of the front and back faces at $z/H_b = 0.7$ $|t_f - 0.7/T|$ and $t_r - 0.7/T$ are given, while the crest height η_c/H_b is smaller than 0.7 because of using the empirical curves. In these cases the crest height is adopted. Also in some cases, the position of abrupt profile change (t_a/T and η_a/H_b) is far from the neighboring points determined by the values of t_r/T . In these cases, only the value of t_a/T is adopted.

Figs. 5, (1)~(3) show three examples of the comparisons between the reproduced and measured breaking wave profiles. In general, the reproduced breaking wave profiles coincide with the measured profiles except for the small deviations.

ESTIMATION OF WATER PARTICLE VELOCITY OF BREAKING WAVE ON BEACHES

The reproduced breaking wave profiles were used to calculate Dean's stream functions. The wave profile as the input to calculate the stream function is dimensional. The measured wave period and breaking wave height were used to convert the non-dimensional reproduced profiles into the dimensional ones. The water levels of the reproduced profiles were read at 15 points of equal distance on the time axis. The value of N was set equal to 13 which corresponds to Stokes waves of the fifth order. The calculations determining the unknown coefficients were 5 times repeated.

The curves denoted by D'' in Figs. 2, (1)~(12) are the velocities obtained from the calculated Dean's stream functions with the reproduced breaking wave profiles. In these figures, are also shown the velocities obtained from the calculated Dean's stream functions with the measured profiles (D) and the velocities of Stokes waves of two different definitions of wave celerity (S and S'). The velocities of cnoidal waves are not shown because the vertical distributions are too steep compared with the measured ones. Also the velocities of small amplitude waves are not shown because the vertical distributions are more uniform than the measured ones.

As well as the velocities based on Dean's stream functions with the measured profiles, the velocities based on Dean's stream function with the reproduced profiles explain the measured velocities better than those of Stokes waves. Table 2 shows the relative errors of the calculated velocities at the still water level of 20 cases in which the water particle velocities were measured. u_F is the measured velocity at the still water level. After all, it is possible to calculate the

horizontal water particle velocity at crest phase of the breaking wave on the beach more exactly by giving only the values of the beach slope and the deep-water wave steepness than with Stokes wave theory.

CONCLUSIONS

The possibility to estimate the horizontal water particle velocity at crest phase of breaking wave on beaches by giving only the values of the beach slope and the deep-water wave steepness was examined. The data of the velocities of breaking waves on the sloping beaches in the wave tank measured by Iwagaki, Sakai, Tsukioka and Sawai(1974) were used. The following conclusions are obtained:

- 1) The coefficients of Dean's stream function are not determined by Iribarren number only.
- 2) The velocity calculated by using the empirical curves relating the coefficients of Dean's stream function to the beach slope and the deep-water wave steepness can not explain the measured velocity.
- 3) As well as the front face, the slope behind the crest of the breaking wave profile above the level($z/H_b = 0.1 \sim 0.3$) which is determined by the beach slope and the deep-water wave steepness becomes steep when the deep-water wave steepness becomes small.
- 4) The breaking wave profile can be reproduced from the empirical curves for the parameters of the profile by giving only the values of the beach slope and the deep-water wave steepness.
- 5) The velocity based on Dean's stream function calculated from the reproduced breaking wave profile explains the measured velocity, as well as the velocity based on Dean's stream function calculated from the measured wave profile.
- 6) It is therefore possible to estimate the water particle velocity of breaking wave on sloping beaches by giving only the values of the beach slope and the deep-water wave steepness.

ACKNOWLEDGEMENTS

The authors wish to express their gratitudes to Mr. T. Asano, Mr. E. Otsuka and Mr. M. Tanaka for their assistances through the data analysis. This work was partly supported by Scientific Research Funds from the Ministry of Education.

CHAPTER 32

ENERGY LOSS AND SET-UP DUE TO BREAKING OF RANDOM WAVES

J.A. Battjes¹⁾ and J.P.F.M. Janssen²⁾

ABSTRACT

A description is given of a model developed for the prediction of the dissipation of energy in random waves breaking on a beach. The dissipation rate per breaking wave is estimated from that in a bore of corresponding height, while the probability of occurrence of breaking waves is estimated on the basis of a wave height distribution with an upper cut-off which in shallow water is determined mainly by the local depth. A comparison with measurements of wave height decay and set-up, on a plane beach and on a beach with a bar-trough profile, indicates that the model is capable of predicting qualitatively and quantitatively all the main features of the data.

INTRODUCTION

Quantitative predictions of wave-induced mean sea level variations and currents in the nearshore region require a specification of the variation of the mean wave energy density (E) in that region. Battjes (1972) and Goda (1975) have presented methods to that effect applicable to random, breaking waves. In these models, E is forced to follow in some sense, to be described below, the variation of the local depth. The energy dissipation rate due to breaking is not estimated independently in these models. This is a shortcoming, since it immediately precludes the use of an approach based on the energy balance. Such an approach is physically more sound, and would e.g. be needed in applications to profiles where the depth is not monotonically decreasing shoreward, such as in the commonly occurring bar-trough profiles. For these reasons an attempt was made to develop a model for the dissipation of wave energy in random waves, breaking on a beach.

The outline of the paper is as follows. Existing models for the prediction of the energy variation across the surfzone are discussed first. Following that, the various elements of a new dissipation model for random waves are described. The results are combined with a conventional model for the prediction of wave-induced variations in mean water level. Subsequently, experiments are described which were carried out to test the model, and to determine the magnitude of a coefficient which in the theory can be estimated in order of magnitude only. Finally, a comparison is given of the results of the theoretical model to the experimental data.

EXISTING MODELS

We consider a two-dimensional situation of waves normally incident on a beach with straight and parallel depth contours.

For given incident wave parameters and beach profile, the variation of mean wave energy density (E) with distance to the shoreline can in principle be calculated from the wave energy balance, written as

$$\frac{\partial P_x}{\partial x} + D = 0, \quad (1)$$

in which P_x is the x -component of the time-mean energy flux per unit length, x is a horizontal coordinate, normal to the still-water line, and D is the time-mean dissipated power per unit area. Knowing the dependence of P_x and D on E and on known parameters such as local mean depth (h), wave frequency (f), mass density (ρ) and gravity acceleration (g), it is possible to integrate (1), subject to the initial condition of the given incident wave, to find E as a function of x .

Outside the surfzone, the wave decay is rather weak, and D can often be neglected entirely. If not, the only contributions to it are from such mechanisms as the formation of a boundary layer near the bed, percolation in a porous bottom, etc., for which the dependence of D on E can be estimated reasonably well. In either case, (1) can in fact be used outside the surf zone.

Inside the surf zone, the dissipation of wave energy in the breaking process is dominant. Because the details of these processes are so little understood, the energy balance is usually abandoned in the surf zone. An exception must be made for LeMéhauté (1962), Divoky et al (1970), and Hwang and Divoky (1970), who do apply an energy balance to breaking solitary or periodic waves, by using a bore model for the dissipation rate. Usually, however, instead of solving the energy balance equation, a self-similarity in the surf zone is assumed (for solitary or periodic waves), such that the wave height (H) decays in constant proportion to the mean depth, or

$$H(x) = \gamma h(x), \quad (2)$$

in which γ is a coefficient of $O(1)$, whose actual magnitude can vary with beach slope and incident wave steepness.

For *random* waves breaking on a beach, a model based on (1) does not seem to have been published. An approach based on (2), using it as an upper bound to the local wave height distribution, has been presented by Battjes (1972) and Goda (1975). Goda's model is similar to Battjes' model in essence, though different in the details.

The use of (1), rather than (2), is in principle much to be preferred for a number of reasons, the most fundamental one being that (1) has a sound physical basis, whereas (2) is assumed ad hoc. Associated with this are the following items:

- Assumption (2) relates the local wave height to the local mean depth. This introduces an unrealistically large dependence of dissipation rate on local bottom slope (Battjes, 1978b). In (1), the local wave height is found from an integration, so that it not only depends on the local depth but also on those further seaward, which is more realistic.
- If necessary, other dissipation mechanisms than that due to breaking can be incorporated in (1) in a straightforward manner, whereas this is not the case for (2).
- Eq. (2) is restricted to profiles in which the depth decreases monotonically in the shoreward direction. This is not the case for (1), which in principle can be applied in bar-trough profiles as well.

A DISSIPATION MODEL FOR RANDOM WAVES

Introduction

As noted above, no model based on the energy balance seemed to be available for the prediction of the energy variation in random waves, breaking on a beach. The preceding comments should make it clear that such a model is in fact desirable. One such model which has been developed will be described in the following.

Before turning to the specifics, some general remarks will be made about the philosophy of approach which has been adopted.

Firstly, since at present there is virtually no systematic quantitative knowledge of the internal structure of breaking waves, the approach used herein is based on knowledge of external, macroscopic properties of breakers only.

Secondly, it was deemed prudent to build a rather crude model at first, containing the simplest possible elements which would still represent those aspects of the problem which were considered essential. A confrontation of such model with real data should serve to indicate whether the model is sufficiently realistic to warrant further refinements. Examples of choices made on this basis are an abrupt upper cut-off of the wave height distribution, the use of a simple, linear approximation for the energy flux P , and the omission of all dissipation mechanisms other than that due to breaking. The results presented in the following represent only the first steps in the sense just described. However, at several places it will be indicated how refinements could possibly be made.

A third point to be mentioned has to do with terminology. When reference is made to a "breaking wave", this could be interpreted as a wave at the moment of incipient breaking, defined in one way or another, or it could perhaps be taken to refer to the turbulent, aerated bore-like structure some time after the onset of breaking. To avoid this possible semantic confusion, we shall here refer to the latter as a broken wave; the breaking itself is then taken to correspond to the transition of the unbroken mode to the broken mode, according to the definition adopted for such transition.

Wave height distribution

Consider a fixed point on a beach, with mean depth h , in the presence of a random incident wave field. It is impossible for waves with heights considerably in excess of h to pass the point being considered, since those which otherwise would do so are reduced in height as a result of breaking. The limited depth effectively limits the larger wave heights in the distribution. A simplified model of this is obtained by defining for each depth h a maximum possible wave height H_m (to be specified subsequently), and to assume that the heights of all^m the waves which are breaking or broken at the point considered, and only those, are equal to H_m .

The assumption just stated is of course a simplification. Not all the heights of broken waves passing a fixed point are equal, nor are they all necessarily larger than those of the non-broken waves. The first of these two aspects can be remedied by providing for a smoother cut-off, as in Goda's model (1975). For the time being the simpler model described here was used. After all, our purpose is not to estimate the details of the wave height distribution in the range near H_m ; it is to derive mean square values from a distribution of wave heights which is somehow suppressed in its upper region by the local depth.

The assumption stated above will now be written in terms of the probability distribution of the wave heights, $F(H)$. The shape of $F(H)$ for the lower, non-broken wave heights is assumed to be the same as it is in absence of wave breaking, i.e. of the Rayleigh-type, with modal value \hat{H} , say. This leads to

$$\begin{aligned}
 F(H) \equiv \Pr\{\underline{H} \leq H\} &= 1 - \exp(-\frac{1}{2}H^2/\hat{H}^2) && \text{for } 0 \leq H < H_m \\
 &= 1 && \text{for } H_m \leq H,
 \end{aligned}
 \tag{3}$$

in which the underscore indicates a random variable. The local value of the parameter \hat{H} is left unspecified for the moment.

Eq. (3) represents a probability distribution with two parameters, \hat{H} and H_m . All the statistics of the wave heights can therefore be expressed in terms of (\hat{H}, H_m) . Among those are the rms value (H_{rms}), defined by

$$H_{rms} = \left\{ \int_0^{\infty} H^2 dF(H) \right\}^{\frac{1}{2}}, \quad (4)$$

and the probability that at a given point a height is associated with a breaking or broken wave (Q_b), which on the assumption stated above equals

$$Q_b = \Pr\{\underline{H} = H_m\}. \quad (5)$$

Substitution of (3) into (4) and (5) gives

$$H_{rms}^2 = 2(1 - Q_b)\hat{H}^2 \quad (6)$$

and

$$Q_b = \exp(-\frac{1}{2}H_m^2/\hat{H}^2). \quad (7)$$

Instead of using (\hat{H}, H_m) as the two parameters of $F(H)$, it is equally possible to use (H_{rms}, H_m) , which have a clearer physical meaning. This can be achieved by eliminating \hat{H} between (6) and (7), which yields for Q_b

$$\frac{1 - Q_b}{\ln Q_b} = - \left(\frac{H_{rms}}{H_m} \right)^2. \quad (8)$$

From this transcendental equation, Q_b can be solved as a function of H_{rms}/H_m :

$$Q_b = f(H_{rms}/H_m). \quad (9)$$

This is a key element in the whole model. It expresses the fraction of waves which at any one point are breaking or broken, in terms of the ratio of the rms wave height (equivalent to mean energy density, E) actually present, to the maximum wave height which the given depth can sustain. The local value of H_{rms} is not known a priori; it is found by integrating the differential equation (1). The importance of Q_b for this equation is due to the fact that the average local energy dissipation rate D is proportional to it, at least in the dissipation model to be described below. It is mainly through Q_b that this model reacts to changes in depth.

In very deep water, where $H_{rms}/H_m \rightarrow 0$, (8) gives $Q_b \rightarrow 0$, as expected. If the waves are shoaling then the ratio H_{rms}/H_m tends to increase, and so does Q_b . In the limit $H_{rms}/H_m \rightarrow 1$, $Q_b \rightarrow 1$, which is a degenerate case since it corresponds to all the waves being broken, and all the wave heights being equal to H_m .

Breaker height

So far the quantitative estimation of H_m was left unspecified. This will be considered next.

The form chosen is based on Miche's criterion for the maximum height of periodic waves of constant form:

$$H_m \approx 0.14 L \tanh(2\pi h/L) \approx 0.88 k^{-1} \tanh kh, \quad (10)$$

in which $k = 2\pi/L$ is the positive real root of the dispersion equation

$$(2\pi f)^2 = gk \tanh kh. \quad (11)$$

Eq. (10) as it stands would predict $H_m \approx 0.88 h$ in shallow water. In application to waves on beaches we want to use a similar functional relationship as in (10) but we also want some freedom of adjustment, to allow for effects of beach slope and of the transformation to random waves, such that in shallow water our expression for H_m reduces to $H_m = \gamma h$, in which γ is a (slightly) adjustable coefficient. In order that the deep-water limit shall not be influenced by the bottom slope the following form was finally adopted:

$$H_m = 0.88 k^{-1} \tanh(\gamma kh/0.88). \quad (12)$$

In application to random waves, (12) will be used, with f in (11) being given a single, representative value, such as \bar{f} , a mean frequency defined as the ratio of the first moment of the surface elevation spectrum about $f = 0$ to the zeroth moment.

It should be pointed out that neither the frequency-dependent transition from deep water to shallow water, as expressed by the tanh-function in (10) or (12), nor the representative frequency to be used, needs to be estimated with great accuracy, inasmuch as most of the wave breaking takes place in shallow water anyway, where $H_m \approx \gamma h$, regardless of the frequency used (within reasonable limits). For the same reason, the use of only one representative value of f is deemed sufficient. In principle it is possible to use a distribution of f -values, leading to a distribution of H_m -values for given h . (A distribution of H_m has in fact been used by Goda (1975), though it was chosen ad hoc.)

Energy dissipation in a broken wave

Following LeMéhauté (1962), the energy dissipation rate in a broken wave will here be estimated from that in a bore of corresponding height.

Consider a bore connecting two regions of uniform flow, with depths Y_1 and Y_2 , respectively (fig. 1a). The macroscopic bore properties are determined by the conservation of mass and momentum across the bore. The power dissipated in the bore per unit span, written as D' , can then be calculated, with the result (Lamb, 1932)

$$D' = \frac{1}{4} \rho g (Y_2 - Y_1)^3 \left\{ \frac{g(Y_1 + Y_2)}{2 Y_1 Y_2} \right\}^{\frac{1}{2}}. \quad (13)$$

This expression will be used to estimate the power dissipated in the crest region of a broken wave. If, as is the case here, the broken wave is one of a sequence on a sloping beach, then the flow conditions on either side of it are non-uniform. Thus, (13) cannot be expected to apply in any exact sense, but at most in order of magnitude. For this reason it is felt to be justified to use further order-of-magnitude estimates in (13) (written as \sim), if applied to broken waves on a beach. In this respect the treatment here deviates from that of LeMéhauté (1962). These order-of-magnitude estimates are (see fig. 1b)

$$Y_2 - Y_1 \sim H \quad (14)$$

and

$$\left\{ \frac{g(Y_2 + Y_1)}{2 Y_1 Y_2} \right\}^{\frac{1}{2}} \sim \left\{ \frac{g}{h} \right\}^{\frac{1}{2}}. \quad (15)$$

Fig. 1 - Sketch of a single, steady bore (1a) and of one out of a sequence of broken waves on a beach.

Substitution of these in (13) yields the following estimate for the power dissipated per broken wave, per unit span:

$$D' \sim \frac{1}{4} \rho g H^3 \left(\frac{g}{h}\right)^{\frac{1}{2}}. \quad (16)$$

If the waves were periodic with frequency f , then the average power dissipated in the breaking process, per unit area, would be

$$D = \frac{D'}{L} = \frac{fD'}{c} \sim \frac{fD'}{(gh)^{\frac{1}{2}}} \sim \frac{1}{4} f \rho g \frac{H^3}{h}, \quad (17)$$

where L and c denote wavelength and phase speed, respectively.

A more refined estimate for the relation between bore strength ($Y_2 - Y_1$) and wave height H than that in (14) has been given elsewhere, and applied to solitary and periodic broken waves (Battjes, 1978a). However, that refinement has not yet been implemented in the present model for random waves.

Mean energy dissipation in a random breaking wave field

In application to random waves, we are interested in the expected value of the dissipated power per unit area. This can be estimated by applying (17) to the broken waves, and to those only. In the model adopted above these have a height equal to H_m , and a probability of occurrence (at a fixed point) equal to Q_b . Furthermore, the mean frequency (\bar{f}) of the energy spectrum is used again as a representative value of f . If lastly the ratio H_m/h is dropped from the order-of-magnitude relationship, as being of order one in the region where most of the dissipation occurs, we obtain for the overall mean dissipation rate per area

$$D \sim \frac{1}{4} Q_b \bar{f} \rho g H_m^2, \quad (18)$$

or, written as an equality

$$D = \frac{\alpha}{4} Q_b \bar{f} \rho g H_m^2, \quad (19)$$

in which - if the model is good - α is a constant of order one.

In interpretations of (19), it is important to note that Q_b , representing the fraction of broken waves passing any one point, was seen to be a function of H_{rms}/H . Thus, the combination of (8) and (19) determines the power dissipated in the breaking process, D , as a function of the unknown local H_{rms} (or the local energy density E), the known local depth (through H_{rms}), and some constants. This is a key result of the present model, enabling the application of the energy balance (1) to the surf zone.

At first sight, it might seem from (19) as if D were decreasing with decreasing H_m (decreasing h), but this is not normally the case. As long as a random wave train of low or moderate steepness is in relatively deep water, Q_b will be virtually zero, and therefore also D . When, upon approaching the beach, the depth becomes less than 2 to 3 times the rms wave height, Q_b increases strongly, such that its increase in fact more than compensates for the reduction in H_m^2 , so that D also increases. Near the limit of very shallow water, Q_b ultimately approaches unity (except for extremely mild slopes), in which case D decreases, ultimately in proportion to H_m^2 .

Likewise, if the wave train passes a bar, then the increase in depth (and consequently in H_m) shoreward of the bar crest, causes a reduction in Q_b which more than offsets the increase in H_m^2 , so that the dissipation rate in the model can become virtually zero again in the trough shoreward of the bar. Examples of this situation will be given below.

Energy balance

Having established a dependence of the dissipation rate D on the rms wave height, it remains to do the same for the energy flux P in order to be able to integrate the energy balance, eq. (1). A simple linear approximation will be used, viz.

$$P_x = P = E c_g, \quad (20)$$

in which

$$E = \frac{1}{8} \rho g H_{rms}^2 \quad (21)$$

and

$$c_g = \left[\frac{2\pi f}{k} \left(\frac{1}{2} + \frac{kh}{\sinh 2kh} \right) \right]_{f = \bar{f}}. \quad (22)$$

This closes the system of equations for H_m . For given depth profile $h(x)$, given incident wave parameters, and a (suitable) choice of the model parameters α and γ , eq. (1) can be integrated to find $H_m(x)$.

From trial calculations it was found that the damping contained in the model appeared to be insufficient to prevent the ratio H_m/H_m from tending to blow up as the waterline (zero depth) was approached. This phenomenon is reminiscent of the classical shoreline singularity for dissipationless progressive waves. As such it need not be of great concern in the sense that it would invalidate the model away from the waterline. However, the wave height distribution assumed here limits H_m to values not exceeding H_m , so that an internal incompatibility arises.

The situation could have been remedied by simply terminating the calculation where the condition $H_{rms} \leq H_m$ is first violated, or, rather more fundamentally, by incorporating additional physical mechanisms of energy dissipation in eq. (1), which would be predominant near the waterline, and of such strength that $H_{rms}/H_m \leq 1$ as $h \rightarrow 0$. In the preliminary results to be given below, neither of these was done. Instead, the integration of (1) was ceased at the point where the condition $H_{rms} \leq H_m$ is first violated. Shoreward of this point, $H_{rms} = H_m$ was assumed.

MOMENTUM BALANCE

We have so far assumed that the mean-depth profile $h(x)$ was given. Normally, only the depth of the bottom below some reference plane, $d(x)$, is given. In the experiments to be described subsequently, the still-water level was chosen as the reference plane for d , which therefore represents the still-water depth.

The height of the mean water level above the reference plane, written as $\bar{\eta}(x)$, can be determined from the mean momentum balance. Following Longuet-Higgins and Stewart (1962) the mean balance of x -momentum is written as

$$\frac{dS_{xx}}{dx} + \rho gh \frac{d\bar{\eta}}{dx} = 0, \quad (23)$$

in which

$$h = d + \bar{\eta} \quad (24)$$

and

$$S_{xx} = \left(\frac{1}{2} + \frac{2kh}{\sinh 2kh} \right) E, \quad (25)$$

the component of the radiation stress tensor normal to planes $x = \text{constant}$. As an initial condition for the integration of (23), it is common to choose $\bar{\eta} = 0$ in a reference point in deep water.

In the applications given below, the energy balance and the momentum balance have been integrated simultaneously, by a process of iteration.

The most important reason for the inclusion of the wave-induced variations in $\bar{\eta}$ in the model is not to correct d (the energy dissipation model could be checked by working from the outset with h), but to provide an independent check on the validity of the model. As noted in the

introduction, the variation of the wave energy density E in the surf zone is important because the radiation stresses are proportional to E , and the gradients of these stresses provide driving forces for the mean flow. It is therefore very useful to have a check of the capability of the present model to predict such driving forces. A limited but nevertheless useful way to do this is to calculate the wave-induced set-up $\bar{\eta}$, and to compare the results with measurements. This then is one purpose of the experiments to be described in the following chapter, the other one being a more direct check on the model through measurements of H_{rms} .

EXPERIMENTS

Arrangements and procedures

The experiments referred to above were carried out in a flume in the Laboratory of Fluid Mechanics, Department of Civil Engineering, Delft University of Technology. The flume has an overall length 45 m, width 0.8 m, and height 1 m.

The flume is equipped with a hydraulically driven random-wave generator. The control signal was obtained by filtering a random noise signal.

At the end of the flume opposite the wave generator, two beaches with different profiles have been built, viz. a plane beach with a 1:20 slope, and a beach with an idealized bar-trough profile, consisting of two 1:20 plane sections sloping seawards, connected by a 1:40 plane section, sloping shoreward, 4.4 m in length, (Fig. 2).

Fig. 2 - Sketch of wave flume with bar-trough beach profile (plane slope indicated by dashed line)

The height of the bar crest was about 0.50 m above the flume bottom, and the depth of the trough below the bar crest was about 0.11 m. The beaches occupied the entire flume width, one at a time. They consisted of compacted sand, finished with a smooth cement-sand mortar layer.

Measurements of the free surface fluctuations were made with 7 parallel-wire resistance gauges. One of these was placed in the constant-depth section, 1.5 m seaward of the toe of the beach; this gauge served as the reference gauge for the incident waves. The other gauges, shoreward of the beach toe, were placed at intervals of 2 m. After a recording time of about 90 min., they were moved by 1 m, so as to obtain an effective interval between adjacent measurement points of 1 m.

The gauges were calibrated immediately before and after each run. Deviations from linearity were less than 0.5%, provided the minimum submergence exceeded 4 cm. This was guaranteed by placing the gauges in the beach, in those points where the minimum required submergence was not available above the beach face (i.e., in the points relatively high on the slope).

The gauge signals were analyzed with respect to the variance (σ^2) and its spectral distribution. To this end they were fed to an eight-channel Pulse Code Modulation recorder, and afterwards from there, at 16 times the recording speed, to a digital correlator and a hybrid spectral analyzer. A total of 2^{15} points per signal were sampled, at intervals of 0.01 s (0.16 s true time). The corresponding Nyquist frequency (f_N) is 50 Hz (50/16 Hz true frequency). Per spectrum, 100 spectral estimates were made, at a separation of $0.01 f_N$, each with about $2^{15}/100 \approx 328$ degrees of freedom.

Values of σ^2 , obtained from the digital correlator, were used to estimate H_{rms} according to

$$H_{rms} = 8^{\frac{1}{2}} \sigma, \quad (26)$$

which is consistent with (21) and with

$$E = \rho g \sigma^2. \quad (27)$$

Paper chart recordings were made incidentally for visual inspection; they were not used in the quantitative analyses.

Wave set-down and set-up were measured indirectly, through the mean piezometric level at the beach face, which in turn was detected by means of 1.5 mm ID tappings placed at intervals of 1 m.

The tappings were flush with the beach face. However, in addition a deviating arrangement was made for some of the higher points, which were above the instantaneous waterline during parts of the time (during draw-down). During such time intervals, conventionally placed tappings at these points would experience a piezometric level equal to the local level of the beach face, even though the point would be momentarily "high and dry" above the water. This would lead to a systematic over-estimation of the wave set-up in that region.

To remedy this situation, a narrow slot, 1 cm wide and 10 cm deep, was gouged into the beach face, parallel to the side walls of the flume. The slot covered an interval of the beach face from a point above the highest run-up expected, to a point which was always submerged. Because the water in the slot can draw down to below the beach face, tappings which were provided in the bottom of the slot can experience piezometric levels lower than the beach face at the local cross section. A comparison of the set-up so obtained with that obtained from a conventional tapping in the same cross section, in a cross section where the latter reading was not suspect, showed them to agree to within the random experimental error (0.1 to 0.2 mm).

The system of measuring the mean water level with tappings in the slot is somewhat similar to another conceivable way of achieving the same objective, viz. through measurements of the mean piezometric level in the pores of a porous beach. If the permeability of such beach is low enough, though not zero, then the beach is virtually impermeable to water motions in the frequency band of the waves. The wave motion would then be the same as on a strictly impermeable beach, while the beach would be permeable to the mean component, making a MWL-measurement possible.

All the piezometer tappings were connected via 9 mm ID plastic tubes to 86 mm ID stilling wells. The waterlevel in the wells was read with a point gauge to 0.1 mm accuracy.

The energy in the frequency band of the incident waves was filtered out to imperceptible values by the system tube-stilling well. However, some lower-frequency oscillations were noticeable in the wells, particularly for the higher points on the beach. For this reason about 10 readings per well were made for each run, with intervals of about 15 min. The arithmetic average of these readings was taken to represent the local mean water level, and the height of this above the still-water level, which was read in the stilling wells before and after each run, was taken as the local set-up. The difference between individual readings was largest for points high on the slope, but even there the maximum deviation from the average was less than 10% of the local set-up.

Tests and results

As mentioned above, tests have been carried out on a plane beach and on a bar-trough beach. A summary of the independent parameters used is given in the following table.

Run	Profile	d_j (m)	d_c (m)	\bar{f}_j (Hz)	σ_j (m)	H_{rmsj} (m)	H_{rms_o} (m)	s_o	d_c
2	plane	.705	-	.544	.051	.144	.157	.030	-
3	plane	.697	-	.407	.043	.121	.126	.013	-
4	plane	.701	-	.463	.050	.142	.152	.021	-
11	bar	.702	.209	.479	.051	.143	.148	.022	1.41
12	bar	.645	.150	.471	.043	.121	.128	.018	1.17
13	bar	.762	.267	.497	.037	.104	.113	.018	2.35
14	bar	.732	.236	.512	.042	.118	.129	.022	1.83
15	bar	.616	.120	.530	.051	.143	.154	.028	0.78

The subscript 1 refers to the reference gauge, 1.5 m seaward of the toe of the beach; d_c is the still-water depth above the bar crest; H_{rms_0} is a deep-water rms wave height, defined as

$$H_{rms_0} = H_{rms1} / K_{s1} = 8^{1/2} \sigma_1 / K_{s1}, \quad (28)$$

in which K_{s1} is the linear shoaling coefficient for depth d_1 and frequency f_1 ; s_0 is a deep-water steepness defined by

$$s_0 \equiv 2\pi f_1^2 H_{rms_0} / g, \quad (29)$$

and

$$\tilde{d}_c \equiv d_c / H_{rms_0}. \quad (30)$$

The incident wave spectrum was rather narrow (half-power bandwidth about 25% of peak frequency), and virtually unimodal, except for a bulge in the range of frequencies about twice the peak frequency.

For the tests on the plane beach, of given slope which was not varied, the deep-water steepness is the most important independent variable. Three such runs were made, with s_0 -values of 1%, 2% and 3% approximately. The results for the run with 2% steepness were intermediate between those of the runs with 1% and 3% steepness. Only the results of the latter two are presented here, the wave heights in figs. 3a and 4a and the set-up in figs. 3b and 4b. These have been plotted against the still-water depth. The variables have been normalized as follows:

$$\begin{aligned} \tilde{H} &\equiv H_{rms} / H_{rms_0} \\ \tilde{\eta} &\equiv \bar{\eta} / H_{rms_0} \\ \tilde{d} &\equiv d / H_{rms_0} \end{aligned} \quad (31)$$

Five runs were made with a bar-trough profile. The most important independent variable in this case is \tilde{d}_c , the relative depth at the bar crest. It was varied from 2.35 to 0.78. In the first case relatively few waves break on the bar, and in the latter case the majority does. Virtually no waves were breaking in the trough region, regardless of the relative depth over the bar crest.

Only the results of the two runs with the largest and the smallest value of \tilde{d}_c are presented here, the wave heights in the figs. 5a and 6a, the set-up in the figs. 5b and 6b. These have been plotted against the relative distance seaward of the still-water line, denoted by

$$\tilde{x} \equiv x / H_{rms_0} \quad (32)$$

Fig. 3 - Run 3; experimental values (x); theoretical values for $\alpha = 1, \gamma = 0.8$ (—)

Fig. 4 - Run 2; experimental values (x); theoretical values for $\alpha = 1, \gamma = 0.8$ (—)

Fig. 5 - Run 13; experimental values (x); theoretical values for $\alpha = 1, \gamma = 0.8$ (—)

Fig. 6 - Run 15; experimental values (x); theoretical values for $\alpha = 1, \gamma = 0.8$ (—)

As an aid in the interpretation, the beach profile has also been plotted, in the figs. 5c and 6c.

In all the plots, except figure 5, the most seaward data point is that of the reference gauge in the constant-depth section of the flume.

Discussion of experimental results

The wave height decay on the plane slope (figs. 3a and 4a) shows a slight steepness effect, in the sense which might be expected. For the lower steepness ($s_0 \approx 0.01$), there is a noticeable enhancement, in fact to values exceeding the deep-water wave height, before the decay due to breaking sets in. No enhancement has been measured for the steeper waves.

For both steepnesses, the maximum set-down occurs near $\tilde{d} = 2$. The maximum relative set-up, occurring at the waterline, and estimated by extrapolation of measured values, decreases with increasing incident wave steepness.

The wave height data for the bar-trough profile (figs. 5a and 6a) show a slight enhancement, followed by a more or less severe decay on the bar, depending on the relative depth over the bar crest. In both cases there is a wave height minimum in the trough of the beach, as would be the case for dissipationless waves in shallow water. This pattern is consistent with the visual observation that there was virtually no breaking going on in the trough region. The fact that the mean water level has a maximum near the trough is also consistent with this.

The mean water level gradient just shoreward of the bar crest is far greater than further toward the trough, but still on the same slope. (This is particularly clear in fig. 6b.) This is due to the fact that in that region there is still dissipation, though the depth is already increasing. The dissipation contributes to the mean water level gradient in the same sense as the increasing depth (both tending to decrease S_{xx}).

COMPARISON OF THEORETICAL MODEL TO EXPERIMENTAL DATA

Results of theoretical model

The equations of the theoretical model described in previous chapters were programmed for numerical evaluation on a digital computer.

The nearshore beach profiles used in the calculations were the same as those used in the experiments. The seaward portion of the profiles was a constant-depth section in the experiments, but in the calculations this section was replaced by a 1:20 slope extending to deep water. The calculations were started in a point of effectively deep water, using experimental values of \bar{f}_1 and H_{rms0} as input parameters.

Due to the finite size of the flume, the wave-induced set-up on the beach causes a lowering of the mean water level in the constant-depth section. Thus, instead of having an initial value for the integration of the set-up equation (23), the constancy of mass in the flume must provide the integration constant. However, there were indications that water was not only stored on the beach, but also behind the wave generator. The latter amount was not predicted. For this reason, the measured set-down in the constant-depth section was used as the reference value for the calculations of the mean water level.

The calculations cannot be initiated until the parameters (α, γ) have been assigned certain values. It is planned to determine a single pair of (α, γ) -values such that the fit of the calculated results for H_{rms} and $\bar{\eta}$ to the complete data set is optimised in some sense. This has not yet been done. In the calculations performed so far, the coefficients α and γ were given some plausible values a priori.

For γ , which indicates a breaker height-to-depth ratio, the value 0.8 was chosen.

The coefficient of proportionality in the expression for the dissipation rate is expected to be of order unity. A logical a priori choice for it would therefore be 1. This has in fact been done in a previous formulation, in which however a coefficient has been used which was a factor 2 smaller than the coefficient α used here, defined in eq. 19. Thus, the initial calculations were in fact performed for $\gamma = 0.8$, $\alpha = 0.5$. The calculated decay rate proved to be too low. The calculations were then repeated with $\gamma = 0.8$, $\alpha = 1$. The results of these calculations have been superimposed on the plots of the experimental data in the figs. 3 through 6.

Discussion of results

A comparison of the theoretical results to the experimental data leads to the following conclusions.

In general, the wave height variation across the surf zone is predicted reasonably well. In some cases, the agreement between model predictions and experimental data is quite good, such as in the figs. 4a and 6a. In other cases the agreement is less good, though still fair.

The set-down and set-up appear to be less well predicted than the wave heights. Although the overall agreement is fair, the model consistently predicts the transition from set-down to set-up in regions somewhat too far seaward. The fact that this discrepancy exists even where the wave height variation is predicted well, suggests that in the breaking process S_{xx} decreases not as fast as the potential energy of the waves, perhaps due to a local relative surplus of kinetic energy of organized wave motions and turbulent motions together. Data obtained previously have given similar indications (Battjes, 1974).

The probability that an arbitrary wave passing a given point shall be a breaking or broken wave, is an important quantity in the description of random waves on a beach. It has not been measured quantitatively.

However, a comparison of theoretical results with qualitative observations is possible, particularly for the runs with a bar-trough profile. In all cases, the calculated value of Q_b in the trough was virtually zero, even though it could be considerable on the bar crest ($Q_b = 0.06$ in run 13, with $\tilde{d}_c = 2.35$, and $Q_b = 0.46$ in run 15, with $\tilde{d}_c = 0.78$). These variations agree at least qualitatively with the visual observations.

Summarising: the model, when given a single pair of plausible values for the coefficients α and γ , appears capable of predicting qualitatively and quantitatively the main features of the complete set of data, both with respect to the wave heights and to the mean water level variations, both on a plane beach and on a beach with a bar-trough profile. This lends strong support to the usefulness of the model proposed herein.

CHAPTER 33

THE ENERGY SPECTRA OF SURF WAVES ON A CORAL REEF

by
Theodore T. Lee^{1/} and Kerry P. Black^{2/}

ABSTRACT

The transformation of waves crossing a coral reef in Hawaii including the probability density function of the wave heights and periods and the shape of the spectrum is discussed. The energy attenuation and the change of height and period statistics is examined using spectral analysis and the zero up-crossing procedure. Measurements of waves at seven points along a 1650 ft transect in depths from 1 to 3.5 ft on the reef and 35 ft offshore were made.

The heights were tested for Rayleigh, truncated Rayleigh and Weibull distributions. A symmetrical distribution presented by Longuet-Higgins (1975) and the Weibull distribution were compared to the wave period density function. In both cases the Weibull probability density function fitted with a high degree of correlation. Simple procedures to obtain Weibull coefficients are given.

Fourier spectra were generated and contours of cumulative energy against each position on the reef show the shifting of energy from the peak as the waves move into shallow water. A design spectrum, with the shape of the Weibull distribution, is presented with procedures given to obtain the coefficients which govern the distribution peakedness. Normalized non-dimensional frequency and period spectra were recommended for engineering applications for both reef and offshore locations.

A zero up-crossing spectrum (ZUS) constructed from the zero up-crossing heights and periods is defined and compared with the Fourier spectrum. Also discussed are the benefits and disadvantages of the ZUS, particularly for non-linear wave environments in shallow water. Both the ZUS and Fourier spectra are used to test the adequacy of formulae which estimate individual wave parameters.

Cross spectra analysis was made to obtain gain function and squared coherency for time series between two adjacent positions. It was found that the squared coherency is close to unity near the peak frequency. This means that the output time series can be predicted from the input by applying the gain function. However, the squared coherency was extremely small for other frequencies above 0.25 Hz.

INTRODUCTION

Most coastal areas of Hawaii, Australia and other tropical regions are protected naturally by a coral reef. Due to complex bathymetry, large energy losses by breaking, friction, scattering and the highly non-linear behavior of impinging waves, the fringing reef presents an extremely complex environment. As a result, the wave transformation on the coral reef is distinctly different from that on sandy coasts. The wave heights, wave

^{1/} Researcher, J.K.K. Look Laboratory of Oceanographic Engineering, Department of Ocean Engineering, University of Hawaii, Honolulu, Hawaii

^{2/} Formerly Research Associate, Department of Ocean Engineering, and Graduate Student, Dept. of Oceanography, Univ. of Hawaii, Honolulu, Hawaii

periods, and energy spectra are thus modified significantly but information on such a modification is very limited (Bushing, 1976), particularly for correlated field measurements. Knowledge of wave characteristics leeward of a reef is necessary in numerous engineering endeavors, such as the assessment of beach stability, design of coastal structures, prediction of dynamic response of small boats in marinas in waters partly protected by a reef, artificial shoal, and submerged breakwaters. Lack of such knowledge has led to grave uncertainties for designing an economical and sound structure. Also, wave transformation is associated with the living coral environment studied by the marine biologists and wave-induced currents are central to the mechanism of food transformation. This paper will provide some new light concerning the transformation and modification of ocean waves as they progress from deep water through breaking on a reef and on into the shallow water beyond.

FIELD EXPERIMENT

Fig. 1(a) Instrumentation location and bathymetry of Ala Moana reef

was mounted on a tower in 35 ft of water (Fig. 1(b)). A floating buoy (number 6) was moored on the outer edge of the reef (6-8 ft depth) and data was recorded by filming the motion of the buoy. The bathymetry with range of location of instruments is shown on Fig. 1(a). All instruments and recording equipment were transported and deployed from a mobile platform equipped with four jack-up legs. At the project site the legs were lowered to the reef to form a fixed platform which allowed the waves to pass underneath. Wave information was cabled back and recorded on a Sangamo Model 3400, 16-channel tape recorder. A portable electric

Field measurements of water level versus time were made in the ocean at seven points (Fig. 1(a)) along a 1650 ft long transect at the Ala Moana Beach on the southern shore of the island of Oahu ($21^{\circ}17'N$, $157^{\circ}52'W$) in Hawaii from July through September 1976. Five capacitance-type probes (numbered 1 to 5, with number 1 most shoreward) were supported on tripods in shallow water on the reef in depths from 1.0 to 3.5 ft. Another capacitance probe (number 9)

Fig. 1(b) Schematic of offshore wave measurement system

generator was used as a power source. Offshore data was cabled to a Sanborn strip chart recorder using a catamaran as a recording station.

TIME SERIES

A typical time series is shown on Fig. 2. A qualitative schematic of the wave transformation is shown on Fig. 3. The waves impinging on the reef had primary period of 12 to 18 seconds and significant height up to 3 ft. Offshore, the waves tend to arrive in groups, modulated at a beat frequency. As they shoal on the reef, secondary waves are formed indicative of a highly non-linear process. The shoaling waves typically plunge and produce a saw-tooth profile (Probe 4, Fig. 2). The reformed waves inside the breaker zone have a shortened period, due to the formation of multiple crests.

The random nature of ocean waves is usually described as a stationary Gaussian process. Figures 4 and 5 show the probability density of sea-level elevation against the theoretical Gaussian distribution for offshore and near-shore probes respectively. Note that the shallow water data deviates significantly from the theoretical distribution due to the modified wave profile which has long shallow troughs and peaked crests.

WAVE HEIGHT

The significant wave height normalized by the offshore significant wave height plotted against the position on the reef is shown on Fig. 6. Due mainly to bottom friction and also to breaking, the ratio decreases

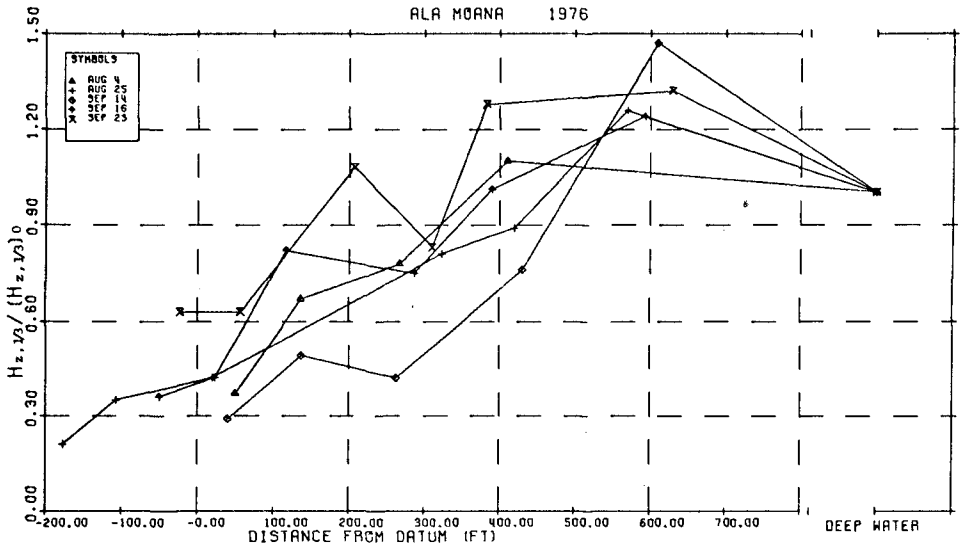

Fig. 6 The significant height normalized by the offshore value against position on the reef, Ala Moana, 1976.

such that the wave height is reduced by approximately 50% every 500 ft travelled on the reef. (The waves generally break at 380 ft from the datum.)

A zero up-crossing analysis was performed on a total on 35 time series and wave height statistics were determined as follows:

$$\begin{aligned}
 H_{z,1/3} / \bar{H}_z &= 1.70 \pm 0.13 && \text{shallow reef} \\
 &1.72 \pm 0.11 && \text{offshore} \\
 &1.64 \pm 0.04 && \text{probes exhibiting Rayleigh distribution} \\
 \text{(NOTE: } 1.60 &&& \text{theoretical Rayleigh)}
 \end{aligned}
 \tag{1}$$

$$\begin{aligned}
 H_{z,max} / H_{z,1/3} &= 1.80 \pm 0.13 && \text{offshore} \\
 &2.60 && \text{shoreward of the breaker zone} \\
 &1.60 && \text{breaker zone} \\
 \text{(NOTE: } 1.74 &&& \text{theoretical ratio given by Longuet-Higgins)}
 \end{aligned}$$

$$\begin{aligned}
 H_{z,1/3} / \sigma &= 3.88 \pm 0.52 && \text{shallow water} \\
 &3.56 \pm 0.13 && \text{offshore} \\
 \text{(NOTE: } 4.00 &&& \text{theoretical Rayleigh)}
 \end{aligned}$$

Rayleigh Distribution. In each case, there is significant deviation from the theoretical Rayleigh value. This coincides with a poor fit of the data to the Rayleigh distribution. Typical distributions are shown in Fig. 7. Using a Chi-squared goodness of fit test, the 35 height distributions were compared to the Rayleigh probability density function and 23 did not fit at the 0.025 level of significance. Two out of the five offshore time series did not exhibit Rayleigh distribution due to an excessive number of short period waves (<2 seconds). After filtering of these waves all offshore height distributions were Rayleigh distributed.

Truncated Rayleigh Distribution. The heights were compared to the truncated Rayleigh distribution (Kuo and Kuo, 1975, Battjes, 1974). The

Fig. 7 Distribution of wave heights plotted as height versus frequency of occurrence against position on the reef, Ala Moana, September 23, 1976.

fit was excellent in the breaker zone, but poor both offshore and shorewards of this region. This means that the truncated distribution can only be applicable on certain parts of the reef.

Weibull Distribution. A more general distribution which fits at all positions on the reef for various meteorological conditions was needed. The Weibull distribution given by

$$f(H) = \alpha \beta H^{\beta-1} \exp(-\alpha H^\beta) \tag{2}$$

was selected, and the correlation coefficient, ρ_{12} , which is unity for a perfect fit exceeded 0.98 at most positions on the reef. Arhan and Ezraty (1975) also used Weibull distribution successfully to fit their wave data in shallow water.

It should be noted that Rayleigh is a special case of the Weibull distribution with $\beta=2$ and $\alpha=1/H_{rms}^2$. Procedures to determine β (peakedness coefficient), and α follow:

(1) Curve fitting.

The probability of exceeding $x=x_n$ is

$$G(x_n) = \int_{x_n}^{\infty} f(x) dx = \exp(-\alpha x_n^\beta) = n/N \tag{3}$$

where n waves exceed x_n of a total of N waves. Taking logarithms twice gives

$$\ln[\ln(N/n)] = \ln(\alpha) + \beta \ln(x_n) \tag{4}$$

which is a linear equation with intercept at $\ln(\alpha)$ and gradient β . The coefficients β and α can be determined using standard linear regression techniques or by plotting the double logarithm term against $\ln(x)$ and fitting a straight line.

(2) Distribution width function.

The distribution width function is defined (Black, 1978) as

$$Q_H = 4 \int_0^{\infty} H f(H)^2 dH \tag{5}$$

For a Weibull distribution.

$$Q_H = \beta \tag{6}$$

The approximate value of β for data divided into bins of width ΔH

$$Q_H = \beta = \frac{4}{N^2 \Delta H} \sum_{i=1}^{NBINS} H_i m_i^2 \tag{7}$$

where N is the total number of waves, $NBINS$ is the number of bins, and H_i and m_i are the heights and number of occurrences respectively in the i^{th} bin. The squared probability density term in the distribution width function tends to magnify small deviations from the theoretical distribution and Q_H is sensitive to the choice of the number of bins which should be selected such that

$$NBINS < N/10$$

(3) Determination of β without curve fitting.

The ratio of two height (or period) statistics is uniquely defined by the peakedness so β may be easily determined using any two statistics such as $H_z, 1/3/H_z$ or $\sigma(H)/H_z$ (which are most stable). To facilitate this approach, the theoretical values of several ratios were plotted against β (Fig. 8). One enters the figure with any of the ratios and reads β . The theory is derived by Black (1978).

Procedures to determine the other coefficient, α , follow:

(i) The Weibull coefficient α may be determined as

$$\alpha = [\Gamma(1 + 1/\beta)/H_z]^\beta \tag{8}$$

where Γ is the gamma function, and H_z is the mean height of the distribution. Figure 9 presents a family of curves for various α using Eq. (8). α may be determined if one enters the figure with β and H_z .

(ii) Another useful equation to determine α which does not

Fig. 8 Theoretical ratios of wave height (period) statistics for waves exhibiting the Weibull distribution against beta, β . (X may be height or period.)

Fig. 9 Theoretical mean of Weibull distribution against β , beta for various α . (Alpha can be determined if given beta and the mean wave height.)

include the gamma function is

$$\alpha = \frac{\beta-1}{\beta} H_p^{-\beta}, \text{ or } [\alpha = \frac{\beta+1}{\beta} f_p^\beta \text{ where } f_p = \left(\frac{\beta-1}{\beta+1}\right)^{1/\beta} T_p^{-1}] \tag{9}$$

The exact solution for the average of the largest n^{th} of waves was determined to be

$$H_{z,n}/N = \frac{N}{n} \bar{H}_z \left(1 - \int_0^{\ln(N/n)} f_G(y) dy\right) \tag{10}$$

where $y = \alpha H^\beta$, \bar{H}_z is given by Eq. (8) and $f_G(y)$ is the incomplete gamma function ratio,

$$f_G(y) = \frac{1}{\Gamma(1+1/\beta)} e^{-y} y^{1/\beta} \tag{11}$$

An approximate solution was also obtained as

$$H_{z,n}/N = \frac{C_1}{2} [(\ln(N)/\alpha)^{1/\beta} + (\ln(N/n)/\alpha)^{1/\beta}] + C_2 \tag{12}$$

where C_1 and C_2 are arbitrary constants, and for $C_2=0$.

Then

$$H_z = \frac{0.65}{2} [\ln(N)/\alpha]^{1/\beta}$$

$$H_{z,1/3} = \frac{0.79}{2} [\ln(N)/\alpha]^{1/\beta} + (\ln(3)/\alpha)^{1/\beta} \tag{13}$$

$$H_{z,1/10} = \frac{0.87}{2} [\ln(N)/\alpha]^{1/\beta} + (\ln(10)/\alpha)^{1/\beta}$$

$$H_{z,\max} = 1.01[\ln(N)/\alpha]^{1/\beta} \quad (13)$$

(cont)

WAVE PERIODS

The significant period normalized by the offshore deep-water period decreases generally as waves cross the reef toward the shoreline due to the formation of multiple crests and a diminishing height to period correlation; the mean values of the ratio are:

$$\frac{T_{H_z,1/3}}{[T_{H_z,1/3}]_0} = \begin{cases} 0.704 \pm 0.176 & \text{shallow reef for offshore wind} \\ 0.642 \pm 0.168 & \text{shallow reef for onshore wind} \\ 0.853 \pm 0.110 & \text{breaker zone} \\ 0.763 \pm 0.103 & \text{outer edge of the reef (4'-8' depth)} \\ 1.000 & \text{offshore in deep water (35 ft depth)} \end{cases} \quad (14)$$

It was found that the rate of change of significant period is small and the correlation is poor ($\rho_{12}=0.31$).

The ratio of the average of the top third of the periods over the significant period is:

$$\frac{T_{z,1/3}}{T_{H_z,1/3}} = \begin{cases} 1.35 \pm 0.14 & \text{shallow reef} \\ 1.11 \pm 0.04 & \text{offshore} \end{cases} \quad (15)$$

The ratio of significant period to mean period is

$$\frac{T_{H_z,1/3}}{\bar{T}_z} = \begin{cases} 1.30 \pm 0.13 & \text{shallow reef} \\ 1.56 \pm 0.12 & \text{offshore} \end{cases} \quad (16)$$

The period distribution was compared to the Weibull probability density function,

$$f(T) = \alpha\beta T^{\beta-1} \exp(-\alpha T^\beta) \quad (17)$$

which offers the best fit with correlation coefficient exceeding 0.98 in most cases. The Weibull coefficients β, α can also be found from Figs. 8 and 9 or from Eq. (5) as the periods and heights were fitted to the same distribution.

The approximate solution for the average of the largest one third of the periods is

$$T_{z,1/3} = \frac{0.77}{2} [(\ln(N/\alpha))^{1/\beta} + (\ln(3)/\alpha)^{1/\beta}] \quad (18)$$

Further, the wave periods were fitted to a symmetrical distribution presented by Longuet-Higgins (1975). The fit is poor due mainly to a positive skewness in the actual period distribution. This symmetrical distribution is generally useful for the narrow spectrum case.

WAVE SPECTRUM

The energy spectra of surf waves on the coral reef were examined in detail by: (1) Fourier spectrum analysis, and (2) zero up-crossing analysis procedures. The transformation of the Fourier spectrum as the waves cross the reef can be seen typically on Fig. 10. Offshore (probe 9), the spectrum has low energy in the high and low frequency ranges which

Fig. 10 Fourier spectrum for time series of 4096 data points digitized at 2.5 points per second. Each spectral estimate has 40 degrees of freedom, Ala Moana, September 14, 1976.

increases as the waves enter shallow water when energy shifts from the peak. The shift results in the production of multiple crests and periodic sea level changes at beat frequencies. Harmonics of the peak frequency are evident.

Cumulative energy (Fig. 11) and response function (Fig. 12) against position on the reef were compared. The contours of cumulative energy showing seven frequency ranges between 0 and 1.25 (Nyquist frequency) were presented so that the energy attenuation or amplification in the low, middle, and high frequency ranges can be examined in greater detail (Black, 1978). It showed that low frequency energy (below 0.05 Hz) increases from the offshore probe but it is not attenuated on the reef. Most of the energy is at frequencies less than 0.4 Hz and virtually no energy lies above 0.81 Hz. There is a decrease in variance from the offshore probe to the most seaward shallow water probe even though an increase is expected due to shoaling friction attenuates the waves over this section. The peak of the spectrum is at approximately 0.075 Hz. The peak always attenuates but high frequency energy ($0.21 < f < 1.25$ Hz) gains occur when waves first enter shallow water and break. The breaker zone is at approximately 380 ft from the datum (Fig. 11) where the gradient of the curves is greatest, which means there is maximum energy loss per unit distance traveled across the reef in this region. Shorewards of the breaker zone, there is attenuation at all frequencies. However, interesting behavior was noted for some days that the total variance is greater just shorewards of the breaker zone than in the breakers due to a significant increase in high frequency energy. This is caused in part by local wind-waves but it is most likely caused by wave refraction which introduces energy from the sides of the transect in this region. This suspicion is based on the fact that this phenomena was not observed in the simulated laboratory experiments (Lee, 1978).

It is interesting to note that energy gains at low frequency are larger if the offshore spectrum has a split peak due to wave-induced set-up at beat frequencies in shallow water.

Fig. 11 Contours of cumulative energy from frequency 0.0 to F, where F is given on the symbol table, against position on the reef, Ala Moana, September 23, 1976.

Fig. 12 Response function, $R(f)$, against frequency, where $R(f) = S(f)_x / S(f)_g$. $S(f)_x$ is the spectral density at probe x and $S(f)_g$ is the spectral density at the offshore probe, Ala Moana, September 23, 1976.

(A) Fourier Spectrum

The period spectrum at either offshore or shallow-reef areas has the shape of Weibull distribution given by

$$S(T) = E\alpha\beta T^{\beta-1} \exp(-\alpha T^\beta) \tag{19}$$

where E is the total energy in the spectrum, T is the wave period, and S(T) is the spectral density (ft²/Hz), and β, α determine the shape of the distribution and govern the spectrum peakedness.

The frequency spectrum with the shape of Weibull distribution can be obtained by a change of variable,

$$S(f) = S(T) \left| \frac{dT}{df} \right| \tag{20}$$

and $T = f^{-1}, \frac{dT}{df} = -f^{-2}$ (21)

then $S(f) = E\alpha\beta f^{-\beta-1} \exp(-\alpha f^{-\beta})$ (22)

At $f=f_p$, peak frequency

$$\frac{dS(f)}{df} = 0$$

$$f_p^\beta = \frac{\alpha\beta}{\beta+1} \text{ or } \alpha = \frac{\beta+1}{\beta} f_p^\beta \tag{23}$$

then $S(f) = E \left(\frac{\beta+1}{f_p}\right) \left(\frac{f}{f_p}\right)^{-\beta-1} \exp\left[-\left(\frac{\beta+1}{\beta}\right) \left(\frac{f}{f_p}\right)^{-\beta}\right]$ (24)

$$S(f_p) = E \left(\frac{\beta+1}{f_p}\right) \exp\left[-\left(\frac{\beta+1}{\beta}\right)\right] \tag{25}$$

To show the effect of β on the shape of the spectrum, the above equation (24) was plotted with fixed mode ($f_p=0.1$), unit variance and for β=1, 5 on Fig. 13. Note that the spectrum widens as β decreases.

Methods to obtain β will follow.

(1) Curve fitting.

The cumulative energy is

$$E_c = \int_0^f S(f)df = E \exp(-\alpha f^{-\beta}) \tag{26}$$

and taking logarithms twice gives

$$\ln[\ln(E/E_c)] = \ln(\alpha) - \beta \ln(f) \tag{27}$$

which is a linear equation with intercept at $\ln(\alpha)$ and gradient -β.

(2) Iteration.

A simple method was developed to determine β, without curve-fitting, from Eq. (25) using a simple iterative technique.

$$\exp\left[\left(\frac{\beta+1}{\beta}\right)\right]/(\beta+1) = E/[S(f_p) \cdot f_p] \tag{28}$$

With the peak frequency (f_p), energy density at peak frequency [$S(f_p)$], and the total energy in the spectrum E, β can be obtained. This relationship was plotted on Fig. 14, and β may be obtained by

Fig. 13 Theoretical spectra with the shape of Weibull distribution with unit variance, peak frequency $f_p=0.1$ Hz and for $\beta=1,5$.

entering the function $E/[S(f_p) \cdot f_p]$. The other coefficient, α , may be obtained by

$$\alpha = \frac{\beta+1}{\beta} f_p^\beta \quad (29)$$

Analysis showed that the spectrum found in this manner fits the peak exactly but does not necessarily describe the rest of the spectrum well. This method should only be used when an "easy-to-obtain" estimate of β is required or if the spectrum has been highly smoothed. In general, the value of β by iteration is greater than that by curve-fitting.

(3) Goda's spectral peakedness parameter.

Another alternative method to obtain β without curve-fitting employs Goda's spectral peakedness parameters Q_p (Goda, 1974).

$$Q_p = \frac{2}{m_0} \int_0^\infty f S(f)^2 df \quad (30)$$

where m_0 is zeroth spectral moment.

It can be shown for a spectrum with the shape of the Weibull distribution that (Black, 1978)

$$Q_p = \beta/2 \quad (31)$$

In which case, the peakedness β can be found using Q_p .

It was found that Q_p represents the shape of the spectrum much better than the spectral width parameter

$$\epsilon_s = \sqrt{1 - \frac{m_2^2}{m_0 m_4}} \quad \text{or} \quad \epsilon_T = \sqrt{1 - \left(\frac{N_z}{N_c}\right)^2}$$

The spectral width parameters vary considerably with the high frequency cut-off choice, therefore, they are not a good parameter to characterize the spectral distribution.

The design frequency spectrum for engineering applications on coral reef environment is recommended as follows:

Fig. 14 Theoretical curve to obtain Beta for the spectrum with the shape of the Weibull distribution using the peak energy density, where $\exp(\beta + 1/\beta)/(\beta + 1) = E/(S(f_p) \cdot f_p)$ and E is total energy in spectrum, f_p is peak frequency and $S(f_p)$ is energy density at peak.

(a) Swell spectrum (offshore 35 ft depth)

$$S(f) = 4E_1 f_p^{-1} (f/f_p)^{-4} \exp[-\frac{4}{3}(f/f_p)^{-3}] \tag{32}$$

(b) Shallow water on the offshore side of the reef (5 ft depth)

$$S(f) = 3E_2 f_p^{-1} (f/f_p)^{-3} \exp[-\frac{3}{2}(f/f_p)^{-2}] \tag{33}$$

(c) Shallow water on the shoreward side of the reef (3 ft depth)

$$S(f) = 2E_3 f_p^{-1} (f/f_p)^{-2} \exp[-2(f/f_p)^{-1}] \tag{34}$$

In all three cases f_p is the offshore peak frequency and the total energy $E = (1/4 H_z, 1/3)^2$ where $H_z, 1/3$ is significant wave height.

The normalized non-dimensional frequency spectrum has the general form of

$$\frac{S(f)}{S(f_p)} = [\exp(\frac{\beta+1}{\beta})] (f/f_p)^{-\beta-1} \exp[-(\frac{\beta+1}{\beta})(f/f_p)^{-\beta}] \tag{35}$$

Then, the normalized design frequency spectra are:

(a) Normalized swell frequency spectrum (offshore 35 ft depth)

$$\frac{S(f)}{S(f_p)} = [\exp(\frac{4}{3})](f/f_p)^{-4} \exp[-\frac{4}{3}(f/f_p)^{-3}]; \beta=3 \tag{36}$$

(b) Normalized design frequency spectrum for shallow water on the offshore side of the reef (5 ft depth)

$$\frac{S(f)}{S(f_p)} = [\exp(\frac{3}{2})](f/f_p)^{-3} \exp[-\frac{3}{2}(f/f_p)^{-2}]; \beta=2 \tag{37}$$

(c) Normalized design frequency spectrum for shallow water on the shoreward side of the reef (3 ft depth)

$$\frac{S(f)}{S(f_p)} = [\exp(2)](f/f_p)^{-2} \exp[-2(f/f_p)^{-1}]; \beta=1 \tag{38}$$

These non-dimensional design frequency spectra are plotted on Fig. 15 and they are compared with the following well-known Bretschneider frequency spectrum with $\beta=4$ for deep water,

$$\frac{S(f)}{S(f_p)} = [\exp(\frac{5}{4})](f/f_p)^{-5} \exp[-\frac{5}{4}(f/f_p)^{-4}] \tag{39}$$

The normalized non-dimensional period spectrum can be obtained from Eq. (19),

$$S(T) = E\alpha\beta T^{\beta-1} \exp(-\alpha T^\beta)$$

At $T = T_p$

$$\frac{dS(T)}{dT} = 0 \quad T_p^{-\beta} = \frac{\alpha\beta}{\beta-1} \quad \text{then} \quad \alpha = \frac{\beta-1}{\beta} T_p^{-\beta}$$

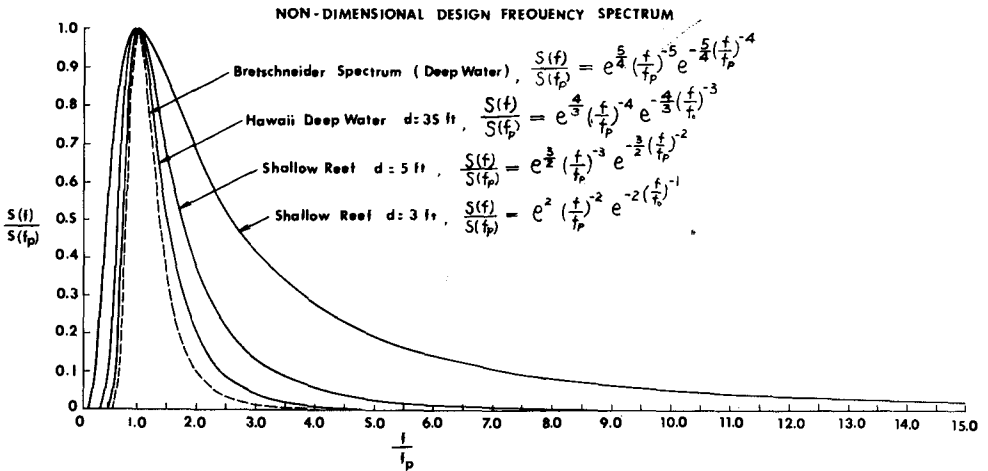

Fig. 15 Non-dimensional design frequency spectra

Then

$$S(T) = E(\beta-1)T_p^{-1}(T/T_p)^{\beta-1} \exp[-(\frac{\beta-1}{\beta})(T/T_p)^\beta] \tag{40}$$

$$S(T_p) = E(\beta-1)T_p^{-1} \exp[-(\frac{\beta-1}{\beta})] \tag{41}$$

The non-dimensional period spectrum has the general form of

$$\frac{S(T)}{S(T_p)} = [\exp(\frac{\beta-1}{\beta})](T/T_p)^{\beta-1} \exp[-(\frac{\beta-1}{\beta})(T/T_p)^\beta] \tag{42}$$

Then, the normalized design period spectra are:

(a) Normalized swell period spectrum (offshore 35 ft depth)

$$\frac{S(T)}{S(T_p)} = [\exp(\frac{2}{3})](T/T_p)^2 \exp[-\frac{2}{3}(T/T_p)^3] \tag{43}$$

(b) Normalized design period spectrum for shallow water on the off-shore side of the reef (5 ft depth)

$$\frac{S(T)}{S(T_p)} = [\exp(\frac{1}{2})](T/T_p) \exp[-\frac{1}{2}(T/T_p)^2] \tag{44}$$

The Bretschneider normalized period spectrum is

$$\frac{S(T)}{S(T_p)} = [\exp(\frac{3}{4})](T/T_p)^3 \exp[-\frac{3}{4}(T/T_p)^4] \tag{45}$$

The shape of the period spectrum was compared in Fig. 16.

Note that the peak frequency is related to the peak period as follows:

$$f_p^{-1} = (\frac{\beta+1}{\beta-1})^{1/\beta} T_p \tag{46}$$

The relationship between the spectrum and zero up-crossing period statistics was established and compared with others as listed in Table 1.

Ratio	Subject Study			Goda [1974]	Haring et al. [1976]	Manohar et al. [1976]
	range	shallow	offshore			
\bar{T}_z/T_p	0.22-0.58	0.38±0.09	0.46±0.08	0.75	0.52	
$T_{H_z, 1/3}/T_p$	0.28-0.80	0.49±0.13	0.71±0.12	0.94	0.75	0.78
$T_{H_z, 1/10}/T_p$	0.29-0.91	0.54±0.15	0.80±0.10		0.76	
$T_{H_z, max}/T_p$	0.23-1.03	0.66±0.31	0.89±0.11		0.77	
$T_{H_z, 1/3}/T_{m01}$	1.02-2.24	1.47±0.30	1.29±0.06	1.30	1.33	
\bar{T}_z/T_{m02}	1.13-2.46	1.62±0.30	1.16±0.03	1.20	1.15	

Table 1 Range, shallow water and offshore mean values with standard deviations, and comparison with other workers, of Ala Moana results, 1976.

Note that the ratios are significantly reduced by shallow water. This occurs because the peak period of the spectrum is usually constant but the zero up-crossing periods are reduced due to the shifting of energy into the high frequency range. The standard deviation or scattering in the data is much greater in shallow water than offshore.

The spectrum contains a height to period relationship which is linearly dependent on the first spectrum moment (m_1). The best-fit equation with excellent correlation coefficient $P_{12}=0.975$, is

$$\frac{H_z^2}{T_z} = 4.828 m_1 \quad (47)$$

Fig. 16 Non-dimensional design period spectra

Furthermore, comparison of the spectrum peakedness and the

peakedness of the period distribution produced linear correlation. A peaked spectrum (large β) should correspond to a peaked period distribution.

(B) Zero up-crossing spectrum (ZUS)

The zero up-crossing spectrum (ZUS) is defined as

$$S(f) = g(f) \cdot \frac{1}{8} H_{rms}^2(f) \quad (48)$$

which states that the energy density at frequency f is equal to one eighth the square of the zero up-crossing root mean square wave height at that frequency multiplied by the probability that frequency f will occur in the record. For the discrete case

$$S(f) = \frac{\sum_{i=1}^m H_i^2(f)}{8N \cdot \Delta f} \quad (49)$$

where Δf is the frequency interval and includes waves with frequencies from $f - \Delta f/2$ to $f + \Delta f/2$; N is the total number of waves in the record; m is the number of waves of zero up-crossing height H_i with frequencies that lie in the interval defined above. The definition states that the energy is large in a band if many waves fall in the band and if the amplitude of those waves is large.

Under the above definition, the energy of each wave is assumed to be $H^2/8$ which is only true for sinusoidal waves. It is not essential to do

this as $H_i^2(f)/8$ can be replaced by $E_i(f)$ where E_i is the variance of the time series between the two zero up-crossings which defined the height $H_i(f)$. For simplicity, the definition of $H^2/8=E$ is retained here.

The confidence interval for each estimate is

$$\begin{aligned} & \log S(f) + \log m/\chi_m(\alpha/2) , \\ & \log S(f) + \log m/\chi_m(1 - \alpha/2) \end{aligned} \tag{50}$$

at the $1 - \alpha/2$ confidence level, where χ_m is Chi-squared with m degrees of freedom.

The Fourier spectrum (FS) and ZUS are compared on Fig. 17. It showed that the FS and ZUS have distinct similarities but cannot be considered identical. The ZUS is more peaked than the FS. The ZUS allocates most energy over a narrower range than the FS, due to the fact that the zero up-crossing technique selects waves in this range. The ZUS is less stable away from the peak where the number of occurrences in each band decreases and the confidence widens.

The major advantage of the ZUS is that linearity is not required. Because each zero up-crossing wave is isolated from its neighbors, when the spectrum is considered in this manner the problem of interpretation of sinusoidal components at harmonic frequencies in a non-linear environment does not arise. This is useful for shallow water applications. Another advantage is that the spectrum contains a height to frequency relationship which is easily retrieved from the spectrum as

$$H_{rms}^2(f) = \frac{8N \cdot \Delta f \cdot S(f)}{m} \tag{51}$$

The major disadvantage is that if one only had the ZUS it would not be possible to recreate the time series, as the spectrum contains no information about the order in which waves occur. This is unfortunate for

Fig. 17(a) Fourier spectrum (Δ) and ZUS (\circ) for September 7, probe 5, Ala Moana, 1976.

Fig. 17(b) Fourier spectrum (Δ) and ZUS (\circ) for September 7, probe 3, Ala Moana, 1976.

applications where a spectrum is used to generate a sea surface for theoretical studies. Other disadvantages are criticisms aimed at the zero up-crossing procedure in general.

The ZUS is a useful tool for describing ocean waves. For engineering applications, the zero up-crossing analysis in general has some specific advantages and the ZUS is an extension of this approach. It shows the energy partition in a fashion similar to the Fourier spectrum and one can obtain all the statistics such as the significant wave height and period, etc. during the analysis. These cannot be easily obtained in shallow water from the Fourier spectrum.

The ZUS was fitted to the shape of the Weibull distribution given by

$$S(f) = E\alpha\beta f^{-\beta-1} \exp(-\alpha f^{-\beta}) \quad (52)$$

The peakedness, β , varies from 2.17 to 4.18 and is largest just seaward of the breaker zone.

The best-fit ZUS spectrum with Weibull distribution can be used to obtain period parameters from the following relationships

$$T_{m01} = m_0/m_1 = \frac{\alpha^{-1/\beta}}{\Gamma(1-1/\beta)} \quad (53)$$

$$T_{m02} = (m_0/m_1)^{1/2} = \frac{\alpha^{-1/\beta}}{\Gamma(1-2/\beta)} \quad (54)$$

The relationship of mean period (\bar{T}_z) from the zero up-crossing analysis to mean period (T_{m01}) of the ZUS, and to mean apparent period (T_{m02}) of the ZUS are given as follows:

$$\bar{T}_z/T_{m01}(\text{ZUS}) = \begin{array}{ll} 1.106 \pm 0.122 & \text{shallow reef} \\ 0.826 \pm 0.061 & \text{offshore} \end{array} \quad (55)$$

$$\bar{T}_z/T_{m02}(\text{ZUS}) = \begin{array}{ll} 1.303 \pm 0.189 & \text{shallow reef} \\ 0.977 \pm 0.085 & \text{offshore} \end{array}$$

It was shown that the peak of the ZUS occurs at or near the peak of the wave frequency distribution so that the confidence is best near the ZUS peak.

In summary, both the ZUS and Fourier spectra are used to test the adequacy of formulae which estimate individual wave parameters. The results for shallow water deviate significantly from the Rice's (1944 and 1945) theory, which is often used to estimate period statistics.

(C) Cross Spectrum

Cross spectra analysis was made to obtain gain function and required coherency for all time series between the adjacent shallow water probes on the reef. It was found that the squared coherency is close to unity near the peak frequency. This means that the output spectrum near the peak can be predicted from the input by applying the gain function because the system is linear in this frequency range. However, the squared coherency was extremely small for other frequencies above 0.25 Hz. There are energy gains from the probe in the breakers to the next probe shorewards in the mid-frequency range. The relative phase of the two adjacent time series showed that the waves were non-dispersive below approximately 0.25 Hz in shallow water. Typical squared coherency and gain function as a function of probe position on the reef is shown in Fig. 18.

Fig. 18(a) Squared coherency, Ala Moana, September 23, 1976.

Fig. 18(b) Gain function, G(f), Ala Moana, September 23, 1976.

ACKNOWLEDGMENTS

This study was jointly supported by Sea Grant, NOAA, the Governor's Office of Marine Affairs, University of Melbourne, and the University of Hawaii. Dr. Edward Thornton of the U.S. Naval Postgraduate School and Dr. J.A. Battjes of the University of Technology, Delft, provided technical assistance while they were at the University of Hawaii as Visiting Colleagues during the academic year 1975-1976 and summer 1976, respectively. Professor F. Gerritsen and George Weber assisted greatly during the course of study.

CHAPTER 34

WIND-GENERATED WAVE DIFFRACTION BY BREAKWATER GAP

by

Hooshang Raissi* and R. L. Wiegel**

SUMMARY

A number of hydraulic laboratory experiments were made of the diffraction of wind-generated waves by a breakwater gap. The directional spectra of the incident wave was used together with the water wave diffraction theory of Penny and Price for a breakwater gap to predict the energy spectra of the diffracted waves.

The difference between the predicted values of the energy spectral density and the measured values demonstrated the limits of using the above techniques. It is likely that this is due to the inadequacy of the diffraction theory of Penny and Price for a breakwater gap for certain ranges of B/L .

INTRODUCTION

For the engineering design and operation of a harbor, the designer often needs to know the wave period and the direction of the wave advance as well as the wave height in certain regions within the harbor.

Until recently, in the design of a harbor one or more predominant wave directions were considered, using the significant wave heights and periods. The effect of diffraction would then be calculated by using the Penny and Price method (1944), which gives a periodic solution for irrotational waves of infinitely long crest, constant amplitude and constant frequency.

Putnam and Arthur (1948) made an experimental study of diffraction by a one-arm ("semi-infinite") breakwater in deep water, using uniform periodic long-crested waves. Their experimental results showed a general agreement with the Penny and Price theory. Blue and Johnson (1949) made a similar experiment using a breakwater gap. Their experimental results also verified the general form of the wave diffraction theory.

* Formerly Graduate Student, University of California, Berkeley.

** Professor of Civil Engineering, University of California, Berkeley.

Due to the development of sophisticated computerized design techniques combined with the availability of new techniques for obtaining estimates of wave directional spectra, it is now desirable for the engineer to predict the power wave spectra at different locations within a proposed harbor during the analysis stages of the design of a harbor.

Mobarek and Wiegel (1967) proposed the use of directional spectra, combined with diffraction theory to determine the wave conditions at any desired location in a harbor. This method was applied to a semi-infinite breakwater and compared with experimental results (Mobarek and Wiegel, 1966; see also Fan, 1968; Fan and Borgman, 1970; Wiegel, Al-Kazily, and Raissi, 1971; Harms, 1975).

After some of these studies had been completed, additional hydraulic laboratory studies were made for the case of a breakwater gap and a new computer program was developed to solve the wave diffraction by a breakwater gap. The results of these studies are presented herein.

THEORETICAL CONSIDERATION

When water waves are intercepted by an obstacle such as a breakwater, diffraction occurs. W. G. Penny and A. T. Price showed in 1948 (see also their 1952 paper) that the solution presented by Sommerfeld in 1896 for the diffraction of light polarized in a plane parallel to the edge of a semi-infinite screen is also a solution of the water wave diffraction phenomenon.

The main assumptions in the Penny and Price solution (see Wiegel, 1964, for a summary of the theory and its verification) are:

1. The motion is irrotational.
2. The water is non-viscous, incompressible and of constant depth.
3. The wave amplitude is infinitely small.
4. The disturbance is propagated without changing form.
5. At the free surface, the pressure is constant.
6. At a fixed boundary, the normal component of the orbital velocity is zero.
7. There is no reflection from the harbor walls.
8. There is no refraction by the harbor bottom.

The water surface elevation, η , can be expressed as (Lamb, 1945):

$$\eta = \frac{A_1 \bar{k} C}{g} e^{i\bar{k} C t} \text{Cosh } \bar{k} d \cdot F(x, y) \quad (1)$$

Assume that the breakwater extends along the x-axis from the origin to infinity and the incident waves are travelling in the direction of the y-axis (Fig. 1). Assume the breakwater to be rigid and impervious. The normal component of the fluid velocity must be zero, there, so that

$$\frac{\partial \phi}{\partial y} = 0, \text{ at } y = 0 \text{ and } x \geq 0 \tag{2}$$

In terms of $f(x,y)$ the condition (2) becomes

$$\frac{\partial f}{\partial y} = 0, \text{ at } y = 0, \text{ and } x \geq 0 \tag{2a}$$

Summerfield's solution of the above problem is

$$f(x,y) = \frac{1+i}{2} \left[e^{-i\bar{y}k} \int_{-\infty}^{\sigma} e^{-\pi i u^2/2} du + e^{i\bar{y}k} \int_{-\infty}^{-\sigma} e^{-\pi i u^2/2} du \right] \tag{3}$$

where

$$\sigma^2 = \frac{4}{L} (\bar{r} - y) \quad \sigma'^2 = \frac{4}{L} (\bar{r} + y) \quad r^{-2} = x^2 + y^2$$

and u is a dummy variable. The signs for σ and σ' depend on the position of (x,y) in the four quadrants (Fig. 1).

The diffraction coefficient, K' , is defined as the ratio of the wave height in the area affected by diffraction to the wave height in the area unaffected by diffraction, which is the height of the incident wave (Penny and Price, 1952); therefore:

$$K' = | F(x,y) |$$

The phase value is given by the argument of $f(x,y)$.

Eq. (3) can be transformed into a form that allows the use of tabulated functions. For detailed mathematical treatment, refer to Putnam and Arthur (1948), Blue and Johnson (1949), and Wiegel (1962).

Penny and Price developed a superposition method by which the problem of diffraction by a gap may be solved by using two solutions for semi-infinite breakwaters, one to the right and one to the left of the opening. Blue and Johnson put the method in a form more convenient to apply, and in an experimental check found that the theory was substantially verified. While Penny and Price and Blue and Johnson studied the

FIG. 4: ARRANGEMENT OF WAVE GAGE ARRAYS

method only for normal incident waves, another study (California Institute of Technology, 1952) shows that the method may be extended to more general angles of incidence.

The two separate values of K' at a given point are combined by very definite rules, depending upon the location of the point.

The rules for combining two values of K' may be explicitly stated, ignoring the diffraction of the reflected wave by breakwater arms (Blue and Johnson, 1948; California Institute of Technology, 1952), as

(a) in the shadow of the right breakwater $K' = K'_1 + K'_2 + 1$

where the subscript 1 and 2 refer to right and left arms, respectively, Fig. 2.

(b) in the geometrically exposed area beyond the gap in the direction of wave travel, $K' = K'_1 + K'_2 - 1$.

(c) in the shadow of the left breakwater $K' = K'_2 - K'_1 + 1$.

The above equations are simple algebraic additions.

A computer program, GAPDFRAK, was developed to calculate the one-dimensional energy spectrum at any specified location inside the breakwater gap, for a measured or assumed two-dimensional ("directional") incident wave spectrum input (Raissi and Wiegel, 1971).

EXPERIMENTAL ARRANGEMENTS

The experiment was conducted in the Hydraulic Engineering Laboratory of the University of California at its Richmond Field Station. Wind waves were generated by means of five blowers located at the one end of a wind-wave tunnel. The blowers were arranged in parallel, each with a 5,000 ft³/min design capacity. The wind-wave tunnel is 11½ feet wide, 2½ feet deep and 60 feet long with its downstream end being connected to an open channel of the same width, but 32 feet long. The tunnel and the channel were both constructed in a corner of the 65 feet by 150 feet by 2½ feet deep wave basin. Wave absorbers were placed all around the basin so that wave reflection was eliminated for all practical purposes (Fig. 3).

Four wave gages in a star-shaped array (Mobarek and Wiegel, 1967) are shown in Fig. 4, and were used to measure the incident waves in front of the breakwater, before the installation of breakwater, in two positions - A and B. Each gage is a parallel wire resistance type made up of two half-round stainless steel wires glued together by an epoxy which has a high electrical resistance.

Also, four wave gages were used to measure the diffracted wave, each gage made of two parallel wires spaced one inch apart. The location of the wave gages are shown in Fig. 4.

Two commercially available four-channel rectilinear writing oscillographs and "Hydra", an electronic digitizer with an 8-channel magnetic tape recorder, were used to record simultaneously the outputs from the wave gages.

A moveable 2 feet by $11\frac{1}{2}$ feet vertical and impervious double-arm breakwater was built. The breakwater was designed in such a way that the size of the gap could be changed (Fig. 5).

EXPERIMENTAL PROCEDURE

Experimental data were taken for two different water depths and for three different wind speeds. Diffracted wave records were obtained for different gap values. The procedure for each run was as follows:

1. The water in the basin was set to the required depth.
2. The breakwater was lifted out of the water.
3. The Sanborn recorder connected to the incident wave gages was balanced.
4. The Sanborn recorder and Hydra were calibrated.
5. A demagnetized tape of 200 density was placed on the Hydra.
6. The required number of blowers were started and allowed to run until equilibrium was achieved.
7. The Sanborn recorders and Hydra were then switched on for a period of 24 seconds.
8. The recorders were switched off and the incident gages were lifted out and disconnected from Hydra.
9. The diffraction wave gages were connected to the recorders and Hydra, and the recorders and Hydra were balanced.
10. The recorders and Hydra were calibrated again.
11. The breakwater gap was set to the required value.
12. The required number of blowers were started and allowed to reach equilibrium.
13. The breakwater was lowered into the proper position very fast (Figs. 6, 7, 8).

FIG. 6: PHOTO SHOWING INCIDENT WIND GENERATED WAVES, BREAKWATER IN PLACE.

FIG. 8: PHOTO SHOWING INCIDENT AND DIFFRACTED WIND GENERATED WAVES.

FIG. 5: MODEL BREAKWATER WITH A GAP

FIG. 7: PHOTO SHOWING DIFFRACTED WIND GENERATED WAVES.

14. The recorders and Hydra were started again for 12 seconds (10 seconds after lowering the breakwater gap).
15. Hydra, recorder and blowers were turned off.

RECORD LENGTH, NYQUIST FREQUENCY,
AND CONFIDENCE INTERVAL

Hydra has eight channels; wave gage #1 was connected to channels 1 and 5, wave gage #2 connected to channels 2 and 6, etc. The complete cycle from channel 1 back to 1 took 0.012 seconds. The data used in the analysis were averages of each pair of two measurements, that is, the output from gage #1 on channel 1 and channel 5 were averaged, etc., which resulted in a "smoothing" of the data. The averaging was done as the work of Fan (1968) indicated that it was appropriate to do so.

For the experiment considered herein (incident waves)

$n = 1998$ (total number of data points)

$T_n = 24$ sec (total effective record length)

$\Delta t = 0.012$ (the sampling interval [sec])

and the Nyquist frequency, $F_N = 1/2 \Delta t = 1/2 \times 0.012 = 41.2$ cps. From previous experiments it was found that there was little energy in the wave spectra for large frequency waves; the highest frequency considered in the analysis was taken as 30.

Blackman and Tukey (1958) give the relationships among the number of equivalent degrees of freedom (K), the number of lags (m), the lag interval ($\Delta\tau$), the length of record ($n\Delta t$) and the resolution (R) as

$$R = 1/m\Delta\tau = 1/T_m \text{ cycles per second}$$

$$K = 2 \left[\frac{T_n}{T_m} - \frac{P_d}{3} \right]$$

$$= 2 \left[\frac{T_n}{T_m} - \frac{1}{3} \right] \text{ for one piece of record}$$

where:

$\Delta\tau = h\Delta t =$ lag interval, seconds ($h = 1$ for this case)

$T_m = m\Delta\tau =$ maximum lag, seconds

$P_d =$ number of separate pieces of record = 1 for our case.

For this experiment, $T_m = 0.6$ sec., $R = 1.66$, and $K = 79.4$.

For calculating the confidence limit, a graph in the report of Borgman (1967) was used. For $K = 79.4$, $\hat{S}(f)$ will exceed $1.42 S(f)$ in only 5% of the samples measured, and will be greater than $0.76 S(f)$ in 95% of the samples measured, where $\hat{S}(f)$ is an estimate of $S(f)$.

DATA REDUCTION

After the water surface elevations at constant intervals were recorded on magnetic tape by Hydra, the calibration records were printed out using the computer program developed for this purpose (Raissi and Wiegel, 1971). This program tabulates the time histories of the water surface elevation from a datum.

The tabulated values of the calibration records were then used as a scale to convert the time history records of the wave to a time history of water surface elevation measured in feet from still water level.

Data were obtained for the following conditions:

TABLE 1. INCIDENT WAVE CONDITIONS

Run No.	No. of Blowers Turned On	Depths of the Water (feet)	No. of Data Points per Gage	Position (Fig. 2)
1	2	1.2	1998	A

12	5	0.72	1998	A

TABLE 2. DIFFRACTED WAVE CONDITIONS

Run No.	No. of Blowers Turned On	No. of Data Points per Gage	x (feet)	y (feet)	D Gap Size (feet)	Water Depth (feet)
1	2	856	2.45	5.5	1.56	1.2
2	3	856	2.45	5.5	1.56	1.2
3	2	856	2.45	5.5	1.87	1.2
4	3	856	2.45	5.5	1.87	1.2
5	2	856	2.45	5.5	2.18	1.2
6	3	856	2.45	5.5	2.18	1.2
7	2	856	2.45	5.5	2.50	1.2
8	3	856	2.45	5.5	2.50	1.2
9	2	856	2.45	5.5	3.00	1.2
10	3	856	2.45	5.5	3.00	1.2

The data for these conditions were recorded on magnetic tapes No. 4941 and 5957, respectively, which are presently stored at the Computer Center and at the Hydraulic Engineering Laboratory, University of California, Berkeley, California, 94720.

RESULTS AND DISCUSSION

The incident energy spectra were computed for each of the records, and also the directional spectra using the computer programs WAVEIN and TRANSFORM (Raissi and Wiegel, 1971). Then, from the directional spectra the diffracted energy spectra were computed using the computer program GAPDIFF (Raissi and Wiegel, 1971).

Also, from the measured diffracted waves records, the diffracted energy spectra were computed using the computer program DFSPEC (Raissi and Wiegel, 1971). Finally, the predicted energy spectra were plotted against frequency.

A few samples of predicted and measured wave spectra behind the breakwater gap are shown in Figs. 9a through 9t.

The results of the predicted wave spectra appear to be smaller than the measured values. Considering the results of Wiegel, Al-Kazily, and Raissi (1971), which shows good agreement between the highest calculated points of the predicted spectra with its equivalent value on the measured spectra, for a single-arm breakwater, together with the experimental results of diffraction coefficient for a gap by Blue and Johnson (1948), the following conclusions can be made:

- (a) For the case: $B = 1.56$ ft. (gap size); $L = 1.56$ ft.
(wave length with highest energy spectral density; $B/L = 1.0$.)

FIG. 9a: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR B=1.56 FT.

FIG. 9b: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR B=1.56 FT.

FIG. 9c: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR B=1.56 FT.

FIG. 9d: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR B=1.56 FT.

FIG. 9e: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR $B=2.18$ FT.

FIG. 9f: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR $B=2.18$ FT.

FIG. 9g: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR $B=2.18$ FT.

FIG. 9h: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR $B=2.18$ FT.

FIG. 9f: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR B = 2.50 FT.

FIG. 9g: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR B = 2.50 FT.

FIG. 9h: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR B = 2.50 FT.

FIG. 9i: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR B = 2.50 FT.

FIG. 9m: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR $B=3.00$ FT.

FIG. 9n: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR $B=3.00$ FT.

FIG. 9o: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR $B=3.00$ FT.

FIG. 9p: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR $B=3.00$ FT.

FIG. 9q: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR $B=1.56$ FT.

FIG. 9r: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR $B=1.56$ FT.

FIG. 9s: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR $B=1.56$ FT.

FIG. 9t: COMPARISON OF MEASURED AND PREDICTED POWER SPECTRA FOR $B=1.56$ FT.

The Penny and Price theoretical solution does not meet the exact boundary conditions along the breakwater, and the main difference between the measured power spectra and the predicted one (the ratio M.P.S/P.P.S. is as high as 2 for some cases) is mainly due to the poor results of Penny and Price theory for this particular condition ($B/L = 1$). The Morse-Rubenstein diffraction theory would be more accurate for small gaps (California Institute of Technology, 1952).

- (b) For the case: $B = 2.18$ ft. (gap size); $L = 1.56$ ft.
(wave with highest energy spectral density); $B/L = 1.4$.

The experimental results verify the predicted values of diffracted wave power spectra. Blue and Johnson obtained good results for the above conditions for regular waves.

- (c) For the cases, $B = 2.50$ ft.; $L = 1.56$; $B/L = 1.6$; and $B = 3.00$;
 $L = 1.56$; $B/L = 1.92$.

The experimental results of power spectra for diffracted wave seem to be higher than the predicted one. This difference was also obtained by Blue and Johnson. They found in areas not very close to the center line (where the wave recording gages of this experiment were located), there is a distinct tendency for experimental values of K' (the diffraction coefficient) to exceed the theoretical ones. This might be due to the increased curvature of the wave crests in the regions of steepest waves which cause greater outward flow of the wave energy from the center line than indicated by the theory. This results in decreased K' values near the gap center line and increase in K' quantities towards the flanks.

In the case of steeper incident waves (wave generated with higher wind velocity) and larger breakwater gap, the tendency of the wave energy to flow outward from the centerline is more, causing greater difference between theoretical K' and the experimental one (experimental results verify it).

For discussion regarding the techniques of measuring directional spectra of incident wave which has been used in this paper, the reader is referred to Wiegel, Al-Kazily, and Raissi (1971).

ACKNOWLEDGMENT

The work presented herein was performed under contract DACW 72-68-C-0016 between the Coastal Engineering Research Center Corps of Engineers, U. S. Army, and the University of California.

CHAPTER 35

DIFFRACTION DIAGRAMS FOR DIRECTIONAL RANDOM WAVES

Yoshimi Goda, Tomotsuka Takayama, and Yasumasa Suzuki

Marine Hydrodynamics Division, Port and Harbour Research Institute
Ministry of Transport, Nagase, Yokosuka, Japan

ABSTRACT

Conventional wave diffraction diagrams often yield erroneous estimation of wave heights behind breakwaters in the sea, because they are prepared for monochromatic waves while actual waves in the sea are random with directional spectral characteristics. A proposal is made for the standard form of directional wave spectrum on the basis of Mitsuyasu's formula for directional spreading function. A new set of diffraction diagrams have been constructed for random waves with the proposed directional spectrum. Problems of multi-diffraction and multi-reflection within a harbour can also be solved with serial applications of random wave diffraction.

INTRODUCTION

Since the proof by Penny and Price [1] that the diffraction of water waves by breakwaters can be analyzed with Sommerfeld's solution, wave heights behind breakwaters have been estimated with the aid of several diffraction diagrams [2~6]. The phenomenon of wave diffraction is a typical problem for which the solution of velocity potential can be applied with accuracy. Published as well as unpublished laboratory investigations have provided the proof of the validity of wave diffraction theory. Disagreement between the theory and experiment if any is usually attributed to inaccuracy in laboratory measurements. The only exception is the appearance of secondary waves around the tip of a breakwater owing to an excessive gradient of wave energy density there [7].

Such a success of theory, however, should be accepted with a caution when the theory is applied for sea waves characterized with irregularity. Most of diffraction diagrams currently available are those prepared for monochromatic waves with a single period from a single direction. The irregularity of sea waves especially of directional spreading produces the pattern of wave diffraction quite different from conventional diffraction diagrams. An experimental study by Mobarek and Wiegel [8] seems to be the first in demonstrating the application of directional wave spectrum to diffraction problems, though they did not present general diffraction diagrams for engineers' usage.

Being aware of these facts, Nagai [9,10] constructed diffraction diagrams for sea waves in 1972, which have been utilized by harbour engineers in Japan. Figure 1 is one of his diagrams, which shows the diffraction diagram for sinusoidal (monochromatic) waves in the left half and that for spectral waves in the right half for the opening width

of five times the wavelength; the difference between them is very clear. The directional wave spectrum employed for computation was of SWOP type [11], which is primarily for wind waves. In the present paper, recalculation is made of diffraction diagrams of random waves with a new proposal of directional wave spectrum, which is a modification of the spectrum originally formulated by Mitsuyasu et al. [12]. Though these diagrams were previously published in Japanese [13], slight corrections have been found necessary and they are duly corrected hereon. The present paper also discusses the behaviour of waves reflected by breakwaters, which can be deduced from Sommerfeld's solution as proved by one of the authors [14]. With the above knowledge, the problem of multi-diffraction and multi-reflection within a harbour can be solved numerically.

SPECTRAL CALCULATION OF WAVE DIFFRACTION

Random waves in the sea are described with a directional wave spectrum under the presumption that random wave profiles are the result of linear superposition of infinite number of infinitesimal wavelets with various frequencies and directions. According to this presumption, the spectrum of diffracted waves at a point (x,y) is calculated as

$$S_d(f|x,y) = \int_{\theta_{\min}}^{\theta_{\max}} S_i(f,\theta) K_d^2(f,\theta|x,y) d\theta, \quad (1)$$

where $S_i(f,\theta)$ denotes the directional spectrum of incident waves and $K_d(f,\theta|x,y)$ is the diffraction coefficient at a point (x,y) for waves with the frequency f and the direction θ . The spectrum of diffracted waves is given here in the form of frequency spectrum only, because the directional spreading of diffracted waves is limited by the aperture of the breakwater gap looked from the point (x,y) .

The representative heights of incident and diffracted waves are derived from the zeroth moment of spectrum by the theory of Longuet-Higgins [15]. For example, the significant heights are given by

$$(H_{1/3})_i = 4.0\sqrt{(m_0)_i}, \quad (2)$$

$$(H_{1/3})_d = 4.0\sqrt{(m_0)_d}, \quad (3)$$

where,

$$(m_0)_i = \int_0^{\infty} \int_{\theta_{\min}}^{\theta_{\max}} S_i(f,\theta) d\theta df, \quad (4)$$

$$(m_0)_d = \int_0^{\infty} S_d(f) df. \quad (5)$$

Though the constant of 4.0 in Eqs. 2 and 3 is better replaced by that of 3.8 for waves observed in the sea on the average, it does not affect the coefficient of diffraction for random waves, which is defined as

$$(K_d)_{\text{eff}} = (H_{1/3})_d / (H_{1/3})_i = \sqrt{(m_0)_d / (m_0)_i}. \quad (6)$$

The representative periods of diffracted waves are not necessarily the same with those of incident waves. The change of wave period by diffraction can be estimated by the theory of Rice [16] as

$$K_{dT} = \sqrt{\frac{(m_0)_d / (m_2)_d}{(m_0)_i / (m_2)_i}} \quad (7)$$

where,

$$(m_2)_d = \int_0^{\infty} f^2 S_d(f) df \quad (8)$$

$$(m_2)_i = \int_0^{\infty} \int_{\theta_{\min}}^{\theta_{\max}} f^2 S_i(f, \theta) d\theta df \quad (9)$$

The effect of the wave spectrum upon diffraction coefficient is demonstrated in Fig. 2, which shows the diffraction diagrams of a breakwater gap with the relative opening of $B = 3L$ for oblique incident waves with the angle of approach of 60° . The diffraction coefficient is calculated with the approximate method by superposition of Sommerfeld's solutions for two semi-infinite breakwaters. The upper diagram is for monochromatic waves and uni-directional irregular waves (with frequency spectrum only). The difference between them is small, thus indicating unimportance of frequency-wise irregularity. The lower diagram is for uni-frequency random waves with directional spreading and very random waves with a directional spectrum, which corresponds to the case of $S_{\max} = 10$ to be discussed in the next chapter. The difference between them is small, but the both are quite different from those in the upper diagram. Thus, Fig. 2 indicates that the directional spreading rather than the frequency-wise irregularity is important in the diffraction of random waves.

PROPOSAL OF DIRECTIONAL WAVE SPECTRUM

Functional Form

The directional wave spectrum is generally expressed as the product of a frequency spectrum $S(f)$ and a directional spreading function $G(f, \theta)$, that is,

$$S(f, \theta) = S(f) G(f, \theta) \quad (10)$$

The frequency spectrum $S(f)$ is given the unit of $m^2 \cdot \text{sec}$ or its equivalent one, while $G(f, \theta)$ is normalized so as to yield the unit value without a dimension when integrated over the full range of wave direction.

The functional form of $S(f)$ can be taken as Bretschneider's spectrum [17] modified by Mitsuyasu [18] to satisfy the condition of Eq. 2. Thus,

$$S(f) = 0.257 H_{1/3}^2 T_{1/3}^{-4} f^{-5} \exp[-1.03 (T_{1/3} f)^{-4}] \quad (11)$$

This is a type of two-parameter spectrum designated by an arbitrary combination of significant wave height and period, $H_{1/3}$ and $T_{1/3}$. The modal frequency or the frequency at spectral peak is set to satisfy the following relation:

$$f_p = \frac{1}{1.05 T_{1/3}} \quad (12)$$

This relation was proposed by Mitsuyasu [18] and has been confirmed to be representative of sea waves [19]. Spectral forms other than Eq. 11 are also eligible as the standard spectrum, but the change of frequency-wise spectral form will affect little the diffraction of random waves as suggested by Fig. 2.

As to the directional spreading function, the formula proposed by Mitsuyasu et al. [12] on the basis of their detailed observations seems most reliable at present. In a slightly modified form, it is written as

$$G(f, \theta) = G_0 \cos^{2S}(\frac{\theta}{2}), \quad (13)$$

where,

$$G_0 = \left[\int_{\theta_{\min}}^{\theta_{\max}} \cos^{2S}(\frac{\theta}{2}) d\theta \right]^{-1}, \quad (14)$$

$$S = \begin{cases} S_{\max} \cdot (f/f_p)^5 & : f \leq f_p, \\ S_{\max} \cdot (f/f_p)^{-2.5} & : f \geq f_p. \end{cases} \quad (15)$$

The term of G_0 is so introduced to normalize $G(f, \theta)$. The directional concentration parameter S has the maximum value at $f = f_p$ and decreases at the both sides of spectral peak.

Selection of S_{\max}

Figure 3 is a demonstration of wave patterns, which shows the contours of surface elevations above the mean water level; the portion of wave troughs is left as blank. This figure is a result of numerical simulation by the principle of linear superposition with the spectrum of Eqs. 10 to 15. The maximum directional concentration parameter S_{\max} is subjectively chosen as 10 and 75, respectively. It will be seen that $S_{\max} = 10$ yields the wave pattern quite random and somewhat resembling that of wind waves, while $S_{\max} = 75$ may corresponds to the wave pattern of swell.

The original proposal of Mitsuyasu et al. [12] for S_{\max} is to relate it with the nondimensional frequency parameter as

$$S_{\max} = 11.5 (2\pi f_p U/g)^{-2.5}, \quad (16)$$

where U denotes the wind speed and g is the acceleration of gravity. Equation 16 is not readily applicable for engineering problems because the design wave height and period are often designated without reference to the wind speed. The knowledge of wave growth depicted in the SMB method suggests that the increase of the parameter $2\pi f_p U/g (= U/C_p)$ is associated with the decrease in the wave steepness H_0/L_0 . Thus, S_{\max} can be assumed to increase as the wave steepness decreases. The assumption is supported by the example of Fig. 3 discussed in the above.

From the above discussions, the authors propose the following values of S_{\max} for engineering applications:

$$S_{\max} = \begin{cases} 10 & : \text{for wind waves,} \\ 25 & : \text{for swell with short to medium decay distance,} \\ 75 & : \text{for swell with medium to long decay distance.} \end{cases} \quad (17)$$

Though the above proposal is somewhat subjective, $S_{\max} = 10$ for wind waves is not without ground because it yields the overall directional distribution almost the same with the law of $(2/\pi)\cos^2\theta$ and the formula of SWOP. Figure 4 shows the nondimensional cumulative curves of wave energy calculated for the directional wave spectrum of Eqs. 10 to 15. The term of $P_E(\theta)$ is calculated by

$$P_E(\theta) = \frac{1}{m_0} \int_{-\pi/2}^{\theta} \int_0^{\infty} S(f, \theta) df d\theta. \quad (18)$$

The diagram can be utilized to allocate the relative wave energy to several wave directions such as expressed in sixteen points bearings. Calculation of $P_E(\theta)$ also yields the approximate relation of

$$\ell = 0.11 S_{\max} : \ell \geq 2, \quad (19)$$

for the type of $G(f, \theta)$ of the following:

$$G(f, \theta) \equiv G(\theta) = \frac{2\ell!!}{\pi(2\ell-1)!!} \cos^2\ell\theta, \quad (20)$$

where $2n!! = 2n \cdot (2n-2) \cdots 4 \cdot 2$ and $(2n-1)!! = (2n-1) \cdot (2n-3) \cdots 3 \cdot 1$.

When applying the above spectrum in shallow water, some correction to S_{\max} is necessary because the phenomenon of wave refraction makes the directional spreading to lessen. Calculation of wave refraction in the water of parallel straight bathymetry has yielded the diagram for the change of S_{\max} in shallow water as shown in Fig. 5. The angle $(\alpha_p)_0$ denotes the incident wave angle to the boundary of deep to shallow waters. As the effect of $(\alpha_p)_0$ is small, the diagram may be utilized for waters of general bathymetry.

RANDOM WAVE DIFFRACTION BY A SEMI-INFINITE BREAKWATER

With the directional wave spectrum specified in the above, the computation of random wave diffraction is straightforward so long as the value of diffraction coefficient for monochromatic waves corresponding to spectral components are computable. The integrals in Eqs. 1, 4, and others are to be evaluated in the form of finite series. The number of frequency components does not need to be great, but the number of directional components should be carefully selected in consideration of the trade-off between the accuracy and computation time. When the diffraction coefficient in the area far distant from the breakwater is to be calculated, a large number of directional components are required.

Examples of the diffraction diagrams of semi-infinite breakwater are shown in Fig. 6 for the case of normal incidence for waves with $S_{\max} = 10$ and 75. The diffraction coefficient of wave heights, or $(K_d)_{\text{eff}}$, is shown with contours of solid lines, while the ratio of wave period is shown with contours of dashed lines. A characteristic feature of Fig. 6 is that the diffraction coefficient takes the value of about 0.7 along the boundary of geometric shadow. This value is about 1.4 times the coefficient of monochromatic wave diffraction. In the sheltered area, the random wave diffraction yields the coefficient far larger than that of monochromatic waves.

An verification of the superiority of random diffraction analysis has been provided by Irie [20] with the wave data at Akita Port. Two wave recorders of inverted echo sounder type were set outside and inside a long breakwater as shown in Fig. 7, and the simultaneous observation was carried out in November and December, 1973. The principal direction of waves incident to the breakwater were read from the images of a radar with the wavelength of 8.6 mm, which is commonly employed in Japan for detection of wave direction since around 1962. During the period of observation, the principal wave direction varied in a narrow range of N85°W to N110°W and the direction of N106°W was employed in the calculation of diffraction coefficient. The result of analysis is summarized in Fig. 8. The observed data were classified by Irie into three categories of dispersive, median, and concentrated wave patterns as judged on the radar image. In the computation of random wave diffraction, the maximum directional concentration parameter of Eq. 17 was subjectively applied for these wave categories with the correction of shallow water effect by Fig. 5. Though the scatter of data makes difficult the assessment of the accuracy of random diffraction analysis, it yields quite reasonable estimates of wave heights behind the breakwater. The monochromatic wave analysis, on the other hand, yields the diffraction coefficient being one half to one quarter of the observed value, thus revealing its inapplicability to the problem of sea wave diffraction.

RANDOM WAVE DIFFRACTION THROUGH A GAP OF BREAKWATERS

Another example of the effectiveness of random diffraction analysis has been given by one of the authors [21]. Wave observation were carried out at three stations in Nagoya Port from 1967 to 1970, which is located at the recess of Ise Bay, Japan. As indicated on the inset of Fig. 9, the stations A and B were positioned outside and inside of a long mole of caisson type. The diffraction coefficient for monochromatic waves at the station B is plotted in this figure for predominant wave period of $T = 3$ sec. The waves diffracted from the east entrance penetrate to the station only when the incident wave direction is from SSSW to SSE, and the waves from the west entrance is appreciable for the incident direction of NW to WNW only. Thus the diffraction coefficient for monochromatic waves is very sensitive to the incident wave direction.

Observed wave records did not exhibit such a directionality, as shown in the example of Fig. 10, where the wave spectra at the stations A and B are compared. The wave direction is estimated as SW from the wind record. As the diffraction coefficient for monochromatic waves is about 0.07, the spectral density of the station B would have been about 1/200 of the density of the station A if the diffraction were to be calculated for monochromatic waves. The observed spectrum at B had the density of about 1/10 to 1/20 of the spectrum at A, and it was nearly in agreement with the spectrum calculated as the random wave diffraction phenomenon although the directional spreading function of $(2/\pi)\cos^2\theta$ was employed in the calculation for the sake of simplicity. The agreement of observed and calculated spectra is an evidence of the necessity of introducing random wave analysis in diffraction problems.

Figures 11 to 14 are the result of the computation of random wave diffraction with the directional spectrum described by Eqs. 10 to 15.

The left half of each diagram is for the change of wave period, while the right half is for the wave height ratio. The abscissa and ordinate are normalized with the opening width B instead of the wave length L . In applying these diagrams, appropriate selection of S_{\max} is to be made and interpolation of the diffraction coefficient from the diagrams for $S_{\max} = 10$ and 75 will be required.

COMBINATION OF WAVE REFLECTION AND DIFFRACTION

In the analysis of wave tranquility in a harbour, wave reflections from quaywalls and other solid structures often become the source of troubles. Breakwaters with vertical faces may also cause additional agitation in the area outside the breakwaters. The height of waves reflected by a semi-infinite rigid breakwater can be estimated by means of the well known Sommerfeld's solution. To illustrate the applicability of the solution, it is rewritten in the following form:

$$F_d(r, \alpha, f, \theta) = F_{id}(r, \alpha, f, \theta) + F_{rd}(r, \alpha, f, \theta) \quad (21)$$

where $F(r, \alpha, f, \theta)$ denotes the dimensionless complex wave amplitude at the point P with the distance r and the angle α from the tip of a semi-infinite breakwater for the incident wave with the frequency f and the direction θ (see Fig. 15). The complex amplitudes F_{id} and F_{rd} are expressed respectively as

$$\begin{aligned} F_{id} &= \frac{1}{\sqrt{2}} \exp[i\{kr \cos(\alpha - \theta) + \frac{\pi}{4}\}] \times [\{C(\gamma_1) + \frac{1}{2}\} - i\{S(\gamma_1) + \frac{1}{2}\}] \\ &= \exp[i\{kr \cos(\alpha - \theta)\}] \\ &\quad + \frac{1}{\sqrt{2}} \exp[i\{kr \cos(\alpha - \theta) + \frac{\pi}{4}\}] \times [\{C(\gamma_1) - \frac{1}{2}\} - i\{S(\gamma_1) - \frac{1}{2}\}], \end{aligned} \quad (22)$$

$$\begin{aligned} F_{rd} &= \frac{1}{\sqrt{2}} \exp[i\{kr \cos(\alpha + \theta) + \frac{\pi}{4}\}] \times [\{C(\gamma_2) + \frac{1}{2}\} - i\{S(\gamma_2) + \frac{1}{2}\}] \\ &= \exp[i\{kr \cos(\alpha + \theta)\}] \\ &\quad + \frac{1}{\sqrt{2}} \exp[i\{kr \cos(\alpha + \theta) + \frac{\pi}{4}\}] \times [\{C(\gamma_2) - \frac{1}{2}\} - i\{S(\gamma_2) - \frac{1}{2}\}], \end{aligned} \quad (23)$$

where,

$$\left. \begin{aligned} \gamma_1 &= \sqrt{\frac{4kr}{\pi}} \cos \frac{\alpha - \theta}{2}, \\ \gamma_2 &= \sqrt{\frac{4kr}{\pi}} \cos \frac{\alpha + \theta}{2}, \end{aligned} \right\} (24) \quad \left. \begin{aligned} C(\gamma) &= \int_0^\gamma \cos \frac{\pi}{2} x^2 dx, \\ S(\gamma) &= \int_0^\gamma \sin \frac{\pi}{2} x^2 dx. \end{aligned} \right\} (25)$$

In the derivation of the second expressions from the first ones of Eqs. 22 and 23, the following equality is employed:

$$\begin{aligned} \{C + \frac{1}{2}\} - i\{S + \frac{1}{2}\} &= [\{C - \frac{1}{2}\} - i\{S - \frac{1}{2}\}] + [1 - i] \\ &= [\{C - \frac{1}{2}\} - i\{S - \frac{1}{2}\}] + \sqrt{2} \exp[-i \frac{\pi}{4}]. \end{aligned} \quad (26)$$

As the distance r increases infinitely, the Fresnel integrals defined by Eq. 25 converge to the values listed in Table 1 depending on

the regions in question. Referring to Table 1, it will be readily understood that F_{id} represents the sum of the incident waves and the associated scattered waves, while F_{rd} represents the sum of the reflected waves and the associated scattered waves. Moreover, the primary reflected waves exist only in the region I, whereas the region III is primarily occupied by scattered waves.

Table 1. Behaviour of Fresnel Integrals at $r = \infty$

Region	$C(\gamma_1)$	$S(\gamma_1)$	$C(\gamma_2)$	$S(\gamma_2)$	Primary Waves
I	1/2	1/2	1/2	1/2	incident, reflected, and scattered waves
II	1/2	1/2	-1/2	-1/2	incident and scattered waves
III	-1/2	-1/2	-1/2	-1/2	scattered waves

The above decomposition of Sommerfeld's solution leads to the calculation of reflected waves by means of F_{rd} . If the reflective boundary is finite in its extension, the amplitudes of reflected waves can be approximately calculated by superimposing the two solutions of F_{rd} for the both tips of the reflective boundary as in the technique of calculating wave diffraction through a gap of two semi-infinite breakwaters. For a partially reflective boundary, the coefficient of wave reflection is introduced to linearly reduce the amplitudes of reflected waves. For example, wave pattern around a semi-infinite breakwater with partial wave reflectivity can be calculated by

$$F_d(r, \alpha, f, \theta) = F_{id}(r, \alpha, f, \theta) + K_r F_{rd}(r, \alpha, f, \theta), \quad (27)$$

where K_r denotes the reflection coefficient. Equation 27 remains as an approximation because K_r usually does not carry the information of phase relation except for the cases of $K_r = 1$ and 0.

An experimental verification of the above analysis [14] has been done for the layout of model breakwaters shown in Fig. 16. The breakwaters are made of vertical walls. Incident waves are diffracted by the right breakwater, but some of them are reflected by the rear face of the left breakwater. Experiments were carried out with uni-directional irregular waves, which had the significant height and period of $H_{1/3} = 1.8$ cm and $T_{1/3} = 1.08$ sec; their spectrum could be approximately expressed by Eq. 11. The result of measurements are shown in Fig. 17 for comparison with the theoretical calculation. Good agreement between them is observed except along the line of $x = 8$ m. The difference is due to an assumption employed in the calculation that the source area of wave reflection can be specified by the principle of geometric optics in order to simplify the procedure of calculation. The error due to such simplification is expected to decrease when the directional spreading characteristic of sea waves is introduced.

The analysis of the reflection of diffracted waves can be proceeded for much complicated harbour layout, even though the algorithm needs to be carefully established. Wave diffraction by overlapping breakwaters can also be solved with the knowledge of decomposed Sommerfeld's solution of Eqs. 21 to 23. An example of wave tranquility analysis for a complicated harbour layout is shown in Fig. 18, which represents

the Port of Yokohama in a slightly simplified form. Wind waves with the significant period of $T_{1/3} = 6.0$ sec are considered to come from the direction of SSE. The maximum directional concentration parameter of $S_{\max} = 10$ is employed in the computation. The specification of wave reflectivity of the boundaries is made somewhat subjectively in order to simplify the process of analysis of multi-reflection and multi-diffraction. Though the field data to verify the calculation is not available yet, Fig. 18 demonstrates the capacity of analyzing wave tranquility in a real harbour. It should be noted that the present analysis has no upper bound of application with regards to the size of harbour relative to wavelengths because of the nature of the theory of wave diffraction.

SUMMARY

The present paper has discussed the diffraction of sea waves with directional spectral characteristics. Major conclusions are as follows:

1. The inapplicability of diffraction analysis by monochromatic wave approach has been demonstrated by two examples of field observation data, which at the same time have proved the effectiveness of random diffraction analysis.
2. A standard form of directional wave spectrum is derived on the basis of the directional spreading function proposed by Mitsuyasu et al. Though the selection of directional concentration parameter is left to somewhat subjective judgement of engineers, it can deal with various stages of wind waves to swell.
3. Several diffraction diagrams are presented for a semi-infinite breakwaters and a breakwater gap for the case of normal incidence of directional random waves. The technique can be extended to the case of oblique incidence as well.
4. Sommerfeld's solution of diffracted wave amplitudes is decomposed into the terms of incident, reflected, and scattered waves. The decomposed solutions can be employed for analyzing the behaviour of waves reflected by rigid breakwaters and other reflective structures.
5. Wave tranquility in a harbour of large dimension can be analyzed by serial calculations of random wave diffraction and reflection.

It is mentioned here that the above technique of random wave diffraction analysis is daily utilized by harbour engineers in Japan with the aid of computer program operatable at the Computation Center of the Port and Harbour Research Institute, Ministry of Transport.

CHAPTER 36

INFLUENCE OF BREAKWATER-REFLECTION ON DIFFRACTION

by

Karl-Friedrich Daemrich and Sören Kohlhase

Franzius-Institut, Technical University of Hannover, Germany

ABSTRACT

Diffraction calculations for breakwaters are often based on SOMMERFELDS solution, which is mathematically exact for thin full-reflecting walls. For breakwaters with low reflecting front-sides, and if guidewalls are used, commonly a modified solution is applied, reducing the second term of the solution-formula proportional to the degree of reflection.

It could be shown that this approach is not sufficient in the region just behind the breakwater, especially for small angles of wave attack.

Regarding the exact solution for wedges it was possible to determine a special weighing factor for the second term of the SOMMERFELD solution, dependent on the degree of reflection and the wave direction, which leads to a better agreement between model tests and theoretical results.

INTRODUCTION

Within the scope of basic research on wave diffraction at harbour entrances with overlapping or displaced breakwaters [1] model tests with simple breakwater gaps and normal wave direction were performed, to get an impression on the comparability between theoretical results and wave heights measured in the hydraulic model.

The investigations were carried out in the wave basin of the SFB 79 (18.45 m) at the Franzius-Institut. The model-breakwaters were constructed of thin plates. Either a low reflecting rip-rap protection at the breakwater front-side, or a guidewall from the breakwater-tip to the wave generator was used, to diminish distortions by rereflected waves.

The theoretical results were calculated by the method of PENNEY and PRICE [3], who superimposed the mathematically exact solution of SOMMERFELD [4] to a solution for simple

breakwater gaps.

The SOMMERFELD solution is as follows (symbols see Fig. 1):

$$F(r, \theta) = f(\sigma) \cdot e^{-ikr \cdot \cos(\theta - \theta_0)} + f(\sigma') \cdot e^{-ikr \cdot \cos(\theta + \theta_0)}$$

with

$$\sigma = 2 \cdot \sqrt{\frac{k \cdot r}{\pi}} \cdot \sin\left(\frac{\theta - \theta_0}{2}\right)$$

$$\sigma' = -2 \cdot \sqrt{\frac{k \cdot r}{\pi}} \cdot \sin\left(\frac{\theta + \theta_0}{2}\right)$$

$$f(\sigma) = \frac{1+i}{2} \int_{-\infty}^{\sigma} e^{-i\pi t^2/2} dt$$

$$f(\sigma') = \frac{1+i}{2} \int_{-\infty}^{\sigma'} e^{-i\pi t^2/2} dt$$

(The modulus of $F(r, \theta)$ is equal to the diffraction coefficient K').

Fig. 1

Definition sketch for the SOMMERFELD solution

The solution is derived and valid for full reflecting breakwaters and cannot be used without restrictions in the case of low reflecting structures.

However, the formula consists of two terms, and because the second term includes the wave field reflected at the breakwater frontside, this term is usually related to the influence of reflection even in the region of diffraction.

As several authors (e.g. [5] , [6]) have suggested, the theoretical results were calculated with a modified formula with the second term reduced proportional to the degree of reflection. For the case, that guidewalls were used, consequently, the second term was neglected and the solution reduces to the so-called "simplified solution".

It shall be pointed out already here, that only the total solution fulfills the boundary condition exactly. If the second term is reduced or neglected the solution is not longer mathematically exact.

Fig. 2 shows exemplarily typical results for an opening width of two wavelenghts for the case, that guidewalls were used. Plotted are relative wave heights in lines parallel to the breakwater.

In the region just behind the breakwater typical differences between theoretical results and wave heights measured in the hydraulic model can be seen. The wave heights should be about zero theoretically, but they reach considerable values in the model. (Similar deviations were observed in the tests with a rip-rap-protected breakwater frontside).

These differences between theory and experiment have been the reason to deal more intensively with the diffraction theories under the special consideration of the influence of reflection.

SOLUTION FOR A BREAKWATER WITH GUIDEWALL

For the case, that guidewalls or wave splitters are used, an appropriate solution is available from the exact solution for semi-infinite vertical wedges.

MITSUI and MURAKAMI [2] have derived solutions for different wedge angles and all wave directions. For an example, the solution for a rectangular wedge is given (symbols acc. to Fig. 3):

$$F(\rho, \theta)_{\nu=\frac{3}{2}\pi} = \frac{4}{3} J_0(\rho) + \frac{8}{3} \sum_{n=1}^{\infty} e^{in\pi/3} \cdot J_{2n/3}(\rho) \cdot \cos^{\frac{2}{3}n\alpha} \cdot \cos^{\frac{2}{3}n\theta}$$

with

$J_0(\rho)$, $J_{2n/3}$ = BESSEL functions, first kind

$$\rho = k \cdot r = \frac{2\pi}{L} \cdot r$$

(The solution has to be halved for wave directions parallel to one wall)

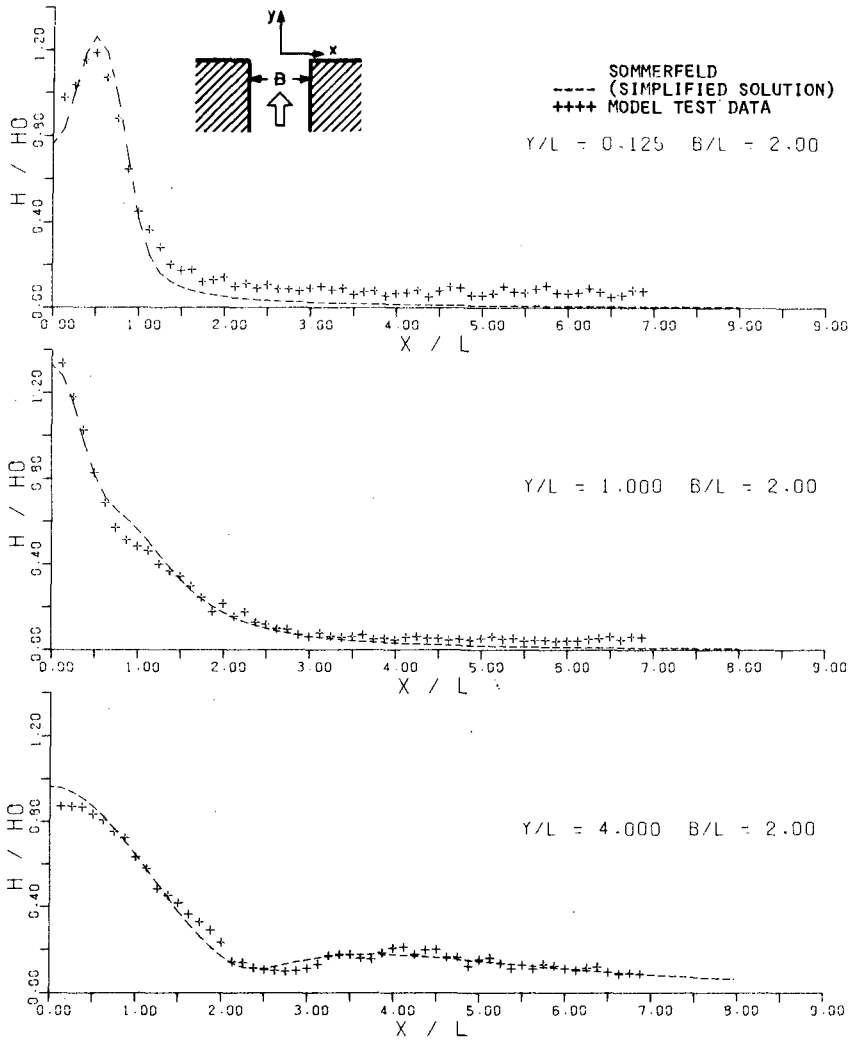

Fig. 2 Comparison of theoretical results with hydraulic model tests

Fig. 3
Definition sketch for
the MITSUI solution

Fig. 4 shows exemplarily the wave heights in the region of diffraction for perpendicular wave approach for different theories.

Fig. 4 Comparison of the diffraction coefficient K' for different theories

It can be seen, that the results according to the MITSUI solution are typically heigher than the results according to the simplified SOMMERFELD solution.

Furthermore, it can be seen that the MITSUI solution may be approximated by a modified SOMMERFELD solution. The difference between total solution and simplified solution corresponds to the influence of the second term of the SOMMERFELD solution and therefore a weighing of this second term may be a good approximation.

Fig. 5 gives a comparison of experimental results with results according to the MITSUI solution. The characteristic better agreement confirms the validity of this solution.

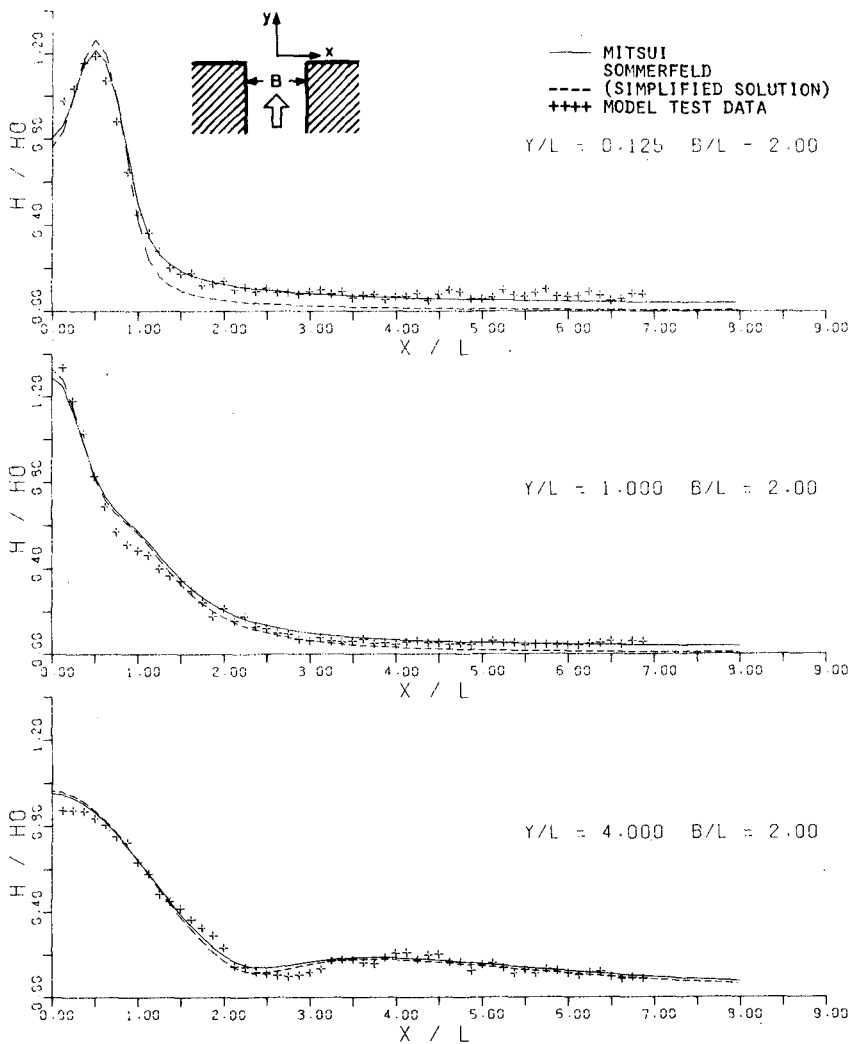

Fig. 5 Model tests in comparison with theoretical results

SOLUTION FOR A BREAKWATER WITH NON-REFLECTING FRONTSIDE

As a basis, the SOMMERFELD solution and the MITSUI solution were used for the theoretical considerations. For illustration, the SOMMERFELD solution shall be briefly discussed.

As mentioned before it consists of two terms. Each term represents a part of the wave field around the breakwater and can be divided mathematically into a straight-crested wavefield, according to the laws of geometrical optics, and a nearly circular scattered wave field. This wave fields, represented by their wave crests, are shown schematically in Fig. 6.

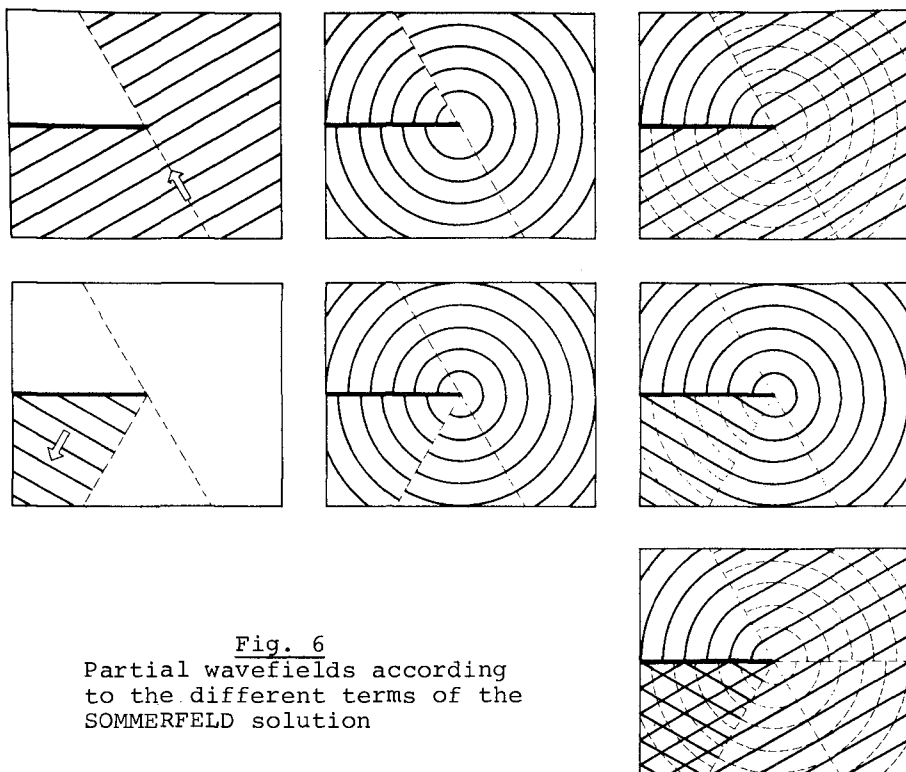

Fig. 6
Partial wavefields according
to the different terms of the
SOMMERFELD solution

The incoming wave field and the pertinent scattered wave field together are represented by the first term of the solution, the reflected wave field and the pertinent scattered wave field by the second term. The characteristics of the scattered wave fields are influenced as well by the boundary condition "breakwater" as by the distribution of the wave heights of the generating straight crested wave field in its geometric shadow line.

Going back to the problem and regarding the wave systems in the upper part of Fig. 6, which correspond to the first term of the SOMMERFELD solution, apparently this case is physically in accordance with the case of a non-reflecting breakwater. There are only incoming waves, together with a pertinent scattered wave system.

However, it must be noticed, that the two scattered wave systems of the two terms of the SOMMERFELD solution fulfill the boundary condition at the breakwater only combined. Each scattered wave field alone does not fulfill the boundary condition, except for a wave direction $\theta_0 = 180^\circ$.

In the following, a similar solution shall be derived for the condition, that the incoming waves are not reflected at the (non-reflecting) breakwater frontside, whilst the pertinent scattered wave system is in accordance to the boundary condition at an impermeable full-reflecting breakwater.

Exemplarily for a given wave direction three similar constellations shall be compared (Fig. 7)

- a non-reflecting thin breakwater according to the above definition, where a solution is searched for (Fig. 7a)
- a breakwater with wave direction parallel to the breakwater, where an exact solution exists, and no reflection can occur (Fig. 7b). (The SOMMERFELD solution has to be halved in this case)
- and a rectangular wedge with wave direction parallel to one wall, where also an exact solution, the MITSUI solution, is known (Fig. 7c)

Fig. 7 Wave crests for different breakwater constellations

By comparing the wave fields according to Fig. 7b and c it is possible to determine the alteration of the scattered wave field for the case that the wall \bar{AO} is moved towards the wall \bar{BO} , i.e. if we subtract the wave system at the right from the wave system in the middle we get a "difference scattered wave system", which represents the effect of the spreading or diffraction of the scattered wave field at the wedge into the region of the wedge.

In the same manner, as the solution for the case "wave direction parallel to the breakwater"(Fig. 7b) can be derived from the case "wedge" (Fig. 7c) by adding the difference scattered wave field to the scattered wave field at the wedge, it is possible to derive the searched solution for the non-reflecting breakwater (Fig. 7a) by adding a difference scattered wave field, representing the spreading of the scattered wave field into the region of the wedge at the line \overline{OB} .

From the fact that the wave heights of the scattered wave field in the line \overline{OB} are relatively exact one third of the corresponding wave heights in the line \overline{OA} , we can conclude, that the characteristic form of the difference scattered wave field is the same as mentioned before. The wave heights, however, are one third only for this special wedge angle.

In Fig. 8 the development and the wave height distribution of the difference scattered wave field is shown.

Fig. 8 Wave heights of the scattered waves according to the constellations b and c in Fig. 7, and pertinent "difference scattered wave" (exemplarily for $r = 3 \cdot L$)

In the upper part the wave heights of the both exact solutions are shown, in the lower part the difference scattered wave heights.

Fig. 9 shows finally the wave height distribution of the scattered wave field for the non-reflecting breakwater, and a remarkable difference can be seen in the region of diffraction in comparison to the up to now recommended simplified SOMMERFELD solution with neglected second term.

Fig. 9 Diffraction coefficient K' of the scattered wave for zero-reflection in comparison to results from the "simplified solution"

APPROXIMATE METHODS BASED ON THE SOLUTIONS OF MITSUI AND SOMMERFELD

The new solution for non-reflecting breakwaters is very similar to the corresponding solution of MITSUI in the region of diffraction. Therefore, the MITSUI solution for wedges with wave direction parallel to one wall can be used as a good approximation.

(The condition - "breakwater with guidewalls or wave splitters" - is equivalent to the condition - "breakwater with non-reflecting frontside" - in the region of diffraction, as it was assumed by different authors before).

Furthermore comparative calculations have shown, that the difficult solutions according to MITSUI can be approximated well in the region of diffraction, by an adequate modified SOMMERFELD solution, which needs only a half percent of the computer time. This modification consists in a weighing of

the second term of the SOMMERFELD solution depending on the wave direction θ_0 (Fig. 10).

Fig. 10 Weighing factor F_r for the second term of the SOMMERFELD solution for various degrees of reflection

The lowest line in Fig. 10 shows this weighing factor for zero-reflection as a function of the wave direction which has been determined by comparative calculations. It can be readily seen the difference to the up to now recommended method, taking this factor for zero for a non-reflecting breakwater without regarding the wave direction.

This modification, weighing the second term of the SOMMERFELD solution, has furthermore the advantage, that partial reflections can be considered easily by linear interpolation between the weighing factors for zero reflection and total reflection.

Finally, Fig. 11 shows a comparison of experimental results with rip-rap protected breakwater front-sides and theoretical results according to MITSUI and to this modified solution.

The weighing factor for the modified solution was chosen to 0.65 for a wave direction of 90° and a degree of reflection of approx. 10%. (The results of the MITSUI solution are given in addition for comparison only)

CONCLUSION

To consider the effect of a low-reflecting breakwater front-side on the wave heights in the diffraction area, it is usually recommended to reduce the second term of the SOMMERFELD solution proportional to the degree of reflection.

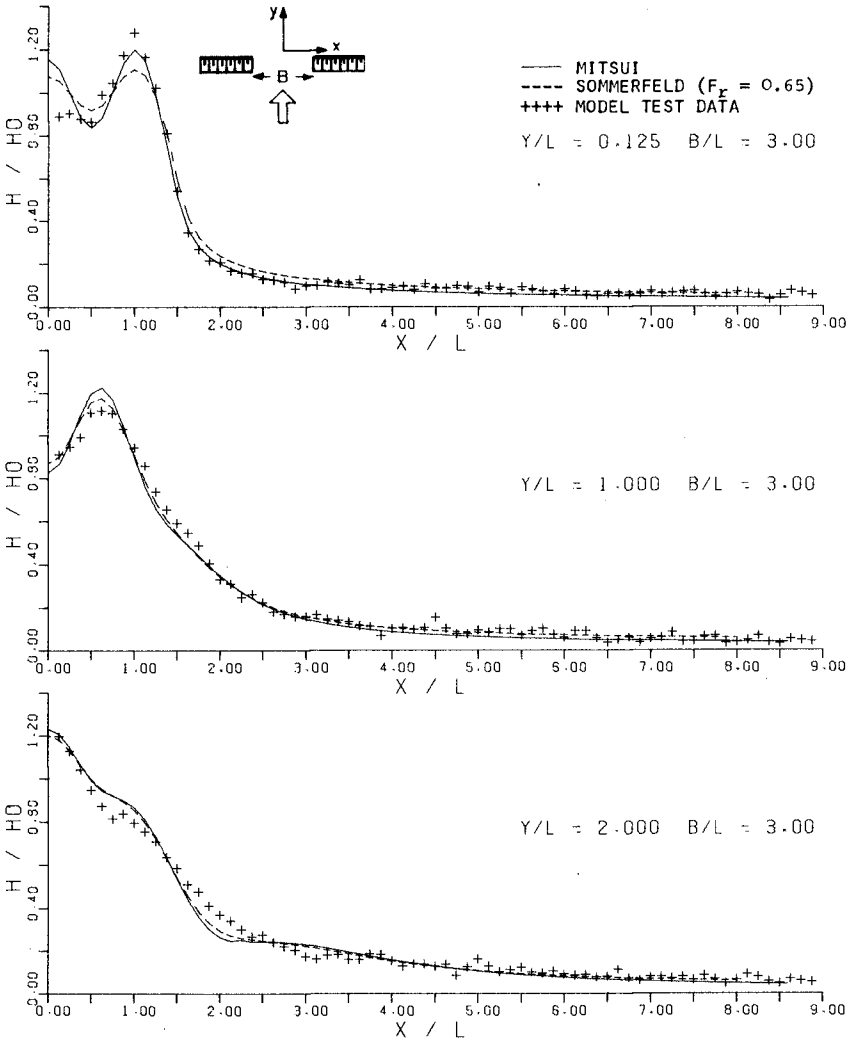

Fig. 11 Model tests in comparison with theoretical results

Within model tests with low-reflecting breakwaters and breakwaters with guidewalls, typical differences between this theoretical approach and the experimental results were observed, specially in the region just behind the breakwater.

It was shown, that the theoretical results according to the MITSUI solution and the developed solution for non-reflecting thin breakwaters are in a better agreement with the experimental results.

Although the commonly used theoretical approach is not acceptable in the region of diffraction just behind the breakwater, it can be used as an appropriate solution introducing a special weighing factor for the second term.

This weighing factor has to be determined with regard to the wave direction and the degree of reflection.

A diagramm with recommended weighing factors is presented (Fig. 10).

A NUMERICAL APPROACH FOR THE DETERMINATION
OF THE WAVE HEIGHT DISTRIBUTION IN A HARBOUR

by

S. Kohlhase, K.-F. Daemrich, U. Berger

E. Tautenhain, O. Burkhardt

Franzius-Institut, University of Hannover

ABSTRACT

The paper deals with a mathematical method to calculate wave heights in harbours caused by diffraction and reflection. Using the complete SOMMERFELD-solution for a semi-infinite breakwater, a linear superposition method is applied. The reflections of the harbour boundary are taken into account using a geometric mirroring principle.

The computer-programme allows the phase-correct superposition of any number of wave systems and, therefore, also the consideration of re-reflections which can be important in the presence of vertical walls. For the presentation of results (K'-lines) an interpolation-plot-programme is used.

The computer-programme has been applied to the harbour Greenville extension (Liberia) (BURKHARDT, 1977). Hydraulic model tests were performed to check the programmes, especially with respect to the influence of harbour reflections and the layout of the breakwater head.

INTRODUCTION

Hydraulic model tests are a reliable aid to investigate the wave height distribution in a harbour, but, with respect to scale effects, normally the model must get considerably large dimensions. The expenditure of construction and operation-time is often high because normally different wave directions have to be checked and the wave heights have to be measured in a narrow grid to allow an objective comparison of results for different wave and harbour-layout conditions.

Because of the simple geometric conditions of the Harbour of Greenville and to save costs a numerical model was used to investigate the wave height distribution in the harbour. The programmes adopted were developed within a special research project (SFB 79) of the GERMAN RESEARCH COUNCIL (DFG).

Fig. 1 shows a plan-view of the Harbour of Greenville which has been built in the 50th and which is now going to be extended. It is planned to elongate the existing breakwater

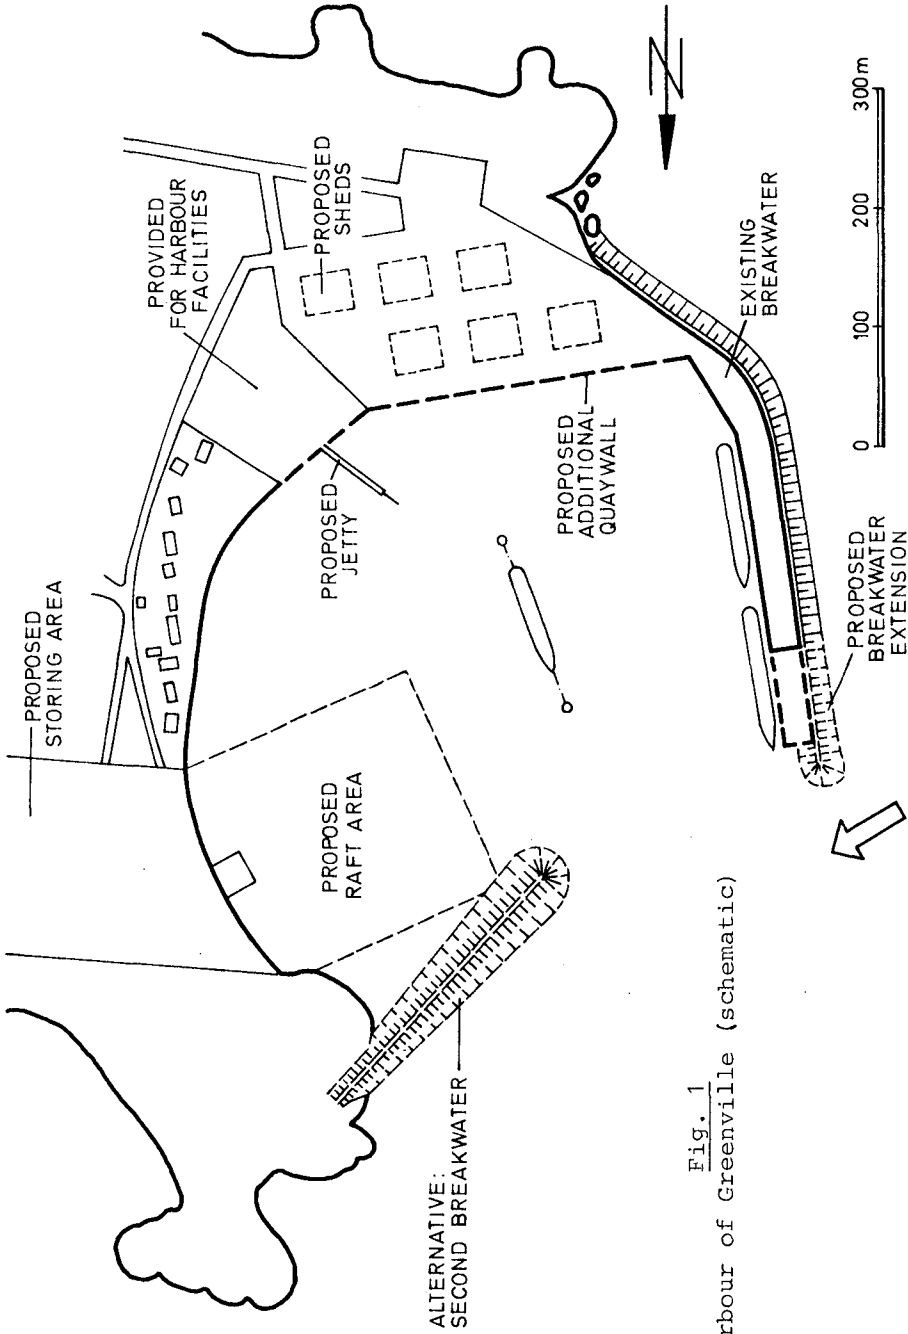

Fig. 1
Harbour of Greenville (schematic)

of the harbour to provide an additional cargo berth. The construction of a second breakwater is considered (RRI, 1976). The breakwater is built as a vertical wall with a rip-rap protected frontside. For the harbour boundaries different alternatives have been discussed.

The directions of the incoming waves are - of course - variable as well as wave heights and periods. The arrow corresponds approximately to the main wave direction.

PRINCIPLE OF CALCULATION

The numerical procedure is based on a simple geometrical mirroring which has been published already by CARR (1952) generally.

The principle of the method used is as follows (Fig. 2): The incoming waves are diffracted at the breakwater head. Diminished by diffraction the waves are propagating into the harbour area and will be reflected at the harbour boundaries.

The diffracted waves are superimposed by the reflected waves, which will be re-reflected at the harbour quays again.

To calculate the influence of reflection and re-reflection the harbour boundaries are idealized as a polygonal course of n elements.

Fig. 2
Explanation of
mirroring principle

According to the rules of the geometric optics the wave reflected at the boundary element $n = N$ can be seen as a diffraction wave starting from the geometric mirror point of the breakwater tip.

The consideration of a reflected wave as a diffraction wave is equivalent to the consideration of the reflecting boundary element as an opening, which implies, that additionally scattered wave systems will be formed at the joints to the neighbouring elements $N-1$ and $N+1$, which have to be superimposed to the other wave systems. These scattered waves provide for a balancing of wave height differences in the lines of geometric shadows.

The calculation of wave systems to be superimposed is based on the SOMMERFELD-solution of the diffraction at a semi-infinite breakwater. The solution-function is as follows (Fig. 3):

Fig. 3

Co-ordinate system and notations

$$F(r, \theta) = f(\sigma) \cdot e^{-ikr \cdot \cos(\theta - \theta_0)} + f(\sigma') \cdot e^{-ikr \cdot \cos(\theta + \theta_0)}$$

with

$$\sigma = 2 \sqrt{\frac{k \cdot r}{\pi}} \cdot \sin\left(\frac{\theta - \theta_0}{2}\right)$$

$$\sigma' = -2 \sqrt{\frac{k \cdot r}{\pi}} \cdot \sin\left(\frac{\theta + \theta_0}{2}\right)$$

$$f(\sigma) = \frac{1+i}{2} \int_{-\infty}^{\sigma} e^{-i\pi t^2/2} dt$$

$$f(\sigma') = \frac{1+i}{2} \int_{-\infty}^{\sigma'} e^{-i\pi t^2/2} dt$$

Details of calculation are outlined in DAEMRICH (1978) and BERGER (1976) respectively.

The programme allows the phase correct, linear superposition of any number of partial wave systems, but to save computer-time for the calculations of the Greenville harbour only 5 elements and not more than about 15 partial wave systems were used. The degrees of reflection, which must be determined before, are variable.

K'-values are calculated in a cartesian grid. For the graphic representation of the wave pattern a plot programme was used, which plots lines of constant K'-values by means of interpolation.

SOME RESULTS OF CALCULATION

Calculations have been carried out for different harbour configurations and wave conditions. But special results for the harbour of Greenville shall not be reported here, rather it shall be demonstrated in which way the resulting wave system is influenced by reflection and diffraction effects.

Fig. 4a shows the pure diffraction at the breakwater and - in this initial stage - reflections and higher order reflections were not considered. In the line of the geometric shadow the wave height is about 50 % of the incident wave height; the wave heights are decreasing rapidly in the area of the geometric shadow and are in the order of 10 to 20 % of the incident wave height.

The influence of reflection at the harbour boundaries is shown exemplarily in Fig. 4b. The degree of reflection was chosen constant with $K_R = 0.3$. Not considered are the additional scattered wave systems at the corners of the harbour boundaries caused by diffraction as outlined before. Also re-reflections at the harbour side of the breakwater have been neglected.

The comparison of the calculations given by the examples of Fig. 4 shows that the wave pattern - as was to be expected - will become very irregular even with small degrees of reflections. The wave heights become throughout higher within the harbour area. The influence of reflection reaches even into the area outside the geometric shadow line.

The influence of re-reflection at the breakwater can be seen exemplarily in Fig. 5.

REINE DIFFRAKTION

L=112m 230°

MSPIEG = 0 CASAB = 0,3 APPAB 6/13 = 0.0

L=112m 230°

Fig. 4

MSPIEG = 0 CASAB = 0.3 APPAB 6/13 = 0.0
L = 75m 230°

MSPIEG = 1 CASAB = 0.3 APPAB 6/13 = 0.0
L = 75m 230°

Fig. 5

On the left (Fig. 5a) the condition without re-reflection, on the right (Fig. 5b) with re-reflection is shown. The degree of reflection has been taken as $\kappa_R = 1.0$ at the breakwater. In other respects, the boundary conditions are the same on both Fig. 5a and Fig. 5b, i.e. same wave lengths and periods and uniform degrees of reflection at the harbour boundaries ($\kappa_R = 0.3$). Additionally occurring scattered waves are not considered.

The effect of re-reflected waves running back into the inner part of the harbour can be clearly seen. Lines of equal K' -values which are relatively smoothed in the left part of Fig. 5 are broken up more and more. This break up is specially marked in the breakwater area due to the geometrics of the harbour.

Only in exceptional cases comparable forms on the left and the right side of Fig. 5 can be found.

The influence of additional occurring scattered waves can be seen exemplarily from Fig. 6.

On the left we have an example without scattered waves caused at the boundary corners, on the right with scattered waves.

Differences of the wave height distribution can be seen quite well, although single forms of K' -lines can be found. As shown in the preceding Figures the consideration of any additional influence causes local increases of the wave heights in the harbour area.

Two more examples of the calculations may show qualitatively the significant influence of the wave parameters period and direction.

In Fig. 7 the wave-direction has been changed by 30° . In other respects the conditions are the same left (Fig. 7a) and right (Fig. 7b) and as well re-reflections at the breakwater as additional scattered waves were considered for calculations.

In this example it is nearly impossible to find again single forms of K' -lines just as in the example of Fig. 8 which shows the influence of the wave-length or period. It can be seen once more, how complicated the wave height distribution can be even in the case of a very simple harbour.

MSPiEG = 1 CASAB = 0,3
L = 112 m 230°

MSPiEG = 1 CASAB = 0,3 APPAB 6/13 = 0,0
L = 112 m 230°

CONCLUDING REMARKS

A numerical procedure to calculate the wave height distribution in a harbour is presented. The method has been applied to the harbour of Greenville. It has been tested using a schematic hydraulic model showing a fair agreement with the theoretical results. But some general restrictions of the method should be mentioned:

- The method requires a constant water depth and does not include refraction effects within the harbour. This simplification is often but not always permissible.
- The influence of the degree of reflection of the breakwater is considered but not the influence of the breakwater head. The design of the breakwater head can have an influence on the wave heights in the harbour, which - in certain cases - will not be negligible as shown by some comparative model investigations.
- The method allows the superposition of any number of wave systems but the computer time is increasing over-proportional with the number of harbour boundary elements, because of the necessary consideration of re-reflections and scattered waves.

Therefore, the number of elements should be restricted which includes some subjectivity and requires some experiences.

The main advantage of the method is its flexibility, i.e. wave directions, periods, degrees of reflection in connection with or structural changes of quays berth etc. can be varied in the model easily.

In this respect the numerical method can also be a good help to select the test conditions of a hydraulic model.

Finally some remarks on the performance of hydraulic model investigations should be given.

The calculations have shown, that the wave height distribution reacts sensitively on small modifications of the boundary conditions of the numerical model. A hydraulic model will do this too but this sensitivity is not always realized.

To compare the results of a hydraulic model fortuities of measurements must be excluded.

Measurements at a few fixed points in a threedimensional model are therefore useless for comparing purposes, because the position of nodal points of the wave oscillation is changing.

For the performance of hydraulic model test this signifies that the wave data have to be measured in a appropriate narrow grid, which is often ignored.

A COMPARISON BETWEEN MODEL AND PROTOTYPE WAVES IN HARBOURS

by Sverre Bjørdal¹ and Alf Tørum²

INTRODUCTION

A common method of estimating the sheltering effects of different breakwater locations and layouts is to carry out physical model wave disturbance tests. Such tests have been carried out in different laboratories throughout the world for many years. But to our knowledge no reports are available in the literature showing comparison between model measurements and field measurements.

The trend is that we know more and more on the wave climate along our coasts. Hence we have a better basis to make our economical calculations on breakwaters. We therefore also want to operate our models on a more absolute basis rather than on a comparative basis. The trend in recent years has also been to study breakwater locations and layouts in order to minimize mooring forces and ship movements.

On this background VHL found a comparison between model test results and field measurements necessary. Full scale measurements of waves were carried out in two harbours by VHL during the winter 1976/77. This paper will present the results of the comparison of the model and the full scale measurements in Berlevåg and Vardø fishing harbours on the open coast of Finnmark in the northern part of Norway (Fig. 1). The model tests, as well as the full scale measurements, have been sponsored by the Norwegian State Harbour Authorities.

BERLEVÅG FISHING HARBOUR

Model tests

In 1960-61 VHL carried out model tests on the breakwater layouts for Berlevåg fishing harbour, and in 1976 the construction of the chosen breakwater layout was completed (Fig. 2). The model tests were carried out in scale 1:110 and regular waves were used, as was usual in every laboratory at that time. Due to the use of regular waves, wave spectra could not be compared from model and field measurements. The input waves during the model tests were based on hindcast and refraction analysis, and the sheltering effects of the breakwaters against waves from N and ENE (deep water) were tested with periods corresponding to $T = 9$ sec and 13 sec. The height of the incoming waves were mostly 5 m but in some tests they were 3 m at the wave generator. The water level during the model tests were +2.5 m.

FIGURE 1.

FIGURE 2.

Fig. 3 shows some of the refraction analysis carried out for waves from directions E and ENE. It is seen that although differences in direction in deep water are large, the differences in direction in front of the breakwaters are only some few degrees.

Fig. 2 shows the model plan for Berlevåg harbour. The waves were mainly measured in the grid points, the distance between each point was approximately 100 m. Detailed measurements were carried out at lines A and B, which are in front of a proposed quay site. These measurements showed that the wave heights varied significantly within short distance and also with time in the model.

During the full scale measurements (see later) the position of the wave meters would vary depending on wave and wind conditions. Hence for the basis of comparisons of model tests and field measurements an average wave height of the grid points closest to the wave meter was used. The three field measurement points are shown in Fig. 2. Since the measurements were carried out in more detail in position 3 than in position 2, we consider the model values more accurate for position 3 than for position 2.

In Table 1 is shown the average wave heights for the different measuring points.

TABLE 1. Average wave heights in meters outside and inside Berlevåg harbour based on model tests.

Wave direction deep water	Wave period sec.	Water level m	Wave height position 1 m	Wave height position 2 m	Wave height position 3 m
ENE	9	+ 2.5	5	1.86	1.21
	9	+ 2.5	3		0.88
	13	+ 2.5	5		1.48
	13	+ 2.5	3		0.83

	9	+ 2.5	3		1.04
	13	+ 2.5	5		2.44
	13	+ 2.5	3		0.99

Field measurements

The wave measurements in Berlevåg harbour was carried out during the time period 20 October - 26 November 1976. Three wave gauges of the Datawell Waverider Buoy type were placed in the positions shown in Fig. 2. The wave meters have some freedom to move, and this is to

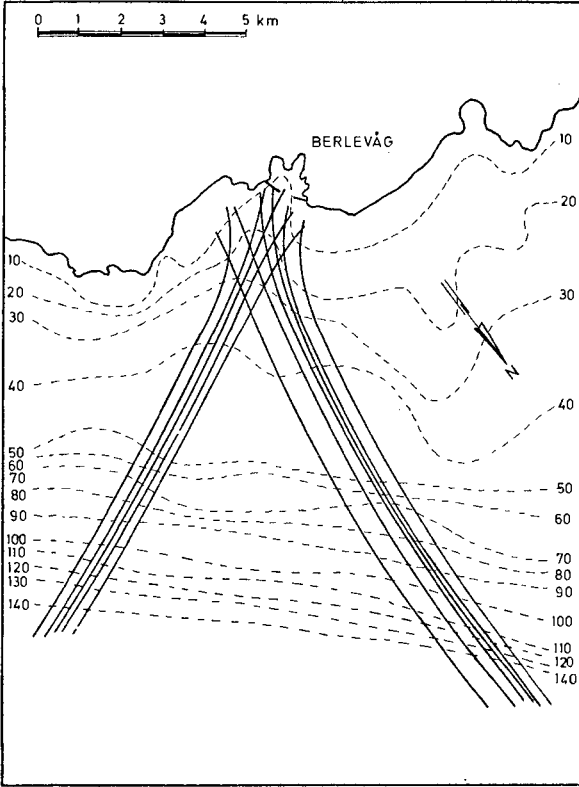

FIGURE 3. Refraction analysis. Wave period $T = 13$ s. Depth contours in meters.

FIGURE 4. Wave spectra at Berlevåg 21 October 1976 at 1000.

some extent considered when comparing the field and model data. The wave gauge outside the harbour was placed as close as possible to the reference point for wave measurements in the model and with due considerations to the navigation in the area.

The weather conditions during the measuring period was, however, good with very little waves for that time of the year.

The waves recorded on 21 October, 25-26 October and 24-25 November 1976 had maximum heights of approximately 4 m, and the waves from these days have been used in our comparison.

The waves were recorded on magnetic tape and the wave recordings were analysed by a computer program.

The wave analysis was based on 300 consecutive waves. A Fast Fourier Transform was used to calculate the wave spectra. 4096 data points were used. The time interval between each data point $\Delta t = 0.5$ s. 2048 components were calculated in the frequency range 0-1 Hz. The averaging was made over 41 components giving data points at frequency intervals $\Delta f = 0.02$ Hz. The 90% confidence interval for each spectral value is within 0.78-0.55 of the calculated value.

Figs. 4 and 5 show simultaneous wave spectra at the three stations.

The main wave directions were visually judged during the measurements. However, wave directions were also calculated by the Norwegian Meteorological Institute using a numerical hindcast model. The wave directions by this numerical model were calculated at grid points 150 km apart. The closest grid points to Berlevåg are shown in Fig. 1. The wave hindcast models give the wave direction in deep water. When considering the wave refraction from deep water to the harbour area, the visually observed wave directions corresponded fairly well to the hindcasted wave direction.

Table 2 shows results of the wave measurements in Berlevåg.

It is also interesting to notice the transfer of energy to higher frequencies of the wave spectrum as shown for position 2 in Fig. 4. The spectra of Fig. 4 are for easterly waves, while the ones in Fig. 5 are for more northerly waves. No significant transfer of energy to higher frequencies is observed for the spectra of Fig. 5.

The reason for the high frequency wave energy at position 2 in Fig. 4 is inferred to be due to waves breaking at the head of the western breakwater. In the breaking process, new short waves are generated. This is a case often observed in model.

$T_p = 1/f_p$; f_p = frequency of maximum energy density;

H_s = significant wave height.

Comparison of waves in the field and the model

Since the waves in the model were regular while the waves in the field are irregular and of different heights than in the model, it is not possible to compare directly the waves in the field and in the model. However, to compare we have defined a sheltering coefficient $K_d = H_h/H_i$, where H_h = wave height in the harbour and H_i = wave height outside the harbour. For irregular waves the significant wave height has been used. It should, however, be noted that the sheltering coefficient varies for different frequencies of the wave spectrum (see later).

In Table 3 is shown the sheltering coefficients from the field measurements and the model tests.

Generally speaking the calculated sheltering coefficients are smaller from the field measurements than from the model tests. This is especially the case for position 2. There may be different reasons for this that will be dealt with in the general discussion.

To obtain some feeling for how the sheltering coefficient varies with the frequency, we have calculated a transfer function for the waves defined as:

TABLE 3. Berlevåg - sheltering coefficients from field and model wave measurements.

	Position 1		Position 2		Position 3		Water level m	Calculated deep water wave direction
	H m	T _p sec	K _d	T _p sec	K _d	T _p sec		
Field H = H _s , T = T _p	2.09	10.0	0.35	4.5	0.16	8.5	+1	ENE
	2.09	8.5	0.40	4.5	0.16	8.5	+1.7	E
	2.17	10.0	0.21	10.0	0.16	10.0	+0.3	NNE
	2.54	10.0	0.20	10.0	0.15	10.0	+0.7	N
	1.56	7.0	0.167	7.0	0.17	7.0	+1.6	WNW
Model, regular H, T	5	9.0	0.41	-	0.24	-	+2.5	ENE
	3	9.0	-	-	0.29	-	+2.5	
	5	13.0	-	-	0.30	-	+2.5	
	3	13.0	-	-	0.28	-	+2.5	
	5	9.0	0.26	-	0.39	-	+2.5	
	3	9.0	-	-	0.35	-	+2.5	N
	5	13.0	-	-	0.49	-	+2.5	
	3	13.0	-	-	0.33	-	+2.5	

$$|T(f)| = \sqrt{\frac{E(f)_h}{E(f)_i}}$$

where $E(f)_h$ = power density spectrum within the harbour

$E(f)_i$ = power density spectrum outside the harbour.

This transfer function is very much used for linear systems.

The calculated transfer functions are shown in Figs. 6 and 7 for measuring stations positions 2 and 3. Apparently the sheltering effect is less for higher frequencies than for lower frequencies contradictory to linear theory. However, as pointed out during the description of the field measurements, there was apparently a transfer of wave energy to higher wave frequencies due probably to wave breaking around the breakwater head.

Thus the transfer functions rather reflect non-linearity effects than physical contradictions. It should also be noted that there is a larger uncertainty of the values of the transfer functions for the higher frequencies because of the rather small values the power density spectra have for the higher frequencies.

It is interesting to note that the transfer function for position 2 for 21 October shows a somewhat lower sheltering coefficient in the frequency range of the peak frequency (0.1-0.15 Hz) than obtained from the ratio of the significant wave heights shown in Table 3.

FIGURE 7. Berlevåg - Transfer functions. Postion 2.

DEPTH CONTOURS IN m.

FIGURE 8. Vardø harbour

The wave sheltering in Berlevåg is apparently better than indicated by the tests with regular waves. How much better is, however, difficult to assess.

VARDØ HARBOUR

Field measurements

The wave measurements at Vardø harbour were carried out prior to the model tests. Fig. 8 shows the area at Vardø harbour and Fig. 9 shows the model plan with depth contours and with the field measuring points.

Waves were measured in Vardø during the time period 1 March - 24 May 1977.

Outside the harbour waves were measured with a Datawell wave rider buoy. At the dock, within the harbour the waves were measured by a pressure type wave gauge. Individual waves are not so easily obtained by pressure wave gauges. However, the wave spectrum is fairly well measured by a pressure gauge, taking into account the wave pressure attenuation with depth.

The waves from the two gauges were recorded on magnetic tape. The wave analysis was based on 300 consecutive waves. The procedure for the spectral analysis was the same as for the waves measured in Berlevåg.

The significant wave heights from the Datawell wave rider buoy was calculated from the wave record, while the significant wave height from the pressure wave gauge was taken as $H_s = 4\sqrt{m_0}$, where m_0 = spectral area. Fig. 10 shows wave power spectra for some of the recorded waves.

Table 4 shows some of the results of the measured waves in Vardø. The wave directions in paranthesis are those calculated by the Norwegian Meteorological Institute, in deep water, while the others are those visually observed.

Model tests

The model tests for Vardø harbour were carried out to improve the wave conditions within the harbour. The model scale was 1:100. Fig. 9 shows the model plan for Vardø harbour with the breakwaters as they were built many decades ago and as they were during the field wave measurements.

Most wave energy will enter the harbour from the north. Hence this wave direction was chosen for the model tests.

Irregular waves were used during the tests. The wave generator had one straight flap. Hence the wave crests were straight when they left the wave generator.

**) Based on 1000 consecutive waves.

Different wave spectra were used for the model tests. Basically the peak frequencies of the model spectra corresponded to the wave periods $T_p = 5.7$ sec, 7.5 sec, 9.0 sec, 10.5 sec and 12 sec. All spectra were relatively narrow, except the spectrum with $T_p = 5.7$ sec. which was based on measured waves in Vardø. The significant wave heights close to the wave generator were in most tests 4.0 m, but for the wave spectrum with $T_p = 5.7$ sec the significant waves at the wave generator were close to the waves measured at Vardø.

In Table 5 is shown some of the wave parameters measured in the Vardø harbour model.

TABLE 5. Significant and maximum measured waves in the Vardø model

Wave direction	Water level m	Position 1			Position 2		
		H_s m	H_{max} m	T_p sec	H_s m	H_{max} m	T_p sec

N	+2.5	1.37	2.30	6.25	0.38	0.61	5.55

Comparison of waves in the field and in the model

Some of the model tests were carried out with waves corresponding to the waves measured in Vardø on 25 March 1977. These waves had rather short periods, and on model scale they were in the order of magnitude 0.5 sec and hence almost on the lower limit of the wave generator.

In Table 6 is shown the sheltering coefficient, $K_d = H_{ns}/H_{is}$, both for the field measurements and from the model tests.

TABLE 6. Vardø - Sheltering coefficient in the field and in the model.

	Position 1		Position 2		Water level m	Calculated deep water wave direction
	H_{is} m	T_p sec	K_d	T_p sec		
Model	1.20	6.25	0.23	5.55	+2.5	N
	1.19	6.25	0.25	5.55	+2.5	N
	1.49	6.25	0.23	5.55	+2.5	N
	1.37	6.25	0.28	5.55	+2.5	N
	2.12	6.25	0.33	5.55	+2.5	N
Field	1.20	6.25	0.31	7.1	+2.8	NW
	1.08	6.25	0.36	6.25	+2.8	NW
	1.51	7.1	0.27	7.1	+1.7	NE
	1.31	8.3	0.31	7.1	+1.8	NW
	1.41	8.3	0.35	8.3	+2.8	NW

Fig. 10 shows the wave spectra from the model and the field for the waves with peak period 6.25 sec.

The sheltering coefficients of Table 6 show that the sheltering is larger in the model than in the field.

Fig. 11 shows the transfer function for different wave conditions. The sheltering varies with the frequency, most for the field measurements. In the model the minimum sheltering is obtained for frequencies around the peak frequencies ($T = 5-8$ s). For higher and lower frequencies the sheltering effect is less. The full scale measurements show the same tendency, except for the highest and lowest frequencies, $T < 3$ s and $T > 10$ s. The field measurements within the harbour were carried out with a pressure type wave gauge. There are uncertainties in calculating high frequency waves from such measurements. This could be one reason for the apparent low sheltering at high frequencies. But it has also to be born in mind that transfer of energy from low to high frequencies has been observed due to breaking of waves at the breakwater heads.

The transfer functions show that the sheltering in the model is better than in the field for almost every frequency. Comparison of the sheltering coefficient based on the significant waves and the transfer function show that the sheltering coefficient is lowest for significant waves both in the model and in the field.

DISCUSSION

The results of the field and model measurements show that there are apparently discrepancies between the field and model measurements. The Berlevåg harbour measurements show that the sheltering is apparently less in the model than in the field, while the opposite is apparently the case in the Vardø harbour measurements. However, there could be different reasons for these apparent discrepancies.

Regular and irregular waves

In the Berlevåg harbour measurements the tests were carried out with regular waves, while in the field measurements the waves were irregular. This makes direct comparisons difficult. Special emphasis is made on the fact that there are some transformation of wave energy from lower to higher frequencies.

In the Vardø harbour tests the waves in both the field and the model were irregular.

Wave direction

The waves were unidirectional in the model at the wave generator flap. In the field the waves were multidirectional at the position of the wave flap. The directional spread at this position was probably, due to refraction effects, not as wide as in the open ocean. The directional spread in the ocean is not fully established yet, but $\cos^n \alpha$ is often used. α is the angular direction from the main direction, n is an exponent, a value of n of 2-4 is often used.

From the refraction analysis shown in Fig. 3 is inferred that although the waves may have almost 90° difference in direction in deep water, the difference in direction at the wave generator flaps is much less. There are, however, still a multidirectionality at the breakwater flap.

There is an uncertainty in the visually observed and hindcasted wave direction from the field measurements at the Berlevåg harbour. This uncertainty can certainly contribute to the discrepancy between the model and the field measurements.

At the Vardø harbour we assume that the main direction of the waves from deep water northerly direction will be from north at the wave generator flap also. The orientation of the flap is such that maximum wave energy will enter into the harbour from that direction. Although we have no wave directional spectrum at the wave generator, there will be some directionality at this place, in the field. However, we believe that the wave direction in the model and the lack of wave directionality in the model is such that we would have relatively higher waves in the model than in the harbour, while the measurements show the opposite.

Another effect that was observed during the model tests was that there was a tendency of cross waves in front of the flap, generated by the flap. These cross waves had a rather short wave period. To what extent the model results are affected by these crossoscillations are not known. However, it is believed that the effect is small.

Another effect that is present at Vardø is a strong refraction effect due to the rather deep "trench" towards the harbour entrance. This effect was particularly observed in the model tests. Also, the depth contours were not true in the vicinity of the wave generator, where the depth corresponded to approximately 40 m along the whole length of the generator. In front of the ends of the generator, the rate of decrease of water depth was larger in the model than in the field to obtain the true depth. This has an effect on the waves, although it is not possible to quantify this effect.

Reflections

There could certainly be different shore and structural wave reflection effects in the field and in the model causing differences in model and field measurements. Different field boundary and gravel shores were tested in the Vardø model, but no significant effects from the different shores were observed. Hence it is inferred that reflection was probably no major cause for differences in the field and model results.

Viscous scale effects

Viscous effects on the wave propagation and wave variation is present both in the field and the model. We have calculated the viscous damping effect in the model using the "Stokes shear wave theory". Over a length with constant water depth the wave damping due to viscous effects is [1]:

$$\frac{H}{H_0} = e^{-\alpha x}$$

where

$$\alpha = \frac{a \cdot 4\pi}{\beta L^2 (\sinh kd + kd)}$$

a = empirical coefficient

d = water depth

$$\beta = \left(\frac{\omega}{2\nu}\right)^{\frac{1}{2}}; \quad \omega = 2\pi/T$$

ν = the water kinematic viscosity

x = wave travel distance

Assuming a water depth of 0.25 m, the average depth in the model from the wave generator to the breakwater, a distance of 9 m, the damping along this distance due to viscous effects is only approximately 2% for a wave with period 0.6 s. If we assume a water depth of 0.05 m, the wave height reduction due to viscous effects is approximately 12% for the same wave period, 0.6 s.

Although there are some effects from viscosity in the model, this effect is almost negligible in our comparisons of field and model wave measurements.

CONCLUSIONS

Although there is a fair agreement between field and model measured waves, it is doubtful if we can use the results from harbour sheltering tests on breakwater layouts on an absolute basis. It is though believed that we will obtain very useful information from such tests on a relative basis.

To improve our model testing technique to obtain information on a more absolute basis, we have to improve our knowledge of field waves, particularly directional wave spectra, especially in shallow water, and general wave climates. We have also to improve our testing equipment. The first basins with directional wave spectra generators have appeared and we need to have a development to use such spectra also for harbour sheltering models.

ACKNOWLEDGEMENTS

We appreciate highly the interest and financial support of the Norwegian State Harbour Authorities who made this study and paper possible.

CHAPTER 39

WAVE HEIGHT DISTRIBUTION AROUND PERMEABLE BREAKWATERS

by

Shintaro Hotta*

ABSTRACT

By superimposing solutions due to Sommerfeld, a calculation was made to obtain the wave height distribution around permeable breakwaters in a constant water depth. The cases dealt with were a semi-infinite breakwater, a single relatively large gap in a long breakwater and a single detached breakwater all with incident waves normal to the breakwater. Some cases were verified through experiments in a shallow water basin.

INTRODUCTION

There are many kinds of permeable breakwater systems. In particular, as a countermeasure against beach erosion, the construction of permeable detached breakwater systems has become widely popular. However, the functioning of such breakwater systems has not yet been fully understood.

Even the wave height distribution around a permeable breakwater, which should be first considered in its construction, has received little effort not in comparison with that made for impermeable breakwater systems, because of the complicated phenomena associated with the former.

Up to data, interest in connection with permeable breakwaters has mainly concentrated on wave reflection and transmission phenomena. Only for some special cases in three dimensions has the study of the wave height distribution and related problems already been carried out. For instance, Ijima, Chou and Yumula(1974) studied the scattering of waves around arbitrary shape permeable bodies and gave figures for the wave height distributions around circular, ellipsoid and rectangular cells. Their methods are applicable to arbitrary shape breakwaters, but it seems that the method requires complicated numerical calculations. The studies above may not give satisfaction to engineers who are faced with problems in practice.

* Research Associate, Dept. of Civil Engineering Tokyo Metropolitan University, Setagaya-ku, Tokyo, JAPAN

The purpose of this study is to attempt to clarify the wave height distribution around permeable breakwater systems. However the phenomena are so complicated that applying Sommerfeld's solution for widely deployed breakwater systems was considered as a first stage in the study.

An advantage of the method used in this study, superposition of Sommerfeld's solution, is that wave heights can be calculated very easily by addition and subtraction, if we have the Fresnel Integrals. At present, even on small computers, Fresnel Integrals are prepared as a subroutine or as a function. A few second calculation gives the wave height distribution. Another advantage is that the time lag of waves transmitted through the breakwater can be easily considered in equations, although this was not done here.

Disadvantages of this method are that the boundary conditions are not satisfied and the wave height becomes discontinuous on the x and y axis and on the lines which divide the regions considered. Calculated results, however, show that the discontinuity in wave height on the x and y axis and the otehr lines was small. So, we may close our eyes to this discontinuity. Experimental or field verification of the calculated results are not yet sufficient, but this method may be acceptable for engineering use to predict the wave height roughly, although further laboratory and field verification under various conditions must still be made.

Brief Summary of Sommerfeld's Solution:

For the case of an infinitely thin, vertical, rigid, impermeable, semi-infinite breakwater as drawn in Fig. 1, Penny and Price have shown that Sommerfeld's solution of the optical diffraction problem is also a solution of water wave diffraction.

Fig. 2. Signs of u_1 and u_2

Fig. 1. Nomenclature for wave diffraction analysis at semi-infinite breakwater end.

The following is a brief summary of the solution by Penny and Price(1952).

$$\phi = A e^{ikz} \cosh kh \cdot F(x, y) \dots\dots\dots (1)$$

$$\eta = \frac{A k z}{g} e^{ikz} \cosh kh \cdot F(x, y) \dots\dots\dots (2)$$

$$\frac{\partial^2 F}{\partial x^2} + \frac{\partial^2 F}{\partial y^2} + k^2 F = 0 \dots\dots\dots (3)$$

$$f(u) = \frac{1}{\sqrt{2}} e^{i\pi/4} \int_{-\infty}^{u_1} e^{i\pi w^2/2} dw \dots\dots\dots (6)$$

$$g(u_2) = \frac{1}{\sqrt{2}} e^{i\pi/4} \int_{-\infty}^{u_2} e^{i\pi w^2/2} dw \dots\dots\dots (7)$$

where

$$i = \sqrt{-1} \quad k = 2\pi/L$$

L = wave length c = phase velocity

h = water depth g = gravity acceleration

$$f(u) = g(u) = \frac{1}{\sqrt{2}} e^{i\pi/4} \int_{-\infty}^u e^{i\pi w^2/2} dw$$

$$= \frac{1}{2} \{ (1 + C(u) + S(u)) + i(C(u) - S(u)) \} \dots\dots (8)$$

$$f(-u) = g(-u) = \frac{1}{\sqrt{2}} e^{i\pi/4} \int_{-\infty}^{-u} e^{i\pi w^2/2} dw$$

$$= \frac{1}{2} \{ (1 - C(u) - S(u)) + i(S(u) - C(u)) \}$$

$$= S + iW \dots\dots\dots (9)$$

$$F(x, y) = \frac{1}{\sqrt{2}} e^{i\pi/4} \int_{-\infty}^{u_1} e^{i\pi w^2/2} dw$$

$$+ \frac{1}{\sqrt{2}} e^{i\pi/4} \int_{-\infty}^{u_2} e^{i\pi w^2/2} dw$$

$$= e^{i\pi/4} f(u_1) + e^{i\pi/4} g(u_2) \dots\dots\dots (4)$$

$$C(u) = \int_0^u \cos \frac{\pi}{2} w^2 dw, \quad S(u) = \int_0^u \sin \frac{\pi}{2} w^2 dw \dots\dots (10)$$

$$u_1 = \pm \sqrt{\frac{4(r-y)}{L}}, \quad u_2 = \pm \sqrt{\frac{4(r+y)}{L}} \dots\dots\dots (5)$$

$$r = \sqrt{x^2 + y^2}$$

$$S = \frac{1}{2} \{ 1 - C(u) - S(u) \}$$

$$W = \frac{1}{2} \{ S(u) - C(u) \} \dots\dots\dots (11)$$

The diffraction coefficient, K, is defined as the ratio of wave height in the area affected by diffraction to the wave height in the area unaffected by diffraction, and given by the modulus of F(x, y) for the diffracted wave: taht is

$$K = |F(x, y)| = \sqrt{R^2 + I^2} \dots\dots\dots (12)$$

R: Real component of F(x, y)

I: Imaginary component of F(x, y)

The final forms of $F(x, y)$ for numerical calculation for a breakwater located on the + x axis as shown in Fig. 1 are:

Region A, $x > 0, y > 0$

$$\begin{aligned}
 F_0^A(x, y) &= e^{-iky} f(-u_1) + e^{iky} g(-u_2) \\
 &= (S_1 + S_2) \cos ky + (W_1 - W_2) \sin ky \\
 &\quad + i[(W_1 + W_2) \cos ky + (-S_1 + S_2) \sin ky] \text{-----} (13)
 \end{aligned}$$

Region B, $x < 0,$

$$\begin{aligned}
 F_0^B(x, y) &= e^{-iky} f(u_1) + e^{iky} g(-u_2) \\
 &= (1 - S_1 + S_2) \cos ky + (-W_1 - W_2) \sin ky \\
 &\quad + i[(-W_1 + W_2) \cos ky + (-1 + S_1 + S_2) \sin ky] \text{-----} (14)
 \end{aligned}$$

Region C, $x > 0, y < 0$

$$\begin{aligned}
 F_0^C(x, y) &= e^{-iky} f(u_1) + e^{iky} g(u_2) \\
 &= (2 - S_1 - S_2) \cos ky + (-W_1 + W_2) \sin ky \\
 &\quad + i[(-W_1 - W_2) \cos ky + (S_1 - S_2) \sin ky] \text{-----} (15)
 \end{aligned}$$

As a matter of convenience later, we shall give the final forms of $F(x, y)$ for numerical calculation for a breakwater located on the - x axis as shown in Fig. 3.

Fig. 3. Nomenclature for wave diffraction analysis at breakwater when located on -x axis.

Region A and C

$$\begin{aligned}
 F_i^A(x,y) &= e^{-iky} f(u_1) + e^{iky} g(-u_2) \\

 &= (S_1 + S_2) \cos ky + (W_1 - W_2) \sin ky \\
 &\quad + i [(W_1 + W_2) \cos ky + (-S_1 + S_2) \sin ky] \text{-----} (17)
 \end{aligned}$$

Region B2

$$\begin{aligned}
 F_i^{B2}(x,y) &= e^{-iky} f(u_1) + e^{iky} g(u_2) \\
 &= (2 - S_1 - S_2) \cos ky + (-W_1 + W_2) \sin ky \\
 &\quad + i [(-W_1 - W_2) \cos ky + (S_1 - S_2) \sin ky] \text{-----} (18)
 \end{aligned}$$

NUMERICAL CALCULATIONS OF WAVE HEIGHT DISTRIBUTION
FOR PERMEABLE BREAKWATER

- (1). A single small gap in a long permeable breakwater as shown in Fig. 4.

The heights of waves which have passed through a single gap small compared with the wave length of a long impermeable breakwater have been already given by Lamb (1945).

Fig. 4. Diffraction at small gap

The solution is:

$$F_a(x, y) = \frac{\sqrt{\frac{L}{4r}}}{\left(\log \frac{kb}{4} + \gamma + \frac{\pi}{2}i\right)} e^{-i\left(\frac{\pi}{4} + kr\right)} \dots\dots\dots (19)$$

γ : Constant of Euler

$$F_b = \alpha e^{-ky} \dots\dots\dots (20)$$

This equation shows a wave which concentrically spreads from a gap. When the breakwater is permeable we assume that the wave heights inside the breakwater can be express of by superimposing Equations (19) and (20). That is:

$$F = F_a + F_b$$

$$= \alpha e^{-ky} + \frac{\sqrt{\frac{L}{4r}}}{\left(\log \frac{kb}{4} + \gamma + \frac{\pi}{2}i\right)} e^{-i\left(\frac{\pi}{4} + kr\right)}$$

The superimposed result is:

$$F = \alpha \cos ky + \frac{\sqrt{\frac{L}{4r}} \sqrt{C_r^2 + C_i^2}}{2kr} \cos\left(\frac{\pi}{4} + kr - \theta\right) - i \left\{ \alpha \sin ky + \frac{\sqrt{\frac{L}{4r}} \sqrt{C_r^2 + C_i^2}}{2kr} \sin\left(\frac{\pi}{4} + kr - \theta\right) \right\} \dots\dots\dots (21)$$

where

$$C_r = \frac{\log \frac{kb}{4} + \gamma}{\left(\log \frac{kb}{4} + \gamma\right)^2 + \frac{\pi^2}{4}}$$

$$C_i = \frac{-\frac{\pi}{2}}{\left(\log \frac{kb}{4} + \gamma\right)^2 + \frac{\pi^2}{4}}$$

$$\theta = \tan^{-1} \frac{C_i}{C_r}$$

The wave heights are given by:

$$R = \alpha \cos ky + \frac{\sqrt{\frac{L}{4r}} \sqrt{C_r^2 + C_i^2}}{2kr} \cos\left(\frac{\pi}{4} + kr - \theta\right)$$

$$I = - \left\{ \alpha \sin ky + \frac{\sqrt{\frac{L}{4r}} \sqrt{C_r^2 + C_i^2}}{2kr} \sin\left(\frac{\pi}{4} + kr - \theta\right) \right\}$$

$$K = \sqrt{R^2 + I^2}$$

Diagrams for a gap width b, b/L ratios of 0.1 and 0.2 and transmission coefficients, α , from 0.1 to 0.5 are given in Appendix 1.

(2) A semi-infinite permeable breakwater

For the waves on the shore side of the breakwater, regions A and B1 ($y > 0$) as shown Fig 5-(3), superposition of waves as shown in Fig 5-(1) and the waves as shown in Fig 5-(2) is assumed.

On the other hand, for the waves on the offshore side of the permeable breakwater, regions B2 and C ($y < 0$), it is assumed that the waves can be expressed by where the reflection coefficient, β , multiplies a free wave propagating in the $-y$ direction, e^{iky} .

$$e^{-iky}f(u_1) + \beta e^{iky}g(u_2) \text{-----(22)}$$

Equations based on those assumptions in their final forms are:

Region A $x > 0, y > 0$

$$F_0(x, y) = e^{iky}f(-u_1) + e^{iy}g(-u_2)$$

$$F_1(x, y) = e^{iky}f(u_1) + e^{iy}g(-u_2)$$

$$F = F_0 + \alpha F_1$$

$$F_2^A = \{\alpha + (1-\alpha)S_1 + (1+\alpha)S_2\} \cos ky + \{(1-\alpha)W_1 - (1+\alpha)W_2\} \sin ky + i\{(1-\alpha)W_1 + (1+\alpha)W_2\} \cos ky - \{\alpha + (1-\alpha)S_1 - (1+\alpha)S_2\} \sin ky \text{-----(23)}$$

Fig. 5. Superposition of waves for semiinfinite permeable breakwater.

Region B₁ $x < 0, y > 0$

$$F_0(x, y) = e^{-ky}f(u_1) + e^{ky}g(-u_2)$$

$$F_1(x, y) = e^{-ky}f(-u_1) + e^{ky}g(-u_2)$$

$$F = F_0 + \alpha F_1$$

$$F_2^{B_1} = (1 - (1 - \alpha)S_1 + (1 + \alpha)S_2) \cos ky + \{- (1 - \alpha)W_1 - (1 + \alpha)W_2\} \sin ky + i \{ \{- (1 - \alpha)W_1 + (1 + \alpha)W_2\} \cos ky - [1 - (1 - \alpha)S_1 - (1 + \alpha)S_2] \sin ky \} \quad \text{----- (24)}$$

Region B₂ $x < 0, y < 0$

$$F = e^{-ky}f(u) + \rho e^{ky}g(-u_2)$$

$$F_2^{B_2} = (1 - S_1 + \rho S_2) \cos ky + (-W_1 - \rho W_2) \sin ky + i \{ \{- W_1 + \rho W_2\} \cos ky + [-1 + S_1 + \rho S_2] \sin ky \} \quad \text{----- (25)}$$

Region C $x > 0, y < 0$

$$F = e^{-ky}f(u_1) + \rho e^{ky}g(u_2)$$

$$F_2^C = (1 + \rho - S_1 - \rho S_2) \cos ky - (W_1 - \rho W_2) \sin ky - i \{ (1 - \rho - S_1 + \rho S_2) \sin ky + (W_1 + \rho W_2) \cos ky \} \quad \text{----- (26)}$$

$$\alpha + \rho = 1$$

$$S_1 = 1 - C(u_1) - S(u_1) \quad , \quad W_1 = C(u_1) - S(u_1)$$

$$S_2 = 1 - C(u_2) - S(u_2) \quad , \quad W_2 = C(u_2) - S(u_2)$$

where

$$C(u) = \int_0^u \cos \frac{\pi}{2} w^2 dw \quad , \quad S(u) = \int_0^u \sin \frac{\pi}{2} w^2 dw$$

If we ignore the energy loss when waves pass the breakwater, α the transmission coefficient plus β , the reflection coefficient equal unity. Taking α equal to zero, the final equations agree with the solution of a impermeable breakwater. However, if α is not zero, the waves becomes discontinuous on the x-axis. Calculated results with $\alpha = 0.0$ through $\alpha = 0.5$ are given in Appendix 2.

(3) A single relatively large gap in a long permeable breakwater.

For the case of an impermeable breakwater, Penny and Price(1952) have already given the solution by superimposing Eqs. (13), (14) and (15) and Eqs. (16), (17) and (18). Johnson(1952; 1953), Morihira and Okuyama(1966) and others have given detailed diagrams for engineering practice.

We shall write again here the final forms of the solution for numerical calculation because they will be needed the in succeeding sections. Suffixs r and l, indicating the cases when the breakwater is located at the + x and - x regions(Fig. 1 and Fig. 2), will be added.

The final forms are:

Region A1, $0 < x < b/2, y > 0$

$$\begin{aligned}
 F_3^{A1}(x,y) &= e^{-iky} f_r(u_1) + e^{iky} g_r(-u_2) + e^{-iky} f_l(u_1) + e^{iky} g_l(-u_2) - e^{-iky} \\
 &= (1 - S_{r1} - S_{l1} + S_{r2} + S_{l2}) \cos ky + (-W_{r1} - W_{l1} - W_{r2} - W_{l2}) \sin ky \\
 &\quad + i [(-W_{r1} - W_{l1} + W_{r2} + W_{l2}) \cos ky \\
 &\quad + (-1 + S_{r1} + S_{l1} + S_{r2} + S_{l2}) \sin ky] \text{ ----- (27)}
 \end{aligned}$$

Region A2, $b/2 < x, y > 0$

$$\begin{aligned}
 F_3^{A2}(x,y) &= e^{-iky} f_r(-u_1) + e^{iky} g_r(-u_2) + e^{-iky} f_l(u_1) + e^{iky} g_l(-u_2) - e^{-iky} \\
 &= (S_{r1} - S_{l1} + S_{r2} + S_{l2}) \cos ky + (W_{r1} - W_{l1} - W_{r2} - W_{l2}) \sin ky \\
 &\quad + i [(W_{r1} - W_{l1} + W_{r2} + W_{l2}) \cos ky \\
 &\quad + (-S_{r1} + S_{l1} + S_{r2} + S_{l2}) \sin ky] \text{ ----- (28)}
 \end{aligned}$$

Region C2, $x > b/2, y < 0$

$$\begin{aligned}
 F_3^{C2}(x,y) &= e^{-iky} f_r(u_1) + e^{iky} g_r(u_2) + e^{-iky} f_l(u_1) + e^{iky} g_l(-u_2) - e^{-iky} \\
 &= (2 - S_{r1} - S_{l1} - S_{r2} + S_{l2}) \cos ky + (-W_{r1} - W_{l1} + W_{r2} - W_{l2}) \sin ky \\
 &\quad + i [(-W_{r1} - W_{l1} - W_{r2} + W_{l2}) \cos ky \\
 &\quad + (S_{r1} + S_{l1} - S_{r2} + S_{l2}) \sin ky] \text{----- (29)}
 \end{aligned}$$

In the case of a permeable breakwater, the same idea described in the preceding section (2) is assumed. To express the waves on the shore side as show in Fig. 6-(4), the waves in Figs. 6-(2) and 6-(3) are superimposed on the waves as shown Fig. 6-(1). On the offshore side of the breakwater, a reflection coefficient, β , multiplies all terms, e^{iky} .

Fig. 6. Superposition of waves for a relatively large gap in permeable breakwater.

According to this assumption. The $F(x,y)$ which should be added to $F_3(x, y)$ because the breakwater is permeable are:

Region A1, $0 < x < b/2, y > 0$

$$F(x,y) = \alpha [e^{-iky} f_l(-u_1) + e^{iky} g_l(-u_2)] + \alpha [e^{-iky} f_r(-u_1) + e^{iky} g_r(-u_2)]$$

$$= \alpha [F_1^{Bl}(x,y) + F_0^A(x,y)] \text{ ----- (30)}$$

Region A2, $b/2 < x, y > 0$

$$F(x,y) = \alpha [e^{-iky} f_l(u_1) + e^{iky} g_l(-u_2)] + \alpha [e^{-iky} f_r(-u_1) + e^{iky} g_r(-u_2)]$$

$$= \alpha [F_1^A(x,y) + F_0^A(x,y)] \text{ ----- (31)}$$

We shall rewrite the function $F_0^A, F_1^A,$ and F_1^{Bl} , adding the suffixes, $r, l.$

$$F_0^A(x,y) = (S_{r1} + S_{r2}) \cos ky + (W_{r1} - W_{r2}) \sin ky$$

$$+ i [(W_{r1} + W_{r2}) \cos ky + (-S_{r1} + S_{r2}) \sin ky] \text{ ----- (14)'}$$

$$F_1^A(x,y) = (1 - S_{l1} + S_{l2}) \cos ky + (-W_{l1} - W_{l2}) \sin ky$$

$$+ i [(-W_{l1} + W_{l2}) \cos ky + (-1 + S_{l1} + S_{l2}) \sin ky] \text{ ----- (16)'}$$

$$F_1^{B1}(x, y) = (S_{\ell 1} + S_{\ell 2}) \cos ky + (W_{\ell 1} - W_{\ell 2}) \sin ky + i [(W_{\ell 1} + W_{\ell 2}) \cos ky + (-S_{\ell 1} + S_{\ell 2}) \sin ky] \text{-----}(17)'$$

Now, we shall consider the coordinate system. For Eq. (28), (29) and (27)

$$r_r = \sqrt{(x - b/2)^2 + y^2}$$

$$r_\ell = \sqrt{(x + b/2)^2 + y^2}$$

On the other hand, for Eq. (14)', (16)' and (17)'

$$r_\ell = \sqrt{(x - b/2)^2 + y^2}$$

$$r_r = \sqrt{(x + b/2)^2 + y^2}$$

If we exchange the suffixes r and ℓ in Eqs. (14)', (16)' and (17)' we can use the same coordinate system in Eqs. (28), (29), (27), (14)', (16)' and (17)'.

Finally, we have:

Region A1, $0 < x < b/2, y > 0$

$$F_{3p}^{A1}(x, y) = F_3^{A1}(x, y) + \alpha [F_1^{B1}(x, y) + F_0^A(x, y)]$$

$$= \{1 - (1 - \alpha)S_{r1} - (1 - \alpha)S_{\ell 1} + (1 + \alpha)S_{r2} + (1 + \alpha)S_{\ell 2}\} \cos ky$$

$$+ \{- (1 - \alpha)W_{r1} - (1 - \alpha)W_{\ell 1} - (1 + \alpha)W_{r2} - (1 + \alpha)W_{\ell 2}\} \sin ky$$

$$+ i \{[- (1 - \alpha)W_{r1} - (1 - \alpha)W_{\ell 1} + (1 + \alpha)W_{r2} + (1 + \alpha)W_{\ell 2}\} \cos ky$$

$$+ \{-1 + (1 - \alpha)S_{r1} + (1 - \alpha)S_{\ell 1} + (1 + \alpha)S_{r1} + (1 + \alpha)S_{\ell 2}\} \sin ky]$$

----- (32)

Region A2, $x > b/2, y > 0$

$$\begin{aligned}
 F_{3P}^{A2} &= F_3^{A2} + \alpha [F_1^A + F_0^A] \\
 &= \{ \alpha + (1-\alpha)S_{r1} - (1-\alpha)S_{l1} + (1+\alpha)S_{r2} + (1+\alpha)S_{l2} \} \cos ky \\
 &\quad + \{ (1-\alpha)W_{r1} - (1-\alpha)W_{l1} - (1+\alpha)W_{r2} - (1+\alpha)W_{l2} \} \sin ky \\
 &\quad + i [\{ (1-\alpha)W_{r1} - (1-\alpha)W_{l1} + (1+\alpha)W_{r2} + (1+\alpha)W_{l2} \} \cos ky \\
 &\quad + \{ -\alpha - (1-\alpha)S_{r1} + (1-\alpha)S_{l1} + (1+\alpha)S_{r2} + (1+\alpha)S_{l2} \} \sin ky] \\
 &\quad \text{----- (33)}
 \end{aligned}$$

Region C2, $x > b/2, y < 0$

$$\begin{aligned}
 F_{3P}^{C2} &= e^{-iky} f_r(u_1) + \beta e^{iky} g_r(u_2) + e^{-iky} f_l(u_1) + \beta e^{iky} g_l(-u_2) - e^{-iky} \\
 &= \{ 1 + \beta - S_{r1} - S_{l1} + \beta(-S_{r2} + S_{l2}) \} \cos ky \\
 &\quad + \{ -W_{r1} - W_{l1} + \beta(W_{r2} - W_{l2}) \} \sin ky \\
 &\quad + i [\{ -W_{r1} - W_{l1} + \beta(-W_{r2} + W_{l2}) \} \cos ky \\
 &\quad + \{ -1 + \beta + S_{r1} + S_{l1} + \beta(-S_{r2} + S_{l2}) \} \sin ky] \text{----- (34)}
 \end{aligned}$$

(4) A single impermeable detached breakwater.

For a single detached breakwater or an insular breakwater that allows waves to diffract around both ends as shown in Fig. 7, Morse and Rubenstein (1938) and Goda, Yoshimura, Ito (1971) developed an exact theory. Numerical calculations for the theory can be done in terms of Mathieu functions. Detailed figures for this have been prepared by Goda et al. (1971). However, if the length of the breakwater is relatively large compared with the wave length, it could be considered that the each end of the breakwater is the end of a semi-infinite breakwater.

The following are the final forms arrived at from this assumption. Detailed diagrams are not given here because of limited space. However, such diagrams may easily be reproduced from the equations.

Region A1, $0 < x < b/2, y > 0$

$$F_4^{A1} = (S_{r1} + S_{l1} + S_{r2} + S_{l2}) \cos ky + (W_{r1} + W_{l1} - W_{r2} - W_{l2}) \sin ky \\ + i[(W_{r1} + W_{l1} + W_{r2} + W_{l2}) \cos ky + (-S_{r1} - S_{l1} + S_{r2} + S_{l2}) \sin ky] \\ \text{----- (35)}$$

Region A2, $x > b/2, y > 0$

$$F_4^{A2} = (1 + S_{r1} - S_{l1} + S_{r2} + S_{l2}) \cos ky + (W_{r1} - W_{l1} - W_{r2} - W_{l2}) \sin ky \\ + i[(W_{r1} - W_{l1} + W_{r2} + W_{l2}) \cos ky + (-1 - S_{r1} + S_{l1} + S_{r2} + S_{l2}) \sin ky] \\ \text{----- (36)}$$

Region C1, $0 < x < b/2, y < 0$

$$F_4^{C1} = (2 - S_{r1} - S_{l1} - S_{r2} - S_{l2}) \cos ky + (-W_{r1} - W_{l1} + W_{r2} + W_{l2}) \sin ky \\ + i[(-W_{r1} - W_{l1} - W_{r2} - W_{l2}) \cos ky + (S_{r1} + S_{l1} - S_{r2} - S_{l2}) \sin ky] \\ \text{----- (37)}$$

Region C2, $x > b/2, y < 0$

$$F_4^{C2} = (1 - S_{r1} - S_{l1} - S_{r2} + S_{l2}) \cos ky + (-W_{r1} - W_{l1} + W_{r2} - W_{l2}) \sin ky \\ + i[(-W_{r1} - W_{l1} - W_{r2} + W_{l2}) \cos ky + (-1 + S_{r1} + S_{l1} - S_{r2} + S_{l2}) \sin ky] \\ \text{----- (38)}$$

When the breakwater is permeable. We assume that the wave in regions A and B ($y > 0$) are the superimposed waves arising from an impermeable breakwater as described above, and the waves multiplied by α passing through a gap as described in (3) [Fig. 8].

In region $y < 0$, the idea is the same in the proceeding sections.

Fig. 7. Diffraction around detached breakwater.

Fig. 8. Superposition of waves for permeable detached breakwater.

We again review the coordinate system.

In Eqs. (36), (37), (38) and (35)

$$r_{\ell} = \sqrt{(x - b/2)^2 + y^2} \qquad r_r = \sqrt{(x + b/2)^2 + y^2}$$

In Eqs. (27), (28) and (29)

$$r_{\ell} = \sqrt{(x + b/2)^2 + y^2} \qquad r_r = \sqrt{(x - b/2)^2 + y^2}$$

To use the same coordinate system, we must exchange the suffixes r and ℓ in Eqs. (27), (28) and (29). Exchanging suffixes r and ℓ in Eqs. (27) and (28) and adding Eq. (36) and Eq. (28) to Eq. (37).

We have finally:

$$\begin{aligned} F_5^{A1} &= F_4^{A1} + \alpha F_3^{A1} \\ &= \cos ky \{ \alpha + (1-\alpha)S_{r1} + (1-\alpha)S_{\ell1} + (1+\alpha)S_{r1} + (1+\alpha)S_{\ell2} \} \\ &\quad + \sin ky \{ (1-\alpha)W_{r1} + (1-\alpha)W_{\ell1} - (1+\alpha)W_{r2} - (1+\alpha)W_{\ell2} \} \\ &\quad + i [\cos ky \{ (1-\alpha)W_{r1} + (1-\alpha)W_{\ell1} + (1+\alpha)W_{r2} + (1+\alpha)W_{\ell2} \} \\ &\quad + \sin ky \{ -\alpha - (1-\alpha)S_{r1} - (1-\alpha)S_{\ell1} + (1+\alpha)S_{r2} + (1+\alpha)S_{\ell2} \}] \end{aligned} \tag{39}$$

$$\begin{aligned} F_5^{A2} &= F_4^{A2} + \alpha F_3^{A2} \\ &= \cos ky \{ 1 + (1-\alpha)S_{r1} - (1-\alpha)S_{\ell1} + (1+\alpha)S_{r2} + (1+\alpha)S_{\ell2} \} \\ &\quad + \sin ky \{ (1-\alpha)W_{r1} - (1-\alpha)W_{\ell1} - (1+\alpha)W_{r2} - (1+\alpha)W_{\ell2} \} \\ &\quad + i [\cos ky \{ (1-\alpha)W_{r1} - (1-\alpha)W_{\ell1} + (1+\alpha)W_{r2} + (1+\alpha)W_{\ell2} \} \\ &\quad + \sin ky \{ -1 - (1-\alpha)S_{r1} + (1-\alpha)S_{\ell1} + (1+\alpha)S_{r2} + (1+\alpha)S_{\ell2} \}] \end{aligned} \tag{40}$$

$$\begin{aligned}
 F_5^{c1} &= e^{-iky} f_r(u_1) + \beta e^{iky} g_r(u_2) + e^{-iky} f_l(u_1) + \beta e^{iky} g_l(u_2) - e^{-iky} - \beta e^{iky} \\
 &= \cos ky \{1 + \beta - S_{r1} - S_{l1} - \beta(S_{r2} + S_{l2})\} + \sin ky \{-W_{r1} - W_{l1} + \beta(W_{r2} + W_{l2})\} \\
 &\quad + i[\cos ky \{-W_{r1} - W_{l1} - \beta(W_{r2} + W_{l2})\} + \sin ky \{-1 + S_{r1} + S_{l1} + \beta(1 - S_{r2} - S_{l2})\}] \\
 &\quad \text{----- (41)}
 \end{aligned}$$

Preliminary experiments

Preliminary experiments were carried out in a small water basin 0.5 m deep, 1.0 m wide and 11 m long. Vertical homogeneous crib-style walls of 8 cm thickness filled with glass ball in diameter were used as the model breakwater.

Because of the limited basin width, standing waves appeared on the shore side of the breakwater and the results were not considered adequate for examining the theoretical development. The following are some general experimental results.

- (1) Eq. (21) is acceptable for situations where the ratio between the gap width and wave length is less than 0.2.
- (2) After the distance of one wave length, calculated diffraction patterns by Eqs. (23) and (24) were similar to the experimental patterns.
- (3) Wave heights at the gaps were not constant when the widths of gaps were less than one wave length.
- (4) Energy transmitted to the shore side region of the breakwater was proportional to the ratio of the gap width, to the wave length, within the range less than a ratio of 0.5.

CHAPTER 40

A COMBINED FE-BIE METHOD FOR WATER WAVES

by
A. HAUGUEL*

ABSTRACT

The finite element method and boundary integral equation method are general approximation processes applicable to a wide variety of engineering problems. After a brief description of the combined method, several examples are given for water waves problems : tides, harbour oscillations and waves diffraction and refraction.

INTRODUCTION

Most of the studies in coastal engineering are in relation with water waves coming from deep sea (tides, long and short waves). The difficulty is to take into account the influence of deep sea (infinite or supposed to be so) as exciting and receiving domain.

COMBINED FE-BIE METHOD

The assumption of simple harmonic linear waves yields elliptic partial differential equations. These equations may be solved by :

(i) the boundary integral equation method (BIE) based on Green's identity which leads, under certain conditions, to an integral equation relating the solution and its normal derivative on the boundary.

(ii) the finite element method (FE) in which the region is divided into a number of elements.

The first one is usefull for simple geometric domains because integral equations can be simpliflicated before integration. The second method is fitted for complex geometric domains owing to elements.

Many anthors (Zienkiewicz, Berkhoff, C.C.Mei...) have already described the combined method. So the purpose of this paper will be to present new results showing its advantages.

In few words, the infinite or semi-infinite domain is divided into two regions where each method is applied.

In the external region, where the water depth is assumed to be a constant, the solution will be a superposition of the incident wave and an outgoing wave which is due to the presence of an harbour or any obstacle. This outgoing wave will be represented by a superposition of waves coming from

* Division Hydraulique Maritime. Laboratoire National d'Hydraulique. Electricité de France. Chatou. France.

point sources at the boundary Γ between the sea and the area of interest and must satisfy the conditions at the other boundaries : full reflection on rigid walls and radiation condition of Sommerfeld at sea. So the solution in the external region can be written in the general form :

$$\alpha (f(P) - \psi(P)) = \int_{\Gamma} \frac{\partial G}{\partial n} (P, M) (f(M) - \psi(M)) dM - \int_{\Gamma} G (P, M) \frac{\partial}{\partial n} (f(M) - \psi(M)) dM \quad (1)$$

where

f is the total potential

ψ is the incident potential

G is the Green function of the problem.

The expression is also correct on the boundary Γ ($M \in \Gamma$) by taking the limit (only α changes).

The solution f must be continuous through the boundary with respect to wave height and phase.

So equation (1) can be interpreted as a boundary condition for the internal region.

In this one, the finite element procedure is possible by direct coupling of the solution f and its normal derivative on the common boundary Γ .

The system is solved only in the internal region but the influence of the external one is taken into account thanks to the boundary integral condition.

APPLICATIONS

Some examples of results from the combined FE-BIE method are briefly described here.

The tides in a semi-enclosed sea opened to a semi-infinite ocean are simulated using a linearized, vertically integrated, dissipative form of the Laplace Tidal Equation. A linear bottom friction is used. The tide is modelled by setting the tide-generating force terms to zero and specifying the free surface elevation to infinity as a Kelvin wave. So the equations can be written as follows :

$$-i\omega\eta + \frac{\partial}{\partial x} (h\mu) + \frac{\partial}{\partial y} (h\nu) = 0$$

$$-i\omega\mu + g \frac{\partial \eta}{\partial x} - \Omega\nu + \rho\mu = 0$$

$$-i\omega\nu + g \frac{\partial \eta}{\partial y} + \Omega\mu + \rho\nu = 0$$

where η , μ , ν are the complex amplitude of surface elevation and current components.

h is the mean water depth
 g is the gravity acceleration
 Ω is the Coriolis number
 ρ is the bottom friction coefficient
 ω is the tide pulsation.

These three equations can be transformed in one :

$$\frac{\partial}{\partial x} \left[h \left(A \frac{\partial \eta}{\partial x} + B \frac{\partial \eta}{\partial y} \right) \right] + \frac{\partial}{\partial y} \left[h \left(A \frac{\partial \eta}{\partial y} - B \frac{\partial \eta}{\partial x} \right) \right] + \eta = 0 \quad (2)$$

where A and B are complex functions of ω , Ω , g and ρ .

In the external region, the water depth is assumed to be a constant, so equation (2) is simplified (the B factors disappear) and it can be shown that the Green function of the problem is an Hankel function.

In the internal region, the finite element procedure is easily applied to equation (2).

The M_2 constituent of the tide in the North sea has been calculated by this way. The numerical results (fig. 1) are in good qualitative agreement with the observations, particularly in the reproduction of the amphydromic points. An important thing to point out, is that there is only two parameters to calibrate to solve this problem :

- the wave direction in the ocean, but its influence is very weak
- the bottom friction coefficient which fixes the position of the amphidromic points.

The repartition of amplitude and phase on the common boundary is obtained from the model.

The response of harbours to long waves of different frequencies coming from deep sea can be obtained by the same way. The oscillations are simulated using the same Laplace equation but Coriolis effects and bottom friction can be neglected. In this case, the B factor disappears in equation (2).

The method yields eigen frequencies and correspondent amplification factors of the harbour opened to the sea (see fig. 2 in the case of Marseille Harbour). This is particularly usefull to study seiches in harbours.

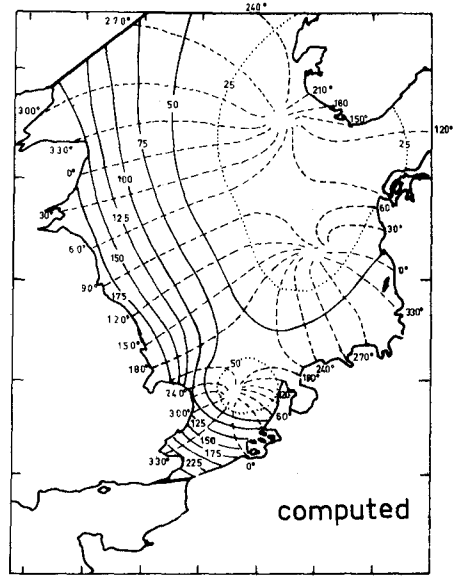

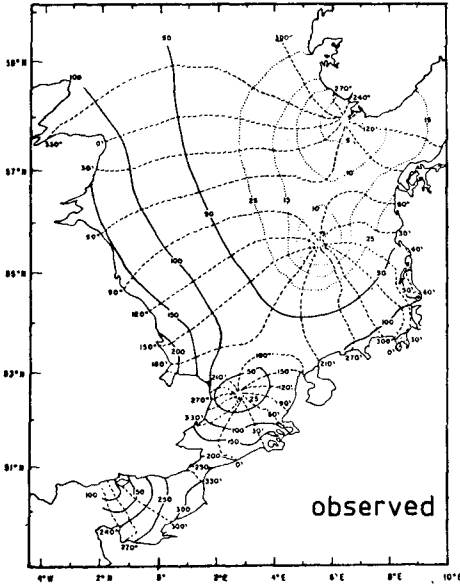

In decreasing the wave length, the last example is the computation of wave diffraction and refraction. In this case the governing equation is

$$\frac{\partial}{\partial x} \left(n \frac{\partial f}{\partial x} \right) + \frac{\partial}{\partial y} \left(n \frac{\partial f}{\partial y} \right) + nk_0^2 f = 0 \quad (3)$$

where k_0 is the wave number

TIDES IN NORTH SEA
CONFIGURATION OF ELEMENTS

M₂ TIDAL CHART
Fig.1

SEICHES IN MARSEILLE HARBOUR
CONFIGURATION OF ELEMENTS

HARBOUR OSCILLATION CURVES

Fig.2

n is the shoaling number

f is the potential.

Equation (3) is similar to equation (2). When the depth and consequently the shoaling number are constant the Green function is also an Hankel function. The same procedure can be applied.

The main restriction of the model is the numerical requirement of about five computing points over one wave length to compute the surface elevation with a sufficient accuracy. Figure 3 shows the solution of wave diffraction and refraction for the case of an island on a flat or parabolic shoal. The numerical results are in good qualitative agreement with the analytical solution. Amplitudes are generally underestimated mainly for short wave lengths (probably in relation with the number of computing points).

CONCLUSIONS

The mathematical model for linear simple harmonic waves described in this paper can be of great help to give some quantitative or qualitative information about waves coming from deep sea (tides and waves). The main restriction of the model is the numerical requirement with respect of large area compared with the mean wave length (especially for short waves) but the rapidity of the resolution, the development of the finite element method and the reduced number of parameters to calibrate the model (one or two for tides) give quite good informations very quickly.

CHAPTER 41

WAVE REFRACTION ACROSS A SHEARING CURRENT

Ivar G. Jonsson¹ and Ove Skovgaard²

ABSTRACT

Conservation of wave crests and wave action is introduced to yield the new wave length L_2 and new wave height H_2 as a wave train of plane incidence crosses a shearing current; refraction angle α_2 is determined by Snell's law. Input parameters are water depth h (assumed constant), absolute wave period T_a , angle of incidence α_1 , current velocities U_1 and U_2 (see Fig 1), and initial wave height H_1 . Solution domains are also given, analytically and graphically. The numerical results for L_1 , L_2 , α_2 , and H_2 are presented non-dimensionally in a number of figures, with dimensionless input parameters. As a direct illustration of the effect of the shearing current, a sequence of graphs are presented, showing in dimensional form the variation of L_2 , α_2 , H_2 , and steepness $S_2 = H_2/L_2$ with U_2 for fixed values of h , α_1 , U_1 , T_a , and H_1 . Large positive and negative currents can increase the steepness significantly. The variation of S_2/S_1 with T_a and h is finally depicted, demonstrating the "filtering" effect of a shearing current on waves.

A numerical example shows how simple it is to calculate accurately quantities L_1 , L_2 , α_2 , and H_2 .

1. INTRODUCTION

The purpose of this study is to examine the transformation of waves advancing across a shear layer, from a region of current velocity U_1 to one of current velocity U_2 , see Fig 1. Changes will occur in wave length and height, and in direction and speed of propagation. The results are presented in a number of graphs.

Studies of this kind were initiated by Longuet-Higgins and Stewart (1961), who considered the special case of deep water waves progressing from still water into a region with a steady, uniform current. Here we shall consider the general case of waves on an arbitrary (constant) depth, with arbitrary (steady and uniform) current velocities on both sides of the shear layer. Large-scale currents are considered, i e the current gradient is assumed small everywhere.

In region 1 we prescribe regular and plane incoming waves, and thus also the transmitted waves in region 2 will be plane. The two regions of flow are denoted by subscripts 1 and 2. In these regions current velocities are therefore specified as U_1 and U_2 . Assuming linear theory, solutions are sought for wave lengths L_1 and L_2 , refraction angle α_2 (see

Fig 2. Wave ray WR and ray tube passing a shear layer, from region 1 to region 2. Horizontal sketch.

Fig 1), and wave height H_2 . Given values are water depth h , current velocities U_1 and U_2 , absolute wave period T_a , angle of incidence α_1 (see Fig 1), and incoming wave height H_1 .

Velocities U are taken positive in the direction of wave travel. If we then consider only positive α -values, a positive (i.e. following) current is one running towards the right in Fig 1.

Since large-scale currents are assumed, reflection is excluded a priori, and the waves are purely progressive in both regions. This means in principle that the width of the shear layer must be several wave lengths. In practice this needs not be so, however. This can be seen from Evans (1975), who found transmission and reflection characteristics for a current discontinuity in deep water. He showed "that the amplitude of the transmitted wave as a function of the angle of incidence and current strength is very close to that obtained by Longuet-Higgins and Stewart [1961] on the assumption of small smooth changes in current velocity". This is not immediately expected, since in the former case the flow is not matched in detail at the discontinuity. Only for larger angles of incidence wave transmission was significantly affected by the no-reflection assumption. Reference is made to Evans' Fig 1 and Peregrine's (1976) Fig 12. So although the correct solution to the general problem has not been found yet (Peregrine, 1976, p 73), there is hope that the wave heights presented herein are good approximations also for narrow shear layers. (The only thing for certain is that the height found for the transmitted wave is too large).

We have also excluded the effect of turbulence generated by the shear layer. Here Evans (1975) concluded on the basis of Savitsky's (1970) investigations that turbulence thus generated will have a smaller influence than the mean velocity gradients in the flow. Another more important aspect (for narrow shear layers) is that they are unstable, so that steady solutions here cannot be expected to give more than somewhat crude approximations (Peregrine, 1976, p 71).

The current is assumed constant over depth. The effect of a possible vorticity was examined by Jonsson et al (1978). Dissipation is neglected, but can be included as described in Chapter 3.

The general case of current depth refraction has been studied elsewhere, see for instance Skovgaard and Jonsson (1977), Jonsson and Wang (1978), and the two review articles by the senior author (Jonsson, 1977, 1978b):

For completeness it is mentioned that fundamentally it is not a requirement that regions exist in which U_1 and U_2 are constant; the results obtained are in fact valid going from any point with current velocity U_1 to any other point with velocity U_2 , the flow being parallel over a horizontal bed, and disregarding dissipation.

2. SOME BASIC CONCEPTS

Since wave motion in a moving medium is so different from that in still water, it is worth while starting with the introduction of some concepts, which are important for this type of flow.

In each region we have two frames of reference. One is a coordinate system fixed on a plane earth, in which the wave period (T_a) is constant. This is the common absolute frame of reference, in which we use subscripts 'a'. The other is a Galilean transformation of the first where

the transformation velocity is the current velocity. Observations in the moving system(s) are referred to as relative, and subscripts 'r' are used here.

It is obvious that an important quantity as for instance the relative wave period is not the same in the two systems. The relation is found in the following way. Looking at Fig 1, it is seen that in the absolute frame, the wave front during time T_a has travelled distance

$$L = c_a T_a \quad (2.1)$$

where L is the wave length, and c is the phase speed (here absolute) of the wave. Seen from the moving observer the front has travelled distance $c_r T_a$ during the same time interval. At the same time, the observer him/herself has travelled distance UT_a in the current direction. By projecting this on the wave orthogonal, we hereafter find for the absolute phase speed, after having divided by T_a

$$c_a = c_r + U \sin \alpha \quad (2.2)$$

where α is the angle between the normal N to the streamlines and the wave orthogonal. Since we also by definition have

$$L = c_r T_r \quad (2.3)$$

we get from (2.1) and (2.2) for the relative period T_r

$$\frac{1}{T_r} = \frac{1}{T_a} - \frac{U \sin \alpha}{L} \quad (2.4)$$

It appears that for a following current ($U \sin \alpha > 0$) we have $T_r > T_a$, as expected. In the literature (2.4) is often written $\omega_r = \omega_a - \vec{k} \cdot \vec{U}$ ('conservation of wave crests'), where $\omega = 2\pi/T$, the angular frequency, and \vec{k} is the wave number vector, which is a vector of magnitude $2\pi/L$ going in the wave orthogonal direction.

In Fig 1 α_1 is the angle of incidence and α_2 the refraction angle.

In current wave systems it is important to distinguish between three sets of curves: Streamlines, wave orthogonals, and wave rays. A streamline gives the (local) mean flow direction. A wave orthogonal is normal to the wave front, and gives the direction of wave travel. Finally a wave ray gives the direction of the absolute group velocity, i e of

$$\vec{c}_{ga} = \vec{c}_{gr} + \vec{U} \quad (2.5)$$

where the relative group velocity \vec{c}_{gr} goes in the orthogonal direction, see Fig 1. Wave rays determine wave heights since the so-called wave action, defined as

$$\text{Wave action} \equiv \frac{E}{\omega_r} \quad (2.6)$$

is conserved along wave rays, see Chapter 3.

In (2.6) E is the specific wave energy

$$E = \frac{1}{8} \rho g H^2 \quad (2.7)$$

and ω_r is the relative angular frequency. In (2.7) ρ is density, g gravity acceleration, and H is the wave height.

The component of (2.5) in the direction of the orthogonal is also an important quantity. It is given by

$$c_{ga\alpha} = c_{gr} + U \sin \alpha \quad (2.8)$$

The complete differential equations for wave orthogonals and wave rays for a general system are presented in the Appendix.

3. THE GOVERNING EQUATIONS

Since linear theory is assumed, the relative phase speed is given by

$$c_r = \sqrt{\frac{g}{k} \tanh kh} \quad (3.1)$$

where $k = 2\pi/L$, the wave number, and h is the water depth. Similarly we have for the relative group speed

$$c_{gr} = \frac{1}{2} c_r (1+G) \quad (3.2) \quad \text{with } G \equiv \frac{2kh}{\sinh 2kh} \quad (3.3)$$

REGION 1 - Wave length L_1 can be found by eliminating c_{a1} and c_{r1} from (2.1), (2.2), and (3.1). The (implicit) result is

$$\sqrt{\frac{h}{L_1} \tanh k_1 h} = \sqrt{\frac{h}{L_0}} \left[1 - \frac{U_1 \sin \alpha_1 T_a}{L_1} \right] \quad (3.4)$$

in which $k_1 = 2\pi/L_1$, and L_0 is the deep water wave length in the absence of currents, i e

$$L_0 = \frac{g}{2\pi} T_a^2 \quad (3.5)$$

Equation (3.4) is identical with (3.5) in Jonsson et al (1971). In a dimensionless representation it gives L_1/L_0 as a function of h/L_0 and $U_1 \sin \alpha_1 / c_0$, where c_0 is the deep water phase speed in the absence of currents, i e

$$c_0 = \frac{g}{2\pi} T_a \quad (3.6)$$

Solutions to (3.4) are depicted in Fig 6. Values of L_1/L_0 can also be read in Tables 6-a and 6-b in Jonsson et al (1971), remembering that entry parameter q^* there equals $(h/L_0)(U_1 \sin \alpha_1 / c_0)$. Also Tables 3.2-I and 3.2-II in Jonsson (1978b) can be used.

REGION 2 - Equation (3.4) is valid for this region also, if subscript 1 is replaced by subscript 2. Inserting Snell's law

$$\frac{L_1}{\sin \alpha_1} = \frac{L_2}{\sin \alpha_2} \quad (3.7)$$

into the "new" (3.4) then yields for the determination of L_2

$$\sqrt{\frac{h}{L_2} \tanh k_2 h} = \sqrt{\frac{h}{L_0} \left[1 - \frac{U_2 \sin \alpha_1 T_a}{L_1} \right]} \quad (3.8)$$

in which $k_2 = 2\pi/L_2$, the wave number in region 2. This determines L_2/L_0 as a function of h/L_0 , $U_1 \sin \alpha_1/c_0$, and $U_2 \sin \alpha_1/c_0$. Solutions to (3.8) are depicted in Figs 7-10.

Note that (3.8) can be solved in quite another way than (3.4). Since we assume that L_1 has now been calculated, the right-hand side of (3.8) is known. Ratio h/L_2 can therefore be found from a conventional table for surface gravity waves (e.g. Wiegel, 1964, Appendix 1) using the square of the right-hand side of (3.8) as entry in the column " h/L_0 ". L_2 is hereafter found as $h/(h/L_2)$; it cannot be found from $L = L_0 \tanh kh$!

Refraction angle α_2 is determined from Snell's law as

$$\alpha_2 = \text{Arcsin} \frac{L_2 \sin \alpha_1}{L_1} \quad (3.9)$$

This equation gives α_2 as a function of h/L_0 , α_1 , U_1/c_0 , and U_2/c_0 , as shown in Figs 11-26.

Wave height H_2 is found from wave action conservation. In the general case this principle reads, see Christoffersen and Jonsson (1979) and Jonsson (1978b)

$$\nabla \cdot \left(\frac{\mathbf{E}}{\omega_r} \frac{\vec{c}}{g a} \right) + \frac{E_d - \vec{\tau}_b \cdot \vec{U}}{\omega_r} = 0 \quad (3.10)$$

where ∇ is the horizontal gradient operator ($\partial/\partial x$, $\partial/\partial y$), \mathbf{E} , and \vec{c}_{ga} are given by (2.7) and (2.5), ω_r is the relative angular frequency, E_d is the dissipation per unit horizontal area, and $\vec{\tau}_b$ the (mean) bed shear stress (wind shear is neglected). It is repeated that \mathbf{E}/ω_r is wave action. The wave action flux is often termed \vec{B} , i.e.

$$\vec{B} \equiv \frac{\mathbf{E}}{\omega_r} \frac{\vec{c}}{g a} \quad (3.11)$$

A simple proof of the wave action conservation principle for irrotational flow has been given by the senior author, Jonsson (1978a). In Christoffersen and Jonsson (1979) the general expression (3.10) was deduced.

In this study dissipation is neglected, and (3.10) reduces to $\nabla \cdot \vec{B} = 0$. Looking at the ray tube in Fig 2 we then find using Gauss' theorem

$$B_1 e_1 = B_2 e_2 \quad (3.12)$$

where $B = |\vec{B}|$ and e is the tube width. Thus we find for H_2 , using (3.11) and (3.12)

$$\frac{H_2}{H_1} = \sqrt{\frac{\omega_r}{\omega_r} \frac{r_2}{r_1} \frac{c}{c} \frac{g a_1}{g a_2} \frac{1}{\sqrt{\beta_r}}} \quad (3.13)$$

where β_r is the ray separation factor $e_2/e_1 = \cos\mu_2/\cos\mu_1$; μ is the angle between the ray and the normal N in Fig 2. From this figure we also have $c_{ga} \cos\mu = c_{gr} \cos\alpha$. Introducing c_{gr} through (3.2) and further using that $c_r/\omega_r = 1/k$ and that $k_2/k_1 = \sin\alpha_1/\sin\alpha_2$ (Snell), we find from (3.13)

$$\frac{H_2}{H_1} = \sqrt{\frac{1+G_1}{1+G_2}} \sqrt{\frac{\sin 2\alpha_1}{\sin 2\alpha_2}} \quad (3.14)$$

Equation (3.14) gives H_2/H_1 as a function of h/L_0 , α_1 , U_1/c_0 , and U_2/c_0 . It shows that in this approach H_2 is a linear function of H_1 . The variation of H_2/H_1 is depicted in Figs 11-26. In deep water ($G = 0$) (3.14) reduces to Longuet-Higgins and Stewart's (1961) expression $H_2/H_1 = (\sin 2\alpha_1/\sin 2\alpha_2)^{1/2}$.

In the special case considered here, the wave height can also be found by a simple momentum consideration. The "shear stress" in a section parallel with the streamlines is according to Jonsson (1978a) or (1978b, Section 3.2.3.2) $F_m \sin\alpha$, where $F_m = 1/16 \rho g H^2 (1+G)$, the momentum part of the radiation stress. Since this "shear stress" must be the same on the two sides of the shear layer, (3.14) follows directly.

As α_2 approaches 90° , H_2 goes towards infinity according to (3.14), and the theory breaks down. The physical situation is U_2 being so much larger than U_1 that the waves are "swept" along the "first" U_2 streamline, and wave orthogonals and rays run parallel with it. The ray separation factor then goes towards zero. In practice this will give a strong reflection, which is disregarded in the theory.

The wave steepness S_2 ($\equiv H_2/L_2$) is given both directly (Fig 30) and relative to S_1 (Fig 31), for one set of parameters.

MEAN WATER LEVELS - There will be a slight difference in mean water level between regions 1 and 2. Using the formulae in Jonsson (1978a) or (1978b, Section 3.2.3.2), equilibrium at right angles to the streamlines gives

$$\frac{1}{2} \rho g h_1^2 + F_{p1} + F_{m1} \cos^2\alpha_1 = \frac{1}{2} \rho g h_2^2 + F_{p2} + F_{m2} \cos^2\alpha_2 \quad (3.15)$$

in which $F_p = 1/16 \rho g H^2 G$, the pressure part of the radiation stress, and F_m is the previously given momentum part. After some manipulations, hereunder using (3.14), we find for the difference in mean water level, defined as $b = h_2 - h_1$

$$b = \frac{H_1^2}{16h} G_1 \left[1 - \frac{G_2(1+G_1)}{G_1(1+G_2)} \frac{\sin 2\alpha_1}{\sin 2\alpha_2} + \frac{1+G_1}{G_1} \frac{\cos\alpha_1 \sin(\alpha_2 - \alpha_1)}{\sin\alpha_2} \right] \quad (3.16)$$

correct to second order. Since the factor to the square bracket is recognized as the conventional wave set-down (over a varying bottom) it appears that b is indeed a small quantity, by order of magnitude 1 cm. For normal incidence ($\alpha_1 = 0^\circ$), and in deep water, b vanishes.

4. SOLUTION DOMAINS

REGION 1 - As shown by Jonsson et al (1971, p 493), there are no solutions to the wave length expression (3.4), if the wave orthogonal component c_{ga}

Fig 3. Solution domains for region 1, corresponding to the component $c_{ga\alpha_1}$ in the orthogonal direction of the absolute group velocity being positive (below full curves), or the Froude number F_1 being smaller than one (below dotted curves).

(2.8) of the absolute group velocity c_{ga} is negative. So in the limit $c_{ga\alpha} = 0$ the ray goes in the wave front direction, and we have from (2.8)

$$c_{ga\alpha_1} = c_{gr1} + U_1 \sin \alpha_1 = 0 \tag{4.1}$$

We further have from (3.10) in the above reference

$$\left(\frac{h}{L}\right)_{lim} = \frac{(1 - G_1)^2}{8\pi} k_1 h \tanh k_1 h \tag{4.2}$$

Combining this with (4.1) gives

$$\left(\frac{U_1 \sin \alpha_1}{c_0}\right)_{lim} = -\frac{1 - G_1^2}{4} \tanh k_1 h \tag{4.3}$$

(Equation (4.1) is in fact a consequence of (4.2) and (3.4).) Equations (4.2) and (4.3) are the bases of the limiting curves in Fig 3. In the limit we attain minimum values of L , see Jonsson et al (1971). (Note: In that reference $c_{ga\alpha}$ was for brevity denoted c_{ga} . This is unfortunate, since c_{ga} should be reserved for the magnitude $|\tilde{c}_{ga}|$ of the absolute group velocity. So in this study we have from Fig 1 $c_{ga\alpha} = c_{ga} \cos(\mu - \alpha)$.) In deep water we find the well-known limit $U_1 \sin \alpha_1 / c_0 = -1/4$.

In Fig 3 we have also shown $(U_1 \sin \alpha_1 / \sqrt{gh})_{lim}$ versus h/L_0 . For the latter going towards zero, the former goes towards $-1+$. It is seen, ge-

Fig 4. Solution domains for region 2, corresponding to L_2/L_0 -figures. Schematic.

Fig 5. Solution domains for region 2, corresponding to α_2 - and H_2/H_1 -figures. Schematic.

nerally, that if we restrict ourselves to consider Froude numbers F_1 (defined as $|U_1|/\sqrt{gh}$) smaller than one, then this requirement can be 'stricter' than the limiting curve in Fig 3, especially so for the smaller α_1 -values. Also for the $U_1 \sin \alpha_1 / c_0$ solution domain, some $F_1 = 1$ limits are sketched.

To sum up, the full curves in Fig 3 both correspond to (a) wave rays being orthogonal to wave orthogonals and (b) wave lengths attaining their minimum value. The dotted curves correspond to $F_1 \equiv |U_1|/\sqrt{gh} = 1$, for different angles of incidence.

The position of the limit $c_{ga\alpha_1} = 0$ is sketched in Fig 4 (L_2/L_0 solutions) and Fig 5 (H_2/H_1 and α_2 solutions). It naturally corresponds to negative U_1 -values. In these figures also the $F_1 = 1$ (and $F_2 = 1$) limits are shown. In Fig 4 the position of the (chosen) $F = 1$ limits depend on α_1 . Note also in this figure that with the requirement $F < 1$, there are never solutions outside the " $F = 1; \alpha_1 = 90^\circ$ frame". The limits can be recognized in the figures in Chapter 5. It appears from these that the mutual positions of the limiting curves in Figs 4 and 5 are not absolute. Thus the $F = 1$ curves in Fig 5 can lie outside the chosen $U_1/c_0 - U_2/c_0$ frame. And the $c_{ga\alpha_1} = 0$ limit can lie to the left of the $F = 1$ limit.

REGION 2 - In this region there is one further restriction on the input parameters: The wave height H_2 must remain finite, corresponding to $\alpha_2 < 90^\circ$. Thus there are restrictions on the current strength, whether negative or positive. In the former case, one obvious condition is the same as that in region 1, that $c_{ga\alpha}$ be positive. In this limit we thus have from (2.8)

$$c_{ga2} = c_{gr2} + U_2 \sin \alpha_2 = 0 \quad (4.4)$$

stating that the ray goes in the direction of the wave front. So (4.2) and (4.3), and Fig 3, are also valid with subscripts 2. Fig 3 is not directly applicable, however, since α_2 is not known beforehand. The position of the limit $c_{ga2} = 0$ is sketched in Figs 4 and 5, and can be found again in the figures in Chapter 5.

It should be observed that - in contrast to plane shoaling, see Jonsson et al (1971) - minimum wave length here does not correspond to infinite wave height. This is because in our case $c_{ga2} = 0$ ($\Rightarrow L_{2,\min}$) does not yield $c_{ga2} = 0$. (Moreover, c_{ga2} can never vanish here.) If, however, U_2 is much larger than U_1 , the waves cannot "penetrate" through the shear layer, and H_2/H_1 tends to infinity. This case was already discussed in Chapter 3, and it corresponds to $\mu_2 = 90^\circ$, giving ray separation factor $\beta_x = 0$. Fig 2 shows that here we must also have $\alpha_2 = 90^\circ$, which is in accordance with (3.14).

The corresponding limiting curves are depicted in Figs 4 and 5, and can be found again in the figures in Chapter 5. Note that in Fig 4 the position is a function of α_1 . The $\alpha_1 = 0^\circ$ limit is peculiar, since it also corresponds to $L_2/L_0 \rightarrow \infty$.

In shallow water the $\alpha_2 = 90^\circ$ limit corresponds to

$$\frac{U_2 - U_1}{c_0} = \frac{1 - \sin \alpha_1}{\sin \alpha_1} \sqrt{\frac{2\pi h}{L_0}} \quad \text{or} \quad \frac{U_2 - U_1}{\sqrt{gh}} = \frac{1 - \sin \alpha_1}{\sin \alpha_1} \quad (4.5)$$

So here, where there is no dispersion, the critical condition - for a fixed value of α_1 - only depends on the current velocity difference.

In the figures, also the limits corresponding to $F_2 \equiv |U_2|/\sqrt{gh} = 1$ are shown.

5. NUMERICAL RESULTS

WAVE LENGTHS L_1/L_0 - Solutions to (3.4) are presented in Fig 6, which clearly demonstrates the "stretching" effect of a positive current, and the "compressive" effect of a negative ditto. Other things being equal, wave length increases with increasing current velocity and depth. The deep water limit ($U_1 \sin \alpha_1 / c_0$, L_1/L_0) = (-1/4, 1/4) is clearly seen. The thin full curve connecting this point with origo corresponds to - for every fixed value of h/L_0 - the minimum value of L_1/L_0 (i.e. $c_{ga1} = 0$). To every angle of incidence the $F = 1$ limit yields two curves - the solution domain lies between these. The solution domains were also illustrated in Fig 3.

WAVE LENGTHS L_2/L_0 - Solutions to (3.8) are presented in Figs 7-10, corresponding to four dimensionless water depths h/L_0 . Note that $\sin \alpha_1$ - not $\sin \alpha_2$ - appears together with U_2 on the ordinate axis. It is seen that other things being equal, wave length in region 2 increases with increasing current velocity, as expected. The variation of L_2 with U_2 gets slower as U_1 grows. As to the solution limit, we can inspect Fig 7; starting at the bottom and going anti-clockwise the limits correspond to:

Fig 6

Dimensionless wave length L_1/L_0 in region 1 vs $U_1 \sin \alpha_1 / c_0$ for $h/L_0 = 0.015, 0.05, 0.15, \text{ and } 0.5$. For $U_1 \sin \alpha_1 / c_0 < 0$ the two dot-and-dash lines correspond to $F_1 = 1$ for $\alpha_1 = 15^\circ$ and 30° . For $U_1 \sin \alpha_1 / c_0 > 0$ the five dot-and-dash lines correspond to $F_1 = 1$ for $\alpha_1 = 15^\circ, 30^\circ, 45^\circ, 60^\circ, \text{ and } 90^\circ$.

Figs 7-8
9-10

Contours for dimensionless wave length L_2/L_0 in region 2 vs $U_1 \sin \alpha_1 / c_0$ and $U_2 \sin \alpha_1 / c_0$. For $L_2/L_0 \leq 1$ the contours are plotted with intervals of 0.1. For $1 \leq L_2/L_0 \leq 3$ the contours are plotted with intervals of 0.5. Dot-and-dash lines correspond to $F_1 = 1$. Dotted curves correspond to $H_2/H_1 = \infty$.

Figs 11-12
13-14 Contours for refraction angle α_2 and relative wave height H_2/H_1 in region 2 vs U_1/c_0 and U_2/c_0 . For α_2 the contours are plotted with intervals of 10° . For $H_2/H_1 \leq 1.3$ the contours are plotted with intervals of 0.1. Dot-and-dash lines correspond to $F=1$. Note that the abscissa axis is reversed for H_2/H_1 .

$F_2 = 1, F_1 = 1, F_2 = 1, H_2/H_1 = \infty, c_{ga\alpha 1} = 0,$ and $c_{ga\alpha 2} = 0$. For details see Chapter 4 and Fig 4. In Figs 8 - 10 the $F=1$ limits lie outside the chosen frame. Some of the limiting curves appear jagged because of the discretization used in the computer software, which was used to plot these curves.

REFRACTION ANGLES α_2 - Solutions to (3.9) are presented in Figs 11 - 26, corresponding to four water depths (same as for L_2/L_0), and four angles of incidence. (H_2/H_1 is shown laterally reversed in the same figures). It appears that the variation of α_2 is slowest for the smallest angle of in-

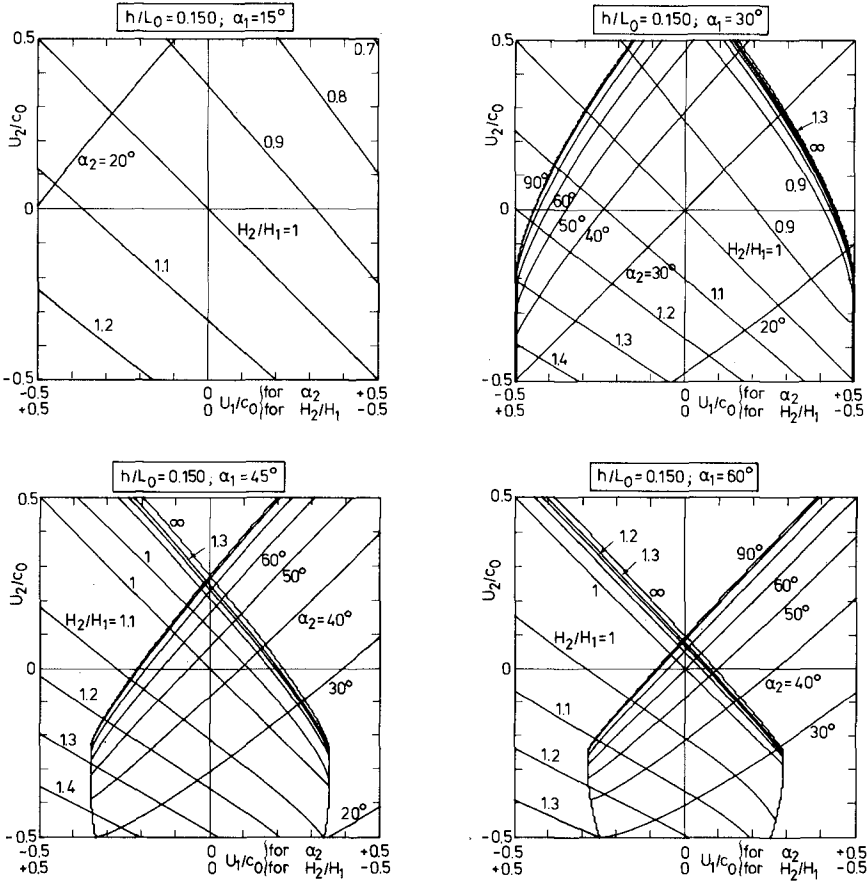

Figs 15-16
17-18

Contours for refraction angle α_2 and relative wave height H_2/H_1 in region 2 vs U_1/c_0 and U_2/c_0 . For α_2 the contours are plotted with intervals of 10° . For H_2/H_1 the contours are plotted with intervals of 0.1 up to 1.3 above the diagonal, and 1.4 below it.

cidence α_1 chosen. Everywhere α_2 increases with increasing U_2 . It can also be seen that (naturally) for $U_2 = U_1$ we have $\alpha_2 = \alpha_1$. Only for the smallest water depth, the $F = 1$ limits lie within the chosen frame. The other limits are discussed in Chapter 4 and illustrated in Fig 5.

WAVE HEIGHTS H_2/H_1 - Solutions to (3.14) are presented (laterally reversed) in Figs 11 - 26, for four water depths and four angles of incidence. It appears that the variation of H_2/H_1 is slowest for the smallest angle of incidence α_1 chosen. It is also seen that - except for this value of α_1 - the variation with U_2 exhibits a minimum for H_2/H_1 within the chosen

Figs 19-20
21-22 Contours for refraction angle α_2 and relative wave height H_2/H_1 in region 2 vs U_1/c_0 and U_2/c_0 . For α_2 the contours are plotted with intervals of 10°. For H_2/H_1 the contours are plotted with intervals of 0.1 up to 1.3 above the diagonal, and 1.4 below it.

frame. This will be discussed later. For $U_2 = U_1$ we have $H_2 = H_1$. The limits are discussed in Chapter 4 and illustrated in Fig 5.

VARIATIONS OF L_2 , α_2 , H_2 , S_2 , and S_2/S_1 - A physical discussion of the transforming effect of the shear layer is facilitated by looking at a few concrete examples. Consider first the sequence in Figs 27 - 30, giving the variation of region 2 quantities with U_2 . Fig 27 shows how L_2 increases monotonously with increasing U_2 ; the maximum value is attained for $\alpha_2 = 90^\circ$. Also α_2 (Fig 28) varies in this way; for $U_2 > 4.3$ m/s (approx) $\alpha_2 = 90^\circ$, and waves cannot penetrate into region 2. In the limit H_2 theoretic-

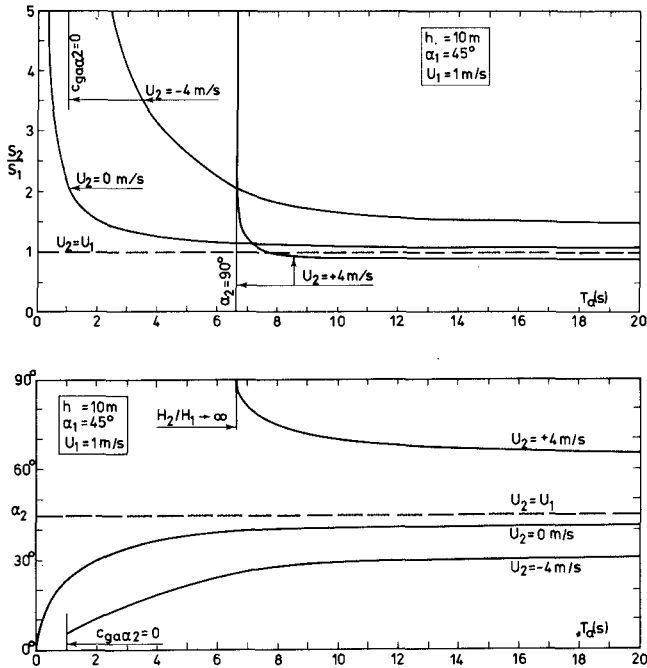

Figs 23-24
25-26 Contours for refraction angle α_2 and relative wave height H_2/H_1 in region 2 vs U_1/c_0 and U_2/c_0 . For α_2 the contours are plotted with intervals of 10° . For H_2/H_1 the contours are plotted with intervals of 0.1 up to 1.3 above the diagonal, and 1.4 below it.

cally tends to infinity (Fig 29). It is also seen from this figure that H_2 has a minimum. This can be anticipated by looking at (3.12); H_2 can become large, if c_{ga} becomes small (Fig 29, left), or if ray width e (see Fig 2) becomes small (Fig 29, right), so a minimum in between is expected. Fig 30 shows that the wave steepness S_2 has a sharper minimum. This is because L_2 is decreasing as U_2 decreases. The figure shows that both a large negative and a large positive current can have a strong steepening effect on the wave; eventually it may break.

The influence of the (absolute) period is illustrated in Fig 31, which gives the ratio between steepnesses in regions 2 and 1. It appears that

Figs 27-30 Wave length L_2 (Fig 27), refraction angle α_2 (Fig 28), wave height H_2 (Fig 29), and wave steepness $S_2 \equiv H_2/L_2$ (Fig 30) vs current velocity U_2 for fixed values of water depth h , absolute wave period T_a , angle of incidence α_1 , current velocity U_1 , and wave height H_1 (Figs 29-30).

Figs 31-32 Relative wave steepness $S_2/S_1 \equiv (H_2/L_2)/(H_1/L_1)$ (Fig 31) and refraction angle α_2 (Fig 32) vs absolute wave period T_a for fixed values of water depth h , angle of incidence α_1 , and current velocity U_1 .

both a large negative and a large positive current have a dramatic steepening effect on waves of smaller period, either because the group speed and wave length become small (opposing current), or because the ray separation factor becomes small (following current), opposing current here meaning $U_2 - U_1 < 0$. In both cases the effect is due to the fact that "short waves are slow waves". This steepening and thus filtering effect was illustrated by Isaacs (1948); in the photo in his Fig 1 the current discontinuity shows up as a foam line because of short wave breaking. Fig 31 also shows that the steepness ratio is remarkably constant for the higher periods.

The period influence on the refraction angle is shown in Fig 32. For $U_2 = +4\text{ m/s}$ the variation towards $\alpha_2 = 90^\circ$ as T_a tends to 6.6 s (approx), reflects that here the ray separation factor goes towards zero.

Finally the influence of the (constant) water depth on S_2/S_1 is shown in Fig 33. It appears that (naturally) the effect is largest on smaller depths, because other things being equal here the phase speed is smallest. For $h > 10\text{ m}$ the variation is quite small in the case considered.

Fig 33 Relative wave steepness $S_2/S_1 \equiv (H_2/L_2)/(H_1/L_1)$ vs water depth h for fixed values of absolute wave period T_a , angle of incidence α_1 , and current velocity U_1 .

EXAMPLE - It can be difficult to read the quantities in the dimensionless delineations in Figs 6 - 26 with any great accuracy (also a number of interpolations are necessary). These figures illustrate the trends, but can give only approximate values. It is not altogether difficult, however, to find the exact figures by calculation. This will be demonstrated in the following. Consider the case with $h = 10$ m, $T_a = 8$ s, $\alpha_1 = 45^\circ$, $U_1 = 1$ m/s, $U_2 = -2$ m/s, and $H_1 = 1$ m (Figs 27 - 30). ($g = 9.80665$ m/s $^2 \Rightarrow g/2\pi \approx 1.561$ m/s 2). Calculation of L_1 - $c_0 = 1.561 \cdot 8 = 12.49$ m/s, $L_0 = 1.561 \cdot 8^2 = 99.90$ m $\Rightarrow h/L_0 = 0.1001$; $q^* = 10 \cdot 1 \cdot \sin 45^\circ / (12.49 \cdot 99.90) = 0.00567$. Table 6-a in Jonsson et al (1971) (or Table 3.2-I in Jonsson, 1978b) then gives $L/L_0 = 0.778 \Rightarrow L_1 = 0.778 \cdot 99.90 = 77.7$ m. (Without a current we find $L = 70.9$ m - the wave is "stretched" by the positive current.) Calculation of L_2 - The right hand side of (3.8) squared is $0.1001(1 - (-2) \cdot \sin 45^\circ / 8 / 77.7)^2 = 0.1314$. Using this as entry in the column " h/L_0 " in a conventional wave table, we find $h/L = 0.1677 \Rightarrow L_2 = 10 / 0.1677 = 59.6$ m, which agrees with Fig 27. (The wave is "compressed" in region 2 by the opposing current). Calculation of α_2 - From (3.9) we find $\alpha_2 = \text{Arcsin}(59.6 \sin 45^\circ / 77.7) = 32.08^\circ$, which agrees with Fig 28. Calculation of H_2 - $h/L_1 = 10 / 77.7 = 0.1287$; $h/L_2 = 0.1677$. From a conventional wave table we then find $G_1 = 0.6682$ and $G_2 = 0.5200$. Then from (3.14) $H_2 = 1 \cdot \sqrt{1.6682 / 1.5200} \cdot \sqrt{\sin 90^\circ / \sin 65.06} = 1.098$ m, which agrees with Fig 29. ($S_2 \equiv H_2/L_2 = 1.098 / 59.6 = 0.0184$, which agrees with Fig 30).

6. CONCLUSIONS

Analytical expressions are presented for the determination of wave length L_2 (3.8), refraction angle α_2 (3.9), and wave height H_2 (3.14), as a wave passes a large-scale shearing current over a horizontal bed. The current velocity is assumed constant in time and over depth. Dimensionless results are presented in Figs 7 - 10 (L_2) and 11 - 26 (α_2 and H_2). The direct effect of the current velocity U_2 in region 2 (see Fig 1) is illustrated in a concrete example in Figs 27 - 30. The most interesting feature here is the display of a wave height (and steepness) minimum. The "filtering" effect of a shear layer on a wave motion is illustrated in Figs 31 and 32, and the influence of the water depth on wave steepness change appears from Fig 33.

The wave length L_1 at the initial state (region 1, see Fig 1) is determined by (3.4); solutions in dimensionless form are illustrated in Fig 6. Solution domains for region 1 appear from Fig 3. Solution domains for region 2 are sketched in Figs 4 (applicable to L_2 -figures) and 5 (applicable to α_2 - and H_2 -figures).

A detailed example of how to obtain numerical results using tables and handcalculations, is given in Chapter 5.

APPENDIX: ORTHOGONALS AND RAYS

In the general case the wave orthogonals are determined by

$$Dx/Ds = \cos A \quad (A.1) \quad Dy/Ds = \sin A \quad (A.2)$$

$$DA/Ds = (\sin A \partial c_a / \partial x - \cos A \partial c_a / \partial y) / c_a \quad (A.3)$$

in which x and y are horizontal Cartesian coordinates, s is distance along the orthogonal, A is the angle from the x -axis to the positive direction of the orthogonal (DA/Ds is the orthogonal curvature), and c_a is the absolute phase speed

$$c_a = c_r + u \cos A + v \sin A \quad (A.4)$$

In (A.4) c_r is the relative phase speed (3.1) and $\vec{U} = (u, v)$ is the current vector. In (A.1) to (A.3) time t can be introduced through $Ds = c_a dt$. Thus formally the wave orthogonal equations are the same as for pure depth refraction, see Skovgaard et al (1975).

In the general case the wave rays are determined by

$$Dx/Dr = \cos \mu \quad (A.5) \quad Dy/Dr = \sin \mu \quad (A.6)$$

$$D\mu/Dr = \cos^2 \mu D(\tan \mu) / Dr \quad (A.7)$$

in which r is distance along the ray and μ is the angle from the x -axis to the positive direction of the ray determined by

$$\tan \mu = (c_{gr} \sin A + v) / (c_{gr} \cos A + u) \quad (A.8)$$

In (A.8) c_{gr} is the relative group speed (3.2). Note that according to (A.8) $\mu = A$ for $(u, v) = (0, 0)$; however, (A.7) does not transform to (A.3) in this limit. This is because (A.7) presupposes (A.3) to be known and solved, giving angle A . (The ray separation factor is determined by (31) in Skovgaard and Jonsson, 1977).

CHAPTER 42

EXPERIMENTAL STUDY OF WIND WAVES GENERATED ON CURRENTS

by

Hajime Kato and Hiroichi Tsuruya*

Port and Harbour Research Institute
Ministry of Transport
Yokosuka, Japan

ABSTRACT

This paper presents some experimental results of wind waves generated on currents in a wind-wave channel with a water circulation pump system. The waves were measured at fetches less than 27.8 m by using resistance-type wave gauges. Surface velocities as well as velocity profiles in water were also measured elaborately and true frequency wave spectra were obtained from observed apparent spectra which were modified by the doppler effect of current.

Significant wave heights $H_{1/3}$ computed from $\overline{\eta^2}$ and peak frequencies of true spectra f_{0m} were examined with emphasis. It was inferred from the variation of true spectra that the most prominent effect of water current is to change the effective fetch length. Then an idea of equivalent fetch length was proposed to express the current effect on the development of total wave energy.

By using the equivalent fetch F' in place of the natural fetch it is shown that $H_{1/3}$ and f_{0m} measured under various current conditions can be represented by the non-dimensional fetch relations, respectively, which were originally obtained in the case of no current.

1. Introduction

It seems to have been known since old times that in the sea where a tidal current exists the wind-generated waves are greatly changed with the direction of current. There was a remark by Lord Rayleigh (1911) in this connection. Francis and Dudgeon (1967) conducted experiments of pilot nature and demonstrated that the water currents actually have an intense effect on the generation of wind waves. Such an effect of current is considered not negligible in the prediction of wind waves in the sea area where a tidal or ocean current exists. However, the effect of current upon the development of wind waves has not been made clear so much quantitatively, and to our knowledge no method is known to evaluate the current effect in the prediction of wind waves.

In order to shed some light on the effect of current and to find some clues to the prediction of waves in the current field we have investigated wind-generated waves on currents in a wind-wave channel which is equipped with a water circulation pump system. A difficult problem in this kind of experiment is the measurement of the waves. In the experiments of Francis and Dudgeon (1967) the waves were measured photographically and crudely averaged. They state that a more sophisticated method of determining the wave characteristics might be justified in the further work.

In our experiments the waves were measured by means of wave gauges. Therefore what are directly computed from the wave records are the apparent spectra with respect to the apparent frequency modified by the doppler effect of current. For exploring intrinsic wave properties, especially the growth rates of component waves, we calculate (as substitutes for the wavenumber spectra) the true spectra defined with respect to the true frequency by making use of the dispersion relation corresponding to the actual current conditions.

In this paper we mainly discuss the non-dimensional representation of significant wave heights $H_{1/3}$ computed from the total wave powers and peak frequencies of true spectra f_{0m} measured under various current conditions. For this purpose we introduce an idea of the equivalent fetch length and show that it is effective for expressing the current effect on the development of wind waves.

2. Experimental procedures

2.1 General description

Rough sketches of the wind-wave channel used for the experiments are shown in Figs. 1 and 2. The uniform test section is 1.5 m wide, 1.3 m high and 28.5 m long. The side walls and most of the ceiling consist of glass plates. On the windward (right hand) side of the test section over the waterway is a wind blower, where wind is generated by an axial fan driven by 50 KW variable-speed motor. Passing through guide vanes, a fine mesh screen and honeycombs the wind is

Fig. 1. A plan of the wind-wave channel

Fig. 2. A side view of the test section

Table 1. Current conditions in the experiments

	Δh (cm)	Q (l/sec)	\bar{U} (cm/sec)
Favorable current	130	224	+29.9
	60.0	152	+20.3
	15.0	76	+10.1
No current	0	0	0
Adverse current	15.0	76	-10.1
	30.0	108	-14.4
	60.0	152	-20.3

allowed to flow onto water of 50 cm depth by means of an adjustable-height guide plate at the inlet section (see Fig. 2), where the wind velocity profile is quite uniform. The wind speed was set up by regulating the speed of fan (rpm). In the experiments the winds at rpm 200, 300 and 400 were used, and the corresponding cross-sectional average wind speeds \bar{U}_a at the inlet section were nearly 5.6, 8.2 and 11.0 m/sec, respectively.

The water currents were generated by a pump between (1) and (4) shown in Figs. 1 and 2. The current condition in each run was controlled by adjusting the flow rate Q accurately by means of a venturimeter. The experimental current conditions are listed in Table 1, where Δh is the differential pressure head of venturi and \bar{U} is the average cross-sectional velocity. The measurements of waves and currents were made at six stations A-2, A-3, B, B-2, C and D shown in Figs. 1 and 2, and the fetches were 2.25 to 27.75 m. Wind velocities were measured at A-2, B, C and D stations.

2.2 Methods of measurement

The waves were measured by means of resistance-type wave gauges. The sensors were made of two parallel platinum wires 0.1 mm in diameter with 2 mm spacing. Wind velocity profiles over the water surface were measured by using a pitot static tube and a differential pressure transducer. A digital data recorder (DATAC-2000B) was used for recording the output voltages of wind and waves on line, and the later data processing was performed by using a computer. A sampling interval for the wave data was taken as $\Delta t = 1/51.2$ second considering the convenience in the computations of wave spectra by FFT.

Current velocities were measured by means of a small propeller-type current meter both with and without wind. The surface current velocities u_0 were measured by using paraffin flakes in the shape of disk about 6 mm in diameter. In order to check the drift current profile near the water surface a hot-film anemometer was also used in several cases with small amounts of detergent mixed in water to suppress wind waves, for otherwise the hot-film could not detect the horizontal velocity component correctly.

2.3 Method of analysis

As mentioned earlier, what are directly obtained from the wave data are the apparent spectra with respect to the apparent frequency f_A which is expressed as

$$f_A = c / L \quad (1)$$

where c is the wave speed for the wavelength L in the actual current field. From the apparent spectra we calculate the true spectra with respect to the true frequency f_0 given by

$$f_0 = \frac{c_0}{L} = \frac{k}{2\pi} \left[\left(\frac{g}{k} + \frac{T_1 k}{\rho} \right) \tanh kd \right]^{1/2} \quad (2)$$

where c_0 is the wave speed under no current for wavelength L , k the wavenumber ($=2\pi/L$), T_1 the surface tension, ρ the density of water, g the acceleration due to gravity, and d the depth of water. If the wave speed c is expressed as a function of wavelength L for a particular current condition, then f_A and f_0 are related by (1) and (2).

In the calculation of c the effect of drift current must be taken into account in addition to various general currents. For this purpose we used the wave speed solution for a logarithmic drift current obtained by Kato (1974). That is, the drift current profile was assumed to be represented by the logarithmic distribution

$$U(y) = u_0 - U_r \ln [(z_{0w} - y)/z_{0w}] - by \quad (3)$$

where y is the vertical position measured upward from the water surface, u_0 is the surface drift current, and U_r , z_{0w} and b are arbitrary constants which are to be determined corresponding to the actual drift current profile. In practice z_{0w} was taken to be 0.01 cm for all cases (cf. Kato (1974) and Duncan et al (1974) for the measured values in the wind-wave channel), and U_r and b were determined by using the observed current velocity profiles.

Since the wind waves have the angular spreading the actual relation between f_A and f_0 is considerably complicated as discussed by Cartwright (1963) and Barnett and Wilkerson (1967) for somewhat different cases where the wave sensor was transferred with a uniform speed. However, the angular spreading is relatively small for the waves in the wind-wave channel, especially for the dominant wave components which are mainly concerned in this paper. If we neglect the angular spreading, then the relation between the true spectrum ϕ_0 and the apparent spectrum ϕ_A is expressed as

$$\sum \phi_0(f_0) \left| \frac{\partial f_0}{\partial f_A} \right| = \phi_A(f_A) \quad (4)$$

where the summation is taken for all possible combinations of f_0 and f_A . In our experiments f_0 and f_A were uniquely related in all cases and the relation (4) can be simplified to

$$\phi_0(f_0) \cdot \Delta f_0 = \phi_A(f_A) \cdot \Delta f_A \quad (5)$$

By using the relation (5) we calculated the true spectra from the apparent spectra.

3. Experimental results

3.1 Data of winds and currents

The values of wind friction velocity u_{*a} which were determined from the wind velocity profiles are shown in Table 2. In general u_{*a} are larger in the cases of adverse current than in the cases of favorable current reflecting the water surface conditions.

Table 2. Values of u_{*a} (cm/sec).

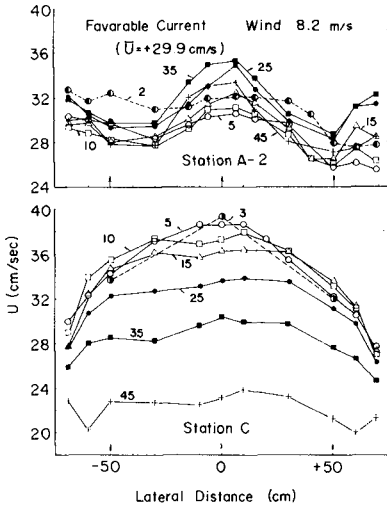

Fig. 3 Lateral current distribution in a case of favorable current.

Fig. 4 Lateral current distribution in a case of adverse current.

The lateral distributions of current velocity at A-2 and C stations in the case of favorable current $\bar{U}=+29.9$ cm/sec at wind 8.2 m/sec are shown in Fig. 3. As seen from this figure, in the cases of relatively large favorable currents ($\bar{U}=+20.3$ and $+29.9$ cm/sec) the velocities near the water surface at C and D stations became somewhat larger at the central part than those at the both sides. On the other hand, in the cases of adverse current the lateral velocity distributions were almost uniform at every station. The distributions with and without wind at A-2 station in the case of $\bar{U}=-20.3$ cm/sec are shown in Fig. 4. Obviously the distributions near the surface were made more uniform by the action of wind.

The values of surface current velocity u_0 under various current conditions at wind 8.2 m/sec are shown in Fig. 5. The measurement of u_0 was so difficult in the case of adverse current $\bar{U}=-20.3$ cm/sec that it was performed in that case by suppressing the waves with detergent mixed in water.

3.2 Variation of wave heights

The measurements of waves at each station were conducted at three lateral positions; at the center of channel width and 50 cm apart from it to both sides. As a parameter to represent the total wave energy we use the significant wave height $H_{1/3}$ evaluated from $\bar{\eta}^2$, the average of the three lateral values, where η is the water surface displacement. Fig. 6 shows the variation of $H_{1/3}$ with fetch under various current conditions at wind 8.2 m/sec.

Fig.5 Values of surface current velocity u_0 .

Fig.6 Variation of $H_{1/3}$.

In the cases of large adverse current the peculiar waves propagating obliquely grew with time at short fetches and the total power there became unusually large. The frequencies of such waves were smaller than those of usual wind waves, and the powers (spectral densities) of such oblique waves were excluded approximately in the computation of $H_{1/3}$. As seen from Fig. 6 the wave heights $H_{1/3}$ change systematically with currents, being small for favorable currents and large for adverse currents.

3.3 True spectra and the peak frequencies f_{0m}

As some examples of the obtained true spectra the results in the cases of $\bar{U}=+29.9$ and -14.4 cm/sec at wind 8.2 m/sec are shown in Figs. 7 and 8. From Fig. 7 it is seen that the low frequency wave components develop remarkably from A-2 to B stations. In Fig. 8 the spectra at short fetches such as A-2 and A-3 have two peaks, respectively. The right peaks of them correspond to the usual wind waves. Concerning the left peaks the obtained spectral densities may not be correct so much, but they correspond to the obliquely propagating waves mentioned above.

Fig. 7 True spectra ; $\bar{U}=+29.9$ cm/sec, Wind = 8.2 m/sec.

Fig. 8 True spectra ; $\bar{U}=-14.4$ cm/sec, Wind = 8.2 m/sec.

We define a dominant wave at each fetch corresponding to the peak frequency of true spectrum f_{0m} . Then the dominant wave length L_m can be calculated from f_{0m} by using the relation (2). Fig. 9 shows the obtained values of L_m under various current conditions at wind 8.2 m/sec. As seen from this figure the dominant wave lengths L_m are just like $H_{1/3}$ small for favorable currents and large for adverse currents. This variation of wavelength with current is quite contrary to the behavior of the waves moving from still water to a region of current. Huang et al (1972) calculated the wave spectra on currents by considering the kinematic and dynamic interaction between a component wave and current and also using the Pierson-Moskowitz spectrum. However, we must be aware of the distinct difference between the waves generated on a current and the waves propagated into the current from still water.

The values of L_m in each case could be represented as a function of fetch F in the form

$$L_m = \alpha F^n + L_0 \tag{6}$$

where α , n and L_0 are constants. The curves in Fig. 9 show the relation (6) applied to the data in each case, where at short fetches in the cases of adverse current the values of L_m measured photographically (but not shown in Fig. 9) were taken into consideration in order to exclude the influence of the oblique waves mentioned earlier.

Fig. 9 Variation of dominant wave-lengths L_m with fetch.

Fig. 10 True spectra under different current conditions.

3.4 Equivalent fetch length

Fig. 10 shows the true spectra obtained under different current conditions at the station A-3 (fetch = 5.25 m) at wind 8.2 m/sec. The high frequency parts of these spectra almost coincide in a curve and the variation of these spectra with currents resemble closely the variation of the spectra with fetch under no current. This fact suggests that the most prominent effect of water current on the development of wind waves is to change the effective fetch length. This effect must be caused by the change of the wave energy transfer velocity due to the current.

Concerning the development of a particular wave component, a fetch length F_1 and a wind duration time t_1 related by

$$t_1 = F_1 / c_g \quad (7)$$

are regarded as equivalent dynamically (Phillips and Katz, 1961), where c_g is the group velocity of the component wave. t_1 of eq. (7) represents the time required for the energy of the component wave to propagate over the distance F_1 . In the sense similar to (7) we assume that the wind duration time which substantially controls the total wave energy at fetch F under a particular current condition is directly proportional to the time \hat{t} given by

$$\hat{t} = \int_0^F \frac{1}{c_{gm}(x)} dx \quad (8)$$

where c_{gm} is the group velocity of the dominant wave at each fetch; \hat{t} of (8) is the time required for the energy of dominant wave to arrive at the measuring spot concerned. Then we can define the effective fetch length F' which is equivalent to fetch F under no current in respect of the development of total wave energy as follows:

$$F' = F \cdot [\hat{t} / \hat{t}_0] \quad (9)$$

where \hat{t}_0 is the value of \hat{t} under no current. In our experiments the values of \hat{t} were calculated numerically by using the empirical relation (6) as well as the current data measured at six stations.

3.5 Non-dimensional representation of $H_{1/3}$ and f_{0m}

Concerning the growth of wave spectra under no current it has been found by Mitsuyasu (1968) that the total wave energy E ($=\overline{\eta^2}$) and the spectral peak frequency f_m are represented in the non-dimensional forms such as

$$g\sqrt{E} / u_{*a}^2 = 1.31 \times 10^{-2} (gF / u_{*a}^2)^{0.504} \quad (10)$$

$$u_{*a} f_m / g = 1.00 (gF / u_{*a}^2)^{-0.330} \quad (11)$$

These fetch relations were obtained using the wind and wave data in a bay as well as in a wave tank and the similar relations were also obtained from the wave data of JONSWAP (Hasselmann et al, 1973). Recently it was found by Mitsuyasu and Rikiishi (1975) that the wave data in a wind-wave channel only are more fitted to the following relations:

$$g\sqrt{E} / u_{*a}^2 = 6.70 \times 10^{-3} (gF/u_{*a}^2)^{0.641} \quad (12)$$

$$u_{*a} f_m / g = 1.19 (gF/u_{*a}^2)^{-0.357} \quad (13)$$

By replacing \sqrt{E} with $H_{1/3}$ the relation (12) can be rewritten as

$$\frac{g H_{1/3}}{u_{*a}^2} = 0.0268 \left(\frac{g F}{u_{*a}^2} \right)^{0.641} \quad (14)$$

Using the equivalent fetch F' of eq. (9) in place of the natural fetch F together with the wind friction velocity u_{*a} , experimental data of $H_{1/3}$ and f_{0m} were plotted in the non-dimensional forms stated above, respectively. Fig. 11 shows the results for $H_{1/3}$. In this figure, at the higher wind speeds (8.2 and 11.0 m/sec) the data from different current conditions are consistent very well in a line and this indicates that the non-dimensional representation by the equivalent fetch F' is adequate. On the other hand, the data at the lowest wind speed (5.6 m/sec) deviate from the points at the higher wind speeds. Such inconsistency, however, has already been reported in the case of no current by Mitsuyasu and Honda (1975), and it is supposed to be due to the undeveloped wave condition. A straight line in Fig. 11, which was determined for the data at the higher winds, is represented by

$$\frac{g H_{1/3}}{u_{*a}^2} = 0.0222 \left(\frac{g F'}{u_{*a}^2} \right)^{0.669} \quad (15)$$

The dotted line in Fig. 11 shows the relation obtained by Mitsuyasu and Rikiishi (1975), eq. (14), and the two relations coincide very well.

Fig. 12 shows the results for the peak frequency f_{0m} . Also in this figure the data at the higher two wind speeds are represented pretty well by a straight line in the figure which is given by

$$\frac{u_{*a} f_{0m}}{g} = 0.939 \left(\frac{g F'}{u_{*a}^2} \right)^{-0.354} \quad (16)$$

The relation (13) by Mitsuyasu and Rikiishi (1975) is also shown in Fig. 12 by the dotted line. Although there is some difference between our result and (13), it is mostly attributed to the effect of drift

Fig. 11 Experimental results of $H_{1/3}$ represented in the non-dimensional form.

Fig. 12 Experimental results of the peak frequency f_{0m} represented in the non-dimensional form.

current; in our experiments the effect of drift current was completely corrected, while no correction was made for the data of Mitsuyasu and Rikiishi (1975). Since, however, it is rather customary under no current to use the frequency data including the effect of drift current, we must notice it in case of extrapolating the present relation (16) up to a field scale.

4. Conclusions

We have described the experiments conducted in a wind-wave channel to investigate the effect of water current upon the development of wind waves.

From the experimental results it was inferred at first that a water current has an effect to change the substantial (effective) fetch length; an adverse current increases the effective fetch and a favorable current decreases it. Considering the change of energy transfer velocity due to the current, we proposed an idea of equivalent fetch length to express the current effect on the development of wind waves.

It was shown that the non-dimensional fetch relations, which were originally obtained for the wind waves under no current, can equally be applied to the wave data, $H_{1/3}$ and f_{0m} , under various current conditions if the equivalent fetch length is used in place of the natural fetch.

The idea of equivalent fetch length is expected to be of use in the prediction of wind waves in the sea when there is a current, although some assumptions will be necessary in the case of adverse current.

Finally the authors are grateful to Mr. Y. Miyazaki and Mr. T. Doi for their assistance in the experiments.

CHAPTER 43

VARIABILITY OF LONGSHORE CURRENTS

BY

R. T. Guza¹ and E. B. Thornton²

ABSTRACT

Simultaneous measurements were made of the offshore directional spectra of gravity waves, and longshore currents within the surf zone. The goal was to test theories which suggest a direct relationship between mean longshore currents (\bar{V}) in the surf zone and offshore values of the off-axis component of radiation stress (S_{xy}). Seventeen minute averages of both S_{xy} and \bar{V} showed considerable temporal variation, and little S_{xy} or no tendency to vary together. There was also considerable longshore spatial variability of the longshore current. Attempts to measure gradients of S_{xy} in the surf zone failed because of small errors in instrument orientation. The measurements suggest that considerable temporal and spatial averaging will generally be required to obtain a representative picture of longshore currents, even if no rip currents are present, due to the presence of "eddy" motions or long edge waves.

INTRODUCTION

Following the introduction of the concept of radiation stress (Longuet-Higgins and Stewart, 1964) many detailed theories for mean longshore currents in the surf zone region have been advanced (for example: Bowen, 1969a; Thornton, 1970; Longuet-Higgins, 1970). Earlier work (Putnam et al (1949), Inman and Quinn (1951) contained much of the essential physics but lacked a quantitative formulation. The newer formulations are fundamentally similar to each other in that they propose a longshore momentum balance between forcing terms related to the mean lateral thrust exerted on the surf zone by non-normally incident incoming gravity waves, and retarding forces associated with bottom drag. Lateral mixing complicates the picture by diffusing longshore momentum across horizontal shear currents. Different authors use

¹Asst. Professor, Shore Processes Lab, Scripps Inst. Oceanography, La Jolla, California

²Assoc. Professor, Naval Postgraduate School, Monterey, CA

different assumptions about the behavior of waves inside the surf zone and about the detailed forms for drag and mixing terms. As a result, the predictions of the magnitude of mean longshore currents and the distribution across the surf zone are somewhat different for identical incident wave conditions. The different theories do agree that for plane parallel contours the total lateral thrust on the surf zone is given by the off-axis term of the offshore radiation stress tensor, S_{xy} , or equivalently by, S_{xy}^B , the "break point" radiation stress value. Evaluation of S_{xy}^B involves estimation of a significant breaker angle, period and height, subjective quantities prone to gross errors (different observers on the same day report values of S_{xy}^B commonly differing by more than 100%). Therefore, in order to test the theories for longshore current with observation we have simultaneously measured S_{xy} offshore (10 m. depth) and longshore currents within the surf zone.

Instrumentation

A large scale field experiment was conducted at Torrey Pines Beach near San Diego, California during the month of March 1977. Properties of the incident gravity wave directional spectrum were measured with a 400 m. long, 5 element linear array of Statham pressure sensors; their mean depth was about 9.5 m. Six biaxial Marsh-McBirney electro-magnetic current meters were installed in the surf zone during low tide. A plan view of instrument positions is shown in Fig. 1A. The pressure sensor signals were telemetered to shore using the SAS system described in Lowe et. al (1972). The current meters were powered and sampled from shore using armored cables. The sampling frequency was 64Hz; the data was immediately block averaged and decimated to 2 Hz.

Figure 1B shows typical shallow water depth profiles for range lines A, C, D on East-West transects. The profiles overlay other when put in a coordinate frame rotated $4^\circ N$ of E (the orientation of the pressure sensor array) suggesting approximately plane parallel contours in this coordinate frame. Contours between the offshore array (not shown) and the current meters show no marked deviation from plane parallel ($4^\circ N$ of E) suggesting that refraction does not lead to significant alongshore gradients of breaker height.

Incident Wave Field

The offshore directional spectrum was analyzed using Fast Fourier transforms in the time domain to obtain phase lags for each frequency band. These phase lags were analyzed using maximum likelihood estimation techniques to obtain the direction distribution of wave energy in each frequency band. Steve Pawka did the offshore wave analysis and subtleties of the analytic methods are discussed extensively in his soon to be completed Ph.D. thesis. We thank him for kindly providing directional spectra for use in this

Figure 1. (A) Plan view of instrument locations. x = pressure sensors, 0 = current meters
 (B) Depth profiles for various range lines on E-W transect.

discussion of offshore radiation stress terms. Fig. 2A shows a typical distribution of variance per frequency band. Each band is .0078 hz wide and has 16 degrees of freedom. The record length is 1024 sec. The energy is centered around periods of about 14 sec., with a background of higher frequency waves. Given the directional distribution of energy in each frequency band, $E(f, \alpha)$, the relevant off-axis component ($S_{xy}(f)$) of the radiation tensor is given by

$$S_{xy}(f) = \int_{-\pi}^{\pi} E(f, \alpha) n(f) \sin \alpha \cos \alpha \, d\alpha \quad (1)$$

where $n(f)$ is the ratio of group and phase velocities (assumed given by linear theory) at the array depth and α is the deviation from normal incidence. On plane parallel contours S_{xy} is a conserved quantity if no dissipation occurs (Bowen, 1969b; Thornton, 1970) so S_{xy} at the array gives S_{xy}^{∞} , the deep water value. The entire topography seaward of the array is not plane parallel, but for simplicity we have assumed that it is. Fig. 2B shows that $S_{xy}^{\infty}(f)$ is maximum at the peak energy frequencies. However, the relatively broader frequency band of high frequency "chop" makes a significant contribution to the total $S_{xy}^{\infty T}$. In this example, the principal peak contributes -5.7×10^3 g/sec² while the "chop" contributes $+3.5 \times 10^3$ g/sec². Thus, the total lateral stress exerted on the surf zone by all frequencies,

$$S_{xy}^{\infty T} = \int_0^{\infty} S_{xy}^{\infty}(f) \, df \quad (2)$$

contains significant contributions from a very broad range of frequencies. Visual observations of a significant breaker height and period generally pick out the swell peak and ignore the chop. In certain cases, strong locally wind generated high frequency waves with large angles of incidence may produce a true S_{xy}^T , which is opposite in sign to S_{xy}^T estimated by visual observations biased towards long swell. This may explain some (but probably not all) of Nummedal and Finaley's (1978) observations showing a stronger correlation between local wind and longshore current than between visual observations of S_{xy} and longshore current. More concisely, the eye simply is not a very good directional spectrum estimator when the incident wave field is broadbanded in both frequency and direction. Figure 2C shows the "principal stress angle of approach" $\hat{\alpha}_{\infty}(f)$ defined (rather arbitrarily) using (1),

$$\sin \hat{\alpha}_{\infty}(f) \cos \hat{\alpha}_{\infty}(f) = \frac{S_{xy}^{\infty}(f)}{n_{\infty}(f) E_{\infty}(f)} \quad (3)$$

where $S_{xy}^{\infty}(f)$ and $E_{\infty}(f)$ are the radiation stress and energy per frequency band in deep water. As is obvious from $S_{xy}(f)$,

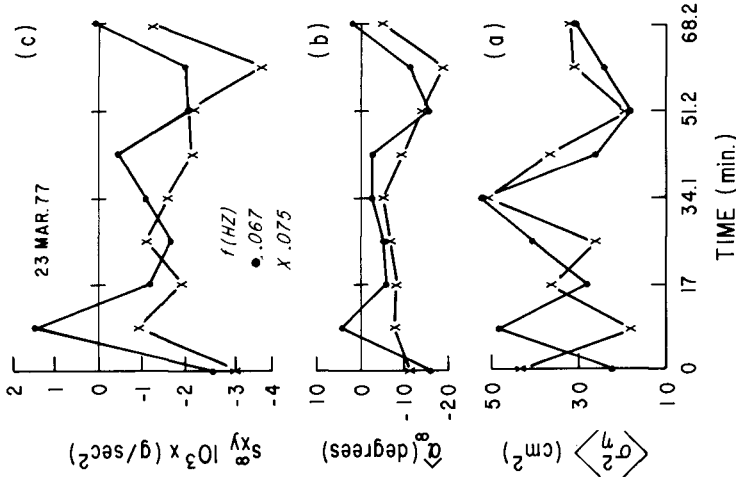

Figure 3. Time series of successive values from records, 1024 secs long, for two adjacent frequency bands in swell peak (Fig. 2) of (a) variance in each band, (b) principal stress angle, (c) radiation stress

Figure 2. (a) Variance Spectrum, $\langle \sigma^2 \rangle$ per frequency band. (b) Offshore radiation stress, s_{xy}^∞ per frequency band. (c) Equivalent deep water principal stress angle of incidence for each frequency band.

$\hat{\alpha}_{\infty}(f)$ shows the swell and chop approach from different quadrants.

Measurements of $S_{xy}^{\infty, T}$ on several different days show it to be a statistically noisy quantity. This is not surprising because each $S_{xy}^{\infty}(f)$ depends on both the variance and directional distribution of energy in that band. Figure 3 shows the time history of variance (Fig. 3a), $\hat{\alpha}_{\infty}$ (Fig. 3b), and $S_{xy}^{\infty}(f)$ (Fig. 3c) for the two adjacent bands in the swell peak S_{xy}^{∞} shown in figure 2a. The energy dances about, as does $\hat{\alpha}_{\infty}$. The combination of the two fluctuating quantities going into $S_{xy}^{\infty}(f)$ leads to statistical variation of $S_{xy}(f)$. We note that the behavior of $\hat{\alpha}_{\infty}$ and $\langle \sigma^2 \rangle$ are somewhat correlated for these adjacent frequency bands, but that $S_{xy}(f)$ is apparently less correlated. Considering that S_{xy}^T is made up of many $S_{xy}(f)$ which all fluctuate, it is not surprising that S_{xy} is statistically unstable. We have done no further statistical analysis of S_{xy} and only make the general comment that, at Torrey Pines Beach, 1024 secs (17.1 min) does not appear to be a long enough sampling time to adequately measure the forcing function $S_{xy}^{\infty, T}$.

Surf Zone Longshore Currents

Fig. 4 shows 1024 sec means of longshore currents inside the surf zone and of offshore measurements of $S_{xy}^{\infty, T}$. Fig. 4a demonstrates the significant temporal fluctuations of S_{xy} discussed previously. Visual observations (whatever they may or may not signify) did not indicate any obvious non-stationarity of the incident wave field. Large breakers (1.5 m. height) were present with pronounced angles of approach. All current meters were in the inner half of the surf zone. No obvious permanent rips were observed between A and D ranges. Figs. 4b, c, d show mean values of longshore current for sensors at various longshore and on-offshore locations (Fig. 1). At this particular tidal stage (during high tide with little mean depth change) the shallowest and deepest current meters were in depths of about 60 cm. and 120 cm. respectively. The instruments on the same on-offshore range line show some tendency to vary together, but range lines 100 m. apart in the longshore direction (A and C for example) show little tendency to vary together (Fig. 4). Furthermore, no instrument showed an obvious covariation with $S_{xy}^{\infty, T}$.

Referring back to theory (Longuet-Higgins, 1970, eqs. 54-55) for guidance, we should actually expect the surf zone width to vary with $E^{\infty, T}$, and the current strength at a fixed location (always inside the breakpoint) to vary with $\hat{\alpha}_{\infty}^T$, some measure of an approach angle characteristic of the entire directional spectrum across all frequency bands (recall $\hat{\alpha}_{\infty}(f)$ represents the principal stress angle for a given frequency band). We made an extremely crude estimate of $\hat{\alpha}_{\infty}^T$ using

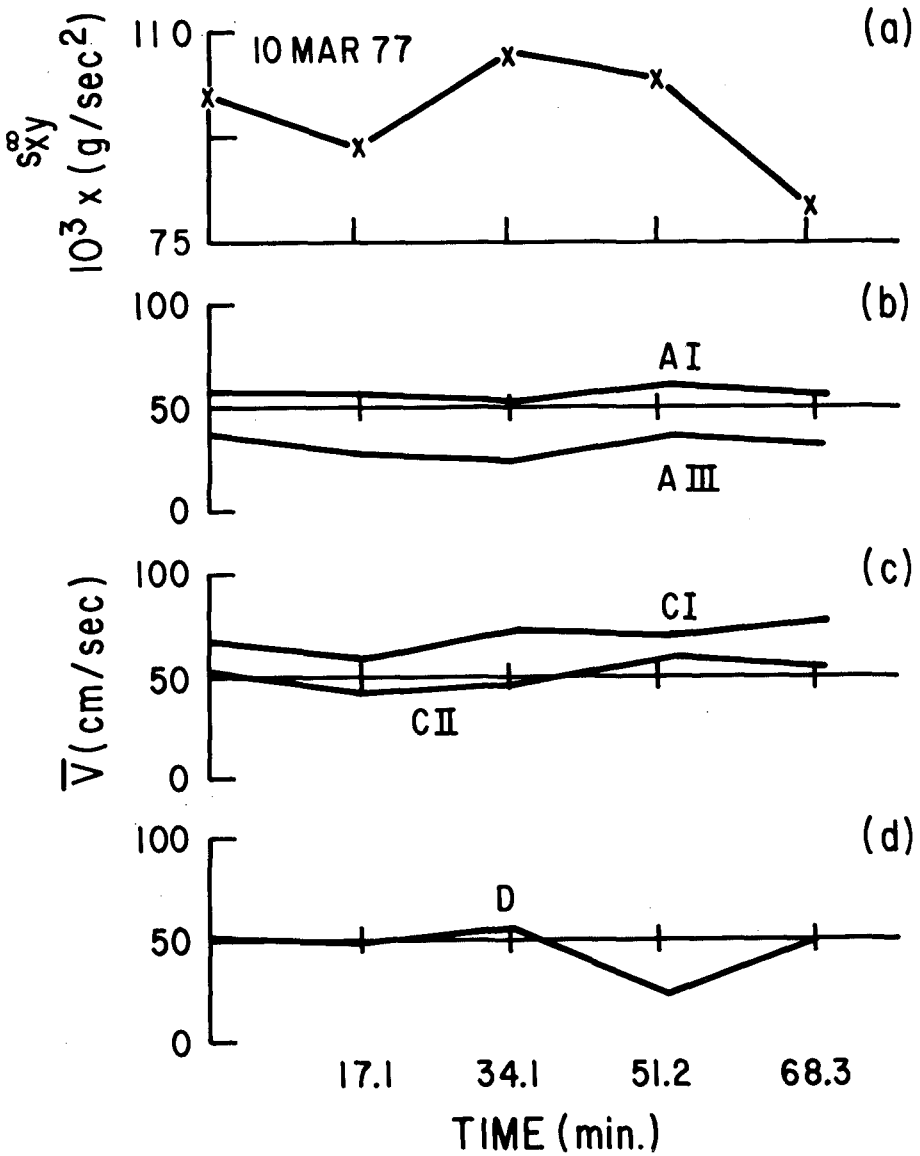

Figure 4. Temporal (1024 secs) averages on 10 March 1977 of
 (a) Total offshore radiation stress
 (b,c,d) Longshore current at different surf zone locations

$$\sin \hat{\alpha}_{\infty}^T \cos \hat{\alpha}_{\infty}^T = \frac{S_{xy}^{\infty, T}}{E_{\infty}^T n_p} \tag{4}$$

where n_p is given by the frequency of the spectral peak. No longshore currents showed an obvious covariation with $\hat{\alpha}_{\infty}^T$. Our conclusion is not a welcome one: considerable longshore variation of mean (temporal) longshore currents can occur even on a relatively straight beach with no obvious rip structures. A large (unknown) amount of longshore spatial averaging, as well as temporal averaging, may be necessary to determine the "mean longshore current" on a given depth contour.

The dominant term in the longshore momentum balance is on-offshore gradients of S_{xy} inside the surf zone, regardless of the contribution of S_{xy} nonlinear terms (for example $\bar{v} \partial v / \partial y$) or alongshore variations in breaker height. If nonlinear terms, longshore variations in mean sea level, and lateral mixing are neglected, the longshore momentum is simply

$$\frac{\partial S_{xy}^T(x)}{\partial x} = \frac{1}{2} \rho C_f \overline{|\vec{U}(x,t)| v(x,t)} \tag{5}$$

where C_f is a Chezy' drag coefficient, $\vec{U}(t)$ and $v(t)$ are the instantaneous total and longshore velocities respectively, $||$ is absolute value, and the overbar indicates time averaging.

Assuming no vertical variations in fluctuating horizontal velocities ($u'(x,t)$ and $v'(x,t)$),

$$S_{xy}^T(x) = \rho h(x) \overline{u'(x,t)v'(x,t)} \tag{6}$$

The usual simplifications of the drag term (Eq. 5) necessary for analytic progress (for example, that $u' > v'$) are not necessary when measured time series are available. We simply computed $S_{xy}^T(x)$ at different offshore locations on the same range line, and solved for C_f

$$C_f = \frac{2(S_{xy}^T(x_2) - S_{xy}^T(x_1))}{\rho \overline{|\vec{U}(x_i,t)| v(x_i,t)}}$$

different values of C_f result from calculating the friction term at location 1 or 2. Fig. 5 shows measured offshore variance, $S_{xy}^{\infty, T}$ and low passed means of surf zone radiation stress gradients. There seems to be a similarity between $S_{xy}^{\infty, T}$ and $\frac{\partial S_{xy}^T}{\partial x}$ in the surf zone. Calculated values of C_f

Figure 5. Temporal (1024 sec) averages on 23 March 1977 of total offshore variance, total offshore radiation stress, and running means of dS_{xy}^T/dx inside the surf zone from instruments AII, AIII.

are shown in Fig. 6a. Different C_f values occur depending on whether time series from A II (mid surf zone) or A III (inner) are used in calculating drag terms. Averaging C_f (mid) and C_f (inner) for the whole data set gives $C_f \approx .003$, which is not considerably different than the commonly used value of .01. This was the first data set analyzed and we thought some of the low value of C_f could be due to neglected nonlinear terms, or longshore and vertical variations in S_{xy} . It was more worrisome, however, that the actual magnitudes of S_{xy} at surf zone locations (also shown in Fig. 6) indicated a larger S_{xy} at mid-surf zone than at the offshore array. This does not seem possible since S_{xy} is conserved quantity during non-dissipative shoaling, and theoretically decays monotonically across the surf zone.

We attempted to test the assumption of no vertical variation in $u|v|$ in another experiment (July, 1978) using 6 flow meters horizontally closely spaced. Three meters were installed on the same depth contour, separated by 1 m. in the longshore direction, at different elevations off the bottom. To insure that no interference between closely spaces electromagnetic current meters occurred, the magnet drivers operated in a synchronous master-slave configuration. The flow meters were dynamically calibrated over the entire frequency range of interest using an oscillating arm. Considerable effort was made to carefully align the current meters. The current meters were mounted on a bracket that allowed three degrees of rotation. A special jig was used to orient the mounting bracket vertically with a bubble level and horizontally with a compass. Tests were conducted to insure that deflections of the compass needle by the ferrous mounting bracket were minimized.

The measurements were initially encouraging in that all instruments showed virtually the same on-offshore velocity spectra. For example, the spectra of instruments the same depth above the bottom, and separated by 7 m. in the on-offshore direction (a total depth difference of 8 cm.) are given in Fig. 7; the spectra show similar variance, a very high coherence, and a phase speed slightly faster than \sqrt{gh} with h the measured mean depth. Fig. 8 shows the similarity between longshore velocity spectra.

Particular note in Fig. 8 should be paid to the large low frequency components in the longshore velocity spectra; this is similar to the low frequency longshore current oscillations described in Inman and Quinn (1951), Woods and Meadows (1975), Woods (1976), and more recently by Holman et al. (1978). Without exception every longshore velocity spectra of the hundred or so we examined (corresponding to about 60 hours of observations over a month long period) showed this tendency towards spectral redness, regardless of record length. The longshore current temporal fluctuations are not site or wave regime specific since the present

Figure 6. (a) Calculated values of drag coefficient, C_f , at mid and inner current meters
(b) Measured values of S_{xy}^T at the offshore array and mid and inner surf zone locations.

Figure 8. Longshore velocity spectra coherence and phase for the same instruments as in Fig. 7.

Figure 7. On-offshore velocity spectra, coherence and phase for instruments in depths differing by 8 cm. with an on-offshore separation of 7 m. Record length is 1024 sec. There are 32 degrees of freedom. Solid lines shown on phase curve is for a phase speed given by \sqrt{gh} , $h' = 160$ cm. The actual mean depth was 120 cm.

observations are from Southern California, Woods and Meadows observations are from the Great Lakes, and these of Holman et al. are from the wilds of Atlantic Nova Scotia. This mass of data suggests a grave danger in any assumptions of temporal stationarity such as are implicitly made when profiling "mean" currents with a movable sled or other such device. An appropriate temporal averaging time for mean longshore currents is not known. Woods and Meadows (1975) show 4 successive 15 minute means, and these averages, about 60 cm/sec, differ from each other by less than 5 cm/sec. Clearly, in this case, 15 mins. is a long enough time to obtain a stable average. On the other hand, Fig. 9 shows sequential 256 sec. (4.3 min) averages from 5 closely spaced instruments at Scripps Beach. The instruments vary together suggesting that the observed fluctuations are not due to sensor malfunction. Sequential means at the same location typically vary by as much as 20 cm/sec., so a single 4.3 min. average is not a representative value of the mean over longer time scales.

Upon calculating S_{xy}^T from these current meter records Figs. 7,8, instead of finding very similar values as anticipated, we found order of magnitude difference, sign reversals, and a general scatter suggestive of useless data! The reason for this is as follows. It can easily be shown that, at a particular current meter

$$\begin{aligned} S_{xy}^T &= \rho h(x) \int_0^\infty C_{xy}(f) df \\ &= \rho h(x) \int_0^\infty (E_u(f)E_v(f))^{1/2} \gamma_{uv}(f) \cos\theta(f) df \quad (7) \end{aligned}$$

$E_{u,v}(f)$ are the energy densities of (u and v) respectively, $\theta(f)$ is the phase angle between u and v, and $\gamma_{uv}(f)$ is the coherence between u and v. Figs. 10 and 11 show these spectral quantities for two closely spaced instruments. Although the spectral values are similar (Figs. 7,8), the values of coherence and phase are not. For example, around the spectral peak at .1 hz, Fig. 10 shows a narrower band of higher coherence than Fig. 11, and a phase of about $\pi/2$ compared with π in Fig. 11. This is typical of the difference between sensors and clearly shows (eq. 7) why S_{xy}^T is so different for the two instruments. Why is this occurring?

Large errors in radiation stress can occur due to even small errors in resolving the direction of fluid motion associated with the angle of incident waves. In terms of the measured spectra, the total energy density and the quadrature-spectrum are invariant with coordinate rotation, but the cospectrum used to calculate radiation stress is very sensitive to coordinate rotation.

Figure 9. Time history of 256 sec. averages of longshore current from 5 closely spaced current meters, maximum separation is 14 m.

Figure 11. Same as Fig. 10, but the instrument is 7 m shorewards.

Figure 10. Spectral values, coherence, and phase for on-offshore and longshore currents at one location.

A simple application of Snell's law to a monochromatic plane wave with period 12.6 sec. shows that refraction reduces a deep water angle of incidence (α_∞) to a local angle (α) in a depth of 1 m. given by

$$\frac{\alpha}{\alpha_\infty} = .17$$

Thus, even a relatively large deep water approach angle of 20° is reduced to a small angle of 3.4° . Now consider correctly measured velocity components (u, v) and incorrectly measured velocity components (u_r, v_r) due to a coordinate rotation of angle Δ as shown in Figure 12. Assuming either all waves approach from the same direction or using a monochromatic wave argument, the radiation stress using equation 6 can be stated proportional to

$$S_{xy}^T(x) \propto \overline{u'(x,t)v'(x,t)} = \overline{u'(x,t)}^2 \tan \bar{\alpha}$$

Assuming small angles of approach and small rotation errors, the incorrectly measured radiation stress is proportional to

$$\begin{aligned} S_{xy}^T(x)_r &\propto \overline{u'_r(x,t)v'_r(x,t)} \\ &= \overline{u'(x,t)v'(x,t)} - \overline{u'(x,t)}^2 \sin \Delta \end{aligned}$$

The relative percent error is given by

$$1 - \frac{S_{xy}^T(x)_r}{S_{xy}^T(x)} = \frac{\sin \Delta}{\tan \bar{\alpha}} \approx \frac{\Delta}{\bar{\alpha}}$$

Therefore, since refraction reduces the local angle of incidence to the size of the orientation errors, the error in radiation stress can be very large.

Given perfect instrument directional response and perfect orientation, there is also the more fundamental problem of defining the longshore direction. What spatial scales should be averaged over to determine a contour orientation? Errors associated with choosing a longshore direction even on the relatively straight and parallel contours of Torrey Pines appear to be on the order of several degrees minimum. Therefore, our calculations of C_r (Fig. 6) are probably nonsensical.

Fortunately the small orientation errors discussed above do not introduce serious errors in measurement of mean longshore current because \bar{V} is generally larger than \bar{U} , so the projection of small fractions of \bar{U} onto the \bar{V} signal is not a large error. Our conclusion is that without further sophistication in instrument orientation and design and a better understanding of length scales, it is not possible to measure radiation stress in the surf zone.

Figure 12. Rotation of coordinate axis for investigation of its influence on radiation stress.

CONCLUSIONS

1. Offshore measurement of radiation stress (the theoretical total lateral thrust exerted on the surf zone) show it to be statistically noisy. This is a preliminary result and it may be site and wave climate specific. Nevertheless, until demonstrated otherwise, short time interval measurements of S_{xy} cannot be considered as necessarily giving an accurate \bar{S}_{xy} estimate of the true mean S_{xy} .
2. Mean longshore currents at a fixed surf zone location are temporally noisy. This has been previously observed by several authors. Mean longshore currents are also spatially noisy, even with no obvious rips, suggesting that nonlinear terms and local short term variations in alongshore breaker height are important in the equations of motion. Free "eddy" motions may also be present in the surf zone.
3. Measurements of S_{xy}^T in the shallow portions of the surf zone are seriously contaminated by even small ($\pm 2^\circ$) sensor orientation errors. This is also true for vertical velocities.
4. A closing philosophical-historical point: the pioneering studies during the early 1950's of Sverdrup, Munk, and Stommel presented a rather simple picture of large scale ocean circulation. The forcing by wind, was represented by a simple long term average. The predicted currents were generally weak and horizontally smooth. The equations used by these authors are basically identical to the standard surf zone equations. They even discussed the relative importance of drag and eddy diffusivity terms, just as is currently done in surf zone dynamics. Nonlinear terms were necessary to explain the jet-like Gulf Stream, just as we currently need these terms to get appropriately strong and narrow rip currents (Arthur, 1962; Bowen, 1969b). Observations with Swallow floats showed, however, that while these theories might correctly predict yearly means, instantaneous (compared to a year) measurements showed large temporal and spatial fluctuations. Even though an enormous amount of energy and money has since been spend on experiments like MODE and POLYMODE to try to determine the importance of shorter scale fluctuations on the longer scale flows, these questions remain unresolved. Considering the strong analogy between developments so far, and the gross nonlinearity of the surf zone, it is probably overly optimistic to hope that out task of accurately difining and understanding mean nearshore flows will be simple.

INTRODUCTION

We consider a straight coastline exposed to large regular waves, of typical wave length, 100 m amplitude 1.6 m, and period 12 sec. The radiation stress gradients in the extensive (up to 2 km wide) surf zone cause set up and long-shore currents. Despite these currents, the beach is known to be fairly stable. If now a cooling water intake basin is introduced on the coast, it is required to determine first whether the wave induced currents in the vicinity of the basin will affect the circulation of cooling water and second, whether sediment transport will occur, leading to a dredging requirement for the basin.

An extensive programme of physical model testing and numerical studies is being undertaken, in order to answer the above questions, and this paper will survey the progress made to date. At the 15th Coastal Engineering Conference a paper on the application of a mathematical model to the prediction of dredging properties inside a cooling water intake basin was presented by Fleming and Hunt, which described the first stage of this work. In that paper a sediment transport model was combined interactively with numerical models of wave refraction, wave diffraction, long shore currents and circulation currents. The last of these numerical models was used to evaluate the current patterns due to the interruption of the continuity of the longshore currents, together with the cooling water flows in the vicinity of the basin. In this paper we describe the development of more sophisticated numerical models for the first three stages of the process.

An understanding of the process of longshore current and set up creation, depends on the concept of radiation stress, introduced by Longuet-Higgins and Stewart,^{12,13,14,15} in a series of papers. A number of workers have since used the radiation stress to determine coastline phenomena, and we now describe a few of the relevant papers, without any attempt at a comprehensive survey. Bowen^{5,6} considered a straight coastline with parallel contours, and determined near shore circulation patterns, using a stream function formulation of the shallow water equations, for normally incident waves, with a sinusoidal coastwise variation in wave amplitude. He used a finite difference method to solve for the stream function. Longuet-Higgins^{10,11} criticized Bowen's use of a constant mixing length (horizontal) viscosity, and introduced a viscosity which varied directly with the distance from the shore, in his one dimensional analytical model for obliquely incident waves. He was able to obtain analytically longshore velocity profiles, which he plotted for a range of viscosities. Sonu¹⁸ showed a wide range of field observations of currents and wave patterns. Recently Dalrymple et al⁸ have

given a comparison of experimental and numerical results for near shore circulation effects.

Probably the most comprehensive numerical attack on the problem is that of Noda^{16,17}. As in the present approach, the calculations fall into two main stages, the determination of the wave pattern, and the determination of the resultant circulation and set up. Noda calculates the wave patterns by using wave ray computations. Subject to the normal restrictions of wave ray theory, which are well known, this method is an efficient method of determining the wave pattern, where there are no wave diffraction, reflection or caustic effects. Noda used the Miche steepness wave breaking criterion to determine the extent of the surfzone. The next stage was the solution of the shallow water equations with radiation stress derivatives as forcing terms. This was done in a domain, whose longshore dimension was unknown a priori, and Noda used an iterative method to determine the extent of the model and to apply the correct boundary condition. A regular finite difference grid was used, and the equations were solved for stream function values using the Gauss-Seidel method.

Most previous attempts to predict near shore circulation have been applied to straight or periodically undulating coastlines. In the present case however, the introduction of the harbour (see Figure 1) complicates the geometry. In order to be able to model such geometries it was decided to use the finite element method for both the wave calculations and the current calculations. It was thought that current refraction effects would not be important, and no attempt has been made to iterate, to see how the currents would modify the wave pattern. The wave calculation is linear and does not require iteration. The use of a finite element model has the advantages over the ray method that wave diffraction, wave reflection and wave absorption are all modelled accurately. Caustics of course are still a problem for any linearised theory.

The calculation of the currents using finite elements usually requires several iterations, because the equations are non-linear. The finite elements can accommodate any problem geometry.

METHOD

DETERMINATION OF WAVE PATTERNS

The shallow water wave equations, or Berkhoff's^{2,3} modification of them for intermediate depths are used in the wave model. The governing equation, in terms of the complex velocity potential ϕ (which is factored by $\exp(i\omega t)$), is⁴

$$\nabla_{\sim} \cdot C C_g \nabla_{\sim} \phi + \frac{\omega^2 C_g}{C} \phi = 0 \quad (1)$$

where C is wave celerity, given by ω/k , where ω is angular frequency, and k is wavenumber $= 2\pi/L$, where L is wavelength. C_g is group velocity, given by

$$C_g = \frac{C}{2} (1 + 2kH/\sinh 2kH) \quad (2)$$

and the dispersion relation

Problem Geometry with depth contours

Fig. 1

$$\omega^2 = gk \tanh kH, \quad (3)$$

holds, where g is acceleration due to gravity, and H is the depth of water. Equation 1 can be recast in a variational form as explained in reference 4, and then discretized by the usual finite element method. This evidently enables the discretization of any finite domain of shallow water. Nodal variables are complex values of the velocity potential, or wave elevations. It is clear therefore that the basis functions used in the elements must actually model the variations in the elevation of the water surface. The elements used are quadratic. It is possible to model quite accurately the sine wave using three or four such elements. Fewer than 3 elements in 1 wavelength leads to increasing inaccuracy in the modelling. The resulting equations are complex and symmetrical.

Two problems in the modelling of the unbounded real problem are the extent of the numerical domain, both normal to the shore, and along it. The radiation condition

$$\frac{\partial \phi}{\partial n} - ik \phi = 0 \quad (4)$$

which is derived in detail in reference 4, must be imposed on the non physical boundaries of the model, in order to eliminate extraneous incoming waves. In reference 21 the various methods of applying this boundary condition, using boundary dampers, series solutions, boundary integrals and infinite elements are all discussed. The efficacy of curved boundary dampers is shown in reference 20. For boundaries normal to the shore a method using dampers to eliminate the longshore components of the incident waves was devised, after considerable numerical experimentation. This device enabled us to analyse any portion of an infinite coastline, without reflection or excessive absorption of waves at the non physical ends of the numerical model. The finite element model had the boundary conditions

$$\frac{\partial \phi}{\partial n} \pm ik_s \phi = 0 \quad (5)$$

enforced at the two ends (+ for one end, - for the other), by the addition of line dampers, where k_s was the longshore component of the incident wave number k . (That is for a wave originally incident at an angle θ to the normal to the coast, prior to any refraction, with wave number, k , then

$$k_s = k \sin \theta \quad (6)$$

The energy dissipation in the surf zone is not at present dealt with exactly. Instead the numerical model ends at a small but non zero depth, at the shore line. Here it is assumed that all waves are effectively normal, and they are completely absorbed by line dampers, with a damping constant depending upon the local wave number¹.

The program can easily accommodate breakwaters that partially or totally absorb waves incident upon them. This is done by using line dampers.

DETERMINATION OF RADIATION STRESS DERIVATIVES

Because most of the waves in the model are progressive all standing wave effects are ignored in calculating radiation stresses¹. This simplifies the computations. The output from the wave program are the complex wave

elevations throughout the mesh of elements⁷. At each point the derivatives of the radiation stress components in the two global co-ordinate directions are determined and they are then supplied to the currents program as forcing terms. The calculation is as follows. At each point the direction of zero phase change is found. This is orthogonal to the direction of wave propagation. The radiation stresses and their derivatives can be found in the curvilinear co-ordinate system so defined. Then using tensor transformations the radiation stress derivatives in the global x-y co-ordinate system can be obtained. Longuet Higgins¹⁵ expression for the stress tensor is

$$S_{\alpha\beta} = E \begin{bmatrix} \frac{2kH}{\sinh 2kH} + \frac{1}{2}, & 0 \\ 0, & \frac{kH}{\sin 2kH} \end{bmatrix} \quad (7)$$

where E is total energy density, $= \frac{1}{2} \rho g a^2$, a being wave amplitude, and ρ density of water. If the curvilinear co-ordinates are θ_1 and θ_2 , and the global co-ordinates are x_1 and x_2 , then the required forces f_i are

$$f_i = S_{ij,j} = S_{\alpha\beta\eta} \frac{\partial\theta\alpha}{\partial x_i} \frac{\partial\theta\beta}{\partial x_j} \quad (8)$$

and the forces can be obtained in the two global co-ordinate directions. (Because of the curvilinear nature of the local co-ordinates defined by the waves, the transformations of the derivatives are fairly complicated).¹

In the surf zone a breaking criterion of wave height proportional to depth is used, as is done by Longuet-Higgins¹⁰. The constant of proportionality, obtained from model tests was 0.4.

DETERMINATION OF CURRENTS

The program for the current calculations uses a version of the shallow water equations²².

$$H \left(u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} - \Omega v + g \frac{\partial \eta}{\partial x} \right) + C \sqrt{(u^2 + v^2)} \cdot u = \frac{2}{\rho} \frac{\partial}{\partial x} \mu \frac{\partial}{\partial x} H u + \frac{1}{\rho} \frac{\partial}{\partial y} \mu \left(\frac{\partial}{\partial y} H u + \frac{\partial}{\partial x} H v \right) + \frac{1}{\rho} f_x \quad (9)$$

$$H \left(u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + \Omega u + g \frac{\partial \eta}{\partial y} \right) + C \sqrt{(u^2 + v^2)} v = \frac{1}{\rho} \frac{\partial}{\partial x} \mu \left(\frac{\partial}{\partial y} H u + \frac{\partial}{\partial x} H v \right) + \frac{2}{\rho} \frac{\partial}{\partial y} \mu \frac{\partial}{\partial y} H v + \frac{1}{\rho} f_y$$

and

$$\frac{\partial}{\partial x} H u + \frac{\partial}{\partial y} H v = 0 \quad (10)$$

where u , v are horizontal velocities, η is the mean wave elevation, H is the water depth, Ω is the Coriolis parameter, C is the Chezy bed friction coefficient, μ is horizontal mixing length viscosity, ρ is density and f_x and f_y are the forcing terms.

The Galerkin weighted residual method is used to obtain a finite element formulation of these equations. The resulting non-linear equations are solved using the Newton-Raphson method. The penalty function approach was used to include the continuity equation, 10. Details are given elsewhere²², suffice it to note that an appropriate penalty factor must be chosen, and reduced integration must be used for the penalty.

In this case 8 noded isoparametric quadrilateral elements were used. A much coarser mesh of elements can be used than is needed for the wave solution, because the element shape functions have only to model the expected velocity profiles, not the actual wave shapes.

RESULTS

As was explained earlier the requirement of about 3 elements per wavelength in the finite element wave model leads to a very fine mesh of elements. For the geometry of the problem of interest such a mesh has not yet been generated or run, although similar large problems have been solved^{4,21}. The simpler problem of waves incident upon a parallel straight beach has been solved using the program¹, and no particular difficulties are envisaged, in the extension to large problems.

At present the radiation stresses are computed from wave elevations and directions obtained from model tests. The derivatives of the radiation stresses give the force vectors to be input to the currents program. Figure 2 shows a typical pattern of such forces. The main component of the radiation stresses is the onshore component, which would normally only lead to a set up. In the 'lee' of the breakwater, because the waves are smaller the surf line is much closer inshore, and the forces are much smaller. There is thus a rapid change in the onshore component of force in the lee of the breakwater.

The most problematical feature of the current calculations is the determination of appropriate value of the horizontal viscosity and the bed friction constant. A suitable value for the bed friction constant, $C = .002$ in equation 9, was suggested by model tests carried out by the laboratory. This was used in the numerical model. In addition a one dimensional model, using only one row of elements was run, with values of the bed friction constant, C , ranging from 0.001 to 0.003. The resulting velocity profiles are shown in Figure 3. It can be seen that changing the constant has very little qualitative effect on the velocity profile, and it was concluded that the behaviour of the numerical model was not too sensitive to this parameter.

The information available on values of the horizontal viscosity is rather sketchy. Bowen⁵ takes eddy viscosity to be constant throughout the numerical model and presents circulation patterns for a range of Reynolds Numbers. Longuet-Higgins¹⁰ argues that an eddy viscosity which is proportional to the distance from the shore is more realistic, and he uses this assumption in deriving his one dimensional velocity profile. In our case both constant and linearly varying eddy viscosities have been used. Typical flow patterns for the two cases are shown in Figures 4 and 5. For constant viscosity we took $\mu = 10 \text{ Ns/m}^2$, and for linearly varying viscosity, $\mu = 10^{-6} \rho |x| \sqrt{gh}$.

Radiation Stress Resultants
Fig. 2

Influence of bed friction on Velocity Profiles

Fig.3

Nearshore Circulation Pattern, linearly varying viscosity

Fig. 4.

Nearshore Circulation Pattern, constant viscosity
Physical Model Pattern shown dotted

Fig. 5

For both types of viscosity variation we encountered difficulties at low values of viscosity, because the dominance of the inertia terms in the shallow water equations led to unrealistic spatial oscillations upstream of the breakwater. Experience with the convection-diffusion equations leads us to believe that these oscillations could be removed by upwinded finite elements, if such low viscosities are physically correct¹⁹.

On Figure 5 we have superposed the currents obtained in model tests. The main feature of both flows is the large strong eddy in the lee of the breakwater, and the agreement obtained is quite reasonable. This eddy seems to be driven by the changes in the onshore component of radiation stress resultant in the lee of the breakwater. While agreeing with Longuet-Higgins' criticism of Bowen's constant viscosity assumption, it seems to us that a viscosity which increases without limit away from the shore is inappropriate for the present geometry. The numerical model would probably be improved if, in determining the eddy viscosity, a mixing length proportional to the distance to the nearest boundary were used, instead of the distance to the shoreline. We conjecture that this would increase the offshore currents adjacent to the downstream breakwater. However, some upper limit should also be put on the eddy viscosity at large distances from the shore. These however, are short term modifications, but what is wanted in the long term is a better mathematical model of turbulence in shallow water problems. Some work along these lines is currently in progress.

The same problem was also run using a longer numerical model by stretching both end layers of elements. The two meshes of elements used are shown in Figure 6. The velocity profile obtained at the end of the model was then closer to that for the one dimensional problem (of an infinite straight coastline without breakwater), as shown in Figure 7. Presumably the presence of the breakwater and the repeatability condition act as a "roughness" on the coast, retarding the entire flow. As the length of the numerical model is increased presumably the velocity profile tends to that of the coast without breakwater.

CONCLUSIONS

The results obtained so far indicate that the patterns of wave induced near shore circulation can be predicted by numerical means. The main difficulties are the uncertainties in the values of bed friction and viscosity. Problems remaining are i, the wave attenuation in the surf zone of the waves model ii, more accurate calculation of radiation stresses, including standing wave effects iii, an improved model for turbulence.

ACKNOWLEDGEMENTS

The authors express their appreciation to the Electricity Supply Commission of South Africa for permission to publish this paper. They are grateful to Watermeyer Halcrow and Partners for providing details of the problem shown in Figure 1, and to NRIO, Stellenbosch, for data from experimental model results.

CHAPTER 45

OBSERVATION OF NEARSHORE CURRENT AND EDGE WAVES

by

Tamio O. Sasaki* and Kiyoshi Horikawa**

ABSTRACT

Nodal lines normal to the shoreline of infragravity low mode edge waves in the nearshore zone were observed with eleven wave staffs simultaneously with the nearshore current spatial velocity field on a gently sloping beach. About five peaks were found in the energy spectrum and their frequencies agreed well with cut-off mode edge waves [Huntley(1976)]. Based on the above observation, conceptual models of nearshore current patterns for the infragravity domain are proposed and general current patterns for the three domains are discussed by combining the horizontal patterns of Harris(1969) and the vertical patterns of Sasaki et al.(1976).

INTRODUCTION

Since the publication of the rip current theories of Bowen(1967) and Harris(1967) which attribute the generation mechanism of rip currents to the interaction between incoming waves and gravity edge waves, numerous theories on rip current generation have been proposed regarding causes of longshore perturbations: these are wave perturbations due to synchronous edge waves [Harris(1967), Bowen(1967)], bottom perturbations [Bowen(1969), Sonu(1972), Noda(1972), Sasaki(1975), Birkemeier and Dalrymple(1975)], cross waves [Dalrymple(1975), Maruyama(1976)], infragravity low mode edge waves [Sasaki(1974), Sasaki and Horikawa(1975), Sasaki et al.(1976), Horikawa(1978a)], surf beats [Bowen and Inman(1969)], wave diffraction [Liu and Mei(1974), Hashimoto and Uda(1974)], an instability mechanism [Hino(1973)], Mizuguchi(1976), Dalrymple(1978)], and wave-current interaction [Dalrymple(1978)]. The numerousness of such generation theories implies the complexity of the phenomena, and multiple causes would be possible simultaneously.

Through use of the Battjes'(1974) surf similarity parameter, Sasaki (1974) pointed out that Bowen and Inman's(1969) gravity edge wave mechanism is applicable to steep beaches where synchronous and subharmonic edge waves are excited [Guza and Inman(1975)] and proposed the Infragravity Domain Hypothesis for gentle beaches where infragravity low mode edge waves should control rip current spacing.

* Chief Engineer, Nearshore Environment Research Center, 1203 Famille Hongo Bldg., 1-20-6 Mukohgaoka, Bunkyo-ku, Tokyo, 113 Japan.

** Professor, Department of Civil Engineering, University of Tokyo, Bunkyo-ku, Tokyo, 113 Japan.

Recently, more dynamical and comprehensive models have been proposed by Chappel and Wright(1978), Wright, Thom, and Chappel(1978), and Short(1975, 1978) regarding the interaction between incident wave spectrum, currents, and beach morphology, and they uncovered the role of infragravity waves on the morphodynamics of dissipative beaches [Guza and Inman(1975)], or in the authors' terminology, beaches in the infragravity domain. Also, several researchers have shown that the previously termed surf beats are in fact infragravity low mode edge waves [Sasaki, Horikawa, and Hotta(1976), Meadows(1976), Huntley(1976), Sasaki, Horikawa, and Kubota(1977), Fujinawa, Okada, and Watabe(1977), Huntley, Guza, and Bowen(1977), Bowen and Guza(1978), Holman, Huntley, and Bowen(1978), Nakamura et al.(1978)].

In the present paper the authors deal with the simultaneous observation of the spatial nearshore current field and infragravity low mode edge waves, carried out in the end of August, 1976, on Ajigaura Beach, Japan. Also, the unsteady current pattern change was observed with a newly adopted Hasselbrad 100 ft magazine in place of the previously used smaller 15 ft magazine. Based on these observations a conceptual model of nearshore current patterns is proposed in considering infragravity low mode edge waves.

Figure 1. Overview of Ajigaura Beach(1:30 p.m., 21st October, 1976).

STUDY SITE

The field observation was carried out on Ajigaura Beach which faces the Pacific Ocean (Fig. 1), and which is located 100 km north-east from Tokyo. On this beach is sited a sediment research pier 200 m long (Fig. 1), built by the Public Works Research Institute, Ministry of Construction [Hashimoto and Uda (1976)]. A headland is located about 1 km from the pier, as shown in the Figure. The beach slope is $1/40 \sim 1/70$. Under ordinary wave conditions, the pier head extends outside of the surf zone.

Figures 2 and 3 show the results of a previous current spacing survey taken on February, 1973 [Sasaki and Horikawa (1975)]. The current speed and direction were measured at midsurf by divers with a tethered float, at a wading depth of about 1 m. In this example, rip currents were equally spaced at 400 m intervals. Figure 3 shows the longshore distribution of longshore components of measured current speeds. The location of rip currents can be defined where the curve crosses the horizontal axis. With close examination of the velocities between rip currents, several seemingly periodic fluctuations can be observed. The authors felt this fluctuation could be due to the coexistence of multiple edge waves existing at that time. Concerning spatial longshore current velocity fluctuations as in this case, Meadows (1976) also presented time dependent fluctuations recorded with flowmeters, attributed to low mode edge waves.

Figure 4 shows a photograph taken with a balloon-borne camera system, BACS [Sasaki et al. (1976)], launched from the pier seen at the center of the photograph, on the 29th August, 1976. This day is the last Sunday of the Japanese school summer vacation. A surfing contest was being held on the right-hand side of the pier, and many cars were parked on the beach. Unfortunately STEREO-BACS to obtain wave height fields [Sasaki et al. (1976)] was failed.

The breaker height and period were 1.2 m and 13 sec respectively, and the wind speed was 3m/s from the south-east. The width of the surf zone was about 100 m, and two waves were observed in the surf zone. Because the pier is 200 m long, the size of the coverage is about 400 m alongshore by 250 m offshore. Eleven letters, from A to K, give the locations of wave staffs, and all of them except "I" on the pier are in the surf zone. The staff array is distributed in an area that covers 200 m alongshore and 140 m offshore. There are 4 staffs attached to the pier piles (K, G, H, and I) in the offshore direction. The water surface fluctuations were filmed with 16 mm memo-motion movie cameras, Bolex H16-SBM, at one second intervals.

The surf zone beach topography up to 3 m depth (Fig. 5) was measured just after the current and wave measurements. No clear rip channels could be defined but the 1 m depth contour-line showed a depression around the pier. The average beach slope up to 2 m was about 1/60. The depth of the furthest offshore wave staff "I" was about 2.5 m.

Figure 4. Observation area and instrument locations, August 29, 1976, Ajigaura Beach.

NEARSHORE CURRENT PATTERN FLUCTUATION

Up to 1975, the authors had used a Hasselblad 15 ft magazine which permitted only 70 frames. Because the shutter interval adopted is close to the wave period, i.e., 10 s to 15 s, the observation time was therefore limited to a synoptic measurement of only 10 min to 15 min. However, a longer observation period became possible by utilizing a newly developed 100 ft magazine which allows 480 frames. This enabled a 37 minute continuous measurement at 15 s intervals at an altitude of 240 m. The resultant 150 frames were split into 3 stages, each consisting of 50 frames, and the nearshore current pattern change during these 3 stages over 37 minutes was analyzed.

Figure 6 shows float velocity vectors for the 3 stages. The water enters the surf zone from the left-hand side of the pier, and branches off to the left and to the right forming longshore currents. A part of the latter longshore current enters a small rip current around the pier, and the remaining longshore current moves away further to the right. The maximum longshore current velocity is about 70 cm/s and the average velocity range is 40 to 50 cm/s. The sparse distribution of floats at Stage III is due to diver fatigue from the strenuous work maintained over half an hour.

There is no major rip current or well defined rip channel in this coverage. The rip current seen around the pier is weak and not a major

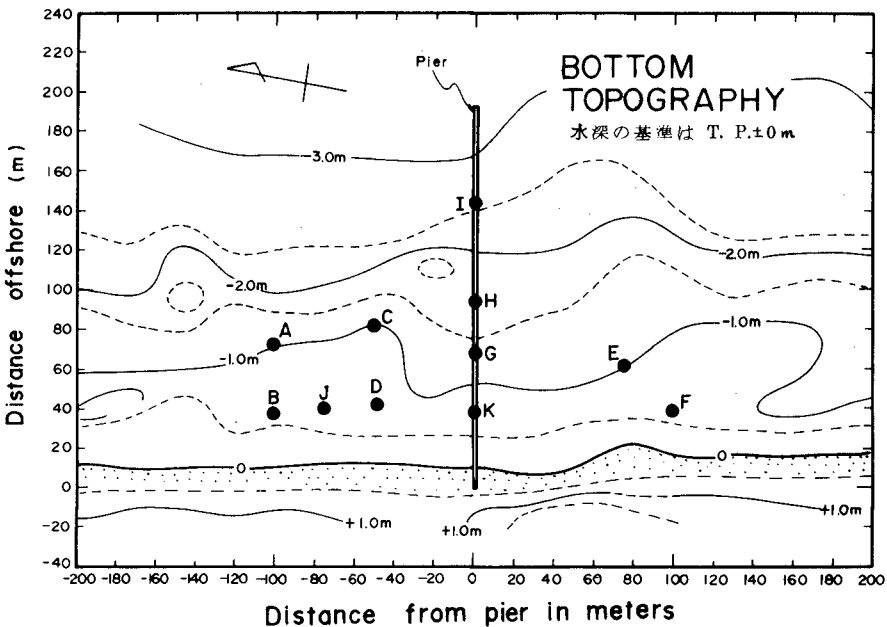

Figure 5. Surf zone topography surveyed on 29th August, 1976.

Figure 6. Float velocity vectors for the three 12 min. observation.

Figure 7. Nearshore current pattern change and associated nodal lines.

one; the current path also seems to be very unstable and unsteady. The maximum velocity is about 40 cm/s.

Figure 7 shows the current pattern change. The longshore current is strong and steady throughout the 3 stages. The reason that the weak rip current is very unsteady may be due to absence of a clear rip channel. A rather wider embayment is formed as seen on the 1 m depth contour line at both sides of the pier. The width of the bottom depression in the surf zone makes the small rip current fluctuate.

The thatched lines in the top diagram indicate the observed nodal lines of edge waves to be mentioned later. The shore parallel nodal line nearest to the shoreline should lie in the swash zone ("swash node"), the second one appears to correspond to the main stream of the longshore current ("longshore current node"), and the third one appears to coincide with the breaker line ("breaker node").

OBSERVATION OF INFRAGRAVITY LOW MODE EDGE WAVES

Observation of the water surface fluctuations was carried out simultaneously with that of the nearshore current. The data obtained from the eleven wave staffs were digitized and analyzed by BMD-02T, i.e., cross-spectrum analysis with $\Delta t = 1$ s.

Figure 8 shows the spectra of input waves around the breaker line "H" and swash zone "K". In the breaker wave spectrum of "H", a broad peak from 6 to 14 s is seen, which, when closely examined, reveals three peaks at 7, 9, and 13 s. In contrast to the input waves, a maximum peak appears in the infragravity wave region, that is, around 40-50 s. Then, to increase the resolution for infragravity waves, data were resampled with $\Delta t = 3$ s after smoothing, and a cross-spectrum analysis was applied.

The power spectra, coherence squared, and phase angle, respectively, for the 11 wave staffs are shown in Figure 9. The left-hand diagram shows the onshore-offshore array attached to the pier, and the middle and the right-hand diagrams are the results from the longshore array. The middle one is the result from the array arranged about 50 m from the shoreline (A, C, G, and E), and the right side is from the array 15-20 m from the shore (B, J, D, and F). In the left-hand diagram,

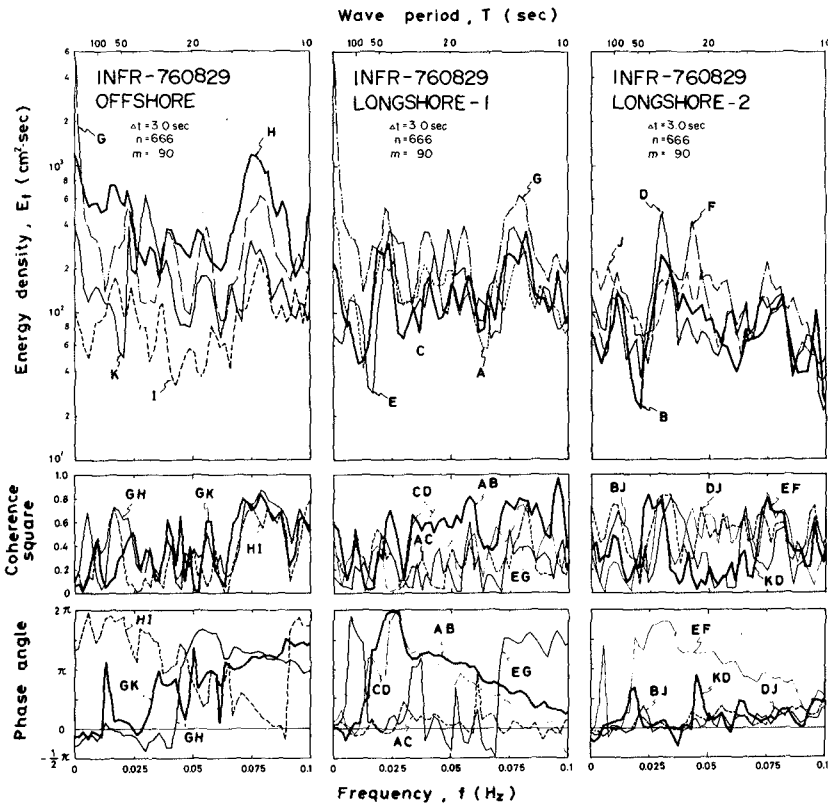

Figure 9. Wave energy density, coherence squared and phase angles for 11 wave staffs.

i.e., the spectrum along the pier, "I" is located the furthest offshore and distant from the surf zone, while "K" is located nearest to the shoreline.

From phase angles, the characteristics of standing waves appear in those waves longer than about 20 s (0.05 Hz). The lowest oscillation occurs in the "G" spectra, which is located along the pier at the mid-surf position. In the power spectrum, about five peaks around 0.01, 0.02, 0.03, 0.04, and 0.05 Hz can be found.

From the phase angles, it is interpreted that each peak is associated with one or two nodal lines parallel to the shore as shown in Table 1. The distance from the shoreline is evaluated from Eckert's (1951) edge wave theory by using a beach slope of $\tan\beta = 1/40$. The distances in parenthesis in the Table indicate inferred nodal lines which could not be confirmed due to the wave staff arrangement. The quantity "n" is an offshore modal number, and each peak frequency corresponds to $n = 1, 2, 3$ and so forth, respectively.

Regarding the nodal lines normal to the shore, proof of edge wave existence can be found in the 0.04 Hz and 0.05 Hz peaks. For lower frequency waves, nodal lines normal to the shore could not be detected due to the narrow distribution of the wave staffs. Huntley (1976) presented the excitation of cut-off low mode edge waves by applying Ball's (1967) edge wave theory for concave beach profile to his field observation. Ball gave a solution for the exponential bottom profile defined as

$$h/h_{\infty} = 1 - e^{-\alpha x} \tag{1}$$

where h is the water depth, x is the distance offshore, and h_{∞} and α are constants determined from the bottom profile. When x tends to infinity, αh_{∞} tends to $\tan\beta$, the beach slope. Defining ν as a peak frequency, ν is simply given as a function of n and bottom profile, that is α and h_{∞} , as shown by Huntley (1976)

$$\nu = \frac{\alpha \sqrt{gh_{\infty}}}{2\pi} \sqrt{n(n+1)} \tag{2}$$

Here, n and g are the offshore modal number and acceleration due to gravity, respectively. Equation (2) was derived from a critical condition of Ball's edge wave excitation, that is, the cut-off mode edge waves. This expression means that if the bottom profile or topogra-

Figure 10. Peak frequency ν verses edge wave modal number n .

graphy were given, the peak frequency of edge waves could be obtained, and also suggests a coexistence of multiple modes of edge waves as suggested in Figure 3.

Figure 10 is a plot of v and n . Also shown in this figure are the infragravity low mode edge waves observed on March, 1976 [Sasaki et al. (1976)] on Ajigaura Beach, as well as Huntley's (1976) results. These results agree well with the empirical fact that in many of our field observations, we have found several minor rip currents between two neighboring major rip currents or, in other words, rip currents are strengthened selectively by the super-position of multiple mode infragravity low mode edge waves. Figure 11 is an example from a 1972 observation on Kujuukuri Coast, east of Tokyo. Very large rip currents developed evenly with a 600 m spacing in the middle part of the stretch, and between them, several minor rip currents are seen.

Figure 11. Rip current spacing distribution observed on February, 1972, on southern end of Kujuukuri Coast, Horikawa, Sasaki and Igarashi (1972), Horikawa (1978b).

TRANSFORMATION OF POWER SPECTRUM ACROSS THE SURF ZONE

In the morning of the same day as the above described current and edge wave observation, observation of the onshore-offshore transformation of the power spectrum across the surf zone was performed using 4 wave staffs along the pier, to study the behavior of such infragravity low mode edge waves near the surf zone. Power spectra from 4 wave staffs arranged along the pier, that is, "E", "G", "H", and "I" and plotted in Figure 12. Only "I" is located outside the surf zone, and "E" is located in the swash zone. A very wide spectrum exists outside the surf zone, but in the surf zone higher frequency waves above 0.2 Hz (5 s) are attenuated due to breaking; further, only waves lower than 0.05 Hz (20 s) exist in the swash zone. In contrast with these, waves below 0.05 Hz are not seen outside the surf zone. These infragravity waves are believed to be

Figure 12. Onshore-offshore wave energy density transformation along the pier.

excited in the surf zone by receiving energy from the gravity waves outside of the surf zone.

CONCEPTUAL MODEL OF THE NEARSHORE CURRENT PATTERN

In conclusion, a conceptual sketch of the nearshore current pattern in the infragravity domain is presented (Fig. 13). Firstly, assuming the existence of multiple mode infragravity edge waves, it is possible to explain in the super-position of major and minor rip currents. Here, a "major" and a "minor" rip current are defined respectively as one which penetrates the breaker line from the surf zone and one which is totally confined to the surf zone. The shapes of the corresponding rip heads differ as illustrated. The number of minor rip currents contained between neighboring major rip currents depends on the frequency of the modes. The major three nodal lines parallel to the shore could be termed as

- 1) "breaker node"
- 2) "longshore current node", and
- 3) "swash node"

since the breaker node appears around the breaker line, the longshore current node appears to correspond to the location of the main stream of the longshore current and the swash node appears to be located in the swash zone.

In our experience, waves break close to the shoreline in the lee of a rip current, because the rip channel is deep and does not satisfy breaking criteria under ordinary wave conditions. Thus the plan shape of a shoreline behind a rip channel is somewhat embayed and has a steep foreshore slope. Two longshore currents from opposite directions meet almost midway in the surf zone resulting in a rip current, and behind this a stagnant zone is produced as shown in the Figure.

Figure 14 gives a more general conceptual model of nearshore current patterns for the three domains [Sasaki(1974), and Sasaki and Horikawa (1975)] combined with the plan view of Harris(1969) and the cross sectional view of the surf zone of Sasaki, Horikawa and Hotta(1976). These three conceptual models can be connected in a probabilistic sense. However, the model proposed here appears to be rather static. From the recent morphodynamic results of Wright, Thom, and Chappel(1978), and Short(1978), various dynamical transition patterns are suggested for the instability domain or asymmetrical cellular circulation system between two typical current patterns, i.e., the infragravity domain and the edge wave domain.

Both domains can be connected with their beach types or stages as in Table 2. To link with the beach type evolution models of Wright et al. (1978) and Short(1978) and to clarify current field associated with them would produce fruitful understanding of the precise coupling mechanism between edge waves, currents and beach topography.

CHAPTER 46

COMPARISON OF MODEL AND OBSERVED NEARSHORE CIRCULATION

by

James H. Allender, John D. Ditmars, Wyman Harrison
and Robert A. Paddock*

ABSTRACT

Results from a two-dimensional numerical model for nearshore circulation induced by waves and wind are compared with observations made during two storms at a beach on Lake Michigan. Model-input data include bathymetry, offshore wave characteristics, wind histories, and local water-level changes. The predicted locations of the breaker zone are in rough accord with those observed during the storms. Data for comparison with model results consist of wave and current observations across the surf zone, especially those acquired by using a towed, instrumented sled. The comparisons show that the model often predicts peak currents near the breaker zone quite well, but underestimates the decay of wave height and the strength of longshore currents across the surf zone. Wave breaking on the bar-trough beach structure prevalent in this study apparently is not well represented by the model. An improved breaking criterion, treatment of breaking waves as traveling bores, and inclusion of horizontal mixing of momentum might add to better simulation of surf-zone currents.

1. INTRODUCTION

Numerous efforts to observe nearshore circulation have been undertaken and reported, and recently, numerical models to simulate nearshore circulation have been developed and described. Seldom, however, have attempts been made to evaluate model simulations against observational data. Two major field studies at a beach on Lake Michigan were planned to provide data for the assessment of the simulative capabilities of a two-dimensional numerical model for nearshore circulation induced by wind and waves. The first field study was scheduled to take place during a fall storm, while the second study was scheduled for a spring storm. The second study was planned to provide an independent data set and to allow for changes in observational techniques suggested by analysis of the data from the first study and application of a model to those conditions.

The numerical model considered in this study was developed by Birkemeier and Dalrymple (1975). It is based on a finite-difference solution of the vertically-averaged equations of motion which are averaged in time over a wave period producing radiation stress terms. Given bottom topography, deep-water wave characteristics, and wind, the model simulates in two dimensions (on a relatively fine horizontal grid), the

*Energy and Environmental Systems Division, Argonne National
Laboratory, Argonne, IL, 60439, U.S.A.

nearshore circulation field, the wave field, and mean water surface elevations. Wave heights and directions in the computational grid are determined by the refraction procedure of Noda *et al.* (1974), that includes wave-current interaction. The merits and failings of the model are discussed in terms of extensive comparisons with the wave and current data acquired in this study.

2. MODEL DESCRIPTION

The numerical model used in this study was described in detail by Birkemeier and Dalrymple (1975). The salient features of the model and the modifications made to it for the present application are noted here.

An explicit finite-difference scheme was used to solve the vertically-integrated equations of motion including radiation stresses. The wave refraction part of the model includes wave-current interaction and was described by Noda *et al.* (1974). No-flow conditions were imposed at the beach and at the last offshore row of the computational domain. Periodic boundary conditions for all variables were imposed at two remaining boundaries, thus defining a periodic length of beach.

Quadratic bottom friction was represented as the product of water density, a friction coefficient, the magnitude of the velocity vector, and the velocity vector itself. This friction formulation was modified to include numerical integration over a wave period of the total velocity vector (orbital wave motion and mean current). This modification resulted in more realistic values of bottom friction for large incident wave angles and for mean currents that were the same order of magnitude as the orbital velocities (Liu and Dalrymple, 1978). The friction coefficient is the only free parameter in the model. Its value was 0.01 for most cases. A dissipation term was added in the equation for wave height as the time average of the product of bottom shear stress and orbital wave velocity. This dissipation term was made zero wherever breaking was predicted by the model. The breaking criterion was a modified Miche formula in which breaking wave height was proportional to the hyperbolic tangent of water depth divided by wavelength at breaking (Noda *et al.* 1974). The model also allowed for flooding of dry beach to occur as a result of set-up and changes in lake level.

In summary, the model formulation included wave refraction, wave-current interaction, anisotropic bottom friction, wave set-up, wind effects, and coastal flooding. An improved representation for bottom friction was used and wave height dissipation outside of breaking areas was added. Finally, the model was applied to a much more complex nearshore environment than in the developmental study of Birkemeier and Dalrymple (1975).

Model application requires site-specific input data. These include deep-water wave characteristics, viz., wave height, period, and direction, detailed bathymetry for the given study area, local still-water-level changes during the study period, and wind data. The

simulated variables (nearshore circulation, wave field, and mean-water-level changes) require other data for model evaluation. These include primarily wave and current measurements in the surf zone. The methods for acquiring all of these data and specific examples of processed information are discussed in the next section.

3. FIELD PROGRAM

The study site covers 0.5 km of sand beach near Zion, Illinois, along the western shore of Lake Michigan. Inland of the beach are low marshlands and dunes that rise about 3 m above lake level. The lake bottom immediately offshore is composed mainly of sands and silty sands. Portions of the sandy beach contain coarse pebbles that are often exposed near the waterline. The shoreline is almost straight in the study area. Longshore sand bars lead to surf zone widths of 40-60 m, typically, and outer bars often result in another breaker zone about 150 m offshore.

The first major field study was conducted during a storm in November, 1977. This study was designed specifically to obtain the required model-input data and to gather data on waves and on currents in the surf zone for comparison with model results. Figure 1 shows a plan view of the nearshore study area, which extends about 0.3 km lakeward. Offshore wave information for the model was obtained from a Wave-Rider buoy moored in 20 m of water about 4 km offshore. Wave data at a transitional depth were obtained from a bottom-mounted pressure cell fixed in 4.4 m of water at the outer extent of the nearshore study area. The cell also was equipped with an integrated output to allow measurement of local still-water-level changes throughout the storm.

Detailed bathymetric surveys were conducted before and after the storm to provide depth data for the model and to assess net changes in bottom topography. Bottom soundings were made on a 20 x 20 m grid using digital, position/depth recording equipment aboard an Argonne survey boat. Standard surveying techniques were used to collect beach topographic data on a 5 m (offshore) x 20 m (alongshore) grid in the region from the storm berm to about 60 m lakeward of the still water line.

Waves across the surf zone were measured with four helically-wound, resistance-wire wavestaffs. The staffs were placed on a line perpendicular to shore in 0.5, 0.75, 1.5, and 2.5 m of water with 1.2 m of their 2-m active element above the still water level. The outermost staff was about 70 m offshore. Longshore-current profiles were measured by using a towed sea sled similar to the one developed by Teleki *et al.* (1975). As shown in Fig. 1, the sled traversed the surf zone on a cable-winch system. The sled was equipped with two Bendix B-10, ducted-impeller current meters, placed at 0.5 and 1.0 m above the bottom of the sled and oriented approximately shore-parallel. The signals from the current meters were electronically averaged over several wave periods. A 4-m wavestaff also was mounted on the sled to provide additional data on waves across the surf zone. In addition, a 10-m meteorological tower was erected on the beach to measure wind speed and direction, and air temperature; steel reinforcing bars (rebars) were jettied

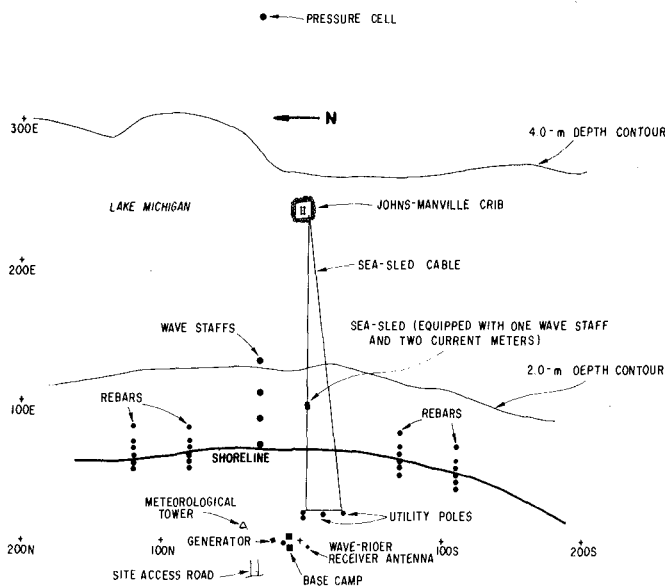

Fig. 1. Plan View of Experiment Site and Horizontal Coordinate System.

into the beach face along four separate transects to allow depth profiling during the storm; dye tracking in the surf zone was used to provide additional information on currents; and aerial photography was conducted during the daylight hours of the storm to provide estimates of wave direction.

Sets of observational data were gathered every three hours over the 27-hr storm period. Each set of data contained: 5-min records taken at each of six locations across the surf zone with the sled-mounted current meters and wavestaff, 5-min records taken with the fixed wavestaffs and the pressure cell when the sled was at the beginning and end of its traverse; and ancillary data taken using the other equipment described above. All wave and current data were recorded on strip charts and subsequently digitized to allow computer analysis. Hourly-averaged wind speeds ranged from 9-15 m/s during the storm. Off-shore significant wave heights and periods varied from about 0.5-2.5 m and 3.8-6.5 s, respectively. Significant breaker heights varied from 0.5-1.5 m, incident breaker angles were 20-30° off normal (ESE), and both spilling and plunging breakers were present. Longshore currents near the breaker line varied from about 0.6-1.5 m/s. The spatial

distributions of longshore current across the surf zone was highly variable. Significant bar movement occurred as a result of the storm, and depth changes as great as 0.8 m were found in the extreme nearshore area.

The second major field study was conducted in April, 1978. It provided an independent data set and allowed for improved observational techniques. The experimental set-up and procedures were similar to those in the first study with the following notable exceptions. The fixed wave staffs were placed outside the breaker zone in a directional array, although only minimal information was acquired due to damage incurred early in the storm. Additional rebar transects were installed. A multi-channel digital data logger was used to record all of the instrument data on magnetic tape at 0.1-s intervals, thus eliminating the need for strip chart recorders. Most data records were still of 5 min duration, but some 17-min wave records were acquired at 3-hour intervals during the storm. For most of the experiment the sled-mounted current meters were oriented perpendicular to each other, thus allowing measurement of the current vector during the sled's transits of the surf zone. Finally, the sled was equipped with a dye-dispensing system to allow the introduction of patches of dye into the surf zone.

Figure 2 shows the pre-storm bathymetry inferred from shipboard soundings and from standard surveying techniques. The beach is characterized by a steep face, a persistent longshore trough, and a somewhat disorganized bar structure that repeats itself on the order of several hundreds of meters. Depth contours beyond 2.0 m are highly convoluted, although a pattern of outer bars exists about 150 m offshore. Depth contours greater than 4.0 m tend to be much more regular.

Observational data during the storm again were gathered at approximately 3-hr intervals over a 24-hr period. Hourly-averaged wind speeds ranged from 7-16 m/s. A summary of offshore (Wave-Rider buoy) and transitional-depth (pressure cell) wave data is given in Fig. 3. Significant wave heights and periods measured by the Wave-Rider buoy (4 km offshore) varied from about 1.25-2.25 m and 4.5-6.3 s, respectively. Significant wave heights as measured by the pressure cell at the outer extent of the nearshore study area (0.35 km offshore) varied from about 0.60-1.25 m before that instrument failed due to storm damage. Wave approach was very oblique (70° off normal incidence, NNE) with breaking angles as large as 45° off normal. Figure 4 summarizes current-meter data acquired by the towed sled during nine different transits of the surf zone. The following specific points should be noted: 1) peak currents near the breaker line ranged from 1.0-1.8 m/s; 2) on/offshore flow was small; 3) the differences between currents measured at 0.5 and 1.0 m above the bottom were small (cycles 1-3); and 4) a relatively strong flow was observed across the entire surf zone in most cases, probably as a result of the bar-trough structure of the beach (note inset showing depth profiles along sled path). Most of the data to be discussed below are taken from this second study, although they are generally representative of the first study, too.

4. MODEL APPLICATION

a. Adaptation to Study Site

Model-input data gathered during the fall and spring field efforts were used to make a site-specific application of the numerical circulation model. The alongshore grid spacing was chosen to be 10 m, while a 5-m spacing was used in the offshore direction to provide the necessary resolution of typical depth profiles. Still-water depths from the bathymetric survey were specified for this grid and were adjusted for calculations made during the storm with local lake-level data from the pressure cell. A conservative time step of 0.5 s was selected based on the linear stability criterion, and a quasi-steady model solution was found for given wind and wave conditions by integrating for 1000 time steps. Root-mean-square (rms) wave heights inferred from the Wave-Rider data were used to drive the model. The incident wave field was increased linearly from zero to full strength over the first 100 iterations to minimize water-level oscillations at the natural frequency of the basin defined by the model topography. The total energy and water-level fluctuations were monitored for as many as 2000 iterations in some numerical experiments before 1000 steps was chosen as a good compromise between a quasi-steady solution and computational expediency. The offshore extent of the model was about 200 m, which was far enough to include the outer bars. The effect of model alongshore extent (and the imposed periodicity) on the model currents near the center of the grid is shown in Fig. 5. The sensitivity of the model currents to alongshore extents greater than about 200 m was found to be small compared to changes produced by uncertainties in other model parameters. An extent of 260 m was chosen for most numerical experiments.

Deep-water wave angle was found to be an important parameter that was difficult to estimate accurately based on the observed data. The model, as formulated, used Snell's law and the given deep-water wave characteristics to estimate incident wave height and direction at the offshore extent of the model grid. The following procedure was adopted to find consistent estimates of offshore wave angle: depth contours were assumed parallel from deep water to transitional depth (5 m); standard refraction and shoaling calculations were used to find the deep-water wave angle that would transform the measured deep-water wave height into the wave height measured at transitional depth. The deep-water wave angles calculated by this procedure were found to bear no simple relation to the contemporary wind directions. However, the resulting wave angles at transitional depth did agree with those inferred from the limited aerial photography conducted during the studies, within the errors inherent in these measurements.

Various numerical experiments were performed to test the sensitivity of the model results to small changes in wave height, wave angle, still water level, and friction coefficient. Discussion of these tests and selected comparisons with observed waves and currents are given in the next subsection.

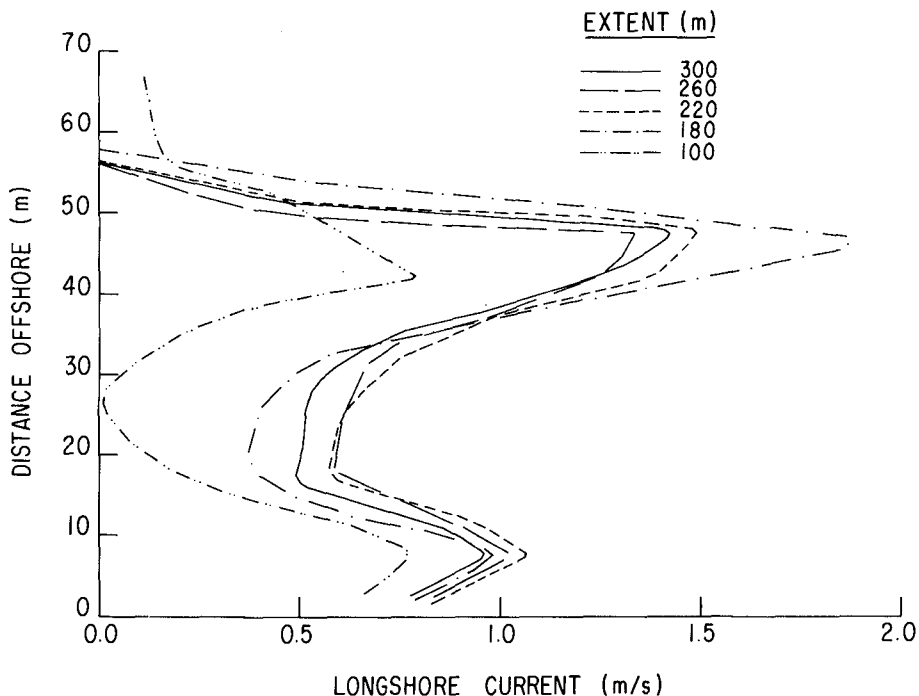

Fig. 5. Effect of Variation of the Model Alongshore Extent on Model Current Profiles (along computation row corresponding to 000 N).

b. Comparisons with Observed Data

Two-dimensional simulations of waves and currents were generated for many of the different wind and deep-water wave conditions observed during the field program. As stated previously, rms wave heights were used to drive the model. Figure 6 is a representative plot of the velocity field predicted by the model, subject to a 1.44-m wave field (5.3 s period) approaching from 73° off normal incidence. A wind of 15 m/s at 80° off normal also was acting, and local still-water level had risen about 0.2 m above the level assumed for the depths given in Fig. 2. The offshore distance in Fig. 6 represents about one-third of the total model extent. The strongest currents are predicted just inside the breaker zone (40 m offshore) and in the trough region (10 m offshore). The overall pattern is highly two-dimensional and the effects of the inner bars are quite apparent (Fig. 2).

Fig. 6. Model Velocity Field for Second Storm Bathymetry, 1.44 m and 5.3 s Deep-Water Waves from 73° Off Normal and 15 m/s Winds from 80° Off Normal (NNE). (Offshore coordinate stretched for clarity.)

Comparisons of model and observed variables are presented in Figs. 7-11, for observational data acquired during six different transits of the surf zone with the towed sled. Profiles of the alongshore component of model currents at two adjacent rows in the grid are shown in Fig. 7a along with current-meter data acquired from the sled (along 000 N). The model results do not show high variability between adjacent rows. Observed current speeds outside the breaker zone (60-70 m) are much stronger than those in the model. However, other contemporary current studies in the lake, outside the surf zone, showed average lake currents of 0.2-0.3 m/s. It is unlikely that the model boundaries represent a periodic segment of the lake itself, and thus, it is expected that inclusion of lake currents in the model would improve comparisons outside the breakers without significantly changing computed results inside the breakers. Figure 7b shows model and observed wave heights, indicating that the height near breaking is in close agreement for this case, although the heights inside of the breaker zone are somewhat over estimated.

Fig. 7. Comparison of Model and Observed Current Profiles (a) and Wave Heights (b). Model Results for Adjacent Computational Rows are Shown in (a).

Changes in wave climate during the time required for the sled to traverse the surf zone (30-45 min) lead to significant changes in the location of the breaker zone predicted by the model. Figure 8a shows the measured currents for a particular sled transit and the model longshore current profile resulting from the observed wave conditions at the beginning (Case A) and end (Case B) of that transit. The location of the breaker zone in the model shifts about 10 m between these two cases, although model currents inside of the breaker zone are essentially unchanged.

Smaller uncertainties in model-input data result in better agreement with observations for some occasions during the study. Figure 8b gives comparative results for an occasion when wave angle is known with more certainty due to the availability of aerial photos, model topography (based on post-storm surveys) is more likely representative because these current data were acquired near the end of the storm, and the wave climate is less severe with little or no breaking over the trough region. The combination of these conditions appears to result in better agreement between model and observations inshore of the breaker zone than in other comparative cases.

Fig. 8. Comparison of Model and Observed Current Profiles for Different Wave Climates at the Beginning (Case A) and End (Case B) of a Sled Transit (a) and for a Less Severe Wave Climate (b).

The model seems to underestimate the *difference* between wave heights near breaking and heights inshore of the breaker zone as evidenced in Fig. 9b. These wave height discrepancies contribute in part to a model current profile that is more sharply peaked than the observed data profile (Fig. 9a). Several numerical experiments were tried in this case and in others to alleviate these discrepancies. Small changes in incident wave angle ($10-15^\circ$) led to 30% or greater changes in calculated wave heights near shore (for large incident angles), but current profile shapes were essentially unchanged. Model lake current profiles also were largely unaffected by moderate changes in lake level (0.3 m) and changes in the model friction coefficient. Model friction might be adjusted to effect agreement between observed and model peak currents. However, discrepancies between observed and model peak currents could also be accounted for by the discrepancies between observed and model wave heights near breaking. Therefore, fine adjustments in the value of the friction coefficient appear unjustified.

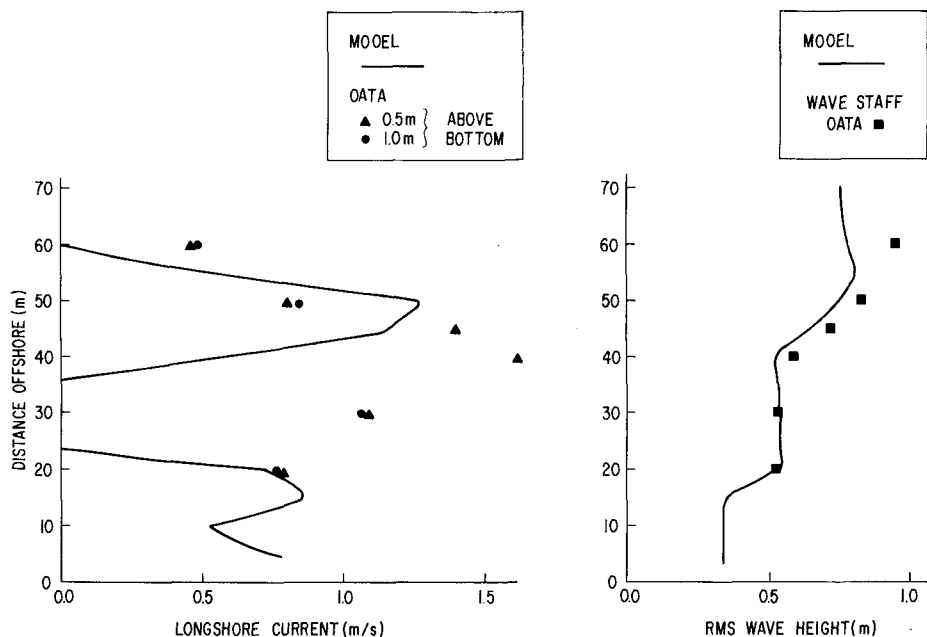

Fig. 9. Comparison of Model and Observed Current Profiles (a) and Wave Heights (b). Model Underestimates Differences between Wave Heights Near Breaking and Heights Inshore of Breaker Zone (b) Resulting in Sharply Peaked Model Current Profiles (a).

A further example of the underestimate of wave height decay in the surf zone model is shown in Fig. 10b. For this case, the observations indicate about a 50% reduction in wave height across the surf zone, whereas model heights decay only about 25%. Again model current profiles (Fig. 10a) deviate significantly from observations, although peak currents agree quite well. The proportionality constant in the model breaking criterion was varied over wide limits in an attempt to better imitate the main features of the observations. In effect, the ratio of breaking wave height to mean-water depth at breaking was varied from 0.65 to 0.95. Results were quite different, of course, but were no more or less in agreement with observations than the results shown here.

In Fig. 11 a final comparison of waves and currents reaffirms the previous statements. Observed currents are relatively strong across the surf zone in contrast to the model results (Fig. 11a). This is due in part to the fact that the model does not predict the observed breaking over the trough region (20-30 m offshore) along the sled path. Observed wave heights suggest that considerably more energy is extracted from the wave field in this region than predicted by the model.

Fig. 10. Sharply Peaked Model Current Profiles (a) Result From Underestimation of Wave Height Decay (b) Across the Surf Zone.

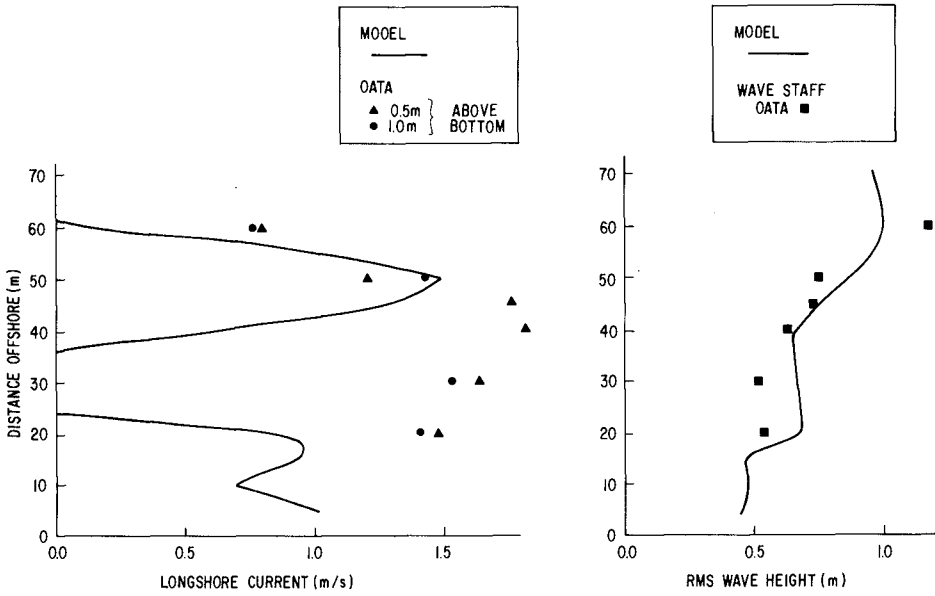

Fig. 11. Additional Comparisons of Model and Observed Current Profiles (a) and Wave Heights (b) Suggest That More Energy is Extracted from the Wave Field Inshore of the Breaker Zone Than the Model Predicts.

5. SUMMARY

New data on waves and currents in the surf zone during two storms were collected. Extensive comparisons were made between these data and results from a state-of-the-art, two-dimensional, numerical model for near-shore circulation. Model current fields showed a highly two-dimensional pattern for all cases that were studied. The tracking of dye packets and relatively large dye clouds in the surf zone also revealed a two-dimensional structure with some regions of stagnant flow and others with strong on/offshore flow. Significant variations in model results were caused by uncertainties in model-input data, such as wave angle, topography, and still-water level. These inherent variations preclude the quantification of the extent to which the model results match the observations. Comparisons do show, however, that the model often predicts peak currents quite well, but underestimates the decay of wave height and also the strength of longshore currents inside of the breaker zone. That is, predicted wave heights lakeward of the breaker zone are often in fair agreement with observed heights. The predicted location of the breaker zone is in rough accord with the location inferred from aerial photos and other visual observations. Thus peak current predictions are quite good. Within the surf zone, however, more energy is extracted from the actual wave field than is predicted in the model. As a result, the distribution of longshore momentum across the model surf zone does not agree well with observations. Apparently, model simulation of waves does not adequately represent the behavior of waves in a region of barred topography. An improved breaking criterion that includes reflection off the bar, or the treatment of a breaking wave as a traveling bore, as suggested by Battjes and Janssen (1978), might improve model results. The present model formulation does not include a specific representation for horizontal mixing of momentum, and provision for such mixing might lead to better simulation of the observed currents within the surf zone.

ACKNOWLEDGMENTS

Studies such as the present one require unusual dedication in the field data-acquisition phases. We wish to acknowledge the assistance of the following colleagues, without whom this study would have been impossible: A.A. Frigo, D.L. McCown, K.D. Saunders, C. Tome, and L.S. Van Loon. We thank the U.S. Army's Coastal Engineering Research Center for loan of their towed sled for our first field experiment. Dr. R.A. Dalrymple is thanked for his continued interest in this work and for his many helpful suggestions.

Funding for this study was provided by the U.S. Nuclear Regulatory Commission.

CHAPTER 47

RIP CURRENT SPACING AS AN EIGENVALUE

by
Noriyuki Iwata*

Abstract

Mass, momentum and wave action conservation laws, including the radiation stress, are used to obtain a rip current spacing as an eigenvalue. A coastal region is divided into two parts: offshore region and surf zone separated by a breaker line. Only the case of normal incidence of the waves is considered. From the matching conditions of the two horizontal velocity components at the breaker line, we can obtain rip current spacing as a function of a nondimensional parameter characterizing the surf zone, for an arbitrary value of a parameter indicating the strength of horizontal mixing.

Introduction

A coastal region with a linear bottom slope is divided into two parts: offshore region and surfzone separated by a breaker line. Wave set-up, wave energy and mean current are assumed to be composed of basic state, which is a function of only the distance from the shore and of superposed two dimensional perturbations.

In the case of normal incidence of the waves, basic steady current system vanishes and perturbations are found to be cellular. When we take into account the horizontal mixing in the surf zone, as LONGUET-HIGGINS(1970) did in the case of the steady longshore current, stream functions of the perturbed motions, which satisfy the boundary conditions at the coastline, can be represented by series expansion, wherein only one of the four roots of the indicial equation is selected. This selected one reduces to the value of the confluent hypergeometric function when the horizontal mixing is ignored(IWATA 1976):i. e. we have in the surf zone chosen a solution corresponding to the confluent hypergeometric equation modified by horizontal mixing, and the other solutions of the differential equation of fourth order are disregarded, partly because of the boundary conditions at

* Director, Institute of Coastal Oceanology, National Research Center for Disaster Prevention, Hiratsuka, Kanagawa, 254 Japan

the coast, partly to take account of the effect of the horizontal eddy viscosity due to wave breaking upon the solution of the inviscid model.

In the offshore region, where wave breaking does not occur, we disregard from the outset horizontal mixing so that the stream function can be represented by the modified Bessel function (IWATA 1976).

The matching conditions at the breaker line must be continuity of the two horizontal velocity components as well as surface elevation and energy. The continuity of energy follows immediately from the energy equation, but the elevation becomes discontinuous, because our model includes the effect of horizontal mixing only in the surf zone mainly due to the wave breaking, so that the elevations do not coincide with each other at the breaker line.

From the matching conditions of the two velocity components at the breaker line, we can obtain rip current spacing numerically as a function of a nondimensional parameter composed from bottom friction coefficient, bottom slope and the ratio of the breaker height to the depth for an arbitrary value of a parameter indicating a ratio of the horizontal mixing to the bottom stress as used by LONGUET-HIGGINS (1970).

§1. Basic equations

Mass, momentum and wave action conservation equations are given as follows,

$$\rho \frac{\partial \zeta}{\partial t} + \nabla \cdot \mathbf{M} = 0, \quad (1.1)$$

$$\frac{\partial \mathbf{M}}{\partial t} + \nabla \cdot (\mathbf{M}\mathbf{U} + \mathbf{s}) + \rho g h \nabla \zeta + \tau - \nabla \cdot (\mu h \nabla \mathbf{U}) = 0, \quad (1.2)$$

$$\frac{\partial}{\partial t} \left(\frac{E}{\sigma} \right) + \nabla \cdot [(\mathbf{U} + \mathbf{C}_g) \frac{E}{\sigma}] + \frac{D}{\sigma} = 0. \quad (1.3)$$

Here ρ is the density of water assumed constant, $h = d + \zeta$ where d is local still water depth and ζ is the mean water level perturbation due to the presence of current and waves, \mathbf{M} and \mathbf{U} denotes the total mean momentum and the mean current respectively

$$\mathbf{M} = \tilde{\mathbf{M}} + \rho h \tilde{\mathbf{U}}, \quad \mathbf{U} = \frac{\tilde{\mathbf{M}}}{\rho h},$$

where $\tilde{\mathbf{U}}$ shows the basic current, supposed independent of the depth and $\tilde{\mathbf{M}}$ denotes the mean wave momentum

$$\tilde{\mathbf{M}} = \left\langle \int_d^{\zeta} \rho \mathbf{u} dz \right\rangle$$

where u is the velocity vector associated with the wave motion. $\nabla (=i\partial/\partial x + j\partial/\partial y)$ is the two dimensional gradient operator. μ denotes the eddy viscosity coefficient, D is the rate of energy dissipation mainly due to wave breaking. E shows the wave energy

$$E = \frac{1}{2}\rho g a^2 ,$$

where a is the local wave amplitude.

$$\sigma = \tilde{\sigma} - k \cdot U$$

σ is the frequency relative to a coordinate system moving with the current velocity U and $\tilde{\sigma}$ is the frequency relative to a fixed coordinate system. k shows wave number. C_g denotes group velocity and its magnitude is

$$C_g = \frac{\partial \sigma}{\partial k} = \frac{1}{2}c \left[1 + \frac{2kh_0}{\sinh 2kh_0} \right]$$

$$c^2 = \frac{g}{k} \tanh kh_0$$

where $h_0 = d + \zeta_0$ and ζ_0 is, as later shown, steady wave set-up.

The radiation stress tensor s and its components referred to the coordinate system shown in Fig.1 are

$$s = \begin{pmatrix} E \left[\frac{C_g}{c} (1 + \cos^2 \theta) - \frac{1}{2} \right] & E \frac{C_g}{c} \frac{\sin 2\theta}{2} \\ E \frac{C_g}{c} \frac{\sin 2\theta}{2} & E \left[\frac{C_g}{c} (1 + \sin^2 \theta) - \frac{1}{2} \right] \end{pmatrix}$$

The bottom stress averaged over one cycle τ is given by (IWATA 1976)

$$\tau = f \begin{pmatrix} U(1 + \cos^2 \theta) + v \frac{\sin 2\theta}{2} \\ V(1 + \sin^2 \theta) + u \frac{\sin 2\theta}{2} \end{pmatrix}$$

where $f = \frac{2}{\pi} \rho K v$, $v = \frac{a}{h_0} c$.

The bottom friction coefficient K is given by (KAJIURA 1968)

$$K = \alpha \left(\frac{v}{\sigma z_0} \right)^{-2/3} , \quad \alpha = \text{const} ,$$

where z_0 is the roughness length of the bottom material.

For the coastal water considered now, we make the

Fig.1 Coordinate axis and incident angle.

Fig.2 Nondimensional rip current wave number $\hat{\omega}$ as functions of a characteristic parameter a^* .

longwave approximation so that $c^2 = gh_0$, moreover in the surf zone we assume $\alpha = \gamma h_0$, $\gamma = 0.4$. From the above approximations we get (IWATA 1976)

$$f = \begin{cases} f_0 \sqrt{z} & ; z < 1 \\ f_0 & ; z > 1 \end{cases}$$

$$\text{where } z = \frac{h_0}{h_*}, \quad f_0 = \frac{2}{\pi} \rho \gamma K_* \sqrt{gh_*}, \quad K_* = \alpha \left(\frac{\gamma}{kz_0} \right)^{-2/3},$$

where h_* is the water depth at the breaker line. K_* is the bottom friction coefficient in the surf zone and becomes constant. μ denotes the horizontal mixing coefficient and we assume (LONGUET-HIGGINS 1970)

$$\mu = \begin{cases} \rho N |x| \sqrt{gh_0} & ; h_0 \leq h_* \\ \rho N |x| \sqrt{gh_*} & ; h_0 > h_* \end{cases}$$

where N is constant.

From now on we consider a straight coastline where the local still water depth is linear: $d = -sx$, and assume that the field variables are composed of basic steady state as well as superposed perturbations,

$$U = U_0(x) + \delta U_1(x, y, t),$$

$$\zeta = \zeta_0(x) + \delta \zeta_1(x, y, t),$$

$$E = E_0(x) + \delta E_1(x, y, t), \text{ etc.}$$

For the steady state we have

$$\nabla \cdot M_0 = 0, \quad (1.4)$$

$$\nabla \cdot S_0 + \rho g h_0 \nabla \zeta_0 + \tau_0 - \nabla \cdot (\mu h_0 \nabla U_0) = 0, \quad (1.5)$$

$$\nabla \cdot \left[(U_0 + C_g) \frac{E_0}{\sigma_0} \right] + \frac{D_0}{\sigma_0} = 0. \quad (1.6)$$

To study the perturbations we consider conveniently a case of normal incidence of the waves ($U_0 = 0$), as well as steady state ($\partial/\partial t = 0$),

$$\nabla \cdot M_1 = 0, \quad (1.7)$$

$$\nabla \cdot S_1 + \rho g h_0 \nabla \zeta_1 + \tau_1 - \nabla \cdot (\mu h_0 \nabla U_1) = 0, \quad (1.8)$$

$$\nabla \cdot \left[C_g (E_1 + E_0) \frac{k \cdot U_1}{\sigma_0} \right] + U_1 E_0 + \frac{k \cdot U_1}{\sigma_0} D_0 = 0. \quad (1.9)$$

To derive the above equations we have assumed,

$$\frac{k \cdot U_1}{\sigma_0} D_0 \gg D_1, \quad h_0 \nabla \zeta_1 \gg \zeta_1 \nabla \zeta_0$$

where $D = D_0 + \delta D_1$.

Before we proceed to the rip current system, let us consider the basic state. For the case of normal incidence there is no basic current, $U_0 = 0$, so that eqs(1.5) and(1.6) can be transformed as follows,

$$\rho g h_0 \frac{\partial \zeta_0}{\partial z} + \frac{3 \partial E_0}{2 \partial z} = 0, \quad (1.10)$$

$$\frac{\partial}{\partial z}(E_0 C g) + x_* D_0 = 0, \quad (1.11)$$

where $h_* = -s x_*$.

(i) In the surf zone ($h_0 \leq h_*$) we assume as usual

$$E_0 = E_* z^2, \quad E_* = \frac{1}{2} \rho g \gamma^2 h_*^2,$$

then eq.(1.10) gives the basic wave set-up,

$$\zeta_0 = \zeta_* + \frac{3}{2} \gamma^2 h_* (1-z), \quad (1.12)$$

where ζ_* shows the value at the breaker line. In this case eq.(1.11) shows simply the rate of energy dissipation mainly due to the wave breaking, because the energy dissipation by the bottom stress is given by

$$\hat{D}_0 = \frac{8}{3\pi} K \frac{\nu}{h_0} E_0,$$

whereas(1.11) gives

$$D_0 = \frac{5s}{2h_0} E_0 \sqrt{gh_0},$$

that is, energy dissipation by the bottom stress is much smaller than that due to wave breaking.

(ii) Outside the breaker zone ($h_0 \geq h_*$) we can neglect energy dissipation, $D_0 = 0$, so that the energy flux becomes constant, $E_0 C g = \text{const}$. It follows then

$$E_0 = E_* z^{-0.5}, \quad (1.13)$$

introducing (1.13) into (1.10) we have at once,

$$\zeta_0 = -\frac{\gamma^2 h_*}{4} z^{-1.5}, \quad (z \geq 1) \quad (1.14)$$

From now on we take a new coordinate system with origin at the basic wave set-up shore line.

§2. Rip current system

From eq.(1.7) we get stream function as follows,

$$hU_1 = \frac{\partial \psi}{\partial y}, \quad hV_1 = -\frac{\partial \psi}{\partial x}.$$

From eqs.(1.8) and (1.9) we can derive an equation for the stream function. We can put in general $\psi = \psi \cos my$, $E_1 = E_1 \sin my$ and $\zeta_1 = \zeta_1 \sin my$, where m denotes the wave number of the rip current circulation cells.

(i) In the surf zone we have,

$$\tau_1 = f_0 \sqrt{z} \left(\frac{2}{h_0} \frac{\partial \psi}{\partial y}, \quad -\frac{1}{h_0} \frac{\partial \psi}{\partial x} \right), \quad \mu h_0 = f_0 \varepsilon |x_*|^2 z^{2.5},$$

where
$$\varepsilon = \frac{\pi s N}{2 \gamma K_*}.$$

This particular mixing parameter ε denotes essentially the ratio of horizontal mixing to the bottom friction and plays an important role in the rip current system.

$$\eta \psi'' - \left(\frac{1}{4} + \eta \right) \psi' - \left(\frac{1}{2a_*} - \frac{1}{4} \right) \psi = \varepsilon P, \quad (2.1)$$

$$P = 4\eta^3 \psi'''' + 9\eta^2 \psi'' - \left(1 + \frac{2\eta}{a_*} \right) \eta \psi'' - \frac{1\eta}{4a_*} \psi' + \frac{1}{8a_*} \left(1 + \frac{2}{a_*} \eta \right) \psi,$$

where
$$a_* = \frac{\pi s \gamma}{8 K_*}, \quad \eta = \frac{1}{2} a_* (\hat{\omega} z)^2, \quad \hat{\omega} = \sqrt{2} m |x_*|.$$

When we ignore horizontal mixing ($\varepsilon=0$) eq.(2.1) turns out to be confluent hypergeometric equation (IWATA 1976).

The solution of eq.(2.1) can be put in the series,

$$\psi = A \eta^\rho \sum g_n \eta^n, \quad (2.2)$$

where
$$g_0 = 1,$$

$$g_n h_0(\rho+n) + g_{n-1} h_1(\rho+n-1) + \dots + g_0 h_n(\rho) = 0,$$

$$h_0(\rho) = \rho [(\rho-1) \left\{ (\rho-2) \left(\rho - \frac{3}{4} \right) - \frac{1}{4} \right\} + \frac{1}{4} \varepsilon \left(\frac{5}{4} - \rho \right)],$$

$$h_1(\rho) = \frac{1}{2a_*} \left(\frac{1}{16} + \frac{7}{8} \rho - \rho^2 \right) + \frac{1}{\varepsilon} \left\{ \frac{1}{8} \left(\frac{1}{a_*} - \frac{1}{2} \right) + \frac{1}{4} \rho \right\},$$

$$h_2(\rho) = \frac{1}{16a_*^2}.$$

In general the indicial equation $h_0(\rho)=0$ gives four roots. For the case of no horizontal mixing $\rho=0$ and $\rho=5/4$ are obtained, however from the boundary conditions at the coast only $\rho=5/4$ was selected.

In order to see the effect of horizontal mixing upon the inviscid solution, we choose in this study one particular root of the indicial equation, which reduces to $\rho = 5/4$ for the case of no horizontal mixing, and the other roots are all omitted.

Energy in the surf zone can be obtained from eq.(1.9),

$$E_1 = \frac{1}{\sqrt{z}} \int_0^z Q dz \tag{2.3}$$

where $Q = \beta \hat{\omega} E_* z (\frac{\partial \psi}{\partial z} - \frac{1}{2z} \psi)$; $\beta = \frac{s}{h_*^2 \sqrt{2gh_*}}$.

Perturbed wave set-up can also be expressed by the stream-function as follows,

$$\zeta_1 = \frac{-f_0}{\rho g h_* z} [\frac{1}{2f_0} E_1 + \frac{1}{\hat{\omega}} (\frac{z}{z})^{0.5} \frac{\partial \psi}{\partial z} - \epsilon L(\frac{1}{z} \frac{\partial \psi}{\partial z})] \tag{2.4}$$

where $L(\phi) = (z^{1.5} \frac{\partial^2 \phi}{\partial z^2} + \frac{1}{2} z^{0.5} \frac{\partial \phi}{\partial z} - \frac{1}{2} \frac{1}{\sqrt{z}} - \frac{\hat{\omega}^2}{2} z^{1.5}) \phi$

(ii) Offshore region.
Outside the breaker zone we can put $E_0 = E_* z^{-0.5}$ and $f = f_0$. Moreover in this region we can neglect horizontal mixing compared to the surf zone, where the mixing is vigorous owing to breaking of the waves.

$$\xi^2 \frac{\partial^2 \psi}{\partial \xi^2} - (2 + a_* \hat{\omega}^2) \xi \frac{\partial \psi}{\partial \xi} - (\xi^2 - 3a_* \hat{\omega}^2) \psi = 0 \tag{2.5}$$

where $\xi = \hat{\omega} z$.

The solution of the above equation is expressed by the modified Bessel function,

$$\psi = B \xi^\alpha K_\nu(\xi), \tag{2.6}$$

where $\alpha = \frac{1}{2}(3 + a_* \hat{\omega}^2)$, $\nu = \frac{1}{2}(3 - a_* \hat{\omega}^2)$.

The energy in the offshore region is given by

$$E_1 = \frac{1}{\sqrt{z}} [\int_1^z R dz + E_1^*] \tag{2.7}$$

where $R = \beta \hat{\omega} E_* z^{-1.5} (\frac{\partial \psi}{\partial z} - \frac{3}{z} \psi)$; $E_1^* = \int_0^1 Q dz$.

Perturbed wave set-up can be expressed,

$$\zeta_1 = -\frac{f_0}{\rho g h_*^2} \left[\frac{1}{2} \frac{h_* E}{f_0} + \frac{1}{\hat{\omega}} \left(\frac{z}{z_*} \right)^{0.5} \frac{\partial \Psi}{\partial z} \right] \quad (2.8)$$

The matching conditions at the breaker line are the continuity of two horizontal velocity components as well as perturbed wave set-up. As we can see from eq.(2.7), energy is always continuous. Perturbed wave set-up outside the breaker zone is obtained under the assumption of no horizontal mixing, so that it becomes discontinuous on the breaker line even if two horizontal velocities are continuous on it.

At the breaker line $z = 1$, $\eta = \eta_0 = 1/2\alpha_* \hat{\omega}^2$ and $\xi = \hat{\omega}$, accordingly the continuity condition of velocity components are

$$\begin{vmatrix} \Sigma g_n \eta_0^n & 1 \\ 2 \Sigma g_n (\rho+n) \eta_0^n & \frac{\alpha + \nu - \hat{\omega} K_{\nu+1}(\hat{\omega})}{K_{\nu}(\hat{\omega})} \end{vmatrix} = 0. \quad (2.9)$$

The eigenvalues $\hat{\omega}$ are numerically obtained and represented in Fig.2 as functions of α_* from eq.(2.9) for $\epsilon=0.2 \sim 0.4$. In Fig.2 is also shown an empirical formula $\hat{\omega} = 5\alpha_*^{-2}$. Another curve $\hat{\omega} = \sqrt{3}\alpha_*^{-0.5}$ is reproduced from the previous paper (IWATA 1976), which is obtained for the limiting case of no horizontal mixing $\epsilon=0$. Fig.3 shows experimental results (HORIKAWA and MIZUGUCHI 1975) from which the above experimental formula is derived.

From Fig.2 we can see remarkably good agreement with the empirical formula is obtained for the case $\epsilon = 0.3$. It must be noticed this value $\epsilon=0.3$ is also obtained for the basic longshore current, when we consider obliquely incident waves (LONGUET-HIGGINS 1970). For a practical application we can put for the range $\epsilon = 0.3 \sim 0.4$,

$$\hat{\omega} = \begin{cases} 5.0\alpha_*^{-2} & ; \alpha_* < 1.5, \\ 2.7\alpha_*^{-0.5} & ; \alpha_* > 1.5. \end{cases}$$

In Fig.4 and Fig.5 we show an example of calculated stream function for $\epsilon = 0.3$, $\alpha_* = 0.6$ and $\hat{\omega} = 8.4$.

Conclusion

Some of the numerous studies of the near shore circulations insist that irregular bottom topography always exerts complete control over the water circulation, that is,

Fig.3 Experimental data and empirical relationship between rip current wave number $\hat{\omega}$ and a_* , where $z_0=1/30z_1, z_1=0.005$ cm are assumed to compute K_* .

Fig.4 An example of stream functions on either side of breaker line $z=1$.

— Obtained from offshore equation.

- - - Obtained from surfzone equation.

$\alpha_* = 0.6$, $\epsilon = 0.3$ and $\hat{\omega} = 8.4$.

Fig. 5 An example of rip current pattern for $\alpha_*=0.6$, $\epsilon=0.3$ and $\hat{\omega}=8.4$.

the topography is a primary cause to generate nearshore circulation. But there remains the basic question of how the original bottom deformation was formed if not by a cell circulation. Rip current can develop on smooth beaches without any bottom irregularities, presumably cause sediment transport and produce bottom topography. At some later stage the deformed bottom topography may be eventually effective to control the nearshore circulation pattern. Based on these reasonings attempt has been made to clarify the rip current spacing as an eigenvalue of a vorticity equation.

Our model is not self-consistent as far as we do not consider the horizontal mixing in the offshore region. When we take into account the effect of this horizontal mixing, right-hand side of eq.(2.5) is not zero but must be

$$\varepsilon[\xi^4 \psi'''' - 2\xi^3 \psi'' + (2-\xi^2)\xi^2 \psi'' - (2-\xi^2)\xi \psi' + \frac{1}{4}\xi^4 \psi]$$

To find the solution which tends to zero at infinity and reduces to eq.(2.6) in the limiting case of $\varepsilon=0$ is a future problem.

Acknowledgment: Many thanks are due I.Watabe for his helpful programmings of the numerical computations.

WIND-INDUCED WATER SURFACE SET-UP AND DRIFT CURRENTS

by

Frederick L.W. Tang¹, Jin Wu², Charles C.C. Chang³,
and Shan-Hwei Ou⁴

ABSTRACT

A systematic experiment to study the wind-induced flow phenomena was conducted in a laboratory tank. The results are related to the wind friction velocity and subsequently scaled for applications at various fetches under different wind velocities. The wind-stress coefficients are found to be well scaled by the Froude number. The bottom friction is measured with an effective shear gauge. The ratios between the bottom stress and the wind stress are obtained. The complete profiles of wind drift current are measured under various wind velocities. A tentative distribution of drift currents in the whole water depth is proposed. The results from the experiment are used to examine the wind-induced flow phenomena in a closed basin.

INTRODUCTION

The water motions induced by wind are involved in many dynamical processes of the mutually-interacting air-sea system. Previous studies on the air-sea interaction, however, seem to concentrate on the atmospheric surface layer and the surface waves. In the past, the wind-induced water-surface set-up and drift currents were measured and analyzed separately. For the surface set-up, it was assumed that the wind stress was balanced by the difference of the hydrostatic pressure due to the surface inclination [Refs. 4 & 7]. Other factors involved were ignored and their influences have not been carefully evaluated. For the drift currents, no systematic experiment has been conducted except for those within the upper layer below the water surface [Refs. 6 & 14]. In the present study, a systematic experiment has been conducted in the wind-wave tank under various wind velocities and wind fetches.

The measurements include the wind profiles, surface waves, surface set-up, current profiles, and bottom friction. All the parameters shown in the free-body diagram of Fig. 1 were measured simultaneously in laboratory wind-wave tank of uniform depth. Various techniques of measurements were illustrated. The results were related to the wind-friction velocity and the wind fetch. The results obtained from all the measurements are substituted into the balancing expression from the free-body diagram; and, the relative importance of each term was also discussed.

EXPERIMENTAL EQUIPMENT AND PROCEDURES

Wind-Wave Tank

Experiments were conducted in the wind-wave tank at the Taichung Harbour Bureau, Taiwan. The tank is 1.5m wide, 2.0m deep and 100m long. Wind is generated by a 75 hp variable-speed fan mounted at the upstream end of the channel. The maximum available wind velocity with a cross section of 0.8m x 1.5m of air passage is above 20 m/s. Wave absorbers were installed at the both ends of the channel to reduce the effect of wave reflection.

Measurements of wind profiles and surface waves were performed at six different fetches: 22^m, 31^m, 37^m, 46^m, 52^m, 58^m and at four different water depths: 1.2^m, 0.9^m, 0.6^m and 0.4^m. Drift current profiles were measured at the fetches of 22^m, 31^m and 37^m, while the bottom frictions were measured only at the middle bottom between fetch 22^m and 31^m.

Fig. 2 is the general outline of the wind-wave tank and the air-water motions. The water motion is assumed to be two-dimensional flow. Select the origin of the axis at the mean water level with x along the channel axis and y vertical and drawn upwards as in Figure 2.

Wind and Wave Measurement Devices

The wind velocities in the channel were measured by pitot-static tube in conjunction with a micromanometer. The tube was supported at the central top of the tank and traversed vertically across the boundary layer of the airflow. The wind velocities were directly read out from the micromanometer.

The surface waves were measured with conductivity probes. The wave signals were recorded on tapes, which were subsequently played back on the analog computer, HP 1000, to determine the wave heights, wave periods, mean water surface elevations and wave spectra. The time interval for the surface data is 0.1 second and the total number of data in each station is 1200.

Current Measurements

Surface drift current was measured by the punched computer cards, 1 cm square saturated with paraffin. The cards were dropped from the channel roof. The surface drift velocities were obtained by timing the

Figure 1. Free-body forces diagram

Figure 2. Sketch of wind-wave tank and air-water motions

movements of the cards along a 3m distance. At least five readings were taken for each condition.

The subsurface drift current profiles were measured by dye method. On injecting the dye from the holes on a pvc tube at various elevations, the dye motions were photographed with an 8mm movie camera from the side of the tank. A clear grid was placed outside the channel on the plate-glass sidewall and an electronic clock is placed just below the grid within the camera's view. The dye motion was not laminar, and the velocity flow patterns were confused about ten seconds after the injection of the dye.

The horizontal distances of dye motion at the various depths within time duration were read out from the grid while the time duration was obtained from the electronic clock. The experiments were repeated five to eight times each wind velocity and the average values were taken at the various depths.

Shear Gauge

The shear stress on the tank bottom induced by the return current was measured by a shear gauge, as shown in Figure 3. It consists of three main parts: shear plates, strain gauge, and supported block. The shear plates contain the upper and the lower plate, both 55 cm wide, 65 cm long, and 0.12 cm thick. The lower plate is hung on the supported block by four steel wires (0.5mm diameter) of equal length. The shear plate is sensitive only to the horizontal forces.

The strain gauge is pasted on a steel sheet which is mounted at both ends on the lower plate and the supported block. The steel sheet is carefully adjusted through the screw such that no bending moment is exerted on it when at rest. The shear force acting on the upper plate is transferred to the bending moment on the steel sheet and is recorded on tapes which are then played back on the analog computer. The steel sheet is 0.5mm thick and 7 cm long, which are experimentally examined. The clearance gaps is 1mm along four sides. The shear gauge was statically calibrated.

WIND STRESS AND SCALING CRITERION

The surface set-up and drift currents are governed by the wind stress acting at the air-sea interface. A model scaling criterion for the wind stress coefficient is necessary for the laboratory studies of the field phenomena.

An equation for scaling the wind stress coefficient was given as [Ref. 11]

$$\frac{1}{\sqrt{C_y}} = \frac{1}{k} \ln \left(\frac{1}{0.0112 C_y F_r^2} \right) \quad (1)$$

in which C_y is the wind stress coefficient defined as $C_y = \tau_o / \rho_a U_y^2$;
 F_r is the Froude number defined as $F_r = U_y / \sqrt{g y}$; k is the Karman's constant;

Figure 3. Shear gauge

Figure 4. Froude number scaling of wind stress coefficients

and τ_0 is the wind stress, U_y the wind velocity at elevation y , ρ_a the density of air, and g the gravitational acceleration.

This Froude scaling criterion for wind-stress coefficient has been verified by Wu [Ref. 11] with the results of 12 laboratory and 30 oceanic independent data. The present result is given in Figure 4. Good agreement with Froude scaling law was shown.

Since the Froude number scaling law is derived from the logarithmic wind profile [Figure 5], the reference height, y , should be within the inner region of the atmospheric boundary layer. Wu [Ref. 12] proposed the anemometer height in Froude scaling as

$$y = \begin{cases} 10 \text{ cm; for } R < 5 \times 10^7 \\ 7.35 \times 10^{-5} R^{2/3} \text{ cm; for } 5 \times 10^7 < R < 5 \times 10^{10} \\ 10 \text{ m; for } R > 5 \times 10^{10} \end{cases} \quad (2)$$

where R is the fetch Reynold number given as $R = \frac{U_y F}{\nu_a}$, and F denotes the wind fetch, ν_a the kinematic viscosity of air.

Therefore, with a single wind velocity either in the field or in the laboratory at a suggested anemometer height, one can calculate the Froude number, which in turn is given to obtain the wind-stress coefficient. The wind stress and the wind friction velocity can also be obtained.

The dependence of the wind stress coefficient, C_{10} , on fetch was plotted in Figure 6, in which C_{10} indicates the C_y at $y = 10$ cm. In general, C_{10} decreases as F increases for the small wind velocities, while for the high wind velocities, C_{10} decreases first, then increases as F increases. The dependence of the wind friction velocity, U_* , on fetch shows the same tendency as C_{10} does.

BOTTOM FRICTION

The total forces on the test plate before and after the experiment were recorded digitally and analyzed through the analog computer to obtain the mean readings and the time-mean forces. By dividing the area of shear plate, the shear stress was obtained.

Since the bottom friction is oscillatory, the inertial force of the shear plate is involved. An attempt was made to lower reasonably the natural frequency of the steel sheet during the development of the shear gauge.

Figure 7 is the definition sketch of the data in which p indicates the mean reading of oscillatory shear stress after the experiment, q the same reading before the experiment, and A the time-mean range of the force waves. Since the resultant bottom stress is in the same direction as the wind stress [Fig. 1], the average bottom stress, τ_b , is interpreted as $(A/2 + p - q)$, which would correct the inertial force.

The measured values of the average bottom stress were shown in Figure 8 as the function of wind friction velocity. The average bottom stress increases slightly as the wind friction velocity increases. It is also seen that the bottom friction increases remarkably as the water depth decreases. Figure 9 shows the ratio between average bottom stress

Figure 5. Vertical wind profiles

Figure 6. Variation of wind stress coefficient with fetch

Figure 7. Sketch of data reading of bottom shear

Figure 8. Variation of average bottom stress with wind friction velocity

Figure 9. Variation of τ_b/τ_0 with U_*

and wind stress in relation to the wind friction velocity. This ratio has strong dependence on the wind friction velocity, as might be expected because the wind stress is calculated from the square of the wind friction velocity. The measured values of the ratio range from 5 to 0.08 according to the wind velocity and water depth. The value 0.5 assumed by Keulegan [Ref. 4] and 0.1 deduced by Baines & Knapp [Ref. 1] should follow their catalog. This deviation indicates the necessity of measuring rather than calculating the bottom friction when working with a force balance of the free body force diagram.

DRIFT CURRENTS

Surface Drift Currents

The surface drift currents were measured in the plate-glass section of the tank at fetch $F = 31\text{m}$. The measured ratio of the surface drift velocity to the wind velocity was calculated as 0.0311. Table 1 gives the ratio of several sets of experiments in which parts of the wind velocity were referred to the free stream wind velocity.

TABLE 1: Ratio of u_0/U_0

Author	Method	u_0/U_0 (%)
Keulegan	Paraffin particle	3.3
Tickner	Dye	3.0
Plate et. al.*	Paper disc	2.60
Shemdin *	Paper disc	2.89
Kato et. al. *	Hydrogen bubble	2.80
Wu	Floats	3.95
Present data	Paper	3.11

*Wind velocity is referred to as free stream wind velocity

The measured surface drift velocity is plotted in Figure 10 in which Figure (a) shows the variation of u_0 with U_* , Figure (b) shows the variation of u_0/U_* with U_* . The variation of the surface drift with the wind velocity is not fully understood. In this study, the ratio u_0/U_* is around the value of 0.45 at the high wind velocity. It is somewhat lower than the previous results of one of the authors [Ref. 12].

The Stokes transport at the water surface was expressed as [Ref. 2]

$$V_0 = C_0 \left(\frac{\pi H}{L} \right)^2 \quad (3)$$

where H is the wave height, L the wave length, C_0 the phase velocity calculated from Airy wave. The surface Stokes transport is also shown in Figure 10(a).

The wind-induced surface drift is the difference between the total surface drift u_0 and the surface Stokes drift V_0 . This leads to $(u_0 - V_0)/U_* = 0.38$, which is lower than the previous results. This is

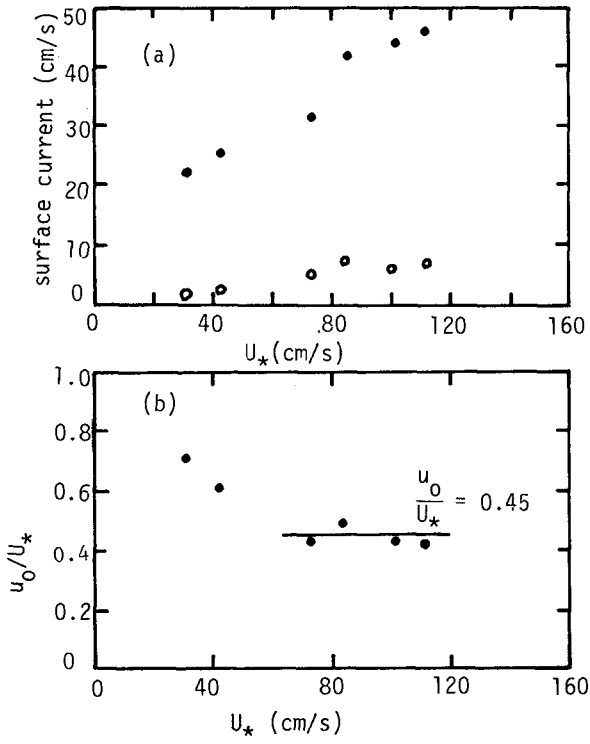

Figure 10. Surface drift velocity for various wind friction velocity
 (Solid: total drift;
 Open : wave-induced)

where more study is needed.

Measurement of Current Profiles

The measurement of the drift current profile is difficult. No complete data have been reported except for Tickner [Ref. 10] and Baines & Knapp [Ref. 1], both of whom made the measurements in shallow water channel at low wind velocities.

Five wind velocities of current profile measurements were conducted in the present study [Ref. 8]. For every wind velocity the profile was worked out from the average of five to eight runs. The current profiles vary with the wind velocity. Five profiles of different velocities were averaged to give the result as the curve E in Figure 11, where previous results are also shown in the figure for comparison.

Curve A in Figure 11 is summarized from the twelve drift current measurements of Wu [Ref. 14] while Curve B is compiled from three profiles of Shemdin [Ref. 6]. The measurements by Wu and Shemdin were aimed at the near surface region. Two curves are very close when y/d is larger than -0.2 , where d denotes the uniform water depth in the tank. Curve C was proposed by Kato [Ref. 3] with the assumption that current velocity at the bottom was equal to that at the half-depth. Curve D was obtained by Tickner [Ref. 10] at the small wind velocities of 3 m/s, in which detergent was added to the water to inhibit the formation of waves.

It is obvious that all of the results show a considerably different shape. In this result, the area under the return current is larger than that under downwind region. The continuity equation of net transport in vertical section is not satisfied. The lateral flow in the channel could cause the inaccuracies.

Analytical Result of Current Profile

Wind stress acting on the water surface causes a forward current in the upper layer and a backward current in the bottom, as shown in Fig. 12. Assuming that the wind stress is steadily and uniformly acting on the water surface, the drift current velocity will change gradually. As a result, the current profile can be separated into two regions: the upper region and the lower region being separated at $y = -\delta$ where $u = u_{\max}$.

The detailed configuration in the upper region is more complicated than the lower region. The wave drag will cause momentum transfer from air to water fluid. However, it is not expected that these effects will penetrate deeply into the fluid. The wind stress exerted on the fluid is like the roughness effect of a boundary. It is convenient to take this flow motion as a semi-pipe flow with the water surface as the pipe-wall. Similarly, the flow in the lower region is taking the flow motion as the semi-pipe flow with the bottom as its pipewall.

Taking the above into consideration, the current profile can be solved as the pipe flow problem. Tang [Ref. 9] solved this turbulent flow by Nikuradse's mixing length formula. The current profiles are given as:

Figure 11. Comparison of drift current profiles

Figure 12. Drift current profile

$$\frac{u_{\max} - u}{u_*} = 2.5 \ln \left(\frac{y}{\delta} \right) + 1.5 \left(\frac{\delta + y}{\delta} \right) - 0.08125 \left(\frac{\delta^2 - y^2}{\delta^2} \right) + 0.06541 \left(\frac{\delta^3 + y^3}{\delta^3} \right) ; \text{ for } -\delta < y < 0 \quad (4)$$

and

$$\frac{u}{nu_*} = 2.5 \frac{d+y+Y}{Y} + 1.5 \left(\frac{d+y}{d-\delta} \right) - 0.08125 \left(\frac{d+y}{d-\delta} \right)^2 + 0.06541 \left(\frac{d+y}{d-\delta} \right)^3 ; \text{ for } -d < y < -\delta \quad (5)$$

where

$$Y = \frac{dn^2}{1+n^2} \exp \left[- \frac{1.760(1+n^3) + 1.484(1-n)}{2.5n(1+n^2)} \right]$$

$$n = \sqrt{\frac{|\tau_b|}{\tau_s}}$$

$$\tau_s = \tau_o - \tau_w$$

u_* = current friction velocity in the upper region

$$\tau_w = \text{wave drag}$$

The computations of Equations (4) and (5) were carried out for cases corresponding to the available experimental results. Good agreement was found, as shown in Figures 13 and 14, with some measured current profiles.

SURFACE SET-UP

The water surface set-up was computed from the data of the surface elevations. The mean water elevation at a station during the test is computed through the computer by sampling the data of surface elevations. The difference between this mean water elevation and the still water level is interpreted as the surface set-up. Surface set-up at the fixed point is sometimes expressed by the surface slope.

Figure 15 shows the relation between the surface slope and the wind friction velocity in the interval of fetches 22^m and 31^m. In general, the surface set-up at the fixed station increases with the increase of wind friction velocity. But the scattered data limit further examination.

The dependence of the surface set-up on the fetch is not clear in this study due to the water oscillation in the tank. Figure 16 gives the relative surface set-up, h/F , as a function of Froude number, including the data from different water depths and different fetches.

The forces exerting on the water body between two sections include the wind stress, bottom friction, momentum flux of drift currents, and hydrostatic pressures at the two sections. For steady condition, the force balance equation can be expressed as

$$\frac{\partial}{\partial x} \int_{-d}^0 \rho_w u^2 dy = -\rho_w g d \tan \alpha + \tau_o + \tau_b \quad (6)$$

Figure 13. Comparison between proposed current distribution and measured

Figure 14. Comparison between proposed current distribution and measured

Figure 15. Relation between surface set-up and wind friction velocity at fetch 22^m

Figure 16. Surface set-up as a function of Froude number

where the left term represents the change of momentum flux due to drift currents and α is the inclination of the water surface between two sections.

Table 2 summarizes the various forces measured at fetch 22^m. If the left term in Equation (6) is neglected, the surface set-up can be estimated as

$$\tan\alpha = \frac{\tau_o + \tau_b}{\rho_w g d} \quad (7)$$

Figure 17 shows the comparison of surface set-up between the measured values and that estimated from Equation (7).

As shown in the figure, the actual water surface set-up is larger than those estimated from the wind stress and bottom friction. In other words, the determination of the wind stress from the water surface slope, which has often been used by the oceanographers, seems to be over-estimated.

TABLE 2: Various Stresses Measured at Fetch 22M

Depth (cm)	Wind friction velocity U_* (cm/s)	Wind stress τ_o (dyne/cm ²)	Bottom stress τ_b (dyne/cm ²)	Surface set-up $\rho_w g d \tan\alpha$

CONCLUSIONS

An attempt has been made for a systematic experiment covering all the dynamical forces on the water free body. Main findings are as follow:

1. Froude scaling criterion for the wind stress coefficient is confirmed, enabling the present results to be scaled for general application.
2. The bottom friction increases slightly with the increase of wind friction velocity, while the ratio between the bottom stress and the wind

Figure 17. Surface set-up from measured and estimated
 (Solid: measured
 Open : estimated)

stress decreases rapidly with the increase of wind velocity.

3. A complete distribution of the mean current velocity is proposed for prediction of drift currents.

4. The wind stress determined from the inclination of the mean water surface is found to be larger than that obtained from the wind profiles.

CHAPTER 49

DRIFT SPEED OF BUOYS IN WAVES

by

John H. Nath, F. ASCE⁽¹⁾

with an Appendix by M.S. Longuet-Higgins

Abstract

The drift speed of small floating objects subjected to periodic waves was investigated experimentally. Although data scatter is evident, the results show reasonably good agreement between Stokes third order mass transport drift speed and the drift speed of small surface floats, for the lower wave amplitudes. For the steepest waves there is good agreement between the data and recent developments of Longuet-Higgins. Surprisingly, the objects of deeper draft, such as a small spar-type buoy, drifted *faster* than the Stokes drift speed in the lower amplitude wave region of the tests. In the steepest waves the deeper buoys drifted a bit slower than the small objects.

1.0 INTRODUCTION

Mass transport currents on the surface of the ocean are sometimes estimated by tracking small floating discs or oceanographic research buoys. The NOAA Data Buoy Office has developed drifting buoys similar to that shown in Fig. 1 for tracking certain oceanographic parameters, such as water temperature, salinity, etc., as a function of the buoy position, commonly called the Lagrangian movement of the buoy. The buoy is often attached to a deeply submerged drogue by means of a tether and it is hoped that the drogue follows the currents at the depths desired. The buoy provides the reserve buoyancy for the system, as well as a habitat for sensors, recorders, transmitters, etc. Such a floating system is acted upon by wind, waves and currents. An ultimate objective is to be able to predict the motion of the system due to the forces of the environment. As part of this goal, it is desired to be able to predict the influence on the motion of the system from the waves alone.

Instead of the complete system, sometimes the buoy is drifted alone in order to more accurately track the surface currents. Floating discs and other objects are also used by engineers and oceanographers to track littoral drift currents near the breaker zone along the shoreline. Frequently, the motion of such drifters is taken as being equal to the speed of the surface currents acting upon them. However, this study shows that the speed of such drifters is significantly influenced by the water waves alone.

- (1) Professor of Civil and Ocean Engineering and Director of the Environmental Fluid Dynamics Laboratory, Oregon State University, Corvallis, Oregon.

Fig. 1 Drifting Buoy Dimensions

One early part of this work was to develop a time domain numerical model (9) for predicting the motion response of the drifting system to periodic waves, wind and current. A lumped parameter approach for the buoy, tether and drogue was utilized. For the buoy alone, at a particular time step, the forces and moments acting on the buoy are determined, thence the accelerations from Newton's second law of motion. The displacements and velocities at the end of the next time step are then determined with Runge-Kutta and predictor-corrector integration methods. The forces are estimated by dividing the buoy into useful discrete elements and applying a Morison-type equation. Therefore, the predicted buoy motion is dependent on certain coefficients. They were determined experimentally as explained in (10) and the total calculation was checked by comparing numerical model results to laboratory testing for buoy drift speed. The emphasis in this paper is on the laboratory results.

1.1 Purpose and Scope

The purpose of this study was to determine the drift speed in periodic waves for the oceanographic research buoy used by the NOAA Data Buoy Office and for smaller objects. A validation of the numerical program which predicts buoy drift speed was desired as well as a comparison with theoretical predictions of mass transport velocities from waves. Ultimately, it is hoped to be able to predict the average drift speed of buoys in a wave spectrum.

The amount of work at this stage is limited to the experimental determination of the drift of such objects in periodic waves. Of prime importance was to gather experimental evidence of such drift speeds for the first time. It was found that Stokes third order mass transport drift speed fairly well predicts the speed for very small objects. However, for the spar-type drifting buoy, the drift speed was faster than for the small surface float for waves not approaching the limiting steepness. Such a surprising outcome was fairly well predicted by the numerical model which predicts the motion of the buoy to periodic waves. Evidently the accelerations in the waves act upon the buoy in such a manner as to more than overcome the additional restraining drag from the lower extremities of the buoy. The lower extremities of the buoy were in depths of smaller particle trajectory.

1.2 Literature Review

A complete systematic study of the drift speed of objects in waves, either in the laboratory or in the field, has not been done to the writer's knowledge. However, several studies have been made of mass transport in waves using dye and neutrally buoyant particles, in the laboratory. In addition, some theoretical developments have been made.

Stokes (12) showed that wave particle orbits are not closed and that the drift term for deep water ($kh \gg 1$) second order computations is

$$\bar{U} = A^2 \sigma k e^{-2Kz} \quad (1)$$

where A is a wave amplitude, σ is the radian frequency, $2\pi/T$, T is the wave period, and k is the wave number, $2\pi/L$, where L is the wave length. The usual axes are considered here with x positive to the right and z positive upward and $z = 0$ at the still water level. In addition, z may be taken as the mean depth of the particle trajectory below the mean surface level.

Wiegel (3) presents a summary of third order equations for wave motion, and the Lagrangian particle displacements yield a steady state term for deep water, at $z = 0$, of

$$\frac{\bar{U}}{gT} = \frac{1}{4\pi} [1 + (ka)^2] [2(ka)^2 - \frac{20}{8}(ka)^3 + \frac{50}{64}(ka)^4] \quad (2)$$

where a is defined from

$$\frac{H}{L} = 2 \frac{a}{L} + 3\pi^2 \left(\frac{a}{L}\right)^3 \quad (3)$$

and at the breaking wave condition (deep water) H/L , 0.1412 and $a/L = .0666$.

These expressions are valid on the assumption that viscous effects are negligible, or have had not time to act, and that the motion is strictly irrotational and thus free of vorticity.

The viscous effects in laminar motion were considered by Longuet-Higgins (5) who presented a derivation based on boundary layer and vorticity concepts for the "conduction" solution ($A \ll \zeta$, where ζ is the

boundary layer thickness) which is sometimes used successfully in practice (2) regardless of the original small amplitude assumption. For a progressive wave in a uniform depth the solution is

$$\bar{U}(z/h) = A^2 \sigma k F(z/h) \quad (4)$$

$$\begin{aligned} \text{where } F(\mu) = & \frac{1}{4\sinh^2 kh} \{2\cosh[2kh(\mu-1)] + 3 + kh(\sinh 2kh)(3\mu^2 - 4\mu + 1) + \\ & + 3\left(\frac{\sinh 2kh}{2kh} + \frac{3}{2}\right)(\mu^2 - 1)\} \end{aligned} \quad (5)$$

Equation 5 is used successfully for predicting wave mass transport speeds near the bottom (2), but near the surface in deeper water it is not applicable. This is because the flow requires a long time, of order (h^2/ν) , to become established, where ν is the kinematic viscosity.

For large kh

$$F(\mu) = \frac{1}{2} kh (3\mu^2 - 4\mu + 1) + e^{-2kh\mu} \quad (6)$$

and

$$F(0) = \frac{kh}{2} + 1 \quad (7)$$

so that, for unbounded water depth, Eqs. 4 and 7 are unbounded.

It is also interesting to compare drift speeds with the maximum calculated particle velocity at the crest of a wave. The kinematic criterion for breaking is that the wave height increases to the point where the crest particle velocity is equal to the phase speed of the wave.

The phase speed relation for small amplitude waves in deep water is

$$c_0 = \frac{gT}{2\pi} = \frac{g}{\omega} \quad (8)$$

Phase speed for Stokes third order theory (12) is very close to that for fifth order theory and Dean's stream function theory, and is given by Eq. 9 for the maximum wave height condition. This is also the particle velocity at the crest of the wave.

$$c_0^2 = gk_0 [1 + (ka)^2] \quad (9)$$

However, the actual mean speed of advance of the water particles at the surface in a limiting finite amplitude wave is calculated by Longuet-Higgins in the Appendix as

$$\frac{\bar{U}}{c} = 1 - \frac{L}{c\tau} = 0.274 \quad (10)$$

where τ is the period for a pendulum with arm length equal to the wave

length. It is also shown in the Appendix that there is a small negative drift velocity compensating for the total mass-transport in the wave. The magnitude of this drift velocity is

$$U = -\frac{1}{h} = \frac{0.070 (g/k)^{1/2}}{kh} \tag{11}$$

where 1 is the total momentum in a highest deep water wave. For the shallowest condition in the wave tank testing, $\tanh kh \approx 0.83$, so that $kh \approx 1.2$ for that condition. Thus, the total drift for this shoaling case, also taking into account the reduction in phase speed, is $\bar{U}/C_0 = 0.16$. So, for this testing one might expect \bar{U}/C to be from about 0.16 to 0.27.

2.0 METHOD

It was desired to obtain experimental values of buoy drift speed in the laboratory under carefully controlled conditions and to compare these with the various predictors.

2.1 Laboratory Facilities and Procedure

The Wave Research Facility at Oregon State University is described in (4) and (11). For this study, a constant water depth of 3.51 m was used in the constant depth test section. It was found in (11) that the measured wave kinematics for periodic waves are fairly well predicted by Stokes third order wave theory. For the conditions investigated, the Stokes third order wave theory, fifth order wave theory and Dean's stream function theory all give nearly the same results. The maximum periodic wave characteristics in the flume test section are shown in Fig. 2.

Fig. 2 OSU WRF Periodic Wave Limiting Curve

The drift tests were performed in the laboratory on two experimental buoys, one small discus and one very small sphere. Thus, four objects were tested. The buoys were a prototype 92.4 kg buoy and a 1:4 scale model weighing 1.5 kg, as shown in Fig. 1. The small buoy is labeled Buoy No. 2 and the prototype buoy is labeled Buoy No. 3. [Buoy No. 1 is reported on in (9).] The discus and sphere are shown in Fig. 3. The discus measured 15 cm in diameter, 2.5 cm thick and weighed 150 g so that it floated horizontally at mid-thickness. The small ball was 3.7 cm in diameter and weighed 29 g so that it just barely floated.

Fig. 3 Small Sphere (3.7 cm) and Small Discus (15 cm dia.) Drift Test Specimens

For each run the specimen was individually subjected to a long series of periodic waves. In the later stages of the testing with the discus and the sphere, a concerted effort was made to provide a long series of waves just prior to performing a drift test so that steady state dynamic conditions would be achieved. However, in the early stages of the testing with the two buoy specimens, such long periods may not have been achieved in each case.

After the wave system was established, the specimen location in the flume was noted just as it appeared at the crest of a wave by placing a marker on the wall in line with that particular wave crest. A stop watch was then started and several waves were allowed before the location was again marked in a similar manner at the crest of another wave. A photo of a typical test is shown in Fig. 4. The elapsed time was noted and the drift distance measured. The average drift speed was calculated therefrom.

2.2 Error Sources

In an experimental study of this sort several sources of error can enter into the measurements. The obvious errors were minimized by making the measurements carefully. Wind currents can create significant surface drift speeds in the shear layer between the wind and water which can

seriously influence the drift speed of small floating objects. In addition, the wind can act on large floating objects and influence their drift merely by the wind drag acting on the object. Therefore, when the wind was blowing at a level which influenced the results, the testing was suspended. In addition, the method of measuring the distance of buoy drift was subject to various sources of parallax which was minimized by using relatively long drift distances which occurred over relatively long periods of time. Thus, the division of these two quantities to obtain the drift speed resulted in a good average value.

Fig. 4 Typical Test Run with Buoy No. 3

In some runs a stray force would initiate a roll motion to the buoy, in a strict nautical sense. It was possible for this motion to become accentuated even though the wave period was not equal to the roll (same as pitch) period of the buoy, or two times that period. This precession was severe in only a few cases. Of course, any precession created a three-dimensional problem from a two-dimensional one. This stray motion was probably a major contributing factor to scatter in the data for the buoys. It will be noted that much more scatter exists for Buoy 3 than for Buoy 2.

It is not known from either theory or experiments how much time is required to establish steady state dynamic conditions in a wave flume. The transient time must be a function of wave board motion characteristics, flume length, water depth, beach absorption and many other variables. In the latter parts of this study, several waves were allowed to pass (20 or 50) prior to starting a test. Thus, it is possible the mass transport circulations had not reached a steady state motion condition prior to a test, and this could conceivably contribute to some of the scatter.

Therefore, a more subtle source of error is in the value and vertical distribution of the reverse flow that must exist in the closed

system wave flume. This reverse flow is a function of the characteristics of wave dissipation at the beach and any reflections that occur. Literature has already been cited that deals with the vertical distribution of mass transport, but an intensive study of the reverse flow, or circulation, mechanism of mass transport in a *closed system wave flume* of the kind used has not been made to the writer's knowledge. According to the results obtained, such reverse flow may not have affected the measurements unduly.

2.3 Data Analysis

The data analysis was quite simple. It was merely necessary to divide the distance traveled by the floating object by the associated period of time. The drift speed results are presented in a non-dimensional form on the graph by dividing the drift speed by gT . It is noted that by multiplying the result by 2π , the resulting values are V/C_0 , where C_0 is the value of wave celerity in deep water from Airy theory.⁶ The buoy drift speed is designated as V . In addition, it may be that the major factor in the motion generation of the buoy is the vertical acceleration of the water particles. They are non-dimensionalized as follows:

$$\frac{\text{particle acceleration}}{g} \approx \frac{H\sigma^2}{g} \quad (12)$$

The linear wave dispersion relation, $\sigma^2 = gk \tanh kh$, is then used, for simplicity, to change the form of Eq. 12 to

$$\frac{\text{particle acceleration}}{g} \approx Hk \tanh kh, \quad (13)$$

which gives some account to shoaling. In the OSU Wave Research Facility tests, most of the waves were deep water waves for which $\tanh kh = 1.0$. The lowest value of $\tanh kh$ was greater than 0.80. It is realized that Eq. 13 is rather crude but refinements from this seem to be lost in the noise of the experiments. By trial, the data collapsed fairly well into coherent plots with this technique. However, it should be noted that the limiting value of $Hk \tanh kh$ in deep water is 0.89, but that the maximum theoretical value of particle acceleration of the wave crest is 0.5 g for a progressing wave.

The nonlinearity of the waves and the influence of shoaling is sometimes approximated by considering the Ursell parameter in the manner similar to that suggested by Hudspeth (3). In this work the Ursell parameter, Ur , is defined as

$$Ur = \frac{H L^2}{h^3} \quad (14)$$

It should be noted that this parameter has little meaning in deep water.

3.0 RESULTS

The general range of wave parameters used for this test are shown in Fig. 5. The basic laboratory results are summarized in Table 1.

Table 1. Basic Laboratory Measurements

Fig. 5 Range of Periodic Waves with Drifting Objects

The results for the drift speeds for each of the buoys or floating objects are shown in Figs. 6 through 9. The dashed lines drawn through the data are the regression curves of

$$\frac{V}{gT} = B (Hk \tanh kh)^C \quad (15)$$

Table 2. Values of B and C, for Eq. 15, from data.

Model	$B \times 10^2$	C
Sphere	3.05	1.97
Discus	2.92	1.72
Buoy 2 - physical	1.79	1.23
Buoy 2 - numerical	2.85	1.60
Buoy 3 - physical	1.66	1.07
Buoy 3 - numerical	3.78	1.71

Figure 10 shows a comparison of the regression curves for each of the four physical models. If the regression lines for the small sphere and disc are extended to the deep water breaking wave condition, (a

Fig. 6 Drift Speed of Small Sphere

Fig. 7 Drift Speed of Small Discus

Fig. 8 Drift Speed of Buoy 2 Physical Model

Fig. 9 Drift Speed of Buoy 3

questionable practice, but nonetheless tempting since data were not obtained in the region of very steep, breaking and nearly breaking waves) values of V/gT of 0.2435 and .02403 are obtained, respectively, so that $V/C_0 = 0.153$ and 0.151, respectively. These values compare very closely with those predicted by Longuet-Higgins if one assumes that $\tanh kh \approx 0.8$. However, the high values of V/gT generally can be attributed to runs with relatively short wave lengths so that $\tanh kh \approx 1.0$.

The numerical model of buoy motion was also used in a manner similar to the wave flume tests. A typical example of plotted computational results is shown in Fig. 11, for quick reference to Fig. 10. The total set of runs contains some scatter because the numerical model was probably not run for a long enough time, in some cases, to reach steady state response. This came from a desire to minimize computer costs. A same regression curve as Eq. 15 is shown and the regression curve for laboratory results is superimposed. The force coefficients for the numerical model could perhaps be slightly modified to achieve better agreement. However, the results appear to be quite good and modification of the coefficients have not been made to date.

Fig. 10 Regression Curves of Four Laboratory Experiments

Fig. 11 Drift Speed of Buoy 2 Numerical Model

The regression lines from Fig. 10 are redrawn on Fig. 12, along with other theoretical information for comparative purposes. It could be considered that a limiting case of specimen drift speed would be when the wave breaks and the specimen surfs with the waves, and thus travels with the phase speed of the wave. This could not be tested for periodic waves in the wave flume because the waves could not be made to break continuously at the incipiently breaking condition. However, the particle crest speed is shown for Dean's stream function theory and Stokes third and fifth order theories, for $\tanh kh = 1.0$ and $\tanh kh = 0.80$, for the breaking conditions, on Fig. 12.

Fig. 12 Composite of Theories vs. Laboratory Results

DISCUSSION

The small discus and sphere drift speeds appear to be fairly closely approximated by the Stokes drift speed as predicted by third order theory. In addition, the drift speed predicted by Longuet-Higgins, with appropriate assumptions for kh , appear to predict the mass transport quite well for very steep waves.

In general, the drifting buoys and other objects tend to be in the region of the predictions by Stokes and Longuet-Higgins. The crest particle horizontal speed is considerably higher than the mass transport drift speed, evaluated at $z = 0$, and approaches the breaking wave phase speed for large kh . The slope of the drift speed curves in Fig. 12 for

the larger buoys is more parallel to the slope of the curves for the crest particle velocity than the slope of Stokes drift.

The regression curve describing the data trends for the large buoy and the small buoys are remarkably close together. In fact, for large wave heights the buoys and the small objects have approximately the same drift speed, in a non-dimensional sense.

The time domain numerical model predicts the drift speed of the buoys quite well. A small modification of the drag and added mass coefficients could be obtained for a closer correlation.

The non-dimensional drift speeds of each object, whether small or large, seem to be independent of Ursell parameter or wave period. Experimentally, at least within the noise of the measurements, widely different Ursell parameters plotted close to one another, indicating that the non-dimensional drift speed is independent of wave length, given other variables are held constant.

Although the information in this research is illuminating, it does not predict the drift of objects in random waves. In order to be able to predict the drift of such buoys in the ocean, one must be able to relate the calculations to the random wave conditions. Since the drift speed is nonlinearly related to the wave amplitudes, it may not be a straight forward matter to develop a nonlinear transfer function to be able to predict buoy drift speed from a random wave spectrum. Until a more careful determination can be made, one might get an estimate of the drift of a buoy in a random sea by working with the modal period, hence the modal wave length, for a narrow wave spectrum. In addition, testing with random waves may be required within the test facility.

ACKNOWLEDGEMENTS

This study was supported by the NOAA Data Buoy Office at the Space Technology Laboratories, Bay St. Louis, Mississippi, through contract 03-78-G03-0500. Part of the effort on this research was supported by the National Science Foundation through contract ENG-76-1623 regarding the slow drift characteristics of moored breakwaters in random waves. I am grateful for the energetic and careful work on the computations from Mr. Cheng-Wen Lin. The laboratory work and model construction was carried out by Mr. Lawrence Crawford and Mr. Terence Dibble, who performed much of the testing independently while I was on leave of absence in Japan. Their careful work and concerned attitude are very much appreciated. In particular, I want to thank Professor Longuet-Higgins for his helpful advice and fascinating Appendix to this paper.

APPENDIX: THE ORBITAL MOTION IN STEEP WATER WAVES⁽¹⁾by Michael S. Longuet-Higgins⁽²⁾

For a steady, irrotational wave of maximum height in deep water, a rough but possibly useful formula for the orbital motion may be found as follows.

Figure A1

In Figure 1A a wave of length L travels to the right with speed c . We can approximate the free surface between the two adjacent crests A and B by the arc of a circle centre C . To agree with the slope angle of 30° at the crests ($A2$) the arc must correspond to a 60° sector. Hence the triangle ABC is equilateral, and the radius of the arc equals the wave length L . This gives a crest-to-trough wave height $L(1 - \cos 30^\circ)$ or $0.1340 L$, which differs from the accurate ($A3$ and $A4$) value $0.1412 L$ by only $0.0072L$.

At the free surface the pressure is constant, so that the pressure gradient is always normal to the surface. A particle travels from B to A in one half-period

(1) Presented at the 16th International Conference on Coastal Engineering, Hamburg, 1978, as a discussion of the paper by John H. Nath, "Drift Speed of Buoys in Waves."

(2) Royal Society Research Professor, Dept. of Applied Mathematics and Theoretical Physics, Silver Street, Cambridge, England and Institute of Oceanographic Sciences, Wormley, Surrey.

$$\tau \doteq \pi (L/g)^{\frac{1}{2}}$$

At A it comes to rest relative to the profile, and assuming it does not surf-ride, it then transfers, like a trapeze artist, onto a similar pendulum at the left of A. In a reference frame which is at rest relative to deep water the particle has advanced a distance $(c\tau - L)$ in time τ . Its mean speed of advance is therefore

$$U = \frac{c\tau - L}{\tau} = c(1 - \frac{L}{c\tau}).$$

Using the expression $c \doteq (gL/2\pi)^{\frac{1}{2}}$ for deep-water waves of low amplitude gives

$$U/c = 1 - \frac{L}{c\tau} \doteq 1 - (\frac{2}{\pi})^{\frac{1}{2}}$$

The more accurate values $c = 1.0923 (gL/2\pi)^{\frac{1}{2}}$ and $\tau = 1.0174\pi(L/g)^{\frac{1}{2}}$ for waves of maximum height (A3 and A4) and for a pendulum of swing $\pm 30^\circ$ (A5) gives $U/c = 0.282$. Thus the average speed of advance is about 0.28 times the phase-speed.

The particle orbits are given approximately by

$$x = ct - L \sin\theta$$

$$y = L(1 - \cos\theta)$$

where t = time, and (A6)

$$\sin \frac{1}{2} \theta = k \sin(k\sqrt{g/L} t), \quad k = \sin 15^\circ$$

(see Figure A2). After describing each orbit the particle has

FIGURE A2

advanced a distance X where

$$\frac{X}{L} = \frac{cT - L}{L} = \left(\frac{cT}{L} - 1\right) = 0.393.$$

Precise numerical calculations (A6) based on the profile of the highest deep-water waves as given numerically by Yamada (A3) yield, respectively,

$$U/c = 0.274 \text{ and } X/L = 0.377$$

quite close to the values we have found.

To summarize, the orbital motion of a particle at the surface of a deep-water gravity wave consists very nearly of a uniform horizontal translation superposed on the backwards swing of a pendulum.

However, it can be shown (A6) that the drift velocity U in waves of slightly less than the maximum steepness is significantly less than the steepest wave. Also that in the steepest wave the gradient of the drift velocity near the surface becomes large. Thus, bodies submerged to a depth of only $0.02 L$ may be expected to drift at about half the speed of particles in the free surface.

Lastly, in wave channels of finite length, the effect of a return flow to compensate for the forward mass flux must be considered. For instance, in steep gravity waves in deep water, the total volume flux I is given by

$$I = 0.070 (g/k^3)^{\frac{1}{2}}$$

approximately [see Figure 2 of reference (A7)] where k is the wave number. Hence, in water of moderate depth h such that e^{-kh} is negligible but not $(kh)^{-1}$, there must be a backwards flow of order

$$U' = -\frac{I}{h} = \frac{0.07 (g/k)^{\frac{1}{2}}}{kh}$$

If kh is about 1.2, then there will be a net reduction in the effective phase-speed of about 6 percent, in addition to other changes arising from the finite depth of water, which may be about 9 percent. Such changes together would be enough to reduce U/c from 0.27 to about 0.16, close to the limiting values found by Nath.

In other words, the net drift-speed is very sensitive to finite-depth effects, particularly the compensating backwards flow, which diminishes only like $(kh)^{-1}$, not e^{-kh} , when kh is large.

The application of these results to irregular sea waves, both swell and waves under the action of wind, will be discussed elsewhere.

CHAPTER 50

NEAR-BOTTOM CURRENT MEASURED BY ACOUSTIC SENSORS

K.A. Selanger[†] and T. Carstens[†],
River and Harbour Laboratory, Trondheim, Norway.

ABSTRACT

A vertical current profile has been measured with three acoustic meters 60 cm, 100 cm and 200 cm from the sea bottom. The depth at the measuring site was 84 metres. The profile is found to depend on the time scale of the water particle motion. An Ekman-like turning of the current is also observed, and the thickness of friction layers is estimated. Comparison of the current data with wave measurements indicates that the vertical transfer of surface wave energy is 30-50 per cent less than first order wave theory prescribes.

INTRODUCTION

To extrapolate a current profile through the bottom friction layer is often requested, but very difficult to do with satisfying accuracy and reliability of the result. One important reason is that there is still a great shortage of field data to support theoretical works on this subject (1,2) or to cover the wide variety of practical situations. The present work is mainly intended to contribute with results and experiences from profiling the near-bottom current by acoustic sensors under natural conditions.

[†] Address: Klaebuvegen 153, N-7034 NTH-Trondheim, Norway.

ARRANGEMENT

The location of the station is illustrated in Fig. 1. The bottom mooring was located at 84 m depth slightly off-shore the south-west part of the Norwegian coastal zone. The geographical position was $N59^{\circ}16'$ $E05^{\circ}04'$. In this area the bottom falls smoothly off at a ratio of about 1:100. One kilometre to the west the slope increases towards the Norwegian trough.

The mooring and the instrument setup is sketched in Fig. 2. Three selfrecording acoustic current meters were mounted on a tetrahedral framework. The measuring levels were $z=60$ cm, 100 cm and 200 cm. Each instrument measured the current simultaneously in two orthogonal directions parallel to the bottom. The power and logging unit also synchronized the measurements of the three instruments.

In the top of the rig, 3 m above the sea bed, an Aanderaa current meter of the integrating type measured absolute-values of the current velocity and the direction of the mooring. None of the instruments were able to rotate.

Wave data were logged from a Datawell Waverider buoy 12 km west of the bottom mooring. This was a permanent wave measuring station, but the bottom topography in that area was too irregular to be suitable for the near-bottom current measurements. Later measurements indicate that the wave power spectrum may be reduced as much as 50 per cent from the location of the waverider to the bottom mooring. The periods of the waves, however, seem to be very similar in the two positions.

Wind observations were made at the island Utsira, see Fig. 1. These data were kindly supplied to us by the Norwegian Meteorological Service.

DATA SAMPLING AND OBSERVATIONS

The common logging unit of the acoustic sensors is programmable, and to measure the water particle movements on various time scales a broken-series sampling was chosen. One time sequence consisted of 60 equal-spaced registrations each third second. This gives 3 minutes long sampling periods, which were repeated four times an hour. The field experiment lasted 8 days, starting the 17th of March 1975 at 10 a.m. and ending the 25th of March at 12 a.m.

Nearly half a million data were stored on a magnetic tape, which was about sixty per cent of the total storage capacity. Of course, a selection of data for presentation here has to be done. Fig. 3 shows the sequential average velocities (u_{jk}, v_{jk}) , while the details from the single sequence $j=696$ are shown in Fig. 4.

At this point an account for the notation may be appropriate. The current vector number i measured in sequence j by instrument k is denoted

$$\vec{w}_{ijk} = (u_{ijk}, v_{ijk}) \quad (1)$$

In our case $i=1,2,\dots,60$, $j=1,2,\dots,775$ and $k=1,2$ and 3 , where k increases with the distance from the bottom. The axis of each instrument were directed 97 degrees and 7 degrees from north, but in this presentation all data are transformed into a uv reference system with positive values of u and v directed to the east (90°) and north (0°), respectively. When polar coordinates (w_{ijk}, ϕ_{ijk}) are used the angle ϕ is identical with the compass direction. By time averaging the indexing is left out. Further, the large symbol W is reserved for absolute-value averaging, while the small letter w is used in conjunction with vector averaging, e.g. $w_{jk} = |\vec{w}_{jk}|$.

The wave height measurements are shown in Fig. 5. The upper curve shows the maximum wave height, H_{\max} , and the lower one is the $H_{1/3}$ parameter. At the time when these measurements were done the wave registration system had a low regularity, which resulted in loss of valuable data both at the start and the end of the registration period.

The presentation of data is closed by the wind observations from Utsira, see Fig. 6. The diagram shows the average wind velocity for the last 6 hours.

3. Sequential mean values of the current velocity components, u_{jk} and v_{jk} , at the three levels z_k from the bottom. $z_1=60$ cm, $z_2=100$ cm and $z_3=200$ cm. A unit increment of the time index j corresponds to 15 minutes.

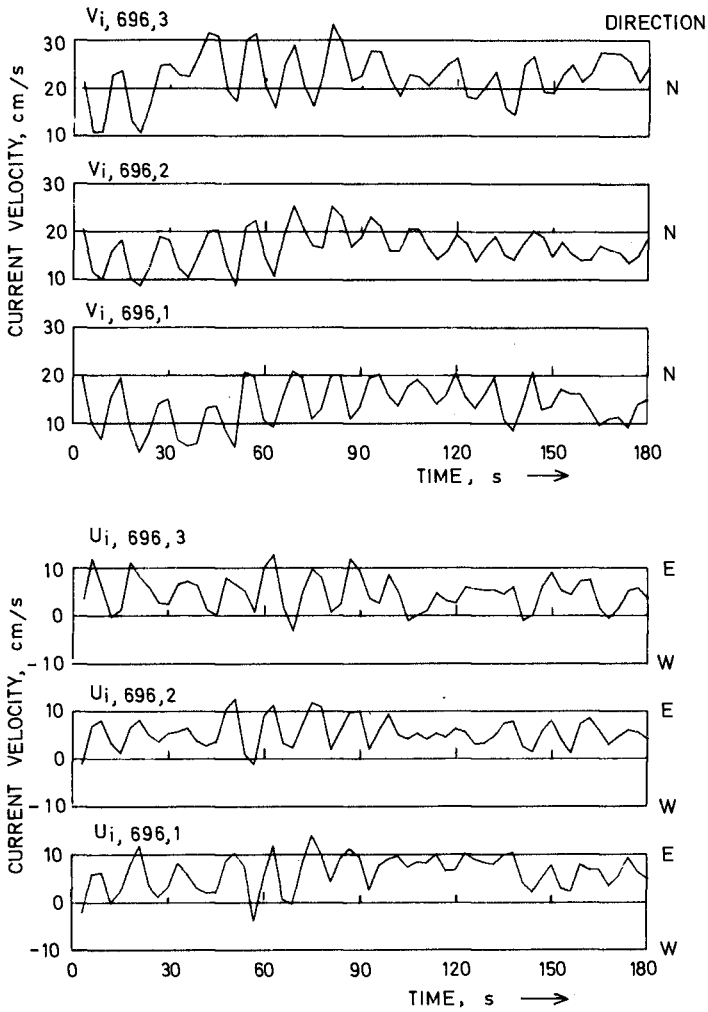

Fig. 4. The acoustic current measurements of the sequence $j=696$, $u_{i,696,k}$ and $v_{i,696,k}$. $k=1,2$ and 3 indicate the distances 60 cm, 100 cm and 200 cm from sea bed, respectively. Sampling interval is 3 s. The measurements were performed the 24th of March, 1975 at 4 p.m. at a station depth of 84 m.

Fig. 5. The measured wave heights H_{max} and $H_{1/3}$.

Fig. 6. Wind observations. The diagram shows the mean wind speed for the last six hours.

THE MEAN CURRENT AND THE EKMAN-LIKE TURNING

The analysis is started with the slowest varying motions of the water. These are illustrated by the progressive vector diagrams in Fig. 7. In fact these curves show the same data u_{jk} and v_{jk} as Fig. 3, but this time the z -dependence of the mean current vector is exposed more clearly. The

characteristic tidal loops are also easily seen.

The average current speeds for the entire registration period are $w_1=2.5$ cm/s, $w_2=1.8$ cm/s and $w_3=4.8$ cm/s. Hence, w_2 is less than w_1 , while w_3 is about twice of w_1 .

Fig. 7. Progressive vector diagrams of the bottom current.

During the five days long period from the 18th to the 22nd of March the flow was reasonably steady towards the east and the south. We therefore use this period for a closer inspection of the turning effect which is so clearly demonstrated in this figure. The mean velocity for these days is listed in Table 1 both on vector component form and as polar coordinates. The vectors are drawn with solid lines in Fig. 8.

Fig. 8. Comparison of the mean velocity measured between the 18th and the 22nd of March with current values calculated from Ekman's theory.

According to Ekman's theory the Coriolis force causes a turning of the current to the left as the distance from the bottom is reduced. The differential equations are well known and shall not be repeated here. Suggesting a geostrophic current $w_G = (u_G^2 + v_G^2)^{1/2}$ for large values of z and a no-slip condition at the bottom the turning of the current is described by the integrated equations

$$u = u_G - w_G e^{-\frac{\pi}{D} z} \cos\left(\frac{\pi}{D} z + \beta\right) \tag{2a}$$

$$v = v_G + w_G e^{-\frac{\pi}{D} z} \sin\left(\frac{\pi}{D} z + \beta\right) \tag{2b}$$

where $D = \pi \left(\frac{2 v_t}{f} \right)^{\frac{1}{2}}$ and $\beta = \arctg \left(-\frac{u_G}{v_G} \right)$. D is the

thickness of the frictional layer, v_t is the eddy viscosity and f is the Coriolis parameter. For $z > D$ the current practically attains the constant velocity (u_G, v_G) . It is also underlined that eq. (2) is based upon the assumption that v_t is independent of z .

By systematic variation of the parameters u_G, v_G and v_t a best fit of eq. (2) to the measured current values in Table 1 has been found. The parameter values, the friction layer thickness D and the theoretical values of the current speed $\vec{w}(z)$ are listed in Table 2. In addition the calculated current vectors are drawn by dashed lines in Fig. 8 to visualize the comparison of experiment and theory. A linear z -dependence of the eddy viscosity v_t did not improve the agreement between the theory and the field data.

THE LONG-PERIODIC COMPONENTS OF THE CURRENT

The power density spectra in Fig. 9 show the long-periodic harmonic components of the current. Note that the peak on the frequency f_{15} is broken to blow up the other components. No blocking or filtering has been applied. The power density e_n is equal to

$$e_n = \frac{a_n^2 + b_n^2}{2 \Delta f}, \quad n = 1, 2, \dots, 30 \quad (3)$$

where a_n and b_n are the amplitudes of the cosine- and sine fourier coefficients, respectively, and Δf is the spectral

z (cm)	u (cm/s)	v (cm/s)	w (cm/s)	ψ
200	- 4.2	0.4	4.2	275°
100	- 1.6	- 0.9	1.8	241°
60	- 1.8	- 0.9	2.7	223°

Table 1. The mean current vectors for the periode from the 18th to the 22nd of March.

z (cm)	u (cm/s)	v (cm/s)	w (cm/s)	ψ
200	- 3.7	- 0.6	3.7	261°
100	- 3.3	- 1.3	3.5	248°
60	- 2.4	- 1.5	2.8	238°

$$u_G = - 3.5 \text{ cm/s}, \quad v_G = - 0.5 \text{ cm/s}, \quad v_t = 0.3 \text{ cm}^2/\text{s}, \\ D = 2.2 \text{ m}.$$

Table 2. Theoretical values of the near-bottom current as calculated from eq. (2). The parameters u_G , v_G and v_t are adjusted to obtain as good agreement between measurements and theory as possible, see Table 1 and Fig. 8.

resolution. In our case $\Delta f = 1/186 \text{ hour}^{-1} = 0.0053763 \text{ hour}^{-1}$. The total energy σ^2 of the spectra is shown in each diagram.

The main peak on frequency f_{15} is readily identified as the semidiurnal tide. Nearly 100 % (per cent) of the energy of the tidal component M_2 (period 12.42 hours) is on f_{15} . In addition N_2 (12.66 hours) and S_2 (12.00 hours) contributes

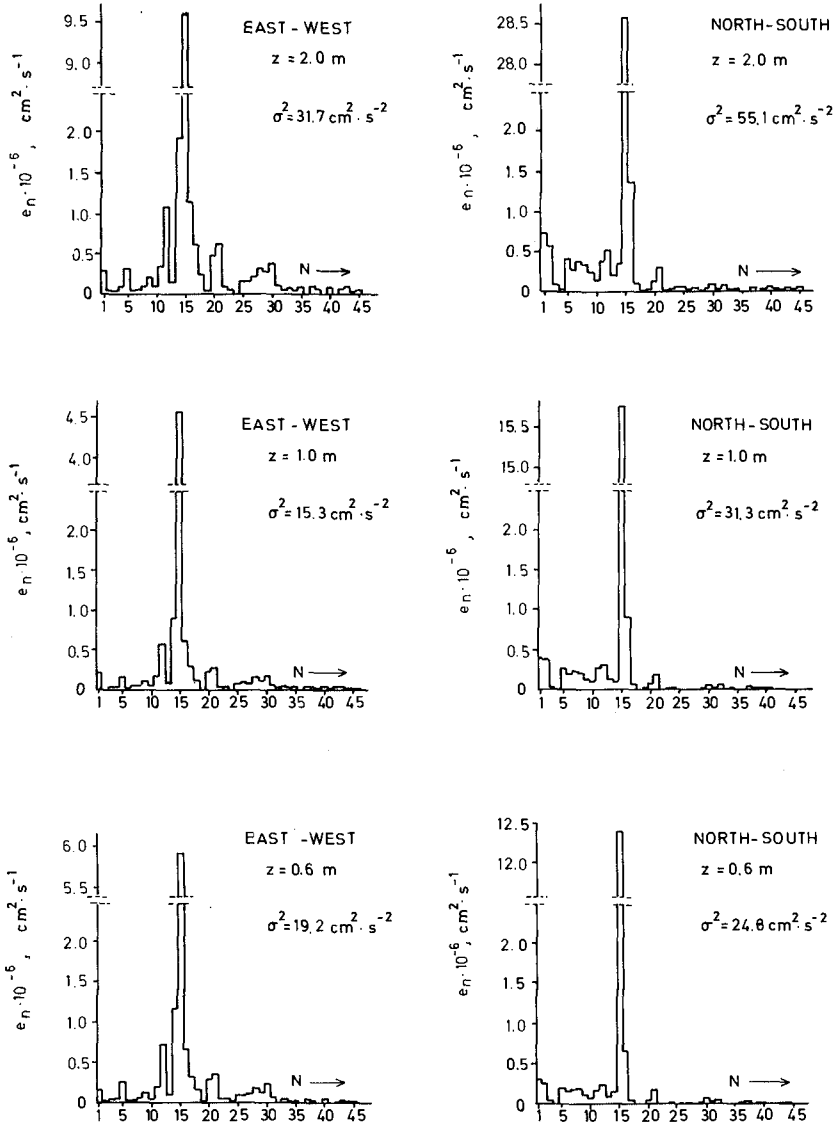

Fig. 9. The longperiodic spectra computed from the data series (u_{jk}, v_{jk}) shown in Fig. 3. σ^2 is the standard deviation of the time series.

by 70 % and 40 %, respectively, of their energy to this frequency. Due to the phase relationship the contribution from S_2 is negative. The energy of f_{14} and f_{16} is mainly due to S_2 and N_2 . The first harmonic component of the main peak, f_{30} , is very weak, but it seems to be significant.

The other spectral peaks are somewhat more difficult to identify. The tidal component M_3 is expected at f_{22} and f_{23} while the nearest top in the spectra is f_{20} and f_{21} . The period of f_5 is 37.2 hours, which is characteristic of the passage of a low pressure. Finally, we compare the period of f_{12} , 15.50 hours, to the inertial period, 13.97 hours.

The attenuation of the longperiodic fluctuations due to the bottom friction is somewhat different from what was observed for the mean current. From 60 cm to 100 cm the energy σ^2 increases very slightly, while the increase of σ^2 is nearly 100 % between 100 cm and 200 cm from the bottom. This corresponds to a difference in velocity of 30-40 %.

The main half axis of the rotational ellipses of the tidal frequencies at f_{15} are about 7 cm/s in the two lowest levels z_1 and z_2 , and 10 cm/s at z_3 . There is no evidence for a turning of the slow periodicities similar to that observed for the mean current.

THE SHORT-PERIODIC FLUCTUATIONS

The variations of the current within each 3-minutes sequence proved to be strongly connected to the windgenerated wave condition on the sea surface, Figs. 5 and 6. Particularly the wind from north the 24th and 25th of March induced horizontal movements of the water particles like those shown in Fig. 4. Spectral estimates of these time series, see

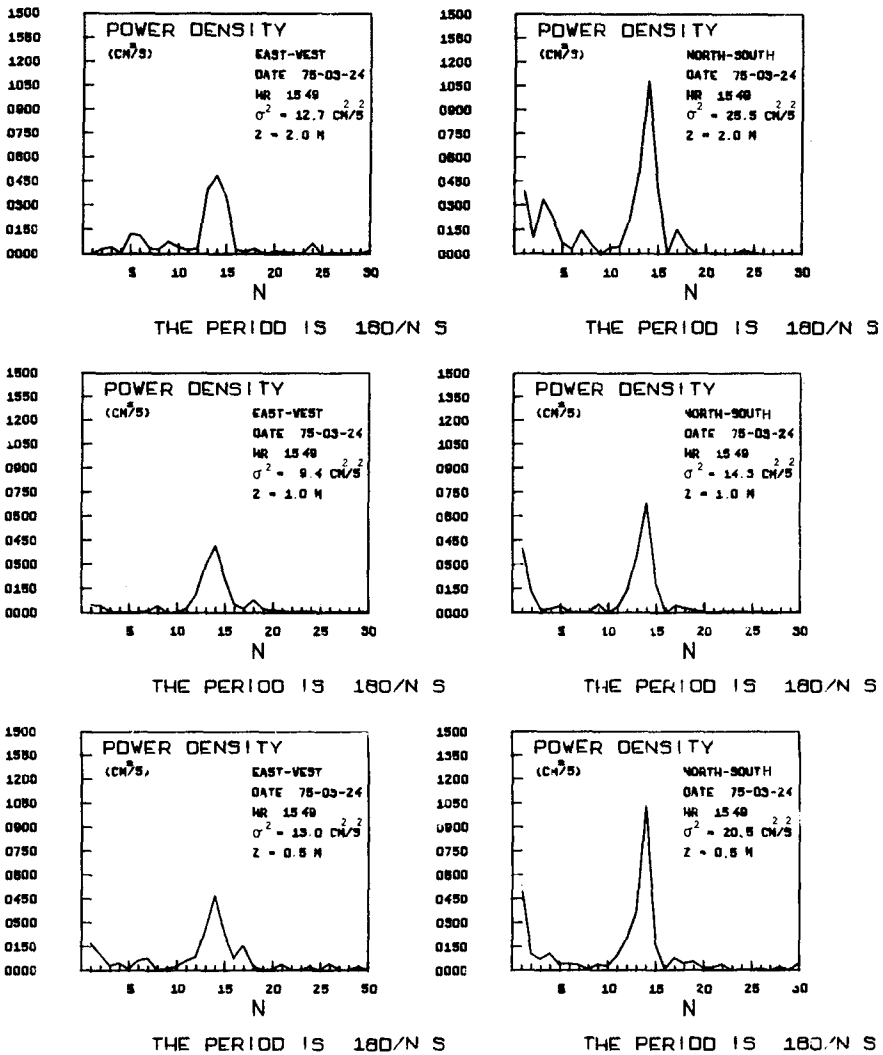

Fig. 10. Power spectra computed from the current measurements ($u_{i,696,k}$, $v_{i,696,k}$). The time series are shown in Fig. 4.

Fig. 10, show a significant peak on typical wave periods between 11 s and 16 s. Only a small part of the spectral energy falls outside this top.

Except for a linear trend reduction the raw data series have been applied for estimating these spectra.

These fast fluctuations seem to be less affected by the bottom friction than the tidal current and the mean velocity. There is a minimum of the peak power as well as the spectral energy 100 cm from the bottom, but from 60 cm to 200 cm the increase of spectral energy is less than 20 %. Similar studies of other time sequences confirm the result that the friction layer thickness for movements on typical wave frequencies is less than 60 cm.

THE VERTICAL TRANSFER OF WAVE ENERGY

According to first order theory the spectral wave power s_η is transferred vertically in the sea as

$$e(\delta) = T_\eta^2(\delta) \cdot s_\eta \quad (4)$$

where δ is the depth and η indicates the wave profile. The transfer function T_η is given by

$$T_\eta = \frac{2\pi f}{\text{sh } kd} \quad (5)$$

where f is the frequency, $k = k(\delta, f)$ is the wave number and d is the total depth. Having measured s_η and a velocity spectrum $e(\delta)$ the transfer function T_η can be tested directly.

Fig. 11. a) The surface wave spectrum s_η ($\delta=0$ m). H_S and H_{max} are the significant and the maximum wave height, respectively.

b) The theoretical velocity spectrum e ($\delta=82$ m) as computed by eqs. (4) and (5), and the measured spectrum e ($z=2$ m). The measurements were made the 22nd of March at 21 p.m., 1975.

Since the wave measurements stopped by accident too early, the sequence of data shown in Fig. 4 cannot be used for this purpose. Instead, the wave spectrum measured the 22nd of March at 21 p.m. is used, see Fig. 11 a. The theoretical

spectrum computed by eqs. (4) and (5) is shown in the diagram below, Fig. 11 b, together with the power density measured simultaneously 200 cm from the bottom. Hence, the parameters $d = 84$ m and $\delta = 82$ m. The power density of both the u and v direction are included in the current velocity spectrum.

The two spectra in Fig. 11 b indeed show a similar shape in several details. However, there seems to be a greater attenuation of the high frequency flange of the central peak than the theory prescribes. The opposite flange fits quite well at periods between 10 s and 12 s.

The energy of the wave-like motion close to the bottom is found to be about 50 % less than expected from linear wave theory applied to a measured wave spectrum. Some proposals for explaining this discrepancy are discussed in the next chapter.

DISCUSSION AND CONCLUSIONS

The acoustic current measurements have revealed how the profile in the bottom friction layer depends on the characteristic time of the water movement. After having smoothed out the semidiurnal tide from the time series, a mean current remains which increases by 100 % from $z_1 = 60$ cm to $z_3 = 200$ cm above sea bed.

The amplitude of the dominating tidal current increases by 40 % or so, while the oscillations on typical wave frequencies remains nearly constant over the same vertical range. Therefore, one may conclude that the thickness of the bottom friction layer is less than 60 cm for wind-generated wave motions.

A current profile including the result from the Aanderaa current meter has been drawn in Fig. 12. Since the Aanderaa instrument did not rotate it only recorded mean values of the absolute current speed, an operation which has been done mathematically for the acoustic data. The registrations made by the two different types of instruments seem to agree quite well. As shown by a dashed line in Fig. 12 the logarithmic function

$$W = \frac{W_{*}}{\kappa} \ln \frac{z + z_0}{z_0} \quad (6)$$

has been fitted to the data points. In eq. (6) W_{*} is the frictional velocity, $\kappa = 0.4$ is von Karman's constant and z_0 is the roughness parameter. Eq. (6) describes the observations reasonably well with the parameters $W_{*} = 1.8$ cm/s and $z_0 = 23$ cm. This value of z_0 is high and characterizes a hydrodynamically rough bottom. However, when interpreting such a current profile, one should have in mind how the friction layer thickness has been shown to depend on the period of the motion.

An Ekman-like turning of the mean current has been demonstrated, see Fig. 7. In Fig. 8 the experimental result is compared with the idealized Ekman theory where the parameter values $v_t = 0.3$ cm/s, $u_G = -3.5$ cm/s and $v_G = -0.5$ cm/s are used. The Ekman friction layer is estimated to be 2-3 m thick. The observed turning is greater than the theory prescribes, and the measured average current for $z = 100$ cm has only half the expected value. This disagreement may be due to a) topographical effects, b) calibration errors, or c) that v_t depends on z and t and also is influenced by the tide. It should also be pointed out that since the mean current is weak small inaccuracies may result in large relative errors.

Fig. 12. The current profile including the registrations by the Aanderaa meter. The broken line shows a logarithmic profile, eq. (6), with $W_{*} = 1.8$ cm/s and $z_0 = 23$ cm.

Later experiments indicate that stratification effects are negligible. The boundary condition (u_G, v_G) was not measured.

A velocity component closely related to the wind-generated surface waves is also observed. The intensity of these fast fluctuations is about 50 % less than expected from linear wave theory. This trend, suggesting a weaker wave action near the bottom than classical theory predicts, is in accord with earlier results obtained with pressure sensors, summarized by Silvester, (3). However, the attenuation we have observed seems to be somewhat stronger, and this discrepancy may be caused by the different location of the Waverider buoy and the bottom mooring. The influence of the bottom friction on these fast fluctuations is found to be insignificant beyond $z = 60$ cm.

CHAPTER 51

OSCILLATORY LAMINAR FLOW ABOVE A ROUGH BED

by

C.B. George¹ and J.F.A. Sleath²

Summary

Measurements are reported of the velocity distribution in the laminar boundary layer above a rough bed oscillating in its own plane in still air. The measurements were made with a hot-wire anemometer and the beds consisted of spheres packed closely together on flat plates. Particular attention was paid to the jets of fluid associated with individual roughness elements reported by Keiller & Sleath (1976). The probe used by Keiller & Sleath could be traversed vertically but not parallel to the bed. Consequently it is not known whether or not the velocities which they measured represent the maximum jet velocity at a given height since the probe was not necessarily in the vicinity of the jet at the moment at which it was maximum. In these new tests the probe could be traversed horizontally as well as vertically. It is found that one jet is formed by each roughness element during each half cycle. This jet is directed upwards from the bed. Its intensity shows relatively little variation with Reynolds number for the range of conditions investigated but increases significantly with the relative roughness parameter βD . The moment in the half cycle at which the jet is formed and the location of its axis appear to vary with both βD and Reynolds number. Visual observations suggest that the jet is associated with incipient vortex formation. The variation in velocity with height in the jets of fluid is significantly different from that given by Stokes' theoretical solution for a flat bed. Except in the immediate vicinity of the bed, the jet velocity predominates over that during the rest of the cycle.

Introduction

A knowledge of the velocity distribution close to the sea bed is of importance in several areas of coastal engineering. The attenuation of waves approaching the shore, the steady drift currents produced by the waves (and hence the dispersion of pollutants) and the transport of sediment are all affected by conditions in the boundary layer at the bed.

Measurements of the velocity distribution close to the bed in oscillatory flow have been made by Jonsson (1963), Kalkanis (1964), Horikawa & Watanabe (1968), Sleath (1970), Jonsson & Carlsen (1976) and

¹ Sir M. Macdonald and Partners, Cambridge, England

² Department of Engineering, University of Cambridge, England

Keiller & Sleath (1976). These measurements show that, except for flat beds of very fine sediment, the velocity distribution is quite different from Stokes' (1851) theoretical solution for flow over a flat bed, even when the flow is laminar.

Only the measurements of Keiller & Sleath were made with a probe small enough to examine the detailed flow structure around individual roughness elements. These showed the existence in laminar flow of a jet of fluid thrown up from the bed by each roughness element. The measurements were made with a stationary probe and an oscillating bed. Unfortunately the probe could not be traversed horizontally and consequently it is not known whether or not the velocity which they measured was the maximum for the jet at a given height since the probe was not necessarily in the vicinity of the jet at the instant at which it reached its maximum. It is also possible that there were other jets which were unrecorded by the probe. The object of the tests described in this paper was to carry out a more complete investigation of this phenomenon.

Experimental apparatus

The apparatus was similar to that described by Keiller & Sleath (1976). A flat plate 2.70 m long and 0.30 m wide was caused to oscillate with simple harmonic motion in its own plane by a Scotch Yoke mechanism driven by a variable speed motor. It is well known that relative to axes fixed in the bed the velocity distribution above an oscillating plate is the same as that produced by waves over a stationary bed provided that both the plate and the length of the waves are effectively infinite. Such an apparatus does not, of course, reproduce second-order effects such as mass-transport which occur when the wave length is not infinite.

The plate was enclosed in a wooden chamber 3.15 m long x 0.77 m high x 0.32 m wide. The clearance between the plate and the bottom of the chamber was 0.18 m except at the ends where the floor of the chamber was raised so that the plate was in continuous sliding contact with its surface. This arrangement prevented vortex shedding from the ends of the plate. Although oscillation of the fluid outside the boundary layer at the bed was not entirely eliminated, in no case did it exceed 5% of the amplitude of oscillation of the bed.

The central 1.65 m in length of the oscillating plate was covered with uniform spheres tightly packed together in a hexagonal array. The distance between sphere crests in the direction parallel to the short edge of the plate was equal to the sphere diameter D . In the direction of oscillation the crest-to-crest distance was $D(3)^{1/2}$. Five different beds were used with sphere diameters of 3.10, 6.32, 12.34, 18.60 and 37.80 mm.

All of the measurements were made in air using a DISA 55D01 constant temperature hot-wire anemometer and 55F31 miniature probe. The output was passed through a DISA 55D10 linearizer to a Thermionic Instruments T3000 tape recorder. The recorded signal was subsequently analysed on an IBM 1130 computer using a WDV analog-to-digital converter. Great care was taken to eliminate all extraneous sources of vibration during the experiments and consequently it was not found necessary to filter the

Fig. 1. Anemometer output during one cycle at $\beta D = 6$, $U_o/\omega D = 6.84$

signal. The probe projected vertically down towards the bed and the wire was aligned at right angles to the direction of oscillation of the bed. With this arrangement the recorded signal represents the resultant velocity in the vertical plane containing the direction of oscillation. The length of the wire was 1.2 mm and its diameter 5 μm . Calibration was carried out after each set of tests by oscillating the probe in still air at various known frequencies and amplitudes.

The normal test procedure was for the apparatus to be started up and left for at least two hours to achieve equilibrium. Velocity measurements were then made at various heights above the bed and at various horizontal positions. In this way a complete record of the flow in time and space could be built up. Velocity measurements were only made in laminar flows, i.e. in which the velocity record was effectively identical from one cycle to the next.

In addition to the velocity measurements with the hot-wire anemometer, visual observations were carried out with a similar bed of spheres in an oscillating water tunnel. A hydrogen bubble device was used to visualize the flow.

Test results and discussion

Fig. 1 shows a typical example of the recorded output from the hot-wire anemometer at two different heights above the bed. Since the calibration curve is highly non-linear the actual velocity record would be somewhat different but the main features are the same. In this figure t is time measured from the instant at which the velocity of the bed is maximum, ω is the angular frequency of oscillation, y is height measured vertically from the crest of a sphere, U_0 is the amplitude of the bed velocity and $\beta = (\omega/2\nu)^{1/2}$, where ν is kinematic viscosity, is inversely proportional to the thickness of the viscous boundary layer. The record is different in the two half cycles because the probe was not symmetrically placed relative to the bed in the two half cycles. If we concentrate our attention on the second half cycle ($180^\circ \leq \omega t < 360^\circ$) we observe the following features:

- (1) There is a pronounced peak in the record in the vicinity of $\omega t = 270^\circ$. This is caused by the jet referred to by Keiller & Sleath.
- (2) The record also shows a fairly high frequency oscillation. This is due to the fact that, by continuity, the velocity over the crest of a wavy bed must be greater than over a trough. Since $U_0/\omega D$ is the ratio of amplitude of oscillation of the bed to sphere diameter it follows that eight spheres pass under the probe as the bed moves from one extremity of its stroke to the other for the conditions of Fig. 1. Close examination of the record shows that the velocity rises to a maximum as a crest passes directly under the probe, falls to a minimum, and then rises to a second maximum when the probe is mid-way between crests, and so on. The reason for this second maximum is that, because the spheres are packed in a hexagonal array, the distance between crests in the direction of oscillation is $D(3)^{1/2}$ but the distance between rows of spheres is only $D(3)^{1/2}/2$. In other words the flow is speeded up when the probe is mid-way between

Fig. 2. Horizontal position relative to the bed at which the maximum velocity in the jet is found at various heights above the bed. $\beta D = 20$

crests in the direction of oscillation because the probe is then directly in line with a second row of spheres. The increase in velocity over the crest in the first row is, of course, greater than the increase in the gap between spheres in the second row but this difference becomes less marked as height above the bed increases.

When the thickness of the viscous boundary layer is small compared with the roughness diameter (i.e. $\beta D \gg 1$) this component of velocity is accurately given by the potential flow solution for the bed, except within the thin viscous layer itself.

(3) When the peak in the vicinity of $\omega t = 270^\circ$ and the high frequency fluctuation are excluded, there remains a component of velocity which varies nearly sinusoidally with time. Keiller & Sleath showed that the variation with height of this component is close to that given by Stokes' theoretical solution for flow over a flat plate.

As stated in the Introduction, the object of the present paper is to examine the peak in the vicinity of $\omega t = 90^\circ, 270^\circ$ etc. The visual observations in the oscillating water tunnel showed that this peak appeared to be associated with incipient vortex formation. As the flow near the bed reverses, the remains of the incipient vortex formed during the preceding half cycle is carried back towards the crest and hurled out into the fluid above. If it is assumed that the locus of the maximum velocities in the peak recorded by the probe represents the axis of the jet hurled up from the bed we can determine the path of this jet. Fig. 2 shows examples of the locii of the maxima recorded at $\beta D = 20$. In this figure x is the horizontal distance measured from the crest of a sphere in the direction of oscillation and L is the distance between adjacent crests, which is equal to $D(3)^{1/2}$ in the present case. The axes have been plotted so as to have the same scale for horizontal and vertical distances. We see that at low values of the Reynolds number $U D/\nu$ the jet is angled at about 60° to the horizontal but that at higher Reynolds numbers the angle becomes steeper. Also, as the Reynolds number increases the axis of the jet moves further out into the trough between crests. The arrow heads marked on the curves drawn through the experimental points indicate the direction of increasing phase. The fact that the maxima are found progressively later in the half cycle as distance from the bed increases is consistent with the visual observation of a jet of fluid hurled up from the bed. The measurements shown in Fig. 2 were obtained during one half cycle. During the next half-cycle the jets would, of course, originate on the other side of the crest and be tilted in the opposite direction.

It should be mentioned in passing that George (1977) drew a distinction between a "crest" jet and a "trough" jet. The reason for this is that at large values of the relative roughness parameter βD the flow in the jet decays only slowly with time. Consequently, the actual maximum velocity in the jet may be followed by a decline and then by a second maximum as the jet is carried over a crest or over the second row of spheres mid-way between crests where the velocity is reinforced by the high frequency fluctuation mentioned during the discussion of Fig. 1.

Fig. 3. Variation with height of the maximum velocity in the jet. $\beta D = 20$. (Symbols as for Fig. 2)

Fig. 4. Variation of the maximum jet velocity with βD and Reynolds number

In reality, there is only one jet whose maximum may, as shown by Fig. 2, be found either over a crest or over a trough depending on the value of $U_0 D/\nu$. At smaller values of βD the jet decays much more rapidly with time after passing its maximum and consequently only one maximum is observed.

An example of the way in which the maximum velocity V_{peak} in the jet varies with height is given in Fig. 3. For purposes of comparison, Stokes' theoretical curve for a flat plate is also shown. It is clear that, except very close to the bed, the velocity in the jet is much greater than that given by Stokes' solution. The peak velocity does not tend to zero at $y = 0$ because, as shown by Fig. 2, the jet does not originate at the crest but some way down in the trough (i.e. below the $y = 0$ level).

The way in which the maximum value, V_{max} , of V_{peak} varies with βD and $U_0 D/\nu$ is shown in Fig. 4. There is clearly significant variation in jet intensity with βD but surprisingly little variation with $U_0 D/\nu$ for the range of values covered. However, the curves must tend to zero as $U_0 D/\nu \rightarrow 0$ if, as suggested above, these jets are associated with incipient vortex formation.

At large distances from the bed the variation of V_{peak} with y tends towards a curve of the form

$$\frac{V_{\text{peak}}}{U_0} = \text{const} \times \exp(-\beta y/X) \quad (1)$$

where X is a constant for given $U_0 D/\nu$ and βD . The way in which the value of X obtained from the present measurements varies with βD and $U_0 D/\nu$ is shown in Fig. 5. The numerical calculations made by Sleath (1974) for two-dimensional bed roughness showed that when βD is sufficiently large a reasonable approximation for X at large distances from the bed is

$$X = \beta D/2\pi \quad (2)$$

The curves obtained for the various values of βD from Eq. (2) are shown in Fig. 5 for purposes of comparison. Although there does appear to be some measure of agreement it should be emphasised that since the bed profiles are very different in the two cases it would be wrong to attach too much significance to it. However, it does seem that the value of X depends mainly on βD and varies only slowly with $U_0 D/\nu$.

Finally, it should be mentioned that although the initiation of the jets is linked with the reversal of flow close to the bed, the phase at which the jet velocities reach a maximum at a given height may vary significantly with βD and $U_0 D/\nu$. For example, Fig. 6 shows the variation in phase of V_{peak} at $\beta y = 0.5$. The numbers over the experimental points at $\beta D = 20$ are the values of $U_0 D/\nu$. The phase is clearly dependent on Reynolds number. At smaller values of βD the spread of values obtained in the various tests is indicated by the error bands. At these smaller values of βD there appears to be a tendency for the phase at which the maximum jet velocity is found to increase with βD .

Fig. 5. Variation of X for the jet velocity with βD and Reynolds number. (Symbols as for Fig. 4)

Fig. 6. Phase of maximum jet velocity at $\beta y = 0.5$

Further details of these tests are given by George (1977).

Conclusions

One of the most important conclusions from the present work is that for oscillatory flow over a rough bed there is a range of Reynolds numbers for which the flow remains laminar, in the strict sense of that term, but in which the velocity profile is significantly different from that over a smooth bed. It has usually been assumed in the past that the flow regime at the sea bed is either fully developed turbulence or that the velocity distribution for laminar flow over a smooth bed applies. It is clear from the present work that a third regime which may be called "rough laminar" may also be important.

It was suggested above that the jets of fluid are associated with incipient vortex formation around each roughness element on the bed. It is well known that vortex formation around bluff bodies is found in turbulent as well as laminar flow. This being the case, effects similar to those investigated here may also occur in rough turbulent flow.

Finally it may be noted that, relative to axes fixed in the free stream, both Kalkanis (1957, 1964) and Sleath (1970) found that the velocity distribution in oscillatory flow above beds of sand followed a similar distribution to that of Eq. (1). Since the roughness of beds of sand is very different from that considered here only qualitative agreement between the two sets of results is to be expected. Nevertheless it is possible that what Kalkanis and Sleath were actually measuring was the velocity distribution of the jets of fluid produced by the grains of sand on the surface of the bed.

CHAPTER 52

EXTREME SEA LEVELS FROM TIDE AND SURGE PROBABILITY

D. T. PUGH* and J. M. VASSIE*

ABSTRACT

This paper considers a method of deriving the probability of occurrence of extreme sea levels by combining the probability functions of surge and tide. As a result the quantity of data required is less than with traditional methods. The philosophy of the method is discussed and the conditions under which the theory can be applied are examined. Finally the technique is applied to a number of ports in the United Kingdom and the results are compared with known estimates of extreme levels.

1. INTRODUCTION

Realistic estimates of the probability, or inversely the 'return period', of extremely high sea levels are necessary, for example, for the design of harbours and coastal defences. Estimates of the probability of extreme low levels, although not so widely used, are needed by the nuclear power industry for example to site cooling water intakes. Other applications came from the harbour authorities and the shipping industry for dredging approaches to ports or for towing deep draught oil rigs from their moorings across shallow banks to the open sea.

There are many ports particularly in northern Britain from which a few years of sea level data are available but not the several decades of data that one associates with traditional studies of extreme levels. It was our intention to make use of some of this data. Traditional estimates of extremes are made by considering the distribution of annual maximum and minimum sea levels (for example Lennon 1963 or Suthons 1963). In general curves are fitted to the distributions to produce a linear function and the sea level corresponding to a particular return period is estimated by linear extrapolation.

The technique developed in this paper enables estimates to be made from a few years of data by considering separately the probability distributions of the tidal and the surge (non-tidal residual) components of sea level. By extracting the surge component a continuous record of all surges that occur during the period is made available and these can be used to reinforce the statistics that otherwise would be generated from a single annual extreme value. For example large positive surges

Bidston Observatory,
Birkenhead,
Merseyside,
U.K.

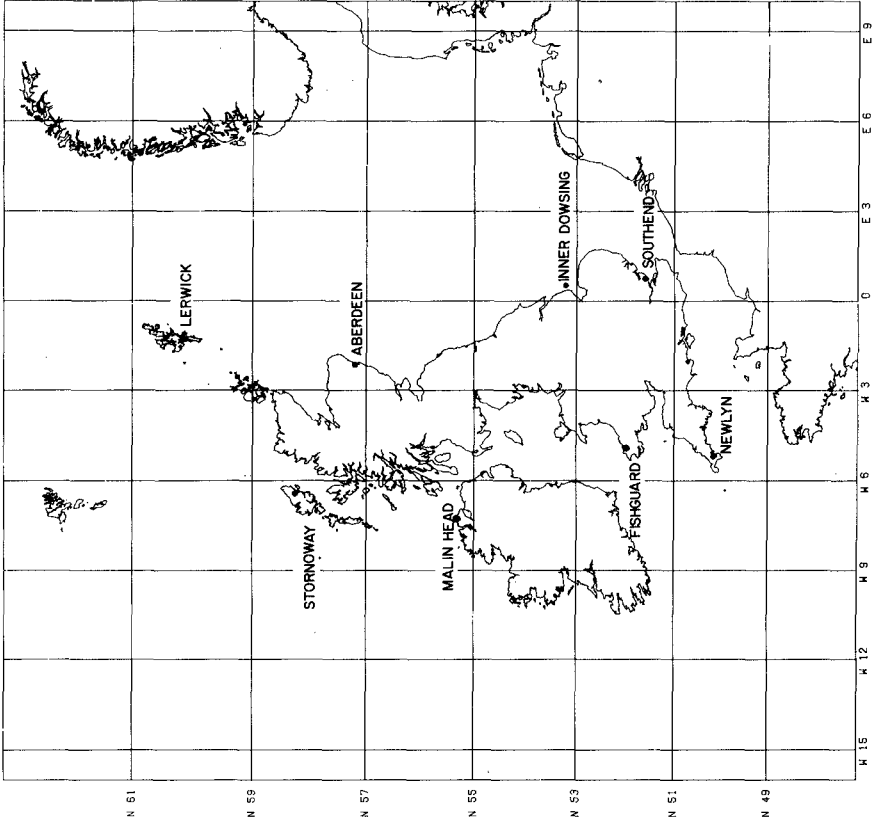

FIG. 1.

that occur at low tide, which do not produce extreme total levels, are included in our analyses. Ackers and Ruxton (1974) used a similar technique for the Essex coastline, but only for surges that occurred at high water, in which they added the surge distribution at high water to the predicted tide at high water.

Our study had two main aims:

- a) To produce estimates of extreme sea levels from data whose duration was much shorter than the return periods by examining tide and surge probability functions separately and combining them in the appropriate way.
- b) To apply the method to a group of ports that would give a reasonable coverage of conditions round the United Kingdom.

The ports for which the technique was applied and the amount of data that was available were Newlyn (19 years), Fishguard (9), Malin Head (12), Stornoway (15), Lerwick (14), Aberdeen (10) and Southend (19). The location of each port is shown in figure 1. Southend was included to study the effect of the strong interaction between tides and surges which exists in the southern North Sea. At the other ports our investigation showed that there was little or no interaction and so tide and surge were treated as independent variables.

One advantage of the technique developed here was that mean sea level was eliminated from the computations. Of course it was defined relative to a local benchmark which in most cases had been levelled to Ordnance Datum Newlyn. Trends in the mean level had little effect because of the short lengths of data used. Rossiter (1966) and more recently Thompson (in preparation) have studied mean sea level trends and these may be easily incorporated into the extremal statistics on the assumption that they are statistically independent of the extremes.

2. Philosophy of the Method

At any time (t) the observed sea level (ξ) can be considered as the sum of a tidal component (x), a surge component (y) and a mean level (Z_0)

$$\xi(t) = x(t) + y(t) + Z_0 \quad 2.1$$

This is illustrated diagrammatically in figure 2.

The tidal component is the coherent part of the sea level that responds directly or indirectly to astronomical forcing. It was removed from the observed sea level records as the finite sum of harmonic constants which had the form:

$$x(t) = \sum_{n=1}^N H_n \cos(\sigma_n t + V_n - g_n) \quad 2.2$$

FIG. 2.

where H_n = amplitude of each constituent
 σ_n = speed " "
 V_n = equilibrium phase
 g_n = phase lag of constituent on the
 equilibrium tide

Removal of the tide did not require an excessive amount of data as a satisfactory tidal analysis was obtained from 1 year of observations.

The surge or non-tidal component is that part of the sea level which remains once the tide and mean level have been removed.

Over a long enough period the surge is a random variable. Obviously over a short period of say one month very few surges are likely to occur and any that do will not produce a random phase. Under these circumstances some of the surge energy is likely to appear in the harmonic constants and be depleted from the surge component. With longer data sets of say one year or more the effect is minimal and the surge is well separated from the tide. Only a few percent of the variance of sea level movements is attributable to the surge for typical shelf measurements. The remainder is tidal. Of course considerable damage is caused if the surge coincides with a high tidal level.

Unlike traditional methods the method of tide surge separation is not one of extrapolation. In this method it is intrinsically assumed that the available surge record is a representative sample of the population of all possible surges and that the surges could occur in a different configuration such that, for example, the largest surge could coincide with equinoctial spring tide. Of course the probability of these two coinciding is very small and should show as a correspondingly low probability in the final statistics.

Whether the above assumption is true is considered later but if it is, which is akin to saying that tide and surge are independent, the tidal and surge probability density functions (p.d.f.) can be combined as the sum of two independent variables (see for example Cramer 1971) to give the p.d.f. for total sea level.

If $p_t(x)$ = p.d.f. for tidal component

$p_s(y)$ = p.d.f. for surge component

and $p(\xi)$ = p.d.f. for total sea level

then $p(\xi) = \int_{-\infty}^{\infty} p_t(\xi - y) \cdot p_s(y) \cdot dy$ 2.3

In simple terms equation 2.3 states that the probability of sea level reaching say 10 metres is the sum of all surge and tidal probabilities that combine to produce a level of 10 m. For example a surge of 2 m and a tide of 8 m, or a surge of 1 m and a tide of 9 m.

The integral is taken over an interval which includes all possible tidal and surge levels.

From $p(\xi)$ the probability of exceedance of a particular level can be evaluated by generating the cumulative distribution function $F(\eta)$, where

$$F(\eta) = \int_{\eta}^{\infty} p(\xi) \cdot d\xi \quad 2.4$$

The 'return period' for the level η is given by the reciprocal of the function $F(\eta)$ provided that the time series representing the surge is not auto-correlated.

In a similar fashion the probability of exposure of a low level is given by

$$F(\eta) = \int_{-\infty}^{\eta} p(\xi) \cdot d\xi \quad 2.5$$

Essentially the method consisted of a tidal analysis of the data for the harmonic constants and a prediction of the tide from these harmonic constants. From this the function p_t was generated and from the difference between sea level and the tidal time series the function p_s was generated. These were combined according to equation 2.3 and finally equations 2.4 and 2.5 were used to generate the cumulative distributions from which the return period and corresponding sea level were extracted.

3. THE DATA

The data consisted of hourly values of sea level digitised from tide gauge charts in the normal way. Each year comprised therefore on average 8766 values of hourly heights of sea level measured relative to the local tide gauge benchmark. The length of the records varied from a minimum of 9 years for Fishguard to 19 years for Newlyn and Southend. For these latter ports an extended record covering 50 years was available but only part of it was chosen for the present study. A summary of the data used is given in Table 1.

FIG. 3

TABLE 1

Newlyn	19 years	1951-69	continuous
Fishguard	9	1963-71	a few gaps
Malin Head	12	1960-71	sections of the record dubious
Stornoway	15	1957-72	a few gaps
Lerwick	14	1959-72	a few gaps
Aberdeen	10	1964-73	many gaps
Southend	19	1951-69	continuous

Most of the records were fairly complete except for short periods when the tide gauges malfunctioned. Malin Head gauge had two breakdowns and three sections lasting several months where the record was dubious for tidal analysis but adequate for surge statistics. The record from Aberdeen had many gaps but the data from the periods when the gauge was working was satisfactory.

The fact that gaps did exist in the data was of no consequence to the analysis procedure which was designed to deal with this. It might have had some effect on the surge statistics if the gaps had been systematic and had occurred only at particular times of the year. For example, if records had been available only from summer months the statistics would have been biased downwards because the surges were more frequent in the winter.

A typical surge record is shown in figure 3. This was produced by subtracting the tidal signal from the sea level record and there was therefore a need for careful editing of the data. This is not so critical in the annual extremes method which deals only with absolute levels.

When the charts were removed from the tide gauge drum they usually contained seven or fourteen days data and were such that every day occupied the same portion of the chart. Occasionally it happened that the chart was digitised erroneously by following the wrong part of the trace. Another fairly common type of error was due to timing, the chart was placed on the drum offset from the timing zero.

In the annual extremes method neither of the above errors would have had any effect as the absolute levels would not have been changed. However when the tide was removed both types of error produced a large tidally varying residual giving the false impression of a surge of significant height. Errors in reading the absolute height of the sea level curve would have affected the annual extreme and surge methods equally.

When the original tide gauge records were digitised they were at that time subjected to error checking routines. A Lagrangian interpolation curve was fitted to adjacent observations and a check was made for discontinuities between the smooth curve and the digitised level. This was found inadequate for detecting all the possible errors to the accuracy required.

The method chosen to examine the sea level record consisted fundamentally of plotting the surge as a function of time and of examining the plotted values by eye for irregularities. Errors were then corrected by referring to the original tide gauge chart.

The method of data editing is summarised below.

1. Pilot tidal analysis from 1 year of data.
2. Generate non-tidal residuals and plot as in figure 3.
3. Identify major extremes and areas of dubious record.
4. Refer to original tide gauge charts to correct errors.
5. Check weather records during periods of extremes.
6. Edit original sea level record.
7. Tidal analysis of the full period of data.
8. Reproduce non-tidal residuals.

This method was found to be very powerful for detecting errors and less time consuming than orthodox methods in cases where the record was consistently bad. Timing errors of a few minutes were easily detectable.

If there was some area of doubt such as a large surge when weather conditions were calm the data concerned was omitted from the analysis, but this rarely happened.

4. THE ASTRONOMICAL TIDES

The tidal part of the record was represented by the harmonic constants given in equation 2.2. From these constants a tidal time series was generated using the same equation and incrementing t from zero in units of one hour. The time series extended over a period of 19 years which is the time of regression of the moon's nodes, a fundamental period in the orbital motion of the Earth-Moon system. 19 years was necessary to generate the correct probability density function (p.d.f.) for the tides as the modulation in tidal elevation due to nodal motion could have been as much as 4%. The resulting p.d.f. for each port is shown in figure 4. These were generated numerically from the tidal time series in class intervals of 0.1 metre.

Observed SURGE frequency distribution for selected British gauges (based on hourly levels)

Numerical computations of TIDAL frequency distribution at selected British gauges (based on 18 years of hourly predictions)

It was possible to get some way towards an analytical expression for the tidal probability distribution from the harmonic constants using the sum of independent sinusoids but all such attempts produced a symmetric distribution whereas almost all the measured tidal distributions were asymmetric.

The measured distribution was always bimodal, the two peaks, or modes, occurring near mean high water neaps and mean low water neaps, but with a considerable tail above and below these levels. The tails did not of course extend to infinity, they terminated at Highest and Lowest Astronomical Tide (HAT and LAT) which in the general case were not evenly distributed about mean sea level. The values of HAT and LAT were extracted from the tidal time series and their values are presented in Table 2 relative to the mean level at each port.

	<u>HAT(m)</u>	<u>LAT(m)</u>
Newlyn	2.914	-2.928
Fishguard	2.791	-2.429
Malin Head	2.177	-2.128
Stornoway	2.626	-2.904
Lerwick	1.188	-1.272
Aberdeen	2.281	-2.576
Southend	3.311	-3.131

One interesting feature of the tidal distribution was the asymmetry of the modes, i.e. they were of different heights. This has been positively related to the shallow water tides M_4 and S_4 which are at exactly twice the frequency of the main lunar and solar tides M_2 and S_2 . It can be shown that the asymmetry is a maximum when the fourth-diurnal tides are in quadrature phase to the semi-diurnal tides. The asymmetry was noticeable even at Lerwick where the non-linear tides were fairly small in relation to the main tide.

5. THE SURGE OR NON-TIDAL RESIDUAL

The mean surge level for all ports was necessarily zero because of the manner in which the tides were removed from the observations of sea level. The time series (figure 3) had the appearance of a background noise continuum with occasional large surges protruding above the noise level. As with the tides the p.d.f. for the surges was generated

numerically from the time series. Figure 4 contains examples of the surge p.d.f's.

The p.d.f's had a Gaussian appearance, but with some asymmetry, which varied in width depending on location. In some cases, particularly Southend, the tail of the distributions were very wide indicating large surges but of infrequent occurrence.

Statistics of surge distributions based on hourly values

Table 3 contains the principal moments of the surge distribution for each port in the form of the standard deviation, the coefficients of Skewness and Kurtosis and the maximum and minimum levels reached during the period. The coefficients were defined as follows:

$$\text{rth moment} = \mu_r = \frac{1}{N} \sum_{i=1}^N (y_i)^r \quad \text{where } y_i = \text{ith surge level}$$

$$\text{standard deviation} = \sigma = (\mu_2)^{\frac{1}{2}} \quad N = \text{total number of observations of surge level.}$$

$$\text{coefficient of skewness} = \mu_3 / \sigma^3$$

$$\text{coefficient of kurtosis} = \mu_4 / \sigma^4 - 3$$

The standard deviation increased down the east coast from 13.6m at Lerwick to 23.0 cm at Southend. On the west coast the variation was found to be smaller lying between 14.9 cm and 16.9 cm. The distributions in all cases showed a positive skewness indicative that extreme high levels (positive surges) were more probable than low levels. This was reflected in the maximum and minimum levels which in all cases showed

extremes on the positive rather than negative side. The kurtosis which is a measure of the flattening of a distribution relative to a normal distribution was always positive, more so where the standard deviation was large, but in general was small.

No allowance was necessary in the moments for Sheppard's corrections due to grouping. These were insignificant in comparison to the moments themselves because of the small class interval used in computing each p.d.f.

Tests were carried out on the variation of the p.d.f. over subsets of a year. These showed a remarkable stability in the main parameters of the p.d.f. except for the very extremes of the distribution with which of course this work was primarily concerned. This was expected because the extremes occurred infrequently during the period of even the longest data set and did not occur during every year.

6. ADDITION OF SURGE TO HAT AND LAT

This section is included in the paper not because it is part of the main theme but because it gave upper bounds to the extreme statistics. Also it was found to be a useful technique in cases where safe design criteria were essential. The method consisted of adding the surge extremes to Highest Astronomical Tide instead of combining surge and tide in the manner discussed in section 8. The procedure is illustrated in figure 5 where Fishguard is used as an example.

To estimate the extremes of surge p.d.f. the upper part of the cumulative distribution, shown in the lower part of the diagram, was linearised by fitting a logarithmic curve. This curve proved adequate even although the uppermost surges, which were only three in number, deviated slightly from it. An extrapolation of the curve gave the surge levels associated with return periods of between 1 year and 1000 years.

The total sea level appropriate to each return period was then derived by adding the surge statistics to HAT.

This technique of estimating extremes tended to overestimate the probability values and therefore gave, as expected, pessimistic results for the levels associated with each return period. The results are discussed in section 9.

7. INDEPENDENCE OF TIDE AND SURGE

The equation for the combination of tidal and surge distributions (2.3) assumes independence between the two and it is important to consider whether or not they can be treated as statistically independent variables.

One form of possible dependence stems from the fact that surges are more prevalent in the winter than at other times of the year and maximum

tides occur at the equinoxes. However this is liable to be of secondary importance because the levels of the tides at the equinoxes are reached by spring tides at other times of the year to within a few tens of centimetres. Also the extreme surges with which we are primarily concerned do occur at times of the year other than winter. For example, one of the highest surges at Avonmouth occurred close to the spring equinox in March 1947. Fortunately it occurred very near low water or it would have caused extensive damage.

The main cause of dependence that has to be considered is surge/tide interaction such as occurs in the southern region of the North Sea. It is well known that at Southend the peak of the surge occurs on the rising tide and is somehow prevented from coinciding with high water.

To find if interaction was a problem at the six other ports a study was made of the moments of the surge distributions as a function of tidal level. Any interaction would have caused a variation of the moments with the height of the tide. Table 4 reproduces the results for two stations, Aberdeen and Southend.

TABLE 4a

2.0	-0.001	0.025	0.001	0.002
2.4	-0.025	0.020	-0.001	0.001

For Aberdeen there was little variation in any of the first four moments. The mean level was of course small but should have been zero. The second moment which is the most important as a test of interaction because it represents the square of the amplitude of the surge, was remarkably constant at 0.024 m² with an increase of only 2 mm² near the mid-tide level.

Southend on the other hand showed a marked increase in the second, third and fourth moments towards the mid-tide level and a decrease in

the mean surge level. The second moment for example increased by a factor of two between the top and middle of the tidal range.

The other ports, although not reproduced here, were very similar to Aberdeen. It was concluded that, except for Southend, any interaction effects were of second order and that tide and surge could be treated as statistically independent variables.

8. COMBINED TIDAL P.D.F. AND SURGE P.D.F.

The sea level probability distribution was derived from the combined tide and surge distributions according to equation 2.3. In practice a discrete form of the integral was used because of the need to generate the individual distributions in discrete bands or class intervals.

$$p(\xi) = \sum_{i=-N}^N p_t(\xi - ih) \cdot p_s(ih) \quad 8.1$$

where $h = \text{class interval} = 0.1\text{m}$.

Summation was over a number of bands $2N+1$ which was wide enough to include all possible tidal and surge levels.

The cumulative distributions $F(\eta)$ were also discrete and were calculated as a discrete form of equations (2.4) and (2.5). For the high levels, these distributions gave the probability that a particular level would be exceeded which of course decreased as the level was increased. Table 5 shows the cumulative distribution function for each port but here the probability value is expressed as the return period.

Return period in years = $1/(\text{exceedance probability} \times m)$
 where m is the number of hourly values in a year = 8766

* Lerwick levels are related to Mean sea level - 1 metre

Table 6 gives the equivalent values for the exposure of low levels again expressed as a return period. In both tables Lerwick has been offset relative to the mean level by 1 metre to fit in the table. The

extremes at Lerwick were very much smaller than those at other ports because the tides had a relatively small range.

The return periods in some cases exceeded 1000 years. This might seem surprising because only a few years of data was used but in fact occurred because the combined probability was the product of two probabilities which near the limits of the distributions were themselves small. The limit of the tidal p.d.f. corresponded to the occurrence of equinoxial tide which lasted only a few hours each year (say $p_t = 0.001$). The surge probability was even smaller than that of the tide as it corresponded to the extreme surge in say 10 years ($p_s = 0.00001$). This gave a product of $(10)^{-8}$ and an equivalent return period of 10000 years. Therefore return periods of 1000 years contained at least 10 samples of surge in the upper levels of the distribution.

It is common practice in extreme levels work to quote return periods of 50 years and 100 years. The combined distribution did not produce these levels automatically. It was necessary to interpolate between height intervals to determine a particular return period. This was best done from the probability function because this was a smoother function of level than the return period. The total levels with a return period of 50 years and 100 years are shown in Table 7.

9. DISCUSSION

One reason for the inclusion of Newlyn in this work was that estimates were already available for high levels using the annual extremes method (Blackman and Graff, 1978). These were useful for comparison of the results from the two methods. The calculated levels which had a return period of 50 years and 100 years are reproduced in Table 8 from the annual extremes method, from the combined surge-tide method and from the addition of the surge distribution to Highest Astronomical Tide.

The values derived from each method can only be estimates of the probable extremes and should not be considered as absolute. Indeed, it is debatable whether absolute or correct values exist. The maximum

observed level during the 62 years from 1915 to 1976 was 3.18m which was close to the 50 year level derived from annual extremes. The 100 year level by the same method was a slight underestimate when compared to the overall maximum.

The combined surge-tide probability produced values for the 50 year and 100 year return periods which were higher than those from annual extremes by 24 cm and 27 cm respectively. The agreement is good when the very different ways in which the data have been treated is considered. The 3.18 m level during the 62 years suggests that the method of annual extremes may give slightly low estimates. For engineering applications slight overestimates are preferable.

Our method will tend to produce overestimates because the surges are auto-correlated in that successive hourly samples of the time series are not independent of one another. Surges persist for more than one hour. If this grouping of hourly values had been taken into account then the estimated extreme levels would have been reduced. This problem is being investigated.

Another problem is the interaction between surge and tide. For this reason the results for Southend are not presented in this paper. Estimates produced for Southend were greater than the values calculated from annual extremes by as much as 60 cm which requires further consideration. The surge probability distribution for Southend is a function of tidal height because of surge tide interaction (Prandle and Wolf, 1978) and it is intended to model this function so that surge and tide may be combined correctly.

TABLE 8

<u>Comparison of return levels computed for NEWLYN</u> <u>(above 1951-1969 mean sea level)</u>		
	50 years	100 years
62 years of annual maxima (1915-1976)	3.14m	3.16m
Combined <u>tide-surge</u> probability (1951-1969 observations)	3.38m	3.43m
<u>Highest astronomical tide + surge</u> (1951-1969 observations)	3.90m	3.93m
Maximum observed value 1915-1976	3.18m	

10. CONCLUSIONS

We have developed a method for estimating extreme sea levels by studying the probability distributions of surge and of tide separately and then recombining them in a manner which assumes that they are statistically independent.

The method produces realistic estimates for extreme sea levels by comparison with traditional methods, but from much shorter lengths of data. This is important because few coastal sites have long sea level records. The assumption of independence of surge and tidal levels is proved to be valid for all the ports considered, with the exception of Southend.

The estimates are slightly biased on the high side for the upper extremes by comparison with traditional estimates. Some overestimation is inevitable because of the grouping of hourly surge values. The effects of this auto-correlation are being examined in an attempt to reduce the bias.

Our method also enables estimates of extreme low level probabilities. However, figures are not available from the annual extremes method for comparison.

The problem of surge-tide interaction is also being examined so that the method may be applied to ports such as Southend which are in shallow water and where, in consequence, surge and tide cannot be considered as statistically independent.

CHAPTER 53

Analysis of maximum sea levels in southern England

J. Graff* & D. L. Blackman*.

Abstract

Along the south coast of England, series of observed annual maximum sea levels, ranging from 16 years to 125 years have been analysed for each of 10 ports. The Jenkinson¹ method of analysis was used to compute the frequency of recurrence of extreme levels. For a number of these ports the series of annual maxima are shown to have significant trends of the same order as those for mean sea level. The Jenkinson method can be simply adjusted to cope with maxima having a component linear trend, making it possible to allow for such trends in computing the frequency of recurrence of extreme levels. If a trend in the annual maxima varies throughout the sample of observations it is shown that difficulties arise in using the Jenkinson method to compute acceptable statistics. It is also shown that for certain ports having long series of observed annual maxima it may be necessary to restrict the sample size of observations in order to compute estimates of the recurrence of extreme levels within reasonable return periods.

Introduction

Around the coastline of England, particularly along the north west, east and south east the occurrence in recent years of abnormal flood levels has created a demand for the reassessment of flood defence levels and a need to revise measures of the frequency of recurrence of extreme levels. Subsequent to the disastrous east coast flooding of 1953, coastal defence levels were established to protect against a further recurrence of these levels. In the past decade, the levels of 1953, which were generally associated with return periods exceeding 100 years, have been overtopped on a number of occasions at certain north west and east coast ports suggesting that factors may have contributed to increase the frequency of occurrence of extreme levels. Lennon² and Suthons³ published studies in 1963 on the analysis of occurrence of observed annual maxima for ports respectively on the west and south east coasts of England. For south east ports Suthons, using Jenkinson's method of analysis, included the effects of a linear trend of 1ft/century, representing an assumed secular trend in mean sea level. The series of observations studied by Lennon and Suthons extended to the average period 1957/60. In recent years the need to update the work of Suthons³ for south east coast ports has led to a number of studies, notably Akers & Ruxton⁴ (1974, Southend), Webber & Davies^{5,6} (1976 Portsmouth, Southampton, Calshot) and Blackman & Graff⁷ (1978). The study⁷ by the authors, covering 10 ports along the south

*Bidston Observatory, Institute of Oceanographic Sciences,
Birkenhead, Merseyside. L43 7RA. U.K.

coast of England forms in part the basic framework of this paper. All the studies mentioned so far (viz. 2, 3, 4, 5, 6, 7) accept that the longest available and reliable series of observed annual maxima should be analysed by extreme level techniques. Although no strict information is available (more so perhaps possible) to indicate how far one may extrapolate the analysis curves showing the frequency of occurrence of extreme levels it is accepted¹⁰ that some reliability can be based on considering a period up to perhaps 4 times the original sample size. It is however not uncommon practice, in considering design criteria for coastal defences that the extrapolated extreme sea level likely to occur once in a period exceeding 15 times the original sample size, is in fact used.

For the coastline of east, south east and south England, secular trends of various order exist in the series of annual maxima. Suthons³ and the authors⁷ included the effects of mean linear trends occurring throughout the sample of observations to provide "more likely" estimates of the recurrence of extreme levels. More recently, in reviewing their work on south coast ports, and extending their studies to other U.K. ports the authors have shown that the use of an analysis method such as the Jenkinson technique can be highly dependent not only on the sample size of observations but also on the nature and linear measure of secular trends in the data. Whereas in the past it was thought acceptable to make an analysis of the full available sample of observed annual maxima, and perhaps adjust these for a mean linear trend, it would now seem that such results can cloud the presence of many anomalies and it may be necessary to make the analysis more detailed in order to provide information of practical use. In this paper the authors present a summary of their already published study⁷ and an account of the more recent work⁸ in the analysis of observed annual sea level maxima.

The form of sea level maxima

An observed sea level can be simply expressed as

$$h_o = h_p + h_w + h_r \quad 1.$$

where h_p is the astronomically generated (predictable) tide.
 h_w is the wave height induced by wind or otherwise.
 h_r is a residual due to non tidal or weather effects.

Tide gauges are generally so designed to filter out the wave height and record only the level h_o^*

$$h_o^* = h_p + h_r \quad 2.$$

In reality however a more explicit form of the recorded level h_o^* should be expressed as

$$h_o^* = h_p + h_R \quad 3.$$

where $h_R = h_r + \epsilon$, ϵ being a small (or sometimes large) error due to effects in the recording mechanism which should be accounted for in the reduction of records.

In considering recorded levels h^* of annual extremes it is not uncommon to find that stresses imposed on the tide gauge often contribute severe perturbations (ϵ) to the recorded tidal trace which can not always be resolved unambiguously from the true level being recorded ($h_p + h_r$).

Equally in instances where the tide gauge breaks down around the time of the extreme level occurring it is necessary to try and extrapolate the recorded trace to the time of the peak level.

In the case of extreme levels being recorded from a tide pole there is inherently a far greater uncertainty in accepting the level to be an accurate height as defined in (2). More likely than not, under associated severe weather conditions (often in the dark) a sea level read from a tide pole, even by an experienced observer, may reflect a significant measure of the superimposed wave effects (h_w).

It seems important to mention the above points here to highlight the form of data being considered in this type of analysis. These data are essentially a measure (often estimate) of the single annual maximum sea level as defined in (2), divorced of wave effects which on such occasions are often of a considerably pronounced form. These single annual maxima can be seen in the context of other peak tidal levels in Figure 1, which shows the distribution of observed monthly maxima over some 20 years for Newhaven, one of the ports studied. This bimodal form of distribution is typical of sea level maxima at many ports around the British Isles.

FIG. 1. Observed monthly sea level maxima at Newhaven.

To date only Akers & Ruxton⁴ have endeavoured to analyse the interaction of the components h_p , h_w and h_r in relation to extreme levels, and the complexity of the problem and lack of suitable wave data have shown to present serious limitations. More recently Pugh & Vassie⁹ have approached the problem of investigating the occurrence of maxima by studying the interactive effects of h_p and h_r at hourly intervals, a technique that is hopeful of finding suitable joint probability distributions (of h_p and h_r), based on reasonably short series of a few years, that can be combined to provide information concerning the recurrent frequencies of abnormal levels.

Referring back to the work presented in this paper it is useful again to be reminded that the observed annual maxima studied are principally as defined in (2) although where tide pole data have been used one must accept that some proportional influence of wave effects are included.

Observational data

For each of the 10 ports indicated in Figure 2 the best series of up-to-date annual maxima were obtained, in some cases extending the data studied by Suthons³ by some 30%. Most of these data were based directly on tide gauge records, which for some ports covered a considerable period. All the sea level records were reduced to the national reference datum of Ordnance Datum Newlyn. Table 1 lists the coverage of data for each port.

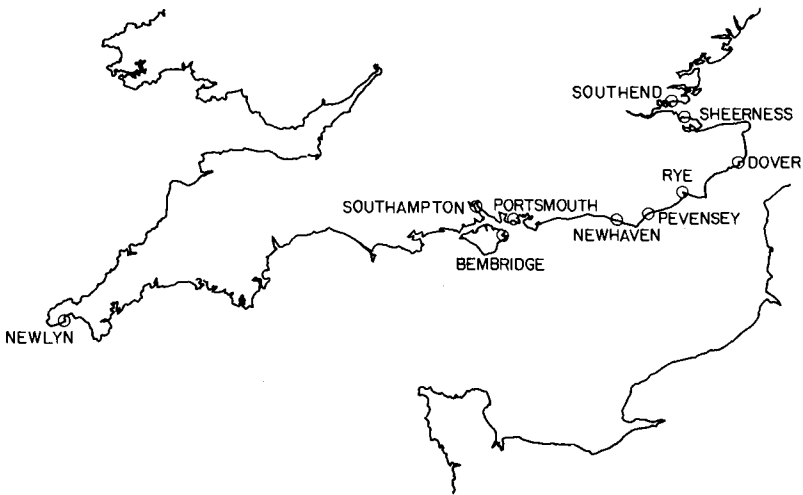

FIG. 2. Location of the 10 ports studied.

The Jenkinson method of analysis

If we assume that any observed annual maximum sea level h is a statistically random extreme event then these data can be analysed by a method such as that suggested by Jenkinson¹ in 1955. If T , the return period of height h is the average interval between occurrences of heights equal to or greater than h , it is easily shown that

$$T = -1/\ln.P \text{ or } \ln T = -\ln(-\ln P) = x$$

where P is the probability that the annual maxima is less than h . Jenkinson suggests that the most general form of curve between h and x is given by

$$x = \frac{1}{k} \ln \left(1 - \frac{h-h_c}{a} \right)$$

where k , h_c and a are constants determined from observations.

k is also a measure of the curve type of the data distribution such that if

$k < 0$, curve bends upwards; Fisher-Typpett Type I

$k = 0$, curve is a straight line; Fisher-Typpett Type II

$k > 0$, curve bends downwards; Fisher-Typpett Type III

Along the south coast of England the nature of the curve changes gradually eastwards, from Fisher-Typpett Type III through Type II to Type I, as seen in Figure 3.

Port diagram curves (Type A)

For the ports shown in Figure 2, the series of observed annual maxima indicated in Table 1 were analysed by the Jenkinson technique, and the results, showing the frequency of recurrence of maxima can be presented in a form as shown in Figure 3. These Port diagram curves are termed type A when related to analysis which do not account for the effect of linear trends.

FIG. 3. Frequency of recurrence of observed annual maxima (excluding effects of trends).

Mean trends in observed annual maxima

The series of observed annual maxima for each port were examined for trends. No evidence was found to suggest that any secular fluctuation of data was correlated with long period tidal effects of astronomical origin. Mean linear trends were resolved by simple linear regression analysis, and for several ports where suitable hourly sea level data were available, it was possible to also obtain the linear trend of mean sea level. These trends are shown in Table 2 and it can be seen that in general, the trends in annual maxima are similar to those for mean sea level. For the ports Newhaven, Dover and Sheerness the linear trends in annual maxima are significant.

TABLE 2

Port	Trend in annual observed maxima, mm/year	Trend in mean sea levels, mm/year
Newlyn	1.31 \pm 0.75 (61 years)	1.95 \pm 0.12 (60 years)
Southampton	1.18 \pm 1.62 (47 years)	1.06 \pm 1.11 (15 years)
Portsmouth	0.68 \pm 0.29 (105 years)	8.35 \pm 0.80 (13 years)
Bembridge	-3.38 \pm 2.06	
Newhaven	5.44 \pm 0.94 (60 years)	4.11 \pm 1.65 (18 years)
Pevensey	4.60 \pm 5.39	
Rye	1.53 \pm 5.54	
Dover	4.99 \pm 1.68 (56 years)	4.52 \pm 0.53 (39 years)
Sheerness	2.41 \pm 0.53	2.37 \pm 0.17*
Southend	0.39 \pm 2.92 (46 years)	1.71 \pm 0.29 (49 years)

* Values established by Rossiter,¹¹ based on 85 years.

One could perhaps suggest, in broad terms, that mean trends observed in series of extreme levels reflect the secular trends in mean sea levels, although one should bear in mind that the mean sea levels are based on continuous hourly observations throughout the years whereas the annual maxima represents a single level occurring generally within the "storm months" August-March (See Figure 1).

Port diagram curves (Type B, C)

The Jenkinson method of analysis can be also applied to data which have a component of linear trend, providing that the data are first reduced to some selected epoch. For instance if the epoch is 1900 and a linear trend of .001 m/yr exists in the annual maxima then an observed level of 10.0m in 1850 reduces to a level of 10.05m in 1900, and similarly an

observed level of 10.0m in 1950 reduced to a level of 9.95m in 1900. The resulting port diagram curves, termed type B, accounting for a linear trend component, are similar to those noted as type A. The interpretation of type B curves is strict in the sense that a linear trend has been accounted for up to the base year of the selected epoch and no trend exists in the data beyond this year.

Suthons³ suggested it is possible to make some allowance for including a trend beyond the epoch by adjusting type B curves (into curves termed type C) in the following manner.

If T is a return period of height h_B (type B curve) or h_C (type C curve) where a mean rate of annual rise S is being considered in the data, then

$$h_C = h_B + T.S/2$$

This gives some guidance to interpreting the additive effects of a continuing trend assumed to exist in the data.

Figure 4 illustrates all three Port diagram curve types (A, B, C) for Sheerness.

FIG. 4. Frequency of recurrence of observed annual maxima for Sheerness.

Curve A. unadjusted for any trend effects.

Curve B. adjusted to the epoch 1976 for a linear trend of 2mm/yr present only in the data analysed.

Curve C. adjusted to the epoch 1976 for a linear trend of 2mm/yr assumed to persist indefinitely.

As the return period T increases beyond a value equal to about twice the sample size of observations, the expected height h_c increases rapidly to unreal proportions. The format of computing the type C curve is subjective and gives guidance only as a broad illustration of including extrapolated trends. Appendix 1 lists for all 10 ports, data from port diagram curves type A, B, C, related to recurrence periods of 10, 20, 50, 100 and 250 years.

Some further considerations in the analysis of annual sea level maxima

Since in general, only a limited series of observed annual maxima, of the order of 10-20 years, are available for most ports, it is of interest to have some feeling for the response of the analysis method (Jenkinson) to different sample sizes. It is also of considerable interest to understand the nature of secular trends which may exist in the data series since they can have a pronounced effect on the analysis of such data. These considerations are particularly important for ports where a substantial investment is to be made in raising flood defences for protection against abnormal levels, subjectively assessed as being of the order of 1-in-100 years or more. At present the terms "return periods" and the associated "expected levels" are perhaps too freely used in the assessment of design criteria for coastal defences and it seems important to illustrate the drawbacks and limitations of interpreting what may seem to be "standard" port diagram curves.

Before any type of port diagram curve is to be interpreted seriously for practical purposes a number of questions would seem to be of prime importance.

1. How real is the sample of observed data in terms of their measured values.
2. Does a trend exist in the sample data set, and if so what is its form.
3. Will a trend persist in the future and can this trend, and that in a sample data set, be approximated by a constant linear term.
4. What is the confidence in extrapolating port diagram curves and how is this related to the size of the sample set.

Although we would not presume to suggest that any of these questions can be strictly answered we do suggest it is possible to illustrate their significance, hereby gaining a far greater awareness of the problem, thus enabling one to make a more objective interpretation of results.

Reliability of observed data

The uncertainty of measured data has already been discussed earlier and it is a simple fact that for good or bad, most early records of annual maxima proceeding the early fifties must be accepted as the "best measures" available. To review such data in terms of the performance and

stability of the measuring instrument presents considerable problems and frustration in what is often a mass of conflicting historically documented heresay. The national reference level, Ordnance Datum Newlyn, was only introduced as a datum measure to most Ports in Great Britain, in various degrees of accuracy, during the period between the late thirties and early fifties. Diligent checking of the annual tidal records, tide gauge histories and datum levelling exercises is the only sure way of attempting to collate a continuous datum level for series of records dating back through the early part of this century. In a few instances, for portions of data, much of the relevant information has been lost to antiquity.

Trends in annual maxima

With a substantial series of annual maxima one can identify fluctuations that can be resolved as a linear estimate of a mean trend. Table 2 already presents such measures for the 10 south coast ports which leads one to assume it is a simple matter to proceed in computing port diagram curves of type B. If we examine the form of these fluctuations or trends, a little closer it becomes obvious that they are far from linear, and like mean sea level data they vary in an ill defined and unpredictable fashion. Figure 5 shows the annual maxima plotted as 5 year running means for Sheerness and Portsmouth which represent the longest data series available in the study.

FIG. 5. Observed annual maxima plotted as 5 year running means for Sheerness and Portsmouth.

For some of the 10 ports a significant mean trend can be identified throughout the full data series but moreso in these cases (Sheerness) more pronounced secondary trends also can be identified within both long and short portions of the data set. Simple regression analysis of the annual maxima in cumulative sets to a 10 year base, both forward and backward (in a time wise fashion) readily show the extreme variability of the linear trend estimate and its generally poor fit to the observed data. These results are illustrated for all 10 ports in Appendix 2.

Since one can in fact adjust for linear trends in computing port diagram curves it is easy to see that the question of "what trend do we adjust for" is not a simple one to answer and indeed is a matter for some, if not considerable conjecture.

The confidence in port diagram curves

Bearing in mind that available series of annual maxima may be short or long, some thought should be given to interpreting resulting port diagram curves against the criteria of sample size. Again we split the series of observed data for each port into cumulative 10 year sets as noted earlier and made a systematic analysis to compute port diagram curves of both type A and type B for each block of data, in the same forward and backward fashion as for the regression analysis. To compute the type B curves the appropriate cumulative data sets were adjusted for the associated mean linear trend, to a common epoch. It would be impractical to try and present here even a summary of such results for all 10 ports, a form of analysis ⁸ which is now being systematically applied to data from many other ports around the British Isles. However, it is of some considerable interest to present typical results, for Sheerness, a port of major importance in the Thames estuary. The series of annual maxima for Sheerness show fluctuations in trend as seen in Figure 5 and Appendix 2, these having a significant positive mean linear trend throughout the full series of 125 annual observed maxima.

In Figure 6, the height with a period of recurrence of 100 years, based on type A curve analysis, has been plotted directly against the cumulative size of sample (number of annual maxima) used for the analysis. The cumulative sample sets relate, as shown, to the base year 1819 and 1970, respectively the start and end of the full observed series. It has also been possible to show these estimates based on analysis of 6 independent sets of 20 maxima taken throughout the period of data available. Similarly on the same diagram the results related to a type B curve analysis are shown, each cumulative data set being adjusted for the associated mean linear trend (Appendix 2) to the epoch 1980.

FIG. 6. Frequency of recurrence of observed annual maxima for Sheerness showing the 1-in-100 year event, based on analysis of different subsets of the data.

We would point out that the results shown in Figure 6 are not untypical⁸ of other ports in Great Britain where a far shorter series of annual maxima (up to 60 years) are available. Figure 6 (for Sheerness) highlights two points of particular interest

1. Depending on the sample set of maxima analysed (some multiple of 10) the 1-in-100 yr level can vary within a range of up to 1 metre. This range diminishes only as the sample size approaches its maximum length.
2. There is a pronounced increase in the estimated height of the 1-in-100 yr level throughout the period 1819 to 1970, e.g. there seems to be a general increase in the recurrence of abnormal levels.

This readily illustrates the considerable uncertainty in trying to interpret such results for practical purposes. In the past, and currently, it is often accepted that results based on analysis of a maximum available data series would provide a confident "best estimate" or a recurrence level for basic design level estimates. However this is clearly not the case, and the above results suggest that the assessment of a frequency of recurrence of an abnormal level (design level perhaps) is much more subjective than hitherto suspected, especially if sea level

maxima are subject to some form of secular trends. If the data were truly devoid of significant trend components (as is the case for other ports) then we would expect considerably less divergence in the plots as shown in Figure 6 above, and consequently would have a greater confidence in making an interpretation of such results. Portsmouth is seen to be a case-in-point where the absence of any significant trends produces a relatively stable set of recurrence levels, as illustrated in Figure 7 in the same fashion as for Sheerness. The high anomalous value associated analysis of the 10 earliest maxima reflects in fact the presence of dubious recorded levels.

FIG. 7. Frequency of recurrence of observed annual maxima for Portsmouth, showing the 1-in-100 year event, based on analysis of different subsets of the data.

Appendix 3 lists heights associated with recurrence periods of 100 years based on type A curve analysis of 10 year cumulative data sets of the observed annual maxima for all the 10 south coast ports.

Conclusion

This paper has summarised results on the analysis of abnormal sea levels at south coast ports in England, and illustrated the revised level of information that is now necessary in order to provide a meaningful interpretation of the frequency statistics. Hitherto, estimates of recurrence levels have been based purely on analysis of the single full

length sample of annual observed maxima. For certain ports this may be acceptable, but it is suggested that there is a need for a more detailed analysis of the data, as illustrated in this paper. Indeed it may be the case that for some ports, irrespective of the length of available annual observed maxima, one may be restricted to assessing levels with recurrence periods less than 50 years, and these based only on analysis of subsets of the full data series. The analysis procedures are highly sensitive to data which contains secular trends that are not of a strictly linear form. A component of such trends may indeed be due to some corrupting effect of errors in the raw observed data.

Although annual observed sea level maxima provide an attractive basis for analysis procedures, such as Jenkinsons, aimed at forecasting recurrence levels, it is proving more unlikely that such treatment of single annual tidal observations will provide a satisfactory standard level of reliable information for practical design purposes. The interactive effects of tide, wave and weather are complicated to such a degree, that coupled with the uncertainty of sea level measurements of maxima it may be necessary to approach such studies of frequency analysis in a more fundamental way.

CHAPTER 53

Analysis of maximum sea levels in southern England

J. Graff* & D. L. Blackman*.

Abstract

Along the south coast of England, series of observed annual maximum sea levels, ranging from 16 years to 125 years have been analysed for each of 10 ports. The Jenkinson¹ method of analysis was used to compute the frequency of recurrence of extreme levels. For a number of these ports the series of annual maxima are shown to have significant trends of the same order as those for mean sea level. The Jenkinson method can be simply adjusted to cope with maxima having a component linear trend, making it possible to allow for such trends in computing the frequency of recurrence of extreme levels. If a trend in the annual maxima varies throughout the sample of observations it is shown that difficulties arise in using the Jenkinson method to compute acceptable statistics. It is also shown that for certain ports having long series of observed annual maxima it may be necessary to restrict the sample size of observations in order to compute estimates of the recurrence of extreme levels within reasonable return periods.

Introduction

Around the coastline of England, particularly along the north west, east and south east the occurrence in recent years of abnormal flood levels has created a demand for the reassessment of flood defence levels and a need to revise measures of the frequency of recurrence of extreme levels. Subsequent to the disastrous east coast flooding of 1953, coastal defence levels were established to protect against a further recurrence of these levels. In the past decade, the levels of 1953, which were generally associated with return periods exceeding 100 years, have been overtopped on a number of occasions at certain north west and east coast ports suggesting that factors may have contributed to increase the frequency of occurrence of extreme levels. Lennon² and Suthons³ published studies in 1963 on the analysis of occurrence of observed annual maxima for ports respectively on the west and south east coasts of England. For south east ports Suthons, using Jenkinson's method of analysis, included the effects of a linear trend of 1ft/century, representing an assumed secular trend in mean sea level. The series of observations studied by Lennon and Suthons extended to the average period 1957/60. In recent years the need to update the work of Suthons³ for south east coast ports has led to a number of studies, notably Akers & Ruxton⁴ (1974, Southend), Webber & Davies^{5,6} (1976 Portsmouth, Southampton, Calshot) and Blackman & Graff⁷ (1978). The study⁷ by the authors, covering 10 ports along the south

*Bidston Observatory, Institute of Oceanographic Sciences,
Birkenhead, Merseyside. L43 7RA. U.K.

coast of England forms in part the basic framework of this paper. All the studies mentioned so far (viz. 2, 3, 4, 5, 6, 7) accept that the longest available and reliable series of observed annual maxima should be analysed by extreme level techniques. Although no strict information is available (more so perhaps possible) to indicate how far one may extrapolate the analysis curves showing the frequency of occurrence of extreme levels it is accepted¹⁰ that some reliability can be based on considering a period up to perhaps 4 times the original sample size. It is however not uncommon practice, in considering design criteria for coastal defences that the extrapolated extreme sea level likely to occur once in a period exceeding 15 times the original sample size, is in fact used.

For the coastline of east, south east and south England, secular trends of various order exist in the series of annual maxima. Suthons³ and the authors⁷ included the effects of mean linear trends occurring throughout the sample of observations to provide "more likely" estimates of the recurrence of extreme levels. More recently, in reviewing their work on south coast ports, and extending their studies to other U.K. ports the authors have shown that the use of an analysis method such as the Jenkinson technique can be highly dependent not only on the sample size of observations but also on the nature and linear measure of secular trends in the data. Whereas in the past it was thought acceptable to make an analysis of the full available sample of observed annual maxima, and perhaps adjust these for a mean linear trend, it would now seem that such results can cloud the presence of many anomalies and it may be necessary to make the analysis more detailed in order to provide information of practical use. In this paper the authors present a summary of their already published study⁷ and an account of the more recent work⁸ in the analysis of observed annual sea level maxima.

The form of sea level maxima

An observed sea level can be simply expressed as

$$h_o = h_p + h_w + h_r \quad 1.$$

where h_p is the astronomically generated (predictable) tide.
 h_w is the wave height induced by wind or otherwise.
 h_r is a residual due to non tidal or weather effects.

Tide gauges are generally so designed to filter out the wave height and record only the level h_o^*

$$h_o^* = h_p + h_r \quad 2.$$

In reality however a more explicit form of the recorded level h_o^* should be expressed as

$$h_o^* = h_p + h_R \quad 3.$$

where $h_R = h_r + \epsilon$, ϵ being a small (or sometimes large) error due to effects in the recording mechanism which should be accounted for in the reduction of records.

In considering recorded levels h^* of annual extremes it is not uncommon to find that stresses imposed on the tide gauge often contribute severe perturbations (ϵ) to the recorded tidal trace which can not always be resolved unambiguously from the true level being recorded ($h_p + h_r$).

Equally in instances where the tide gauge breaks down around the time of the extreme level occurring it is necessary to try and extrapolate the recorded trace to the time of the peak level.

In the case of extreme levels being recorded from a tide pole there is inherently a far greater uncertainty in accepting the level to be an accurate height as defined in (2). More likely than not, under associated severe weather conditions (often in the dark) a sea level read from a tide pole, even by an experienced observer, may reflect a significant measure of the superimposed wave effects (h_w).

It seems important to mention the above points here to highlight the form of data being considered in this type of analysis. These data are essentially a measure (often estimate) of the single annual maximum sea level as defined in (2), divorced of wave effects which on such occasions are often of a considerably pronounced form. These single annual maxima can be seen in the context of other peak tidal levels in Figure 1, which shows the distribution of observed monthly maxima over some 20 years for Newhaven, one of the ports studied. This bimodal form of distribution is typical of sea level maxima at many ports around the British Isles.

FIG. 1. Observed monthly sea level maxima at Newhaven.

To date only Akers & Ruxton⁴ have endeavoured to analyse the interaction of the components h_p , h_w and h_r in relation to extreme levels, and the complexity of the problem and lack of suitable wave data have shown to present serious limitations. More recently Pugh & Vassie⁹ have approached the problem of investigating the occurrence of maxima by studying the interactive effects of h_p and h_r at hourly intervals, a technique that is hopeful of finding suitable joint probability distributions (of h_p and h_r), based on reasonably short series of a few years, that can be combined to provide information concerning the recurrent frequencies of abnormal levels.

Referring back to the work presented in this paper it is useful again to be reminded that the observed annual maxima studied are principally as defined in (2) although where tide pole data have been used one must accept that some proportional influence of wave effects are included.

Observational data

For each of the 10 ports indicated in Figure 2 the best series of up-to-date annual maxima were obtained, in some cases extending the data studied by Suthons³ by some 30%. Most of these data were based directly on tide gauge records, which for some ports covered a considerable period. All the sea level records were reduced to the national reference datum of Ordnance Datum Newlyn. Table 1 lists the coverage of data for each port.

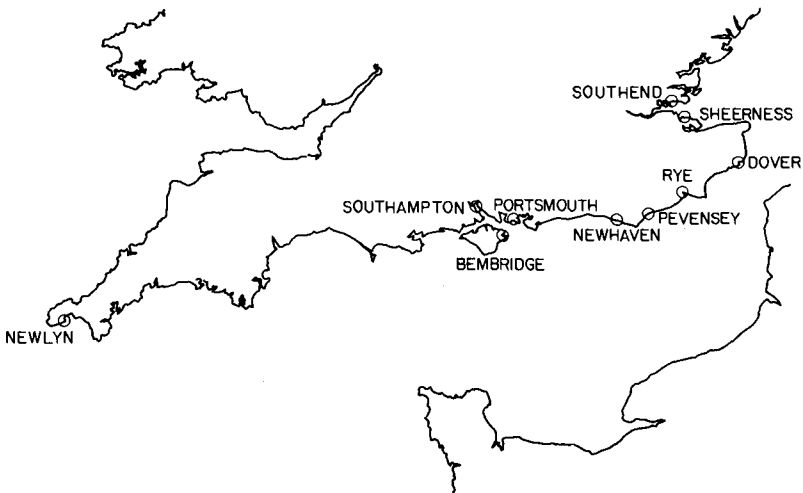

FIG. 2. Location of the 10 ports studied.

TABLE 1

Port	Years	Observed maxima
Newlyn	1916-76	61
Southampton	1924-75	47
Portsmouth	1813-75	105
Bembridge	1947-76	29
Newhaven	1913-76	60
Pevensey	1953-76	24
Rye	1949-74	16
Dover	1912-75	56
Sheerness	1819-70	125
Southend	1929-75	46

The Jenkinson method of analysis

If we assume that any observed annual maximum sea level h is a statistically random extreme event then these data can be analysed by a method such as that suggested by Jenkinson¹ in 1955. If T , the return period of height h is the average interval between occurrences of heights equal to or greater than h , it is easily shown that

$$T = -1/\ln.P \text{ or } \ln T = -\ln(-\ln P) = x$$

where P is the probability that the annual maxima is less than h . Jenkinson suggests that the most general form of curve between h and x is given by

$$x = \frac{1}{k} \ln \left(1 - \frac{h-h_c}{a} \right)$$

where k , h_c and a are constants determined from observations.

k is also a measure of the curve type of the data distribution such that if

$k < 0$, curve bends upwards; Fisher-Typpett Type I

$k = 0$, curve is a straight line; Fisher-Typpett Type II

$k > 0$, curve bends downwards; Fisher-Typpett Type III

Along the south coast of England the nature of the curve changes gradually eastwards, from Fisher-Typpett Type III through Type II to Type I, as seen in Figure 3.

Port diagram curves (Type A)

For the ports shown in Figure 2, the series of observed annual maxima indicated in Table 1 were analysed by the Jenkinson technique, and the results, showing the frequency of recurrence of maxima can be presented in a form as shown in Figure 3. These Port diagram curves are termed type A when related to analysis which do not account for the effect of linear trends.

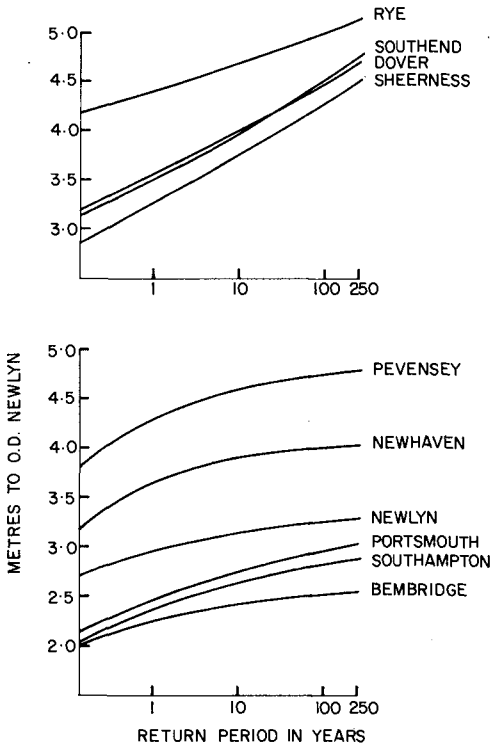

FIG. 3. Frequency of recurrence of observed annual maxima (excluding effects of trends).

Mean trends in observed annual maxima

The series of observed annual maxima for each port were examined for trends. No evidence was found to suggest that any secular fluctuation of data was correlated with long period tidal effects of astronomical origin. Mean linear trends were resolved by simple linear regression analysis, and for several ports where suitable hourly sea level data were available, it was possible to also obtain the linear trend of mean sea level. These trends are shown in Table 2 and it can be seen that in general, the trends in annual maxima are similar to those for mean sea level. For the ports Newhaven, Dover and Sheerness the linear trends in annual maxima are significant.

TABLE 2

Port	Trend in annual observed maxima, mm/year	Trend in mean sea levels, mm/year
Newlyn	1.31 \pm 0.75 (61 years)	1.95 \pm 0.12 (60 years)
Southampton	1.18 \pm 1.62 (47 years)	1.06 \pm 1.11 (15 years)
Portsmouth	0.68 \pm 0.29 (105 years)	8.35 \pm 0.80 (13 years)
Bembridge	-3.38 \pm 2.06	
Newhaven	5.44 \pm 0.94 (60 years)	4.11 \pm 1.65 (18 years)
Pevensey	4.60 \pm 5.39	
Rye	1.53 \pm 5.54	
Dover	4.99 \pm 1.68 (56 years)	4.52 \pm 0.53 (39 years)
Sheerness	2.41 \pm 0.53	2.37 \pm 0.17*
Southend	0.39 \pm 2.92 (46 years)	1.71 \pm 0.29 (49 years)

* Values established by Rossiter,¹¹ based on 85 years.

One could perhaps suggest, in broad terms, that mean trends observed in series of extreme levels reflect the secular trends in mean sea levels, although one should bear in mind that the mean sea levels are based on continuous hourly observations throughout the years whereas the annual maxima represents a single level occurring generally within the "storm months" August-March (See Figure 1).

Port diagram curves (Type B, C)

The Jenkinson method of analysis can be also applied to data which have a component of linear trend, providing that the data are first reduced to some selected epoch. For instance if the epoch is 1900 and a linear trend of .001 m/yr exists in the annual maxima then an observed level of 10.0m in 1850 reduces to a level of 10.05m in 1900, and similarly an

observed level of 10.0m in 1950 reduced to a level of 9.95m in 1900. The resulting port diagram curves, termed type B, accounting for a linear trend component, are similar to those noted as type A. The interpretation of type B curves is strict in the sense that a linear trend has been accounted for up to the base year of the selected epoch and no trend exists in the data beyond this year.

Suthons³ suggested it is possible to make some allowance for including a trend beyond the epoch by adjusting type B curves (into curves termed type C) in the following manner.

If T is a return period of height h_B (type B curve) or h_C (type C curve) where a mean rate of annual rise S is being considered in the data, then

$$h_C = h_B + T.S/2$$

This gives some guidance to interpreting the additive effects of a continuing trend assumed to exist in the data.

Figure 4 illustrates all three Port diagram curve types (A, B, C) for Sheerness.

FIG. 4. Frequency of recurrence of observed annual maxima for Sheerness.

Curve A. unadjusted for any trend effects.

Curve B. adjusted to the epoch 1976 for a linear trend of 2mm/yr present only in the data analysed.

Curve C. adjusted to the epoch 1976 for a linear trend of 2mm/yr assumed to persist indefinitely.

As the return period T increases beyond a value equal to about twice the sample size of observations, the expected height h_c increases rapidly to unreal proportions. The format of computing the type C curve is subjective and gives guidance only as a broad illustration of including extrapolated trends. Appendix 1 lists for all 10 ports, data from port diagram curves type A, B, C, related to recurrence periods of 10, 20, 50, 100 and 250 years.

Some further considerations in the analysis of annual sea level maxima

Since in general, only a limited series of observed annual maxima, of the order of 10-20 years, are available for most ports, it is of interest to have some feeling for the response of the analysis method (Jenkinson) to different sample sizes. It is also of considerable interest to understand the nature of secular trends which may exist in the data series since they can have a pronounced effect on the analysis of such data. These considerations are particularly important for ports where a substantial investment is to be made in raising flood defences for protection against abnormal levels, subjectively assessed as being of the order of 1-in-100 years or more. At present the terms "return periods" and the associated "expected levels" are perhaps too freely used in the assessment of design criteria for coastal defences and it seems important to illustrate the drawbacks and limitations of interpreting what may seem to be "standard" port diagram curves.

Before any type of port diagram curve is to be interpreted seriously for practical purposes a number of questions would seem to be of prime importance.

1. How real is the sample of observed data in terms of their measured values.
2. Does a trend exist in the sample data set, and if so what is its form.
3. Will a trend persist in the future and can this trend, and that in a sample data set, be approximated by a constant linear term.
4. What is the confidence in extrapolating port diagram curves and how is this related to the size of the sample set.

Although we would not presume to suggest that any of these questions can be strictly answered we do suggest it is possible to illustrate their significance, hereby gaining a far greater awareness of the problem, thus enabling one to make a more objective interpretation of results.

Reliability of observed data

The uncertainty of measured data has already been discussed earlier and it is a simple fact that for good or bad, most early records of annual maxima proceeding the early fifties must be accepted as the "best measures" available. To review such data in terms of the performance and

stability of the measuring instrument presents considerable problems and frustration in what is often a mass of conflicting historically documented heresay. The national reference level, Ordnance Datum Newlyn, was only introduced as a datum measure to most Ports in Great Britain, in various degrees of accuracy, during the period between the late thirties and early fifties. Diligent checking of the annual tidal records, tide gauge histories and datum levelling exercises is the only sure way of attempting to collate a continuous datum level for series of records dating back through the early part of this century. In a few instances, for portions of data, much of the relevant information has been lost to antiquity.

Trends in annual maxima

With a substantial series of annual maxima one can identify fluctuations that can be resolved as a linear estimate of a mean trend. Table 2 already presents such measures for the 10 south coast ports which leads one to assume it is a simple matter to proceed in computing port diagram curves of type B. If we examine the form of these fluctuations or trends, a little closer it becomes obvious that they are far from linear, and like mean sea level data they vary in an ill defined and unpredictable fashion. Figure 5 shows the annual maxima plotted as 5 year running means for Sheerness and Portsmouth which represent the longest data series available in the study.

FIG. 5. Observed annual maxima plotted as 5 year running means for Sheerness and Portsmouth.

For some of the 10 ports a significant mean trend can be identified throughout the full data series but moreso in these cases (Sheerness) more pronounced secondary trends also can be identified within both long and short portions of the data set. Simple regression analysis of the annual maxima in cumulative sets to a 10 year base, both forward and backward (in a time wise fashion) readily show the extreme variability of the linear trend estimate and its generally poor fit to the observed data. These results are illustrated for all 10 ports in Appendix 2.

Since one can in fact adjust for linear trends in computing port diagram curves it is easy to see that the question of "what trend do we adjust for" is not a simple one to answer and indeed is a matter for some, if not considerable conjecture.

The confidence in port diagram curves

Bearing in mind that available series of annual maxima may be short or long, some thought should be given to interpreting resulting port diagram curves against the criteria of sample size. Again we split the series of observed data for each port into cumulative 10 year sets as noted earlier and made a systematic analysis to compute port diagram curves of both type A and type B for each block of data, in the same forward and backward fashion as for the regression analysis. To compute the type B curves the appropriate cumulative data sets were adjusted for the associated mean linear trend, to a common epoch. It would be impractical to try and present here even a summary of such results for all 10 ports, a form of analysis ⁸ which is now being systematically applied to data from many other ports around the British Isles. However, it is of some considerable interest to present typical results, for Sheerness, a port of major importance in the Thames estuary. The series of annual maxima for Sheerness show fluctuations in trend as seen in Figure 5 and Appendix 2, these having a significant positive mean linear trend throughout the full series of 125 annual observed maxima.

In Figure 6, the height with a period of recurrence of 100 years, based on type A curve analysis, has been plotted directly against the cumulative size of sample (number of annual maxima) used for the analysis. The cumulative sample sets relate, as shown, to the base year 1819 and 1970, respectively the start and end of the full observed series. It has also been possible to show these estimates based on analysis of 6 independent sets of 20 maxima taken throughout the period of data available. Similarly on the same diagram the results related to a type B curve analysis are shown, each cumulative data set being adjusted for the associated mean linear trend (Appendix 2) to the epoch 1980.

FIG. 6. Frequency of recurrence of observed annual maxima for Sheerness showing the 1-in-100 year event, based on analysis of different subsets of the data.

We would point out that the results shown in Figure 6 are not untypical⁸ of other ports in Great Britain where a far shorter series of annual maxima (up to 60 years) are available. Figure 6 (for Sheerness) highlights two points of particular interest

1. Depending on the sample set of maxima analysed (some multiple of 10) the 1-in-100 yr level can vary within a range of up to 1 metre. This range diminishes only as the sample size approaches its maximum length.
2. There is a pronounced increase in the estimated height of the 1-in-100 yr level throughout the period 1819 to 1970, e.g. there seems to be a general increase in the recurrence of abnormal levels.

This readily illustrates the considerable uncertainty in trying to interpret such results for practical purposes. In the past, and currently, it is often accepted that results based on analysis of a maximum available data series would provide a confident "best estimate" or a recurrence level for basic design level estimates. However this is clearly not the case, and the above results suggest that the assessment of a frequency of recurrence of an abnormal level (design level perhaps) is much more subjective than hitherto suspected, especially if sea level

maxima are subject to some form of secular trends. If the data were truly devoid of significant trend components (as is the case for other ports) then we would expect considerably less divergence in the plots as shown in Figure 6 above, and consequently would have a greater confidence in making an interpretation of such results. Portsmouth is seen to be a case-in-point where the absence of any significant trends produces a relatively stable set of recurrence levels, as illustrated in Figure 7 in the same fashion as for Sheerness. The high anomalous value associated analysis of the 10 earliest maxima reflects in fact the presence of dubious recorded levels.

FIG. 7. Frequency of recurrence of observed annual maxima for Portsmouth, showing the 1-in-100 year event, based on analysis of different subsets of the data.

Appendix 3 lists heights associated with recurrence periods of 100 years based on type A curve analysis of 10 year cumulative data sets of the observed annual maxima for all the 10 south coast ports.

Conclusion

This paper has summarised results on the analysis of abnormal sea levels at south coast ports in England, and illustrated the revised level of information that is now necessary in order to provide a meaningful interpretation of the frequency statistics. Hitherto, estimates of recurrence levels have been based purely on analysis of the single full

length sample of annual observed maxima. For certain ports this may be acceptable, but it is suggested that there is a need for a more detailed analysis of the data, as illustrated in this paper. Indeed it may be the case that for some ports, irrespective of the length of available annual observed maxima, one may be restricted to assessing levels with recurrence periods less than 50 years, and these based only on analysis of subsets of the full data series. The analysis procedures are highly sensitive to data which contains secular trends that are not of a strictly linear form. A component of such trends may indeed be due to some corrupting effect of errors in the raw observed data.

Although annual observed sea level maxima provide an attractive basis for analysis procedures, such as Jenkinsons, aimed at forecasting recurrence levels, it is proving more unlikely that such treatment of single annual tidal observations will provide a satisfactory standard level of reliable information for practical design purposes. The interactive effects of tide, wave and weather are complicated to such a degree, that coupled with the uncertainty of sea level measurements of maxima it may be necessary to approach such studies of frequency analysis in a more fundamental way.

FREQUENCIES AND PROBABILITIES OF EXTREME STORM SURGES

(On the Time-Dependent Changes of the Probability of
Extreme Storm Floods at the German North Sea Coast)

by

Alfred FÜHRBÖTER ¹⁾

Abstract

The North Sea as a very shallow sea with high wind set-up effects is acting highly as extremely sensitive measuring equipment for climatic changes, especially for surge producing weather conditions. The flood disaster in the Netherlands 1953, in Germany 1962, the Adolph-Bermphol-Orkan (1967), with mean wind speed of 37 m/sec. over 5 hours, the strong continental storm with high damages in the forests from France till Poland in November 1972, a series of 6 heavy floods in November/December 1973 and two extreme floods in January 1976 with the highest water levels ever registrated in the German bight are indications for some changes in meteorological conditions.

In this paper some hypothetical models shall be introduced which are able to show how extreme storm surge frequencies and probabilities are changing with time.

It is well known, that, on behalf of the high variability and possibilities of superpositions from meteorological parameters (wind velocity, direction, duration a.s.o.) with tidal regimes nobody can give an exact prediction about the highest possible storm surge. As early as in 1939, WEMELSFELDER therefore introduced a method to predict the probability of a storm surge level using the observed frequencies of storm flood levels from long-time series of observations from tidal gauges. In semilogarithmic coordinates, he found for high water levels (= low frequencies) a nearly linear relation between water levels and frequencies; by extrapolation, water levels can be computed which are to be expected - in the average, according to the laws of probability theory! - once, in 100 years, 500 years a.s.o. The basis for this method, however, is, that the stochastic process producing storm surges is a stationary one, i. e. not a time-dependent process.

For these calculations long time series are necessary. They are available on the German North Sea coast at the tidal stations of Cuxhaven (1813 - 1976, n = 164 values), at Wilhelmshaven (1854 - 1976, n = 123 values) and at Husum (1867 - 1971, n = 110 values) as collections of the highest annual storm surge levels.

For Cuxhaven, Fig. 1 shows the logarithmic plotting of this collection for the original values and for the same values adjusted to the year 1975 due to the centennial rise of the water level which was found for

¹⁾ Professor Dr.-Ing., Technical University Braunschweig, Germany,
Director of LEICHTWEISS-Institut für Wasserbau

Cuxhaven to nearly 23 cm/100 years. For all stations, these corrections are necessary in order to eliminate longterm trends which are not connected directly with the actual meteorological conditions. For Cuxhaven, for example, it can be seen that by this correction the storm flood of 1825 was ranked from the third to the second place (fig. 1) in the collection.

Fig. 1: Frequency curves of annual HW (Harbour diagram) for the station CUXHAVEN from 1813 till 1976 (n = 164 values)
 a) original values
 b) adjusted to 1975 due to centennial rise of water level

Fig. 1 shows observed frequencies; the question is to compute the abstract probability (after POISSON) from these frequencies. It can be seen, that for low frequencies (i. e. extreme surges) the linear approximation by WEMELSFELDER is quite satisfactory.

From the exact theory of probability, always an "event" is defined for instance by a game with dices; also for such a game here the "abstract probability" is exactly known as 1 to 6 when the dice is not "prepared". But for instance in 1973, 6 heavy storm surges occurred inside the German bight during 2 months; it is evident that this, seen from theory of probability, only was one event according to the meteorological conditions. Moreover, it can be assumed that even the meteorological behaviour of sequences of years may not be independent in the light of probability theory.

Contrary to the classical applications of the probability computations (v. MISES 1972) namely in the game of chance e. g. in the game of dice, where every throw represents an

"Event" and the sum of the throw represents the "Collection of Events", in the case of extreme storm floods, the expression "Events" and the connected expression "Collection of Events" have to be defined first, as they do not correspond to discrete events. The chain of storm floods as in 1962, 1973 and 1976 cannot possibly be viewed as independent events in the realm of probability computations.

As the equipments to register storm weather (meteorologically conditioned accidental events) are coupled with other similar equipments in large space and over long years of at least the North Atlantic region, if not globally, it can only be taken as an assumption, and not as a confirmation, to observe for example that an yearly HW is an independent event.

The approach of "Extreme Storm Flood Levels" of WEMELSFELDER results in a simple logarithmic representation of an approximately linear relationship between the water levels and their corresponding frequencies. From the observed frequencies the abstract probabilities for the period of investigation (time series) are interpolated and for the future extrapolated. The abstract probability according to POISSON (1841) is then known already deductively, as for e. g. in a game of dice with $W = 1/6$, for each number it is known; but in the case of storm flood events it must first be calculated from the observed frequencies. An estimate of abstract probabilities from the observed frequencies demands an exact and reproducible definition of "Events" and "Collection of Events" (v. MISES 1972). Irrespective of arbitrary definitions of the expression "Storm Flood", it can be shown through a proof of convergence (FÜHRBÖTER 1976) that the values H_{100} , which represent the abstract probabilities according to POISSON and assign by stationary probability the water levels - in the mean! - occurring once in 100 years, in the form of a function $H_{100}(N)$ for $N > 5$ years, converge to nearly constant values, when the water level HW is assigned as the "Event" in a series of $N = 1, 2, 3, \dots$ up to 20 years in the case of a long series of gauges as in CUXHAVEN, as also till $N = 30$ years. This holds good for the linear approach of WEMELSFELDER. For non-linear fitting functions (GUMBEL, FRECHET, JENKINSON etc.) the convergence can be expected to be already by $N < 5$ years. This proof of convergence which leads from the observed frequencies to abstract probabilities (POISSON) delivers for the three North Sea gauges uniformly asymptotically reaching constant values for H_{100} with $N > 5$ years. As "Event" in the sense of independence an extreme water level HW is to be assigned which occurs in the series of $N = 5$ years.

Fig. 2 shows the convergence test (FÜHRBÖTER 1976) with the behaviour of the functions $H(N)$ with their constant pattern for $N > 5$ years for all 3 stations; on fig. 3 (Cuxhaven), fig. 4 (Wilhelmshaven) and fig. 5 (Husum) it is to be seen that the linear fitting for $N = 5, 10, 15$ and 20 years is nearly the same independently from N (FÜHRBÖTER 1976).

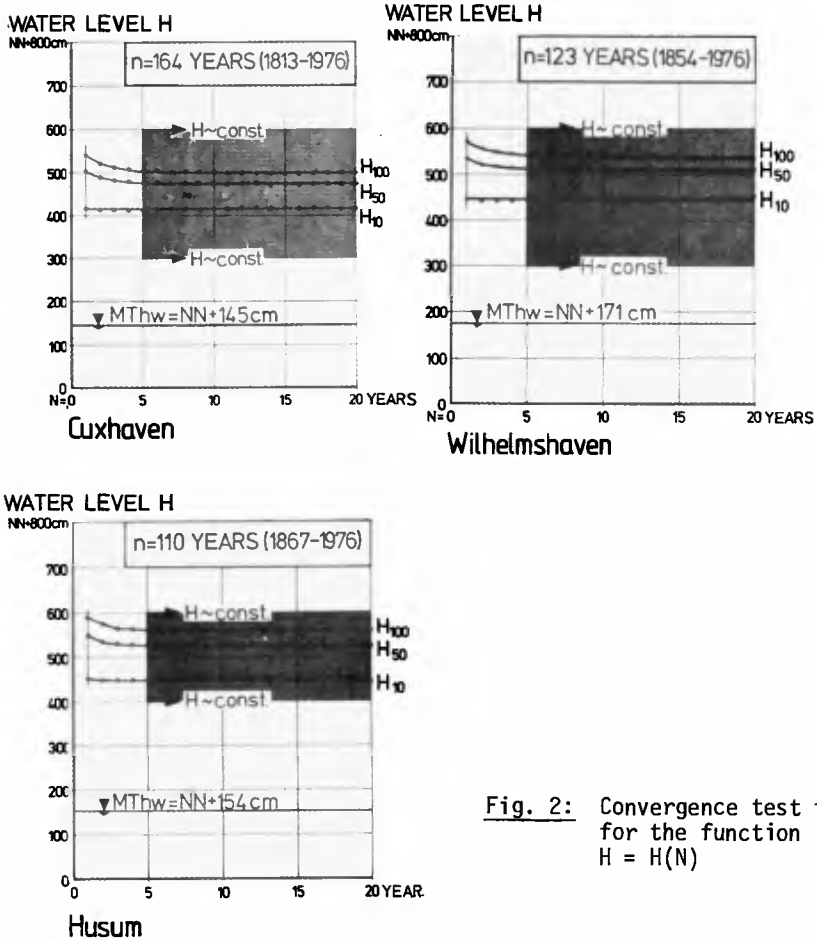

Fig. 2: Convergence test for the function $H = H(N)$

With this the possibility is open for the investigation of the time-dependent changes of the abstract probabilities with a reproducible method which are calculated from the observed frequencies as per WEMELSFELDER method. For the non-stationary applications of WEMELSFELDER method the value H_{100} , the storm flood level - in the mean! - which is reached or exceeded once in 100 years, will be used as the representative value of the corresponding best fit straight line (fig. 2 - 5).

Fig. 3: Convergence test Station CUXHAVEN 1813 - 1976 (n = 164 years)

*

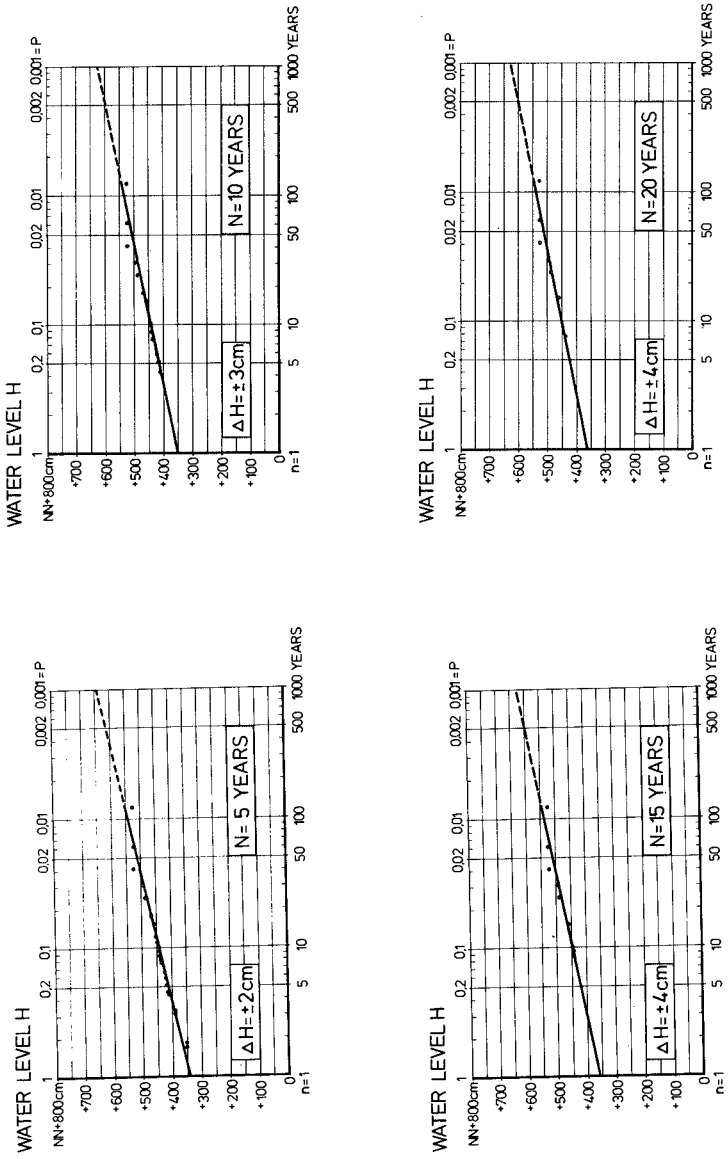

Fig. 4: Convergence test Station WILHELMSHAVEN 1854 - 1976 (n = 123 years)

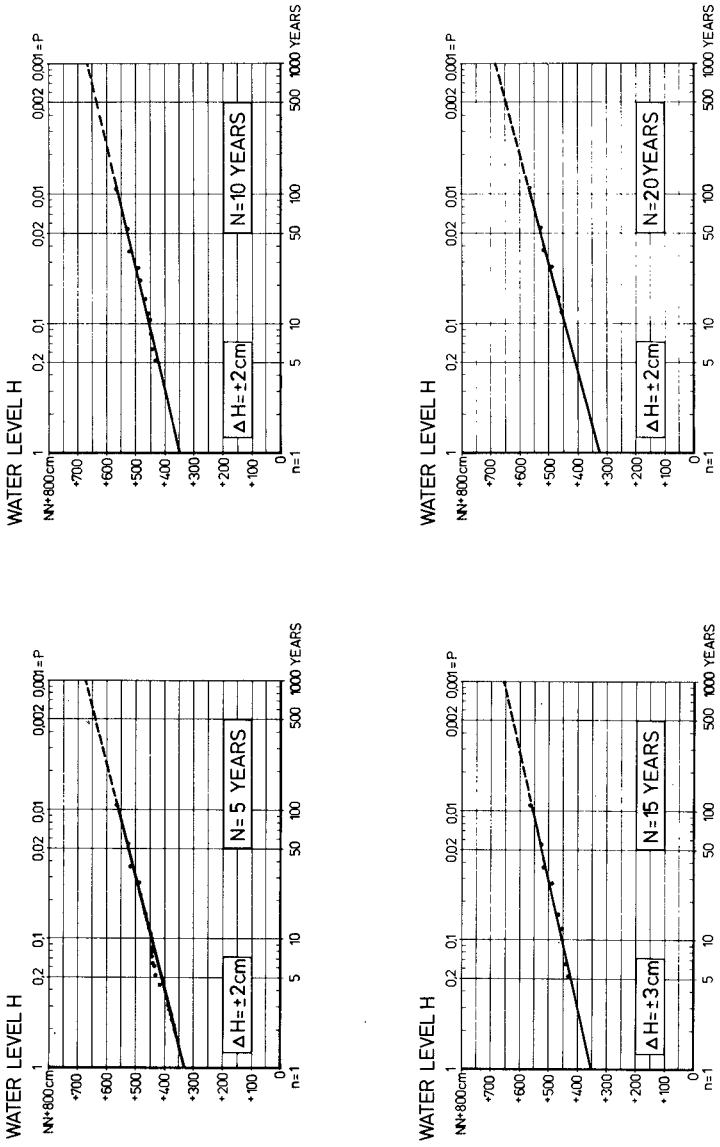

Fig. 5: Convergence test Station HUSUM 1867 - 1976 (n = 110 years)

Fig. 6: Hypothetical model: "Long Living Historian" (Station Cuxhaven)

One of the methods of investigation in non-stationary cases is the hypothetical model named "Long living Historian". He begins his work after supplying a 50 years series at the given gauge and examines after every following 5 year period its predictions for the value H_{100} vis-a-vis the new HW of these 5 years. This gives rise to a function $H_{100}(t)$ which can give information about the time-dependent changes of the probability of extreme water levels (FÖHRBÖTER 1976).

Fig. 6 shows the results from the model "Long living Historian" for Cuxhaven; the curve $H_{100}(t)$ ("abstract probability") is combined with the presentation of the HW for each $N = 5$ years ("observed frequency").

It is to be seen here that the function $H_{100}(t)$ has an always falling trend till 1962. Here and 1976 firstly discontinuities occur in form of jumps towards higher levels.

The comparison of the function $H_{100}(t)$ on fig. 6 with this on fig. 7 shows that there is no stationary pattern in the function $H_{100}(t)$ from the "Long living Historian".

Fig. 7: Example for a function $H_{100}(t)$ from a stationary process

A model opposite to the "Long living Historian" is the "Remembering Historian" who begins his work in 1976 with a 50 year series from 1927 - 1976 and goes than back into the past with his memory.

For Cuxhaven, fig. 8 shows the function $H_{100}(t)$ for this model; here a general rising tendency with some small discontinuities is to be seen.

Another method of investigation is represented by the hypothetical model "Forgetting Historian" (FÖHRBÖTER 1976). He begins with the first 50 year series of the given gauge, similar to the "Long living Historian", but forgets as the time function $H_{100}(t)$ develops all the values that lie behind 50 years, but applies uniformly a 50 year series as moving investigation period. Corresponding to the greater weightage of the events in that period of 50 years in this hypothetical model, the discontinuities since 1962 occur somewhat stronger than in the previous model; at the CUXHAVEN gauge the jumps in 1962 and 1976 result in an increase in the value of H_{100} by about one meter (fig. 9).

Fig. 8: Hypothetical model: "Remembering Historian" (Station Cuxhaven)

Fig. 9: Hypothetical model: "Forgetting Historian" ($n = 50$ years) (Station Cuxhaven)

Whereas in the "Long living Historian" it is assumed that the meteorological parameters, whose eventual superimposition determines the occurrence of the storm flood, are remaining the same in the mean value, in the model "Forgetting Historian" the meteorological events of the previous 50 years alone are considered as determining the storm flood, also for the period of 100 years, to which the value H_{100} will be extrapolated.

The stations of Wilhelmshaven and Husum show similar trends. It may be of high interest that also on the east coast of England for the harbour of Immingham GRAFF (to be published 1979) found comparable results with time series from 1920 - 1978 (fig. 10).

Fig. 10: Sea levels from $H_{250}(t)$ till $H_{10}(t)$ for the harbour of Immingham (from GRAFF, to be published 1979)

The curves "to base 1920" can be compared with the hypothetical model "Long living Historian" (fig. 6), those "to base 1978" with the "Remembering Historian" (fig. 8).

Fig. 11: Comparison of different approximation functions with the value H_{100} for the station of CUXHAVEN (values adjusted to 1975) (from WOLPERS, to be published 1979)

GRAFF used for his computations the distribution function of JENKINSON (1955). On fig. 11, for different probability distributions the values computed after WEMELSFELDER (1939) and with $N = 5$ years (FÜHRBÖTER 1976) are compared for Cuxhaven. It is to be seen that the question which time series are taken for the computation is much more predominant than the question which distribution was used (fig. 11).

The same effect is illustrated for Cuxhaven on fig. 12. The water level H_{100} computed with $n = 50$ years is for the series 1927 - 1976 nearly one meter higher than for the series 1912 - 1961 (FÜHRBÖTER 1976).

Fig. 12: Changes of $H_{100}(t)$ with different time series for Cuxhaven

The North Sea as a very shallow sea with high wind set-up effects is acting highly as extremely sensitive measuring equipment for climatic changes, especially for surge producing weather conditions. The flood disaster in the Netherlands 1953, in Germany 1962, the Adolph-Bermphol-Orkan (1967), with mean wind speed of 37 m/sec. over 5 hours, the strong continental storm with high damages in the forests from France till Poland in November 1972, a series of 6 heavy floods in November/December 1973 and two extreme floods in January 1976 with the highest water levels ever registered in the German bight are indications for some changes in meteorological conditions.

Three possibilities must be taken into consideration for the future (fig. 13);

a) There is a sort of flip-flop mechanism in climate with higher but constant probabilities P for extreme surges for the next future (fig. 13a)

b) Like some periods during the Middle Ages, there is a temporary maximum with a trend of reduction in future (fig. 13b) or

c) the worst development: the probability P shows a furtherly increasing trend (fig. 13c).

Fig. 13: Possibilities of futural development of storm surge probability P

From meteorology, no exact prediction can be given for the next future (see FLOHN 1967, LAMB 1976). Also how far human impacts on the climate may be responsible for the events, cannot be answered at time, but meteorologists and engineers should observe very carefully this development for the future (FÜHRBÖTER 1976).

CHAPTER 55

STORM SURGE PREDICTION BY COMBINED WIND AND TIDE DATA

by
Hermann Christiansen^{*)} and Winfried Siefert^{*)}

ABSTRACT

The authors suggest a storm tide forecasting method that allows high water predictions for a coastline 3 to 4 hours in advance with an accuracy of ± 30 min in time and ± 20 to 30 cm in height. It is based on actual (not on predicted) data, i.e. exact wind velocity and direction data from a reference station and tide data from two gauges. The method was developed by analysing storm surge curves and wind data of those 50 storm tides that occurred since 1965 in the German Bight. Another 50 storm tides back to the year of 1930 were taken into account, though without exact wind data.

The method was proved at all storm tides since 1965 and applied with good success to the events during fall and winter 1977/78 for the coastline off Cuxhaven.

INTRODUCTION

Storm tide forecastings and quick propagation of warnings are of high importance for people living at coastlines and tidal rivers behind the dykes. This yields to the demand, that a storm tide forecasting method must satisfy the highest level of scientific solidity that can be reached. Methods that are developed by hindcasting 5 to 10 special storm tides are not serious enough. Our investigations show that we have to live with at least 20 different surge types.

Lots of forecasting methods often remain insufficient as they are based on weather forecasts and these weather forecasts - mainly wind speed and wind direction developments - are not accurate enough.

The other reason for unsatisfactory predictions are the methods in itself, as usually only the peaks of storm tides are taken into consideration, and that is only one point on a curve. Characteristics of tide and surge curves are not developed, and tide/surge interactions are not evaluated.

To exclude such difficulties the presented storm tide forecasting method was developed

1. by analysing storm surge curves of those 100 storm tides that occurred since 1930 at several tide gauges on our coastline. A storm surge curve is defined as the differential curve between storm and mean tide curves;
2. by taking into consideration wind data of 50 storm tides back to 1965 (data from earlier events were not available);
3. by using only exact (not predicted) tide and wind data

STORM TIDE CONDITIONS IN THE GERMAN BIGHT

Fig. 1 shows the situation with the German North Sea coast. In the German Bight the astronomical tide is progressing anti-clockwise. Wind at storm tides comes from western directions like the storm surge wave. By this, a forecast for a point B on this coastline needs informations from a location westward of it. We found this point with the tide gauge A at the Island of Borkum. This gauge A is the so-called input gauge for the forecast gauge B.

Fig. 2 shows in the upper part the storm tide curves for one event at A and B. High water level at A occurs 2 to 3 hours earlier than at point B. A comparison of high water levels at A and B (Fig. 3) shows that there is already a remarkable trend. On the other hand single deviations up to 1 m show that a use only of this trend is not exact enough to forecast high water levels at B. That means that water level informations merely from an input gauge are not sufficient.

FORECASTING METHOD I

Further investigations showed that an explanation for the runaways of Fig. 3 can be given if wind speed and wind direction development in the last 3 hours before high tide at A (Borkum) are taken into account. The wind development in this 3 hours intervall (about 3 hours before the expected high water level at B) is the best indicator for what will happen with the water level changes in the following 3 hours after high tide at A. The conclusion is, that about 3 hours before high tide at B no further wind informations are needed to forecast the highest level at B. These conditions are in agreement with results at the Dutch and British coast.

Fig. 1: Situation

Fig. 2: Tide- and Storm Surge Curves at A and B

Fig. 3: Comparison of High Water Levels at A and B

The high water level at B (HW_B) can be calculated by the simple formula:

$$HW_B = 1.2 \cdot HW_A + \Delta v + \Delta R - 80 \text{ cm}$$

where

- $1.2 \cdot HW_A - 80 \text{ cm}$ gives the trend of high water level comparison at A and B (Fig. 3) and
- Δv (Fig. 4) and ΔR (Fig. 5) are the partial amounts for wind speed and wind direction developments within 3 hours before forecasting time

The wind data is needed with an accuracy of 1 m/s in speed and 10° in direction. The example in Fig. 4 demonstrates the necessity of exact wind speed data. A change in wind speed from 20 to 24 m/s over the 3 hours intervall gives a positiv amount of $\Delta v = + 40 \text{ cm}$. A change of only 2 m/s more (to 26 m/s) doubles this amount to $\Delta v = + 80 \text{ cm}$.

Fig. 5 shows that highest amounts for wind direction developments are given by changes from other directions to 280° , what is the most effective wind direction for high storm surges at Cuxhaven. Direction changes further northward give high negative amounts, up to $\Delta R = - 80 \text{ cm}$.

FORECASTING METHOD II

There is at least a second chance to forecast high water levels at B to control the first method mentioned above. This possibility is given by analysing the surge curves at A and B. The surge curve (see Fig. 6) is defined as the difference curve between the storm tide curve and the mean tide curve. This curve includes all deviations from the mean tide, such as wind influence, astronomical disproportion, external surges, temperature, atmospheric pressure etc.

Fig. 4 : Wind Speed Development Value Δv in cm

Fig. 5 : Wind Direction Development Value ΔR

Fig. 6 : Definition Sketch Surge Curve

Fig. 7 : Extrapolation of Storm Surge Curve B by the Shape of Curve A

Fig. 2 shows in the lower part, that surge curves of the same event at neighbouring gauges are not only very similar, but there is also a phase lag of about 3 hours between these curves. That means, that what happened in the last 3 hours with the surge curve at A, will happen qualitatively in the same way within the next 3 hours at B. So it is possible to extrapolate the surge curve at B by the trend of A 3 hours in advance (Fig. 7). Addition of the extrapolated surge curve and the attached part of the known mean tide curve gives the expected storm tide curve at B, including the highest peak.

In practice we found, that the mean value of methods I and II gives the best result for the high water level forecast. The comparison of computed and observed HW data for Cuxhaven is given on Fig. 8.

WHAT CAN WE DO IN FUTURE?

To improve and to reform the presented forecasting method, first of all we have to include all informations that can be reached by further storm tides.

While the high accuracy in forecasting is satisfactory we should try to find a way to give the forecasts earlier than 3 or 4 hours in advance. We believe that this is only practicable if we get exact wind forecasts for the next 2 or 3 hours. For better, i.e. earlier storm tide forecastings it would be greatly helpful if programs could be started to research not only in the development of wind conditions for the next 2 or 3 days but also for this short interval we are interested in.

CHAPTER 56

NUMERICAL STORM SURGE FORECASTING

Manfred Engel⁺

Abstract

The present state of the development of an operative storm surge prediction system in Germany is described. It is based on numerical models of the atmosphere and the North Sea. First simulations of the storm surge on Jan. 3, 1976 yield the result, that the observed water levels along the North Sea coasts can be recalculated quite well using a meteorological input derived from observations, whereas the forecasted water levels, using the predicted geostrophic winds of the atmospheric model, are too low since the pressure gradients are too weak. A series of storm surge recalculations with observed and predicted meteorological data shall answer the question, whether parameter fits, applied to the predicted wind stress, lead to satisfying results, suitable for practical applications.

Introduction

After the severe storm surge of January 3, 1976, the German Hydrographic Institute, being responsible for warnings, arranged a meeting with the aim to bring together all people working on numerical modelling of storm surges in Germany.

Meanwhile the Sonderforschungsbereich "Meeresforschung" - special research organisation "Marine Research" - of the University of Hamburg had started a program for the development of a storm surge prediction system. On this

⁺ Institut für Meereskunde, University of Hamburg
Sonderforschungsbereich 94, Meeresforschung

meeting it was concluded that the different activities of numerical modelling of storm surges should be coordinated by a Model Group North Sea. Some of its intentions, its work and some preliminary results shall be discussed in the following. Although e.g. in our institute many storm surge calculations, yielding encouraging results for different events with different models, have been carried out during the past 20 years, it was felt that for the development of a prediction system as a first step it is necessary to get a consistent set of storm surge hindcasts on the basis of observed meteorological data with only one model. Therefore a first goal of the Model Group was the recalculation of a certain number of storm surges.

For this purpose our Sea Weather Office reanalyses very carefully threehourly weather maps, the surface pressure and additionally the air-sea temperature differences. Parallel to this work the meteorological fields for every of these analysed events are hindcasted with a hemispherical prediction model, developed by the Meteorological Institute of the University of Hamburg.

Both data sets are used for storm surge calculations and following analyses of the results.

When these tests are done and when possible improvements of the presently used models are finished, and if it can be shown that the predicted storm surge heights are closer to the observed ones than the conventionally estimated predictions, then we hope that a data link between the German Weather Service in Offenbach, running the meteorological model, and the German Hydrographic Institute, computing the water elevations, will enable us to give better storm surge warnings earlier than it is possible nowadays.

The Models

The North Sea model is a two-dimensional vertically inte-

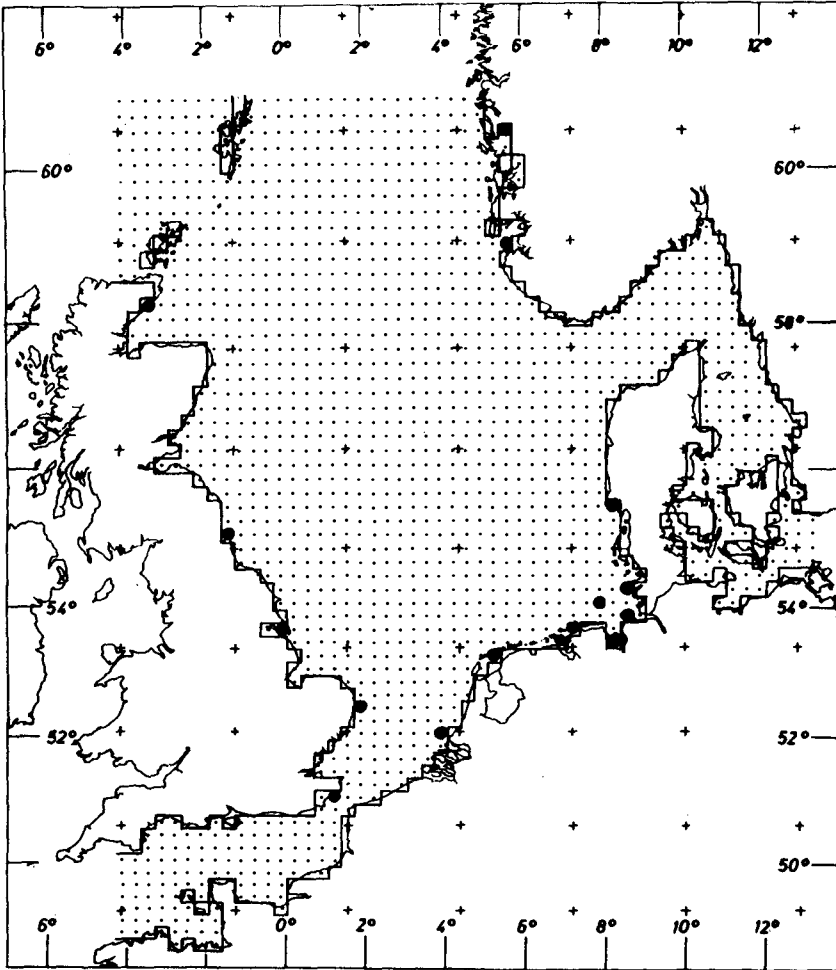

Figure 1 The HN-North Sea model
The crosses (+) denote grid points of the meteorological prediction model.
The dots (•) represent points for comparisons with tide gauge data.

grated HN - model (hydrodynamical-numerical model) with a grid point distance of about 22 km (Fig. 1). It is formulated in spherical coordinates. In addition to an earlier version it now includes parts of the English Channel. On the open boundaries the M_2 - tide is prescribed. It is intended to use later on 10 tidal constituents, but until now the results of such tidal computations are not satisfying since the boundary values are not known exactly enough.

In order to correct for meteorologically induced variations of water levels on the open boundaries a coarser model of parts of the North Atlantic is run parallel to our prediction model.

Figure 2

The External Surge Model

The water levels of this model, driven by wind and atmospheric pressure alone, are taken along the open boundaries of the finer model and are added there to the M_2 -tide water levels. It is known that sometimes storm surges are significantly influenced by external surges, yielding contributions to the water levels in the German Bight up to the order of magnitude of one meter.

The meteorological model is an 8-layer baroclinic model of the northern hemisphere with an horizontal resolution of 1.4° meridionally and 2.8° zonally, i.e. about 150 km in the North Sea area. The lowest computation layer for wind velocities lies at about 500m height. It predicts wind, pressure, temperature and humidity. Bottom friction is assumed to be different over land and sea areas.

Figure 3a shows the bottom pressure over the northern hemisphere on the 2nd of January at 12⁰⁰ GMT (this information belongs to the set of initial values for the computation) and Fig. 3b gives the predicted field 24 hours later. The cyclone on the 10° meridian lies over the North Sea.

On Figure 4 observations and forecasts of bottom pressure over western Europe are blown up. For a further comparison the predicted bottom pressure of the German Weather Service is added. Both models underestimate the pressure gradients. We will come back to this feature when discussing the predicted storm surge results.

From the meteorological model the pressure is interpolated on the grid points of the North Sea model and then the wind stress is calculated. When using observed meteorological data for surge computations, the pressure information is taken from isobars of weather charts. The pressure gradients are determined as the slope of triangular planes between the isobars and thus can be used directly for stress computations in the North Sea model.

So far we have studied only the already mentioned storm

Figure 4 Observed and predicted bottom pressure fields over western Europe

surge of the 3rd of January in 1976 with this system. This storm surge caused the highest water level, at least at Hamburg, which was ever observed.

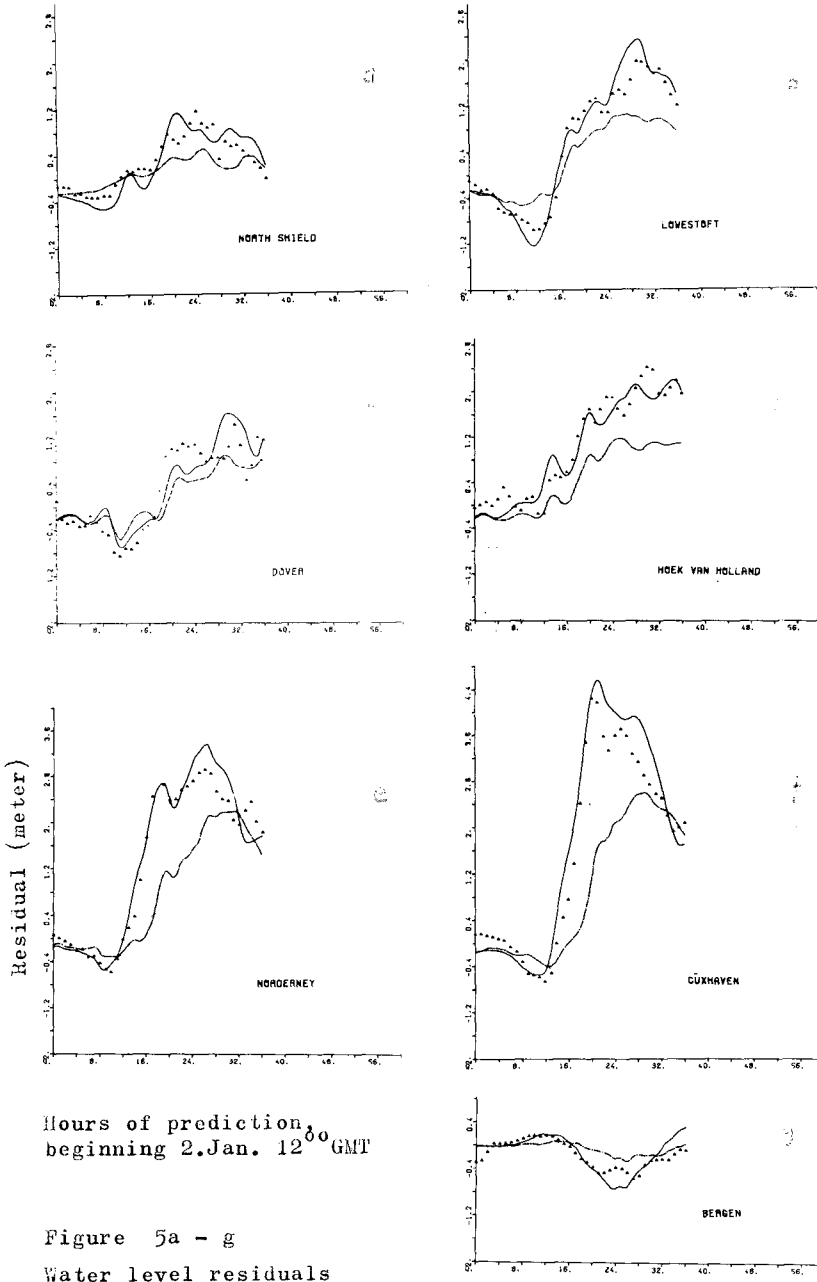

Calculations of a series of storm surges from the 19th through 21st of January, 1976 are under preparation.

Results

On figures 5a-g computed and observed residuals of water levels for different locations around the North Sea are compared. The residual is defined as the difference between water levels as observed or computed with wind, pressure and tides and those which were predicted for the tide or computed in the model for the M_2 -tide alone. All plots show a much better correspondence between observed and hindcasted residuals than between observed and predicted ones. From the results at Dover one can deduce that it is necessary to extend the model into the English Channel.

These first results, yielding the largest prediction errors in the German Bight, are of course not yet suitable to demonstrate the reliability of our prediction system. The discrepancies in the residual forecasts are the direct consequence of the discrepancies of the predicted geostrophic winds, being too weak during the period of interest (Fig. 6).

Both surge computations have been carried out with the same formulation of wind stresses. Since it is a common feature of many atmospheric circulation models to underestimate geostrophic winds, a further surge simulation using the forecasted geostrophic wind and a drag coefficient, tuned at the maximum water levels, has been carried out. The results are looking better, at least up to the maximum water level, but since the predicted low did not decay quickly enough, the following water levels were overestimated.

Hours of prediction,
beginning 2.Jan. 12⁰⁰ GMT

Figure 5a - g
Water level residuals

▲ observed ——— hindcasted - - - - forecasted

Whether such a parameter fit is suitable for our prediction system or not, this can only be decided if we have computed enough events to make a statistical analysis. Beside this attempt, other improvements must be considered to get better meteorological input. For this purpose three projects are under investigation within the Model Group:

Figure 6 Comparison of observed and predicted geostrophic wind V_{g0}

- (a) to improve the meteorological forecast by means of a nested meteorological model of the North Sea area,
- (b) to test wind stress calculations based on resistance law formulations for the boundary layer,
- (c) to separate the contributions of wind and wave set-up to the storm surge water levels.

In any case it can be concluded that the meteorological data for the North Sea model must be known with high accuracy in order to get satisfying storm surge predictions within the shallow German Bight, which is very sensitive to the meteorological input in nature and in model simulations.

Acknowledgements

The results presented herein were obtained in the course of research supported by the Deutsche Forschungsgemeinschaft. The permission of Prof. Dr. G. Fischer to present the figures of the meteorological model is gratefully acknowledged. Thanks are due to L.F. Dolata, who performed the North Sea simulations and placed the corresponding figures to the authors disposal.

CHAPTER 57

STORM SURGE PREDICTION IN TIDAL RIVERS: A NEW CONCEPTION

by Winfried Siefert^{*)}

INTRODUCTION

The heights of extreme storm surges in the North Sea rise up to 4 or 5 m above mean high tide. Warning services are established along the coast, mainly based on empirical connections between weather and tide data. A lot of wrong announcements are given especially for places up the tidal rivers. This can become disastrous for a lot of modern, highly sensitive harbour facilities.

Thus storm surges are the famous plagues of the southern North Sea coast. Moreover, the "ten plagues of Germany" occurred during the last 16 years.

So recently a new conception for storm surge prediction in tidal rivers was developed - with the result of a lot of new understandings of tidal dynamics in rivers (SIEFERT, 1968). We investigated about 130 storm surges, hindcasting all of them and forecasting about 20 of them, and analysed their behaviour in tidal rivers. Now we are able to forecast the upstream heights and even the shape of the surge curve in the Elbe with an accuracy of ± 2 dm, 6 hours in advance. In order to do this, informa-

Fig. 1

tions about the boundary values are necessary. We tried to obtain informations from the stations on fig. 1 (circles = tide gauges, triangles = weather stations). It turned out that for a sufficiently exact prediction for the Elbe region data from Borkum (tide), Cuxhaven (tide) and Scharhörn (wind) are necessary.

CONCEPTION

The new conception for understanding the dynamics of storm surges in rivers and for developing a reliable warning system is very simple: Storm surge behaviour in a river is treated as a problem of combination of boundary values and eigenvalues. To solve these problems mathematically, a lot of differential equations have to be treated. This is not yet sufficiently possible. It can easier be solved in a hydraulic model (including all eigenvalues) with variation of the boundary values. This was done for the Elbe (for 200 river-km), with special respect to Hamburg, and thereafter transferred to other rivers (fig. 2).

Fig. 2

It turned out that all other than astronomic influences result in a special, individual surge curve in the estuary. So we have to consider as seaward boundary values only two curves: the (more or less regular) tide curve and the (irregular) surge curve. These have to be combined with the eigenvalues by tide-river-dynamics. The latter can be considered constant during individual storm events. They are mainly changed by man (deepening and widening of fairway, course corrections, new dyke lines, weirs, dams, sluices etc.) and so are varying through the decades. The upper boundary value (discharge) can also be treated as constant during a surge.

The identification of the seaward boundary values is done by separation of the astronomical or (in first-order approximation for this area) of the mean tide wave and the surge wave (fig. 3):

Fig. 3

The surge curve is characterized by 5 parameters as shown in fig. 4. After these treatments we investigated how these curves behave, when they proceed in a river, and especially, how they interact.

CHARACTERISTIC SYSTEM NUMBER

Correlations between storm tide heights of different gauges along a tidal river show no significant coherences. For interpretation of tidal dynamics it is necessary to take into account the complete curves.

HARLEMAN and LEE (1969) give some methods for the solution of tidal propagation in estuaries. The harmonic solution of the linear function equation for the tidal elevation at any x and t

$$\eta = \frac{\eta_{0H}}{2} \cdot e^{-\frac{\delta x}{2}} \cdot (e^{\mu x} \cos(\sigma t + kx) + e^{-\mu x} \cos(\sigma t - kx))$$

contains the amplitude attenuation coefficient μ . The authors computed the damping parameter μx for the Delaware estuary. So did PARTENSKY and BARG (1977) for the rivers Elbe, Weser, Ems and St. Lawrence.

Using μ and the variation of the damping parameter $\frac{d\mu x}{dx}$, the simple equation for wave propagation in shallow water could be modified to

$$c = S \cdot \sqrt{g \cdot d^*}$$

with g = acceleration of gravity

d^* = representative water depth in a river

It turned out that the characteristic system number S of a river can be computed as

$$S = \sqrt{\frac{1}{\mu} \cdot \frac{d\mu x}{dx}}$$

Fig. 4
Storm Surge Parameters

The values vary from 0.56 for the Elbe to 1.11 for the Delaware (SIEFERT, 1978). It changes with time, i.e. with secular changes in the river as were mentioned before.

Computations of a lot of tides and storm surges showed that the "representative water depth" d^* in a river is characterized by the depth of the fairway d_F . This fact is best proved in rivers with a distinct fairway of a certain length, as the tide and storm surge dynamics are the more concentrated at the fairway the deeper it is, relative to the rest of the cross-section.

So the equation

$$c = \sqrt{\frac{1}{\mu} \cdot \frac{d\mu x}{dx} \cdot \sqrt{g \cdot d_F}}$$

shows that c is a function of d_F alone only as long as μ and $\frac{d\mu x}{dx}$ are constant. It can be started from the principle that they are during the time of a storm tide.

LONG WAVE INTERACTIONS

If that is so, the so-called pick-a-back-effect during propagation of tide and surge waves in a river results in special interactions as shown in fig. 5. Thereby it

Fig. 5

Fig. 6
Example Shape Variation of Tide Curves Between two Locations

becomes very difficult to identify real and comparable peak heights and peak velocity differences between two locations (fig. 6).

The interactions result in differing propagation velocities not only of the surge, but also of the tide waves. This may be illustrated by the shape of the surge curves on fig. 7. They occurred on Jan. 3, 1976 during the highest storm tide ever registered in the Elbe. The comparison of the shapes

Fig. 7

- Thick solid line: surge wave in Cuxhaven
 Thin solid line : surge wave in Hamburg (101 km upstream),
 evaluated under the hypothesis of un-
 disturbed tide wave propagation
 Dashed line : surge wave in Hamburg, evaluated under
 the hypothesis that tide wave propaga-
 tion from C. to H. lasted 3 h instead
 of (normal) 4 h

give the hint that tide waves must run a lot faster than usual. As only small alterations of the surge curves are to be expected, best fit shifts have to be found. (This is one of the first results of an extensive computer investigation that is still in progress.)

ACCURACY OF PREDICTIONS

At the moment the "Hamburger Sturmflut-Warndienst" (WADI) is working on the basis of data from Borkum and Cuxhaven (tides) and Scharhörn (wind), fig. 1. The evaluation is based on the parametrisation of the surge curve as indicated on fig. 4. This allows predictions of the storm tide maximum in Hamburg 6 to 8 h in advance with an accuracy of

$$\begin{aligned} &\pm 25 \text{ cm in height} \\ &\pm 30 \text{ min. in time.} \end{aligned}$$

All values scatter within these borders.

Note: The results were not only obtained by hindcoasts, but also by about 20 forecasts since 1976.

As soon as the quantitative effects of interaction dynamics will be physically understood, they will be taken as a new basis for predictions of complete storm tide developments in tidal rivers.

DEVELOPMENT OF STORM TIDE HEIGHTS SINCE 1900

The analysis of more than 130 storm tides proved to give a suitable data collection to answer the question, why the heights of storm tides in tidal rivers of the southern North Sea increased so remarkably during the last decades. It is often presumed that this development is an effect of river improvements in Ems, Weser, and Elbe respectively.

For the purpose of finding the real reason, mean heights of high storm surges - each mean height representing about 4 to 12 events in a decade - were calculated. Their heights above mean high water level (MHW) varied considerably, with a resultant increase of about 80 cm from 1900 to 1975 (fig. 8). But variations as well as total increase in Hamburg can be explained by changes of surge curve parameters in Cuxhaven (101 km downstream). On fig. 8 only the influences of ALPHA and HEIGHT (see fig. 4) are taken into account. That yields to the conclusion that the increase in surge heights in Hamburg is almost completely an effect of higher surge curves in the Elbe estuary, i.e. an effect of stronger wind in a critical direction.

CHAPTER 58

STORM SURGE FORECASTING METHODS IN ENCLOSED SEAS

P.F. Hamblin

Applied Research Division, National Water Research Institute,
Canada Centre for Inland Waters, Burlington, Ontario, Canada

Storm surges in enclosed seas although generally not as large in amplitude as their oceanic counterparts are nonetheless of considerable importance when low lying shoreline profiles, shallow water depth, and favourable geographical orientation to storm winds occur together. High water may result in shoreline inundation and in enhanced shoreline erosion. Conversely low water levels are hazardous to navigation.

The purpose of this paper is to discuss the problem of storm surge forecasting in enclosed basins with emphasis on automated operational procedures. In general, operational forecasting methods must be based on standard forecast parameters, require a minimum of computational effort in the preparation of the forecast, must be applicable to lakes of different geometry and to any point on the shore, and to be able to resolve water level changes on an hourly basis to 10 cm in the case of high water level excursions associated with large lakes and less than that for smaller lakes. Particular physical effects arising in lakes which make these constraints difficult to fulfill are the reflections of resurgences of water levels arising from lateral boundaries, the stability of the atmospheric boundary layer and the presence of such subsynoptic disturbances as squall lines and travelling pressure jumps.

METHODS AND STUDY AREA

Interest in the study was centred on Lakes Ontario, Erie, and St. Clair as representative examples of large and intermediate sized lakes. Observations of past storm surges were collected from water level recordings over the period 1961 to 1972 at sites at the ends of these lakes (see Figure 1). Meteorological data, namely surface winds at Belle River on Lake St. Clair, and surface barometric pressures at a number of points around the lakes, as well as archived operational forecast elements from the U.S. National Meteorological Center primitive equation model, were gathered for the periods preceeding and during the observed occurrences of storm surges.

In the case of Lakes Ontario and Erie, surface barometric pressures were interpolated to the synoptic grid points of the numerical weather model by means of the nearest three surrounding stations. Longitudinal and transverse winds at the centers of these lakes were calculated from regression relations established between shipboard wind measurement and the various forecast elements computed by the numerical weather model by Feit and Barrientos (1974).

Unfortunately for Lake St. Clair neither the regression relations existed

Figure 1. Study area and location of measurement points.

nor did the synoptic grid point pressures account for more than 3% of the water level variance. Relaxing somewhat our requirement for a standard automated forecast parameter, we chose the local hourly winds measured at Windsor Airport as an input parameter.

In Lake St. Clair, and in some cases in Lakes Ontario and Erie, the air-water temperature difference during the storm was computed from measured data.

STATISTICAL METHODS

The most widely employed statistical method for forecasting storm surges is the multiple regression method. It has the advantage of being simple to develop and straightforward to employ, and generally results in a minimum of computational effort in the preparation of the forecast. It has the disadvantage that a relatively long series of data, both water levels and meteorological data, must be available at the point of interest. For details of the development of the multiple regression relations given here the reader is referred to Venkatesh (1974). At the time this study was undertaken, routine forecast variables were available at six hourly intervals and at the synoptic grid points of the Canadian Meteorological Centre weather forecast model which is identical to the U.S. weather model in the Great Lakes region. Therefore, barometric pressure at the time of the surge and six hours previously at the synoptic grid points surrounding the lake were chosen as predictors.

In Lakes Erie and Ontario (also Huron) expressions of the type were developed,

$$\eta_i = A_i + \sum_{ijk} B_{ijk} P_{ijk} + \sum_j C_j \Delta T_j$$

where η_i = surge height at i hours after the time of the pressure forecast ($i = 0, , 5$);

P_{ijk} = surface pressure at grid point j,k and at lag, i , hr;

ΔT_i = air-water temperature differences over the lake at a lag of i hours; and $A, B,$ and C are regression coefficients.

An expression of the type

$$\eta = A + BV^2 + CV^2(\Delta T_0 + D\Delta T_1)$$

was developed for Lake St. Clair, where V^2 is the average of the past three hours of the components of wind squared in the maximum fetch direction. In general two to three dozen storms were used to establish the regression coefficients, A, B, C and D .

A more advanced statistical analysis was undertaken on the Lake St. Clair data only involving a Box-Jenkins transfer function model, (Box and Jenkins, 1970).

As basic input data for this technique, the two normal components of surface wind stress, τ_x and τ_y , corrected for surface stability and wind speed dependence of the drag coefficient (to be outlined later), were prepared for each of the 24 storms. First, the nonstationarity of both the input and output series was removed by first order differencing. Then a transfer function model of the type

$$\Sigma C_j \eta_{t-j} = \Sigma_j A_j \tau_{xt-t-j} + \Sigma_j B_j \tau_y \ t-t-j$$

was fitted to the data.

If at some future time, histories of the past water levels could be made available at the time of forecast, then they could be usefully employed in a statistical procedure known as one-step-ahead forecasting. An autoregressive and moving average model of the type

$$\Sigma C_j \eta_{t-j} = \Sigma_j A_j \tau_{xt-t-j} + \Sigma_j B_j \tau_y \ t-t-j + \Sigma D_j a_{t-j}$$

was determined, where a_t is the observed water level history. For a detailed discussion of these more advanced statistical techniques the reader is referred to Budgell and El-Shaarawi, 1978.

DYNAMICAL METHODS

In enclosed seas on account of the relatively weak flows associated with storm surges, the linearized shallow water equations on a plane of constant rotation ($2f$) serve as the basic mathematical model along with the usual boundary conditions.

$$\frac{\partial u}{\partial t} - fv = -g \frac{\partial \eta}{\partial x} + \frac{\tau_x - \tau_{bx}}{\rho h}$$

$$\frac{\partial v}{\partial t} + fu = -g \frac{\partial \eta}{\partial y} + \frac{\tau_y - \tau_{by}}{\rho h}$$

$$\frac{\partial \eta}{\partial t} + \frac{\partial hu}{\partial x} + \frac{\partial hv}{\partial y} = 0$$

where g is the acceleration of gravity, h is the equilibrium depth, and τ_b is the bottom stress.

The conventional method of integrating this equation set is to discretize the differentials and solve for the free surface, η , and the velocity components, u and v at each point in a horizontal grid and at each time step. The classical computation of this type was performed by Platzman (1963) on Lake Erie in a simulation of nine storm surges. Unfortunately, this form of the dynamical method is too demanding computationally for routine forecasts. In general a large difference exists between the time step required for numerical stability (several minutes) and the forecast time step (here, 6 hrs.)

Figure 2. Free surface displacement (cm) for a steady wind stress of 1.0 dyne/cm for Lake St. Clair computed by the finite element method.

Figure 3. Free surface displacement (amplitude, ---, ———) for the fundamental gravitational seiche of Lake St. Clair computed by the finite element method.

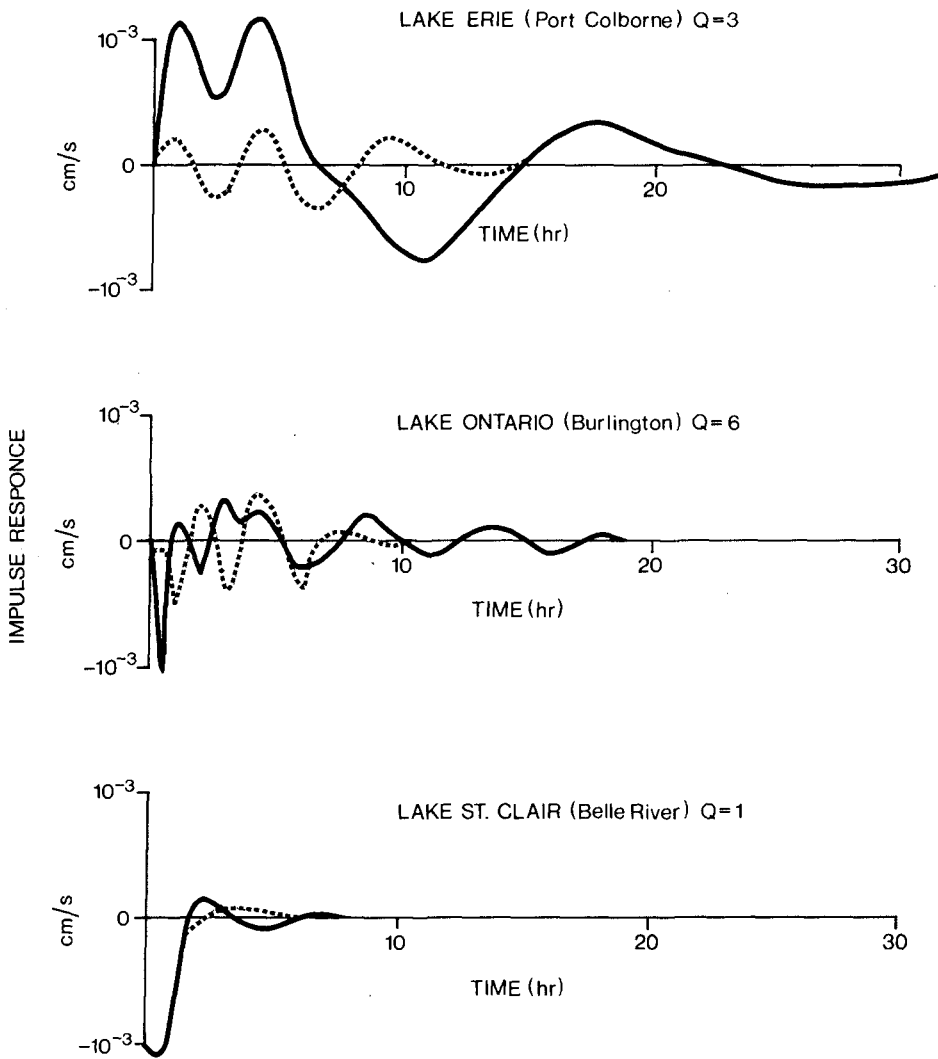

Figure 4. Impulse response functions computed by the spectral method. Lakes Ontario, Erie, and St. Clair, Q refers to the friction assumed.

An alternative approach which avoids the unnecessary routine computation of free surface and velocity components at points at which they are not needed is based upon the computation of the impulse response function or Green's function for the point of interest from a dynamical model such as equation (1). Once this function is determined, then the storm surge at a given point is simply the convolution of the impulse response function for that point with the forecast forcing function. If the weights of the impulse function are considered as regression coefficients, the two methods may be seen to be equivalent in computational effort. Thus the storm surge forecasting problem is reduced to the evaluation of one or more convolution integrals which are essentially digital filters in their discrete form.

Here we adopt the spectral method of determining the impulse response functions in which the impulse response function is expanded in terms of the steady solution and in terms of the lowest six to twelve free modes of oscillation. This number is based on power spectral analysis of water level fluctuations during storm surges which reveals that, in general, only the lowest modes of oscillation are excited at the points of largest storm surge excursion. The complex expansion coefficients are determined from least squares methods but essentially the amplitudes of the oscillation are determined from the steady solution of the free surface and the relative phases from the initial conditions. Both the steady state free surface displacement and the characteristic functions for the basin are computed by finite element methods. The spectral response method is developed in detail by Hamblin (1976) where it is applied to wind generated surges and by Hamblin and Hollan (1978) who applied this technique to excitation of surges by both barometric pressure gradients and winds.

A typical example of a finite element solution for the steady state free surface is given in Figure 2 and of a seiche solution in Figure 3. These solutions may be considered as components of the impulse response. Examples of the computed impulse response functions are given for three lakes of interest in Figure 4. The Q factor refers to the amount of frictional damping assumed in the bottom stress. Alternatively impulse response functions have been obtained for Lake Erie by Schwab (1978) by applying a unit wind stress to a time-stepping model for the first time step only. Results employing the two impulse response functions, determined by the spectral and the time stepping methods are in close agreement in Lake Erie.

SURFACE STRESS

In both the cases of the forecast winds in Lakes Ontario and Erie, and of the observed winds in Lake St. Clair, surface stress is taken as proportional to the product of the wind speed, and the wind vector, v .

$$\tau = \rho_a C_d |\vec{v}| \vec{v}$$

where the air density, ρ_a , is assumed constant and the drag coefficient, C_d , is assumed to be a function of wind speed after the empirical studies

Figure 5a. Ratio of lake wind to land wind after Phillips and Irbe, 1978, as a function of wind speed and air-water temperature.

Figure 5b. Dependence of drag coefficient on wind speed and atmospheric stability employed in the study.

of Smith and Banke (1975) and a function of atmospheric stability of the form, $(1-AT_0)$ which has been employed by McClure (1970). The constant A, was arrived at by trial and error. The behaviour of C_d with wind speed and air-lake temperature difference is shown in Figure 5b. For neutral conditions C_d is 3.0×10^{-3} at a wind speed of 14 m/s which is a typical value employed for storm surge studies in enclosed basins. The effect of stability is to increase the effective drag coefficient under unstable conditions and to decrease it under stable conditions. In the case of Lake St. Clair, since the wind data were measured at the shoreline, experiments were performed employing an empirical relation for the overlake wind speed from the land wind which is based on fetch, wind speed, and atmospheric stability, (Phillips and Irbe, 1978). The behaviour of the wind ratio is shown in Figure 5a for the constant fetch case.

RESULTS

Statistical Methods

Multiple regression analysis of barometric pressures and air-water temperature difference accounted for approximately 60% of the variance of water level fluctuation as defined as the deviation from the undisturbed level before the storm and based upon dependent storms. The largest standard errors of the estimates of 20 cm occurred in the case of Lake Erie as a result of the higher excursions in that lake.

In the case of the smallest of the Great Lakes, Lake St. Clair, use of the six hourly temperatures and pressures at grid spacing separated by 380 km explained only several percent of the variation. Based on hourly wind observations one hour before the forecast time and air-water temperature differences the regression approach accounted for 54% of the variation of 24 dependent storms.

For Lake St. Clair a direct comparison was made between the three statistical techniques. The transfer function approach is evidently superior to the standard multiple regression approach, (Table 1), while the one-step-ahead forecast although not suitable for routine forecasting is the best of the three methods. It may be seen from the example shown in Figure 7 the regression method fails to predict the peak immediately following the main surge. It is thought that one reason for the improvement of the transfer function approach over the standard regression techniques is that it can readily account for resurgences or seiches which in certain cases such as Lake Erie form a significant portion of the storm surge response.

The Dynamical Method

An example of a dynamical forecast employing the spectrally determined impulse response function is compared to the standard regression method in Figure 6 for Lake Erie. In general both methods account for disturbances lasting for periods of half a day or more and that when seiches are present the dynamical model alone accounts for these

Figure 6. Simulation of a storm surge forecast. Port Colborne, Lake Erie, January 1972.

Figure 7. Comparison of various storm surge prediction methods, Lake St. Clair.

TABLE I

% Explained Variance of 24 Storms Lake St. Clair

	Filtered	54
(2) Regression		54
(3) Transfer Function		68
(4) Transfer Function plus one step ahead		90

seiches when the period of the seiche is longer than the six hour forecast period. Of course, neither method can account for seiches when the seiche period is less than the forecast period.

The comparison between the various methods has been examined in most detail for the case of Lake St. Clair. For the purpose of comparison, the storm exhibiting the largest excursion is shown in Figure 7. In this example the dynamical method underestimates the peak slightly more than the other methods. All methods except the one-step-ahead forecast fail to account for the negative surge occurring after the end of the storm. The dynamical method accounts for 49% of the variance of 24 storms. This compares favourably with the regression method when it is considered that the storms are dependent storms as far as the regression technique is concerned and in consideration that no attempt has been made to optimize the coefficients in the stability and wind speed dependence of the drag coefficient.

A characteristic feature of the Lake St. Clair storm surge is the gradual and continuous build up of water level during the storm. The source of these long term trends is not known but it is suspected that they may be due to enhanced river discharge during the storm. In order to remove this influence, both the water levels and winds were filtered by means of a high pass filter. The proportion of explained variance was augmented to 54% in the filtered dynamical forecasts. It may be noted that removal of trends is another reason for the superiority of the transfer function approach.

Finally, it is worth mentioning that correcting the land wind for the overlake effect after the empirical relations of Phillips and Irbe (1978) unexpectedly does not improve the dynamical forecasts. At high wind speeds the lake-land wind ratio approaches unity whereas at low winds, land winds are amplified considerably. Probably at low wind speeds the land winds are more representative of the local conditions on land than over the lake and thus fail to account for the surge.

DISCUSSION

In the regression study treatment of the air-water temperature difference as an independent predictor indicated that taking account of the stability of the atmospheric boundary layer over the water could improve the forecast. The effect of stability is greatest for the smallest lake studied, Lake St. Clair, where 5% of the variance is accounted for by the air-water temperature difference. Taking account of the stability in Lake St. Clair also improved the dynamical forecast results. Unfortunately it was impossible to account for this effect on the dynamical forecasts in the other lakes studied since the air-water temperature difference is not at present a standard forecast element.

Among the storms considered there were frequently cases of sudden changes in water level or shifted peaks in water level that could not be accounted for by either the dynamical or the regression methods.

It is likely that these effects are caused by spatially varying wind fields. In order to examine this method of generation of rapid fluctuations in water level occurring over several hours a simple analytical model was formulated for the generation of storm surges by a travelling stress field.

In a one-dimensional channel of constant depth, h , and length, L , the model equations,

$$\frac{\partial u}{\partial t} = -g \frac{\partial \eta}{\partial x} + \tau / \rho h$$

$$\frac{\partial \eta}{\partial t} + h \frac{\partial u}{\partial x} = 0$$

have the solution for a suddenly turned on uniform wind stress, τ ,

$$\eta(x,t) = -\sum_{m=1,3,5,\dots}^{\infty} \left[\frac{1}{\sigma_m^2} \frac{4\tau}{L\rho} [1 - \cos \sigma_m t] + \eta(0) \cos \sigma_m t + \frac{\partial \eta(0)}{\partial t} \frac{\sin \sigma_m t}{\sigma_m} \right] \cdot \cos \chi_m x$$

where $\sigma_m = \frac{\sqrt{gh_m \pi}}{L}$ and $\chi_m = \frac{\sigma_m}{\sqrt{gh}}$

In the case of a semi-infinite stress band travelling at a speed $v \neq \sqrt{gh}$, starting from a state of rest,

$$\eta(x,t) = \sum_{m=1,2,\dots}^{\infty} \frac{2\tau}{\sigma_m L \rho} \left[\frac{\cos \sigma_m t - 1}{\sigma_m} + \frac{\cos \chi_m vt \cos \sigma_m t}{2\sigma_m + 2\chi_m v} + \frac{\cos \sigma_m t - \cos \chi_m vt}{2\chi_m v - 2\sigma_m} \right] \cos \chi_m x$$

As seen in the accompanying figure in the case of a semi-infinite wind stress, taking account of spatial variation results in a more sharply rising surge than in the uniform case although the peaks occur concurrently when the wind is measured at the shoreline on the side of the lake opposite to the water level gauge.

I Semi-infinite Stress Band Travelling at Speed, v

Downwind water level with respect to wind measured on upwind shoreline versus time.

Solutions for a finite stress field may be constructed from a superposition of the fundamental solutions presented above.

II Stress Band of Finite Width $l < L$

In the above example it may be seen that resonant excitation of the surge results in amplitudes much larger, of different shape and time of arrival than in the spatially uniform case.

CONCLUSIONS

Strictly speaking the results are not exactly comparable; for instance, only in the cases of dynamical forecasts in Lakes Erie and Ontario were true storm surge forecasts simulated. Nonetheless it is possible to draw a number of conclusions from the study.

Based on the applications of several statistical methods and a new dynamical approach to the simulation and forecasting of over three dozen storm surges in the Great Lakes reveals that in most cases all methods account for disturbances lasting for periods of half a day or more, that when seiches are present the dynamical and transfer function methods account for the seiche when the period of the seiche is longer than the forecast period and that these methods fail to account for seiches when the seiche period is shorter than the forecast period.

Horizontal variations in the wind field are particularly important in accounting for fairly rapid fluctuations in the water. Operational forecasts may be improved by a more detailed temporal and spatial resolution of the forecast data including the specification of such subsynoptic disturbances as squall lines and atmospheric pressure jumps. In particular, synoptic forecast surface pressures do not offer sufficient resolution in subsynoptic scale lakes such as Lake St. Clair.

Atmospheric stability is a significant factor in storm surge prediction in enclosed seas as it affects the surface momentum transfer, especially in smaller water bodies. At present the air-water temperature difference is not a standard automated forecast element. Wind speed dependence of the drag coefficient is also a significant influence. The question of correction of land winds for overlake modification is not yet resolved for storm surge forecasting in the Great Lakes but does not appear to improve the forecasts in the case of Lake St. Clair.

It is recommended that attention be given to the removal of long term trends in water levels and meteorological input data when developing and testing forecast relations and that trend removal may result in an improved forecast.

It is concluded from a comparison of various approaches to storm surge forecasting that dynamical and statistical methods give comparable errors. The fact that the discrepancy between the methods is less than between observation and forecasts suggests that the main source of error is due to uncertainties in the meteorological forecasts rather than to the failings of the methodology.

ACKNOWLEDGEMENTS

The author would like to thank W.P. Budgell and A. El-Shaarawi for many useful discussions and for allowing him to use some of their results in the preparation of this manuscript.

CHAPTER 59

Analysis of Storm Tide Waves

by

Volker Barthel*

ABSTRACT

First results of a wave investigation program in the Outer Weser (German Bight of the North Sea) point out, that under storm conditions higher waves than computed by the normal prediction methods are possible in the exterior estuary. In the interior estuary higher waves occur mainly as a sort of swell. The influence of bad weather conditions on the probability of runs of waves with $H^* > H \frac{1}{3}$ is shown in two examples in comparison with a theoretical investigation.

INTRODUCTION

The importance and necessity of field investigations as far as waves are concerned has been underlined by experts again and again. Though there were several investigations in the deep water of the North Sea, in the wadden area and on sandy shores of islands one can't find hardly any in estuaries. There are given computation and prediction methods for straight shores with parallel contours or islands and shores with concentric circular contours, but there is hardly any example for shores, bars and sand-banks with deep channels between them and another bar following a few kilometers behind (1). The knowledge of the often very complicated wave systems in an estuary, i.e. the correlation of water level, tidal currents, waves,

orbital currents and morphological changes leads to an estimation of the effect of waves on structures and morphology (1) in the distinct regions of an estuary and vice versa. For this reason a field investigation program was started in 1975, which is carried out by the Wasser- und Schifffahrtsamt Bremerhaven, an office of the Federal Waterways Administration, and is supported by the Federal Ministry of Research and Technology. FIG. 1 shows a part of the Weser estuary with the locations ST, RSO, RSW, TPO and TPW. The following investigations are planned on this locations in detail:

* Dipl.-Ing., Wasser- u. Schifffahrtsamt Bremerhaven,
2850 Bremerhaven, Federal Republic of Germany

- a. alteration of significant data of waves entering the estuary
- b. distribution of wave energy behind reefs and bars
- c. influence of waves on the morphological shape of the bottom and - vice versa - the influence of morphology on the waves
- d. determination of design data for all structures
- e. influence of waves on the assignment of ships and particularly of long-period-waves on the lurch of deep-drawing ships with a small keel-clearance.

STORM TIDE WAVES

On the 3rd of January, 1976, the wind in the German Bight grew from 16 m/s to nearly 30 m/s (Beaufort 11). The direction changed from 175° (S) to 295° (WNW). The water level at gauge ALTE WESER rose to NPH + 9.10 m, while the mean Low Water (MLW) is NPH + 6.32 m.

STORMTIDE ON JANUARY 2nd/3rd 1967

FIG. 2

Though the wave buoys and gauges were not yet installed completely we succeeded in gaining some data at the locations ST and TPO. A third wave gauge failed by collision with a drifting ship.

Loc. ST lies at a water depth of about 22m. It is to record the waves coming from the open sea and produces prototype data for the exterior estuary. Loc. TPO lies in front of a sand-bank at about 4m water depth and represents the interior estuary.

In FIG. 2 the measured values are plotted as a function of time. You can see the mean and significant wave height H and $H 1/3$ in the exterior, growing with increasing wind-velocity very quickly and becoming smaller with decreasing wind-velocity. Unfortunately the recorder broke down at 3.00 p.m. because the measuring range wasn't expected to be so wide. The mean and significant periods T and $T 1/3$ show nearly the same attitude dependent on wind-velocity.

With a time-lag of about two hours the mean and significant wave heights H and $H 1/3$ come to their maximum values in the interior estuary. A second peak was registered on the 4th of January at about 3.00 a.m. It is obvious that in this case the height follows the water depth during a decreasing wind-velocity. Striking is the strong increase of the periods $T_H 1/3$ in the interior estuary up to values of 16 sec. But I'll come back to this phenomenon later on.

ALTERATION OF HEIGHTS AS A FUNCTION OF WIND - VELOCITY AND WATER DEPTH

As there had been a lot of measurements in the meantime, the slope of wave height, wind-velocity and water depth for this region could be investigated more thoroughly. For this purpose records

at an almost coincident water level or wind velocity were combined. FIG. 4 shows, that in the interior estuary the correlation between \bar{H} respectively $H^{1/3}$ and the water depth ($r= 0.85 - 0.87$) is much better than in the exterior ($r= 0.46 - 0.52$).

FIG. 5 shows a good correlation between heights and wind-velocity for the exterior e. as it is to be found in literature --- mostly as a linear slope. The values obtained in the storm tide ($U=20 - 25$ m/s) fit this drawing.

$H = f(U)$

FIG 6

In FIG. 6 the same values for the interior e. are plotted, split into single graphs for \bar{H} and $H_{1/3}$. In this case the values can be clearly arranged in groups with different water depths, showing that the depth-dependency is more important than in the exterior estuary.

ALTERATION OF WAVE PERIOD AND STEEPNESS

An astonishing fact gave the strong increase of the wave periods in the interior during the storm tide. The significant period $T_{1/3}$ came up to more than 15 s. The evaluation of more data in this field gave the latest findings, that waves in extraordinary weather conditions occur mainly as swell in this region. With the simplified assumption, that

$$L = \bar{T}^2$$

a mean wave length of 80 m is to be found, which may have a dangerous influence on deep-drawing ships in a narrow channel.

One should believe that - similar to a tidal wave - waves coming from the open sea into an estuary become steeper and shorter by shoaling, refraction and diffraction. Just the opposite seems to be true in this case. After evaluating a lot of additional records it could be pointed out, that as a general principle periods become longer during the penetration of waves into this estuary, though there are deep channels between the shoals. The local wind influence seems to be of subordinate importance.

FIG. 7 shows the alteration of the significant wave period $T_{1/3}$ and the so called steepness factor

$$s = \frac{\bar{H}}{g \cdot \bar{T}^2}$$

for two groups of waves with different height.

FIG. 7

You can see that the periods increase and the steepness factor becomes small with decreasing water depth, i.e. while the waves approach the interior estuary. The same phenomenon was detected by SIEFERT (10) with measurements in the wadden sea of the Outer Elbe. (Loc. RSO in this case lies on a bar where breaking of waves occurs at a smaller water depth (Fig. 7).

The increasing period of waves penetrating the interior estuary necessarily reduces the steepness factor s with a constant or decreasing height. While in the exterior estuary during a high wind velocity and water depth (that is for example during a storm tide) the steepness increases and comes to a constant value (limitation line of the scattered values of $s = \frac{\bar{H}}{gT^2}$);

the scattering of values with a larger water depth in the interior e. is wider, the maximum values however are smaller. The values for a different wind-direction are plotted in comparison to show the irritability of wave climate against the different factors of influence. Obviously the steepness in the interior e. decreases with increasing mean wave height, dependent on wind-direction

and therefore the fetch-length too. This fact seems to be important for the design criteria of structures.

Alteration of wave parameters

FIG. 9 shows the mean period \bar{T} as a function of the mean wave height \bar{H} . Apart from the differences between the interior and exterior e. on normal conditions one can see, that a storm tide causes a considerable alteration of wave characteristics. By this chance it becomes obvious that abnormal wind conditions evoke shorter periods and steeper waves in the exterior, while in the interior just the opposite is true.

FIG. 10 shows the mean ratio of periods and height in the interior and exterior e. during normal and storm conditions.

TABLE 1 (FIG. 10)

		(16 REC)				

In a few words:

Interior: The ratio of the mean to the sign. periods increases at a storm tide very much. That is a hint to the transformation into swell. The ratio of the height doesn't change so much; maximum height decreases.

Exterior: Wave periods become smaller, the waves therefore become steeper. The ratio of mean to significant respectively maximum height increases. These results fit the frame of the words said before.

MAXIMUM WAVE HEIGHT

Because in the Outer Weser no investigations in the wave field had been carried out for a long period, the results of the storm-tide records were astonishing and startling at the same time, especially because the high wind-velocities had had only a short-time-occurrence and the direction had changed permanently. After Mc Cowan a theoretical maximum wave height (for deep water) $H_{max} = 0.78 d = \sim 19 \text{ m}$ ($d = 24 \text{ m}$) is possible. But waves with higher wind-velocities in the German Bight with its limited water depth are to be considered as shallow water waves and therefore wall turbulence friction takes effect in addition to the free turbulence friction. Wave energy and height are reduced by this. DRAPER (3) has predicted (for this region of the North Sea) a maximum wave height of 17 m under conditions of a 50-year-design storm with a duration of 12 hours.

If you consider a design storm with

wind-velocity: $U = 40 \text{ m/s}$

duration: $t = 5 \text{ hours}$

fetch-length: $F = 250 \text{ km}$

effective fetch: $w = 150 \text{ km}$

different prediction methods for the German Bight result in a significant wave height

of

$$H_{1/3} = 7.0 - 10.5 \text{ m (8)}.$$

With the revised prediction method of BRETSCHNEIDER (2) for shallow water under the above mentioned conditions a significant wave height of

$$H_{1/3} = 6.70 \text{ m was evaluated for the exterior e.}$$

and with the ratio of

$$\frac{H_{\max}}{H^{1/3}} = \left(145 \frac{g \cdot d}{U^2} \right)^{0.1} \pm 10\% \quad (2)$$

a maximum wave height of 10.0 m is possible.

ROLL (6) deducts a maximum wave height up to 8.0 m from observations on lightships. During the storm tide of January 3rd a significant wave height of

$$H_{1/3} = 6.72 \text{ m was registered in}$$

the exterior estuary until the instrument failed. The max. wave height, which could be read in the incomplete record, was

$$\underline{10.0 \text{ m}} \text{ (end of registration width).}$$

According to the steepness of the wave and its incomplete period one could estimate its height of about

$$\underline{12 - 13 \text{ m.}}$$

The maximum height in the interior estuary can hardly be predicted by well-known methods, because the ratio of

$$\frac{H_{\max}}{d} = f(d, \text{topography}),$$

which is a function of water depth and surrounding topography (10), is very complicated in this area.

The highest possible propagating wave is after KISHI (5)

$$H_{\max} = 0.9 d \quad \text{for } d < 0.1 L$$

$$H_{\max} = 0.146 d \quad \text{for } d > 0.4 L$$

(with a parabolic change between the two borders)

For normal waves with $L = \bar{T}^2$:

$$H_{\max} = 0.9 d \quad \text{for } d < 0.1 T_{H_{\max}}^2$$

$$H_{\max} = 0.146 T_{H_{\max}}^2 \quad \text{for } d > 0.4 T_{H_{\max}}^2$$

and with the given ratio of mean to significant period $\bar{T}/T_H^{1/3}$ respectively max. period $\bar{T}/T_H^{1/3}$ the max. height becomes

$$H_{\max} = 0.9 d \quad \text{for } d < 0.18 \bar{T}^2$$

$$H_{\max} = 0.26 \bar{T}^2 \quad \text{for } d > 0.72 \bar{T}^2$$

The theoretical max. height $H_{\max} = 8.4 \text{ m}$ for gentle slopes.

The comparison between normal and storm conditions in FIG. 12 turns out, that with the investigated wind-directions a higher probability of consecutive waves $H^* > H_{1/3}$ is not to be found. Its obvious that in the interior e. shorter runs of waves occur under bad weather conditions. This seems to be important for the design of all structures in this area.

FIG. 12

CONCLUSIONS:

The results of the relatively short measurements during the storm tide in comparison with records under more normal conditions can be comprised as follows:

- The wave heights in the exterior e. are mostly wind-dependent, while the local wind-influence in the interior e. is subordinate to the water depth.
- After wind-velocities more than 15-20m/s the higher waves in the interior e. occur with long periods changing to a sort of swell. Therefore there is a certain danger for deep-drawing ships, which has to be investigated more thoroughly. Max. wave heights are influenced by the reefs and bars in front of the interior e. and are reduced at a rate of about 50 - 60 %.
- The max. heights in the exterior e. came up to a value of more than 10.0 m already in a short storm. Heights of more than 15.0 m are not impossible.
- The wave parameters change with a different range in unusual weather conditions according to the above mentioned facts.
- Runs of waves with $H^* > H_{1/3}$ don't occur more often under bad weather conditions than normally. In the exterior e. the distribution fits a theoretical one; in shallower water it is nearly the same as in the adjacent area of the Outer Elbe.

In the present investigations the influence of tidal currents upon

According to the measurements in question this height cannot be found in the interior estuary, because a considerable transformation of energy occurs on the reefs and bars. During the storm tide the measured max. wave height read

$$H_{\max} = 4.05 \text{ m with a period of } 18.2 \text{ s.}$$

Later on we gained records after two hours with wind from WNW with 20 m/s, in which the max. height was 3.5 m with a period of 12s.

CONSECUTIVE HIGH WAVES

In addition to the highest water level and max. or significant wave height a certain dynamic strain by vibration or perhaps resonance caused by a run of waves of certain height can be important for the design of structures in coastal areas. Because of the unexpected high waves it was of great interest, to analyse the records of the storm tide and those under normal conditions in this regard. The problem has already been treated numerically by GODA (1970) (4) for wide spectra. Evaluations of field data under storm conditions were done by RYE (1975) (7). SIEFERT (1976) (9) determined the probability of consecutive high waves for an adjacent area of the Outer Elbe with its wadden sea. A comparison of the results is plotted in FIG. 11.

FIG. 11

The drawing in semi-logarithmic scale shows, that the probability of groups of waves greater than the significant wave height $H_{1/3}$ in the exterior estuary best fits the theory of GODA (4). In the computation of 40 records there was no run of more than 3 consecutive waves. The probability in the interior e. shows a good correspondence with the results in the Outer Elbe.

the wave parameters has been neglected. It will be the task for the next time to find out this influence by measurements for distinct regions of the Weser estuary.

CHAPTER 60

COASTAL FLOOD SIMULATION IN STRETCHED COORDINATES

by

H. Lee Butler
Wave Dynamics Division, Hydraulics Laboratory
USAE Waterways Experiment Station
Vicksburg, Mississippi

ABSTRACT

Coastal flooding in developed areas can be catastrophic. As an essential element in coastal water level prediction, a two-dimensional numerical model of long period wave behavior is presented. The time dependency is treated implicitly for cost-effective simulation of coastal flooding from hurricane surges or other hydrodynamic phenomena such as extratropical storm surges, tides, tsunamis, etc.

An important feature of the model is use of a coordinate transformation in the form of a piecewise exponential stretch. Such a technique permits simulation of a complex landscape by locally increasing grid resolution and/or aligning coordinates along physical boundaries.

The model is applied to Galveston Bay, Texas, for storm surge and coastal flooding from Hurricane Carla 1961. Verification for the Galveston area was accomplished by using physical model data from simulations of free gravity waves (tide and design surge). Subsequent hindcasting of Carla produced good agreement between observed and computed surges with a mean absolute error of 0.18 m for peak elevations.

INTRODUCTION

Reliable prediction of coastal inundation from tidal or hurricane surge is extremely complex and is usually complicated by the presence of channels, barriers, bays, and highly variable bathymetry and topography which redistribute water flooding inland from the open sea. The Corps of Engineers, and in particular, the Waterways Experiment Station (WES), have had to address the problem of providing reliable estimates of coastal flooding in order to make sound engineering decisions regarding the design, operation, and maintenance of various coastal projects. Physical models have been used in the past to simulate free gravity surge, however they have the disadvantage of not being able to effectively simulate wind effects. The need of a more generalized numerical model for treating the flooding from storm surges (Wanstrath et al., 1977) in coastal areas has therefore been apparent for some time. Many two-dimensional storm surge models have been presented in the literature during this decade. Each model has exhibited certain advantages but most models have been developed for application to specific locations. The model presented here has been under development at WES (Butler and Raney, 1976; Butler, 1978) for use in storm surge applications as well as other applications where shallow water wave equations can be employed.

The most popular approach to solving the system of differential equations describing storm driven surges has been the application of finite difference techniques (Reid and Bodine, 1968; Leendertse, 1967, 1970, 1971; Pearce, 1972; Reid et al., 1975; Wanstrath, 1976). The model described herein, known as the WES Implicit Flooding Model (WIFM), employs the implicit solution scheme developed by Leendertse (1967). Dependent variables of the centered, alternating-direction procedure used in the model are the vertically integrated fluid transports and surface elevations as a function of position and time. Included in the model are actual bathymetry and topography, time and spatially variable bottom roughness, inertial forces due to advective and coriolis accelerations, rainfall, and spatial and time-dependent wind fields. Horizontal diffusion terms in the momentum equations are optionally present and can be used, if desired, for aiding stability of the numerical solution. Inundation, drying, and/or draining of low-lying terrain during a hurricane surge is simulated by making the location of a land-water boundary a function of local water depth. The model also is capable of treating subgrid barrier effects. Exposed, submerged, and overtopping barriers can be represented within the grid system permitting proper simulation of surge waters breaching narrow barriers such as elevated highways, railroads, control structures, etc. WIFM uses a coordinate transformation in the form of a piecewise exponential stretch to map real space, discretized with a smoothly varying grid, into computational space employing a regular spaced grid. Such a scheme permits a local increase of resolution in strategic areas while minimizing computational cost.

Calculation of coastal water levels from surges requires an estimation of storm windfields. The hurricane windfield model currently used in WIFM follows that used by Jelesnianski (1965) and Wanstrath (1976). An improved windfield model has been suggested by Cardone (1969) and research is ongoing to extend the work of Resio and Vincent (1977) and Cardone to develop a planetary boundary layer windfield model which also accounts for windfield transformation as the storm propagates from the open ocean across coastal flood-prone lands.

Application to Galveston Bay included verification to physical model data and subsequent simulation of storm surge and coastal flooding from hurricane Carla. An open-coast curvilinear coordinate surge model of the continental shelf (Wanstrath, 1977) was used to specify seaward boundary conditions for WIFM. Hindcast results for Carla indicate WIFM's predictive capabilities.

SHALLOW WATER WAVE EQUATIONS

The hydrodynamic equations used in WIFM are derived from the classical Navier-Stokes equations in a Cartesian coordinate system (Fig. 1). By assuming vertical accelerations are small and the fluid is homogeneous, and integrating the flow from sea bottom to water surface, the usual two-dimensional form of the equations of momentum and continuity are obtained:

FIGURE 1. CARTESIAN COORDINATE SYSTEM.

MOMENTUM

$$\frac{\partial U}{\partial t} + \frac{\partial}{\partial x} \left(\frac{U^2}{d} \right) + \frac{\partial}{\partial y} \left(\frac{UV}{d} \right) - fV + gd \frac{\partial}{\partial x} (s - s_a) + F_x + \frac{gU}{C^2 d^2} (U^2 + V^2)^{1/2} - de \left(\frac{\partial^2 U}{\partial x^2} + \frac{\partial^2 U}{\partial y^2} \right) = 0 \quad (1)$$

$$\frac{\partial V}{\partial t} + \frac{\partial}{\partial x} \left(\frac{UV}{d} \right) + \frac{\partial}{\partial y} \left(\frac{V^2}{d} \right) + fU + gd \frac{\partial}{\partial y} (s - s_a) + F_y + \frac{gV}{C^2 d^2} (U^2 + V^2)^{1/2} - de \left(\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} \right) = 0 \quad (2)$$

CONTINUITY

$$\frac{\partial s}{\partial t} + \frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} = R \quad (3)$$

where s is the water surface elevation; s_a is the hydrostatic elevation corresponding to the atmospheric pressure^a anomaly; U , V are the vertically integrated transports per unit width at time t in the x and y directions, respectively; $d = s - h$ is the total water depth; h is the still water elevation; f is the Coriolis parameter; C is the Chezy frictional coefficient; g is the acceleration of gravity; e is a generalized eddy viscosity coefficient; R represents the rate at which additional water is introduced into or taken from the system (for example, through

rainfall and evaporation); and F_x , F_y are terms representing external forcing functions such as wind stress in the x and y directions.

Many numerical modelers have found it difficult to obtain meaningful solutions to the above equations when advective terms (second and third terms of equations 1 and 2) are included. Current research at WES is underway to assess the role of advective terms in the numerical simulation of long period, large amplitude water wave behavior in coastal regions. These terms are not included in the application presented herein, but have been modeled successfully in other simulations (Butler, 1976, 1978). The last terms in the momentum equations are representative of equivalent internal stress resultants due to turbulent and dispersive momentum flux (Vreugdenhil, 1973). They provide a mechanism for dissipating wave energy of wavelength on the order of twice the spatial step by smoothing curvatures developing in the solution. Since energy is transferred to this scale by the non-linear advective terms and these terms have been neglected in the Galveston Bay application, the flux terms have also been omitted. Both terms are presented here for completeness.

STRETCHED COORDINATES

A major advantage of WIFM is the capability of applying a smoothly varying grid to the given study region. For each direction a piecewise reversible transformation (analogous to that used by Wanstrath, 1976) is independently used to map prototype or real space into computational space. The transformation takes the form

$$x = a + b\alpha^c \quad (4)$$

where a, b, and c are arbitrary constants. The transformation is such that all derivatives are centered in α -space. By applying a smoothly varying grid whose functional as well as first derivatives are continuous, many stability problems commonly associated with variable grid schemes are eliminated. A time-share code has been designed to calculate the mapping defined by equation (4) allowing complete control of grid resolution at any point along each grid axis.

By using equations similar to (4) the equations of motion in α -space can be written as

MOMENTUM

$$\frac{\partial U}{\partial t} + \frac{1}{\mu_1} \frac{\partial}{\partial \alpha_1} \left(\frac{U^2}{d} \right) + \frac{1}{\mu_2} \frac{\partial}{\partial \alpha_2} \left(\frac{UV}{d} \right) - fV + \frac{gd}{\mu_1} \frac{\partial}{\partial \alpha_1} (s - s_a) + F_{\alpha_1} + \frac{gU}{C^2 d^2} (U^2 + V^2)^{1/2} - T_1 = 0 \quad (5)$$

$$\frac{\partial V}{\partial t} + \frac{1}{\mu_1} \frac{\partial}{\partial \alpha_1} \left(\frac{UV}{d} \right) + \frac{1}{\mu_2} \left(\frac{V^2}{d} \right) + fU + \frac{gd}{\mu_2} \frac{\partial}{\partial \alpha_2} (s - s_a) + F_{\alpha_2} + \frac{gV}{C^2 d^2} (U^2 + V^2)^{1/2} - T_2 = 0 \quad (6)$$

CONTINUITY

$$\frac{\partial s}{\partial t} + \frac{1}{\mu_1} \frac{\partial U}{\partial \alpha_1} + \frac{1}{\mu_2} \frac{\partial V}{\partial \alpha_2} = R \quad (7)$$

where

$$\mu_1 = \frac{\partial x}{\partial \alpha_1} = b_1 c_1 \alpha_1^{c_1 - 1} \quad (8)$$

$$\mu_2 = \frac{\partial y}{\partial \alpha_2} = b_2 c_2 \alpha_2^{c_2 - 1} \quad (9)$$

Quantities μ_1 and μ_2 define the stretching of the regular spaced computational grid in α -space to approximate a study region in real space. The terms T_1 and T_2 represent the transformed flux terms.

FINITE DIFFERENCE MODEL

Since obtaining a solution to the governing non-linear equations on a region with highly complex geometry and topography is intractable using a pure analytical approach, a numerical technique is employed. A variable rectilinear grid is first developed for the model area. The appropriate variables are defined on the grid in a space-staggered fashion as depicted in Fig. 2 for a typical cell.

FIGURE 2. COMPUTATIONAL CELL DEFINITION.

An alternating-direction technique (Leendertse, 1967) is used to develop a finite difference scheme for solving the transformed equations (5-7). Computations are separated into two cycles corresponding to a sweep of the grid in both directions. The first cycle consists in solving for s and U implicitly; the second cycle computes s and V implicitly. The omitted transport is assumed constant for that cycle. Applying a centered difference operator to the momentum equation (5), and the continuity equation (7), along a grid line parallel to the x -axis, results in a system of linear algebraic equations whose coefficient matrix is tri-diagonal. The form of the difference equations for the first cycle is given by

$$\begin{aligned}
 U_{n,m+1/2}^{k+1/2} = & U_{n,m+1/2}^{k-1/2} + \Delta t \left\{ f\bar{v}_{n,m+1/2}^k + F_{\alpha_1}^k - \frac{g}{2\Delta\alpha_1} \left(\frac{d^*}{\mu_1} \right)_{n,m+1/2} \right\} s_{n,m+1}^{k+1/2} \\
 & - s_{n,m}^{k+1/2} + s_{n,m+1}^{k-1/2} - s_{n,m}^{k-1/2} - 2 \left[(s_a)_{n,m+1}^k - (s_a)_{n,m}^k \right] \left\{ \right. \\
 & \left. - \frac{g \left(U_{n,m+1/2}^{k+1/2} + U_{n,m+1/2}^{k-1/2} \right)}{2(d^*C^k)^2} \left[\left(U_{n,m+1/2}^{k-1/2} \right)^2 + \bar{v}_{n,m+1/2}^2 \right]^{1/2} \right\} \quad (10)
 \end{aligned}$$

$$\begin{aligned}
 s_{n,m}^{k+1/2} = & s_{n,m}^k - \frac{\Delta t}{2} \left[\frac{1}{\Delta\alpha_1(\mu_1)_m} \left(U_{n,m+1/2}^{k+1/2} - U_{n,m-1/2}^{k+1/2} \right) \right. \\
 & \left. + \frac{1}{\Delta\alpha_2(\mu_2)_n} \left(V_{n+1/2,m}^k - V_{n-1/2,m}^k \right) \right] + \frac{\Delta t}{2} R_{n,m}^k \quad (11)
 \end{aligned}$$

where $d^* = \bar{s}^k - \bar{h}$. In these expressions a single bar represents a two point average and a double bar a four point average. The subscripts m and n correspond to spatial locations and superscript k to time levels. Equations for the second cycle are similar to (10) and (11) and are not presented.

The implicit difference scheme when applied to the linear system of governing equations exhibits unconditional stability as shown by Leendertse (1967). Longer time steps are usually permissible with the implicit scheme in contrast to explicit formulations. In many instances this fact permits a more cost-effective simulation. Inclusion of non-linear terms into the implicit scheme, however, may result in an inherent

instability. As mentioned previously, flux terms have been used to overcome this problem but current research is being directed at finding a more satisfactory solution without giving up advantages of the implicit procedure. Weare (1976) has attempted to analyze conditions under which the system is unstable and has obtained a condition which relates velocity, advection, and friction. A fully time-centered scheme is suggested to avoid the problem.

A variety of boundary conditions are employed throughout the computational grid. These include prescribing water levels or flow rates, fixed or movable land-water boundaries, and subgrid barrier conditions.

Open boundaries. Included in this category are seaward boundaries terminating the computational grid or channels exiting the two-dimensional grid at any point in the system. Water levels or flow rates are prescribed as functions of location and time, and are given as tabular input to the code. For economical storm surge application, an open coast surge model may be used to develop the open sea boundary values to drive the inland flooding model.

Water-land boundaries. These conditions relate the normal component of flow at the boundary to the state of the water level at the boundary. Hence, water-land boundaries are prescribed along cell faces. Fixed land boundaries are treated by specifying $U = 0$ or $V = 0$ at the appropriate cell face. Low-lying terrain may alternately dry and flood within a tidal cycle or surge history. Inundation is simulated by making the location of the land-water boundary a function of local water depth. By checking water levels in adjacent cells a determination is made as to the possibility of inundation. Initial movement of water on "dry" cells is controlled by using a broad crested weir formula (Reid and Bodine, 1968). Once the water level on the "dry" cell exceeds some small prescribed value, the boundary face is treated as open and computations for s , U , and V are made for that cell. The drying of cells is the inverse process. Mass conservation is maintained within these procedures.

Subgrid barriers. Such barriers are defined along cell faces and are of three types: exposed, submerged, and overtopping. Exposed barriers are handled by simply specifying no-flow conditions across the appropriate flagged cell faces. Submerged barriers are simulated by controlling flow across cell faces with the use of a time dependent frictional coefficient. Overtopping barrier is a terminology used to distinguish barriers which can be submerged during one segment of the simulation and totally exposed in another. Actual overtopping is treated by using a broad-crested weir formula to specify the proper flow rate across the barrier. Water is transferred from the high to low side according to this rate. Once the barrier is submerged (or conversely exposed), procedures as described for submerged barriers (or exposed) are followed.

Graphics play an important role in presenting model results. Typical model output and data displays for W1FM include water level hydrographs,

contours of water levels over the computational region, time history plots of velocity and volumetric discharge, and vector plots of either velocities or transports over the computational region. Normally, output from this model is used to produce color slides and color movies facilitating portrayal of the coastal flooding.

APPLICATION TO GALVESTON BAY

Galveston Bay, located in southeast Texas, is a large shallow bay covering more than 1000 square kilometers. There are three Gulf of Mexico entrance channels to the bay system, Galveston Entrance Channel, San Luis Pass Channel, and Rollover Pass Channel. Since Rollover Pass is so narrow and carries no more than one percent of the total discharge, it was not included in the simulation. The major channels in the bay are the Houston Ship Channel, Trinity River Channel, Galveston Channel, Texas City Channel, and the Intracoastal Waterway. The average depth of the bay is 2.75 meters while major channels average over 9 meters depth.

The objective of this application was to evaluate and/or illustrate WIFM's use as a predictive tool in simulating coastal flooding. By hindcasting the storm surge and flooding from hurricane Carla (1961) in the Galveston Bay area, such an assessment could be made. The first step was to verify the model for the study area. A variable grid consisting of 3572 grid cells was developed for the Galveston Bay region. The minimum cell width used was 604 meters and the maximum was 2583 meters. Various subgrid barriers were used throughout the grid system to represent features such as jetties, spoil banks, reefs, and major elevated highways. A one-dimensional channel computation extended 30 kilometers beyond the two-dimensional grid for simulating the Houston Ship Channel. A time step of 180 sec per cycle (permissible in the implicit scheme) was selected for both the verification and hindcast phases of application. Fig. 3 depicts the Galveston Bay grid and gage locations used in establishing high water marks and hydrographs for comparison with observed data.

VERIFICATION

The objective of the verification phase of any model study is to demonstrate the model's ability to produce results that agree with data for known conditions. Such a test gives a reasonable degree of confidence for applying the model as a predictive tool. The difficulty in attempting to verify a model for storm surge is usually a lack of prototype data. In the case of Galveston Bay a physical model study was conducted at WES and reported by Brogdon (1969). A wealth of both prototype and physical model data was available for the verification process. Unfortunately the prototype tide data included wind effects, the magnitude of which were unknown. Consequently, it was decided to use physical model results (both for a normal tide and a design surge) in this phase of the study.

Gage locations for verification purposes are shown in Fig. 3. Seven tide gages and four velocity stations were used, and gages T-A, -B,

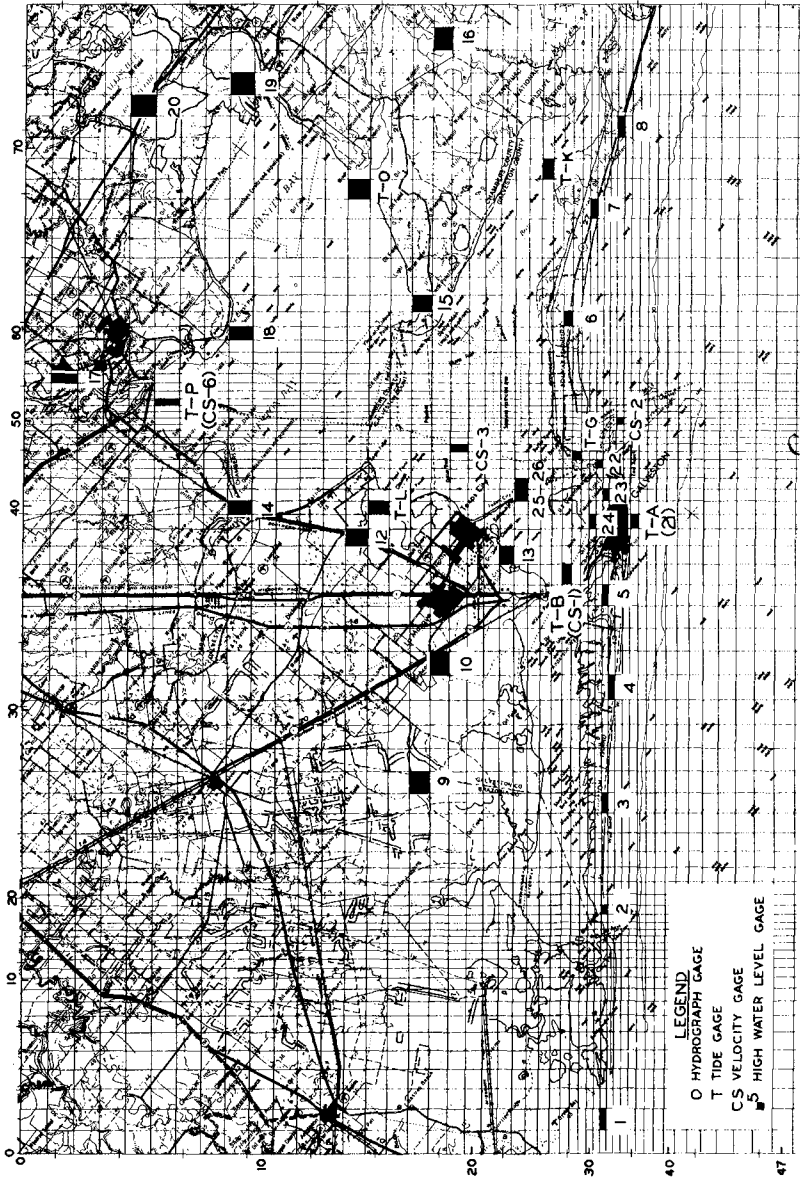

FIGURE 3. COMPUTATIONAL GRID AND GAGE LOCATIONS FOR GALVESTON BAY.

-L, -P and station CS-2 are presented in Figs. 4-8 for displaying sample results. Computation was begun at $t = -2$ hr, setting the entire water surface down to -0.2 meters msl and assuming a quiescent body of water.

As an additional check and test of the model's predictive capability, an application for a large radius high translation design surge (Brogdon, 1969) was performed. The design surge had a peak elevation of 4.4 meters and a duration of 20 hr. The WIFM simulation was terminated at hour 18. Comparison for gages T-A, -B, -L, and -P between physical and numerical model are displayed in Figs. 9-12. The results were in good agreement at most gages indicating that the model was ready for use in a predictive mode.

Experience in using the model has indicated that once proper resolution of the study area is adopted, application can be carried out with minimal adjusting or tuning of the model. The major adjustment made in the verification phase of the Galveston Bay application was a change in frictional characteristics of the Galveston entrance channel.

CARLA HINDCAST

In order to hindcast surge elevations and coastal flooding from hurricane Carla, two major forcing functions were required: time dependent open sea boundary values and a time and spatially dependent wind field describing winds from Carla. Open sea boundary values were developed by first applying an orthogonal curvilinear open-coast surge model (SSURGE 111, Wanstrath, 1977) to the continental shelf region. The curvilinear model avoids necessity of stairstepping the coastline eliminating problems associated with such an approximation. The open-coast model also has a finite-height barrier coast boundary condition and allows for ponding areas. Therefore the boundary conditions computed by SSURGE 111 for WIFM are not contaminated with excess water caused by an infinite wall boundary condition commonly used in open-coast models. Both WIFM and SSURGE 111 employ the same wind model using appropriate modifications to account for wind deformation due to land influence (Shore Protection Manual, 1977). This model and the atmospheric pressure model are given by Jelesnianski (1965) but modified by Wanstrath (1976). An additional parameter, maximum wind speed, is required by the wind model. Values for this parameter cannot always be obtained, an important disadvantage for simulating hurricane winds in a predictive mode. The problem can be resolved by incorporating a wind model, based on the physics of the marine boundary layer, that will provide a windfield as a result of dynamic meteorological computations. The composite model would be appropriate for both forecasting and hindcasting. However, the wind model used in this study did produce results in good agreement with observed meteorological data. Comparison of computed and observed wind speed at the Weather Bureau Office, Galveston, Texas, is depicted in Fig. 13. Wind direction comparison for this station is shown in Fig. 14. The astronomical tide was included in the open coast simulation (and consequently in the driving function for the seaward boundary conditions for the inland flooding model) to eliminate uncertainties due to the linear superposition of tide and surge elevations.

FIGURE 14. COMPARISON OF COMPUTED AND OBSERVED WIND DIRECTION AT GALVESTON, TEXAS.

The variable grid employed by WIFM is of finer resolution and lies askew to the open-coast grid, and thus interpolation of discrete values of water level from the open-coast grid is required. The interpolation scheme is based on a four-point, distance-weighted averaging procedure. The open-coast simulation, began at 12 noon on 8 September 1961, continued for 93 hours to 0900 on 12 September, and was calibrated to give good agreement between observed and model data at Pleasure Pier (gage 21, same as T-A). For economy of application the inland simulation was begun at hour 18 of the open-coast run and continued for 72 hours to hour 90. The water level throughout the model area at hour 18 was approximately 1.1 meters and thus the bay was spun up from a quiescent state with initial elevation of the entire bay at +1.1 meters. No change in model parameters was made after the verification phase was completed. Fig. 15 displays observed and model results at the Pleasure Pier open coast gage 21. Additional hydrograph comparisons are given in Figs. 16 and 17 for gages at Pelican Bridge (24) and Texas City Dyke-North (26). The major difficulty in the application was the calibration of the wind model to simulate Carla's winds. The overshoot in the computed results around program hours 60-66 is possibly due to the inability of the wind model to account for sheltering effects from the city of Galveston (winds were directly on-shore during this period).

Table 1 illustrates a comparison of observed high-water levels at various locations throughout the system with those computed by WIFM. Mean absolute error for 26 gages was 0.18 meters. The largest deviation from observed high water levels at any one gage was 0.64 meters at Sea Isle Beach (gage 3). The observed peak water level at Sea Isle was nearly 0.5 meters higher than that at any neighboring gage, indicating (assuming the data were correct) that some local anomaly existed which was not modeled by WIFM. All observed data were taken from a USAE Galveston District Report (1962). Peak elevation data were obtained from a tide gage reading crest of tide or still high water elevation marks. The reported gages were taken as representative of conditions experienced around the bay.

CONCLUSIONS

The following conclusions can be drawn from the material presented:

1. A two-dimensional implicit finite difference coastal flooding model in stretched coordinates has been developed. It is applicable to predict coastal flooding from storm surges, tides, tsunamis, or any long-period wave phenomena where boundary conditions can be specified.
2. The variable grid characteristic of WIFM (its principle advantage relative to other two-dimensional models) permits the capability to obtain finer resolution in important local areas without sacrificing economical application of the model.
3. A verification of the efficacy of the model was clearly demonstrated through application of the model to hindcast hurricane surge

elevations and coastal flooding for Hurricane Carla. The mean absolute difference between observed and computed water levels was 0.18 m and the observed and computed hydrographs (time dependency of surge elevations) were in good agreement.

4. The relative ease of application, variable grid capability, implicit computing scheme, and flexible output characteristics (when considered together) make W1FM a very useful model for performing practical engineering computations to aid in the solution of real-world problems.

RECOMMENDATIONS

A number of recommendations for future efforts are apparent as a result of the work contained herein and are delineated below:

1. Although W1FM has been successfully applied with the nonlinear advective terms incorporated into the solution on several occasions, there are more stability problems associated with their use than desirable. Additional research is needed to develop better methods of treatment of these instabilities. Some work is proceeding along these lines at WES and it is hoped that others also will actively pursue this important problem in order to minimize the time when use of the nonlinear advective terms in practical engineering applications becomes routine.

2. Additional research also is needed to better define the role of the advective terms in problems involving catastrophic flooding (such as storm surges and tsunami inundation). It may turn out that the advective terms have little effect on the extent of catastrophic flooding, in which case, they may be neglected from a practical engineering point of view.

3. Simulation of narrow rivers or channels would be improved in W1FM with even more potential cost savings by incorporation of a scheme similar to that of Reid et al. (1975) which uses the concept of dynamically coupled one-dimensional subgrid channels. It is planned to add this capability to W1FM during the next application of the model.

4. For storm surge predictions, a planetary boundary layer wind-field model which also accounts for windfield transformation from ocean to land would represent a substantial improvement to W1FM and other two-dimensional flooding models.

ACKNOWLEDGEMENTS

The author wishes to acknowledge the Office, Chief of Engineers, for granting permission to publish this paper and Dr. J. J. Wanstrath, Research Oceanographer, Wave Dynamics Division, WES, for his many helpful discussions during the various phases of this study.

CHAPTER 61

ADJUSTMENT AND VERIFICATION OF THE RANDELTA II MODEL

A. Langerak,¹ M. A. M. de Ras,² and J. J. Leendertse³

I. INTRODUCTION

In the mid-1950s the Netherlands government embarked on a massive construction program, called the Delta Plan. Its purpose was to enhance protection from floods caused by the North Sea in the estuaries of the Rhine, Meuse and Scheldt. According to the plan, all connections to the sea were to be closed by dams, except the New Waterway to Rotterdam and the Western Scheldt. In 1974 all dams and dikes were complete except the dam closing off the Eastern Scheldt from the sea. In view of growing opposition to a complete closure, plans were revised in 1976, and instead of the dam, a storm surge barrier will be constructed. This barrier will reduce the tidal range in the Eastern Scheldt and will be closed during storm surges.

In support of engineering and environmental studies related to the construction and operation of this barrier, a large numerical model has been developed, which covers the Eastern and Western Scheldt and the adjacent offshore area. The section of the North Sea which is included in the model is about 120 km long and 30 km wide, running from Blankenberghe in Belgium to Scheveningen in the Netherlands (Fig. 1).

The bathymetry of the model area varies widely. In general it slopes from the shore to about 25 m at 30 km from the coast. In certain sections of the offshore area, the bottom is relatively flat; in other areas it has offshore bars and the bottom contains underwater sand dunes with a height of several meters. In the estuaries the tidal flow has scoured deep channels. The tidal flats near the North Sea are generally sandy, but the ecologically important tidal marshes located more inland contain much finer material.

The flow and the water levels in the region which is modeled are generally tide-induced. However, the influence of meteorological effects is always present and sometimes dominates water movements and water levels (storm surges). The influence of the fresh water discharges is of much less importance; generally their effects can only be noticed in the immediate vicinity of the discharge.

The tides in the offshore area of the model are part of the complicated tide system in the North Sea. The semidiurnal tidal wave propagates along the coast in a northeasterly direction. During this propagation the amplitude reduces from about 1.90 m near Blankenberghe to about .85 m near Scheveningen.

² Rijkswaterstaat, Delta Service, The Netherlands

³ The Rand Corporation, Santa Monica, California, U.S.A.

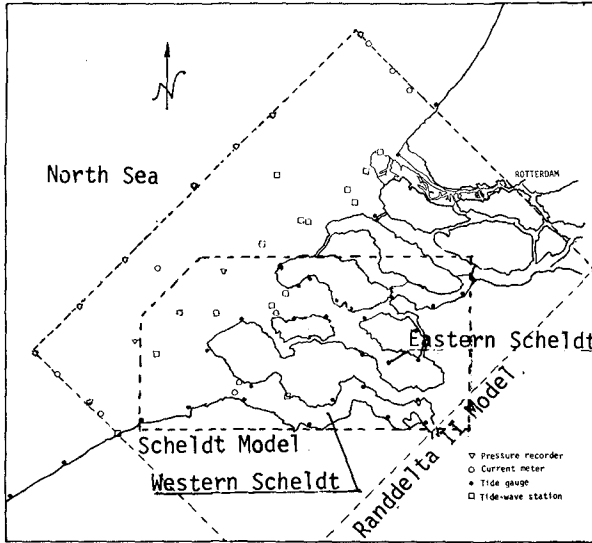

Fig. 1--Layout of models and location of recording stations

In the Eastern and Western Scheldt, the semidiurnal tidal wave penetrates into the estuary and is partially reflected. In the Eastern Scheldt the amplitude increases from 1.35 m near the mouth to 1.95 m at the eastern extremity; in the Western Scheldt the amplification is from about 1.75 m near Vlissingen to 2.30 m at the Dutch-Belgian border.

As the tides are waves, the best visual representation can be obtained by looking at amplitude and phase relations between stations. In Fig. 2 the results of such an analysis are presented in the form of a polar plot of frequency response estimates for the semidiurnal tide. The top part of the figure shows how the respective amplitude and phase relations were established by cross-spectral analysis and the locations of the recording instruments. All stations are numbered and the respective amplitude and phase are shown in relation to a station in the center of the model. For example, station 26 (Rak Zuid Volkerak) lags 1.6 hours behind the reference station 13 (BG II) and is about 1.6 times as large.

The diurnal tide is much smaller and is not much amplified in the model area. In some parts of the model area, the nonlinearities in the hydrodynamics generates strong overtides. This is particularly the case in the northern part of the model. Figure 3 shows the observed water levels obtained by a bottom pressure recorder during the survey described in Ref. 1, corrected for density variations, settling and atmospheric pressure. In the same graph, the quarter-diurnal tide component is shown. This component was obtained by filtering the tide data with Coulomy's quarter-diurnal bandpass filter, described by Godin [2]. The existence of these strong nonlinearities in the system complicated the modeling work considerably.

Fig. 2--Polar plot of the frequency response estimates of the semidiurnal tide from a central station (BG II) to other stations in the model area

The velocities in the model area vary considerably in space and time. The large variations which are present near tidal channels put high demands on the stability of the computation method and the accuracy of the representation of these spatial variations.

In the estuaries the tidal current can be as high as 1.50 m/s in the offshore area; the currents range from 0 to 1 m/sec.

The seaward boundaries of the Randdelta II model are situated at the same location as the boundaries of an earlier model with a much coarser grid. Only the model area at the northern end was reduced. The location of the boundaries of that model were determined on the basis of a numerical model study of the southern North Sea with a model described in Ref. 3. Studies with that model indicated that the influence of the closure dams in the Delta region on the water levels at the boundary of the Randdelta models would be very small--much smaller than the accuracy at which water level data can be obtained at that water depth. In part the exact location of the long open boundary was determined from the feasibility of data collection. As described in Ref. 1, many limitations existed in placing instruments in these heavily traveled waters.

At the boundary, water level and current data was measured, by which the boundary conditions for the model were well determined.

Fig. 3--Observed tides at a station in the corner of the model (Knikpunt V), together with the quarter-diurnal tide obtained from the record by a bandpass filter

II. MODEL FORMULATION

The model is based upon the so-called vertically integrated semi-momentum equations which have been derived in Ref. 4. In this case the atmospheric pressure differences are added as driving forces. The momentum equations now contain a viscosity term and pressure differences due to salinity gradients. The equations are written as

$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + V \frac{\partial U}{\partial y} - fV + g \frac{\partial \zeta}{\partial x} + \frac{1}{2}g \frac{H}{\rho} \frac{\partial \rho}{\partial x} + g \frac{U(U^2 + V^2)^{\frac{1}{2}}}{C^2 H} - \frac{\theta \rho_a W^2 \sin \psi}{\rho H} - \frac{\partial P}{\partial x} - k \left(\frac{\partial^2 U}{\partial x^2} + \frac{\partial^2 U}{\partial y^2} \right) = 0 \quad (1)$$

$$\frac{\partial V}{\partial t} + U \frac{\partial V}{\partial x} + V \frac{\partial V}{\partial y} + fU + g \frac{\partial \zeta}{\partial y} + \frac{1}{2}g \frac{H}{\rho} \frac{\partial \rho}{\partial y} + g \frac{V(U^2 + V^2)^{\frac{1}{2}}}{C^2 H} - \frac{\theta \rho_a W^2 \cos \psi}{\rho H} - \frac{\partial P}{\partial y} - k \left(\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} \right) = 0 \quad (2)$$

$$\frac{\partial \zeta}{\partial t} + \frac{\partial (HU)}{\partial x} + \frac{\partial (HV)}{\partial y} = 0 \quad (3)$$

$$\frac{\partial (HP)}{\partial t} + \frac{\partial (HuP)}{\partial x} + \frac{\partial (HVP)}{\partial y} - \frac{\partial \left(HD_x \frac{\partial P}{\partial x} \right)}{\partial x} - \frac{\partial \left(HD_y \frac{\partial P}{\partial y} \right)}{\partial y} - R = 0 \quad (4)$$

where D_x, D_y = dispersion coefficients

f = Coriolis parameter

g = acceleration of gravity

h = distance from the bottom to the reference plane

H = temporal depth (= $h + \zeta$)

k = horizontal velocity diffusion coefficient

P = vector of dissolved constituent concentrations

ρ = atmospheric pressure

U = vertically averaged velocity component in x direction

V = vertically averaged velocity component in y direction

W = wind speed

ζ = water level elevation relative to a horizontal reference plane

θ = wind stress coefficient

ρ = density of water

ρ_a = density of air

ψ = angle between wind direction and the positive y direction

Several coefficients can be computed. The Chezy value can be computed from the Manning's coefficients and the temporal depth, and the dispersion coefficient from the temporal depth, the local velocity and the Chezy coefficient.

In the model a horizontal velocity diffusion can be used. From a theoretical point of view, the horizontal momentum diffusion is small, but because of computational effects, it may be desirable to use a value which is larger than we would expect from theory. More sophisticated users of the model would like to see a larger coefficient used only when considerable variations occur in the velocity field, for example, in such areas where we would expect vortex streets which we naturally cannot represent on a grid system. To accommodate such users we have introduced

$$k = k_0 + k' \left| \frac{\partial \omega}{\partial y} \right| (\Delta s)^2 \quad (5)$$

$$\text{where } \omega = \frac{\partial U}{\partial y} - \frac{\partial V}{\partial x}$$

The horizontal density gradient is computed from the salinity distributions and an equation of state. For the equation of state we use

$$\rho = (5890 + 38T - .375T^2 + 3S) / [(1779.5 + 11.25T - .0745T^2) - (3.8 + 0.01T)S + 0.698(5890 + 38T - 0.375T^2 + 3S)] \quad (6)$$

where T = temperature
S = salinity

The temperature differences in the model area appear to be small; also, the influence of temperature on density is small. Consequently, it can be assumed for the computation of density that the temperature is constant in the whole model area.

III. COMPUTATION APPROXIMATIONS

The model is based upon finite difference approximations of the partial difference equations (1)-(4). The grid system and the method of computation are an extension of an earlier computation method described in Ref. 4. To write these finite difference equations, the following notations for averages, derivatives and time shifts are used:

$$\bar{F}^x = \frac{1}{2} \left\{ F[(j+\frac{1}{2})\Delta x, k\Delta y, n\Delta t] + F[(j-\frac{1}{2})\Delta x, k\Delta y, n\Delta t] \right\} \quad (7)$$

$$\delta_x F = \frac{1}{\Delta x} \left\{ F[(j+\frac{1}{2})\Delta x, k\Delta y, n\Delta t] - F[(j-\frac{1}{2})\Delta x, k\Delta y, n\Delta t] \right\} \quad (8)$$

$$\nabla_x^2 F = \frac{1}{(\Delta x)^2} \left\{ F[(j+1)\Delta x, k\Delta y, n\Delta t] - 2F[j\Delta x, k\Delta y, n\Delta t] + F[(j-1)\Delta x, k\Delta y, n\Delta t] + F[j\Delta x, (k+1)\Delta y, n\Delta t] - 2F[j\Delta x, k\Delta y, n\Delta t] + F[j\Delta x, (k-1)\Delta y, n\Delta t] \right\} \quad (9)$$

$$F_+ = F[j\Delta x, k\Delta y, (n+\frac{1}{2})\Delta t] \quad (10)$$

$$F_- = F[j\Delta x, k\Delta y, (n-\frac{1}{2})\Delta t] \tag{11}$$

$$\delta_{+\frac{1}{2}t} F = \frac{2}{\Delta t} \{ F_+ - F \} = \frac{2}{\Delta t} \{ F[j\Delta x, k\Delta y, (n+\frac{1}{2})\Delta t] - F(j\Delta x, k\Delta y, n\Delta t) \} \tag{12}$$

In the finite difference equations variables which are computed by iterations are indicated by special symbols, for example, F_* , F_+ .

By the introduction of iterations in determining the value of certain variables, the user of the model has some choice in the approximations of the partial differential equations. This choice refers mainly to the time level at which the approximation of a certain term is made, thus we can say that the user has certain integration options.

The integrations are performed with two different operations. In one of the operations we are computing the new velocity components and the new water levels at timestep $n+\frac{1}{2}$ from information which is available at timestep n and timestep $n-\frac{1}{2}$ by use of

$$\begin{aligned} \delta_t u - f\bar{v} + 1/3 \left\{ \left(\frac{\bar{u}^x \bar{u}^x}{\bar{u}_*^x \bar{u}_*^x} \right)_x + \frac{1}{2} \left[\bar{u}_* (u_* + \Delta^2 \nabla^2 u_*) \right]_x^{-x} + 2\bar{v} \left(\frac{\bar{u}_*^y}{\bar{v}_*^y} \right)^y + \bar{v}^x \left(\frac{\bar{u}_*^y}{\bar{v}_*^y} \right)^y \right\} \\ + g \frac{\bar{\zeta}^t}{\bar{\rho}_x} + \frac{1}{2} \frac{g}{\rho} (\bar{h}^y + \bar{\zeta}^x) \delta_x \rho + g \frac{\bar{u}^t [(u_*)^2 + (\bar{v})^2]^{\frac{1}{2}}}{(\bar{h}^y + \bar{\zeta}^x) (\bar{C}^x)^2} \\ - \frac{\theta \rho_a W^2 \sin \psi}{\rho (\bar{h}^y + \bar{\zeta}^x)} - \delta_x \rho - k \nabla^2 u_- = 0 \end{aligned} \tag{13}$$

at $j+\frac{1}{2}, k, n$

$$\delta_{+\frac{1}{2}t} \zeta + \delta_x \left[(\bar{h}^y + \bar{\zeta}_+^x) u_+ \right] + \delta_y \left[(\bar{h}^x + \bar{\zeta}_+^y) v \right] = 0 \tag{14}$$

at $j+\frac{1}{2}, k, n$

where $\Delta = \Delta x = \Delta y$

The integration can be made without iteration at which u_* and h_+ are taken at the time level of the last available data, which would be $n-\frac{1}{2}$ for u and n for ζ . The results of this step can also be introduced again into u_* and ζ_+ , for example, by using the average of the newly-found velocity and u . Many options are available to the investigator, as described in Ref. 5.

Generally initially an option is used which results in a second order approximation in time and space of all terms in the equations except the momentum diffusion term. For constituent 1, the mass-balance equation is approximated in finite-difference form at time level n by

$$\begin{aligned}
 & \delta_{+\frac{1}{2}t} \left[\bar{P}_i (\bar{h} + \zeta) \right] + \delta_x \left[(\bar{h}^y + \bar{\zeta}_+^x) u_+ \bar{P}_{i+}^x \right] + \delta_y \left[(\bar{h}^x + \bar{\zeta}_+^y) v_+ \bar{P}_i^y \right] \\
 & - \delta_x \left[(\bar{h}^y + \bar{\zeta}_+^x) D_{x+} \delta_x P_{i+} \right] - \delta_y \left[(\bar{h}^x + \bar{\zeta}_+^y) D_y \delta_y P_i \right] \\
 & + \sum_{\ell=1}^{i-1} (\bar{h} + \zeta_+) K_{i\ell} P_{\ell+} \alpha_i + \frac{\text{---}t/2}{(\bar{h} + \zeta) K_{ii} P_i} + \sum_{\ell=i+1}^{\ell_{\max}} (\bar{h} + \zeta) K_{i\ell} P_{\ell} \beta_i \\
 & + (\bar{h} + \zeta) S_i = 0 \quad \text{at } j, k, n \tag{15}
 \end{aligned}$$

where $\alpha_i = \begin{cases} 0 & i = 1 \\ 1 & 1 < i \leq \ell_{\max} \end{cases}$

$\beta_i = \begin{cases} 0 & i = \ell_{\max} \\ 1 & 1 \leq i < \ell_{\max} \end{cases}$

ℓ_{\max} = maximum number of constituents

K = reaction matrix term

No iteration is required for the computation of the concentrations.

In the second operation, the new velocity component v and the new water levels at timestep n+1 are computed from information which is available at timestep n+1/2 and timestep n by use of

$$\begin{aligned}
 & \delta_t v + f\bar{u} + 1/3 \left\{ 2\bar{u}(\bar{v}_*)^x_x + \bar{u}^y(\bar{v}_*)^x_x + (\bar{v}_*^y \bar{v}_*^y)_y + \frac{1}{2} \left[\bar{v}_* (\bar{v}_* + \Delta^2 \bar{v}_*)^y \right] \right\} \\
 & + g \frac{\delta_y \zeta^t}{\rho} + \frac{1}{2} \frac{g}{\rho} (\bar{h}^x + \bar{\zeta}_+^y) \delta_y \rho + g \frac{\bar{v}^t [(\bar{u})^2 + (\bar{v}_*)^2]^{\frac{1}{2}}}{(\bar{h}^x + \bar{\zeta}_+^y) (\bar{C}^y)^2} \\
 & - \frac{\theta \rho_a W^2 \cos \psi}{\rho (\bar{h}^x + \bar{\zeta}_+^y)} - \delta_x P - kV^2 v_- = 0 \\
 & \text{at } j, k, t+\frac{1}{2}, n+\frac{1}{2} \tag{16}
 \end{aligned}$$

$$\begin{aligned}
 & \delta_{+\frac{1}{2}t} \zeta + \delta_x \left[(\bar{h}^y + \bar{\zeta}_+^x) u \right] + \delta_y \left[(\bar{h}^x + \bar{\zeta}_+^y) v_+ \right] = 0 \\
 & \text{at } j, k, t+\frac{1}{2}, n+\frac{1}{2} \tag{17}
 \end{aligned}$$

It will be noted that u is computed only in the half-integer timesteps,

while v is computed in the integer value of the timestep, and the water levels are computed every half timestep.

The concentrations are also computed every half timestep, and in the second operation of the computation method the following equation is used:

$$\begin{aligned} & \delta_{+\frac{1}{2}t} \left[P_i (\bar{h} + \zeta) \right] + \delta_x \left[(\bar{h}^y + \bar{\zeta}^x) u P_i^x \right] + \delta_y \left[(\bar{h}^x + \bar{\zeta}^y) v P_i^y \right] \\ & - \delta_x \left[(\bar{h}^y + \bar{\zeta}^x) D_x \delta_x P_i \right] - \delta_y \left[(\bar{h}^x + \bar{\zeta}^y) D_y \delta_y P_i \right] \\ & + \sum_{\ell=1}^{i-1} (\bar{h} + \zeta) K_{i\ell} P_{\ell} \alpha_i + \frac{t}{2} (\bar{h} + \zeta) K_{ii} P_i + \sum_{\ell=i+1}^{\ell_{\max}} (\bar{h} + \zeta_+) K_{i\ell} P_{\ell} \beta_i \\ & + (\bar{h} + \zeta) S_i = 0 \qquad \text{at } j, k, n+\frac{1}{2} \end{aligned} \tag{18}$$

The rather extensive fourth order expressions for the advection terms of the momentum equations are required for stability. In the large computational fields with much variation in velocities, simple second order approximation of the advection terms appeared to be unstable, generating interactions between the two momentum equations, and thus generating high vorticities with the dimension of the grid spacing. The Arakawa [6] expression used here prevents this occurrence.

The model requires a large number of time-varying boundaries. At the seaward boundaries, water levels (or currents) are prescribed by linear interpolation of amplitudes and phases between points of prototype measurement, as described in Ref. 1.

If water levels are used as boundary conditions, the advection terms near the seaward boundaries of the model are omitted. This omission simplifies the boundary description. It can be shown that, in addition to the water levels, velocity data is required to describe the boundary when the flow is into the model when the advection terms are included. The contributions of these terms are very small, as the velocities in the Randdelta II model are either nearly perpendicular or nearly parallel to the boundary and the rate of change is also small. More important than the advection terms are the contributions of the pressures induced by salinity differences. The salinities are prescribed during inflow and computed from inside the field during outflow. The transition in the salinity between outflow and inflow is according to half the cycle of a cosine function over a period which can be set.

All discharges into the system, wind intensity and direction and atmospheric pressures are time-varying.

The computations of the tidal marshes and flats are described in Ref. 5.

IV. MODELING SYSTEM

For successful model investigations with numerical models a system of interlocking programs is required for data handling, simulation and graphical representation. The system used in this investigation has three major parts, namely, the Input Data Processor (IDP), the Simulation program (SIMSYS2D) and the Simulation Data Display system (SDD).

One of the functions of IDP is to order the input data from a logical input form into a form that permits it to be readily used by the simulation. For example, discharges and wind speed and direction can be inserted as individual time series. The processor will order all this data in a sequence fit for simulation. Another very important function of this processor is to document the data in an easily readable report and in easily accessible data files for graphical representation.

The system which is used for data display is designed to make charts and graphs of simulation results and inputs for study and reporting purposes. For example, Fig. 4 shows a chart made with the system to indicate which area is under water when the static water level is .50 m above the reference level. Also, comparisons of simulation results with other simulation data or with observed data can be made.

The system is designed to be used by civil engineers. Its operation requires no special knowledge of the computer science aspects of data handling and manipulation other than a thorough understanding of the computation procedures outlined briefly in the previous section of this paper.

Fig. 4--SDD chart of submerged area at a still water level of 0.5 m above the reference level

V. ASPECTS OF TIDAL WAVE PROPAGATION IN THE MODEL AREA

The tidal flow in the sea area of the Randdelta II model is part of the flow in a much larger system, thus to properly represent this flow in the model area, boundary conditions along the open sides of the model have to be obtained. These boundary conditions can be derived from a model covering a larger area or from a field survey. For some of the studies with the model involving storm surges, results from a larger model are being used, but for the adjustment of the model, results of a large field survey are available in which water levels and currents on each of the open sides of the model were determined. In the computational procedures of the simulation system water levels or currents could be used as boundaries. Consequently, in the beginning of the investigation the question arose as to what would be the best combination of water level and current boundary conditions, taking into account that the boundary data contain errors and that these errors may be amplified. For example, if only flow is used on all boundaries, their errors would lead to a gradual increase or decrease of the water levels in the system. Naturally, it would be better if at least one of the boundaries was prescribed by water levels.

The type of boundary conditions along the seaward sides of the model should be chosen in such a manner that

- o errors in the boundaries have a direct and easily detectable response in water levels and currents of the model results.
- o errors in the boundary are not amplified in the interior of the model.
- o errors in amplitudes should only influence the amplitudes in the system and errors in phase should only influence the phases of the tide.
- o the vertical tide in the sea area just outside the estuary is not much influenced by the choice of the Manning's coefficient and the accuracy of the bathymetry.

If the last condition can be fulfilled, the estuaries can be adjusted more or less independent from the adjustment of the offshore area of the model.

The three open boundaries of the model indicated in Fig. 5 are each in a different position as to the semidiurnal tidal wave, which is the dominating wave in the system. The tidal wave enters the model through boundary (1) and exits through (3). Boundary (2) is nearly parallel to the direction of tidal wave propagation. For each of these three boundaries we have two choices, namely, a water level boundary, designated by H in the following discussion, and a flow boundary, designated by Q.

Table 1 shows the possible combinations of boundary conditions. Note that the combinations a through d are the same as the combinations e through h, except in the condition for boundary (2).

Fig. 5--Boundary designation

Table 1

Combination	Boundary		
	1	2	3
a	H	H	H
b	Q	H	Q
c	Q	H	H
d	H	H	Q
e	H	Q	H
f	Q	Q	Q
g	Q	Q	H
h	H	Q	Q

The following suppositions can be made:

- o The errors are relatively small compared to the measured values.
- o The errors are more or less equally distributed along the boundary.
- o Those errors are gradually diminishing along the perpendicular boundary 2.

These suppositions are partially supported by the fact that in preparing the results of the survey efforts were made to make the results coherent. In section I it is noted that the tide progresses parallel to the coast. This and the aforementioned suppositions make it plausible to first investigate the interaction of boundaries 1 and 3 in a one-dimensional analytic model with the axes along boundary 2, thus leaving the possibility of considerably reducing the number of combinations to be investigated later in connection with boundary 2.

For the one-dimensional analytic model the area in view was schematized to a channel with a constant width and depth. To find an analytic solution to the partial differential equations describing the long-wave motion in a tide, the equations are linearized with respect to the roughness term. Furthermore, the advection term and the Reynolds stresses in the momentum equation and the wave height with respect to the depth are neglected.

The following partial differential equations remain:

$$\frac{\partial Q}{\partial t} + \lambda Q + gDB \frac{\partial \zeta}{\partial x} = 0 \quad (19)$$

$$B \frac{\partial \zeta}{\partial t} + \frac{\partial Q}{\partial x} = 0 \quad (20)$$

where B = width (m)
 D = depth (m)
 g = gravity acceleration (m/s²)
 Q = flow (m³/s)
 ζ = wave height (m)
 λ = roughness parameter (1/s), equal to $\frac{gu}{C^2 D}$, with
 C = Chezy parameter (m^{1/2}/s)
 u = representative velocity (m/s)

These equations have a general solution of the type:

$$Q(x,t) = A_Q(X) \cos [\omega t + P_Q(X)] \quad (21)$$

$$\zeta(x,t) = A_\zeta(X) \cos [\omega t + P_\zeta(X)] \quad (22)$$

By substituting Eqs. (21) and (22) into Eqs. (19) and (20) and by use of boundary conditions, solutions for the amplitudes and phases of the tidal waves can be obtained. As the system is linear, several constituents can be considered, but in the analysis only the semidiurnal tide was considered.

From the field survey, good estimates of water levels and currents of the semidiurnal tide could be made. These were used for the combinations a through d of Table 1. For the depth the average of the region was taken and the friction factor was estimated. In these tests comparisons were made of the horizontal and vertical tide for each combination with increased and decreased amplitudes at one of the boundaries and with phase shifts at that boundary. Also, tests were made with increased and decreased depth and bottom friction. Some of the combinations of boundary conditions were very sensitive to changes in the friction factor. For example, if an H boundary is taken at (1) and a Q boundary at (3), a decrease in the resistance factor of 20% increases the amplitude at boundary (3) by about 50%. The distribution of the error along the model is shown in Fig. 6 for an increase and decrease of the friction factor of 20%. Figure 7 shows the distribution of the error in a similar manner for Q.

The result of this analysis was that water levels at each of the sides of the model was by far the best combination. In that combination the model is insensitive in the water levels to changes in bottom friction and has a relatively small response in the amplitude and phase of the horizontal tide to changes in bottom friction.

Fig. 6--Influence of change in bottom resistance factor λ on the vertical tide by use of H at boundary 1 and Q at boundary 3

Fig. 7--Influence of change in bottom resistance factor λ on the horizontal tide by use of H at boundary 1 and Q at boundary 3

After having established the best combination of boundary conditions for boundaries 1 and 3, an analysis was made of the long open boundary 2. This analysis was made with a submodel of the Randdelta II model. This submodel, described in section VI, models the offshore area of the Randdelta II model with a grid size of 1600 m. Simulations with flow data obtained from the field survey at boundary 2 indicated that errors in Q had a large effect upon the water levels in the model region. Errors in water levels along boundary 2 appear to have a minimal effect upon water levels in the model area and would affect only the flow field locally. Consequently, a water level boundary condition was also chosen here. The errors in that water level boundary were reduced by procedures outlined in Ref. 1.

The results of the analysis of the boundary conditions for this offshore area are not generally applicable. The optimum choice depends on the size of the offshore area to be modeled, the depth and the bottom friction.

For example, an extensive research effort with one- and two-dimensional models made by the Delft Hydraulic Laboratory, for determining the optimal combination of boundaries for a hydraulic model of an offshore area near the entrance of the New Waterway, indicated that a combination of H and Q boundaries was to be preferred. This model covers a small section of the Randdelta II model.

To assist in the adjustment of the estuary sections of the Randdelta II model, a one-dimensional analysis of the tidal wave propagation into the Eastern and Western Scheldt was also made. As shown in Figs. 8 and 9, incremental increases in depth and the linear bottom resistance term do not give a linear change in amplification and phase shift.

Fig. 8--Influence of change in bottom resistance on amplification and phase lag for the Eastern Scheldt

Fig. 9--Influence of change in depth on amplification and phase lag for the Eastern Scheldt

VI. SUBMODELS

The adjustment of tides and currents in the estuaries appeared to be difficult. The estuaries are relatively poorly represented on the 800m grid, certainly in comparison with the offshore area. To progress more rapidly with the adjustments of these sections of the model, several submodels were built based upon data abstracted from the Randdelta II model.

The depth array for the Randdelta II model was obtained by drawing all cross-sections at lines through the depth grid points which are more or less perpendicular to the main current direction. Subsequently depth approximations at the grid points were made in such a manner that the area of the cross-section in the model is about the same as in nature. Care was taken that channels were well represented. With the submodels the opportunity existed to verify the adequacy of this representation.

The first step in the adjustment process is to check the submergence of tidal flats. The criteria used in the flow simulation are quite complicated, mainly due to the demands of conservation of the mass of water and the mass of the constituents.

The submergence is checked by procedures in the SDD system which operate in the same way as in the simulation (Fig. 4). With the SDD system charts can then be made indicating the area which is submerged at certain specified water levels. On these charts it can be checked if small channels become closed by the procedures.

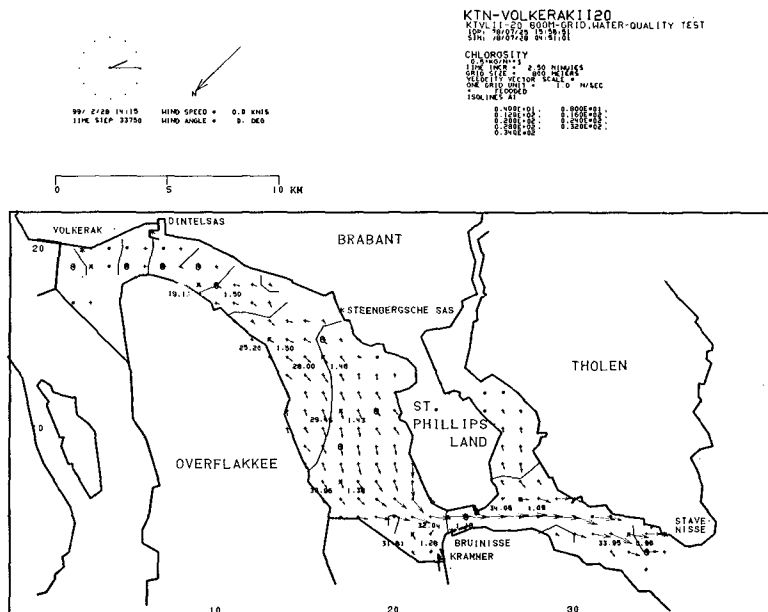

Fig. 10--Chlorosity distributions computed with the KTN-Volkerak II submodel of the Randdelta II model

Figure 10 shows a typical graphical result obtained from a simulation with a submodel. For the adjustment of this submodel observed water levels were used as boundary conditions. The first simulation with this submodel was made with an initial estimate of the Manning's coefficient. Subsequently a simulation was made in which in a certain well-defined region between two water level stations the Manning's coefficient was increased. Also a simulation was made in which the depth in that defined region was increased proportionally 10%, but using Chezy values in that region obtained from the original run of that region. By analyzing the computation results for water levels, functional relationships between changes in Manning's coefficient and depth increases for the amplification and phase lag of the semidiurnal tide in the considered section of the model could be determined. From these relations it was possible to make a good estimate of the required changes to match the propagation in the model with that in the prototype. If depth changes were required, those were made by reviewing the used depth approximation in relation to the actual cross-sections. Other sections of the submodel were adjusted in a similar fashion.

The depth appeared to be rather sensitive in the shallow water areas and the shape of the tidal curve in the eastern part of this submodel is determined to a very large extent by the time of submergence of the tidal marshes. Even though it was realized that only a rough approximation of the flow in this submodel could be obtained, considerable

effort was expended, as the phase of the currents at the boundary of the submodel would be of importance in simulating the Eastern Scheldt proper. In this submodel, fresh water discharges through sluices at the eastern extremity of the model were present. These discharges are of considerable magnitude, and in a part of the submodel area salinity differences in the vertical existed in the simulation period. Consequently, the basic model assumption that the area is well mixed was violated. The salinity differences in the vertical induce vertical circulations which can be represented locally by a larger diffusion coefficient.

To adjust this coefficient long duration simulations were made of a condition in which the discharge into the system was kept approximately constant. The model was started with the salinity of the open boundary everywhere in the whole model. By simulating two months and adjusting the diffusion coefficient in the region with vertical density differences, equilibrium conditions could be obtained which matched quite well the observed conditions.

Dronkers [7] presents an analytical study of the longitudinal dispersion in shallow well mixed estuaries based upon a study of exchange processes in the model area. He concluded that for well mixed systems, in addition to the dispersion process in the main channel, the exchange of water between the channel and the tidal flat or marsh area is of importance, as well as the mixing process on the tidal flat itself. As the water movements and the resultant exchanges are apparently quite well represented even with the relatively coarse grid, no further adjustment of diffusion coefficients in the well mixed region of the model other than the original estimate was required.

This submodel was also used in many experiments for checking and evaluating computation procedures. It was found that the computation is insensitive to the time levels in the advection terms, and that the phase of the tide is influenced when the time step is increased beyond 2.5 minutes.

In addition to the submodels which have the same grid size and depth as the Randdelta II model, a model of the offshore area with a grid size of 1600m was used in the adjustment process. This model had the same seaward boundaries as the Randdelta II model, and it had water level boundaries at the mouths of the Eastern Scheldt and Western Scheldt.

This model was relatively small and inexpensive to run. Many effects in this offshore zone could be studied effectively with this model. For example, the boundary conditions developed by cross-spectral analysis, as described in Ref. 1, were tested and evaluated with this model. Presently it is being used to evaluate the seaward boundaries for storm surge conditions, which were abstracted from a model of a section of the North Sea.

The Randdelta II model will furnish the boundary conditions of a model of the Eastern and Western Scheldt and a small adjacent offshore area with a 400m grid (Fig. 1). This model will be used for more detailed computations. Since this model is very large, submodels are again being used for adjustment and for experiments.

VII. MODEL ADJUSTMENT AND VERIFICATION

Modeling with a numerical model requires large data sets, and setting up the Randdelta II model has been a major effort. Much of the time-varying data for the tidal inputs originated from a field survey (Ref. 1), but also much data from other sources were used.

For example, all the major discharges in the system had to be obtained from the different logs which were kept by government officials at many places. Weather data had to be obtained and digitized. As already mentioned, determining the depth array from various survey charts was a major undertaking, and all data for making charts used for graphical representation of water level, velocity and concentration fields had to be digitized. Furthermore, all coordinates of the measuring stations on the national grid system had to be translated to those on the computational grid so that the closest available grid point can be used for abstracting similar data out of the model.

After the adjustment of the submodels, the depth and Manning's data were transferred back into the Randdelta II model and a series of experiments were made. The studies about the propagation of the semidiurnal tidal wave in the offshore area and in the estuaries gave guidance as to making increasingly better fits between observed and computed data. Even though the model is not considered completely adjusted in all respects, the agreement between observed and computed is good (Fig. 11). In one of the four graphs, the observed as well as the input tide is shown. All other graphs show the observed and computed vertical tides.

The recording station Steenbergse Sas is about 90 km from the closest open boundary and the recording station Baarland about 80 km. The small disturbances shown in the computed record for the station Steenbergse Sas originate from the incremental changes in the land-water boundary by the computation procedures.

The agreement between the observed magnitudes of currents and directions is also good, particularly if one takes into account that the observed currents are obtained at a certain point in a vertical. Figure 12 shows a comparison of currents. The Knikpunt III station is near the boundary and reflects all errors made in the data inserted.

With the simulation system, charts can be made of the velocity distributions at a particular time. Figure 13 shows such a velocity distribution on a much reduced scale. Note that extensive areas in the estuaries are exposed.

Presently, the model has been verified only to a limited extent by use of boundary data not previously used for adjustment. The results are very similar to those shown. Since it is the intention to use the model also for time periods at which no boundary input data are available, the verification process has to include the prediction of the boundaries from the fixed stations.

CHAPTER 62

WAVE SET-UP IN THE SURF ZONE

by Uwe A. Hansen¹⁾

In designing coastal protective structures the knowledge of the static load due to the water level elevation is as important as that of the dynamic load due to the waves.

The structure, designed at sandy coasts with well formed surf zones on the beach - these areas are the basis of this examination - has to stand against both, the superposition of the static and dynamic load, which are dependent on each other. Undoubtedly a rise in the design water level (a summation of different influences - see figure 1) will cause an increase in the wave heights and the reverse will happen, when the design water level decreases.

Fig. 1. - Design water level for the determination of the height of a sea dyke

The location of the wave breaking point in the surf zone will also shift with changing water levels and also the magnitude of the wave run-up and the unknown wave set-up. That shows that only the exact knowledge of all possible factors - including wave-

1) Dr.-Ing. Hydraulic Engineer, Heide, Federal Republic of Germany, formerly Leichtweiß-Institut für Wasserbau, Techn. Univ. of Braunschweig

set-up, influencing the height of the design water level, makes a construction safe and economical.

Up to now, the magnitude of the phenomenon wave set-up and its influence on the design water level remains practically unknown. Though formulas exist to compute the magnitude of wave induced set-up in the surf zone, which mainly were developed out of small scaled model tests, e.g. Munk(13), Savage(14), Fairchild(4), Dorrestein(3), and Longuet-Higgins and Stewart(12) and many others (see Hansen(8)), comparisons with measurements show, that the existing wave theories are not adequate to describe the difficult processes in the surf zone as a non-stationary three-phase-flow of water, air and solid particles. Comparisons of measured run-up heights at sea dykes after heavy storms with calculated values showed, that there must be an unknown factor up to now, which could be the wave set-up.

Therefore field measurements were made by the LEICHTWEISS-INSTITUT of the Technical University of Braunschweig, sponsored by the GERMAN RESEARCH FOUNDATION (Bonn), at the west coast of the island of SYLT in the North Sea (see figure 2) in winter 1975/76 to determine the wave set-up in the surf zone under prototype conditions.

The measuring profile is shown in figure 3 with the locations of the measuring points. At stations W_4, W_3 and W_1 wave measurements were made with ultrasonic wave gauges. At the stations in the surf zone wave sensors with pressure cells were installed. The incident significant wave height $H_{0,s}$ was measured at station W_4 , 1280 m seaward of the toe of the dune.

Fig. 2. - Location of the island of SYLT in the North Sea

Fig. 3. - Measuring profile at the west coast of SYLT in North Sea

Though the definition of wave set-up is a simple one:

the height difference between MEAN WATER LEVEL
and STILL WATER LEVEL,

the determination of those two different water levels in field measurements under prototype storm conditions is a rather difficult task.

The water level, even under calm conditions and without any movements by waves, changes with the tide.

In the area off SYLT the difference between high and low water is about two meters. To compute or measure wave set-up in the surf zone, the height of the water level, defined as SWL, must first be determined there. As this water level can not be measured directly in the surf zone because of the influence of the unknown wave set-up, the place for registration this SWL must be positioned at a far seaward location where this unknown influence of wave set-up does not exist. As former measurements had shown, that the wave climate at the most seaward measuring point W_4 (1280 m seaward of the top of the dune) is not influenced by the shore and that shelf response effects are negligible there, this tide gauge was used to give the time variations of the SWL, the tide, by filtering out the wave components and translate it into the surf zone.

The second necessary value, the time variation of the MWL, was not defined by one of the well-known methods like "crest-to-crest" method or "zero-crossing" method. The analog wave records, obtained at the five measuring stations in the surf zone were first converted into digital values with a time span of 0.4 seconds.

The water level variations between two extremes, the maximum and the following minimum, was then defined as a wave (see figure 4).

Fig. 4. - Determination of MWL out of prototype wave records by dividing height between wave crest and following trough into parts of $a:b$ after Hansen (8)

Within a time span of 5 minutes measuring time the result was a number of 750 digital values z_i , representing the water level fluctuations, out of which the MWL was computed as the mean value of all these water level variations. This method, done by a computer, is not very difficult and gives good results as comparisons showed.

These comparisons were the following:
 due to the well known behavior of the vertical asymmetry of waves in the surf zone, the part of the wave over the MWL is about 66% to 85% of the total wave height just before breaking (see Gaillard (6), Galvin and Eagleson (7) and Inman and Quinn (10),

so that only 33% to 15% of the wave height remains below the MWL. With these criterions the MWL was determined by dividing the heights in water level fluctuations between wave crests and wave troughs into these parts of percentage. Then the MWL was defined as the mean value of all these resulting points within a designated time span of 5 minutes (see figure 5).

Fig. 5 - Time variation of MWL at station 80 m after dividing all wave heights by differnt parts

The comparison showed, that the results of these more time-consuming methods of dividing all wave heights into parts between 66% to 85% over and 33% to 15% below the MWL differ only a few centimeters from those calculated by taking only the mean values of all water surface variations measured over a certain time span of 5 minutes.

The reason, that this method - the arithmetic mean value of all water surface variations over a certain time span - is equally suitable to yield the MWL for

these irregular waves in the surf zone is due to the great horizontal asymmetry of these waves. Just before breaking the waves have a form with very short leeward and long windward slopes (see figure 6). As a result, balance of the areas in a wave form above and below the MWL - which is equal to the arithmetic mean value of all water surface variations - can only be reached, when the waves steepen in the surf zone.

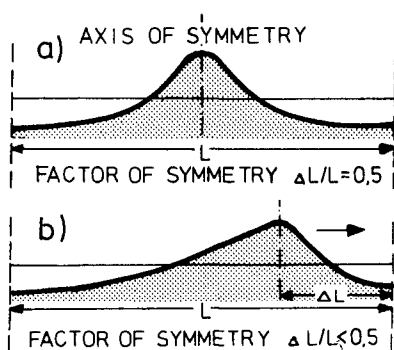

Fig. 6. - Asymmetries: (a) vertical and (b) horizontal of waves in the surf zone after Führböter (5)

Now some results of the field measurements at the west coast of the island of SYLT in the North Sea: The measurement program included 27 separate measurements of about occasionally 60 minutes registration time at different sea and wind conditions. Those who are interested in detail should refer to the report by the writer (8).

Figure 7 shows the spatial variations of wave set-up at a certain time span for run nr. 15 with an incident significant wave height of 1.58m and a

Fig. 7 - Spatial variation of wave set-up in measuring profile at the west coast of SYLT during falling tide

measuring time of about 60 minutes. The envelopes of the wave crests and troughs, measured at the stations in the surf zone are also given in this figure to clearly reveal their relationships with respect to the MWL.

Based on the 27 sets of measurements the maximum wave set-up $\bar{\eta}_{\max}$ on the beach at the so called set-up line is estimated to be

$$\bar{\eta}_{\max} \approx 0.3 H_{0,s}$$

as seen in figure 8, where $H_{0,s}$ is the significant wave height measured at station W_4 , 1280 m seaward of the toe of the dune (see fig. 3). The relationship shows good agreement with theoretical results of Collins (2), but less so with those of Dorrestein (3) and Saville (15).

Fig. 8. - Maximum wave set-up in dependence on significant incident wave height after Hansen (8)

In relation to the significant wave height at the breaking point in the surf zone $H_{B,S}$, the maximum wave set-up can be expressed as

$$\bar{\eta}_{max} \cong 0.5 H_{B,S}$$

as seen in figure 9, in which also the theoretical results of Hwang and Divoky(9), Battjes(1) and Jonsson and Jacobsen(11) are given.

Beside these maximum values of the wave set-up, measured at the set-up line on the beach, the values at the breaking point in the breaking zone are of great interest too. The measurements and computations showed in the area of the sandy beach off SYLT, that the wave set-up there not only depends on the height of the incident offshore wave, but also on the width and location of the breaking zone, which varies with the tidal cycle.

Fig. 9. - Maximum wave set-up in dependence on wave height at breaking point after Hansen(8)

As shown in figure 10, in wide breaker zones mainly intermediate forms of spilling and plunging breakers predominate, whereas in narrow breaker zones plunging breakers occur.

Fig. 10 - Wave set-up at breaking point versus significant wave height in dependence on width of breaking zone versus location of breaking zone after Hansen(8)

With the variation of the width of the breaking zone and the breaker forms (classification after Führböter(5)), the values of wave set-up at the breaking point vary too: values greater than 1 - a rise in water level (MWL above SWL)- were measured in wide breaker zones, values less than 1 in narrow ones (MWL under SWL).

From these interesting results the following conclusions were drawn (see figure 11 - a schematical drawing):

Fig. 11 - Wave set-up in breaking zone in relation to tide, measuring profile, and energy dissipation

As the underwater slope of the sandy beach varies with the tidal cycle, the wave set-up at the breaking point varies too. The reason for this variation of $\bar{\eta}_B$ is that the slope of the underwater profile in the surf zone changes more or less periodically with the tide, as profile measurements at this

sandy coast of SYLT had shown. With falling water levels the slope becomes steeper. With rising water levels it becomes more gentle, so that the position and width of the breaker zone changes.

In wide breaker zones, where plunging and spilling breakers predominate, the rate of energy dissipation is less, so that a greater part of wave energy is preserved to create wave set-up and the MWL in the breaking zone remains above the SWL. On the other hand, the increased energy dissipation in narrow breaker zones, where plunging breakers predominate causes a wave set-down at the breaking point, that means the MWL lies below the SWL (see figure 11).

As a conclusion it can be said, that the field investigations at the sandy coast of the island of SYLT have shown, that the maximum wave set-up on the beach (at the set-up line) can reach values up to 30% of the incident significant wave height and up to 50% of the significant breaker height. For engineering purposes the maximum values are more important, as they directly influence the height of the design water level for coastal protective structures. The results of this study can be used for other areas, when boundary conditions like sandy beach, similar slopes and well formed surf zone are given.

CHAPTER 63

ROLE OF 2D AND 3D MODELS IN JONSDAP '76

by

A. M. Davies

Institute of Oceanographic Sciences, Bidston Observatory,
Birkenhead, Merseyside, L43 7RA, England.

Abstract

This paper describes how a two-dimensional numerical model of the North Sea was used to determine optimum positions for the deployment of off-shore tide gauges during the JONSDAP '76 oceanographic exercise.

A three-dimensional model of the North West European Shelf is also described. Using this model the three-dimensional distribution of the M_2 tidal current over the shelf has been computed. This model has also been used to compute the wind induced circulation of the North Sea for the INOUT period of JONSDAP '76.

1. Introduction

In order to gain a more comprehensive understanding of the physical and biological oceanography of the North Sea, a large scale observational program took place in the northern North Sea during 1976, namely JONSDAP '76 (Joint North Sea Data Acquisition Program 1976), involving a number of European maritime countries.

This paper describes two hydrodynamic North Sea models. The application of one of these in determining optimum positions for off-shore tide gauges, prior to the JONSDAP '76 exercise is described. The use of these models in the interpretation of the physical data collected during the exercise is also considered. Employing a model to determine positions for off-shore tide gauges it is possible to take tidal measurements around its open boundaries at locations which have the greatest influence upon the tidal regime subsequently computed by it. Observational data collected at these points during the exercise constitutes an optimum open boundary data set for use with the model to simulate the motion of the sea for the period of the exercise.

The numerical model used to determine tide gauge sites, is two-dimensional, comprehensively non-linear, with a fine grid resolution of $1/9^\circ$ latitude by $1/6^\circ$ longitude; it covers the North Sea, the Skagerrak, the Kattegat and the eastern half of the English Channel (see Figure 1). The open boundaries correspond to those monitored during JONSDAP '76. Thus, the open boundary in the north runs along the line between the port of Wick and position $59^\circ 20'N$, $0^\circ 0'W$ and then along latitude $59^\circ 20'N$ between this point and the Norwegian coast. The southern open boundary is the line of longitude crossing the English Channel at $2^\circ W$. The southern end of the Kattegat is a very shallow region and has been considered closed.

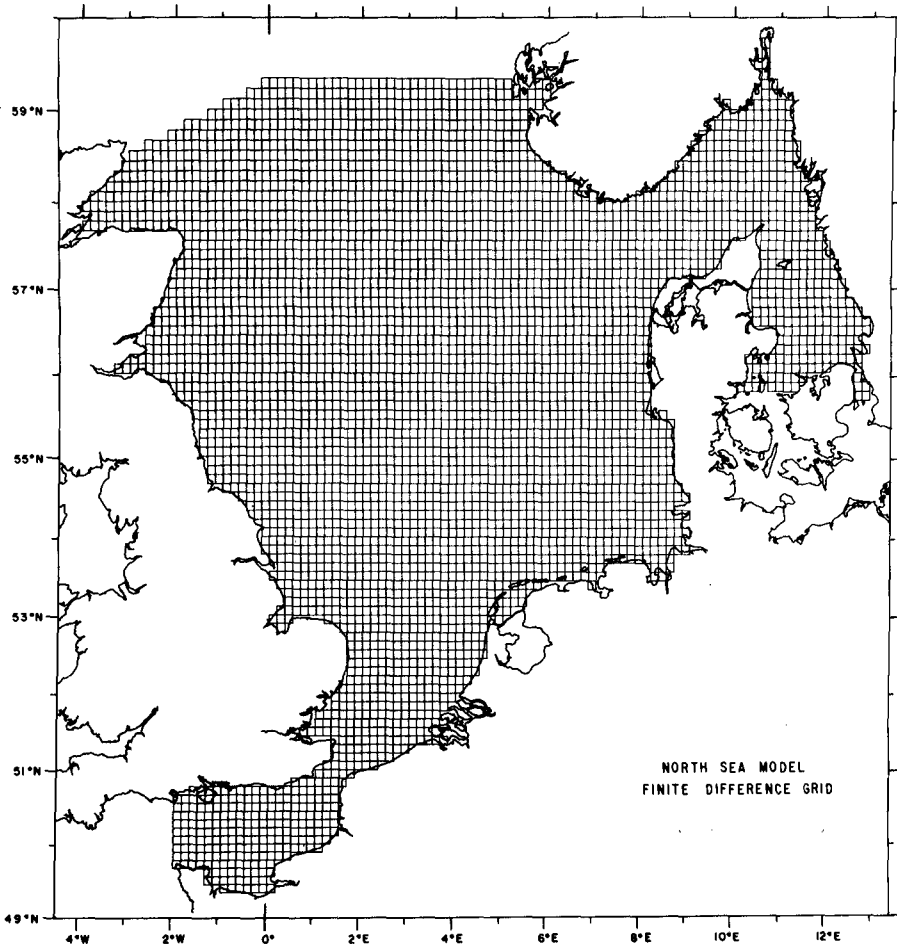

Figure 1. Two-dimensional North Sea model : finite difference grid.

Figure 2. Three-dimensional shelf model : finite difference grid.

The second model employed is three-dimensional with a coarser grid resolution of $1/3^\circ$ latitude by $1/2^\circ$ longitude, covering the continental shelf as shown in Figure 2. The region in the northern North Sea, marked FLEX area on this diagram, denotes the sea area in which an intense biological measurement program took place concurrently with the physical measurements made during JONSDAP '76. The hydrodynamical equations include a quadratic bottom friction but are otherwise linear. Along the open boundaries, a radiation condition is employed to allow disturbances from the interior of the model to pass outwards.

This model is used initially to compute the distribution of the M_2 tide over the continental shelf. In this case boundary forcing is provided by M_2 tidal elevation alone. In a subsequent calculation the wind-induced circulation on the shelf for the period 15 March 1976 to 15 April 1976 (the INOUT period of JONSDAP '76) is computed. Boundary forcing for this case involved the M_2 tidal elevation and a meteorologically-induced elevation computed using the hydrostatic approximation. Meteorological forcing at the sea surface consisted of a time-average wind stress field and a time-averaged field of atmospheric pressure gradients. The time averaging was over the period cited above. The meteorologically induced circulation for the period was computed by subtracting the pure tidal motion from that computed with tide and meteorological forces.

2. Two-dimensional North Sea model (Figure 1)

The depth averaged equations of continuity and motion, including the non-linear advective terms and non-linear bottom friction may be written in polar coordinates as follows :

$$\frac{\partial \xi}{\partial t} + \frac{1}{R \cos \phi} \left\{ \frac{\partial (dU)}{\partial x} + \frac{\partial (dV \cos \phi)}{\partial \phi} \right\} = 0 \quad (1)$$

$$\begin{aligned} \frac{\partial U}{\partial t} + \frac{U}{R \cos \phi} \frac{\partial U}{\partial x} + \frac{V}{R \cos \phi} \frac{\partial (U \cos \phi)}{\partial \phi} - 2\omega \sin \phi V \\ + \frac{R U (U^2 + V^2)^{1/2}}{d} + \frac{g}{R \cos \phi} \frac{\partial \xi}{\partial x} = 0 \end{aligned} \quad (2)$$

$$\begin{aligned} \frac{\partial V}{\partial t} + \frac{U}{R \cos \phi} \frac{\partial V}{\partial x} + \frac{V}{R} \frac{\partial V}{\partial \phi} + \frac{U^2 \tan \phi}{R} + 2\omega \sin \phi U \\ + \frac{R V (U^2 + V^2)^{1/2}}{d} + \frac{g}{R} \frac{\partial \xi}{\partial \phi} = 0 \end{aligned} \quad (3)$$

where the notation is :

λ, ϕ east-longitude and latitude, respectively,

t time,

ξ elevation of the sea surface above undisturbed level,

h undisturbed depth of water

$d = h + \xi$ total depth of water,

R radius of the Earth,

ω angular speed of the Earth's rotation,

R coefficient of bottom friction,

g acceleration due to gravity,

u, v components of current in the directions of increasing λ, ϕ respectively, at a depth z below the undisturbed sea surface,

U, V components of depth mean current given by

$$U = \frac{1}{h + \xi} \int_{-h}^{\xi} u(z) dz, \quad V = \frac{1}{h + \xi} \int_{-h}^{\xi} v(z) dz \quad (4)$$

Equations (1) to (3) are approximated using finite difference methods : details are given by Davies and Flather [1978] and will not be presented here. An explicit finite difference technique is used to generate solutions through time and space over a staggered grid in which ξ, U and V are calculated at different mesh points. Solutions are generated from a state of zero displacement and motion, expressed by,

$$\xi = U = V = 0 \quad (5)$$

Along open and closed boundaries, appropriate dynamical conditions have to be satisfied. Thus, along a closed boundary the normal component of current is set to zero, i.e.

$$U \cos \psi + V \sin \psi = 0 \quad (6)$$

where ψ denotes the inclination of the normal to the direction of increasing λ . Along the open boundaries tidal elevation is specified according to the harmonic theory. Here we consider only the M_2 component of the tide, thus the tidal elevation on the open boundary is given by :

$$\xi = H \cos(\sigma t - g), \quad (7)$$

where for this component, H denotes the amplitude, σ the speed and g the phase.

3. Calculation of the M_2 tide and determination of an optimum deployment pattern for tide gauges.

In principle in order to calculate the M_2 component of the tide throughout the region covered by the two-dimensional model (Figure 1) it is necessary to have a detailed knowledge of the tide along the open boundaries of the model. Obviously prior to the JONSDAP '76 exercise this data was not available, and thus it was necessary to take M_2 tidal input from a numerical model of the continental shelf (Flather [1976]). Input data around the open boundaries of the latter model was derived from the observational data taken by Cartwright [1976]. A distribution of the M_2 tide over the North Sea in good agreement with observation (Davies [1976]) was obtained from the two-dimensional model shown in Figure 1.

Having thus proved the model it was possible to determine the sensitivity of the distribution of the M_2 tide computed with the model to changes in amplitude and phase of the M_2 tidal input along various sections of the open boundary. To this end, the northern open boundary of the model was divided into seven sections. Section 1 spans the seven grid boxes between the Scottish coast and the point ($58^{\circ}40'N$, $2^{\circ}0'W$), Section 2 the seven grid boxes between ($58^{\circ}40'N$, $2^{\circ}0'W$) and ($59^{\circ}0'N$, $0^{\circ}50'W$) and so on up to the seventh section which spans eight grid boxes between point ($59^{\circ}20'N$, $3^{\circ}50'E$) and the Norwegian coast. An eighth section comprised the whole of the southern boundary. In order to test the response of the model, the amplitudes of the M_2 tide in the first section were increased by 10 cm; at the same time the phase in this section and the amplitudes and phases in the other sections were kept constant. The numerical model was then run until the tidal regime was established and differences in amplitude and phase, ΔH and ΔG , between the tides of the new distribution and those of the original one were compared at a number of ports throughout the region. In a similar experiment, the phase of the M_2 tidal input in Section 1 was changed by 10° , and the changes ΔH and ΔG at a number of ports were determined. Similar numerical experiments were performed for all seven northern boundary sections, and for the eighth boundary section across the English Channel.

This sensitivity analysis showed that the tides along the north-east coast of Britain from Aberdeen to Inner Dowsing were particularly sensitive to changes along the north-western part of the boundary. They were also sensitive to changes near the Norwegian coast. Changes in tidal amplitude along this section of boundary also affected the tide along the south-east coast of England and in the Channel.

Obviously it is not practical to measure the tide at each northern boundary point of the model. However based on the results of the sensitivity analysis, it was evident that the most important regions

for tidal specification lay on the western and eastern sections of the Northern boundary and thus a distribution of five off-shore tide gauges that reflected this fact was used (Davies [1976]). Since the gauges were situated along the open boundaries of the model the tidal data measured during JONSDAP '76 can be readily incorporated in the model, and calculations using this data are presently in progress, aimed at determining the distribution of various tidal constituents over the North Sea.

4. Three-dimensional shelf model (Figure 2)

The equations of continuity and motion for homogeneous water, neglecting non-linear terms and shear in the horizontal, may be written in polar coordinates as :

$$\frac{\partial \xi}{\partial t} + \frac{1}{R \cos \phi} \left\{ \frac{\partial}{\partial \lambda} \int_0^h u dz + \frac{\partial}{\partial \phi} \int_0^h v \cos \phi dz \right\} = 0 \quad (8)$$

$$\frac{\partial u}{\partial t} - \gamma v = -\frac{g}{R \cos \phi} \frac{\partial \xi}{\partial \lambda} - \frac{1}{\rho R \cos \phi} \frac{\partial p}{\partial \lambda} + \frac{\partial}{\partial z} \left(N \frac{\partial u}{\partial z} \right) \quad (9)$$

$$\frac{\partial v}{\partial t} + \gamma u = -\frac{g}{R} \frac{\partial \xi}{\partial \phi} - \frac{1}{\rho R} \frac{\partial p}{\partial \phi} + \frac{\partial}{\partial z} \left(N \frac{\partial v}{\partial z} \right) \quad (10)$$

where we denote by :

- P atmospheric pressure at the sea surface,
- N the coefficient of vertical eddy viscosity, assumed to be a function of λ, ϕ, z and t . All other symbols are as defined previously.

In order to solve (8), (9) and (10) for ξ, u, v , boundary conditions have to be specified at the sea surface and at the sea bed. The surface conditions are

$$-P \left(N \frac{\partial u}{\partial z} \right)_0 = F_s, \quad -P \left(N \frac{\partial v}{\partial z} \right)_0 = G_s \quad (11a,b)$$

where F_s, G_s denote the components of wind stress acting on the water surface in the λ and ϕ directions, suffix 0 denoting evaluation at $z=0$.

Similarly at the sea bed, $z=h$, assuming a slip condition and

using a quadratic law of bottom friction, gives

$$\begin{aligned} -\left(N \frac{\partial U}{\partial z}\right)_h &= \bar{k} U_h (U_h^2 + V_h^2)^{1/2} \\ -\left(N \frac{\partial V}{\partial z}\right)_h &= \bar{k} V_h (U_h^2 + V_h^2)^{1/2} \end{aligned} \quad (12a,b)$$

where \bar{k} is the coefficient of bottom friction assumed constant.

We now seek a solution of equations (8), (9) and (10) for ξ, U, V subject to boundary conditions (11) and (12). Expanding the two components of velocity U, V in terms of m depth dependent functions $f_r(z)$ and horizontal-space and time-dependent coefficients $A_r(x, \phi, t)$ and $B_r(x, \phi, t)$ gives

$$U(x, \phi, z, t) = \sum_{r=1}^m A_r(x, \phi, t) f_r(z) \quad (13)$$

$$V(x, \phi, z, t) = \sum_{r=1}^m B_r(x, \phi, t) f_r(z) \quad (14)$$

Using the Galerkin method in the vertical space domain, equations (9) and (10) are multiplied by each of the basis functions f_k , and integrated with respect to z over the interval 0 to h . By integrating the term involving the vertical eddy viscosity, boundary conditions (11a,b) and (12a,b) can be included (Davies [in preparation]) giving

$$\begin{aligned} \int_0^h \frac{\partial U}{\partial t} f_k dz &= \gamma \int_0^h v f_k dz - \frac{g}{R \cos \phi} \frac{\partial \xi}{\partial x} \int_0^h f_k dz - \frac{1}{PR \cos \phi} \frac{\partial P}{\partial x} \int_0^h f_k dz \\ &+ f_k(0) \frac{G_s}{\rho} - f_k(h) \bar{k} U_h (U_h^2 + V_h^2)^{1/2} - \int_0^h N \frac{\partial U}{\partial z} \frac{\partial f_k}{\partial z} dz \end{aligned} \quad (15)$$

and

$$\begin{aligned} \int_0^h \frac{\partial V}{\partial t} f_k dz &= -\gamma \int_0^h u f_k dz - \frac{g}{R} \frac{\partial \xi}{\partial \phi} \int_0^h f_k dz - \frac{1}{PR} \frac{\partial P}{\partial \phi} \int_0^h f_k dz \\ &+ f_k(0) \frac{G_s}{\rho} - f_k(h) \bar{k} V_h (U_h^2 + V_h^2)^{1/2} - \int_0^h N \frac{\partial V}{\partial z} \frac{\partial f_k}{\partial z} dz \end{aligned} \quad (16)$$

for $k = 1, 2, \dots, m$

Consider now the choice of basis functions $f_r(z)$. Davies [in preparation] has demonstrated that an expansion of 10 cosine functions is sufficient to accurately reproduce the depth variation of current, and has successfully applied such an expansion to the computation of the wind induced circulation of the North West European Continental Shelf (Davies [1979]). In this paper we again use an expansion of 10 cosine functions, with $f_r(z)$ given by,

$$f_r(z) = \cos \alpha_r z/h \tag{17}$$

The choice of α_r is quite arbitrary, provided $f_r(h)$ is non zero, and a suitable choice for α_r is,

$$\alpha_r = (r-1)\pi \quad \text{for } r=1, 2, \dots, m \tag{18}$$

Substituting expansions (13) and (14) into equations (15), (16) and (8), gives a set of $2m + 1$ equations, which when integrated forward through time subject to initial and boundary conditions, yields ξ and the set of coefficients A_r, B_r at progressive time steps. Using expansions (13) and (14), the u and v components of current at any depth can be computed from the set of A_r and B_r . Details of the method for the solution of the equations are given by Davies (1979) and will not be repeated here.

In order to solve equations (15) and (16) it is necessary to specify how N will vary with x, ϕ and t . The horizontal variation of N over the North Sea for semi-diurnal tidal motion has been computed by Kraav (1969). He shows that N increases rapidly in the shallow coastal areas, particularly along the east coast of England, where the tidal currents are high, and to a first approximation it is evident that N increases with the square of the tidal current. On the basis of Kraav's results, an appropriate parameterization of vertical eddy viscosity is, using M.K.S. units,

$$N = 0.2 (\bar{u}^2 + \bar{v}^2)$$

where \bar{u} and \bar{v} are depth mean currents given in terms of the present theory by

$$\bar{u} = \sum_{r=1}^m A_r a_r, \quad \bar{v} = \sum_{r=1}^m B_r a_r \tag{19}$$

$$a_r = \frac{1}{h} \int_0^h f_r(z) dz \tag{20}$$

This parameterization of vertical eddy viscosity was used in the tidal computations to be described in Section 5.

Alternatively Heaps (1972), from computations of the wind induced circulation of a simple rectangular basin, suggested that the term $\frac{\bar{K} h}{N}$ should be constant and accordingly this term was fixed in the calculation of the wind induced circulation of the North Sea (see Section 6) in such a way that, in water of depth 65m, N had a value of 650 cm²/s - a value suggested by Heaps (1972). In this calculation a coefficient of bottom friction $\bar{K} = 0.0025$ was assumed over the whole shelf.

Solutions were generated from a state of zero displacement and motion, expressed by,

$$\xi = A_r = B_r = 0 \text{ at } t = 0 \quad (r = 1, 2, \dots, m) \quad (21)$$

Along a closed boundary the normal component of current was set to zero, for all $t \geq 0$, thus,

$$A_r \cos \psi + B_r \sin \psi = 0 \quad (r = 1, 2, \dots, m) \quad (22)$$

where ψ denotes the inclination of the normal to the direction of increasing x .

Consider now the open boundary conditions. For the computation of tidal motion alone over the continental shelf, M_2 tidal input determined from the two-dimensional model of Flather (1976) was used, together with a radiation condition. Details of this radiation condition can be found in Davies (1979). For the computation of the tidal motion, the pressure gradient and wind stress terms in equations (15) and (16) were set to zero.

In computing the wind induced motion over the continental shelf the radiation condition was again used along the open boundaries of the model, with M_2 tidal input as described previously, together with meteorological input along the open boundaries, computed using the hydrostatic approximation.

The meteorological forcing functions, namely the two components of wind stress F_s and G_s , and the pressure gradients $\frac{\partial P}{\partial x}$ and $\frac{\partial P}{\partial \phi}$ were calculated from data supplied by the British Meteorological Office. Hourly values of wind stress and pressure gradients were computed at the grid points of the model for the period 0000h 15 March to 0000h 15 April 1976 from the hourly geopotential height data. From this time series mean values of pressure gradients and wind stresses over the sea area for this period were computed.

The meteorologically induced circulation for the period was computed by subtracting the pure tidal motion (computed using identical values of \bar{K} and N to those used with the meteorological input) from that computed with tide and meteorological forces.

Figure 3a. Distribution over the continental shelf of M_2 current ellipses at sea surface.

Figure 3b. Distribution over the continental shelf of M_2 current ellipses at sea bed.

5. Computed M_2 tidal currents

The distribution of the M_2 tidal currents over the continental shelf, and through depth were computed using the three-dimensional shelf model described previously. The variation of vertical eddy viscosity with tidal current described in Section 4 was used in the model.

In an initial series of calculations the computed amplitude of the M_2 tidal elevations and currents in shallow areas was found to be sensitive to the value of the coefficient of bottom friction k_b . Using a value of $k_b = 0.0025$ (an appropriate value for a two-dimensional model [Davies 1976]) the amplitude of the tidal velocity in shallow areas was higher than the observed value. However, increasing k_b to 0.0050 reduced the magnitude of these elevations and currents, although currents in the deeper areas were only slightly reduced.

Plots of the magnitude and direction of the major and minor axes of the M_2 tidal current and the sense of rotation of the ellipse computed using $k_b = 0.0050$, together with the time of lunar transit at Greenwich, at every third grid point of the model are given in Figures 3a,b. Figure 3a shows such a plot for the surface current, and the bottom current is presented in Figure 3b.

From Figures 3a,b it is evident that the maximum currents occur in the English Channel, between Cherbourg and the Isle of Wight, where the flow is nearly rectilinear. Tidal surface currents in excess of 100 cm/s occur in this area. Surface velocities of the order of 70-90 cm/s occur along the east coast of England, essentially flowing parallel to the coast. In the northern North Sea, surface tidal velocities are much lower, of order 5-15 cm/s with the orientation of the major axis of the ellipse in a north-south direction. However in the central North Sea, the orientation of the major axis is in a west-east direction, see Figures 3a,b, and the magnitude of the current is of order 25 cm/s.

Comparing Figures 3a and 3b it is evident that over most of the North Sea, both major and minor axes of the tidal current ellipse diminish with depth. However close to the Norwegian coast the computed ellipses do not exhibit this behaviour; the minor axis increases with depth close to the sea bed, and this increase is present in the M_2 current obtained from the harmonic analysis of the observations taken in this area during JONSDAP '76.

It is evident from Figures 3a and 3b that the current ellipses to the east of Aberdeen, rotate in the opposite directions at sea surface and sea bed. Computed current ellipses close to the Norwegian coast also have a different sense of rotation between surface and bottom, and these differences agree well with observational data taken in the area.

As more tidal data becomes available from the JONSDAP '76 program, a more rigorous comparison between computed and observed current ellipses will be possible.

Figure 4. Distribution of mean-wind stress for the period 15 March to 15 April 1976 over the continental shelf.

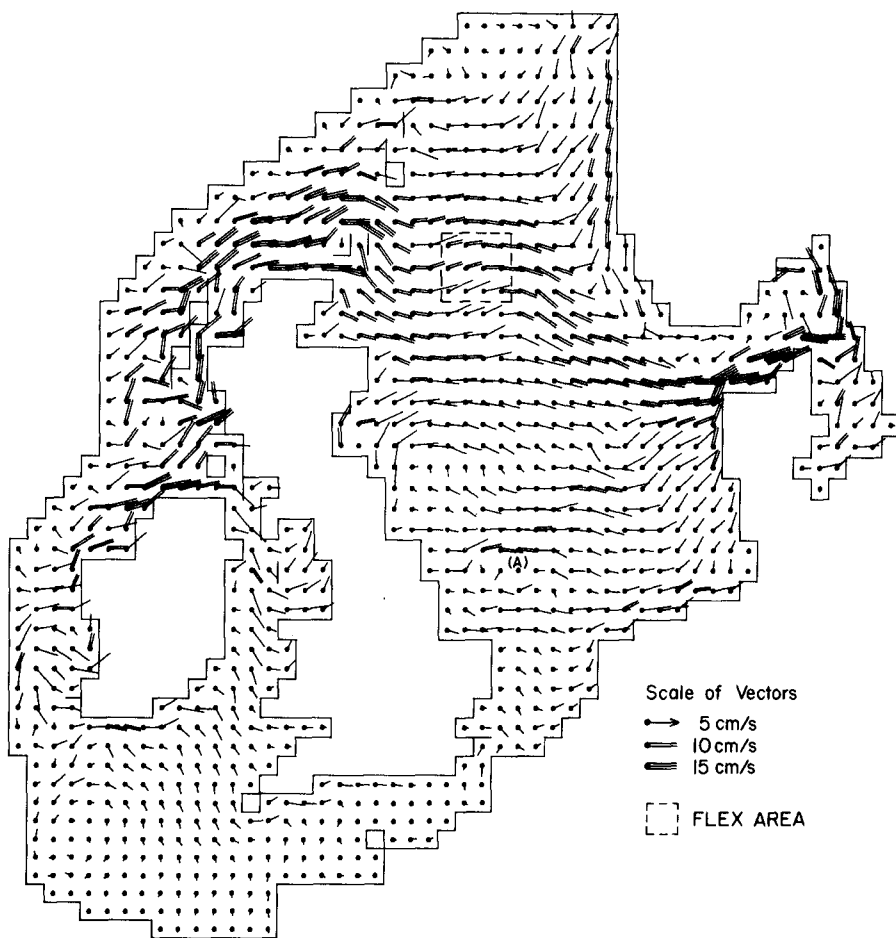

Figure 5a. Meteorologically-induced surface currents, means for the period 15 March to 15 April 1976, computed with the three-dimensional shelf model.

Figure 5b. Meteorologically-induced bottom currents, means for the period 15 March to 15 April 1976, computed with the three-dimensional shelf model.

6. Wind induced circulation for the period 15 March to 15 April, 1976.

Initial conditions corresponding to a state of rest were assumed, and the three-dimensional motion three days after the imposition of the meteorological forcing terms was calculated by integrating equations (8), (15) and (16) forward through time.

The distribution of the mean wind stress over the shelf is given in Figure 4.

The computed spatial distribution of meteorologically induced surface current over the shelf is shown in Figure 5a and comparing this with the computed distribution of bottom current in Figure 5b, it is evident that over most of the shelf the magnitude of the current decreases with depth, and that in certain areas significant differences in current direction, up to 180° , occur between surface and bottom currents.

The horizontal variation of surface current in the region of the FLEX box, to a first approximation is fairly uniform, reflecting the uniform wind stress field, being essentially an eastward flow, at about 45° to the right of the wind field, as would be expected from Ekman theory. However, the bottom flow (Figure 5b) shows a large horizontal variation, being directed southward down the Scottish coast in the sea area to the east of Wick, then flowing eastward at the latitude of Aberdeen, and subsequently turning northward at a point about 100 km to the south of the FLEX box. The flow through the FLEX box shows the current turning from a northward to an eastward flow, which then continues to the south east into the Skagerrak. This high horizontal spatial variation of bottom current in the northern North Sea presumably being due to the influence of bottom topography.

Differences in direction between surface and bottom currents in the German Bight are also evident from Figures 5a and 5b. The surface current is mainly to the north east, moving water towards the coast, whereas the bottom current is to the north west, taking water away from the coast.

A particularly interesting circulation pattern exists off the east coast of England in the region of the grid point marked (A) in Figures 5a and 5b. At grid point (A) the surface current is near zero, while the bottom current is the order of 3 or 4 cm/s towards the coast. The surface currents in the area surrounding point (A) are predominantly off shore, whereas at point (A), and due west of it, the bottom current is towards the coast. This type of circulation has been observed a number of times (Hill [1973]).

Further calculations are presently in progress to compute the daily residual circulation of the North Sea for the period considered here.

7. Concluding Remarks

The results described in Section 3 show that a numerical model can play an important role in the design of an oceanographic exercise. By making measurements at critical points along the open boundaries of the model, an optimum set of open boundary data can be derived and

subsequently used with the model to simulate the motion of the sea during the period of the exercise.

Preliminary comparisons of the three-dimensional tidal currents, computed using the shelf model, with the observational data collected during JONSDAP '76 suggest that the model is reproducing the observed distribution of the tide over the North Sea. As more data becomes available a more rigorous comparison will be possible.

The three-dimensional meteorologically induced circulation of the North Sea, computed with the model, clearly shows the importance of bottom topography and coastal features upon the meteorologically induced circulation of the North Sea.

Further calculations to determine the daily residual flow of the North Sea are in progress and a comparison between these and observed residual flows measured during JONSDAP '76 will provide a rigorous test of the model.

Acknowledgements

The author is indebted to Dr. N. S. Heaps for useful comments during the course of this work. The depth distribution used in the three-dimensional shelf model and the open boundary input data to this model were provided by Dr. R. A. Flather from his two-dimensional shelf model.

The care and effort taken by the Meteorological Office in extracting the meteorological data from their atmospheric model is much appreciated, as is the work performed by Mr. R. A. Smith in preparing the diagrams.

The work described in this paper was funded by a Consortium consisting of the Natural Environment Research Council, the Ministry of Agriculture and Fisheries, and the Departments of Energy and Industry.

CHAPTER 64

A NEW APPROACH FOR TIDAL COMPUTATIONS

C. LE PROVOST

Chargé de Recherche C.N.R.S.

Institute of Mechanics - GRENOBLE (FRANCE)

During the twenty last years, tidal modelling has been intensively developed. Following the growth of engineering needs in coastal areas, more and more accurate models have been established, and this constant research of better accuracy in the representation of real phenomena brings us to very expansive models. One way of reducing these costs is to use variable grids in space, in order to concentrate refined meshes in areas of interest. But the finite difference schemes are not well adapted to this kind of procedure : this is why several attempts have been made recently to use finite element technics : C. TAYLOR and J.M. DAVIS in 1975 [1], C.A. BREBBIA and P.W. PARTRIDGE in 1976 [2], ... But these applications are not easy.

During the same period, since 1975, more complex tentative have been made using Fourier transform of the equations, previously to any kind of numerical integration : tides are effectively quasi periodic phenomena, and their spectra are well known. Two important points arise in doing this :

- time variable is eliminated from the hyperbolic problem of propagation, transformed into a set of elliptic problems.
- for each elliptic problem, a variational formulation is available.

It becomes thus possible to look at the various components of the real tides, and to use finite element technic to integrate numerically these problems in real basins. In this way, B.M. JAMART and D.F. WINTER have used recently a purely numerical procedure based upon the Fast Fourier Transform to carry their tidal computations in fjords, cf. [5], while A. ASKAR and A.S. CAKMAK introduced a perturbation technic to handle the non linearities, very important in such problems, cf. [1]. We have followed a similar approach to study the complete spectrum of the tides in shallow water areas for the european seas : North Sea and English Channel, cf. [9]. The aim of this paper is to illustrate the main ideas of our method applied on an academic one-dimensional problem.

I. THE EQUATIONS.

In the study of the dynamics of tidal waves in shallow waters, the long wave equations are classically used. They are obtained from the Navier Stokes equations by integration over the vertical coordinate, under the assumption that the characteristic vertical scale H is much smaller than the horizontal scale L ($H/L \ll 1$). With this assumption, it can be shown that the pressure is hydrostatic. Without any meteorological effect at the sea surface, and neglecting the horizontal eddy viscosity, the NS equations reduce to :

$$(1.1) \quad \begin{aligned} \frac{\partial \tilde{u}}{\partial \tilde{t}} + \tilde{u} \frac{\partial \tilde{u}}{\partial \tilde{x}} + \tilde{v} \frac{\partial \tilde{u}}{\partial \tilde{y}} - \tilde{f} \tilde{v} + g \frac{\partial \tilde{\zeta}}{\partial \tilde{x}} + \frac{\tilde{c}}{\tilde{h} + \tilde{\zeta}} \sqrt{\tilde{u}^2 + \tilde{v}^2} \tilde{u} &= 0 \\ \frac{\partial \tilde{v}}{\partial \tilde{t}} + \tilde{u} \frac{\partial \tilde{v}}{\partial \tilde{x}} + \tilde{v} \frac{\partial \tilde{v}}{\partial \tilde{y}} + \tilde{f} \tilde{u} + g \frac{\partial \tilde{\zeta}}{\partial \tilde{y}} + \frac{\tilde{c}}{\tilde{h} + \tilde{\zeta}} \sqrt{\tilde{u}^2 + \tilde{v}^2} \tilde{v} &= 0 \end{aligned}$$

Similarly, the continuity equation can be written :

$$(1.2) \quad \frac{\partial \tilde{\zeta}}{\partial \tilde{t}} + \frac{\partial(\tilde{h} + \tilde{\zeta})\tilde{u}}{\partial \tilde{x}} + \frac{\partial(\tilde{h} + \tilde{\zeta})\tilde{v}}{\partial \tilde{y}} = 0$$

with : \tilde{x}, \tilde{y} : horizontal cartesian coordinates in the plane of undisturbed sea surface

\tilde{z} : vertical coordinate

\tilde{t} : time

\tilde{h} : undisturbed depth of water

$\tilde{\zeta}$: elevation of the sea surface

\tilde{u}, \tilde{v} : components of the depth averaged currents in the \tilde{x}, \tilde{y} directions

$$(1.3) \quad \tilde{u} = \tilde{u}(\tilde{x}, \tilde{y}, t) = \frac{1}{\tilde{h} + \tilde{\zeta}} \int_{-\tilde{h}}^{\tilde{\zeta}} \tilde{u}(\tilde{x}, \tilde{y}, \tilde{z}, \tilde{t}) d\tilde{z}, \quad \tilde{v} = \tilde{v}(\tilde{x}, \tilde{y}, t) = \frac{1}{\tilde{h} + \tilde{\zeta}} \int_{-\tilde{h}}^{\tilde{\zeta}} \tilde{v}(\tilde{x}, \tilde{y}, \tilde{z}, \tilde{t}) d\tilde{z}$$

\tilde{f} : Coriolis parameter ($\tilde{f} = 2\tilde{n} \sin \lambda$, with $\tilde{n} = \frac{2\pi}{24h}$ and λ : latitude of point (\tilde{x}, \tilde{y}))

\tilde{c} : coefficient of quadratic bottom friction

g : acceleration due to gravity.

Tidal problems are generally solved in areas \mathcal{D} limited by coastal boundaries Γ_1 and open boundaries Γ_2 . Along Γ_1 the classical boundary condition is $\tilde{v}_n = 0$ (impermeability of coastal lines). Along Γ_2 , several conditions are used :

$$(1.4) \quad \tilde{\zeta} = \tilde{\zeta}^*(\tilde{x}, \tilde{y}, \tilde{t}) \quad \text{or} \quad \tilde{v}_N = v_N^*(\tilde{x}, \tilde{y}, \tilde{t}), \quad \text{normal velocity to } \Gamma_2$$

f^* being a given function on $(\tilde{x}, \tilde{y}) \in \Gamma_2$, for all t .

It should be noted that, with formulation (1.1), tides are assumed to be induced in \mathcal{D} by the open boundaries Γ_2 . But the method here presented can be applied to the more general case of an oceanic basin influenced by the tide generating potential (cf. C. LE PROVOST and A. PONCET, 1977 [8]).

II. GENERAL PRESENTATION OF THE SPECTRAL METHOD.

II.1. Dimensionless equations.

In order to simplify, it is convenient to use non dimensional variables :

$$x = \frac{\tilde{x}}{\tilde{L}}, \quad y = \frac{\tilde{y}}{\tilde{L}}, \quad \zeta = \frac{\tilde{\zeta}}{\tilde{H}}, \quad h = \frac{\tilde{h}}{\tilde{H}}, \quad t = \frac{\tilde{t}}{\tilde{L}/\tilde{c}}, \quad u = \frac{\tilde{u}}{\tilde{c}}, \quad v = \frac{\tilde{v}}{\tilde{c}} \quad \text{with } \tilde{c} = \sqrt{gH}$$

$$\Omega = \frac{\tilde{\Omega}}{\tilde{c}/\tilde{L}}, \quad \omega = \frac{\tilde{\omega}}{\tilde{c}/\tilde{L}}, \quad A = \frac{\tilde{A}}{\tilde{c}}, \quad A' = \frac{\tilde{A}'}{\tilde{H}}, \quad k = \tilde{c} \frac{\tilde{L}}{\tilde{H}}$$

Thus equations (1) are :

$$\begin{aligned} (2.2) \quad & \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} - 2\Omega \sin \lambda v + \frac{\partial \zeta}{\partial x} + \frac{k}{h + \zeta} \sqrt{u^2 + v^2} u = 0 \\ & \frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + 2\Omega \sin \lambda u + \frac{\partial \zeta}{\partial y} + \frac{k}{h + \zeta} \sqrt{u^2 + v^2} v = 0 \\ & \frac{\partial \zeta}{\partial t} + \frac{\partial hu}{\partial x} + \frac{\partial hv}{\partial y} + \frac{\partial \zeta u}{\partial x} + \frac{\partial \zeta v}{\partial y} = 0 \end{aligned}$$

which can be written :

$$(2.3) \quad MS = B + E$$

with

$$M = \begin{vmatrix} \frac{\partial}{\partial t} & & -2\Omega \sin \lambda & & h \frac{\partial}{\partial x} \\ & 2\Omega \sin \lambda & & & h \frac{\partial}{\partial y} \\ \frac{\partial}{\partial x} & & & & \frac{\partial}{\partial t} \\ & & \frac{\partial}{\partial y} & & \\ & & & & \frac{\partial}{\partial t} \end{vmatrix} \quad S = \begin{vmatrix} hu \\ hv \\ \zeta \end{vmatrix}$$

$$B = \begin{vmatrix} -h(u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y}) \\ -h(u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y}) \\ -\frac{\partial}{\partial x} (\zeta u) - \frac{\partial}{\partial y} (\zeta v) \end{vmatrix} \quad E = \begin{vmatrix} -\frac{kh}{h + \zeta} \sqrt{u^2 + v^2} u \\ -\frac{kh}{h + \zeta} \sqrt{u^2 + v^2} v \\ 0 \end{vmatrix} = \begin{vmatrix} f_x \\ f_y \\ 0 \end{vmatrix}$$

II.2. Introduction of small parameters procedure.

We know from the theory of oceanic tides, and from observations, the structure of the tidal spectrum at the open boundary Γ_2 . We can thus suppose that (1.4) are of the form :

$$\begin{aligned}
 \tilde{U}_N &= \sum_{i=1}^{N_p} \tilde{A}_i \tilde{U}_{N_i}^* \cos(\tilde{\omega}_i t + \tilde{\psi}_{N_i}^*) & U_N &= \sum_{i=1}^{N_p} A_i U_{N_i}^* \cos(\omega_i t + \psi_{N_i}^*) \\
 (2.4) \quad \text{or } \tilde{U} &= \sum_{i=1}^{N_p} \tilde{A}_i \tilde{U}_i^* \cos(\tilde{\omega}_i t + \tilde{\psi}_i^*) & \text{i.e.} & \quad \text{or } U = \sum_{i=1}^{N_p} A_i U_i^* \cos(\omega_i t + \psi_i^*)
 \end{aligned}$$

where $U_{N_i}^*$, $\psi_{N_i}^*$, and U_i^* , ψ_i^* are given functions on Γ_2 corresponding to the N_i^p tidal components of pulsation ω_i inducing the movement in \mathcal{D}^p through the open boundary ; the orders of magnitude of each of these components are characterized by parameters A_i or A_i' .

When vectors B and E are neglected, resolution of (2.3) with boundary conditions (2.4) is not difficult (cf. HANSEN, 1962 [4]). But in coastal areas, non linearities are important. In order to handle the different orders of magnitude of these non linearities, we have introduced a perturbation method (cf. J. KRAVTCHENKO and C. LE PROVOST, 1977 [6]). Solutions of (2.3) are considered under the form :

$$(2.5) \quad S = A_i S_{i1} + A_i^p S_{ip} + A_i^q A_j^r S_{ijqr} + \dots$$

where $i, j = 1, 2, \dots, N_p$ and $p, q, r = 1, 2, \dots, \infty$
 Taking (2.5) in (2.3), and gathering the terms of same power in A_i , we obtain for each order of magnitude in A_i a set of equations defining S_{i1} , S_{ip} , S_{ijqr} , ... :

$$\begin{aligned}
 (2.6) \quad M S_{i1} &= 0 \\
 M S_{ip} &= B_{ip} + E_{ip} && \text{with corresponding limit conditions} \\
 M S_{ijqr} &= B_{ijqr} + E_{ijqr} && \text{coming from (2.4)} \\
 &\dots\dots\dots
 \end{aligned}$$

Following a classical procedure in forced vibration theory, solutions of (2.6) are expected under the form :

$$\begin{aligned}
 S_{i1} &= \begin{vmatrix} h u_{i1}(x,y) \cos[\omega_i t + \psi_{i1}(x,y)] \\ h v_{i1}(x,y) \cos[\omega_i t + \chi_{i1}(x,y)] \\ \gamma_{i1}(x,y) \cos[\omega_i t + \varphi_{i1}(x,y)] \end{vmatrix} \\
 (2.7) \quad S_{ip} = S_{ip}^{(a,b,c,\dots)} &= \begin{vmatrix} h u_{ip}^{(a,b,c,\dots)} \cos[(a\omega_1 + b\omega_2 + c\omega_3 + \dots)t + \psi_{ip}^{(a,b,\dots)}] \\ h v_{ip}^{(a,b,c,\dots)} \cos[(a\omega_1 + b\omega_2 + c\omega_3 + \dots)t + \chi_{ip}^{(a,b,\dots)}] \\ \gamma_{ip}^{(a,b,c,\dots)} \cos[(a\omega_1 + b\omega_2 + c\omega_3 + \dots)t + \varphi_{ip}^{(a,b,\dots)}] \end{vmatrix} \\
 S_{ijqr} &= \dots\dots\dots
 \end{aligned}$$

with $a, b, c, \dots = 0, \pm 1, \pm 2, \dots \infty$

The resolution of each system (2.6) is consequently splitted into a set of systems of the following form, of which time is eliminated :

$$\bar{M}_{i1} \cdot \bar{S}_{i1} = 0 \quad (2.8)$$

$$\bar{M}_{ip}(a,b,c\dots) \cdot \bar{S}_{ip}(a,b,c\dots) = \bar{B}_{ip}(a,b,c\dots) + \bar{E}_{ip}(a,b,c\dots)$$

where S_{i1} are vectors of 6 unknowns of two variables x and y :

$$hu_{i1} \cos \psi_{i1}, hu_{i1} \sin \psi_{i1}, hv_{i1} \cos \chi_{i1}, hv_{i1} \sin \chi_{i1}, \zeta_{i1} \cos \varphi_{i1}, \zeta_{i1} \sin \varphi_{i1}$$

(and the same for $S_{ip}(a,b,c\dots), \dots$).

The matrices $\bar{M}_{i1}, \bar{M}_{ip}(a,b,c\dots)$ are easy to deduce from (2.3), (2.6) and (2.7) ; it is the same for vectors $B_{ip}(a,b,c\dots), B_{ip}(a,b,c\dots), \dots$. But an important difficulty arises for vector E , the terms of which are not analytical in the vicinity of small values of the parameters A_i , and impossible "a priori" to develop under a form $E_{ip}(a,b,c\dots)$.

II.3. Development of the quadratic terms of friction.

We have established an approximate development of vector E , in the form of generalized Fourier series (cf. C. LE PROVOST, 1973 [7]), under the assumption of the existence of a "dominant" wave in the complete tidal spectrum over the studied area. This "dominant constituent" must have everywhere in \mathcal{D} a maximum of velocity much bigger than the other constituents in the spectrum. As an example, the M_2 constituent of the tide is the "dominant" wave for the european seas. Taking index l for this "dominant" constituent, f_x and f_y are expanded as follows :

$$f_x = A_i A_j k \sum_{i=1}^N FX_i \cos(\omega_i t + \phi X_i) \quad (2.9)$$

$$f_y = A_i A_j k \sum_{i=1}^N FY_i \cos(\omega_i t + \phi Y_i)$$

where $FX_i, FY_i, \phi X_i, \phi Y_i$ are functions of the amplitude and the phase of the dominant constituent, and of the other constituents of the spectrum. N is theoretically infinite, but in fact it can be limited to a finite value $N_F (> N_0)$.

The aim of this paper is not to present the details of this development. Let us notice only that two classes of terms can be distinguished in (2.9).

a. A first group corresponds to the damping effect played by friction for all the constituents in the tidal spectrum. Considering these terms, it appears that :

- For the dominant wave, this damping can be considered independently of the other constituents of the spectrum, as a first approximation.
- For the other constituents, this damping is strongly influenced by the local characteristics of the dominant wave.

b. A second group of terms corresponds to linear combinations of the pulsations of the different constituents of the complete tidal spectrum : they represent the generating effect of new constituents played by friction in shallow water areas.

II.4. The perturbation method.

In coastal areas, friction is so much important that a simple small parameter method applied as presented in II.2 to solve (2.2) is not rapidly converging towards the real solution within practical limits : this has been noticed in 1971 by B. GALLAGHER and W. MUNK. It is necessary to use a perturbation method in which the first approximation of the solution is already representative of the damped solution. The developments (2.9) show us the way : the first order solution must be the dominant wave studied in the presence of the damping effect of friction, and the other constituents of the tide will appear as perturbations, studied separately as prescribed by a classical process of successive orders of approximation, cf. [6].

III. ILLUSTRATION OF THE PERTURBATION METHOD APPLIED TO A MONO DIMENSIONAL PROBLEM.

Let us consider a channel \mathcal{E} of constant depth h , closed at one end by a vertical wall, and connected with the ocean at the other end. The problem is reduced to a monodimensional one, with the following equations :

$$(3.1) \quad \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + \frac{\partial \zeta}{\partial x} + \frac{kh}{h + \zeta} |u| u = 0$$

$$\frac{\partial \zeta}{\partial t} + \frac{\partial hu}{\partial x} + \frac{\partial \zeta u}{\partial x} = 0$$

The limit conditions are expressed in such a way that they correspond to a monophasic wave coming inside the channel, of pulsation ω , and that every non linear wave induced in \mathcal{E} by non linear processes is coming out of this channel through the limit $x = 0$ without any reflexion. This kind of radiation condition has been established from the theory of characteristics and is formulated as follows :

$$(3.2) \quad \tilde{u} + 2 \sqrt{g(\tilde{h} + \tilde{\zeta})} = 2\tilde{A} \cos \tilde{\omega} \tilde{t} + 2 \sqrt{g\tilde{h}}$$

i.e. $u + 2 \sqrt{1 + \zeta} = 2A \cos \omega t + 2$

III.1. Development of the friction term.

Let us assume that, limited to the second order of approximation, the solution can be written :

$$u = \sum A^p u_p = A u_{11} \cos(\omega t + \psi_{11}) + A^2 [u_{02} + u_{12} \cos(\omega t + \psi_{12}) + u_{22} \cos(2\omega t + \psi_{22}) + u_{32} \cos(3\omega t + \psi_{32}) + \dots] + O(A^3)$$

$$(3.3) \quad \zeta = \sum A^p \zeta_p = A \zeta_{11} \cos(\omega t + \varphi_{11}) + A^2 [\zeta_{02} + \zeta_{12} \cos(\omega t + \varphi_{12}) + \zeta_{22} \cos(2\omega t + \varphi_{22}) + \zeta_{32} \cos(3\omega t + \varphi_{32}) + \dots] + O(A^3)$$

As it was said in § III.3, the friction term :

$$F = \frac{k}{1 + \zeta} |u| u$$

can be expanded into a Fourier serie. We do not present here the details of the analytical development (see. C. LE PROVOST and A. KABBAJ, 1978, [10]) ; let us write only the result of these computations :

$$f = |u| u =$$

second order	≠ damping	$A^2 \cdot \frac{8u_{11}}{3\pi} u_{11} \cos(\omega t + \psi_{11})$
	≠ generation of non linear constituents	$A^2 \left[\frac{8}{15\pi} u_{11}^2 \cos(3\omega t + 3\psi_{11}) - \frac{8}{105\pi} u_{11}^2 \cos(5\omega t + 5\psi_{11}) + \dots \right]$
third order	≠ damping	$A^3 \frac{4u_{11}}{\pi} [u_{02} + u_{12} \cos(\omega t + \psi_{12}) + u_{22} \cos(2\omega t + \psi_{22}) + u_{32} \cos(3\omega t + \psi_{32}) + \dots]$
	≠ generation of non linear constituents	$A^3 \left\{ \frac{4}{\pi} u_{11} u_{22} + \frac{4}{3\pi} u_{11} [u_{12} \cos(\omega t + 2\psi_{11} - \psi_{12}) + u_{32} \cos(\omega t + 2\psi_{11} - \psi_{32})] - \frac{4}{15\pi} u_{11} [u_{32} \cos(\omega t + 4\psi_{11} - \psi_{32}) + u_{52} \cos(\omega t + 6\psi_{11} - \psi_{52})] + \frac{4}{35\pi} u_{11} [u_{52} \cos(\omega t + 6\psi_{11} - \psi_{52}) + \dots] \right\}$

The different terms considered as "damping" terms appear to be a kind of linearization of friction. Using the notations :

$$(3.4) \quad \lambda = \frac{8k}{3\pi} Au_{11} \quad , \quad \lambda' = \frac{4k}{3\pi} Au_{11} \quad , \quad \lambda_{32} = \frac{8k}{15\pi} \quad , \quad \lambda_{52} = -\frac{8k}{105\pi}$$

F can be written :

$$F = \frac{1}{1+\gamma} \left[\lambda Au_1 + \lambda' A^2 u_2 + \lambda_{32} A^2 u_{11}^2 \cos 3(\omega t + \psi_{11}) + \lambda_{52} u_{11}^2 \cos 5(\omega t + \psi_{11}) + \dots + O(A^3) \right]$$

i.e., using development : $(1 + \gamma)^{-1} = 1 - A\gamma_1 + O(A^2)$

$$(3.5) \quad F = \lambda Au_1 - \lambda A^2 u_1 \gamma_1 + \lambda' A^2 u_2 + \lambda_{32} A^2 u_{11}^2 \cos 3(\omega t + \psi_{11}) + \lambda_{52} u_{11}^2 \cos 5(\omega t + \psi_{11}) + \dots + O(A^3).$$

We must notice that coefficients λ and λ' , which can be called "linearized friction coefficients" are not constants and depend on the solution Au_{11} itself.

III.2. Application of the perturbation method.

First order : Following the formulation (2.6), the system giving the first order solution is :

$$(3.6) \quad \begin{aligned} \frac{\partial \zeta_1}{\partial t} + \frac{\partial u_1}{\partial x} &= 0 \\ \frac{\partial u_1}{\partial t} + \frac{\partial \zeta_1}{\partial x} + \lambda u_1 &= 0 \end{aligned}$$

with the limit conditions deduced from (3.2), (using development $(1 + \gamma)^{1/2} = 1 + \frac{\gamma}{2} + \dots$) :

$$(3.7) \quad \begin{aligned} u_1(1) &= 0 \\ u_1(0) + \zeta_1(0) &= 2 \cos \omega t \end{aligned}$$

Notice that, doing this, we introduce in the definition of the first order solution, the damping effect of friction λu_1 which is, strictly speaking, a term of second order.

Let us use the complex notations :

$$(3.8) \quad \begin{aligned} \alpha_{ki} &= \frac{1}{2} \zeta_{ki} e^{j\varphi_{ki}} \\ \mu_{ki} &= \frac{1}{2} u_{ki} e^{j\varphi_{ki}} \end{aligned}$$

$$\begin{aligned} \text{i.e. } \zeta_{ki} \cos(k\omega t + \varphi_{ki}) &= \alpha_{ki} e^{jk\omega t} + \alpha_{ki}^* e^{-jk\omega t} \\ u_{ki} \cos(k\omega t + \psi_{ki}) &= \mu_{ki} e^{jk\omega t} + \mu_{ki}^* e^{-jk\omega t} \end{aligned}$$

with f^* being the conjugate of the complex function f . Equations (3.6) and (3.7) reduce so to :

$$(3.9) \quad \begin{aligned} j\omega \alpha_{11} + \frac{d\mu_{11}}{dx} &= 0 & \mu_{11}(1) &= 0 \\ j\omega \mu_{11} + \frac{d\alpha_{11}}{dx} + \lambda \mu_{11} &= 0 & \alpha_{11}(0) + \mu_{11}(0) &= 1 \end{aligned}$$

which can be written :

$$(3.10) \quad \begin{aligned} \alpha_{11} &= \frac{j}{\omega} \frac{d\mu_{11}}{dx} & \mu_{11}(1) &= 0 \\ \frac{d^2 \mu_{11}}{dx^2} + \omega^2 (1 - j \frac{\lambda}{\omega}) \mu_{11} &= 0 & \mu_{11}(0) + \frac{j}{\omega} \frac{d\mu_{11}(0)}{dx} &= 1 \end{aligned}$$

Finally, we have to solve a second order differential equation of the complex function μ_{11} of one variable only : x . This equation is non linear, because of the presence of $\lambda = \lambda(u_{11})$. We have solved this equation by a numerical finite difference scheme, using a method of successive approximations for the non linearity : as a first approximation, λ is taken equal to zero, which corresponds to the linear solution of (3.1) without friction.

A numerical application has been done with the following numerical values :

$h = 50$ m, $L = 495$ km, $T = 12$ h. 25 mn, $A = 1$ m/s, $c = 3.10^{-3}$ MKSA (which schematically corresponds to the semi-diurnal tidal wave in the English Channel). On figure 1, we have plotted the amplitude of the sea surface elevation and of the current at $x = 0$, $x = L/2$ and $x = L$, obtained at the different steps of the iterative process used for the integration of (3.10). As it can be seen, the solution is stable after five iterations.

In order to check our solution, we have integrated problem (3.1) under the same limit conditions, with the same numerical values by a classical Lax Wendroff finite difference scheme. The solutions $u(x,t)$ and $\zeta(x,t)$ thus obtained have been expanded by Fourier analysis under the form :

$$(3.11) \quad \begin{aligned} u^{LW}(x,t) &= u_0^{LW}(x) + \sum_k u_k^{LW}(x) \cos [k\omega t + \varphi_k^{LW}(x)] \\ \zeta^{LW}(x,t) &= \zeta_0^{LW}(x) + \sum_k \zeta_k^{LW}(x) \cos [k\omega t + \varphi_k^{LW}(x)] \end{aligned}$$

We have plotted on figure 2 and 3 the results for u_1^{LW} and ζ_1^{LW} in order to compare these values with u_{11} and ζ_{11} deduced from the integration of (3.10). The results fit very well.

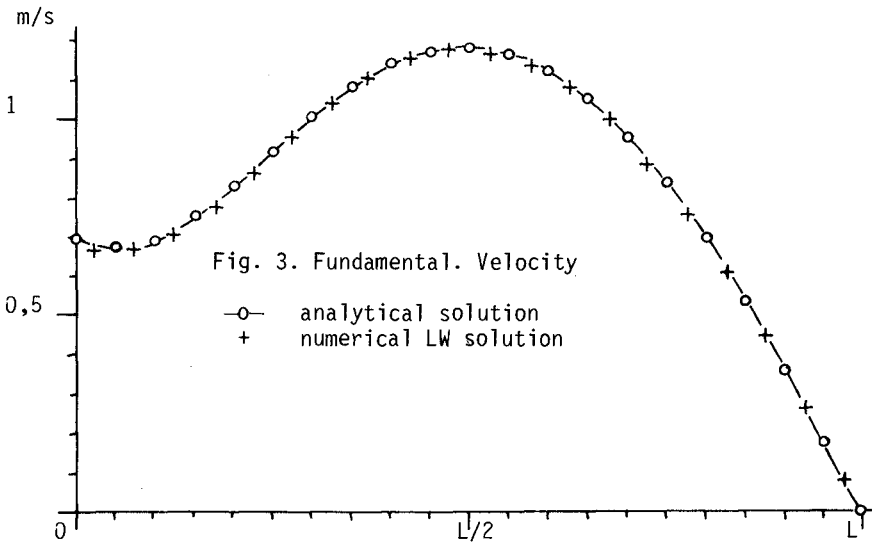

Fig. 1. Convergence of the iterative method

— Velocity - - - - Sea surface elevation
 • mouth of the channel
 x middle of the channel
 o end of the channel

This numerical example illustrates the details of our method : the basic solution used for our perturbation procedure is the damped dominant wave ; it can be seen on figure 1 the important role played by the friction term : iteration 1 corresponds to no damping, and the corresponding solution is 1,8 the exact solution, for the maximum of amplitude of the velocity field. The agreement shown on figure 2 between our approximate solution and the Lax Wendroff solution, which can be considered the exact one, is sufficient to convince of the interest of the proposed method.

Knowing this dominant solution with a good accuracy, we calculate now the second order solution, following formulation (2.6).

Second order : The system giving the second order solutions is :

$$\begin{aligned} \frac{\partial \zeta_2}{\partial t} + \frac{\partial u_2}{\partial x} &= - \frac{\partial (\zeta_1 u_1)}{\partial x} \\ (3.12) \quad \frac{\partial u_2}{\partial t} + \frac{\partial \zeta_2}{\partial x} &= - \frac{1}{2} \frac{\partial u_1^2}{\partial x} - F_2 \end{aligned}$$

$$u_2(1) = 0$$

$$u_2(0) + \zeta_2(0) = \frac{\zeta_1(0)^2}{4}$$

with
$$F_2 = \lambda'_{u_2} - \lambda_{u_1} \zeta_1 + \lambda_{32} u_{11}^2 \cos 3(\omega t + \psi_{11}) + \lambda_{52} u_{11}^2 \cos 5(\omega t + \psi_{11})$$

Using the complex notation defined in (3.8), the second members of (3.12) can be written :

$$\begin{aligned} \frac{\partial \zeta_1 u_1}{\partial x} &= \frac{\partial}{\partial x} (\alpha_{11} \mu_{11}^* + \alpha_{11}^* \mu_{11}) + \left[\frac{\partial}{\partial x} (\alpha_{11} \mu_{11}) e^{2j\omega t} + \text{c.c.} \right] \\ \frac{\partial u_1^2}{\partial x} &= 2 \frac{\partial \mu_{11} \mu_{11}^*}{\partial x} + \left[\frac{\partial \mu_{11}^2}{\partial x} e^{2j\omega t} + \text{c.c.} \right] \quad (\text{c.c. : complex conjugate}) \\ \zeta_1^2 &= 2\alpha_{11} \alpha_{11}^* + \left[\alpha_{11}^2 e^{2j\omega t} + \text{c.c.} \right] \\ (3.13) \quad F_2 &= \lambda'_{u_2} - \lambda [\alpha_{11} \mu_{11}^* + \alpha_{11}^* \mu_{11}] + [\lambda' \mu_{12} e^{j\omega t} + \text{c.c.}] \\ &\quad + [(\lambda' \mu_{22} - \lambda \mu_{11} \alpha_{11}) e^{2j\omega t} + \text{c.c.}] \\ &\quad + [\lambda' \mu_{32} + 2\lambda \mu_{32} \mu_{11}^2 e^{j\psi_{11}}] e^{3j\omega t} + \text{c.c.}] \\ &\quad + [(\lambda' \mu_{52} + 2\lambda \mu_{52} \mu_{11}^2 e^{3j\psi_{11}}) e^{5j\omega t} + \text{c.c.}] \end{aligned}$$

(3.12) is a linear system of equations which therefore can be splitted up into differential systems of the variable x only :

Term of zero frequency H_0 :

$$\begin{aligned} \frac{du_{o2}}{dx} &= - \frac{d}{dx} (\alpha_{11} \mu_{11}^{\bar{x}} + \alpha_{11}^{\bar{x}} \mu_{11}) \\ (3.14) \quad \frac{d\gamma_{o2}}{dx} &= - (\mu_{11} \mu_{11}^{\bar{x}})_x - \lambda' u_{o2} + \lambda (\alpha_{11} \mu_{11}^{\bar{x}} + \alpha_{11}^{\bar{x}} \mu_{11}) \\ u_{o2}(1) &= 0 \\ \gamma_{o2}(0) + u_{o2}(0) &= \frac{1}{2} \alpha_{11}(0) \alpha_{11}^{\bar{x}}(0) \end{aligned}$$

Term of frequency 1 :
