No forcing term occur in the corresponding equations deduced from (3.12) and (3.13). The corresponding solution is evidently 0. No correction of solutions u_1 , γ_1 occurs at the second order of approximation.

Term of frequency 2, H_2 :

$$\begin{aligned} \frac{d\mu_{22}}{dx} + 2j\omega\alpha_{22} &= - \frac{d}{dx} (\alpha_{11} \mu_{11}) \\ (3.15) \quad \frac{d\alpha_{22}}{dx} + 2j\omega\mu_{22} &= - \frac{1}{2} \frac{d}{dx} (\mu_{11}^2) - \lambda' \mu_{22} + \lambda \alpha_{11} \mu_{11} \\ \mu_{22}(1) &= 0 \\ \mu_{22}(0) + \alpha_{22}(0) &= \frac{\alpha_{11}^2(0)}{4} \end{aligned}$$

Term of frequency 3, H_3 :

$$\begin{aligned} \frac{d\mu_{32}}{dx} + 3j\omega\alpha_{32} &= 0 \\ (3.16) \quad \frac{d\alpha_{32}}{dx} + 3j\omega\mu_{32} &= -\lambda' \mu_{32} - 2\lambda \mu_{32} \mu_{11}^2 e^{j\psi_{11}} \\ \mu_{32}(1) &= 0 \\ \mu_{32}(0) + \alpha_{32}(0) &= 0 \end{aligned}$$

System (3.14) can be numerically integrated without any difficulty. Systems (3.15) and (3.16) are of the same kind as system (3.9), but with second members, and purely linear coefficients (λ' is function of the dominant solution u_{11} only). These systems can be numerically integrated without any difficulty.

With the numerical values already used to illustrate the computation of the dominant wave, we obtain solutions presented on figures 4 and 5 for the harmonic H_2 , and on figures 6 and 7 for the harmonic H_3 (higher harmonics are too small to be considered). As comparison, on the same figures, the numerical solutions obtained from integration of the time dependent problem with the Lax Wendroff scheme are plotted. We can see that the correspondence is quite good. This agreement illustrates the ability of the method to reproduce the non linear harmonic constituents produced by sinusoidal tidal waves propagating in coastal areas. Let us notice in (3.14), (3.15) and (3.16) the presence of damping terms $\lambda' u_{i,j}$, with λ' function of the dominant velocity field u_{11} : as for the definition of the first order dominant wave, it is essential to take into account these damping terms for the computation of the non linear wave of second order.

In the numerical case here considered, the second order is sufficient to correctly represent the complete solution, but for smaller relative depth areas, the non linear contributions can be amplified, and higher order approximations may be necessary.

With this very simple mono-dimensional problem, the principal steps of the perturbation spectral method have been clearly illustrated:

- computation of the "dominant" solution: resolution of a non linear problem (damping coefficient being function of the solution itself) solved by an iterative process
- computation of the other components of the spectrum: resolution of linear problems (with damping coefficients fixed by the dominant solution).

IV. CONCLUSION. EXTENSION TO THE TWO DIMENSIONAL PROBLEM.

No important difficulty arises when the two dimensional problem is considered. Similarly to (3.10), the dominant wave is defined by a second order differential equation of the complex variable α_{11} , corresponding to the sea surface elevation; because of the damping effect of friction, this equation is non linear. It can be shown that a variational formulation is available for this problem (C. LE PROVOST and A. PONCET, 1978 [9]), so that the natural way to realize numerical integrations in real basins is to use finite element methods. A first application has been done for the M_2 tide in the English Channel: the primarily results published in [9] are satisfactory (cf. figures 8, 9). We are actually computing the M_4 constituent in the same area.

With such a procedure, computations are very cheap, because we have to solve a stationary problem for each important component of the tide in the studied area: except the dominant wave, for which an iterative process is necessary to take into account the non linear damping effect of bottom friction, the second order differential equation defining the amplitude of each constituent is solved only one time. It becomes thus

possible to realize a detailed study of all the components of the tidal spectrum in coastal areas, which has still not be realized in any case, because of excessive computing time necessities.

CHAPTER 65

HYDRODYNAMIC MODELLING OF THE SOUTHERN NORTH SEA

by

David Prandle*

ABSTRACT

Numerical modelling of rivers, estuaries and shallow seas has attracted increasing interest over the last two decades. The models have developed from one dimensional (1D) applications to tidal propagation and flood routing through two and, finally, three dimensional applications to motions ranging from "pseudo-turbulence" to annual-mean residual flows. The present account describes the development, over the last five years, of the modelling studies carried out by the author concerning the hydrodynamics of the southern North Sea and River Thames. The objective is to identify those major points which have emerged that may have a wider significance.

1. INTRODUCTION

The modelling work considered is restricted to one and two (horizontal) dimensional applications; explicit finite-difference solutions are used throughout. The motions involved are assumed to be represented by the following shallow water wave equations :

$$\text{motion (-x)} \quad \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + V \frac{\partial u}{\partial y} + g \frac{\partial Z}{\partial x} + \frac{K u (u^2 + V^2)^{1/2}}{(D+Z)} - \Omega V = 0 \quad (1)$$

$$\text{motion (-y)} \quad \frac{\partial V}{\partial t} + u \frac{\partial V}{\partial x} + V \frac{\partial V}{\partial y} + g \frac{\partial Z}{\partial y} + \frac{K V (u^2 + V^2)^{1/2}}{(D+Z)} + \Omega u = 0 \quad (2)$$

$$\text{continuity} \quad \frac{\partial Z}{\partial t} + \frac{\partial [u(D+Z)]}{\partial x} + \frac{\partial [V(D+Z)]}{\partial y} = 0 \quad (3)$$

where u and V are depth-averaged velocities along the respective directions of the orthogonal axes x and y ;

Z the elevation of the water surface above a fixed horizontal datum;

*Principal Scientific Officer, Institute of Oceanographic Sciences, Bidston Observatory, Merseyside, England.

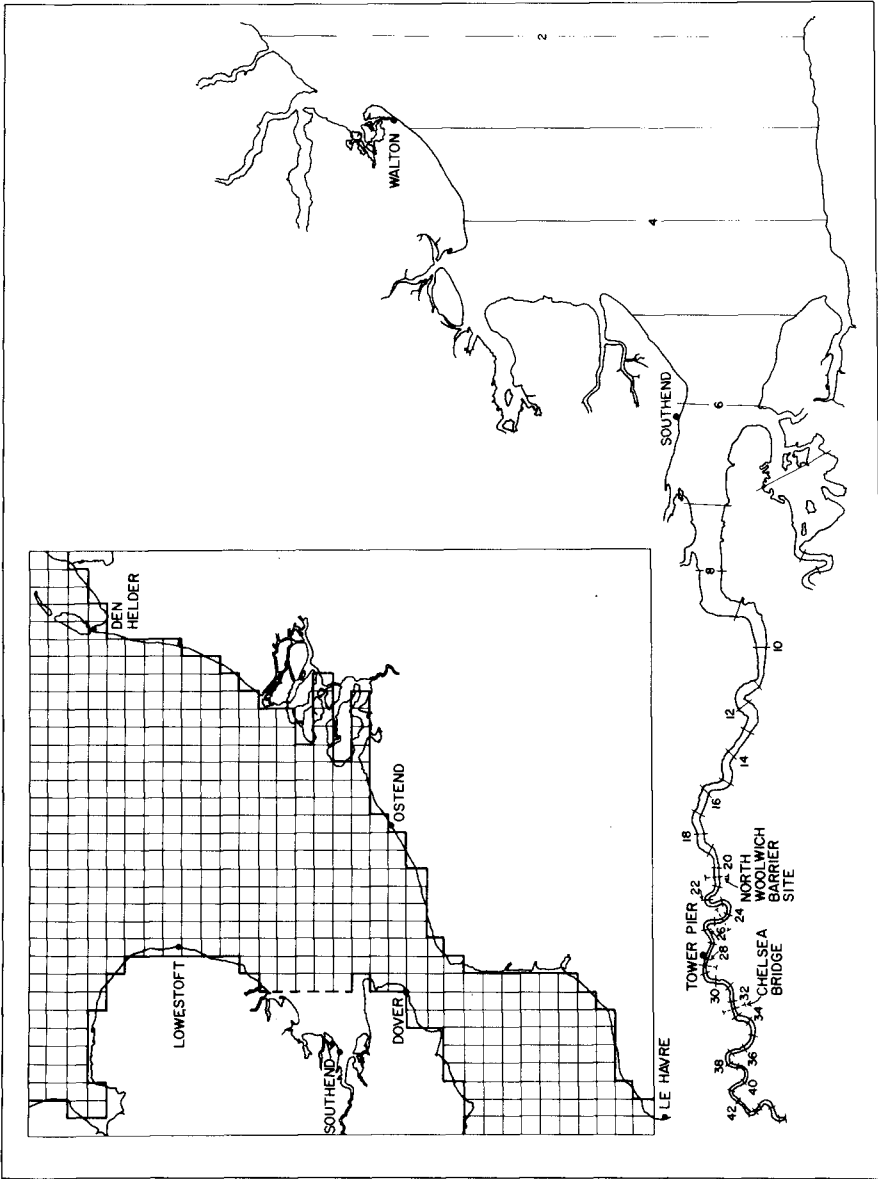

Figure 1. Schematic representation of the southern North Sea and River Thames.

D the depth of the bed below that same datum;
 t time;
 g gravitational constant;
 K friction coefficient;
 and Ω the Coriolis parameter.

The schematic representation of the southern North Sea and River Thames is shown in figure 1.

In using these equations as the basis of the modelling work, the following assumptions have been made : (a) vertical accelerations are negligible (b) variations in the vertical velocity profiles may be neglected (c) density effects may be ignored and (d) energy dissipation may be described by the bed friction formula adopted. Amidst the growing sophistication of numerical models and the competing claims of various numerical methods it is sobering to recognise that the flows produced in a model are limited to those motions which may be described by the original equations. At best, the numerical technique approaches the true analytical solution to the equations subject to the imposed boundary conditions; it cannot in any way improve upon this solution. The discussion of the merits of the various techniques revolve around the question as to which methods minimise the inaccuracies and approximations of numerical solutions. In many three dimensional models it is necessary to specify some additional physical expression concerning the velocity profile or nature of the eddy viscosity. In such cases the dependence of the computed flow values upon this additional restriction should be clearly recognised.

2. DATA

(i) General

In a region as intensively studied as the southern North Sea much of the data is essentially historical providing an important generalised description of the area against which specific modelling applications may be formulated. Flow in this region is dominated by the effects of the M_2 tidal constituent, the amplitude of this constituent exceeding the sum of the amplitudes of all other tidal constituents. The amplitude of this constituent exceeds 3m, since the depth of water in this region is of the order of 10-50m, the region is

characterised by strong tidal mixing with significant non-linearities producing tide-tide interactions. In the winter period surges of up to 3m in height occur fairly frequently with resulting surge-tide interactions. Frictional forces are important in this region, particularly in respect to current magnitudes for which the following general relationship applies :

$$U_{M_2} > U_{SURGE} > U_{RESIDUAL} \quad (4)$$

(ii) Specific

Specific data implies quantitative field measurements used in either calibrating or evaluating the model. The coastline of this region includes over 25 permanent tide gauge stations providing data of excellent quality extending over periods in excess of 50 years. In the off-shore region there have been numerous current measurements and a limited number of tide-gauge deployments, over the last decade the quality and duration of this off-shore data has improved markedly.

In the Dover Strait measurements of the voltage induced across the channel by the flow of sea water across the vertical component of the earth's magnetic field provide an estimate of the net flow through the channel. These measurements have been made using cross-channel telephone cables⁶ and recordings are available over a period of 25 years.

Indications of residual flow patterns over a range of time scales are available from the following sources : (a) movement of drogues and bottom drifters (b) synoptic distributions of salinity and temperature (c) spread of radioactive tracers from the nuclear plant at Cherbourg and (d) observed sand wave movements.

In the following description of modelling studies many comparisons are made between computed and observed measurements, in assessing the validity of these comparisons due regard should be given to the prior filtering involved. In the modelling only a limited part of the spectrum of water movements is considered, the frequency band considered being limited by the validity of equations (1) to (3) and by the specification of the appropriate boundary conditions, some parametric representation of other scales of motion is implicitly

included in the friction coefficients. In the case of observed data, filtering may be deliberately incorporated into the instrument design, for example the use of a tide gauge stilling well, or may be carried out at the data processing stage. Although such filtering techniques may be highly efficient it should be recognised that some mutual contamination of the energy spectra occurs in nature that may be impossible to include in the model. Obvious examples include the interaction between the highly energetic tidal and wind wave bands where tidal currents affect wave heights and, conversely, wind wave propagation is accompanied by changes in mean sea level. Interactions of this type mean that certain errors must be accepted between model results and field measurements, thus manipulation of model parameters to force a more and more exact fit may, in reality, reduce the accuracy to which the model simulates the specific phenomenon.

3. TIDES

Because of the predominance of the M_2 tidal constituent it can be shown that it is valid to simulate this constituent in isolation. Likewise in simulating any other tidal constituent it is sufficient to consider only the interaction with M_2 .

(i) Boundary Conditions

Tidal elevations along the two open boundaries of the model were specified using data from the Admiralty Charts and from the German Navy tidal atlas. These charts were originally constructed using the method outlined by Proudman and Doodson¹² whereby interpolation between coastal data points is achieved by using off-shore current measurements. Thus the accuracy of the tidal distributions along the open boundaries is questionable and it seems valid to make any minor adjustments that might improve the agreement between model and recorded results in the interior of the region. In the present application, adjustments to the chart data were found to be ineffective.

At the other extreme, in certain applications the paucity of available data may make it necessary to concoct the tidal distribution along the open boundary by a trial and error procedure

(a)

(b)

Figure 2. Comparison of (a) co-range (ft) and (b) co-tidal charts; ----- Admiralty, ——— computed.

based on improving the observed fit within the model. Some recent investigations have shown that, mathematically, this procedure presents an ill-posed problem and that numerical solutions may well not converge to the true solution.

(ii) Major tidal constituents

The reproduction of the observed M_2 co-tidal and co-range distributions are shown in figures 2(a) and 2(b) respectively.⁴ The agreement shown was achieved using a constant value for the friction factor. Having thus determined a suitable value for this friction factor it is possible to extend the simulation to other major tidal constituents. Tide-tide interactions must then be accounted for by incorporating the influence of the M_2 tide, thus an accurate simulation of, say, S_2 requires the model to be operated for a full 15 days to simulate the complete cycle of M_2 - S_2 interactions. As an alternative, since the interaction via the quadratic friction is predominant it is possible to simulate S_2 alone by using a linearised friction term in which the friction coefficient at each position is determined by reference to the M_2 tidal velocities.

(iii) Higher harmonics

The main concern with higher harmonics is the reproduction of M_4 and M_6 , in the present model it can be shown that these constituents are generated largely by the non-linear shallow water and friction terms, in other regions the convective terms may be of greater significance.³ Although the overall spatial distribution of these constituents in the model is in reasonable agreement with observations, this agreement tends to deteriorate in the very shallow regions where the constituents are largest e.g. in the River Thames as shown in figure 3. In such regions it may be shown that the usual assumption that the shallow water term produces M_4 and the friction term M_6 is invalid, figure 4 shows that M_4 and M_6 may be produced by both terms.

The inaccuracy in the reproduction of these constituents is attributed to the inadequacy of the bed friction formula. In some applications it may be justifiable to include additional terms in the friction formula to force an agreement between model and observed

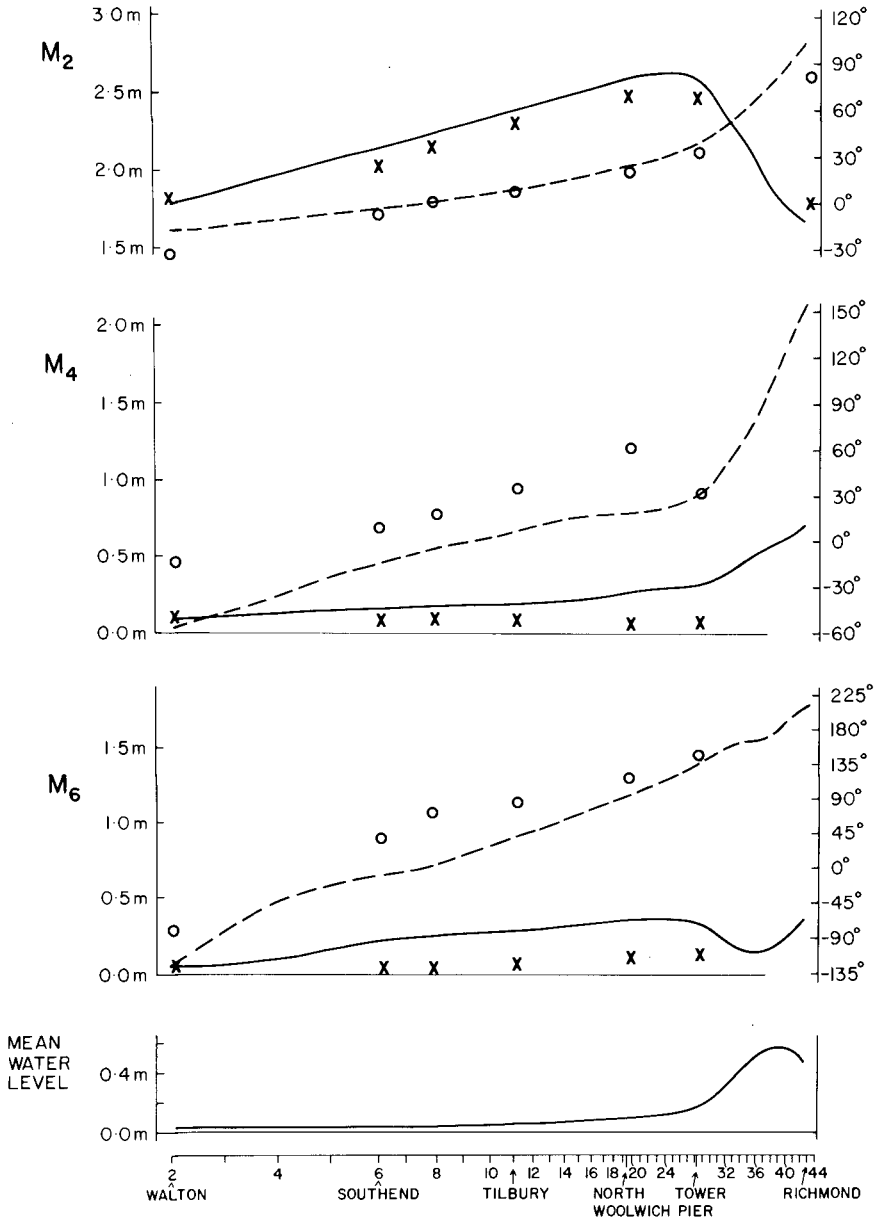

Figure 3. Computed and recorded values of M_2 , M_4 and M_6 along the Thames. Tidal amplitude : ———— computed, X observed; tidal phase : - - - - - computed, O observed.

Figure 4. Harmonic constituents for each term in the equation of motion at two positions in the Thames. F - friction term, G - surface gradient, convective term is not labelled.

results. However where there is no clear physical basis for such additional terms the model must be suspect when used for alternative applications i.e. in an extrapolative rather than interpolative mode. An obvious example of this danger is in the simulation of the impact of tidal barriers where, for the River Thames, it has been shown that changes to high and low waters due to barrier construction are more influenced by changes in the M_4 and M_6 constituents than by changes in the predominant M_2 tide.

4. SURGES

(i) 1953 Surge

A detailed examination has been made of the disastrous storm surge of January/February 1953.⁵ The simulation of the surge event involved the addition of four components to the tidal model previously described : (a) the observed surge heights along the northern boundary (b) the observed surge heights along the western boundary (c) the wind stress over the surface of the region and (d) the observed horizontal variation in atmospheric pressure. A comparison of observed and computed surge heights showed that the model could accurately simulate surge propagation. Simulating successively (a) the surge alone, (b) tide plus surge and (c) tide alone, then comparing the results from (a) with the values given by (b) - (c) it was possible to identify the importance of surge-tide interaction.

(ii) Sensitivity analyses

An analysis of the influence of each of the four components, (a) to (d) above, was carried out by operating the model of tide plus surge a further four times and on each occasion omitting a single component. In this way it was shown that the surge from the North is of most significance in the Thames followed by the effect of the local wind field. The rapidity of the water level response, in the Thames, to this local wind field demonstrated the difficulty in using statistical methods for storm surge forecasting.

The influence of the surge component from the West is more significant along the Dutch coast than along the English coasts, this explains why the surge forecasting for the Dutch coast takes account

of this component while the English system does not.

Sensitivity analyses of this type are subject to misuse, strictly it is only appropriate for linearly independent systems. However it is useful in weakly non-linear processes where each of the separate terms omitted is, by itself, a relatively small part of the total system. A frequent application of this approach is to operate models with and without the Coriolis term, the difference in the results is then assumed to represent the influence of the earth's rotation. However the Coriolis term also influences the boundary conditions and hence the physical interpretation of such sensitivity analyses must be questionable.

(iii) Energy budget

The mechanics of energy transfers during the course of the storm were examined, one facet of this examination is shown in figure 5 where the spatial distribution of energy dissipation by bed friction is plotted. This distribution is a representation of $\int u^3 dt$, in a similar fashion functions such as the stratification parameter u^3/D may be readily displayed.

5. RESIDUALS

Interest in residual flows has grown in recent years for such applications as siting of power plants, sewage outfalls, fisheries studies and so on. Field measurements of residual currents suggested considerable spatial and temporal variability in these flows combined with an obvious dependence on wind forcing. However, prior to the modelling study,⁷ the mechanics of the residual circulation and its sensitivity to effects such as wind forcing were poorly understood.

(i) Tidal residuals

The non-linear terms present in the equations of motion which describe the propagation of the M_2 tide produce a time invariant (or residual) flow component that accompanies the oscillating component. An examination of these non-linear terms shows that their magnitude is proportional to the square of the tidal range. Once again, because of the predominance of M_2 it may be shown that

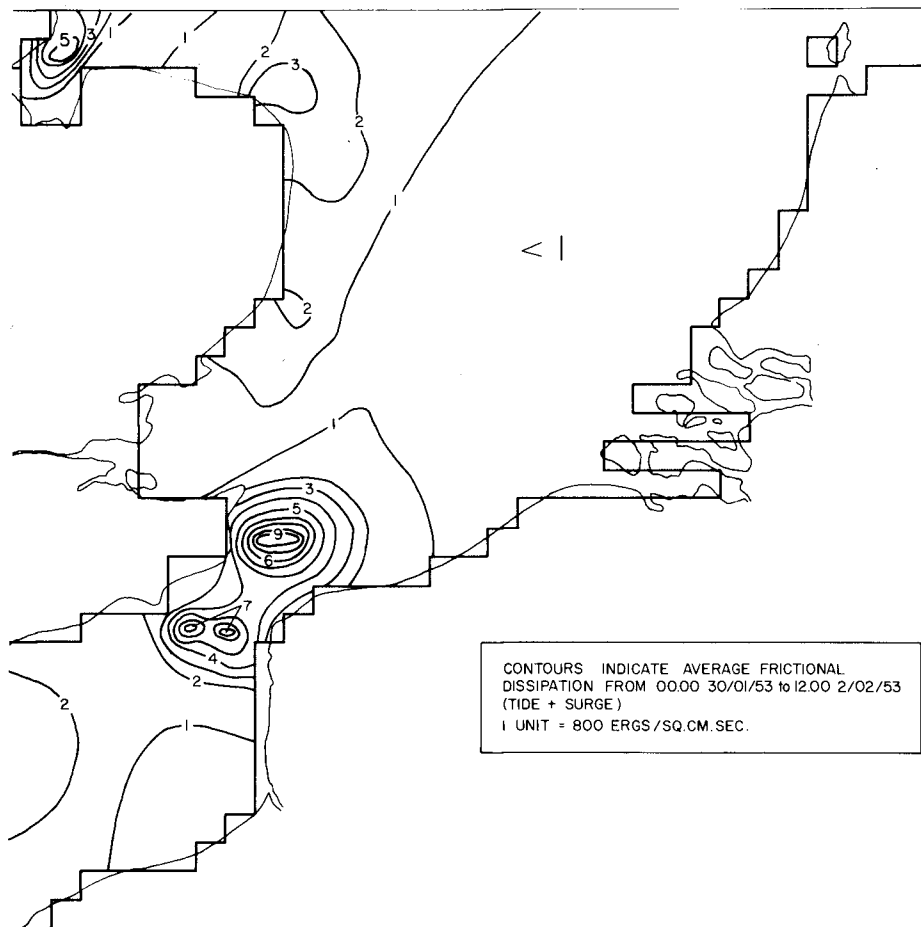

Figure 5. Spatial distribution of frictional dissipation. Mean values over the period 30 Jan to 2 Feb 1953, one unit represents $80 \mu\text{J cm}^{-2}\text{s}^{-1}$.

the average value of the square of the tidal range is equal to the square of the M_2 tidal range and hence an estimation of the M_2 tidal residuals should approximate the net tidal residual.

In extracting residual flow from a time-stepping simulation of the M_2 tide an erroneous residual circulation develops in the vicinity of the open-boundaries. This circulation is due to the assumption of a constant mean sea level along these boundaries, i.e. the neglect of the tidal stress component.² A technique of incorporating a radiation boundary condition was developed to overcome this problem. The tidal residual flow was computed as $8 \times 10^4 \text{ m}^3 \text{ s}^{-1}$ into the North Sea.

(ii) Wind driven residuals

Since the residual flows are much smaller than the tidal flows it is possible to describe these flows using linearised equations in which the friction coefficient is determined by reference to the tidal velocities. It is then possible to use linear superpositioning to combine the separate components of residual flow.

In computing the annual-mean wind driven flow three points of general significance emerged.

(a) Wind data from off-shore (in this case Light Vessels) were found to be much more coherent and therefore representative of spatially averaged surface wind stress than corresponding data from adjacent shore-based stations.

(b) The value of monthly mean wind stress calculated from $\sum_{i=1}^N W_i^2 / N$ for successive 3 hourly wind speed observations W_i was found to be a factor of around 4 times the corresponding value calculated from

$$\left\{ \sum_{i=1}^N W_i \right\}^2 / N$$

(c) The model responds in an irregular fashion to winds from different directions. Thus in order to compute the annual-mean wind driven flow it was necessary to compute separately the response for those periods when the wind was blowing from a particular sector. The net effect was then obtained by adding vectorially the results from each sector. A figure of $4 \times 10^4 \text{ m}^3 \text{ s}^{-1}$ was estimated as the annual-mean wind driven flow. The variability of this component over a twenty five year period has been examined.¹⁰

(iii) Sea surface gradient

Residual flows due to horizontal density gradients were shown to be negligible and, hence, the only remaining residual component was from sea surface gradients. This remaining component was determined by comparing the observed variation in mean sea level along the Continental coast with the corresponding values obtained for the sum of the level variations computed for the tidal and wind driven residual flows. An additional component was then included to obtain the best fit between observed and computed mean sea levels, this component consisted of an imposed sea surface gradient between the two open-boundaries of the model. The flow produced by this additional component was approximately $4 \times 10^4 \text{ m}^3 \text{ s}^{-1}$.

(iv) Total residual flow

Combining the three components gives the total residual flow ($16 \times 10^4 \text{ m}^3 \text{ s}^{-1}$ into the North Sea) and the spatial variation in mean sea level (figure 6). It was then possible to make four quantitative checks on these results.

- (a) A comparison of observed and computed variation in mean sea level along the English Coast.
- (b) An estimate of the level difference between the British levelling datum (O.D.N.) and the French levelling datum (I.G.N.) was calculated and compared with an earlier independent estimate.
- (c) The total residual flow was compared with a corresponding value obtained from 8 years of continuous cable recordings.
- (d) The residual flow in the absence of wind forcing was compared with current meter measurements made in the Dover Strait under tranquil conditions.

6. INTERACTION

An intriguing feature of surge propagation in the Thames is that large surge peaks almost always occur 3 to 4 hours before high tide. This is precisely the time when flood contingency plans have to be decided upon. The existing prediction techniques implicitly assume that the observed surge peak will decrease as high tide approaches.

Figure 6. Total residual flow. Streamlines represent $\Psi / (10^4 \text{ m}^3 \text{ s}^{-1}) = \text{constant}$.

However no clear explanation for this phenomenon had been presented and no guidance was available regarding those circumstances under which the surge peak might be sustained.

(i) Surge statistics

A careful examination^{8,9} was made of surge statistics for a number of ports along the east coast of the British Isles and also along the Thames estuary. This showed that surges tend to develop a peak on the rising tide in the Thames irrespective of the phase relationship between the tide and the initial surge development in the northern North Sea. It also showed that although interaction tended to develop progressively as the surges propagated southwards there was an important exception at Lowestoft where interaction appeared to be reduced.

(ii) Parallel models

A new conceptual approach was used to examine the physics of surge-tide interaction, this involved two separate models, one of surge propagation and the other of tidal propagation. The two models are operated simultaneously and interaction, via the non-linear terms, is introduced by cross-linking between the models. To illustrate this consider the quadratic friction term :

$$K (u_s + u_T) |u_s + u_T| = K u_s |u_s + \underline{u_T}| + K u_T |\underline{u_s} + u_T| \quad (5)$$

(combined model) (surge model) (tidal model)

subscripts S and T refer to surge and tide respectively.

Thus in the model of surge propagation the friction term, is modified by the additional term underlined in (5). Similarly the parameter D in the surge model is modified to $D' = D + Z_T$ to represent the shallow water influence of tidal heights on surge propagation. The validity of this approach rests upon the results from these separate models combining to approximate the results from a combined simulation (subscript c), this requires that

$$Z_c = Z_s + Z_T \quad (6)$$

$$u_c = u_s + u_T \quad (7)$$

Figure 7. Elevations at Tower Pier.

T - tide alone; S - surge alone; T' tide with interaction from surge; S' surge with interaction from tide.

Figure 7 shows some results for surge and tide elevations at Tower Pier obtained from this approach. The figure contains results from four versions of the model :

- (a) a simulation of tide alone T
- (b) a simulation of surge alone S
- (c) simulation of tide with interaction from the surge T
- (d) simulation of surge with interaction from the tide S } Parallel models

One important result which emerged from this approach was that the magnitude of these cross-linkage terms, and hence the magnitude of the interaction, was shown to be proportional to a product of the tidal amplitude and surge height.

(iii) Conclusions

An analysis of results such as those shown in figure 7 revealed the following features of surge-tide interaction.

- (a) The non-linear friction term is predominant in producing surge-tide interaction, it is particularly effective in reducing higher-frequency surge peaks.
- (b) Shallow water terms produce a phase advance in the tidal component for positive surges and vice versa.
- (c) Interaction can develop rapidly in both space and time. The occurrence of surge peaks on the rising tide in the Thames was attributed to interaction, mainly via the friction term, resulting from the large values of both tidal and surge velocities found in the near-shore region between Lowestoft and Walton.
- (d) At any instant, the separate interactions of tide on surge propagation and of surge on tidal propagation tend to be in opposition. Thus the observed interaction is the small difference between two larger components. This explains why observed interaction appears to include an unexpected high frequency component and, also, why it is so difficult to relate the time series of interaction directly to either surge or tide.

7. FURTHER PROBLEMS

To conclude this summary of recent studies a brief description is

included of current work and some comments included about possible future applications.

(i) Open boundary problem

In a model of limited spatial extent used to examine the impact of some change in channel geometry such as the introduction of a tidal barrier, the problem arises as to the validity of assuming fixed conditions along the open-boundary. An extreme example of this type of problem is the proposed Bay of Fundy tidal power project where it is sensibly suggested that the model might have to extend to the whole of the North Atlantic Ocean in order to overcome this problem. In this particular application, an alternative approach¹ has been developed whereby conditions at the mouth of the model are modified to reflect the combined influences of the model region and the external ocean. A similar approach,¹¹ employing the analogy between tidal flow and A-C electrical circuit theory, has been used to examine the influence of tidal barriers in the Thames and Bristol Channel.

(ii) Inclusion of higher-order physical mechanisms

Previous reference has been made to the inadequacy of the friction formula as used in the shallow water wave equations. Strong arguments can be expressed suggesting that some account should be taken of changing bed formations; turbulent energy levels; temperature, density and stratification of the water mass and so on. Similar arguments might be used to suggest a wind-stress coefficient varying in time and space. However good results have been obtained by the existing, perhaps crude, parameterisation of these other effects. In practical terms an extension into these higher-order effects must be justified on a number of counts. First it must be shown that present methods are inadequate and second some realistic chance of improving the modelling must be shown.

Such extensions may be necessary for applications such as the simulation of sediment transport. However an extension of the spectral range of the model will also imply an equivalent extension of the data base against which the model must be evaluated. Where the objective of this extension in spectral range is to improve the

simulation in the original frequency band it is necessary to have a dynamic feed-back from the higher spectral range into the original. However, in many applications the physics in the higher frequency range are simulated less accurately than is the case for tidal propagation. Hence as the links between different scales of motion become stronger the possibility of reducing the accuracy of tidal propagation is increased.

ACKNOWLEDGEMENTS

The work described in this paper was funded by a Consortium consisting of the natural Environment Research Council, the Ministry of Agriculture, Fisheries and Food, and the Departments of Industry and Energy.

WAVE POWER AND BEACH-STAGES: A GLOBAL MODEL

Andrew D. Short

Coastal Studies Unit, Dept. of Geography

University of Sydney, Sydney, N.S.W. 2006

Australia

ABSTRACT

A three-dimensional morphodynamic model of sequential beach changes is presented. The model is based on variations in breaker wave power generating a predictable sequence of beach conditions. The spectrum of beach conditions from fully eroded-dissipative to fully accreted-reflective is characterised by ten beach-stages. Using the breaker wave power to beach-stage relationship the model is applied to explain temporal, spatial and global variations in beach morphodynamics.

INTRODUCTION

Beach and surfzone morphodynamics have received increasing attention in recent years (for review see Wright and Thom, 1977). While much progress has been made there exists a general lack of understanding and awareness of the total spectrum of beach conditions. Individual beach studies in diverse locations, wave conditions and coastal environments are often difficult to relate or compare, and in general there is no overall conceptual model within which beach studies and their results can be framed. Most studies are of too short a duration and too limited range of wave and beach conditions to generate data for a larger model. This paper presents a model within which all previous beach studies can be framed (Short, in preparation) and which can be applied globally to all microtidal, open coast, sand beaches. The model is the result of more than 2½ years of daily observations of beach morphodynamics (Figure 1) and associated deepwater and breaker wave characteristics. The main field site was located at Narrabeen Beach, New South Wales, a 4km long, medium to fine sand beach ($M\phi = 1.3\phi$) receiving moderate to high power east coast swell on a microtidal coast. These observations are supplemented by ground and aerial surveys and aerial photographs of the 3,300 km southeast Australian coast, a microtidal coast which receives east and west coast swell wave conditions, on beaches composed of fine to coarse sand (Short, 1978).

Using the 30 month time series of wave and beach conditions a three-dimensional model of sequential beach changes was formulated. The model depicts continuous changes in beach morphodynamics, with decreasing breaker wave power leading to onshore bar migration, beach accretion and reflective surfzone conditions, and increasing wave power generating

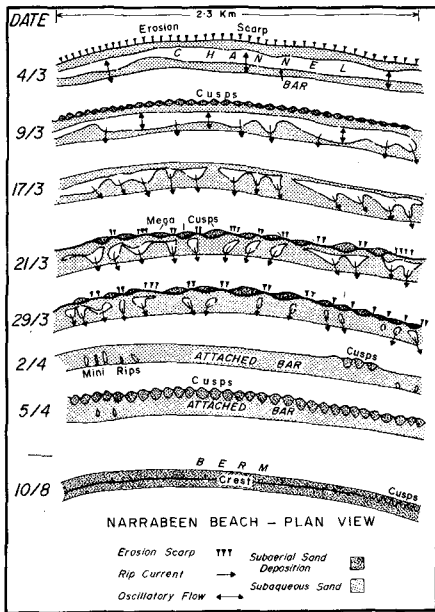

Figure 1 :

An example of the field observations during a four week accretionary period under low wave conditions (4.3 to 5.4.1977 and 10.8.1977) illustrating the migration of a parallel bar (4.3.77) onshore; resulting in crescentic bars (9 and 17.3.77); accretionary rip cells (21 and 29.3.77); welded bar, mini-rips and cusps (2 and 5.4.77); and at a later stage a continuous subaerial berm (10.8.77).

beach erosion, bar-channel formation and dissipative surfzone conditions. The model applies to the subaerial beach and subaqueous surfzone to the seaward slope of the inner bar (~ 3 m at Narrabeen Beach). Second and outer bars are not included.

The model is now briefly presented. It is then applied to explain temporal, spatial and global variations in beach morphodynamics.

THE MODEL

The time series of wave and beach conditions was separated into ten *beach-stages*, four erosional, four accretional with two terminal stages of fully eroded and fully accreted (Figure 2). The ten stages represent ten characteristic beach morphodynamic conditions in a continuum of beach changes. Movement through the model is generated by variations in breaker wave power. At any stage the direction of movement to adjoining erosional or accretionary stages depends on the direction of change in wave power. Increasing wave power causes movement through the erosional stages, decreasing power produces movement through the accretionary stages. The model is now outlined for an idealised situation of continuously decreasing wave power, the accretionary sequence, and increasing wave power, the erosional sequence. It assumes waves arrive normal to shore on an open, microtidal sand coast. For a more complete description of the model see Short (in preparation).

The accretionary sequence (Figure 2a and 3) begins at *beach-stage* 6, a parallel bar-channel system, where the position of the bar is

determined by low frequency standing waves generated by waterlevel setup in the channel during high wave power conditions, (Figure 3a). If the offshore slope is gentle multiple bars result. All flow is shore normal and no rips are present, the beach is in 'equilibrium', with no longshore variation in profile or dynamics. With a decrease in wave power, resonance generated by reflection of the incident waves off the beach face, and possibly lower mode reflection against the inside of the bar, results in edge waves that respectively generate systematic longshore variations in waterlevel on the beach face and bar. The longshore variations in waterlevel result in preferential shoreward flow of water across the beachface and bar at the antinodes of the edge waves. This flow in turn produces greater shoreward movement of sediment at those points initiating cusps and crescentic bars (Narrabeen mean bar spacing 150m), (*beach-stage 5*, Figure 2a and 3b, c and d). Decreasing wave power causes the crescentic bars to migrate shoreward during *stage 4*, filling the now overfit channel, (Figure 3 d and e). The increasingly crescentic bar-channel morphology produces marked longshore variations in wave power and direction at the beach face generating a second phase reworking of the beach face as megacusps horns are deposited and embayments eroded. During *stage 3* the accretionary rip channels completely infill as the bar welds to the base of the beach, (Figure 3 e - h). Continuing low wave power conditions moves the 'bar' up the beach face (*stage 2*) where increasing beach steepness and beach reflectivity usually result in edge waves and cusp deposition (Wright, et. al., 1977) (Figure 3 i and j). Finally the cusp swales fill (Figure 3 j and k) and a continuous berm is formed (*stage 1*). The berm face is now too reflective for edge wave generation resulting in a straight berm crest, (Figure 3k). The beach is again in an 'equilibrium' condition with no longshore variation in beach morphology or dynamics. The erosion sequence (Figure 2b) begins with increasing wave power generating saturation and collapse of the steep berm face. The slumping sand is moved immediately seaward of the beach face as a narrow attached bar (*Stage 2'*). As wave power continues to increase in *Stage 3'*, narrow channels are initiated at the apex of the beach face and bar. The channels permit storage and longshore transport of water before it pluses seaward at lower frequencies. In *Stage 4'*, increasing wave power results in greater onshore flow of water which requires larger storage and transport channels. The resulting channel excavation moves the bar and breakpoint further seaward. At this stage relative closely spaced (spacing 200-500m), poorly developed erosional rips are initiated to facilitate seaward return of the water. The spacing of the rips is probably controlled by edge waves generating longshore variation in water level. As wave power continues to increase the size of the edge waves also increases resulting and more widely spaced megarip currents by *Stage 5'* (spacing 500-1,000m). Finally by *Stage 6* the longshore channel is large enough to temporarily store water moving shoreward so as to allow it to return to normal to the shore, instead of being transported laterally into high velocity rip currents. The shore normal return is achieved by a water level set-up in the channel that returns seaward in the form of a low frequency standing wave. It is this standing wave and its seaward effect that in turn determines offshore bar or bars spacing.

In nature wave power rarely moves smoothly between such extremes,

rather depending on the wave environment it oscillates with varying amplitude and frequency around a modal wave power. The effect of these oscillations is to generate smaller cycles within the sequence shown in Figure 2. Cycles of this nature are shown in Figure 4, which plots part of the time-series of deepwater wave power and height, beach-stage and subaerial sand volume over a period of 13 months for Narrabeen Beach. Note the close correlation between all parameters as wave power varies. Increasing wave height and power produces higher beach-stages and erosion of the subaerial beach (January to June, 1978), while decreasing height and power result in low beach-stages and subaerial beach accretion (August-December, 1977). Also note that the transit time between erosional beach-stages is faster than between accretionary stages. This reflects the relative power associated with the erosive and accretive conditions. However, the absolute amount of wave power required to erode a beach is balanced over a longer period by the same magnitude of lower wave power through the accretionary sequence.

Figure 4 :
A time series of wave and beach parameters at Narrabeen Beach. Note the close correlation between breaker wave height (H_b), deepwater wave power (P_0), beach-stage, and subaerial beach volume. Subaqueous beach volume (0 to - 3 m) reflects the movement of eroded subaerial sediment to beyond the - 3 m depth contour.

Figure 5 :
a. Correlation between erosional (6 to 2¹) and accretionary (5 to 1) beach-stages and deepwater wave power (P_0) and height (H) for Narrabeen Beach.
b. Narrabeen Beach beach-stage curves, plotting the percent frequency of occurrence of erosion, accretion and combined beach-stages between April 1976 and January 1978.

WAVE POWER AND BEACH STAGES

Absolute Wave Power

The model is based on the response of beach morphodynamics to variations in the level of absolute deepwater and breaker wave power,

Po and Pb respectively, where

$$P_o = \rho g H^2 C_o / 8 \text{ W cm}^{-1} \text{ wave crest}$$

where ρ is seawater density, g gravity, H significant wave height and C_o wave group velocity. Figure 5 a indicates the level of H and P_o associated with the 10 *beach-stages* on Narrabeen Beach. High stages are associated with high wave power, and erosive stages with the highest power. A threshold appears to exist at around $H = 1.2\text{m}$ and $P = 3 \times 10^2 \text{ Wcm}^{-1}$ above which erosive stages dominate and below which accretion dominates. Therefore for a given level of absolute deepwater and breaker wave power a corresponding beach-stage is generated with its associated morphology, dynamics and relative level of subaerial sediment volume.

Temporal Variations in Wave Power

Temporal variations in deepwater wave power produce variations in breaker wave power and thereby temporal variations in beach-stage. Over time the deepwater wave climate, will through its spectrum of wave power affect a corresponding spectrum of beach-stages. The amplitude and frequency of wave power oscillations determine beach-stages cycles. The frequency of occurrence of a particular beach-stage reflects the occurrence of the associated deepwater and breaker wave power. In order to apply this association to the model the beach-stage curve is now presented.

The *beach-stage curve* plots the percent frequency of occurrence of all beach-stages over a given time period for a particular site. Because of the direct linkages between accretion and erosion beach-stages of the same level (Figure 2) they can be combined as one in a total curve. The annual or total beach-stage curve is therefore the summation of the accretion and erosion beach-stage curves, which plot the occurrence of their respective beach-stages. Figure 5b illustrates the beach-stage curve for Narrabeen Beach. The modal breaker wave ($T = 10 \text{ sec}$, $H = 2 \text{ m}$) which arrives 10% of the time explains the modal 4/4' *beach-stage*. Rarer occurrences of very high ($> 3 \text{ m}$, 5%) and low ($< .5 \text{ m}$, 4%) waves explain the infrequent excursions to *stages 6* and *1* respectively. The *mode* and *range* of the beach-stage curve reflect the modal breaker wave power and range of wave conditions respectively. The beach-stage curve depicts quantitatively the morphodynamic character of a beach. It not only provides a mechanism for rigorously classifying and describing a beach but also for comparing it to beaches in other locations and wave environments.

APPLICATION

Temporal variations in wave power account for the morphodynamic character of a beach over time. In order to apply the model more widely the effect of spatial variations in deepwater and breaker wave power are now incorporated.

Spatial Variations in Breaker Wave Power

For a given deepwater wave climate the breaker wave power varies longshore in response to wave attenuation across the shelf (Wright, 1976) and wave refraction and diffraction. Along a coast the deepwater wave power will be attenuated and redistributed at the breakpoint depending on the shelf, nearshore and coastal morphology.

Longshore variations in breaker wave power affect a longshore variation in the relative level of beach-stage generated. In an idealised embayment (Figure 6), the longshore variation in breaker wave power generates a longshore variation in beach-stage, with low wave power producing lower stages, and high power higher stages. This effect is apparent on Narrabeen Beach which is protected in its southern portion (Collaroy Beach) from the dominant southeast swell. As a result when southeast swell dominates Narrabeen has a modal *stage 4*, while Collaroy with significantly lower breaker wave power has a modal *stage 2* (Figure 7a). However during the period of dominant northeast waves, Figure 7b, when the entire beach is equally exposed, the modal beach-stages are more similar. The annual beach-stage curves (Figure 7c) reflect the long term bias toward higher stages at Narrabeen and lower stages at Collaroy.

Figure 6 : Idealised coastal embayment showing the relationship between longshore variation in breaker wave power, due to wave refraction and attenuation, and corresponding level of beach-stage.

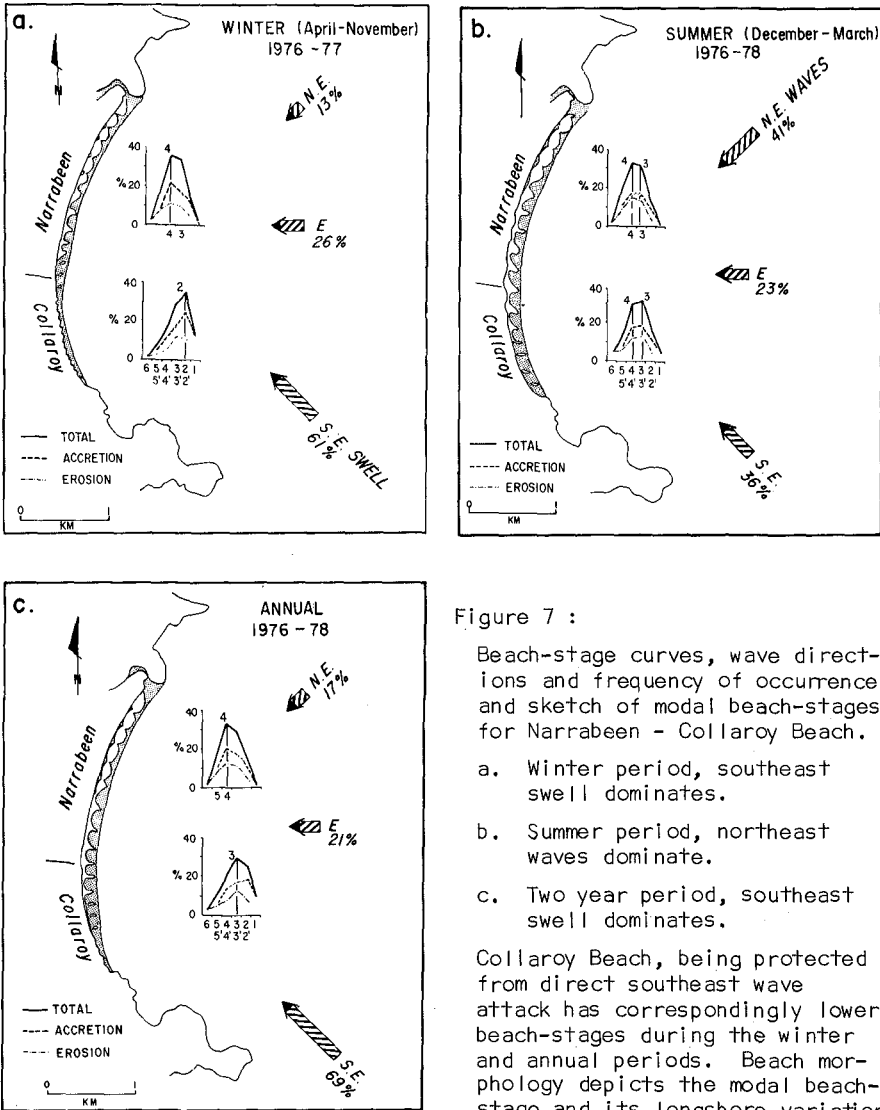

Figure 7 :

Beach-stage curves, wave directions and frequency of occurrence, and sketch of modal beach-stages for Narrabeen - Collaroy Beach.

- a. Winter period, southeast swell dominates.
- b. Summer period, northeast waves dominate.
- c. Two year period, southeast swell dominates.

Collaroy Beach, being protected from direct southeast wave attack has correspondingly lower beach-stages during the winter and annual periods. Beach morphology depicts the modal beach-stage and its longshore variation.

The same effect can occur in longer embayments. The Coorong coast of South Australia is exposed to year round, high power, west coast swell, resulting in very high deepwater wave power. Along The Coorong however breaker wave power varies from very high in the northwest to zero in the southeast (Figure 8) due to nearshore wave attenuation over dunerock reefs in the southeast. The modal beach morphodynamics adjusts accordingly having modal beach-stage 5 to 6 for the first 100 km, then

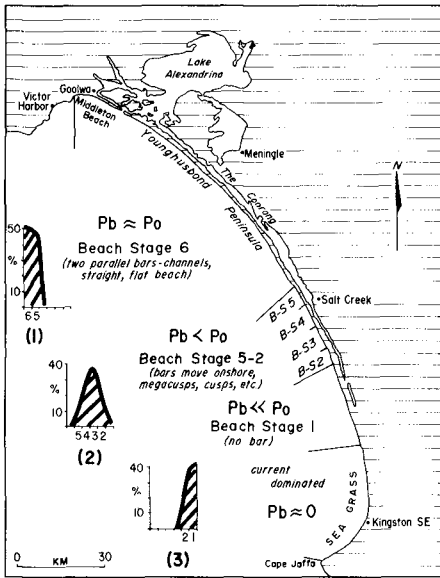

Figure 8 :

The Coorong, South Australia, illustrating the relative levels of deepwater (P_o) and breaker (P_b) wave power, and corresponding effect on modal beach-stage (1), (2) and (3).

as breaker wave power decreases between 100 to 130 km a transition zone occurs with modal *beach-stage* decreasing from 5 to 2, and finally with very low breaker wave power from 130 to 160 km, *beach-stage 1* dominates. Beyond 160 km to Cape Jaffa, breaker wave power is zero and the shoreline is dominated by current-generated sand waves with seagrass growing to the shoreline.

Therefore while deepwater wave power will determine the potential mode and range of beach-stages, breaker wave power governs the actual mode and range for a given location.

Global - Absolute, Temporal and Spatial Wave Power

Global deepwater wave climates are associated with the oceans' wave environments. Davies (1964 and 1973) classified the ocean wave environments into storm wave, west coast swell, east coast swell, trade wind and monsoon influence, and tropical cyclone influence, (Figure 9). Using Davies' basic wave environments, the characteristic deepwater wave spectrum associated with each environment can be used to generate a characteristic beach-stage curve. Figure 10 presents idealised annual and seasonal beach-stage curves for the major wave environments as would be expected on open, microtidal, sand coasts receiving maximum breaker wave power.

Storm wave environments with persistent high wave power have a modal *stage 5 - 6* with rare excursions to lower stages (Figure 10a). West coast swell have high winter wave power and corresponding *stage 6*. In the northern summer low power dominates and *stage 2* and *1* persist

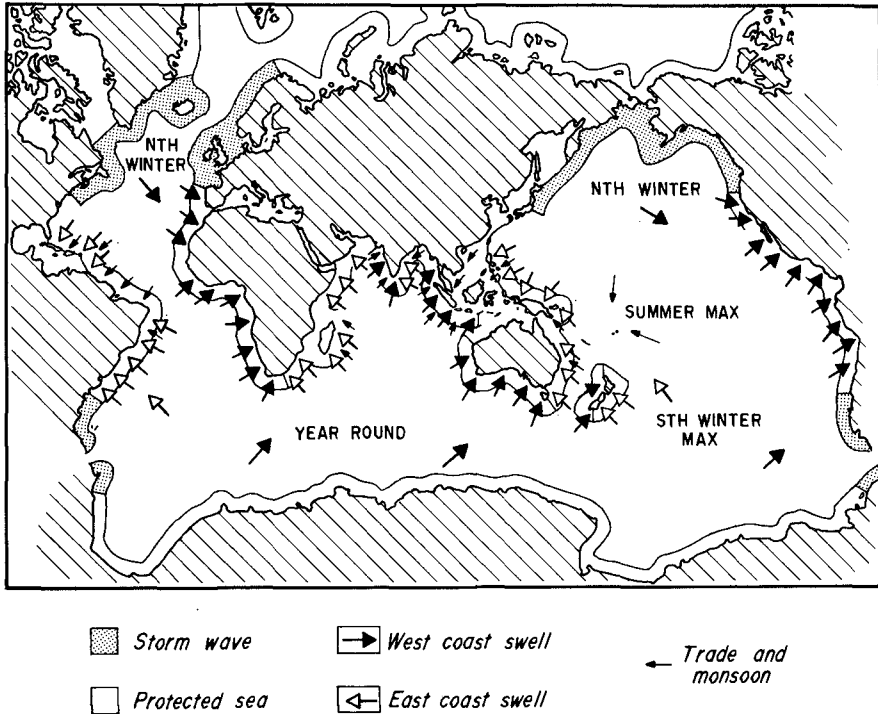

Figure 9 : Global wave environments. (Modified from Davies, 1973). Midocean arrows and lettering indicate direction and season of highest wave power.

(Winant and Aubrey, 1976), however in the southern hemisphere summer power remains high generating *stage 5* and *6* (Figure 10b). East coast swell environments, such as the study area and elsewhere (Wright et.al., in press), have a modal *stage 4* and experience the entire range from *6* to *1*, (Figure 10c). Trade wind coasts have a late summer maximum in wave power generating a modal *stage 4* to *6*, and a lower late winter wave power resulting in a modal *stage 3 - 4* (Figure 10d). Monsoon coasts have a moderate power summer maximum during the onshore monsoon generating a modal *stage 3 - 4*, and low winter wave power producing a modal *stage 2 - 1* (Figure 10e). Protected coasts away from background ocean swell rely on the passage of storms. They are therefore characterised by low beach-stages with infrequent storm generated higher beach-stages, (Figure 10f). Storm generated morphologies often remain as 'relic' forms in the absence of subsequent low waves to return the sand onshore. This is the likely explanation of the common occurrence of multiple parallel bars off relatively low power, through storm prone coasts, including the Mediterranean (King, 1972), Great Lakes (Davis and Fox, 1971) and Alaskan Arctic (Short, 1975).

Figure 10 :

Idealised beach-stage curves for the major global wave environments. Curves describe expected occurrence of beach-stages on open coast, sand beaches receiving maximum deepwater wave power.

Other global implications of wave power and the beach-stage model are as follows.

The potential range of beach-stages is determined by the spectrum of absolute P_o , whereas the actual range depends on P_b .

Daily variations in P_o and P_b generate daily adjustments in the associated beach-stages. These adjustments may however have a lag of a few days particularly during low wave power (see Figure 4).

The seasonality of P_o will determine the bias toward erosional or accretionary stages during the seasons. Note that the commonly used terms of 'winter' cut and 'summer' fill are based on studies in California, a northern hemisphere, west coast swell environment. Application of these terms to other wave environments including southern hemisphere west coast swell coast is often inappropriate and has led to much confusion and misunderstanding. Contrary to the west coast U.S.A. beach cycles, one would expect erosion stages to dominate or be significant during the summer season in east coast swell, (see Figure 7a and b), trade wind, monsoonal, and low and high latitude protected sea coasts, with little seasonal variation in southern hemisphere west coast swell environments (Figure 10b). Only in northern hemisphere west coast swell and mid-latitude protected sea coasts, are the terms 'winter' cut and 'summer' fill applicable. Therefore the terms are quite meaningless on a global scale and if must be used, should be with caution. More important than the present grossly simplified, emphasis on seasonal beach cycles, the present model illustrates how in east coast swell environments 'cut' and 'fill' cycles can occur at relatively high frequency throughout the year, though seasonal trends may be apparent (Figure 4 and 7).

To understand the cycles of beach morphodynamics in a particular location we must know the deepwater wave climate, shelf and nearshore wave transformation and associated breaker wave climate. Given a time series of the wave and beach conditions and resultant beach-stages and beach-stage curves, beaches can be understood and compared temporally and/or spatially between and among any suite of open coast environments.

DISCUSSION AND CONCLUSIONS

A beach model is presented which relates three-dimensional changes in beach and surfzone morphodynamics to variations in breaker wave power. The model covers all beach conditions from fully eroded to fully accreted, linked by both erosional and accretionary sequences. The entire cycle of sequences are presented as ten characteristic beach-stages. Using the relationship between wave power and the beach-stages, the beach-stage curve is introduced. The curve plots the percent frequency of occurrence of the ten beach-stages, over a given time period for a given beach site. The beach-stage curve, enables for the first time, the morphodynamic character of the beach to be quantified. The mode, range and shape of the curve all rigorously define the morphodynamic character of the beach over time. Beach-stage curves for different beaches and time periods permit comparison of all sandy beach beaches both temporally and spatially.

Variations in wave power generate the following predictable response in the model and beach morphodynamics in general.

1. Absolute wave power through breaker wave power controls the level of beach-stage present at any point in time.
2. Temporal variations in P_o and P_b affect sequential changes in beach-stages (Figure 1), the greater the variation in P_b the greater the range of stages.
3. Spatial variation in P_b produces longshore variation in beach-stage. Along a section of coast as P_b varies so does the associated beach-stage.
4. Global wave environments (storm wave, west and east coast swell, trade wind, monsoon and protected) through their characteristic P_o spectrum will generate a characteristic beach-stage curve.
5. Locally, the spectrum of P_b at the shoreline will determine for any wave environment the actual beach-stage curve.

The model allows beach morphodynamics to be explained at any point, period or place in the time, and can be used to compare beaches in all open coast wave environments over any time scale. In doing so it provides a framework within which all past, present and future beach studies can be located, so that their results can be seen in the overall context of a single unified model. The model also indicates that the major proportion of beach morphodynamic situations (particularly beach-stages 6, 5', 5, 4', 3', 2') have not been previously identified

or rigorously investigated.

Finally the model illustrates the four-dimensional complexity of the beach and surfzone. This complexity must be taken into account when dealing with the coastal zone whether it be in field, laboratory or mathematical experiments, or in designing management or engineering criterion for safeguard of the zone.

CHAPTER 67

MATHEMATICAL MODELING OF SHORELINE EVOLUTION

Bernard Le Mehaute¹
Mills Soldate²

ABSTRACT

A mathematical model for long term shoreline evolution is developed. The combined effects of variations of sea level, wave refraction, wave diffraction, loss of sand by density currents during storms, by rip currents and by wind, bluff erosion and berm accretion as well as effects of man-made structures such as long groin or navigational structures and beach nourishment are all taken into account. A computer program is developed with various subroutines which permit modification as the state-of-the-art progresses. The program is applied to a test case at Holland Harbor, Michigan.

I. INTRODUCTION

The purpose of this paper is to establish a mathematical model for shoreline evolution and to calibrate it with a test case, located at Holland Harbor, Michigan. The present mathematical model includes many of the characteristics already covered in the literature. In addition, it presents an integrated approach covering a large number of phenomena previously neglected. It is extracted from a more general investigation on three dimensional modeling of shoreline evolution.

It is recalled that three time scales of shoreline evolution can be distinguished:

- (a) Geological evolution taking place over centuries;
- (b) long-term evolution from year-to-year or decade; and
- (c) short-term or seasonal evolution and evolution taking place during a major storm.

Associated with these time scales are distances or ranges of influence over which changes occur. The geological time scale deals, for instance, with the entire area of the Great Lakes. The long-term evolution deals with a more limited stretch of shoreline and range of influence; e.g., between two headlands or between two harbor entrances. The short-term evolution deals with the intricacies of the surf zone circulation; e.g., summer profile-winter profile, bar, rhythmic beach patterns, etc.

For the problem under consideration, long-term evolution is of primary importance, the short-term evolution appearing as a superimposed perturbation on the general beach profile. Evolution of the coastline is characterized by low monotone variations or trends on which are superimposed short bursts of rapid development associated with storms.

¹ Professor and Chairman of Ocean Engineering, Rosenstiel School of Marine and Atmospheric Science, University of Miami. Formerly Senior Vice President of Tetra Tech, Inc.

² Senior Engineer, Engineering Division, Tetra Tech, Inc.

The primary cause of long-term evolution is water waves or wave-generated currents. Three phenomena intervene in the action which waves have on shoreline evolution:

- (a) Erosion of beach material by short period seas versus accretion by longer period swells;
- (b) effect of (lake) level changes on erosion; and
- (c) effect of breakwaters, groins, and other structures.

II. MATHEMATICAL FORMULATION

Let us consider a coastal zone limited by boundaries at a small distance from the surf zone (Figure 1). The bottom topography is defined in a three coordinate system, $oxyz$, by a function $z_b = f(x, y, t)$ where the axis, ox , is parallel to the average shoreline direction, the axis, oy , is perpendicular seaward and, oz , is positive upward from a fixed horizontal datum. The angle of the shoreline with the axis, ox , is small. The shoreline is defined by $y = y_s$, $z = z_s = z_b(x, y_s, t)$ which also defines the sea level as function of time.

The deepwater limit of the beach is, $y = y_c$. (This limit defines the contour line where the sand is no longer moved by wave action). The water depth at $y = y_c$ is D_c . It will be assumed that D_c remains constant as sea level and beach profiles change. Therefore $\partial z_s / \partial t = \partial z_c / \partial t$.

B is the height of the bluff in case of erosion (i.e., when $\frac{\partial y_s}{\partial t} < 0$), and the height of the berm in case of accretion, (i.e., when $\frac{\partial y_s}{\partial t} > 0$),

The quantity of sand over a stretch of shoreline, Δx , unity and bounded by the datum, $z = 0$, $y = 0$, and the beach profile z_b

at time, t , is:
$$V(t) = \int_0^{y_1} z_b(x, y, t) dy$$

Let us assume that, for some reasons, the beach profile changes during an infinitesimal amount of time, dt . Let us further assume that the initial beach profile which is considered at time, $t = t_1$, could be the normal "equilibrium profile".* The departure and modification from this initial beach profile can be characterized by:

(a) A translation in the yz plane defined by an elementary vector of components.

*The "equilibrium profile" may never exist under varying prototype conditions (similarly two-dimensional wave never exists), but it is a convenient idealized concept which could be approached in two-dimensional wave tank experiments. In the present case, it could be defined as the statistical long term average beach profile which exists under a given wave climate. The model presented herewith is actually independent from this definition.

$\frac{\partial y_s}{\partial t}$, $\frac{dD}{dt}$ is the rate of change of sea level.

Note that this translation is independent from the beach profile and in particular, if the beach profile normally exhibits a number of significant bar formations, under normal conditions, this translation will reproduce this characteristic at the same water depth.

(b) A perturbation characterizing the departure or variation from the initial profile. Since the rate of the vertical component of translation is $\frac{dD}{dt}$, the perturbation can be defined by only a horizontal displacement. This effect is neglected in the present layer and will be presented in a sequel at a later date.

Note that this translation is independent from the beach profile and in particular, if the beach profile normally exhibits a number of significant bar formations, under normal conditions this translation will reproduce this characteristic at the same water depth.

Figure 1 Notation

The variation of sand quantity in the considered domain is:

$$\frac{dV}{dt} = \int_0^{y_l} \left(\frac{\partial z_b}{\partial t} + \frac{\partial z_b}{\partial y} \frac{dy}{dt} + \frac{\partial z_b}{\partial x} \frac{dx}{dt} \right) dy$$

On which if one neglects the variation of z_b with respect to x yields:

$$\frac{dV}{dt} = (B + D_c) \frac{\partial y_s}{\partial t} - (y_c - y_b) \frac{dD}{dt}$$

This variation of volume is due to the variation

of littoral drift along the ox axis and the onshore-offshore motion. The following terms are included:

(a) The discharge of sand leaving the beach per unit of width which includes:

1. Q_{yw} due to loss of sand by wind.

2. $Q_{ys}(x)$ due to the quantity of silt contained in the bluff and which tends to move offshore by suspension. This loss occurs

only in case of erosion $\frac{\partial y_s}{\partial t} < 0$ and is equal to $Q_{ys} = K_s B \frac{\partial y_s}{\partial t}$ where K_s is the percentage of silt in the bluff.

3. Q_{yf} due to the loss of sand from the beach by density current during storm. Q_{yf} is a function of the size distribution and density of material. A beach of fine material ($< 0.1^{mm}$) will tend to erode more rapidly than beach made of coarse material ($> 1^{mm}$). The coarse material tends to move along shore while the fine sand moves offshore.

The determination of these three quantities are given from sand budget investigations.

(b) A general term $M(x,t)$ expressing the local variation in the sand budget due to

1. loss of sand by rip currents along groins.
2. sudden dumping of sand in case of beach nourishment or flood.

(c) The variation of littoral drift along the axis ox which is

$$Q_s(s) - Q_x(x + dx) = - \frac{\partial Q_s}{\partial x} dx$$

$Q_s = 7.5 \times 10^3 P_l$ where Q_s is in yd^3 year. P_l is in $ft - lbs/sec/ft$ of shoreline and is expressed by the relationship:

$P_l = \frac{\rho g^2}{64\pi} H_o^2 T K_R^2 \sin 2\alpha_b$ where K_R is the refraction coefficient from deep water to the line of breaking inception: T is the wave period, H_o is the deepwater wave height, α_o is the angle of the deep water wave with the shoreline, α_b is the angle of breaking with the shoreline.

This formula will be assumed to hold in case of gentle beach curvature. The refraction coefficient K_R and angle α_b can be determined as functions of the deep water wave characteristics H_o , T , α_o (or α) and the angle of the shoreline at breaking, $\approx \frac{\partial y_s}{\partial x}$. At $x \rightarrow -\infty$, the deep-water wave angle α with bottom contours is equal to α since the shoreline has the same direction as the axis ox . In the general case, i.e., for any value of x

$$\alpha_o = \alpha - \tan^{-1} \frac{\partial y_s}{\partial x}$$

The breaking waves characteristic: wave height, H_b , water depth d_b , and the angle breaking α_b , can be obtained from the deepwater wave characteristics, H_o , T , and α_o . α_o is given by the previous equation

in terms of α and $\frac{\partial y_s}{\partial x}$ which takes into account the curvature of the

shoreline. The following equation is valid provided the bottom contours are parallel along a wave ray, (Le Mehaute and Koh, 1967) (Figure 2):

$$\alpha_b \approx \alpha_o \left[0.25 + 5.5 \frac{H_o}{L_o} \right] \text{ where } L_o = \frac{gT^2}{2\pi}$$

Therefore, the refraction coefficient,

$$K_R = \left[\frac{\cos \left(\alpha - \tan^{-1} \frac{\partial y_s}{\partial x} \right)}{\cos \left[\left(\alpha - \tan^{-1} \frac{\partial y_s}{\partial x} \right) \left(0.25 + 5.5 \frac{2\pi H_o^2}{gT^2} \right) \right]} \right]^{1/2}$$

Now it is possible to formulate the variation of littoral drift:

$$\frac{\partial Q_s}{\partial x} = A H_o^2 K_R^2 2 \cos 2\alpha_b \frac{\partial \alpha_b}{\partial x} + A H_o^2 2K_R \frac{\partial K_R}{\partial x} \sin 2\alpha_b$$

where $A = 7.5 \cdot 10^3 \frac{\rho g^2}{64\pi} T$. On the other hand one also has

$$\frac{\partial \alpha_b}{\partial x} = \frac{0.25 + 5.5 \frac{H_o}{L_o}}{1 + \left(\frac{\partial y_s}{\partial x} \right)^2} \frac{\partial^2 y_s}{\partial x^2}$$

In case of wave diffraction, the wave height varies significantly along a wave crest. Then the

previous refraction coefficient K_R has to be replaced by a combined coefficient, say $K_D K_R$. Also, in a diffraction zone, α_b is due to the sum of variation of shoreline direction

$\tan^{-1} \frac{\partial y_s}{\partial x}$ and because of diffraction, the rotation of the wave crest around the end of the groin: θ (Figure 3). θ is the angle which has the end of the groin as apex and extends from the limit of the "shaded" area to the considered location defined, therefore,

$$\alpha_b \approx \tan^{-1} \frac{\partial y_s}{\partial x} + \alpha_o - \tan^{-1} \frac{x}{\ell},$$

$$-\frac{\partial \theta}{\partial x} = \frac{\partial \theta'}{\partial x} = \frac{1}{\ell} \frac{1}{1 + \left(\frac{x}{\ell} \right)^2}$$

An empirical formulation for determining the combined effect of diffraction and refraction is more suitable to quantitative analysis of a real sea spectrum than more exact theories of wave diffraction which are valid for periodic waves over a horizontal bottom and are represented by Fresnel integral.

FIGURE 2 EFFECTS OF WAVE REFRACTIONS ON A CURVE BEACH

For this, it will be assumed that the energy travels laterally along a wave crest as well as along a wave ray. This lateral transmission of energy results into a decrease of wave energy from the exposed area to the shaded area,

$$\int_A^C H^2 dx = \int_0^D H_0^2 ds$$

In the case where the long groin is in the previously defined wave diffraction zone as in Figure 3, it is assumed that the wave energy which reaches the groin is absorbed by friction. It is assumed that the combined effects of diffraction refraction of a wave spectrum can simply be represented by a sinusoidal variation of wave height along the breaking line. (Mobarek and Weigel, 1966). One has finally

Figure 3 Diffraction Zone Notation

$$K_D(x) = \left(\frac{\sqrt{2}}{2} \frac{\cos(2\alpha_0)}{\sin \alpha_0} \right)^{1/2} \sin \left[\frac{\pi \cos(2\alpha_0)}{4l} (x + l \tan(45^\circ - \alpha_0)) \right]$$

Inserting this value in the littoral drift formula previously described permits us to complete the mathematical model.

III. TRANSFORMATION OF THE PHENOMENOLOGICAL EQUATION AND NUMERICAL SCHEME

Now that all the phenomenological equations have been established we will find it more convenient to express them in dimensionless form. The general equation expressing the sand budget balance can still be written. (The loss terms have been dropped for sake of simplicity and can easily be included whenever necessary).

$$(B(x,t) + D_c) \frac{\partial y_s}{\partial t} + (y_c - y_b) \frac{dD}{dt} = \frac{\partial Q}{\partial x}$$

For purposes of analysis we consider this equation in dimensionless form.

$$\text{let } (\text{length})^{\hat{}} = \frac{\text{Length}}{B_o + D_c} \quad B_o \text{ to be chosen later}$$

$$\hat{t} = \frac{At}{(B_o + D_c)^3}$$

$$Q = \frac{A}{2} K_R^2 K_D^2 \sin 2\alpha_b$$

The general equation is thus transformed to:

$$\frac{B + D_c}{B_o + D_c} \frac{\partial \hat{y}_s}{\partial \hat{t}} + (\hat{y}_c - \hat{y}_b) \frac{d\hat{D}}{d\hat{t}} = \frac{\partial}{\partial \hat{x}} \frac{K_D^2 K_R^2 \sin 2\alpha_b}{2}$$

α_b = function of α_o , say $f(\alpha_o)$, (the function f depends only on H_o/L_o as previously shown). The hats and subscripts will be dropped from all variables from this point on.

$$\text{Therefore } \frac{1}{2} K_D^2 K_R^2 \sin 2\alpha_b = K_D^2 \cos \alpha_o \sin \alpha_b$$

$$\text{Note } \frac{\partial}{\partial x} \cos \alpha_o \sin \alpha_b = \left[\cos \alpha_o \cos \alpha_b \frac{\partial f}{\partial \alpha_o} - \sin \alpha_o \sin \alpha_b \right] \frac{\partial \alpha_o}{\partial x} = F(\alpha_o) \frac{\partial \alpha_o}{\partial x}$$

The general equation then becomes (after some rearrangements)

$$\frac{\partial y}{\partial t} = \frac{B_o + D_c}{B + D_c} F(\alpha_o) \frac{1}{1 + \left(\frac{\partial y}{\partial x}\right)^2} \frac{\partial^2 y}{\partial x^2} + R(x,y,t)$$

$$\text{where } R(x,y,t) = \frac{B_o + D_c}{B + D_c} F(\alpha_o) \frac{\partial \alpha_o}{\partial x} - (y_c - y_b) \frac{dD}{dt} + 2K_D \frac{\partial K_D}{\partial x} \cos \alpha_o \sin \alpha_b$$

$\alpha = \alpha(x)$ in the diffraction zone

The above equation is the general dimensionless form which gives us the time dependent sand budget. This general equation is nonlinear and appears to be impossible to solve analytically. Some numerical results are presented

The uniform depth theory of Penny and Price is used as an approximation (not substantiated) for diffraction about the end of the breakwater. The shoreline is calculated for various multiples of a fixed At (Figure 4a). Of interest is to note that the undulatory patterns of the shoreline seen in Figure 4a disappear in Figure 4b. Hence, diffraction induced undulations in natural shoreline probably rarely appear since offshore wave climates are usually multi-directional.

FIGURE 4a SHORELINES AT SUCCESSIVE TIMES 5Δt, 10Δt, 15Δt

FIGURE 4b SHORELINES FOR TIME 2Δt

The numerical scheme generally used to solve this problem is based on the use of implicit finite differences. Such schemes, whether implicit or explicit, or both, are commonly used to efficiently solve parabolic problems. However, even in the case where only refraction is considered, the boundary condition

$\frac{\partial y}{\partial t} = - \tan \alpha$ at $x = 0$ numerically gives a solution which initially may not conserve mass, i.e., the integrated transport equation

$\frac{\partial}{\partial t} \int_0^L y dx = Q(L)$ may not be satisfied. Unfortunately this feature is unavoidable for most such schemes (the exceptions will be discussed below) as the following will demonstrate. Shown on Figure 5 is an initially straight shoreline. In any finite difference scheme, after 1 time increment the shoreline is bounded below by the solid shoreline of Figure 5.

This shoreline has the least possible area A, where $A = \frac{\Delta x^2}{2} \tan \alpha$

The conservation of mass equation requires $\Delta t Q(L) = \cos \alpha \sin \alpha_b \geq A$

Thus, Δt must satisfy the inequality

$$\Delta t > \frac{1}{2} \frac{\sin \alpha}{\sin \alpha_b} \frac{\Delta x^2}{\cos^2 \alpha} \quad \text{Since the accuracy (and in explicit schemes, stability as well) depends}$$

on the ratio $\lambda = \frac{\Delta t}{\Delta x^2}$ the above inequality places a lower bound on the

accuracy of the solution which may be unacceptable in practice. The finite difference form of the equation for the conservation of mass may be incorporated directly into the numerical scheme. In this case a solution exists which is similar to the previous case but shows a small erosion throughout the reach. For engineering applications the primary quantity of interest is the amount of sand on a given shoreline. It is then more important to conserve mass than to satisfy the shoreline boundary condition as written in the present form. The general equation will now be used to derive an equivalent equation for the transport Q which, even though subject to similar numerical problems, will satisfy the transport boundary conditions exactly.

Consider, for the moment, the situation in which only refraction is important. The general equation then becomes $\frac{\partial y}{\partial t} = \frac{\partial Q}{\partial x}$

where $Q = \cos \alpha_o \sin \alpha_b$

$$\alpha_b = f(\alpha_o)$$

$$\alpha_o = \alpha + \tan^{-1} \frac{\partial y}{\partial x} \quad \text{Differentiating by } x \text{ gives } \frac{\partial}{\partial t} \frac{\partial y}{\partial x} = \frac{\partial^2 Q}{\partial x^2}$$

The transport function Q can be considered as a function of α_o which may be solved for α_o , say $\alpha_o = g(Q)$.

Thus the above transport equation becomes

$$\frac{\partial}{\partial t} \tan(\alpha_o - \alpha) = \frac{\partial}{\partial t} \tan(g(Q) - \alpha) = \frac{\partial^2 Q}{\partial x^2}$$

$$\therefore \frac{\partial g(Q)}{\partial t} = \cos^2(g(Q) - \alpha) \frac{\partial^2 Q}{\partial x^2}$$

$$\text{but } \frac{\partial g(Q)}{\partial t} = \frac{dg(Q)}{dQ} \frac{\partial Q}{\partial t}$$

$$\therefore \frac{\partial Q}{\partial t} = \frac{\cos^2(g(Q) - \alpha)}{dg(Q)/dQ} \frac{\partial^2 Q}{\partial x^2}$$

Assuming a solution for this equation is known, the shoreline y can be calculated from the equation

$$y(t,x) = y(0,x) + \int_0^t \frac{\partial Q}{\partial x}(t,x) dt$$

FIGURE 5 COMPUTED AND MINIMAL SHORELINES FOR FINITE DIFFERENCE SCHEME OF TIME = 1Δt

In practice the equation for Q is not solved in the above form. Implicit in the above formulation is the assumption that the function g exists. However, as is illustrated in Figure 6, g is not single valued if the maximum range of the angle α_0 is greater than approximately 41 degrees. This difficulty may be removed by considering the equation for Q and y as a system subject to the boundary conditions for Q .

Figure 6: Transport function $Q(\alpha_0) = \cos \alpha_0 \sin z\alpha_0$ for selected values of z .

Note that
$$\frac{\cos^2(g(Q)-\alpha)}{dg(Q)/dQ} = \frac{dQ}{d\alpha_0} \left/ \left[1 + \left(\frac{\partial y}{\partial x} \right)^2 \right] \right.$$

Hence, the equation for Q becomes
$$\frac{\partial Q}{\partial t} = \frac{dQ}{d\alpha_0} \frac{1}{1 + \left(\frac{\partial y}{\partial x} \right)^2} \frac{\partial^2 Q}{\partial x^2}$$

This together with the equation $\frac{\partial y}{\partial t} = \frac{\partial Q}{\partial x}$ is solved in a cyclic scheme.

One possible method is the centered Crank-Nicolson type implicit-explicit scheme discussed in the following. Suppose y is given for all x at a given time t , and that from time t the wave climate is specified by the (constant) triple (α, H_0, T)

$$\text{Let } L(t,x) = \frac{dQ}{d\alpha_0} \frac{1}{1 + \left(\frac{\partial y}{\partial x} \right)^2}$$

$$\lambda = \frac{\Delta t}{\Delta x^2}$$

$L(t,x)$ = an approximation to $L(t,x)$

Integrating the Q equation gives

$$Q(t+\Delta t, x) = Q(t, x) + \frac{\Delta t}{2} \left[L(t, x) \frac{\partial^2 Q}{\partial x^2} \Big|_t + \tilde{L}(t+\Delta t, x) \frac{\partial^2 Q}{\partial x^2} \Big|_{t + \Delta t} \right]$$

where $\frac{\partial^2 Q}{\partial x^2} = \frac{Q(x+\Delta x) - 2Q(x) + Q(x-\Delta x)}{\Delta x^2}$

Integrating the y gives

$$y(t+\Delta t, x) = y(t, x) + \frac{\Delta t}{2} \left[\frac{\partial Q}{\partial x} \Big|_t + \frac{\partial Q}{\partial x} \Big|_{t+\Delta t} \right]$$

where $\frac{\partial Q}{\partial x} = \frac{Q(x+\Delta x) - Q(x-\Delta x)}{2\Delta x}$

The equations are solved numerically, subject to the appropriate boundary conditions, by the cyclic algorithm:

- 1) Let $L(t+\Delta t, x) = L(t, x) \forall x$
- 2) Calculate $Q(t+\Delta t, x) \forall x$ subject to the appropriate boundary conditions
- 3) Calculate $y(t+\Delta t, x) \forall x$
Calculate $L(t+\Delta t, x)$, set this equal to $L(t+\Delta t, x)$
Calculate new Q
- 4) If new Q compares with old Q stop, if not go to step 3

Tests with this scheme have shown that it converges to its limit after one application of step 3.

This method can easily be modified to solve the equation where both diffraction and variations in lake level are allowed, i.e., (s is the beach slope)

$$\frac{\partial y}{\partial t} = \frac{\partial}{\partial x} K_D^2 \cos \alpha_o \sin \alpha_b - \frac{1}{s} \frac{dD}{dt}$$

For convenience let $Q = \cos \alpha_o \sin \alpha_b$

$$\tilde{Q} = K_D^2 Q$$

As before

$$\begin{aligned} \frac{\partial}{\partial t} \frac{\partial y}{\partial x} &= \frac{\partial}{\partial t} \tan (g(Q)-\alpha) \\ &= \frac{1}{\cos^2 (g(Q)-\alpha)} \frac{dg(Q)}{dQ} \frac{\partial Q}{\partial t} - \frac{1}{\cos^2 (g(Q)-\alpha)} \frac{\partial \alpha}{\partial t} \end{aligned}$$

Also $\frac{\partial Q}{\partial t} = K_D^2 \frac{\partial Q}{\partial t} + 2K_D \frac{\partial K_D}{\partial t} Q$

The second term in each of the above two equations are negligible in physical situations of usual interest, where the distance between the shoreline and the tip of the breakwater is large compared to the distance the shoreline changes during a time Δt .

Therefore, the transport equation becomes

$$\frac{\partial \tilde{Q}}{\partial t} = \frac{K_D^2}{dg/dQ} \cos^2(g(Q)-\alpha) \frac{\partial^2 \tilde{Q}}{\partial x^2} \quad \text{and} \quad \frac{\partial y}{\partial t} = \frac{\partial Q}{\partial x} - \frac{1}{s} \frac{dD}{dt}$$

This system is solved using the same type of algorithm as previously employed.

In the present situation where only refraction is important several approximations are possible which produce problems having analytic solutions. The most direct approximation, and essentially the assumption of Pelnard-Considere, is to approximate

$$\frac{\partial y}{\partial t} = \left[z \cos \alpha_o \cos \alpha_b - \sin \alpha_o \sin \alpha_b \right] \frac{1}{\left(\frac{\partial y}{\partial x} \right)^2} \frac{\partial^2 y}{\partial x^2}$$

(subject to the boundary conditions

$$\left. \frac{\partial y}{\partial x} \right|_{x=0} = -\tan \alpha$$

$$y(x,t) = 0 \quad \text{for } x = \infty$$

by $\frac{\partial y}{\partial t} = a \frac{\partial^2 y}{\partial x^2}$ where a is a constant. For the standard breakwater problem, the most logical choice for this constant is given by

$$a = \frac{z}{1 + \tan^2 \alpha} = \left[\quad \right]_{x=0} \quad \text{since the shoreline in this case is principally governed by its behavior at the breakwater. This problem has solution}$$

$$y(x,t) = 2 \tan \alpha \frac{\sqrt{at}}{\sqrt{\pi}} e^{-x^2/4at} - \tan \alpha x \operatorname{erfc}\left(\frac{x}{\sqrt{4at}}\right)$$

which is exactly the same as that of Pelnard-Considere except that the constant a has been changed. This problem however doesn't conserve mass since

$$\frac{\partial}{\partial t} \int_0^\infty y(x,t) dx = z \sin \alpha \cos \alpha \neq \sin \alpha \cos \alpha$$

When this approximation is used in the transport equation for Q , the problem becomes

$$\frac{\partial Q}{\partial t} = a \frac{\partial^2 Q}{\partial x^2} \quad \text{subject to the boundary conditions}$$

$$Q(x=0) = 0$$

$$Q(x=\infty) = \cos \alpha \sin \alpha_b$$

which has solution

$$Q(x,t) = \cos \alpha \sin \alpha_b \operatorname{erf}\left(\frac{x}{\sqrt{4at}}\right)$$

Integrating the equation

$$\frac{\partial y}{\partial t} = \frac{\partial Q}{\partial x}$$

$$\text{gives } y(x,t) = \cos \alpha \sin \alpha_b \left(\frac{\sqrt{2}}{\sqrt{\pi a}} t^{1/2} e^{-x^2/4at} - \frac{x}{a} \operatorname{erfc}\left(\frac{x}{\sqrt{4at}}\right) \right)$$

which is of the same form as the previous solution.

IV. APPLICATION

The evolution of the shoreline at Holland was studied using the present model. The relevant physical data as well as the estimates of offshore sediment losses were used in the analysis (Figure 7). The historical shorelines were interpolated to give the shoreline every 100 feet along the baseline. The results of these computations are not given. The height of the berm is assumed to be 10 feet. The depth to no sediment motion was estimated at 30 feet, based on visual consideration of the offshore bathymetry as well as the use of the method of Weggel (private communication). An offshore line loss of 3.2 yd³/yr/ft of beach is also included.

Figure 7: Summary of sand budget north of Holland, Michigan.

Choice of wave climate is the remaining input parameter to be determined, and is the most controversial. The wave climate most desirable for the study of shoreline evolution is a time series giving wave height H, period T, and direction D. Unfortunately, this is almost never available and hence statistical summaries must be used. The monthly statistical summaries given by the SSMO for Lake Michigan South previously described are chosen for use. One possible employment of these summaries is to construct monthly times t for each possible (H,T,D) triple, i.e., t (H,T,D), and then calculate the evolution of the shoreline as the (H,T,D) triples are chosen in some deterministic order or at random. This method would be computationally very expensive and is not used. The most simple approach is to assume that these are but 2 (H,D,T) triples representing the gross transport north and south, each occurring for some length of time per month. The entire shoreline is alternately calculated for an incremental time assuming the direction of the incoming wave is positive, then negative. The period T used is taken to be the average T, i.e.

$$\bar{T} = \frac{\sum p(H,T)T}{\sum p(H,T)}$$
 where the p(H,T) are the (H,T) probabilities given in the SSMO (). The choice of (H,D) for north and south, denoted (H_N,D_N) and (H_S,D_S) respectively, must now be made. This choice is subject to the condition that the actual northerly transport, as calculated using the statistics and given a straight shoreline for the reach of interest, be preserved, i.e., that

$$t_N H_N^2 \bar{T} \cos \bar{\alpha}_0 \sin \bar{\alpha}_b = t_h \sum_{H,T} p(T|H) p(H,D) T H^2 \cos \alpha_0 \sin \alpha_b$$

H,T
D giving north
transport

holds where

- t_h = number of hours in a given month
- $p(T|H)$ = conditional probability T occurs given H
- $p(H,D)$ = probability of (H,D) pair, using SSMO Table 18 as a data base
- α_0 = D_N - shoreline orientation
- α_b = f (α₀)
- t_N = number of hours the "average" wave condition exists
- H_N = "average" wave height
- $\bar{\alpha}_0$ = D_N - shoreline orientation
- D_N = "average" direction

And similarly for the directions giving southerly transport.

The average directions of the shoreline at the breakwater are calculated using the historical records. The directions are chosen for the incoming wave angles since the complex geometry of the harbor breakwater shields the nearby shoreline from waves arriving from most directions. At present, the time duration of waves arriving from the

north is assumed to be the same as from the south. Hence, $t_N = t_S = 0.5 t_h$. The conservation of transport equation is then used to calculate the average wave heights H_N and H_S .

A computer program was used to calculate the evolution of the shoreline from September 1967 to May 1968. The historical 1967 and 1968 shorelines, as well as the computed 1968 shoreline, are shown on Figure 8. The calculation assumed that $\Delta x = 100$ feet with $\lambda \approx y$ which gives a value for Δt which varies from 8 to 20 hours depending upon the month and wave characteristics. The principal discrepancy between the predicted and actual 1968 shoreline occurs in the vicinity of the breakwater. While the shapes agree there is an erosion in the calculated shoreline which is probably due to the approximations used in calculation of the diffraction coefficients, and incoming wave angles which are functions of x in the shadow region of the diffraction zone. The unaltered theory of Penny and Price was incorporated into the numerical scheme since most breakwaters can be represented as line barriers, and hence is almost always useful. However, for the case of Holland Harbor a universally valid prediction of the shoreline would require the detailed calculation of the diffraction effects due to the geometry of the breakwaters. Also, the convenient choice of incoming wave direction obscures the fundamental problem of how to properly use the statistical wave summaries.

FIGURE 8 COMPUTED vs. ACTUAL DATA

V. CONCLUSION

The basic idea of Pelnard-Consideré, i.e., to investigate shoreline evolution by concentrating on conservation of mass as a spacial one dimensional problem, has been generalized to essentially its limits of applicability. These physical processes of refraction and diffraction (where applicable) have been incorporated, as have deterministic variations in lake level, bluff height and beach slope. The inclusion of refraction makes possible the proper use of the known physical relationships between wave energy and littoral drift on a priori basis without necessarily determining these as results from the past recorded shorelines at a given location. Accurate determination of the behavior of the shore in the lee of a breakwater requires inclusion of diffraction in some form. This could be done in a heuristic manner, as presented here either in the global approximation described in a previous section or in the use of the constant depth theory of Penny and Price. It could also be done in a more rigorous manner which would include the effects of a sloping beach. Thus quantitative predictions of the shoreline can, in theory, be attempted in situations where on-offshore transport of sand in either negligible or as known from other sources of information.

The resulting theory is presented in several equivalent forms, one in terms of the behavior of the shoreline $y(x,t)$ alone, the other expressed explicitly in the longshore transport $Q(x,t)$ and implicitly in $y(x,t)$. The former has the advantage that numerical schemes, such as that of Crank-Nicolson described earlier, can qualitatively indicate the behavior of the shoreline in regions of rapid change. However, the conservation of mass is difficult, if not initially impossible to achieve since any approximation of a transport derived term (i.e. a term arising from $\partial Q/\partial x$) will alter the transport balance. On the other hand, the later form allows employment of analytical or numerical approximations in the transport equation which will not disturb the total sand content of the system, but only its local distribution.

The most severe and unavoidable limitations to the engineering application of these methods is the use of the statistical wave summaries. While one possible use of these was attempted, many others are possible. Efficient and accurate employment of the offshore wave statistics is endemic to the problem of large scale shoreline prediction, and must be achieved before any theory, whether one line, multiple lines, or grid can successfully produce accurate results.

Also, the problem of shoreline evolution sensitivity to time step in the input wave climatology would require further research.

Despite this limitation, it is felt that by taking into account effects of wave refraction, wave diffraction and change of lake level, as done in this paper, a mathematical model with multiple bottom contour lines could be formulated which will, if the problem of wave statistics input is solved, permit us to calculate the evolution of the complete bottom topography.

It is important to point out that wave refraction effect on shoreline evolution have been found particularly important. It is particularly necessary in order to determine a planform stability criteria, which can be established from the present formulation.

ACKNOWLEDGMENT

The writers acknowledge Dr. Rich Weggel of the Coastal Engineering Research Center, and Mr. Charles Johnson of the U. S. Army, Corps of Engineers, Chicago Division for their pertinent remarks during the course of this investigation. Informal discussions with Dr. Robert Dean, University of Delaware, have been very constructive.

Abstract

Field observations of beach and inshore morphology and of surf and inshore current spectra using an array of pressure transducers and low-inertia bidirectional flow meters interfaced with an in-field mini-computer/logging system have been replicated on several beaches in southeastern Australia under a range of energy conditions. Two broad extremes of beach conditions are distinguished spatially and temporally: (1) reflective systems in which much of the incident wave energy is reflected from the beach face; and (2) dissipative systems with wide surf zones and high turbulent viscosity. Reflectivity increases as the ratio of wave steepness to beach (or bed) steepness decreases. Compared to steep, unbarred reflective beaches which are common in deeply indented or partially protected compartments, the topography of exposed dissipative systems is more complex and varied: six time-and-environment-dependent morphologic types with different bar patterns and bar-beach relationships are recognized. The greatest total dissipation prevails in regions of most abundant inshore sediments or during and immediately after severe storms. Between the reflective and dissipative extremes there is a hierarchy of observed resonant frequencies with the highest frequency resonance occurring in the most reflective cases. Results indicate that near the beach face, motions associated with resonance at periods greater than incident wave periods exhibit strong net seaward resultants and are probably important sources of beach erosion. Reflective beaches are sensitive to resonant excitations over a wider range of frequencies and under lower energy conditions than are dissipative beaches. Hence, although reflective beaches represent the accretive end point of a "beach cycle" they are also more delicately poised with a higher potential for erosion.

Introduction

Beach and inshore systems on the New South Wales coast of south-eastern Australia (*Fig. 1*) exhibit pronounced morphologic and dynamic variability with respect to both time and local environment (Wright *et al.*, in press). The coast is characterised regionally by a steep marine-dominated inner shelf. Rocky headlands separate embayed beaches which occupy pronounced coastal compartments, of widely varying dimensions. Inshore processes are dominated by a relatively high energy wave regime with a highly variable wind-wave climate superimposed on persistent long southerly and southeasterly swell. Significant wave heights of 1.5m, 2.5m and 4m are respectively exceeded for 50%, 10% and 1% of the time; storm waves exceed heights of 10m (Lawson and Abernethy, 1975). Semi-diurnal spring tide range is 1.6m.

Field observations of beach and inshore morphology, surf and inshore current spectra, and inshore circulation patterns have been replicated in several contrasting beach environments for a range of energy conditions. An array of pressure transducers and low-inertia bidirectional flow meters interfaced with an in-field mini-computer/data acquisition system was used to obtain wave and current data. The system permits simultaneous logging and analysis of time series from 16 channels. (See Bradshaw *et al.*, 1978 for detailed description of field instrumentation)

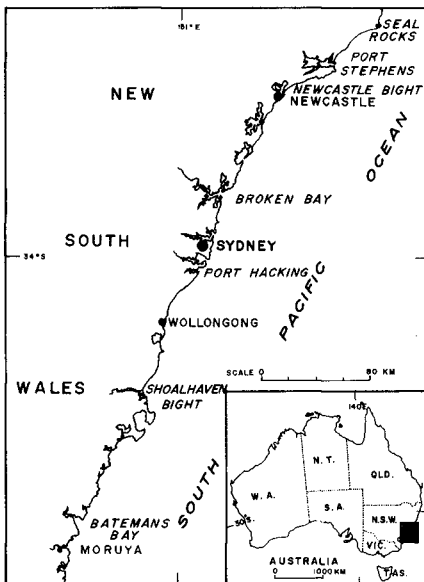

Figure 1: Location Map of study area and major beach sites

Variability of Beach Conditions

Two broad extremes of beach conditions are distinguished spatially and temporally: (1) reflective systems in which much of the incident wave energy is reflected from the beach face; and (2) dissipative systems with wide surf zones and high turbulent viscosity. The degree of reflectivity depends in a gross sense on the surf scaling parameter as defined by Guza and Bowen (1975) by

$$\epsilon = a\omega^2 / g \tan^2 \beta \quad (1)$$

where a is breaker amplitude, ω is radial frequency ($2\pi/T$ where T is period) of the waves, g is the acceleration of gravity and β is beach or inshore slope. Highly reflective conditions are associated with ϵ values less than ~ 2.0 whereas in the case of fully dissipative systems ϵ normally exceeds 30.0 in the vicinity of the breakers. Reflective conditions persist for most of the year in deeply indented compartments, on partially protected estuarine beaches, and on beaches composed of coarse material. Dissipative systems prevail in most of the exposed, open coast situations except after prolonged periods of accretion and low wave energy (Wright et al., in press).

Reflective Beaches

Reflective beaches are characterised by the profile configuration shown in *Figure 2*. Distinguishing features include: (1) a linear, low gradient nearshore (i.e., seaward of break) profile composed of fine sand; (2) a pronounced step composed of the coarsest available material; (3) a steep, linear beach face surmounted by a high berm; (4) well-developed beach cusps; and (5) surging breakers with high runup and minimum setup. The step below the beach face is situated beneath the shore break which is also the position of collision between backwash and incident waves. The depth of the step base increases with increasing wave energy. The reflective condition is normally maintained throughout the tide cycle. Features such as ridge and runnel topography, swash bars, and inshore troughs are consistently absent from such reflective systems. Large-scale inshore (subaqueous) rhythmic topographies are completely absent. Similarly, inshore circulation cells and rip currents are rarely present except during storms. The most conspicuous three-dimensional features are well-developed beach cusps on the beach face and berm. An oblique view of Bracken (McKenzie's) Beach, a typical reflective beach on which many of our experiments were conducted, is shown in *Figure 3*.

Wave height and current spectra (*Figure 4*) from reflective beaches consistently have their dominant peaks at incident wave (T) and subharmonic ($2T$) periods and cross spectra indicate the existence of low-mode edge waves at those periods. Edge wave lengths are consistently well correlated with cusp spacing (Wright et al., 1977, in press). Infragravity peaks are not important. Under low energy conditions subharmonic peaks are low relative to incident wave peaks; however,

Increasing breaker height tends to be accompanied by increasing subharmonic energy. Growth of subharmonic resonance is accompanied by an increase in the strength of seaward flows which pulse at the subharmonic period. Subharmonic seaward pulsing thus appears to be a major mode of erosion of reflective beaches, at least, in the early erosional stages.

Figure 4:
Typical Power Spectra of wave height and shore normal current time series from a reflective beach (Bracken Beach Dec. 1977; sensors located 3 metres seaward of step)

Dissipative Beach Systems

Dissipative systems are fronted by concave upward nearshore (seaward of break) profiles and wide flat inshore profiles (Figure 5). Waves break 75 to 300+ metres seaward of the beach and dissipate much of their energy before reaching the beach, creating significant radiation stress gradients and setup. Topography is much more complex and varied than in the case of reflective beaches; one or more bars, three-dimensional inshore topography, and different scales of rip cells are frequently present. It is common for dissipative systems to become segregated into subregions of contrasting turbulent viscosity such that a highly dissipative inshore zone may front a moderately reflective beach face. It is therefore necessary to separate the surf scaling parameter into an inshore value, ϵ_s and a beach face value ϵ_b . Wright et al. (In press) have classified dissipative beaches into the six basic types shown in Figure 6. Each type is dominated by a distinctive combination of surf-zone processes and by different scales and frequencies of resonant phenomena.

Figure 5 : Typical cross section of a dissipative beach

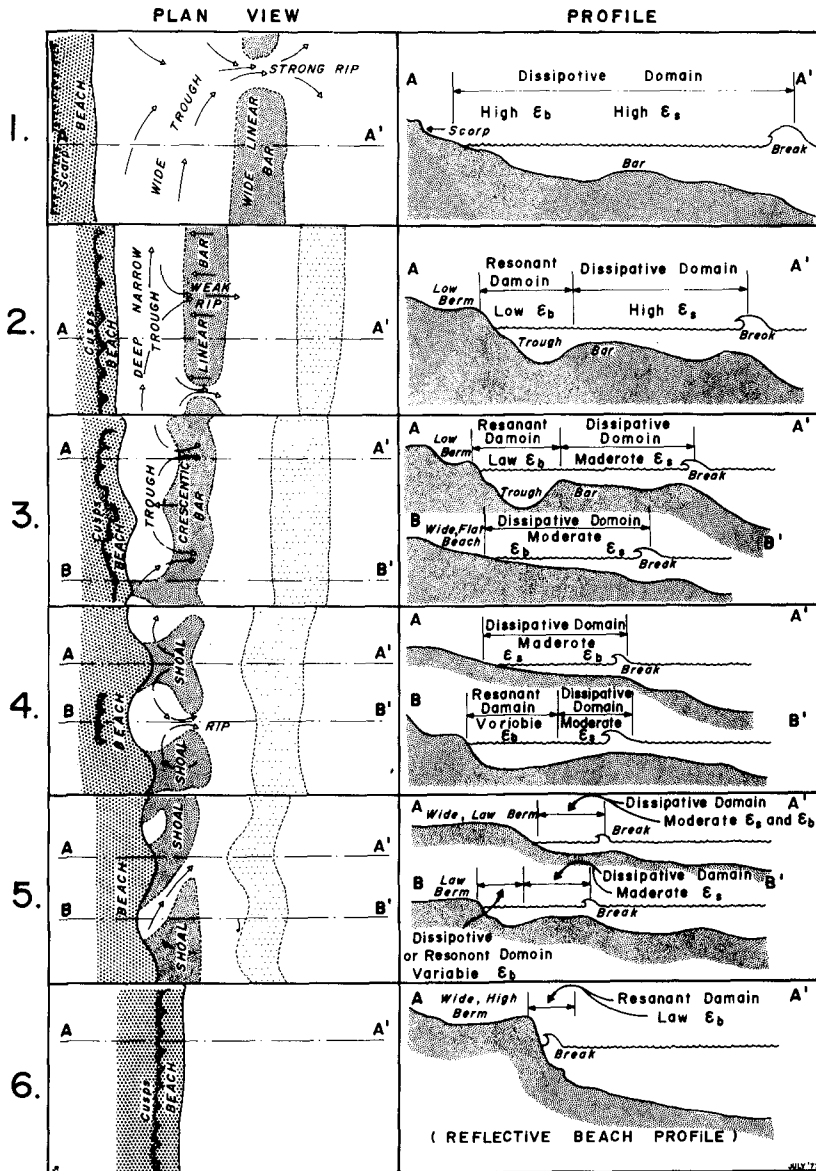

Figure 6 : Six major types of high-energy dissipative beach/inshore systems

The greatest total dissipation is associated with *Type 1* (*Figure 6*) which prevails in the regions of most abundant inshore sediments or during and immediately after severe storms. *Type 1* is dynamically similar to beaches in deltaic regions where abundant inshore sediments sustain very flat profiles. Where it develops on high-energy beaches away from major depositional regions, *Type 1* is a manifestation of sub-aerial beach erosion under extreme energy conditions. At least one well developed bar lies 100-200 metres seaward of a flattened beach face. Additional bars may occur farther seaward. Both the inshore zone and the beach face are highly dissipative. Setup is highest and runup is lowest with *Type 1* and the dominant energy near the beach is at surf beat periods (80-150 sec.). Along longer and straighter beaches multiple longshore bars may remain unbroken by rips. Multiple bars are particularly prominent at the northern ends of large depositional bights (e.g., *Figure 7*) where accumulation of abundant sediments creates wide, flat nearshore/inshore profiles. As in deltaic settings, this situation can result in the maintenance of highly dissipative conditions even under moderately low energy conditions. Under these conditions the parallel bar patterns conform well with patterns predicted from the theory of long-crested leaky-mode infragravity standing waves (Suhayda, 1974; Short, 1975). However, on the more highly compartmented beaches the development of *Type 1* topography is often accompanied by one or two rips which extend up to 1 to 2 km seaward (*Figure 8*). These large, powerful rips commonly exhibit a very low frequency pulsing at periods of 5 to 10 minutes and are very destructive in their effects. Observations of storm-rip pulsing on Palm Beach (*Figure 8*; Cowell, 1975) and on Cronulla Beach (Lees, 1977) show remarkable correspondence with the natural frequency of the compartments.

Figure 7: Multiple Parallel bars related to *Type 1* topography (Shoalhaven Bight, N.S.W.)

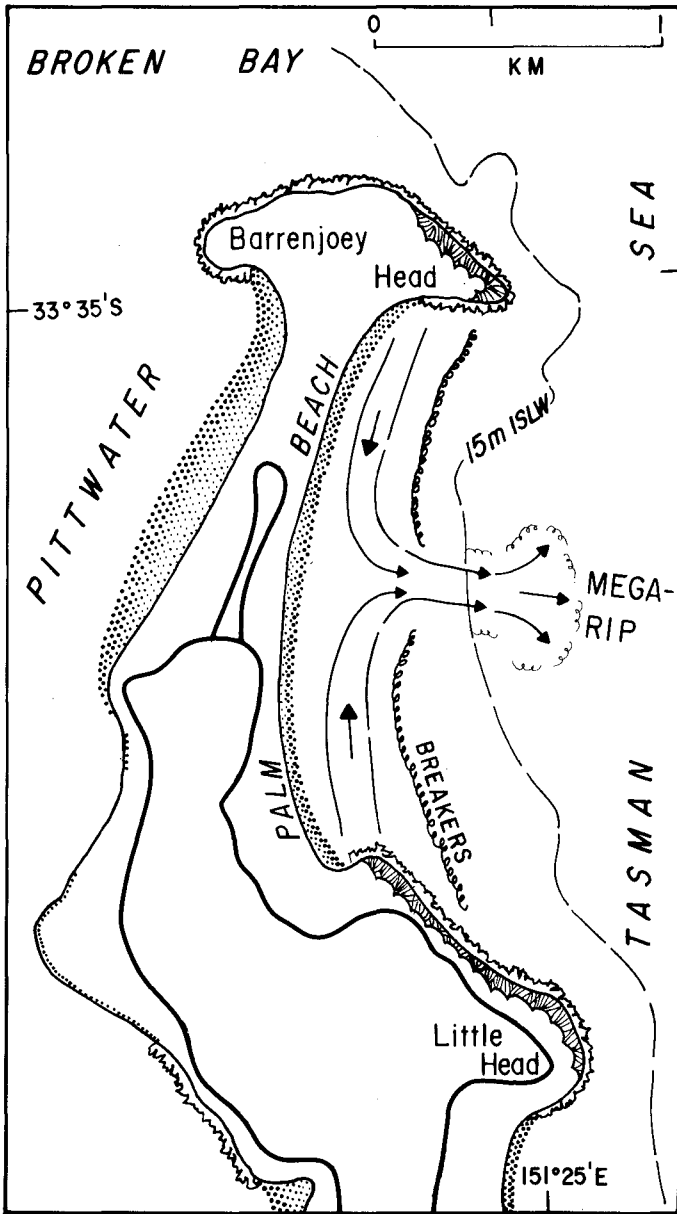

Figure 8 : Large scale "megarip" circulation system related to Type 1 conditions on a highly compartmented beach (Palm Beach, N.S.W.)

Type 2 develops as the bar migrates shoreward under the influence of the progressive shorter period (incident wave period, T and its harmonic $T/2$) components of surf motion when the wave height diminishes to more moderate energy levels. As the bar migrates shoreward the beach face steepens and a deep trough develops within which the partially dissipated waves reform (*Figure 9*). Although the outer surf zone remains dissipative, low turbulent viscosity prevails within the trough and low ϵ_b values characterize the beach face. Synchronous and subharmonic resonance occurs near the beach face, and, as with reflective beaches, low-mode edge waves form beach cusps. A conspicuous feature of *Type 2* and *3* is the occurrence of pronounced resonant spectral peaks at $4T$ (40-50 sec.) within the trough and on the bar. Lower frequency surf beat peaks also remain present but are secondary. An example of power spectra of surf zone surface oscillations over the bar and within the trough of *Type 2* is shown in *Figure 10*. The development of the narrow-band peak at $4T$ within the trough is readily apparent. Rips which pulse at surf-beat periods (100-150 secs.) commonly cross or cut the bar at widely spaced intervals. *Type 2* can persist for several weeks under swell-dominated conditions.

Type 3 is distinguished by a highly regular and rhythmic crescentic bar (*Figure 11*). Shoreline undulations and well-developed circulation cells with evenly spaced rips are also common. Rips and crescentic features have spacings of 100-200 metres. Edge waves with periods corresponding to the observed resonant spectral peaks at $4T$ (40-50 secs) are probably responsible for the crescentic forms and periodic circulation cells. Rip-current spectra exhibit dominant peaks at $4T$ indicating pulsing at that period. As with *Type 2*, the beach face remains relatively reflective, but with the lowest ϵ_b values and highest runup prevailing behind crescentic embayments, where low mode synchronous and subharmonic edge waves commonly exist near the beach face.

Well-developed rhythmic topography with alternating transverse bars and pronounced embayments characterize *Type 4* (*Figure 12*). Transverse bars are frequently anvil-shaped but cusped bars similar to those described by Sonu (1973) may also occur. The topography may also be skewed alongshore under conditions of oblique breaker angles. Narrow, well-defined rips occupy embayments while net shoreward transport occurs over shoals as observed by Sonu (1972, 1973). Where shoals weld to the beach, both ϵ_s and ϵ_b remain high and runup is low; however, the beach face behind embayments remains steep, ϵ_b is normally less than 2, and runup is high. A step is usually present at the base of the beach face. In an accretionary sequence, the spacings of rips and transverse bars appear to be largely inherited from *Type 3*. However, the primary rip circulation cells associated with *Type 4* are probably topographically induced.

Spectra of shore-normal and shore-parallel current motion and water surface oscillations as observed in the presence of *Type 4* topography show dominant, broad surf beat (80-150 secs) peaks near the beach face where the transverse bar attaches to the shore. Rips pulse at corresponding periods. In contrast to transverse bar spectra, current and surface oscillation spectra from the step region behind rip bays also show strong peaks at T and $2T$.

Figure 9 : Shore-parallel bar and deep pronounced trough of Type 2 topography (Moruya Beach, N.S.W.). Note wave breaking and partial dissipation over the bar and reduced turbulence in the trough.

Figure 10 :

Power spectra of water-surface oscillation over the bar and within the trough of Type 2 topography (Moruya Beach, N.S.W.)

Rhythmic crescentic bar patterns associated with *Type 3* topography (Erunderee embayment near Seal Rocks, N.S.W.)

Figure 12 : Rhythmic transverse bars and rip embayments of *Type 4* topography (Cronulla Beach, N.S.W.)

Extensive inshore shoals at the base of a moderately steep beach face distinguish *Type 5* (*Figure 13*). The shoals develop following long periods of low energy or in relatively protected regions with abundant inshore sediment. The shoals are crossed at irregularly-spaced intervals by narrow rip channels which atrophy with continued accretion. With *Type 5*, ϵ_b varies appreciably with tide. At low tide dissipation is virtually complete before the waves reach the beach; runup is very low and motion near the beach is dominated by low-energy infragravity oscillations. At high tide, however, runup is high and synchronous and subharmonic resonance occurs. *Type 5* can persist for prolonged periods of 2 to 3 months under sea-breeze dominated summer conditions provided no high energy events occur.

Figure 13 : Intertidal shoals and atrophied rip channels associated with *Type 5* topography

Type 6 morphology (*Figure 14*) represents the fully accreted beach state and occurs after prolonged periods of low swell. It is generally rather rare on exposed, otherwise dissipative surf beaches. *Type 6* is a reflective beach with a steep linear beach face and a very high berm which remains continuous for long distances alongshore; rips are always absent. Wave and current spectra are also similar to those described for reflective beaches.

Figure 14 : Steep Reflective beach and high berm associated with *Type 6* topography (near Port Stephens, N.S.W.)

Discussion

The spectrum of motions in any given surf zone is made up of numerous progressive (dissipative) and standing (reflective) components (Huntley *et al.*, 1977). On a steep reflective beach oscillations at incident wave period are normally standing near the beach; however, with increasing ϵ and increasing surf zone viscosity, high frequency reflection is suppressed and the periods which can be standing increase through a progression of subharmonics (jT ; where $j = 2$ or 4) to surf-beat ($T_b = 80$ -150 secs) to a very low frequency seiching at periods ($T = 5$ -10 min) near the natural compartment period. The standing oscillations can exist either as "leaky" modes in which the reflected energy is re-radiated back to sea (e.g., Suhayda, 1974), or as resonant trapped edge waves; the latter appear to be common except under the most dissipative extremes (*Type 1*) on long straight beaches. Increasing resonant period is accompanied by increasing scale (i.e., spacing between rips and associated rhythmic morphology) and intensity (i.e., rip velocity) of circulations. The progression of resonant modes through a series of discrete frequencies implies firstly that beaches do not vary between reflective and dissipative extremes on a continuum but probably shift abruptly to different states. Secondly, a hierarchy of "nested" circulation and morphologic elements can occur.

Segregation of shore-normal current spectra into shoreward and seaward components (e.g., Wright *et al.*, in press) indicates that on any given beach or inshore slope, significant shoreward movement near the bed is dominated by progressive dissipative bores with periods equal

to those of the incident waves (T) and their harmonics ($T/2$). Near-bed current motions associated with resonant oscillations at periods greater than incident wave period (i.e., $2T$, $4T$, and surf beat) exhibit strong net seaward-directed resultants, suggesting that low frequency resonance plays a major role in causing seaward sand transport. Where synchronous resonance at the dominant incident wave period, T , prevails (e.g., on reflective beaches), the shoreward and seaward velocities are approximately balanced for oscillations at that period. This balance tends to prevail on steep reflective beaches and in the immediate vicinity of the beach face of some dissipative beach types (*Types 2, 3* and *6*, and in the rip embayments of *Type 4*) where incident waves are commonly standing. However, cross spectra reveal that away from the beach face over flat, dissipative inshore profiles the higher frequencies (T and $T/2$) are progressive and dissipative. The shoreward decay of these progressive components is accompanied by a shoreward increase in resonant energy at lower frequencies. The shore-normal direction (i.e. onshore or offshore) of net sediment transport at any given inshore position depends on the energy of the high frequency progressive components relative to the energy of lower frequency resonant components.

On very flat, highly dissipative, profiles resonance at intermediate frequencies ($2T$, $4T$) is suppressed or weak whereas possible resonance at very low frequencies (surf beat or compartment seiching periods) requires high energy dissipation in order to become dominant over the accretive progressive bores. Hence, although the fully dissipative system represents the end point of an erosional sequence, its large inshore sediment storage and flat gradient give it the greatest potential for experiencing future accretion. In contrast, highly reflective beaches (and *Type 6* profiles: the accretive and point) are, owing to their steep gradients and subaqueous sediment deficit, sensitive to resonant excitations over a wide range of frequencies and may experience erosion under moderate swell conditions as soon as resonant energy at $2T$ (first subharmonic) exceeds incident wave energy near the beach. The reflective beach is thus delicately poised with a high erosion potential.

At any specific beach locality the morphodynamic state can vary from *Type 1* to *Type 6* with time and depending on antecedent energy conditions. The most exposed localities show the greatest variability between states. The persistence of a given type also varies spatially with local environment. *Types 1* and *2*, often with multiple bars, are common at the northern ends of large depositional bights, particularly in cases where there is an abundance of sediment. *Types 2, 3* and *4* are frequently encountered in fully exposed middle sections of coastal compartments. *Type 5* is most likely to be persistent on stretches of beach less exposed to high energy swell, but exposed to shorter wind-generated waves. *Type 6* is often present in the partially protected southern ends of compartments in the lee of headlands; it is particularly prominent in the southern arcs of log-spiral or "zeta-curved" compartments. Significantly, although these last environments experience low energy for most of the time, they are chronically susceptible to appreciable erosion under heavy swell conditions.

Acknowledgements

This study is supported by the Australian Research Grants Committee (ARGC). Mr. M.P. Bradshaw, Mr. P. Cowell, and Dr. A.D. Short have provided essential and able assistance in all facets of the study. Long-term surveys of Moruya Beach, which formed the basis of the 6-state model, were initiated by Dr. R. McLean in collaboration with one of us (B.G.T.).

CHAPTER 69

VARIATIONS OF WAVE-ENERGY LEVELS AND COASTAL SEDIMENTATION, EASTERN NICARAGUA

by

E. H. Owens and H. H. Roberts

Coastal Studies Institute, Louisiana State University,

Baton Rouge, Louisiana 70803

Abstract

High rates of weathering, abundant rainfall, and high discharge rates combine to supply large volumes of sediment to the coastal zone of eastern Nicaragua. This terrigenous sediment is confined to a narrow section of the inner shelf (<30 km wide) due to the circulation pattern within a coastal boundary layer. Sediment transport within the inner shelf and shore zone is to the south. This simple transport pattern is considerably modified by variations in wave-energy levels that are a function of shelf width, bottom friction, and wave sheltering. In northern sections, the shelf is up to 200 km wide but narrows to less than 20 km in the south. A direct result is that wave-energy levels at the shoreline are of the order of three times greater in the south. In the north the Rio Coco delta is prograding seaward in a fluvially dominated environment, whereas the Rio San Juan delta in the south has a wave-dominated morphology characterized by deflected distributaries. Other major accumulation features have developed where wave-shadowing is produced by offshore reefs and cays. Alongshore a spatial variation was recorded, with straight beaches and simple linear bars in the north that change to rhythmic beach topography and crescentic nearshore bars as wave-energy levels increase toward the south.

Introduction

A 2-year multidisciplinary study (1976-77) on the eastern Nicaragua shelf (Figure 1) was directed toward the investigation of macro- and meso-scale shelf and nearshore processes (Murray et al., in preparation). One aspect of the investigations was to determine the regional pattern of sediment supply, transport, and deposition for the shelf and nearshore environments. This subject is considered in more detail elsewhere (Roberts et al., in preparation) but forms the basis for the present discussion, which focuses on an explanation of the variations in the morphology of the beach and nearshore sediments as a function of spatial variations in wave-energy levels at the shoreline.

The primary characteristics of the Caribbean shelf of Nicaragua are (1) persistent northeast trade winds with high average speeds (15 to 20 km/hour) throughout the year; (2) rainfall values in the coastal zone that increase from 2500 mm/year in the north to 5500 mm/year in the south; (3) a large drainage basin of volcanic rocks, with high weathering and erosion rates; (4) high river discharge; (5) a unidirectional wave approach out of the northeast; (6) a dominant system of north to south nearshore and inner shelf currents; (7) a narrowing of shelf width from 200 km in the north to less than 20 km in the south; (8) shallow depths on the shelf, generally less than 30 m; and (9) a microtidal environment (20 to 60 cm range).

Supply of Sediment to the Coast

The continental divide in this section of Central America is adjacent to the Pacific coast (Figure 1), so that the drainage basins that discharge into the Caribbean Sea are relatively large. The eastern Nicaragua drainage basin is approximately 133,000 km², and erosion rates are very high. Intense weathering of the

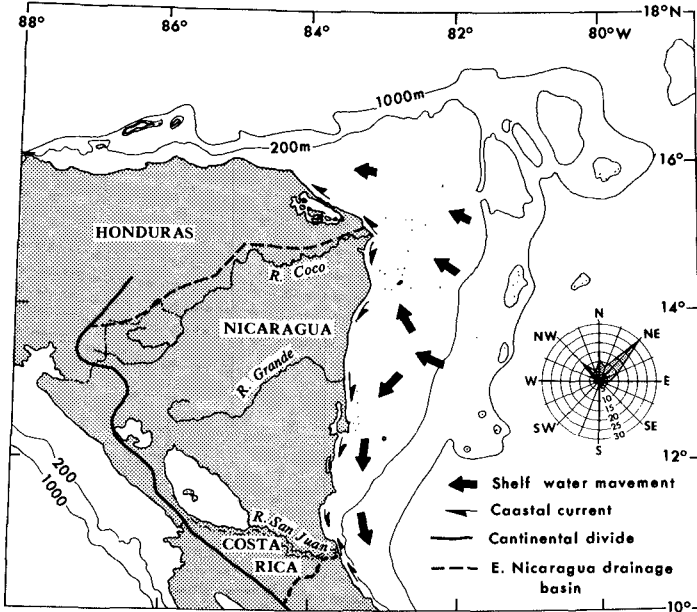

Figure 1. Shelf and coastal currents, Eastern Nicaragua. The wind rose indicates annual frequency (percent) by direction.

volcanic rocks, which are the major geologic outcrop in the mountains of the upper basins, results from high temperatures and large rainfall amounts, coupled with the seasonality of the rainfall distribution. The abundant rainfall also leads to high erosion and high river discharge rates.

Although the data base is limited for this region, extrapolation from available discharge and sediment load measurements indicates a total sediment supply to the shelf by rivers that is in the order of 25 to $30 \times 10^6 \text{ m}^3/\text{year}$ (Table 1). This sediment yield is equivalent to an estimated basin erosion rate of $4.0 \times 10^5 \text{ kg/km}^2/\text{year}$, a rate that is comparable with the high-rainfall, high-temperature, and high-relief areas of southwestern Asia that have erosion rates at the same order of magnitude (Strakhov, 1967).

Table 1
Major Terrestrial Sediment Sources

Drainage Basin	Area (km ²)	Estimated Annual Discharge (m ³ x10 ⁶)	Estimated Annual Sediment Supply (m ³ x10 ⁶)
Coco	24,761	36,460	5.5 - 7.4
Prinzapolka	10,548	20,766	3.1 - 4.2
Grande	17,556	29,104	4.5 - 6.0
Escondido	12,308	26,464	4.0 - 5.4

Estimated total sediment supply to shelf from rivers:
25 - 30 x 10⁶m³/year

For further comparison, in terms of unit lengths of coast, the Nicaragua shelf receives about three times more fresh water and about thirty-three times more sediment from river discharge than does the Atlantic shelf of the United States (Murray et al., in preparation).

Coastal erosion as a source of sediments is limited to a 5- to 10-km section of shoreline in the north, near Puerto Cabezas, where 10-15-m cliffs of sands and gravels are undergoing wave attack. Elsewhere, sections of barrier beaches are subject to erosion, but this process involves redistribution of sediments rather than the supply of new sediments to the coastal zone.

An estimated 16 to 22 x 10⁶ m³/year, the majority of the sediment that is supplied to the shelf, enters the coastal zone in that section to the north of and including the Rio Grande (Figure 1). This northern section accounts for two-thirds of the eastern Nicaragua drainage basin due to the geometry of the Central American isthmus, which narrows from north to south in this region.

Shelf Processes and Sediment Transport

The distribution of terrigenous sediments supplied to the coastal zone and shelf is characterized by two major features. The first is the dominant north to south transport of sediment along the Nicaraguan coast, and the second is the confinement of

the terrigenous sediments to a narrow (less than 30 km) band of the inner shelf adjacent to the coast.

The percentage of calcium carbonate in sediments collected on a transect from the mainland coast (between Punta Perlas and El Bluff) to the shelf edge reflects the rapid facies change to carbonates away from the coast (Figure 2). In less than 20 km terrigenous sediments of the strong longshore drift system are replaced by in situ derived carbonates. Sediments confined to this narrow band along the coast vary from coarse volcanic sands near the river mouths and in the beach and bar systems to fine-grained kaolinitic-montmorillonitic clays in coastal recesses and away from the shoreline. Variations in river discharge and therefore sediment input, as well as perturbations in the strength and direction of the northeast trade winds, cause the sediment-rich coastal plume to expand and contract.

The transition areas between dominantly terrigenous bottom sediments and carbonates are generally found to be rather flat and featureless depositional plains. In these areas, terrigenous clays are deposited in association with in situ generated aragonitic muds derived from the growth and disintegration of numerous varieties of calcareous green algae. Geomorphically, the belt of terrigenous sediments and the terrigenous-carbonate transition areas are associated with a depositional ramp that interfaces with the coast (see zone 1 of Figure 3).

Beyond the limits of the belt of terrigenous sediments (approximately 20 km from the coast), the shelf sediments are generally composed of more than 95% calcium carbonate. The shelf interior consists of vast flat areas blanketed by bimodal sediments consisting of Halimeda-rich carbonate muds. These intermediate shelf areas of carbonate deposition generally have very

Figure 2. Percent calcium carbonate in bottom sediment samples across the south-central part of the Eastern Nicaragua shelf. Sample locations are given on the inset diagram. X-ray diffraction of representative bottom sediments is shown for sample stations 2, 5, and 15.

little relief and are found in water depths between 20 m and 30 m (see zone 2 of Figure 3).

Extremely rough-bottomed topography, resulting from the growth of coral-algal reefs, is associated with well-defined areas of the shelf (see zone 3, Figure 3). Island platforms such as the Pearl Cays, the Mosquito Cays, and the Corn Islands, as well as submerged topographic highs and a belt along the seaward margin of the shelf, exhibit active reef growth (Figure 3). These reef zones are important source areas for carbonate sediments derived from both biological and mechanical degradation of reef components. In addition to being generation sites for carbonate debris, the extremely irregular bottom topography of these zones is a major factor in the attenuation of open-ocean waves as they intersect the shelf and translate across it. Reefs commonly have

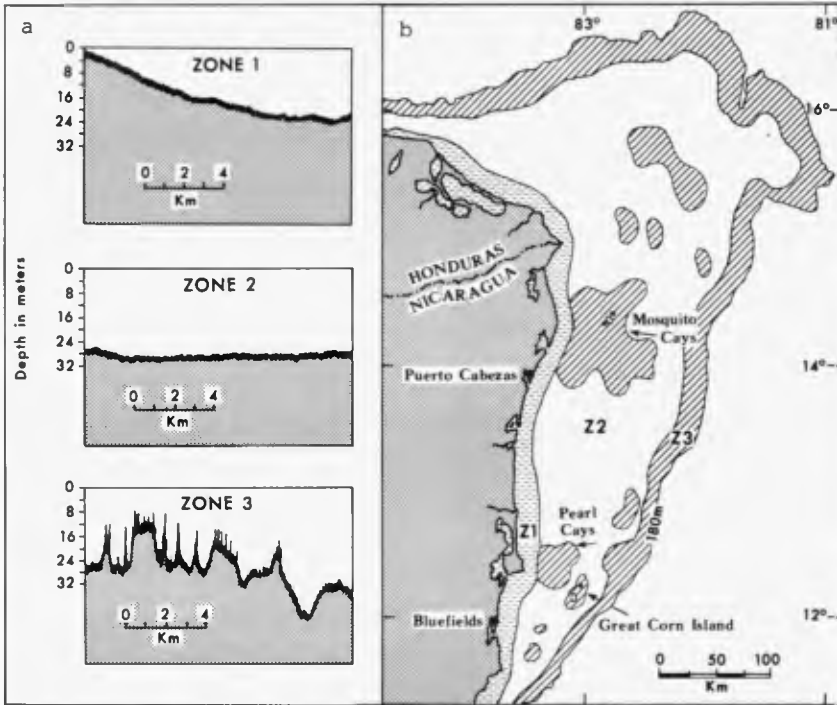

Figure 3. Bottom roughness zonation of the Eastern Nicaragua shelf can be defined by three categories:

Zone 1--Smooth depositional ramp near the coast.

Zone 2--Featureless mid-shelf areas of carbonate deposition.

Zone 3--Rough-bottomed conditions reflecting reef growth on island flanks, mid-shelf platforms, and the shelf margin.

(a) Examples of echo-sounder records for the three zones; (b) geographic distribution of bottom roughness types.

relief of 10 m, and at the shelf margin relief in excess of 20 m is not unusual. The shelf margin reefs are continually bathed in open ocean water and are developing in an environment free of terrigenous sediment, whereas shelf and island platform reefs, for example the Pearl Cays, may be subject to various levels of interaction with terrigenous sedimentation.

The north to south transport of terrigenous sediment is a function of both oceanic and wave-induced currents. In the near-

shore zone the dominant wave approach is out of the northeast, as a result of the effects of the northeast trades, and this situation produces a strong littoral current and longshore drift at the shoreline. Adjacent to the coast wave heights are less than 1.5 m for 75% of the year, with significant periods of 5 to 7 s in the north and 7 to 9 s in the southern areas (Livesey and Henderson, 1968).

Offshore, oceanic currents are characterized by an onshore movement across the shelf of the central Caribbean drift and by a bifurcation of the drift toward the northwest and southwest (Figure 1). Although the mean drift is to the northwest in northern sections of the shelf, the shallow-water countercurrent adjacent to the coast moves toward the south under the influence of the northeast trades and of quasi-geostrophic adjustment to the large freshwater influx along the coast. On the inner shelf the currents are confined to a 10-30-km-wide coastal boundary zone characterized by strong baroclinic structures and by the frictional effects of the northeast trades (Crout and Murray, 1979). In addition, these currents are enhanced by the surface slope of the nearshore waters, so that velocities of 40 to 70 cm/s are common in the upper layers of the coastal currents (Murray et al., in preparation). The primary effect of the oceanic currents is to confine the terrigenous sediments to a relatively narrow (less than 30 km) band adjacent to the coast (Roberts et al., in preparation).

The primary north to south sediment transport system along this 450-km section of coast reverses direction at the Nicaragua borders. In the north the change in coastline orientation from north-south to northwest-southeast at the mouth of the Rio Coco (Cabo Gracias a Dios) leads to a divergence in the littoral drift system and a coastal current that transports sediment to the

northwest along the northern shore of the Coco delta (Figure 1). In the south the coast of Costa Rica also trends northwest-southeast, and this section is affected by easterly and southeasterly winds that become progressively more important toward the south. These winds generate a strong south to north current along the coast of Costa Rica that meets the north to south current in the vicinity of the Rio San Juan delta at the Nicaragua border (Figure 1). The result of these reversals in sediment transport directions is that the Rio Coco delta is a zone of sediment divergence and that the Rio San Juan delta is a zone of convergence.

Coastal Processes and Sedimentary Responses

The macro-scale coastal geomorphology of eastern Nicaragua is characterized by four major sediment accumulation features. Two extensive deltaic systems have developed at the mouths of the Coco and San Juan rivers, and two large cusplate forelands at Punta Gorda and Punta Perlas represent sedimentation in the lee of offshore reef systems. Also, at the regional scale there is a longshore spatial variation in beach and nearshore morphology that is a response to a major change in shoreline processes along this coast.

(a) Comparison of the Coco and San Juan deltas. The variability of shoreline processes on this coast is best exemplified by comparison of these two major deltaic systems. Although only 450 km apart, they represent morphological responses to totally different sets of shoreline processes.

The delta of the Rio Coco (Figure 4a) has assumed a large prograding cusplate shape that reflects the dominance of fluvial over marine processes. The cusplate form has developed as a single river channel has extended the delta by flank deposition. This seaward growth results from the high discharge and high sediment

Figure 4. Generalized morphology of the (a) Coco and (b) San Juan-Colorado deltas.

load of the river (Table 1) and from the inability of marine processes to redistribute the sediments alongshore.

Despite the dominance of fluvial processes, evidence of wave action is given by the relatively smooth outline of the delta. Therefore, applying the terminology of Wright and Coleman (1973), the Coco delta is defined as characterized by a river-dominated morphology with a low level of wave modification. In terms of morphology, this delta is comparable to the Ebro of northeastern Spain (Wright and Coleman, 1973, Fig. 4). The low wave-energy levels at the mouth of the Rio Coco are a function of the wide (up to 200 km), shallow shelf offshore that is characterized by numerous reefs and cays. Incoming waves therefore are subject to considerable frictional attenuation, and at the shoreline waves are generally of short period and low amplitude.

The morphology of the Rio San Juan delta, 450 km to the south, is totally different (Figure 4b). Although the estimated discharge rates and sediment loads of the two rivers are similar (Table 2), and although this is a zone of convergence of the longshore currents, the delta protrudes only slightly onto the adjacent shelf. The river has two major distributaries, both of which

have been deflected toward the north. In particular, at the mouth of the Rio Colorado a series of blocked distributary channels that parallel the shoreline (Figure 4b) are evidence of a seaward progradation that is controlled by marine reworking of the deltaic sediments. The shelf adjacent to the San Juan delta is less than 20 km wide (Figure 1), with a mean slope of 1:80 (cf. the shelf adjacent to the Coco delta, which has a slope less than 1:200, Table 2). The morphology of this delta clearly reflects the dominance of marine over fluvial processes on this section of coast.

The variation that exists between these two delta systems is due to the significant change in the balance between fluvial and marine processes. This change results from a variation in wave-energy levels at the shoreline that is controlled by shelf width. As the shallow shelf narrows toward the south, and as frictional attenuation therefore also decreases, wave energy at the shoreline increases significantly. (Computed values for wave energy show a

Table 2
Comparison between the Deltas of the Rios Coco and San Juan

	Coco	San Juan
Shelf width (km)	150-200	<20
Shelf slope	<1:200	1:80
Wave-energy levels (ergs/m/s)	Low: ~1.2 x 10 ¹⁰	High: ~4.3 x 10 ¹⁰
Discharge (m ³ /year)	~40 x 10 ⁹	~25 x 10 ⁹
Estimated sediment load (m ³ /year)	5.5-7.4 x 10 ⁶	4.0-5.4 x 10 ⁶
Littoral drift	Zone of divergence	Convergence, dominantly to north
Primary processes	Fluvial	Marine (wave dominated)
Delta morphology	Single protruding channel	Straight coast, deflected distributaries

threefold increase, from 1.2×10^{10} ergs/m/s in the north to 4.3×10^{10} ergs/m/s in the south.)

(b) Punta Gorda and Punta Perlas. In addition to the systematic alongshore changes in wave energy at the shoreline, the presence of offshore reef and cay complexes causes local variations in the coastal geomorphology. The Mosquito Cays and Pearl Cays (Figure 3) act as barriers to incoming waves, and accretion of sediments within the longshore transport system has occurred in the lee of these two reef systems. Both Punta Gorda and Punta Perlas have developed on the low-lying swampy coastal plain by the seaward progradation of a series of well-defined beach ridges.

Punta Gorda is in the lee of the Mosquito Cays (Figure 5a) and has developed downdrift of the Coco delta. As much of the sediment supplied by the Coco is diverted to the northwest at the mouth of the delta (Figure 4a), the estimated annual supply of fluvial sediment from the Coco and Ulang rivers is in the order of 3 to 5×10^6 m³/year.

Farther to the south, Punta Perlas (Figure 5b) lies downdrift of several major rivers, including the Prinzapolka and the Grande, so that sediment input in this section is much greater, in the order of 9 to 12×10^6 m³/year. Therefore, although the Pearl Cays are a less effective filter to incoming waves, when compared to the Mosquito Cays, there is more sediment in the longshore transport system. This situation has favored the development of a large cusped feature that now extends 10 km seaward from the general trend of the coast. The Punta Perlas system acts as a large groin-like feature with a resulting downdrift offset of the coast to the south.

(c) Comparison of river-mouth characteristics. As a measure of wave competence and its effect on local coastal geomorphology,

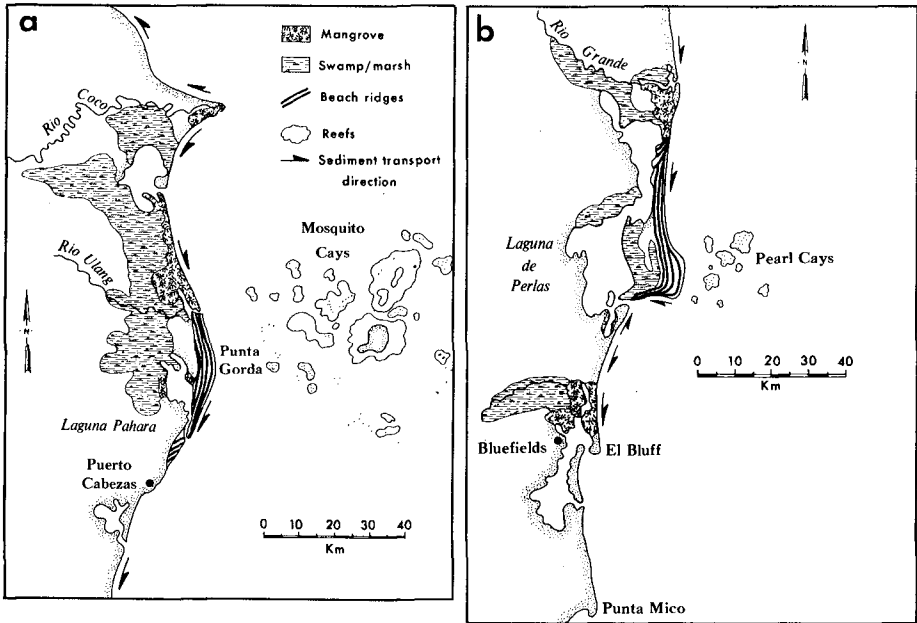

Figure 5. Generalized morphology of (a) Punta Gorda and (b) Punta Perlas (from topographic maps and aerial photographs).

a comparison has been made between the river exits of the Rio Ulang (Figure 5a) and the Rio Indio (Figure 4b). Both rivers have relatively small drainage basins and enter the shore zone at sections of unimpeded sediment transport. Although the Ulang drains an area twice the size of the Indio (Table 3), the increase in annual rainfall amounts between the two areas (from 2500 to 5000 mm) results in similar discharge rates and sediment loads. The Ulang river mouth is characterized by a large ebb-tidal delta system in which the main ebb channel has been deflected to the south by wave-induced littoral currents (Photograph 1). Although this deflected channel system is characteristic of rivers with small drainage basins, such as the Wawa and Kukalaya, the tidal deltas associated with large rivers in the northern half of the shelf (the Prinzipolka and Grande) show no evidence of channel deflection. In

these cases the very high discharge rates are sufficient to counterbalance the processes associated with the longshore transport system.

In contrast to the Ulang, the channel of the Rio Indio has been deflected 15 km to the south due to the effects of strong wave-induced longshore currents. The channel parallels the shoreline and is separated from the sea by a narrow (300-400 m), low (<3 m) barrier (Photograph 2). The mouth of the Rio Indio has become part of the outlet system associated with the northern distributaries of the San Juan delta (Figure 4b).

(d) Beach-nearshore morphology variations. At a smaller scale, field measurements and reconnaissance observations have shown that there is a marked change in beach and nearshore planform morphology from north to south on this coast. This systematic alongshore variation is a direct function of the changes in wave-energy levels at the shoreline.

In northern sections of this coast, to the north of Punta Perlas, the beaches are narrow (~10 m) and straight. A single continuous linear bar is present in the nearshore zone, usually at

Table 3
Comparison Between the Ulang and Indio Rivers

	Ulang	Indio
Drainage basin (km ²)	3830	1820
Discharge (m ³ /year)	5840 x 10 ⁶	5140
Sediment load	0.9-1.2 x 10 ⁶	0.8-1.1
River-mouth morphology	Large ebb-tidal delta - partially deflected channel	River channel deflected 15 km to south
Wave energy at shoreline (ergs/m/year)	-1.2 x 10 ¹⁰	-4.3 x 10 ¹⁰

Photograph 2. Aerial photograph of the lower course of the Rio Indio. The river exit is indicated by the arrow.

about 60 m from the shoreline (Photograph 3). Generally trough and bar depths are in the order of 1.5 and 1.0 m, respectively. Due to the wide shelf (up to 200 km) and shallow gradients, frictional attenuation values are high, particularly as much of the outer shelf is composed of active coral reefs. Computed energy levels at the shoreline are in the range 0.7 to 1.2×10^{10} ergs/m/s.

The central section, between Punta Perlas and Punta Mico (Figure 5b), is a transition zone. Beaches are generally wider and steeper, and the morphology is a series of irregular protuberances and embayments (Photograph 4). The nearshore zone is characterized by rip cells and by a nonlinear bar system with some longshore periodicity that has wavelengths in the order of 50 to 70 m. Trough depths vary between 1.0 and 2.0 m on the landward side of the inner bar, and the inner bar shoals to 1.5 to 2.5 m. Computed shoreline energy levels are between 0.9 and 1.5×10^{10}

Photograph 3. Straight shoreline with a single linear nearshore bar near Laguna de Wounta, to the north of Prinzapolka (12 April 1977).

Photograph 4. Wide breaker zone and irregular beach-nearshore topography north of El Bluff (12 April 1977).

ergs/m/s as shelf width decreases to between 100 and 150 km.

The beaches to the south of Punta Mico exhibit a rhythmic morphology (Photograph 5). This configuration is mirrored in the nearshore zone by a well-developed crescentic bar system with wavelengths in the order of 100 to 125 m. No field data were collected in this section, but computed wave-energy values are in the range 2.5 to 4.3×10^{10} ergs/m/s.

The increase in energy levels alongshore results in a distinct transition from simple morphological features to a complex system of rhythmic topography (Table 4).

Table 4
Eastern Nicaragua Beach/Nearshore Morphology

	North	Central	South
Shelf width (km)	200	100-150	20
Wave-energy levels	Low	Moderate	High
Nearshore wave power (ergs/m/sec)	$0.7-1.2 \times 10^{10}$	$0.9-1.5 \times 10^{10}$	$2.5-4.3 \times 10^{10}$
Beach morphology	Straight narrow beaches	Irregular protuberances and embayments	Wide beach, rhythmic morphology
Nearshore morphology	Single linear bar 60 m from shore	Nonlinear bar(s), some longshore periodicity (50-70 m wavelength)	Well-developed rhythmic bar system (100-125 m wavelength)

Conclusions

1. Although the Nicaragua shelf receives an estimated three times more fresh water and thirty-three times more terrigenous sediment per unit length of coast than the Atlantic shelf of the United States, the shelf has developed as a vast carbonate

province with terrigenous sediments confined to a narrow, well-defined belt (<20 km) along the coast.

2. The shelf margin (50-70 m depth), mid-shelf platforms, and island flanks are sites of active coralgall reef growth. These areas of extreme bottom roughness affect energy levels along the shoreline by the combined effects of frictional attenuation and sheltering.

3. Decreasing shelf width and decreasing frictional attenuation from north to south cause a threefold increase in wave-energy levels at the shoreline.

4. The spatial variation in nearshore and shoreline wave-energy levels results in (a) a fluvial dominated deltaic environment at the mouth of the Rio Coco, in the north; (b) a marine (wave) dominated deltaic environment at the mouth of the Rio San Juan, in the south; and (c) a systematic change from straight linear bars and beaches in the north to rhythmic topography in the south.

5. The distribution, transport, and morphology of sediments supplied to the shelf and shore zones on this coast are controlled by shelf and coastal currents and by the spatial variation in shoreline wave-energy levels.

Acknowledgments

The research was performed under a contract between the Geography Programs, Office of Naval Research, Arlington, Virginia, 22217, and the Coastal Studies Institute, Louisiana State University, Baton Rouge. J. N. Suhayda computed the wave-energy values, and Gerry Dunn prepared the illustrations.

ABSTRACT

Sediment dispersal patterns in tidal inlets within the German and the Georgia Bights are found to be controlled by three major environmental factors: (1) the tide range, (2) the nearshore wave energy, and (3) the geometry of the back-barrier bay. Both embayments chosen for study are characterized by high wave energies and low tide ranges on their flanks, and low wave energies and high tide ranges in their centers. The spatial variability in inlet morphology, therefore, contains information on the relative role of tides and waves in inlet sediment dispersal. The paper concludes by proposing a simple model for inlet morphologies for successively greater relative role of tidal currents in the sediment dispersal.

INTRODUCTION

Investigations of process-response characteristics of tidal inlets along the southeast coast of the United States (Bruun, 1966; Finley, 1976; FitzGerald *et al.*, 1976; Hubbard *et al.*, 1977; Nummedal *et al.*, 1977) have demonstrated that the geometry of the inlet entrance and the associated sand shoals depends upon three major environmental factors: (1) the tide range, (2) the nearshore wave energy, and (3) the bathymetry of the back-barrier bay.

The relative magnitudes of factors 1 and 2 control to a large extent the inlet stability. Inlets along the Georgia coast, which has high tide range and low wave energy, are much more stable than those along North Carolina's Outer Banks where the wave energy is high and the tide range relatively low. These observations support, in a qualitative sense, Bruun's (1966) stability criterion which is based on the ratio between the tidal prism and the longshore sediment transport rate.

The third factor listed above, the bathymetry of the bay, controls the degree of velocity asymmetry through the inlet gorge (Nummedal and Humphries, 1978). The bays in the southeastern United States are typically filled with intertidal salt marsh (*Spartina alterniflora* being the dominant grass species), leaving only about 20 per cent of the total bay area as open water (tidal creeks). The consequent large variation in water surface area during the tidal cycle tends to develop strongly ebb-dominant flow in such a bay-inlet system. The peak ebb current and the consequent seaward-directed sediment transport, far exceed that moving landward during flood. In cases where the back-barrier bay is essentially all open water (as in the lagoons behind the Outer Banks of North Carolina) there is no such tendency for ebb dominance.

In order to determine the response of the tidal inlets to the three controlling factors one must examine coastal segments within which all factors undergo significant changes in magnitude according to a well-known geographic pattern. The coastal segments chosen for this investigation were the southeast coast of the United States from Cape Hatteras to Cape Canaveral (Fig. 1) and the northwest coast of Europe from the Netherlands to the west coast of the Jutland peninsula in Denmark (Fig. 2). For short, the first region will be referred to as the Georgia Bight, the second one as the German Bight.

TIDE RANGE

Along the east coast of the United States the open coast tide range is primarily a function of shoaling of the tidal wave across the continental shelf. Therefore, the wider the shelf, in the direction of advance of the tidal wave, the larger the tide range (Redfield, 1958; Silvester, 1972). Figure 3 (from Nummedal et al., 1977), shows the regional tide range variation along the U.S. east coast as well as the accompanying variation in shelf width. The tide range dependency on shelf width can clearly be seen.

Fig. 1. Location map of the Georgia Bight.

Fig. 2. Location map of the German Bight.

Fig. 3. Mean tide range along the east coast of the United States. Data from: National Oceanic and Atmospheric Administration, 1978.

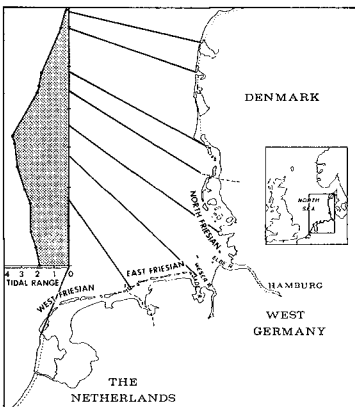

Fig. 4. Mean tide range along the shores of the German Bight. Data from Deutschen Hydrographischen Institut, 1978.

In the North Sea, the entire region is essentially a continental shelf. The variation in open-coast tide range within the German Bight, therefore, is largely controlled by the amphidromic system. Classical models of the M_2 tide within the North Sea (Defant, 1958), demonstrate the existence of a counter-clockwise rotation of the tidal wave in the North Sea around an amphidromic point between Jutland and the east coast of England. Iso-range lines are nearly concentric around this point. Therefore, the central part of the German Bight which is further away from the amphidromic point than is the northwest Netherlands or the coast of Jutland, has the larger tide range. The tide range variability within the coastal segment of interest in this study is plotted in figure 4.

By comparing figures 3 and 4 it is evident that both the Georgia and the German Bights are characterized by low tide range at their flanks and high tide range in the center. Mean tide range in the center of the Georgia Bight exceeds 2 meters; in the center of the German Bight it exceeds 3.5 meters.

WAVE ENERGY

Evaluations of the regional variability in nearshore wave climate is presently impossible because reliable wave records are very scattered and typically of too short duration to be of much use in long-range sedimentation studies. In order to derive a consistent picture of wave energy variability, therefore, it was decided to utilize the Summary of Synoptic Meteorological Observations (SSMO - data) published by the U.S. Naval Weather Service Command (1974, 1975). Wave energy flux distributions within pre-established data squares were calculated by a procedure outlined in Nummedal and Stephen (1978). In this same article the authors have also discussed in some detail the assumptions and problems associated with the utilization of SSMO-data in studies of coastal sedimentation dynamics. Results of the wave energy flux calculations for data squares off the southeast coast of the United States and in the North Sea are summarized in figures 5 and 6, and tables 1 and 2.

The deep water energy flux shows a distinct southward decrease along the U.S. east coast from a total onshore flux at Cape Hatteras of $7.7 \cdot 10^3$ Watts/m to $4.6 \cdot 10^3$ Watts/m at Jacksonville. In spite of this deep water trend, however, the mean annual breaker height in northeast Florida exceeds that of the central part of the Georgia Bight (58 cm at

Daytona Beach versus 12 cm at St. Simon Island; Coastal Engineering Research Center, 1975) probably because of the steeper inner shelf profile off the Florida coast (Nummedal et al, 1977).

Fig. 5. Wave energy flux distribution off the southeast coast of the U.S.

Fig. 6. Wave energy flux distribution along the margins of the North Sea.

Along the southeast coast of the North Sea one also finds a distinct southward decrease in total wave energy flux. This is thought to reflect a combination of a decrease in storm frequency as well as westerly fetch in the same direction. Total onshore wave energy flux in the Esbjerg data square (Fig. 6) is about $17 \cdot 10^3$ Watts/m, compared to $7 \cdot 10^3$ Watts/m along the North Friesian Islands and only $3.5 \cdot 10^3$ Watts/m along the East Friesian Islands.

By combining the information presented on the wave energy and tide range variations one can derive a generalized pattern of wave and tide dominance along the shores of these two bights (Fig. 7). The flanks have high wave energy and low tide range. They are wave dominated. Further towards the center the two factors will both be of major importance; therefore, this will be a zone of mixed energy. In the center of both bights the tidal currents clearly control the sedimentation patterns. These areas are tide dominated.

INLET MORPHOLOGY

Both the Georgia and the German Bights show distinct and similar trends in inlet morphologic changes as one progresses from the flanks toward the centers. These changes provide unambiguous evidence regarding the relative role of tidal and wave induced sediment dispersal in the total inlet circulation pattern. This paragraph will review the characteristics of inlet morphology, moving from the wave dominated embayment flanks to increasing tidal dominance at the embayment centers.

Fig. 7. Generalized distribution of wave and tide dominance along an embayment coast

Fig. 9. Map of the southern part of Ringkøbing Fjord, including the old flood-tidal delta at Nyminde Gab. Depth contours in meters.

Inlets along the wave dominated coastal segments of both bights are typified by Drum Inlet, North Carolina, at the northern flank of the Georgia Bight (Figs. 1 and 8). Although the Drum Inlet flood-tidal delta was developed over a very short time immediately after the inlet was artificially opened in 1972 its morphology is typical of the much larger deltas behind Ocracoke, Hatteras and Oregon inlets as well. Today, the Drum Inlet flood-tidal delta is rather inactive (Hubbard, 1977).

Within the German Bight the wave dominated barrier-lagoon coast is restricted to the west coast of Jutland. Furthermore, all these lagoons now have artificially cut and maintained entrances. However, it is clear from old maps and the present lagoon morphology that the natural entrance to Ringkøbing Fjord was associated with a large flood-tidal delta, the remains of which are clearly recognizable at Nyminde Gab (Figure 9).

The morphology of an inlet at a wave dominated coast is summarized in frame 1, figure 10.

Fig. 10. Tidal inlet morphological models. Frames 1 through 6 reflect an increasing role of tidal currents in inlet sediment dispersal.

As illustrated, such an inlet is characterized by sand bodies exclusively on the landward side of the inlet gorge. The gorge itself is relatively stable, the ebb tidal delta (outer shoal) is present only as a minor subtidal shoal.

With an increase in tidal range, and consequent tidal current capacity for sediment transport, one observes an intriguing change in inlet shoal configuration. Both Little River inlet on the North Carolina-South Carolina border

(Fig. 11) and Matanzas Inlet in northeast Florida (Fig. 12) are good examples of this inlet type which will be called mixed energy, low tide range, inlets.

Based on the distribution of sand bodies within these inlets the generalized model shown in frame no. 2, figure 10, was developed. This type of inlet has a smaller, and less continuous, flood-tidal delta than inlet type no. 1, it has a wide and rather unstable inlet gorge, and a significant ebb-tidal delta reflecting main channel ebb-current dominance (Hayes *et al.*, 1973).

The inlets between the East Friesian Islands on the coast of Lower Saxony, Germany, must also be termed mixed energy inlets. However, both tide range (Fig. 4) and wave energy (Fig. 6) exceed those within the Georgia Bight. As the gross differences in morphology appear to reflect primarily the larger tide range, these inlets are classified as mixed energy, high tide range, inlets. Excellent examples would be the inlet between Norderney and Baltrum (Fig. 13), and the Harle Inlet between Spiekeroog and Wangerooge (Fig. 14).

As demonstrated by Luck (1976) these Friesian inlets have a large ebb-tidal delta with a nearly continuous arc of swash bars along its margin, the "reef-bow." The high wave energy appears to cause rapid swash bar migration contributing to the instability of the seaward end of the main ebb channel. The inlets are very wide and the ones that are not yet stabilized by sea walls and groins on the adjacent island shores typically have multiple channels. According to historical studies by Luck (1975) prior to stabilization the Harle Inlet also had multiple sand bars in the gorge section and two or three major channels. Reduction in tidal prism as a function of the reclaiming of large areas of back-barrier tidal flat appears to be the main factor contributing to the changes morphology of the Harle Inlet.

A generalized morphological model of the Friesian inlets is presented in frame no. 3, figure 10. The only essential difference from model no. 2 is the larger ebb-tidal delta, projecting further out to sea in response to much stronger tidal currents. Strong wave action also produces a more continuous series of swash bars along the swash platform margin.

Fig. 14. Bathymetric map of Harle Inlet, Lower Saxony. The contour interval is 2 meters.

True tide dominance characterizes the inlets of the central part of the Georgia Bight. Although the tide range there is less than that along the Friesian coast, tidal dominance is brought about by the extremely low nearshore wave energies. Though small, Price Inlet (Fig. 15) illustrates well the morphology of the larger tidal inlets along this segment of the coast. Descriptions, photos and maps of numerous other inlets in the central Georgia Bight can be found in Hubbard (1977), Nummedal *et al.* (1977), Oertel (1975), and FitzGerald *et al.*, (1978).

Fig. 15. Oblique air photo of Price Inlet, South Carolina. Photo, March, 1977.

The morphology of tide dominated inlets is generalized in frame no. 4, figure 10. These inlets consist of a single, straight, and deep main ebb channel, a large swash platform projecting far out to sea, and numerous, often large swash bars migrating towards the inlet gorge across the swash platform. There are no sand bodies in the inlet gorge section nor on its landward side, reflecting strong ebb dominance in the main inlet channel.

With a further increase in the ratio between tide range and wave energy, beyond the conditions found in the central part of the Georgia Bight, barrier islands with distinct individual tidal inlets cease to exist. As an example one can consider the central part of the German Bight where the mean tide range in places exceeds 3.5 meters (Fig. 4).

As shown in the bathymetric maps of the entrance to the Weser estuary (Fig. 16 and 17), small, unstable, supratidal sand bodies like Alte Mellum, have replaced the barrier islands of lower tidal range. A series of linear, lunate and sigmoidal shoals dominate the estuary entrance. Their long

axes are typically parallel to the main estuary axis. The total sand body associated with this estuary is large and extends much further out to sea than any of the tidal deltas of the mixed energy inlets between the Friesian Islands further west.

Inlets (or estuary entrances) of this type are summarized in frame 5, figure 10. They are high tide range, tide dominated inlets.

Fig. 16. Bathymetry of the entrances to the Weser and Jade estuaries.

Fig. 17. Bathymetry of the area enclosed by frame in figure 16. Arrows refer to hydrographic data obtained by Barthel (1976). Open arrows indicate flood dominance, solid arrows show ebb dominance.

The high tide range end member of this spectrum of inlet types had to be found outside the German or the Georgia Bights. Hayes (1975) and Hayes and Kana (1976) present maps of Nushagak Bay, Alaska, as an example of a macrotidal embayment. Extremely high tide ranges, as in Nushagak Bay, can only develop in narrow embayments where there is a significant funneling of the tidal wave. The strong tidal currents, in turn, prevent the development of barrier islands across the embayment entrance. As indicated in the simplified morphological model of frame 6, figure 10, the shoal distribution within an embayment like Nushagak Bay is fairly similar to that of the high tide range, tide dominated embayment of frame no. 5. The main difference appears to be the degree of development of the sigmoidal shoals. An increase in tide range, and the associated tidal current strength, appears to develop larger sigmoidal shoals and more distinct flood and ebb segregated channels.

DISCUSSION

The paper demonstrates that there clearly exists a continuum of tidal inlet morphologic types. Examples of most types within this continuum can be found within the Georgia and the German Bights because of large regional variations in tide range and wave energy.

The wave dominated inlets (frame 1, figure 10) typically have the majority of the shoals on the landward side of the inlet gorge because the net direction of wave induced sand transport will be towards the lagoon. Furthermore, the existence of a largely open-water lagoon rather than a marsh or tidal flat in the back-barrier environment will reduce the ebb dominance of the main inlet channel and cause flood dominance of some inlets (Nummedal and Humphries, 1978). Complex wave-current interactions on the swash platform have been found to produce a higher concentration of suspended sediment on flooding than on ebbing tide at one inlet (Hubbard, 1977). This factor might also contribute to the landward-directed net sediment transport at some wave dominated inlets.

The mixed energy inlets within the Georgia and German Bights are all hydraulically ebb dominated, because of the extensive back-barrier marshes and tidal flats (Nummedal and Humphries, 1978). The seaward extent of the swash platform must reflect an equilibrium between the capacity for seaward transport by the ebb flow and landward transport by wave breaking on the platform. Consequently, the primary change in the ebb-tidal delta with an increase in the ratio of tidal range to breaker energy will be its seaward growth. Secondly, the inlet gorge will become better defined and less subject to changes due to bar migration as wave-induced bar development will take place on platform margins further away from the inlet. These patterns of response to increasing tidal influence on the sediment dispersal mechanism are well illustrated in models two, three and four in figure 10.

Barrier islands cease to exist along depositional coast of high tide range because the longshore sediment movement due to wave action becomes completely subordinate compared to the on-offshore movement of sediment by the tides. For the wave energy of the German coast the critical tide range appears to be about 3 meters (Fig. 4). The development of sigmoidal shoals in these high tide range embayments is an expected consequence of the deflection of a current around

the leading face of any sedimentary deposit formed by another current flowing in the opposite direction. This causes strongly segregated channels for ebb and flood flow, hence the sigmoidal shape of the bar crest. This segregation of ebb and flood flow in the Weser estuary has been well documented by Barthel (1976).

CONCLUSIONS

1. The pattern of variability in tidal inlet sand body geometries within the Georgia and the German Bights suggests the existence of continuum of inlet morphologic types. In this continuum the shoals assume a configuration which directly reflects the relative capacity for sediment transport by waves and tidal currents. Six discrete stages of inlet morphology are presented in figure 10.

2. The diagram applied by Hayes (1979) to classify barrier island shorelines is used here to show the relationship between the inlet morphologic types and the two dominant environmental parameters: wave height and tide range (Fig. 18). To establish the boundaries, 19 inlets were classified, based on shoal geometry, as wave dominated, mixed or tide dominated. The mean tide range was well known for each, mean annual breaker heights, however, are much less precisely known. Nevertheless, a distinctive pattern did emerge, permitting the establishment of fairly precise boundaries for each inlet type on this bivariate graph. The boundaries slope such that with an increase in mean annual wave height an increase in tidal range is required to produce the same type of inlet shoal geometry.

3. The regional variability of the inlets within the Georgia and German Bights can be represented by the arrow in figure 18. Towards the center of both bights one finds an increase in tidal range and a decrease in the mean annual wave height. Therefore, the inlet change from wave dominated ones at the flank to tide dominated ones at the centers.

ACKNOWLEDGMENT

Work on the coast of West Germany was sponsored by the Office of Naval Research, Geography Programs, through contract no. N00014-78-C-0612 to L.S.U. Work on the southeast coast of the United States was sponsored largely by the Army Research Office, Division of Terrestrial Sciences, through contract no. DAAG 29-76-6-0111 to the University of South Carolina.

CHAPTER 71

MORPHOLOGY OF COASTAL BARRIERS, DELAWARE, U.S.A.

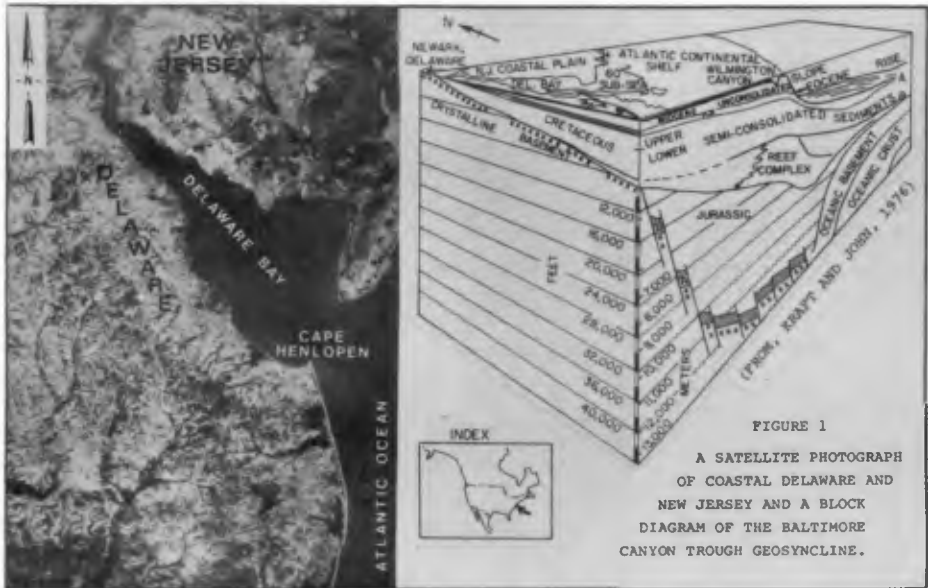

John C. Kraft, Chacko J. John, and Evelyn M. Maurmeyer
Dept. of Geology, University of Delaware
Newark, Delaware 19711

ABSTRACT

The Atlantic Coast of Delaware consists of four separate but continuous segments including (from north to south): (1) a northward-projecting spit complex (Cape Henlopen); (2) eroding Pleistocene headlands; (3) a linear coastal washover barrier; and (4) an area of migrating inlets with associated modern and relict ebb and flood tidal deltas. Coastal process studies show that continuing coastal erosion is accompanied by longshore transport of sand eroded from headlands, offshore transport to the nearshore marine area, and overwash processes transporting sand landward across the barrier. Studies of the adjacent nearshore marine area show that the barrier and its various geomorphic elements lay at the outer edge of the continental shelf approximately 12,000 years ago, and migrated landward and upward to the present position as the Holocene marine transgression continued. The sequence of coastal sediments of the barrier system consist of (landward to seaward) tidal marsh fringe, lagoonal muds and sands, barrier sands (including washover, dune, and beach deposits), and shallow nearshore sand and gravel. Drill-hole studies provide information on the subsurface configuration of the barrier from which the three-dimensional structure and stratigraphy of coastal sedimentary environmental lithosomes may be defined.

INTRODUCTION

The Atlantic coast of Delaware lies on the northwestern flank of the Baltimore Canyon Trough geosyncline of the Atlantic continental shelf of eastern North America (Figure 1). This geosyncline has been subsiding at various rates since Jurassic time (180-135 million years B.P.) and includes marine and non-marine sediments deposited along the eastern edge of the North American continent. There appears to be a geologic "hinge line" near the present Delaware shoreline indicated by different rates of subsidence northwest and southeast of this hinge line (Kraft & others, 1976; Kraft & John, 1976; Belknap & Kraft, 1977). The Atlantic coast of Delaware is presently undergoing a marine transgression causing landward and upward movement of the coastal barrier in time and space. This transgression is the result of a combination of eustatic sea level rise as a consequence of the melting of continental glaciers over the past 12,000-14,000 years, and of tectonic subsidence and compaction.

GЕOMORPHIC DIVISIONS AND COASTAL PROCESSES

The Atlantic coastal barrier of Delaware can be divided into four separate but continuous segments from north to south (Figure 2) as follows:

- (1) A spit-beach-dune complex;
- (2) Barrier against marsh;
- (3) Barrier against pre-Holocene highlands, and
- (4) Linear barrier-ebb and flood tidal delta-lagoon system. (Kraft, 1971; John, 1977).

Studies of the barrier and the nearshore marine area adjacent to the Atlantic continental shelf show that the barrier and its various geomorphic elements at one time lay farther to the east of the present position, towards the outer edge of the continental shelf. Since about 12,000 years before present, this barrier system has been migrating landward and upward as the marine transgression continues. Continuing coastal erosion is accompanied by northward longshore transport of sands eroding from pre-Holocene highlands which crop out along the barrier coastline. Sand and gravel are deposited at the spit, Cape Henlopen, and into deeper water (20 m) at the mouth of the large estuary, Delaware Bay, at the northern end of the barrier system. In addition, sand is trapped in the ebb and flood tidal deltas associated with this barrier system at the Indian River inlet (Figure 2). It is estimated that the net longshore transport to the

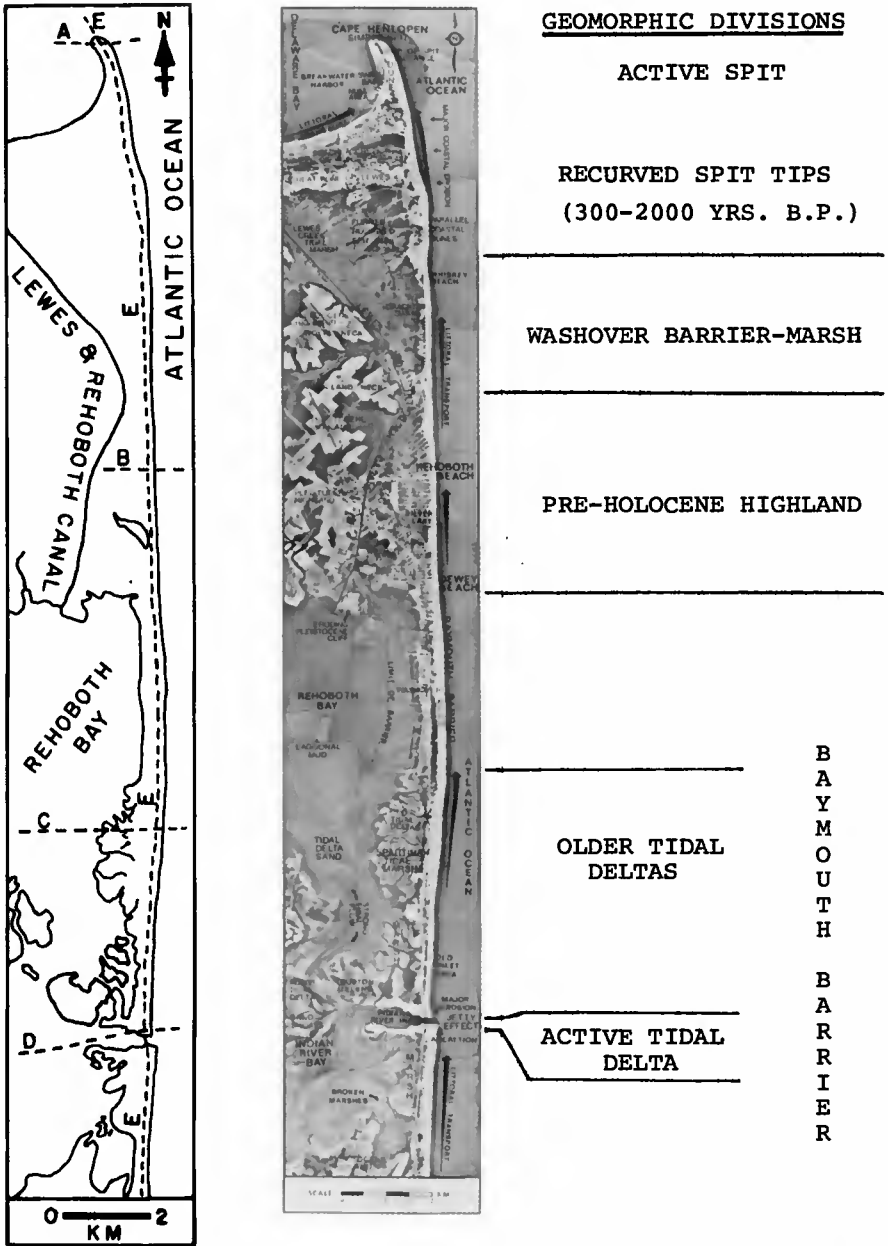

Figure 2. An index map and an aerial photo mosaic of Delaware's coastal zone indicating prominent geomorphic features. Lines of cross-section of figures in this paper are shown.

north along the Atlantic Coast ranges from 100,000-340,000 cubic meters per year (Turner, 1968).

In this area the average wave approach direction is from the east or southeast throughout the year. High intensity storms known as "northeasters" with a northeasterly wave component occur approximately once every two years in this region (Mather, 1965). Depending upon the position of the storm center as it passes the Atlantic Coast of Delaware, the longshore transport during storms may be to the north or south. In addition, large amounts of sand along the edge of the barrier may be transported offshore into the inner shelf region, or washed landward across the barrier into adjacent tidal marshes and coastal lagoons, forming washover fans. The major coastal processes in action are littoral transport of sand along the shoreface of the barrier accompanied by overwash of the barrier during times of high intensity

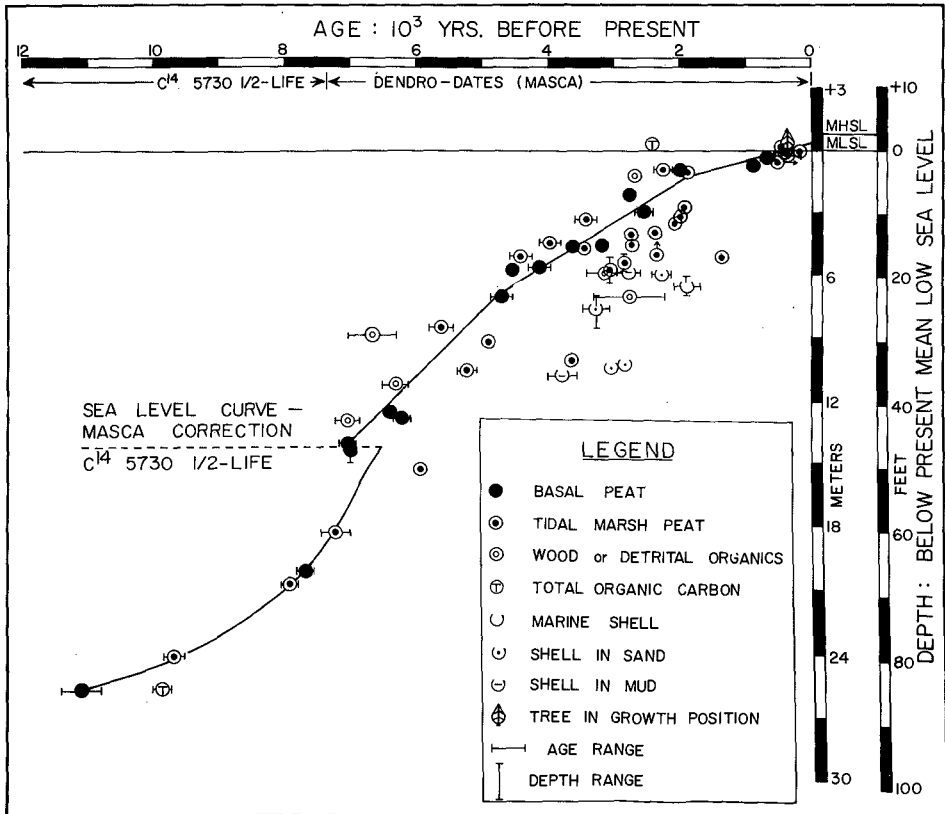

Figure 3. A local relative sea-level rise curve for coastal Delaware (Kraft, 1976).

storms. Transport of sand in the beach-berm and foreshore area can be by littoral transport in northerly or southerly direction, overwash across the barrier, transport by winds into dunes along the barrier, erosion and seaward transport and deposition on offshore bars, and transport through tidal inlets into flood and ebb tidal deltas.

Radiocarbon dates from basal salt marsh peats have enabled the construction of a local relative sea level curve for this area (Figure 3). This curve shows a continuing relative sea level rise in the Delaware Atlantic coastal region. During the Holocene Epoch (past 10,000 years) the local relative sea level shows different rates of change varying initially from 30 cm/century to the present 20 cm/century from approximately 5000 years before present (Kraft, 1976; Belknap and Kraft, 1977).

Tide gage records from the Delaware coastal area supported by tidal information from adjacent areas in New Jersey and Virginia, indicate a relative sea-level rise of approx. 33 cm/century based on an observation over the past 50 years (Figure 4).

Historical map records from various sources including the U. S. Coast and Geodetic Survey, U. S. Army Corps of Engineers, and National Ocean Survey may be used to determine average annual rates of shoreline change (Figure 5). These maps show persistent landward migration of the barrier system as a whole. Erosion rates varied from 0.4 to 3.1 meters per year over the time interval from 1765 to 1972. The only exceptions to these pervasive rates of landward erosion of the coast are those caused by construction of groins and jetties for stabilizing the coastline. However, even in the areas of groin fields net landward migration of the shoreline is occurring.

GEOLOGY

Figure 6 is a schematic representation of coastal processes in action modifying the coastline and the coastal environments undergoing transgression. Surface coastal environments, proceeding from land to sea, include pre-Holocene highlands, a tidal-marsh fringe, lagoonal muds and sands, back-barrier marshes, the Atlantic washover barrier including dunes, and the nearshore marine sands and gravels. Barrier sands tend to fill in the seaward side of the lagoon while tidal marsh sediments form at the leading edge of the Holocene transgression on the landward side of the lagoon. The beach-berm area is one of continual erosion and deposition with infrequent large washovers caused by hurricanes or "northeasters". Drill core studies of the subsurface stratigraphic units that have resulted from the landward Holocene

Figure 4. Tidal gage records from Breakwater Harbor at Lewes, Delaware showing relative sea-level rise during the 20th century (modified from Hicks and Crosby, 1974, and Demarest, 1978).

Figure 5. Average annual rate of shoreline changes for the Atlantic coast of Delaware (compiled from Moody, 1964 and U. S. Army Corps of Engineers, 1968).

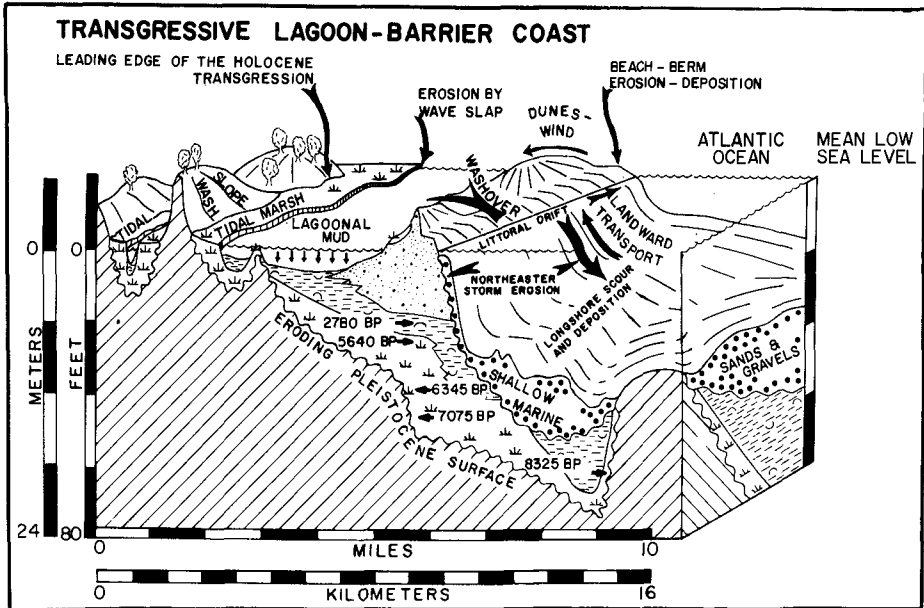

Figure 6. A schematic block diagram illustrating coastal sedimentary facies of the Delaware coastal zone (Kraft and John, 1976).

transgression of the coastal zone indicate that the vertical stratigraphic sequences of sediments seen in cores are equivalent to the lateral surficial sedimentary lithosomes undergoing land transgression (Figure 6). Essentially, this is an excellent illustration of Johannes Walther's Law of Correlation of Sedimentary Facies. In the vertical sequence, barrier sands overlie lagoonal muds and sands overlying a sequence of marsh fringe muds which unconformably overly the pre-Holocene sediments undergoing transgression.

The subsurface structure of this coastal barrier has been clearly delineated with the aid of a large number of drill cores taken along the length of the barrier, in the lagoon, and in the nearshore marine area (Figures 7 and 8). Cross sections of the four geomorphic variations of Delaware's Atlantic coastal barrier, described earlier in this paper, are shown in Figure 7. The Cape Henlopen spit (Fig. 7-A) is advancing rapidly (about 10 m/year averaged over the past 150 years) in a northwest direction into deep waters (20 m) at the junction of Delaware Bay and the Atlantic Ocean, as a result of deposition of sediment moving by littoral transport from the south. Erosion of the coastal barrier and pre-Holocene highlands such as at Rehoboth Beach

Figure 7. Schematic cross-sections of geomorphic variants of Delaware's Atlantic coastal zone. See Figure 2 for lines of cross-section (modified from John, 1977).

provide sediment to the littoral transport system. Erosion of the Atlantic coast of Cape Henlopen has been relatively constant, averaging approximately 3 m/yr. over the past two centuries (Moody, 1964; U. S. Army Corps of Engineers, 1968). Rates of advance of the spit tip, however, increased steadily from 5 m/yr (in the 18th century) to 30 m/yr (at present) (Maurmeyer, 1974). At present, the Cape Henlopen spit is in the form of a simple linear spit with narrow recurves at its tip and is tending to arc from the north and west around a breakwater built early in the 19th century. Formerly, this spit had the form of a cusped foreland and recurved spit over the past 300 to 2,000 years (Kraft and others, 1978). Ebb tide currents winnow out sand from the spit tip and deposit it on an offshore shoal (Hen and Chickens Shoal) lying to the east and extending southeast of the spit tip into the Atlantic Ocean. The thickness of the spit sands and gravels is 18 m and they overlie shallow marine-estuarine sediments.

Pre-Holocene highlands such as at Rehoboth Beach (Figure 7-B) are encountered at various positions in the landward marine transgression across a pre-Holocene drainage system which includes the large drowned river estuary, Delaware Bay, of the ancient Delaware River of more than 14,000 years before present. The barrier here is in the form of a narrow beach with the beach sediments directly overlying pre-Holocene sediments. The beach in this case is so narrow that it could be completely destroyed by large waves resulting from high intensity storms. However, after such storms abate the thin beach is built back again but this time a little farther landward than its position before the storm.

The internal structure of the linear barrier (Figure 7-C) shows a number of back-barrier marshes in the internal composition of the barrier. These sediments represent the back-barrier marsh positions during the past 3000 years, when the barrier was farther east (seaward) of its present position. As shown in Figure 7-C the barrier sediments extend laterally to about 2.5 km into the Rehoboth Bay lagoon and interfinger with the lagoonal muds and sands and overlie them. In this section of the Atlantic coastal barrier the thickness of the barrier including the dunes and the back-barrier marsh sequences within the barrier is about 10 m.

In some areas along the Atlantic coastal barrier, tidal inlets cut across the barrier and form ebb and flood tidal deltas. Tidal inlets are known to have migrated along the barrier in historic times. Figure 7-D shows the barrier associated with the Indian River inlet which is now stabilized by a rock jetty. The barrier sands in inlet areas, including dunes, are 12 m thick and thin out laterally where they interfinger with the tidal delta and lagoonal sediments. In this case the sub-lagoonal barrier and flood tidal delta extend to about 4 km into the Indian River Bay lagoon (Figure 7-D). In all the four cases illustrated (Figure 7) the

barrier sands unconformably lie against nearshore marine sands on the ocean side.

The present transgression is overriding a pre-Holocene trellis-patterned drainage system incised up to 70 m below sea-level in the Delaware coastal area. As the Holocene transgression continued landward across the Atlantic continental shelf, accompanied by sea level rise, the trellis drainage system was inundated by tidal waters. This led to the highly irregular surface of inundation being filled with sediments of various coastal environments. Lagoonal and marsh sediments were deposited along the axes of the stream valleys. Subsurface studies in the Delaware estuary and in the area of Delaware's Atlantic coast suggest that tidal intrusion commenced approximately 12,000 years before present (Kraft and others, 1976).

A cross section parallel to the Atlantic coastal barrier of Delaware is shown in Figure 8. The nature of the tributary valleys incised in the pre-Holocene surface and the in-fill of lagoonal, salt marsh, and shallow marine-estuarine sediments can be seen in this cross section (Figure 8). It is apparent from this cross section (Figure 8) that the thickest sections of Holocene sediments are found infilling the ancestral stream valleys. Hence, in such areas, the chances of preservation of barrier sediments in the geologic record are much better than at other areas along the barrier.

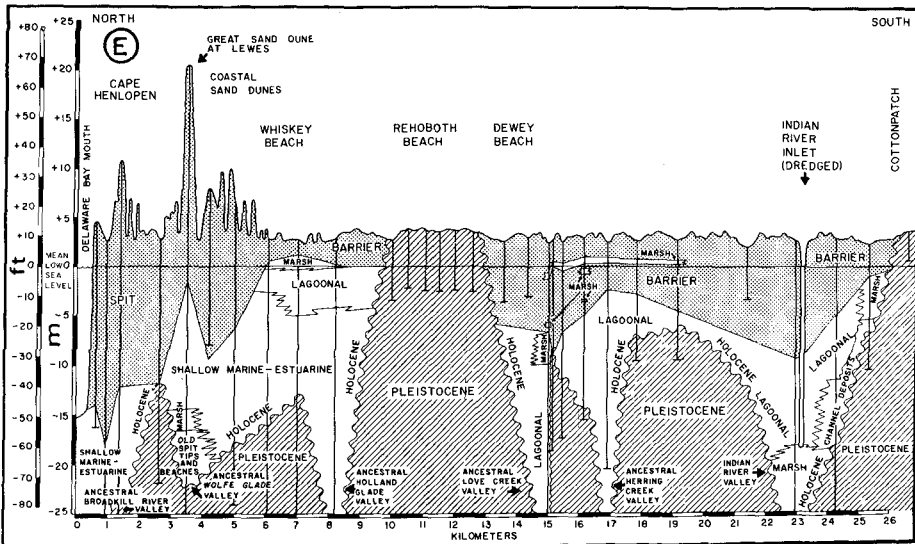

Figure 8. A longitudinal section of Delaware's coastal zone parallel to the shoreline (John, 1977). Holocene coastal sedimentary facies are shown relative to the incised pre-Holocene stream valley topography.

CONCLUSIONS

Based on analysis of the long-term stratigraphic record (past 10,000 years), historic rates of erosion and accretion, and present coastal processes, the nature of coastal change along the Delaware Atlantic Coast may be precisely defined. Thus it should be possible to make logical projections of change in the coastal environments in the short-term future. An understanding of the short- and long-term geological processes in the coastal zone should allow prediction of the impact of engineering structures on the nearshore marine and coastal areas, so that rational plans for the development of the coastal zone can be made.

CHAPTER 72

A New Method for the Representation of Sedimentary Sequences in Coastal Regions

Hansjörg Streif*

1. Introduction

Coastal lowlands usually consist of a body of unconsolidated sediments of up to 30 m thickness which have been deposited under the influence of a rising sea level during the past 10,000 years. These lowlands increasingly are acquiring importance for industrial plants, harbour construction, pipelines, and for the exploration of mineral resources. Consequently a basis for planning is required which will permit an economic exploitation of the coastal zone.

Geological mapping at scale of 1 : 25 000, which has been going on in Germany for more than 100 years, is of fundamental importance for this. Especially the newest type of geologic maps - the sequence map - offers the possibility of classifying and representing (BARCKHAUSEN, PREUSS & STREIF 1977) the coastal deposits in a way that is well suited for technical and scientific purposes.

Its range of application covers tidal flat areas, marshes and coastal bogs, as they occur for example in the coastal zone of the southern North Sea. Combined with a documentation system of the field data and the techniques of automatic data processing this type of map offers new aspects which by far exceed the possibilities of conventional geological mapping.

*Hansjörg Streif, Niedersächsisches Landesamt für Bodenforschung, Stilleweg 2, D 3000 Hannover 51, Federal Republic of Germany.

2. The system of classification and representation

Conventional geological maps - so called surface maps - represent the geographical distribution of individual layers within 2 m of the surface. The sequence map in contrast offers the possibility of representing the spatial extension of complete sedimentary sequences - so called profile types (DE JONG & HAGEMANN 1960, HAGEMAN 1963) - in the body of coastal deposits. This gives the sequence map a three-dimensional character.

A hierarchic system of lithological classification has been developed, based on the vertical succession and the lateral interfingering of clastic sediments on the one hand and peat on the other hand. Three different hierarchic levels can be distinguished in the new system of classification (BARCKHAUSEN, PREUSS & STREIF 1977). Complexes (with 3 profile types), sequences (with 12 subordinate profile types), and facies units (with a variable number of special profile types).

This lithological system has to be linked with a chronostratigraphic system based on radiocarbon ages (BARCKHAUSEN, PREUSS & STREIF, 1978: Fig 4.). As the time interval represented by a specific sedimentary layer or peat horizon varies from place to place, the lithological classification system on the one hand and the chronostratigraphical system on the other hand, must be regarded as two independent methods of subdividing the Holocene. A clarification of the coastal development in terms of time and space, i.e. in a paleogeographic sense, can be done only with a combination of both systems.

2.3. Complexes

In the first level of the hierarchic system the following 3 lithological complexes and 3 profile types have been established (Fig. 1):

- a clastic complex (seaward region)
a body of clastic sediments without intercalated peat layers.

Fig. 1: Schematic cross section through the coastal deposits with the labels for the principal profile types (X_1 , X_2 , X_3 , X_4 , Y_1 , ... etc. Z_4). The sequences are labeled with stratigraphic symbols according to BARCKHAUSEN, LOOK, VINKEN & VOSS (1975). qhK = clastic sequence, qhOB = organic basal sequence, qhOD = organic cover sequence, qhKU = lower clastic sequence, qhA = splitting up sequence, qhKO = upper clastic sequence, qhO = organic sequence, qhKB = clastic basal sequence, qhKE = clastic interbedded sequence, and qhKO = clastic cover sequence.

- Peat may occur, however at the base or on top of the complex. Sediments are dominant in this complex,
- an interfingering complex (transition zone)
a body of coastal deposits in which clastic sediments are intercalated by peat layers. Sedimentary and sedentary deposits are occurring in this complex mutually,
 - a peat complex (back swamp region)
a body of peat and limnic ooze. Thin layers of clastic sediments can either be intercalated in the peat complex or can occur as a single layer at the base or on top of the peat complex. Sedentary organic deposits are dominant in this complex.

These complexes can be represented in sequence maps in the form of principal profile types. Thereby, the clastic complex is labeled as X-profile type, the interfingering complex as Y-type, and the peat complex as Z-type (Fig. 1). Usually the use of the principal profile type without subdivisions is limited to maps at a small scale. A more detailed subdivision of the coastal Holocene deposits can be achieved on the second level of the hierarchic system.

2.2 Sequences

Sequences are units of lithological classification which rank in the middle of the hierarchy. They are subdivisions of the above mentioned complexes and consist of one or more facies units. Some interrelations-hips between organic and clastic deposits can be deduced from the vertical succession and the lateral interfingering of the sequences. The variety of possible interrelations is represented in Fig. 1 in form of a schematic section. The vertical lines indicate the boundaries between the above mentioned complexes. The sequences, which are defined in the following, are looked upon as stratigraphical elements and therefore are labeled with stratigraphic symbols (Fig. 2) according to "Symbolschlüssel Geologie" (Symbol Key Geology, BARCKHAUSEN, LOOK, VINKEN & VOSS 1975).

Fig. 2 Example of a data form for field data capture.

The necessary characteristics of the bore hole are given in a fixed format. The strata description is recorded in a free format, and its various elements (depth, stratigraphy, petrography etc.) are separated from each other by a slash. The symbols of the sequences (qhK0, qhA, qhKU, and qhOB) are given in the column stratigraphy, the profile type (Y2) is given in the lowermost layer of coastal Holocene.

- clastic sequence (qhK): clastic sedimentary succession without intercalation of peat layers. Soil horizons and layers in which rootlets of phragmites are abundant are regarded as a part of the clastic sequence;
- organic basal sequence (qhOB): succession of peat and limnic ooze or organic soil horizons at the base of clastic Holocene deposits;
- organic cover sequence (qhOD): succession of peat or limnic ooze which occurs at the present surface and which is underlain by clastic Holocene sediments.

The organic basal sequence and the organic cover sequence can occur in the clastic complex as well as in the interfingering complex, but which may also be absent. The following elements are found only in the interfingering complex and are characteristic of it:

- lower clastic sequence (qhKU): clastic sedimentary unit at least 5 cm thick, which underlies the lowermost intercalated peat layer and may be underlain by an organic basal sequence;
- splitting up sequence (qhA) sedimentary succession between the bottom of the lowermost intercalated peat layer and the top of the uppermost one. Thus, the splitting up sequence consists of peat layers (in a special case only layer) as well as clastic sediments which lie between the intercalated peat layers;
- upper clastic sequence (qhK0) clastic sedimentary unit at least 5 cm thick which overlies the uppermost intercalated peat and may be overlain by an organic cover sequence.

The following sequences are found in the peat complex and are characteristic of it:

- organic sequence (qh0) succession of peat and limnic ooze with at most one interbedded layer of clastic sediments more 5 cm thick;

- clastic basal sequence (qhKB) clastic sedimentary unit which occurs in the basal part of the coastal Holocene deposits and which is covered by an organic sequence. The thickness of the basal clastic sequence is less than of the covering organic sequence;
- clastic interbedded sequence (qhKE) unit of clastic sediments which is interbedded in the organic sequence unrelated to an upper or lower clastic sequence as defined above or to clastic units of a splitting up sequence. This clastic interbedded sequence may not exceed 50 % of the total thickness of the organic sequence. The qhKE may consist of one individual layer and/or of several thin layers, less than 5 cm thick;
- clastic cover sequence (qhKD) clastic sedimentary unit which occurs at the present surface and which is underlain by the organic sequence. The thickness of the clastic cover sequence must be less than that of the underlying organic sequence.

There are 12 possible arrangements of these sequences as defined above. These possibilities define the 12 subordinate profile types and are labeled (Fig. 2) as X1, X2, X3, X4, Y1, ..., etc. (BARCKHAUSEN, PREUSS & STREIF 1977).

Any bore hole in the coastal zone can be immediately ascribed to one of the 3 main profile types and one of the 12 subordinate profile types in the course of the field data capture or during an evaluation of archive material (Fig. 2). If a bore hole does not penetrate the Holocene deposits, hence incomplete profile types are following. This is indicated by adding an "u" to the label. The following incomplete subordinate types are possible: X1u, X3u, Y1u, Y3u, Z1u, Z2u, and Z3u.

2.3. Facies units

A more detailed subdivision of the sedimentary units can be achieved within the lowest hierarchic level of the system. The above-defined sequences often consist of several facies units; special profile types must then be defined for these cases. In contrast to the first and second levels, with their well-defined elements and their established number of profile types, the lowest level of the system is a variable one.

The facies units are variable in number and in range, so that petrographic, genetic, structural, and other criteria can be taken into account and represented in an unlimited number of special profile types. Thus, the facies units and the special profile types have to be selected or defined individually with respect to the specific objectives and the prevailing local conditions. Besides geological findings, special technical or economic factors can be evaluated and represented in these maps. For instance, the spatial extension of:

- sediments susceptible to compaction and therefore unsuitable for building foundation;
- deposits of special consistency, for which specific excavating and dredging methods are necessary;
- sedimentary units that contain raw material of economic interest such as sand, gravel or mineral deposits.

These examples of possible utilisation of this classification the system might be greatly enlarged. Consequently the lithological subdivision of the coastal deposits combined with the representation of profile types offers totally new aspects which by far exceed the possibility of conventional mapping.

3. Practical application

During the course of field data capture it is nearly impossible to foresee all the aspects which might be of technical or scientific interest. However, most of the information necessary for any application can easily be recovered from the pool of geological

basic data by a systematic evaluation. A selection can be made from an immense amount of basic data within a very short time by computer methods.

A close link between the above-mentioned classification system for coastal deposits on the one hand and data bank management systems on the other hand has been achieved in the following way: All basic data are collected on special data forms (Fig.2) during the field data capture. All information, such as depth, stratigraphy, petrography, genesis, colour and additional remarks, is recorded according to a symbol key (BARCKHAUSEN, LOOK, VINKEN & VOSS1975) on this data form. These strata descriptions are then stored on punch cards magnetic tape or disc. All necessary characteristics of the bore hole (such as bore hole number, longitude and latitude, elevation, etc.) are recorded in "fixed format"; description (depth, stratigraphy, petrography, genesis, colour, additional remarks, and samples) are recorded in a "free format". For instance: for the mapping of sheet Emden West, which is situated by the Ems River estuary, about 650 bore holes have been sunk. Altogether about 10,000 m of sedimentary cores have been described and about 25,000 to 30,000 individual layers have been distinguished and sedimentologically characterized.

The documentaion and retrieval system DASCH has been developed to handle such an immense pool of different data (MUNDRY 1975). The strata descriptions which were recorded and stored in a free format can be converted into a fixed format in so-called documentation lists. The various parts of the description such as depth, stratigraphy, petrography etc. are arranged in these lists in defined fields. The most important part of the DASCH system, however, is retrieval. A selection of specific data can be retrieved from the mass of basic data. This is done by a sequential search of all of the basic data. Those basic data that correspond to a retrieval query can then be printed out or stored on magnetic tape or disc for further processing. For practical use it is very important that the structure of the

query is the same as the structure of the strata description. Thus, the DASCH system can be easily used by field geologists or technicians who are directly involved with the specific problems. Other data processing programs have been developed, especially for the production of geologic maps, profile and cross sections (MUNDRY 1975, BARCKHAUSEN 1973). At present we are able to produce starting the following constructions from the basic data:

- individual profiles, cross sections and profile maps;
- isoline maps (contourlines, isopach plans and geological boundaries constructions);
- signature maps, bore hole symbol maps;
- sequence maps or profile type maps.

These all have two objectives. One is the graphic representation for a general overview. Second, they serve as a base for specialized evaluations, whereby much troublesome and lengthy manual work is avoided.

The first sheet of this new type of geological map, the sequence map sheet Emden West 1 : 25,000, has been published (BARCKHAUSEN & STREIF 1978). Two further sheets, Wilhelmshaven and Emden are in preparation. The advantages of the new map are quite obvious. The system is more flexible and its utilization is easily manageable. Furthermore it offers the possibility of representing the whole sequence of sedimentary deposits in the coastal zone. Consequently, this new type of maps covers scientific and practical requirements much better than conventional geological maps and is of better use for planning purposes. Combined with data bank management systems, the sequence map offers totally new aspects for geological mapping in coastal areas. This concerns the production of the maps as well as their practical evaluation. As the system of the sequence map can be applied to nearly all coastal lowlands, it may be regarded as an important part of the technical and scientific know how of coastal engineering.

CHAPTER 73

COASTAL PROCESSES AT OREGON INLET, NORTH CAROLINA

James T. Jarrett*, M.ASCE

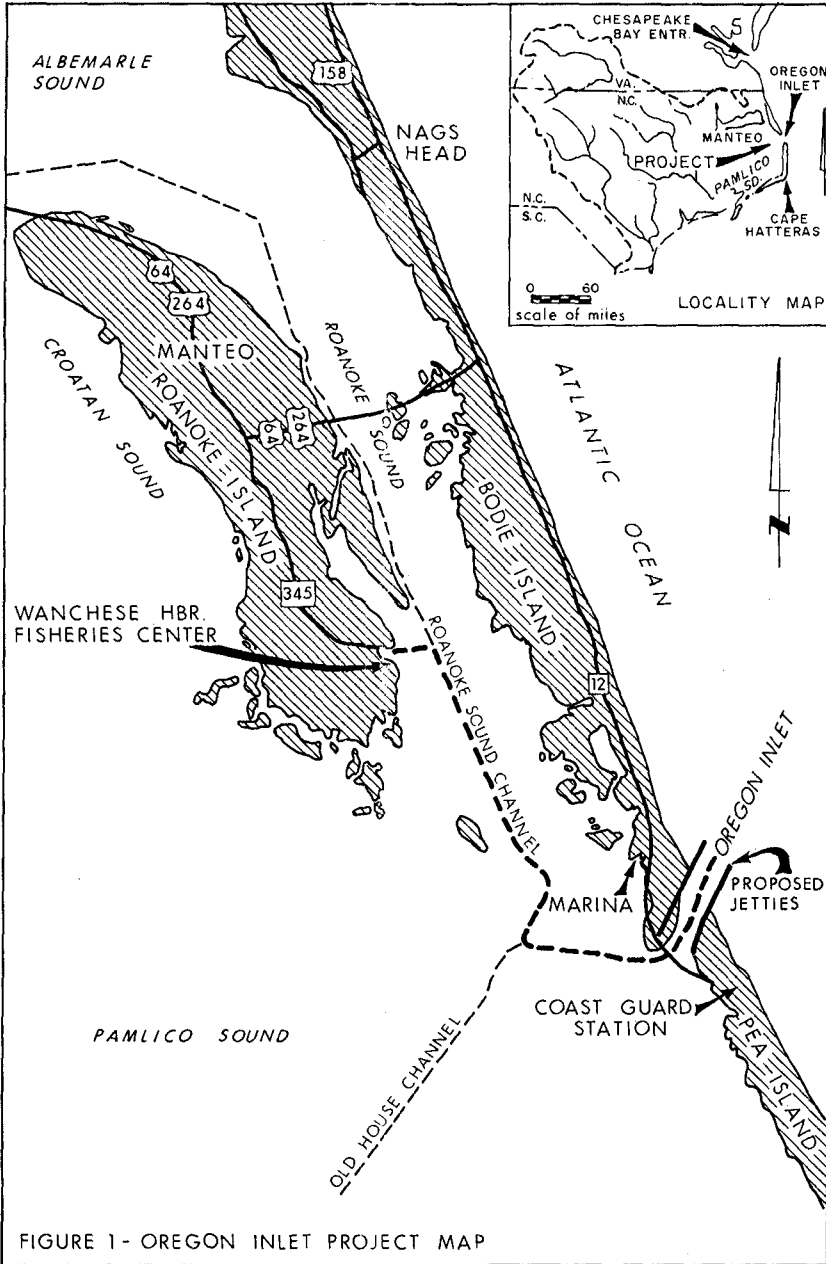

INTRODUCTION

Coastal processes in the vicinity of Oregon Inlet, North Carolina were studied in connection with the design of a dual jetty system for that inlet. Oregon Inlet is the northernmost breach through the "Outer Banks" of North Carolina and is situated approximately 40 miles (64 km) north of Cape Hatteras and 90 miles (145 km) south of the ocean entrance to Chesapeake Bay, see Fig. 1. The improvements planned for this inlet are part of an overall plan of development directed at enhancing the fisheries industry of North Carolina through the provision of a modern fisheries center at the village of Wanchese, located on Roanoke Island, see Fig. 1. The general layout of the proposed jetty system is shown on Fig. 2. Certain aspects of this design will be referred to later in this paper.

In addition to their structural and functional aspects, a major part of the design of the jetties concerns the structure-shore interaction and means whereby adverse shore processes will be prevented in operating the project. Obviously, the construction of jetties or any other type of littoral barrier at an inlet would disrupt the normal movement of and processes associated with longshore sediment transport. Therefore, artificial means of moving littoral materials around a stabilized inlet must be employed to assure that the adjacent beaches are maintained in at least the same state existing prior to any navigation related improvements. The need for a reliable sand bypassing method at Oregon Inlet is accentuated by the fact that the inlet is bounded on the north by the Cape Hatteras National Seashore and on the south by the Pea Island Wildlife Refuge, both of which are Federally owned beach areas managed for the purpose of preserving the natural quality of the Outer Banks environment.

The design of a sand bypassing system must be based on a knowledge of the existing shore and inlet processes, particularly as they relate to the rate and directional distribution of longshore sediment transport. When the existing conditions are known, it is possible to estimate the sediment transport rates with the structures in place and, thus, predict the amount and direction in which material will have to be bypassed. This paper describes the approach taken to evaluate the existing and future longshore sediment transport in the vicinity of Oregon Inlet and briefly discusses the proposed bypassing system for the stabilized inlet.

*Project Engineer, Coastal Engineering Studies Section, U.S. Army Engineer District, Wilmington, N.C.

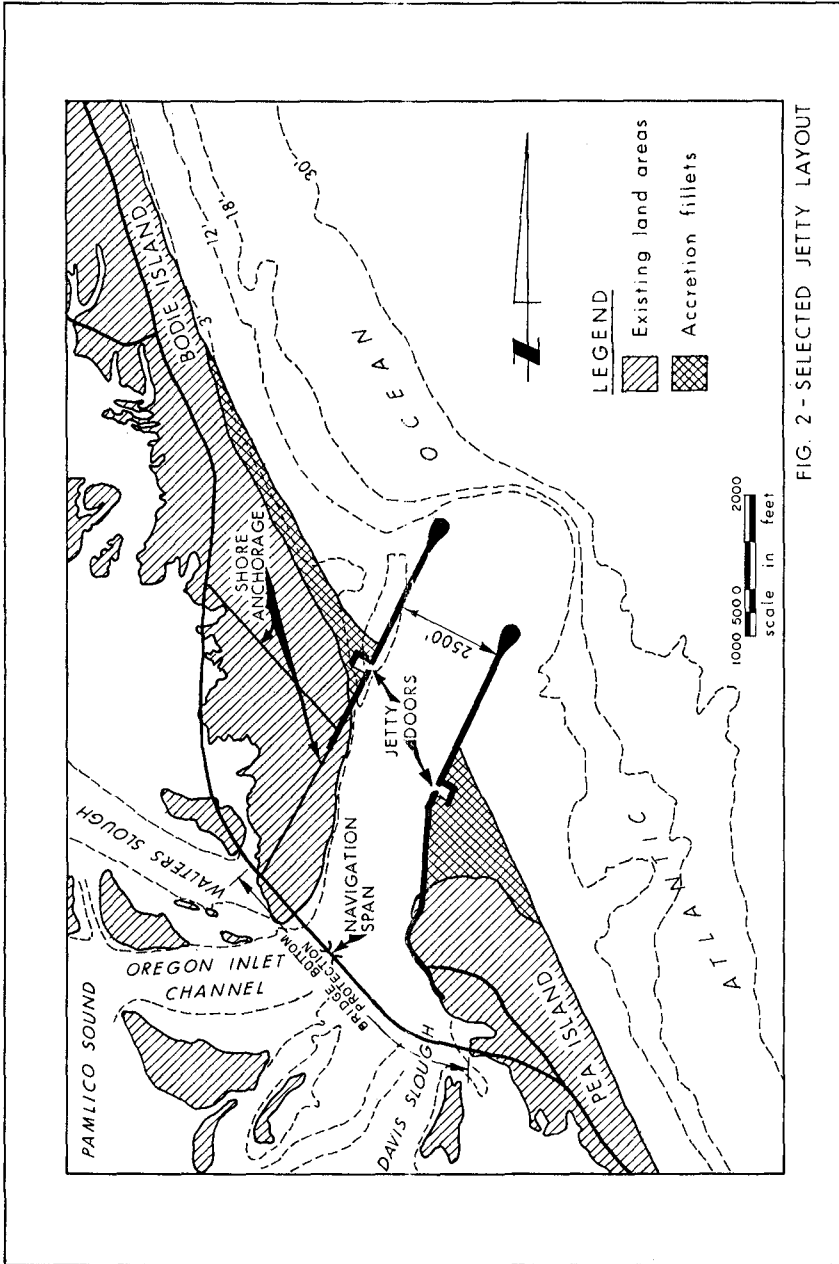

FIG. 2 - SELECTED JETTY LAYOUT

EXISTING LONGSHORE SEDIMENT TRANSPORT RATES

The estimate of the existing rate and directional distribution of longshore sediment transport in the vicinity of Oregon Inlet was accomplished through a sediment budget analysis which involved (1) an estimate of volumetric changes from the beaches and in the inlet for a selected time period, (2) wave refraction analysis to determine the variation of longshore energy flux along the shorelines north and south of the inlet, and (3) an estimate of the transport quantities by correlating the beach and inlet volume changes with the computed longshore energy flux distribution. The time period chosen for this analysis extended from 1965 to 1975, primarily because relatively accurate wave data was available for this period.

Beach Changes.

Changes in the shoreline position for the beaches adjacent to Oregon Inlet were determined from nearshore beach profiles surveyed in 1937 and 1964 and from a comparison of 13 sets of aerial photographs made between 1940 and 1975. As a result of these shoreline comparisons, the study area was divided into six segments or littoral cells, as shown on Fig. 3, based, in part, on the behavior of the beaches during the analysis period and on the relative orientation of the shoreline cells. Also indicated on Fig. 3 are the shoreline changes for the 1965-1975 period selected for the sediment budget analysis.

Fig. 3 - Shoreline Segments (or Littoral cells) and 1965-1975 Shoreline Changes

In order to perform the sediment budget analysis, the linear shoreline movements were converted to volumetric changes. This was accomplished by assuming that the entire active profile, i.e., that portion of the nearshore area influenced by wave action, moves at the same rate as the shoreline. In making this assumption, the beach volume changes were directly related to the total vertical distance of the active profile measured from the crest of the berm to some limiting depth. The identification of the limiting depth is difficult without comparative surveys; however, a reasonable estimate of this depth appears to be the deepest depth contour that maintains parallelism with the shoreline. In the case of the immediate study area, outside the influence of tidal currents flowing through Oregon Inlet, the -30 foot (-9.1 m) mean low water (MLW) depth contour satisfied this criterion. The crest elevation of the berm is about +8 feet (+2.4 m) MLW, thus the total vertical distance of the active profile was taken as 38 feet (11.5 m). This resulted in a volumetric equivalent factor (C) of 1.41 cu.yds/lin. ft. of shoreline/foot of erosion or accretion of the shoreline (11.5 m³/m shoreline/m of shoreline change). The equivalent volumetric changes obtained by applying this factor to the 1965-1975 shoreline movements within each segment are given in table 1. Note that no volume changes are given for Segment IV since changes in this segment are included in the estimated volume changes for Oregon Inlet.

TABLE 1
Beach Volumetric Changes, 1965-1975

Segment	Length of Segment		Estimated Total Volume Change ^{1/}		Offshore Losses Due to Rising Sea Level	
	(ft)	(m)	(cy/yr)	(m ³ /yr)	(cy/yr)	(m ³ /yr)
I	15,000	(4,572)	+155,000	(+118,513)	21,000	(16,057)
II	18,000	(5,486)	-188,000	(-143,745)	25,000	(19,115)
III	12,000	(3,658)	+ 10,000	(+ 7,646)	17,000	(12,998)
IV	Volume change included in Oregon Inlet					
V	10,000	(3,048)	-264,000	(-201,854)	14,000	(10,704)
VI	22,000	(6,706)	-127,000	(- 97,104)	31,000	(23,703)

^{1/} + = accretion, - = erosion

The total volume changes given in table 1 include the affects of longshore movements of material and additions or losses associated with material moving normal to the beach such as the amount of sediment transported bayward when the beach is overtopped or onshore-offshore movements by wave activity. During the 1965-1975 analysis period, no overtopping of any consequence occurred along the study area. However, there was undoubtedly some losses offshore. Offshore losses from the littoral cells were estimated by a procedure developed by Bruun (1) in which shoreline erosion is related to sea level rise. These losses are also given in table 1.

Inlet Changes.

The recent history of Oregon Inlet dates from 1846 when the present-day inlet was opened by a hurricane. Prior to 1846 New Inlet, which was located 8 miles (12.9 km) south of Oregon Inlet (see Fig. 3),

was the only inlet through the North Carolina Outer Banks north of Cape Hatteras. Since its opening, Oregon Inlet has migrated an average distance of 10,000 feet (3,050 m) to the south as indicated by the superposition plots of the inlet shoreline positions shown on Fig. 4. This southward migration of the inlet has been accompanied by alternate widening and narrowing of the inlet in response to varying weather patterns. For example, between 1953 and 1962, the Oregon Inlet area experienced one of the most active storm periods of record. Included during this period was the Ash Wednesday Storm of March 1962 which caused considerable damage along the northeastern coast of the United States. As a result of these storms, Oregon Inlet, which has a normal width of about 2,100 feet (640 m), had attained a width of 7,150 feet (2,180 m) following the March 1962 storm. Since 1962, no severe storms have affected the Oregon Inlet area; consequently, the north shoulder of the inlet migrated rather rapidly to the south in the form of an elongated spit as shown by the 1975 shoreline in Fig. 4.

Changes in the volume of material in Oregon Inlet associated with its migratory history were determined from hydrographic surveys made in 1937, 1962, and 1975, and from dredging records associated with the construction and maintenance of the interior bay channels and the ocean bar channel.

Between 1937 and 1962, the ocean bar at Oregon Inlet lost a total of 3,343,000 cubic yards (2,556,000 m³) of material. Since the March 1962 storm occurred just prior to the 1962 survey, it appears that the comparison of the 1937 and 1962 ocean bars reflect more on the losses resulting from the 1962 storm than on the general trend prior to this storm. For example, during the latest time period, 1962-1975, which has been relatively storm-free, the ocean bar has accumulated a gross amount of 2,835,000 cubic yards (2,168,000 m³). This represents an annual accumulation rate of about 218,000 cubic yards/yr (167,000 m³/yr). In addition to the buildup of material on the ocean bar between 1962 and 1975, the volume rate of accumulation associated with the development of the north spit following the Ash Wednesday storm amounted to 452,000 cu.yds./year (345,000 m³/yr). Thus, the total volume rate of change on the ocean bar and north spit between 1962 and 1975 was 670,000 cu.yds/yr (512,000 m³/yr).

With respect to volumetric changes in the bay area, the 1937 survey showed that the main channel connecting Oregon Inlet and Roanoke Sound passed through Walters Slough, see Fig. 1. As Oregon Inlet migrated southward, Walters Slough shoaled to such an extent that it had to be abandoned and a new channel excavated to connect Oregon Inlet with Old House Channel. This new channel, designated as the Oregon Inlet Channel, was dredged in 1960 and followed essentially the same alignment as exists today. As was evident from the comparison of the hydrographic surveys and aerial photographs of the inlet, most of the volume changes in the bay associated with the migration of Oregon Inlet actually occurred prior to 1965. Since 1965, very little net change has taken place in the bay with the average accumulation estimated to be only 20,000 cu.yds/yr (15,000 m³/yr).

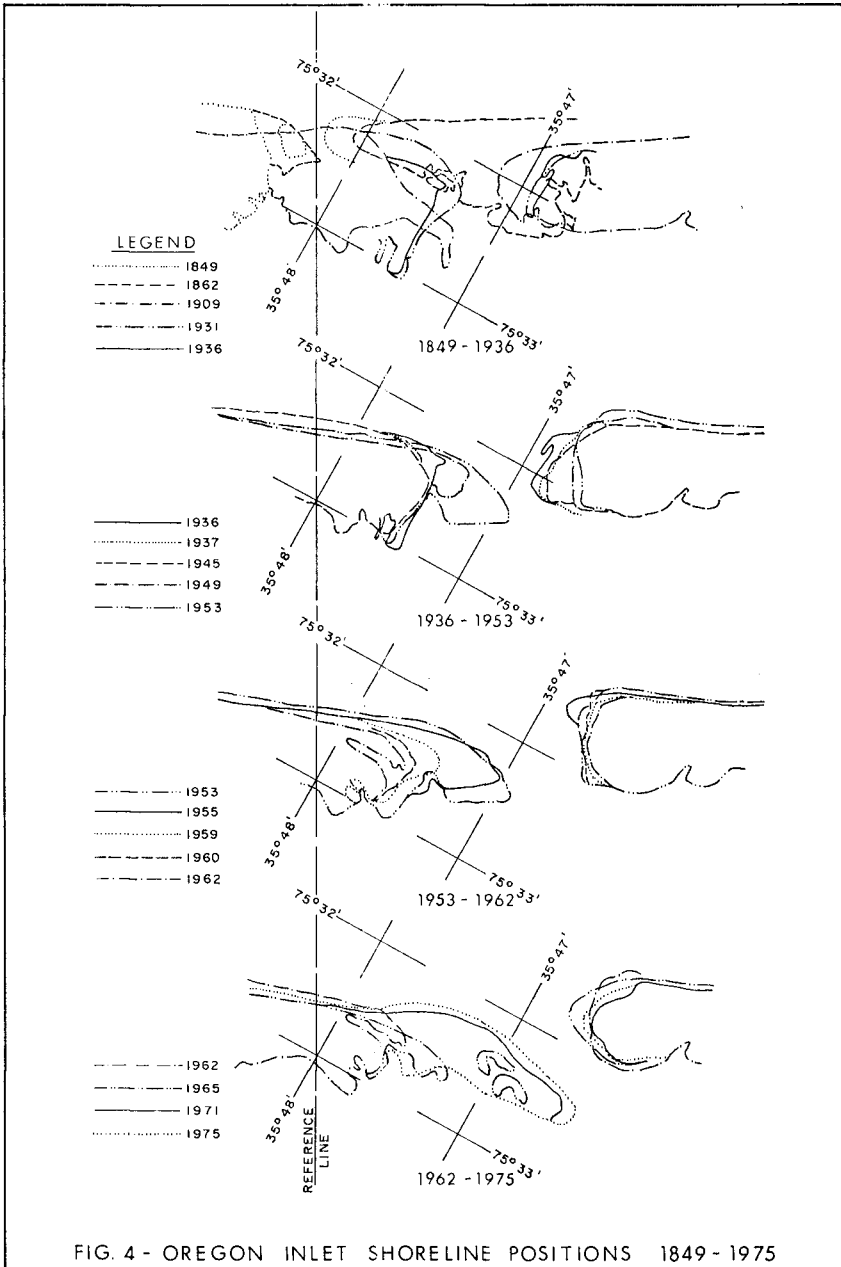

FIG. 4 - OREGON INLET SHORELINE POSITIONS 1849 - 1975

Based on these observed volume changes in Oregon Inlet, a volume rate of accumulation of 690,000 cu.yds/yr. (527,000 m³/yr) was assumed to be representative of the volume changes in Oregon Inlet during the 1965 to 1975 period selected for the sediment budget analysis.

Wave Refraction-Longshore Energy Flux Analysis. The amount of material that moves parallel to the shoreline is directly related to the longshore component of wave energy flux in the surf zone. The computation of longshore energy flux at a particular site requires information on (a) the wave climate at the site, and (b) the effects of wave refraction on the distribution of the longshore energy flux along the shoreline as waves propagate toward shore from deep water.

Wave Climate. The wave characteristics used for this analysis were obtained from a Coastal Engineering Research Center (CERC) wave gage, located on an ocean fishing pier 9 miles (14.5 km) north of Oregon Inlet, see Fig. 3. A summary of the observed waves for the period July 1964 to April 1976 is given in table 2. The wave characteristics measured by this gage represent essentially 100 percent of all the waves (and, consequently, the wave energy flux) reaching the study area at the gage site. However, since the gaged data is non-directional, it was impossible to determine differences in the wave height-period distribution for the various directions of wave approach. Therefore, the same relative height-period distribution was used for all wave directions.

With the gaged wave data representing 100 percent of the wave energy flux from all possible directions at the gage location, this total energy flux was proportioned to the various directions of wave approach based on visual wave observations made by U.S. Coast Guard personnel at the Diamond Shoals (Cape Hatteras) and Chesapeake Bay light towers. The relative directional distribution of the wave energy applicable to the study is tabulated in table 3.

Longshore Energy Flux (P_{1s}). The method used to compute the distribution of longshore energy flux along a given reach of shoreline has been given previously in reference (2) and will not be repeated here. In essence, the computational procedure requires the refraction of a large number of wave rays toward the study area. In this analysis, 101 wave rays were refracted toward shore for each combination of wave period and direction applicable to the study area, resulting in the generation of 7,272 wave rays. For each wave ray pair, the value of the longshore energy flux was computed at the breaking point of eleven wave heights ranging from 0.5 ft. (.15 m) to 11 ft. (3.35 m). The results of each individual longshore energy flux computation for all combinations of wave height, period, and direction was interpolated at specific intervals along the coast and summed to yield the total downcoast and upcoast distributions of longshore energy flux. The resulting longshore energy flux distribution is shown on Fig. 5.

Computation of Littoral Transport Rates. The relationship between longshore sediment transport and longshore energy flux has the form:

$$\begin{aligned}
 Q_s &= \beta P_{1s} \text{ where:} & (1) \\
 Q_s &= \text{the volume of sediment transported per year} \\
 \beta &= \text{constant} \\
 P_{1s} &= \text{annual longshore component of wave energy flux.}
 \end{aligned}$$

FIG. 5 - LONGSHORE ENERGY FLUX DISTRIBUTION

Although values of β have been proposed based on field and laboratory measurements, in this analysis, β is assumed to be unknown. Also, since the longshore energy flux analysis is not applicable to the immediate area of the inlet, due to the complex bottom and tidal current-wave interactions, two unknowns in addition to β are introduced into the sediment budget analysis to represent the amount of natural bypassing of sediment across the inlet in the downcoast (SB) and upcoast (NB) directions. Thus, with three unknowns, three conditions must be established to solve for these values. This was accomplished by balancing the sediment budget between the inlet cell and the two littoral cells immediately adjacent to the inlet as shown schematically on Fig. 6. It is remarked that the relative longshore transport values expressed as $(P_{1S})\beta$ in Fig. 6 were determined from the results of the longshore energy flux computations at the boundaries of the littoral cells. The solution of the sediment budget for the condition shown in Fig. 6 resulted in a value of β of 6,018 for sediment transport expressed in cu.yds/yr. This gave computed natural bypassing quantities of 1,232,000 cu.yds/yr (942,000 m³/yr) to the south (SB) and 133,000 cu.yds/yr (102,000 m³/yr) to the north (NB).

With the value of β determined, the sediment budgets of the other shoreline segments (or littoral cells) was computed. However, in order to balance the amount of sediment moving into and out of each cell, the assumption was made that the estimated volume rates of change within each cell are absolute and that any adjustments required to obtain a complete sediment balance would be made in the computed values of the longshore energy flux at the cell boundaries. For the most part, the amount of adjustment required to obtain a sediment balance was less than 12 percent. The adjusted values of P_{1S} required to balance the sediment budget for all littoral cells are indicated on Fig. 5, whereas the final results of the longshore transport analysis for the 1965 to 1975 time period is summarized schematically on Fig. 7.

SHORELINE ADJUSTMENTS AND LONGSHORE TRANSPORT RATES FOLLOWING JETTY CONSTRUCTION

Changes in the shoreline configuration and sediment transport rates adjacent to the proposed jetties at Oregon Inlet were estimated based on the assumption that sediment transport would vary in direction proportion to changes in the breaker angle ($\Delta\alpha_b$) relative to the pre-jetty shoreline. If α_b is the average breaker angle relative to the pre-jetty shoreline associated with a longshore transport rate Q_s , then the transport rate along a shoreline reach having an average breaker angle of $(\alpha_b + \Delta\alpha_b)$ would be:

$$Q_{Sn} = \psi_n Q_s \quad (2)$$

where:

Q_{Sn} = transport rate along reach n

$$\psi_n = \frac{\sin 2(\alpha_b + \Delta\alpha_{bn})}{\sin 2\alpha_n}$$

$\Delta\alpha_{bn}$ = change in average breaker angle within reach n.

FIG. 6 - SCHEMATIC OF SEDIMENT BUDGET ANALYSIS (1965 - 1975)

FIG. 7 - SUMMARY OF SEDIMENT TRANSPORT ANALYSIS (1965 - 1975)

In setting up the procedure to compute the shoreline adjustments adjacent to the jetties, the shoreline was divided into reaches of various lengths (L_n) as shown on the definition sketch in Fig. 8, where L_n does not have to be the same for each reach. The midpoint of reach n, measured from the intersection of the pre-jetty shoreline with the jetty, is designated as X_n .

Fig. 8 - Definition Sketch for Shoreline Adjustment Computations

If the volume of material in a reach changes by an amount ΔVOL , during some time interval Δt , then the average seaward or landward movement of the reach, measured at its midpoint, would be:

$$\Delta Y_n = \frac{\Delta VOL}{L_n C} \quad (3)$$

where:

ΔY_n = average movement of reach n occurring during a time interval Δt

L_n = length of reach n

C = volumetric equivalent factor relating volume changes to linear movements (see previous discussion)

$$\Delta VOL = (Q_{sn} - Q_{sn-1})t \Delta t$$

$(Q_{sn} - Q_{sn-1})t$ = difference in the volume rate of longshore transport at the downdrift and updrift boundaries of the reach at time step t.

Δt = time interval between shoreline position computations

At the end of some time period t, the midpoint of reach n would have moved through a total distance Y_n measured from the pre-jetty shoreline. If the rate of longshore transport varies from reach to reach, then the amount of movement of the various reaches would not be the same. This would result in a change of shoreline orientation between the reaches relative to the original shoreline by an angle given by:

$$\Delta\theta_n = \tan^{-1} \left(\frac{Y_{n-1} - Y_n}{X_{n-1} - X_n} \right) \quad (4)$$

Therefore, for the simplified case in which the effects of changes in wave refraction are ignored, the breaker angle in reach n at time t would be:

$$(\alpha_{bn})_t = \alpha_b + \Delta\theta_n \quad (5)$$

and the associated longshore transport within this reach during time step t would be computed as:

$$(Q_{sn})_t = Q_s \left(\frac{\sin 2(\alpha_b + \Delta\theta_n)}{\sin 2\alpha_b} \right) \quad (6)$$

Equation (6) is valid as long as wave angles, relative to the bottom contours are small and the waves are not diffracted by the structure. However, if diffraction does occur, the angle at which the diffracted wave would break relative to the original shoreline (designated as α_b') would differ from the average breaker angle associated with Q_s . Furthermore, the height of the waves in the diffraction zone would be reduced by the diffraction coefficient K' , which in turn would reduce longshore transport by an amount proportional to $(K')^2$. If the shoreline within the diffraction zone has also undergone an angular change ($\Delta\theta$), then the transport rate in the shadow zone of the structure would be:

$$Q_{sn}' = \psi_n' Q_s \quad (7)$$

where:

$$\begin{aligned} Q_{sn}' &= \text{transport rate in the diffraction zone} \quad (8) \\ \psi_n' &= (K')^2 \left(\frac{\sin 2(\alpha_b' + \Delta\theta)}{\sin 2\alpha_b} \right) \end{aligned}$$

In applying the above procedure to Oregon Inlet, an average breaker angle (α_b) of 12° , determined from the wave refraction analysis, was used for the longshore transport rates along the pre-jetty shoreline in both the north and south directions. North of the inlet, the pre-jetty shoreline transport rates (Q_s) used were 1,377,000 cu.yds/yr (1,053,000 m^3 /yr) to the south and 480,000 cu.yds/yr (367,000 m^3 /yr) to the north, whereas south of the inlet, the pre-jetty shoreline transport rates were 1,259,000 cu.yds/yr (963,000 m^3 /yr) south and 728,000 cu.yds/yr (557,000 m^3 /yr) north. These annual longshore drift rates correspond to the rates computed for Segment V and III, respectively, as shown on Fig. 7.

Since the shoreline adjustments and sediment transport rates adjacent to the jetties are time dependent, realistic results can only be obtained if the time increment (Δt) between shoreline position computations is relatively small. For this analysis, the time increment varied from about 1 to 2 weeks, with the amount and direction of longshore transport occurring during a particular time increment being based on a simulated yearly time distribution of the longshore drift as developed from the wave gage and light tower wave records.

For the shoreline updrift of the north jetty, wave diffraction effects associated with waves approaching from the southern quadrants were estimated by using an average angle of wave incidence relative to the north jetty of 60° . This angle of wave incidence was based on the seaward refraction of a wave having an 8.5-second period (approximately the average period for the study area) and a breaker angle of 12° , out to the head of the proposed north jetty. On the south side of the inlet, wave diffraction would be of minor importance as the average angle of wave approach from the northern quadrants is less than the angle the proposed south jetty makes with the shoreline.

The predicted shoreline changes north and south of Oregon Inlet, following jetty construction, are given on Fig. 9(a) and 9(b), respectively. As noted on these figures, the total shoreline changes include some initial adjustments associated with the redistribution of the ocean bar deposits toward shore once tidal flow over these shoal areas is eliminated. On the north side, a total of 3,600,000 cu.yds. ($2,753,000 \text{ m}^3$) of material was distributed along the shoreline in a shape predicted by the shoreline evolution theory developed by Pelnard-Considere (3). This 3,600,000 cu.yds. ($2,753,000 \text{ m}^3$) of fillet material represents approximately 75 percent of the estimated total volume of material north of the inlet that would be subject to redistribution once the jetties are built. This percentage of the total volume was assumed to move on-shore next to the jetty since approximately 75 percent of the gross drift in this area is to the south. On the south side of the inlet, the initial shoreline adjustment simply involved the projection of the shoreline alignment of Segment III from the existing south shoulder of the inlet to the point of intersection with the south jetty. The volume of material required to straighten this portion of the shoreline would be about 1,200,000 cu.yds. ($918,000 \text{ m}^3$), whereas the total volume of material south of the inlet that may eventually be redistributed is estimated to be in excess of 9,400,000 cu.yds. ($7,187,000 \text{ m}^3$). The time required for these initial adjustments to occur is not known; however, since the construction of the jetties will take 3 to 4 years, most of these initial adjustments will probably take place during this period.

With respect to the deposition of the net southward drift of 897,000 cu.yds/yr ($686,000 \text{ m}^3/\text{yr}$) along the shoreline north of the inlet, the shoreline adjustment computations indicated that approximately 50 percent would be deposited within about 5,500 feet (1,676 m) of the north jetty. The balance of the net drift would be spread over about 14,500 feet (4,422 m) of shore further north. On the south side, most of the 531,000 cu.yds/yr ($406,000 \text{ m}^3/\text{yr}$) deficit would be felt within a 6,500-foot (1,981 m) segment immediately south of the jetty. Obviously, in order to maintain a stable shoreline south of Oregon Inlet, an average of 531,000 cu.yds/yr ($406,000 \text{ m}^3/\text{yr}$) would have to be placed along this beach.

SAND BYPASSING AT OREGON INLET

The bypassing plan being developed for Oregon Inlet will require a cutter-suction pipeline dredge to operate on the accretion fillets immediately adjacent to the jetties. In order to limit the dredge to a minimum amount of wave exposure, special openings or "doors," as shown

FIG. 9(a) - SHORELINE ADJUSTMENT NORTH OF INLET

FIG. 9(b) - SHORELINE ADJUSTMENT SOUTH OF INLET

on Fig. 2, have been designed near the landward ends of both jetties to permit a dredge to cut its way onto the bayside of the fillets. Note that these openings have been included in both jetties to allow for bypassing from either side of the inlet if conditions so dictate. Although most of the material to be bypassed can be removed from the subaerial fillet accumulations, a certain amount will have to be taken from the normally turbulent nearshore zone in order to prevent the movement of material around the seaward end of the jetty. During this nearshore phase of the bypassing operation, a floating breakwater will be positioned seaward of the borrow area in order to increase the production time of the dredge. A schematic representation of the bypassing operation is shown on Fig. 10. As a result of the bypassing operation, a deposition basin will be created in the fillet area adjacent to the jetty, which would serve to entrap littoral materials for subsequent bypassing operations.

In an attempt to determine the feasibility of this bypassing arrangement, at least from the sediment transport aspects, a simulated sediment trap was imposed on the shoreline immediately adjacent to the north jetty as shown on Fig. 11. The size of this trap equaled a two-year bypassing requirement for the south side of the inlet. By applying the shoreline adjustment procedure outlined above, an estimate was made of the shoreline configuration in the vicinity of the sediment trap at the end of three months, one year, and two years following the bypassing operation. These shorelines are also shown on Fig. 11.

On the basis of this analysis, bypassing directly from the fillet appears feasible in that the sediment trap was essentially filled at the end of the two-year period. Just as important, however, was the indication that material would not be transported around the seaward end of the jetty and that a stable beach would be created for a considerable distance updrift. Some verification of the functional aspects of the fillet deposition basin should be available following movable-bed hydraulic model tests which will be conducted in the near future.

CHAPTER 74

MAINTENANCE OF SANTA CRUZ HARBOR, CALIFORNIA, USA

by

Orville T. Magoon¹

Don C. Baer²

ABSTRACT

In planning and operating coastal harbors subjected to shoaling, it is imperative that the characteristics and regime of the sediments which deposit in the harbor entrance be quantified to the maximum extent possible in order that the economic impacts of the channel shoaling and along adjacent shores may be evaluated.

This paper presents a brief progress report on the study of a coastal harbor in an area subjected to shoaling. This study represents the input of many engineers and researchers in the United States.

INTRODUCTION

Santa Cruz Harbor is located at the northern end of Monterey Bay on the California Pacific Coast (Figures 1 and 2). Harbor elements include an entrance channel 100 feet wide and 20 feet deep protected by jetties as well as interior channels and turning basins. The harbor serves as the home port for recreation and commercial fishing vessels. The main (west) jetty is 1,200 feet in length and protected with 28-ton concrete quadripods. The major navigation features of the harbor were completed in 1964. (1)

Inasmuch as the harbor is located in an area of considerable littoral movement, the Federal project authorization included provisions for sand by-passing at the harbor entrance. The harbor entrance has generally been maintained with contract hydraulic cutter pipeline-type dredges. Recently an experimental eductor type sand by-passing system was installed by the US Army Waterways Experiment Station, Vicksburg, Mississippi, and evaluated.

²Civil Engineer, US Army Engineer Division, South Pacific, San Francisco, California, Chief, Construction and Operations Division

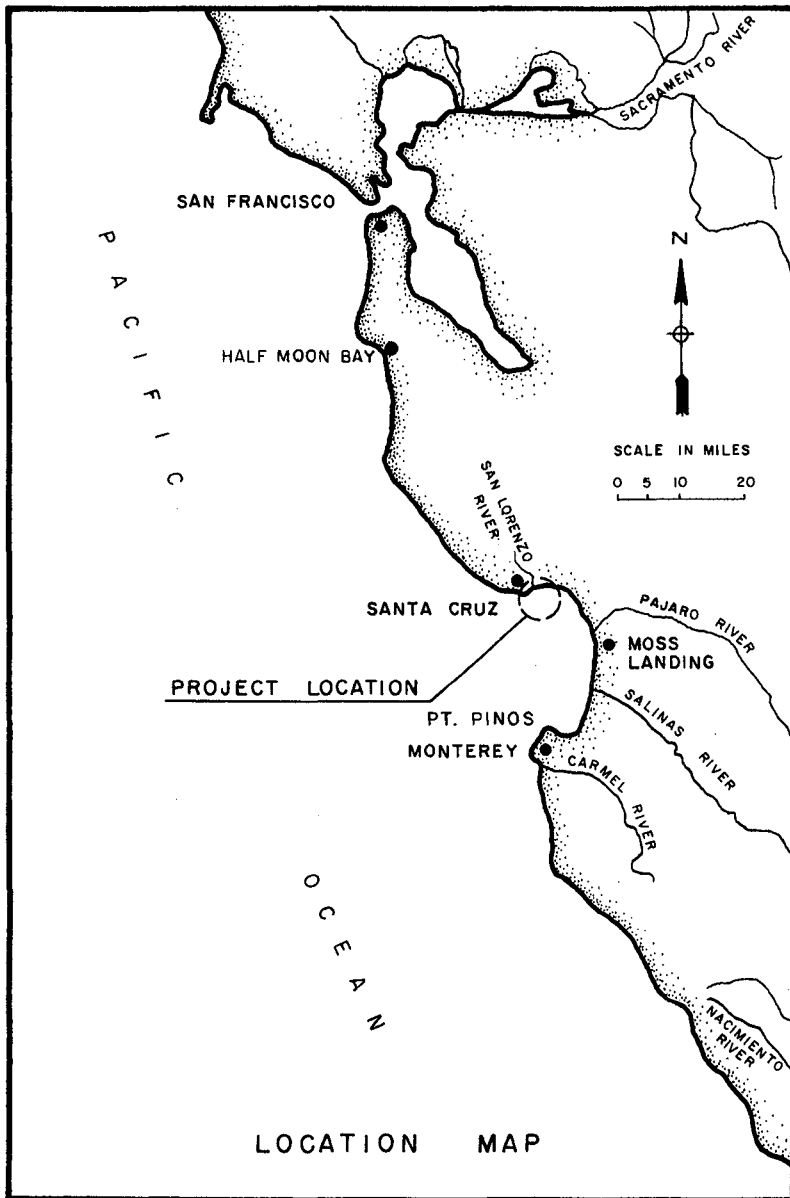

Figure 1. Location Map

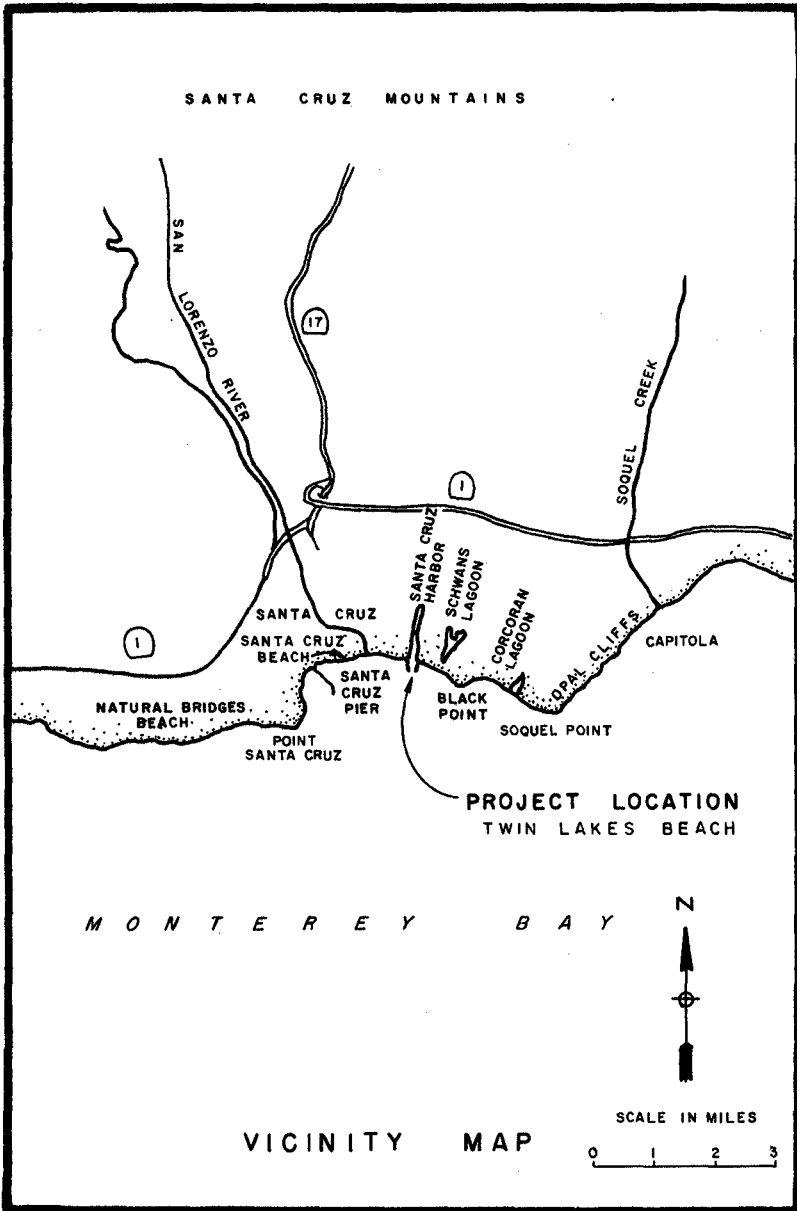

Figure 2. Vicinity Map

In order to quantify the coastal processes at Santa Cruz, an extensive prototype data collection program was initiated. This information includes beach and hydrographic surveys, LEO measurements,⁽²⁾ aerial photography, alongshore energy flux measurements, wave heights^{(3), (4)} at other locations along Monterey Bay, and offshore wave measurements.

CHARACTERISTIC ENTRANCE SHOALING

Shoaling of Santa Cruz Harbor entrance has been documented in a report entitled, "Santa Cruz Harbor Shoaling Study, Santa Cruz Harbor, California," by Walker, et al, of Moffatt & Nichol, Engineers.⁽⁵⁾ Walker found that the harbor entrance shoaling followed a relatively predictable pattern as shown on Figure 3. It should be noted that the harbor entrance experiences only relatively light shoaling until approximately October and relatively rapid shoaling until March or April when the pattern is repeated. Areas of deposition are similarly characteristic.

WAVE REGIME

In order to understand and quantify the movements of sediments at coastal locations, it is necessary to understand and quantify the offshore and nearshore wave regime, with particular emphasis on the determining of the direction and quantity of coastal littoral sediments. Traditionally this has been done through the use of deepwater wave hindcasts followed by appropriate transformation of these deepwater waves to the nearshore area. These nearshore wave characteristics were then translated to littoral drift calculations through the use of relations between the wave energy and the expected alongshore transport. Although these methods are useful in understanding coastal phenomena, they necessitate a complex chain of calculations which are difficult to make and which must often be made with insufficient information.

In order to better understand the littoral regime and to provide a usable technique of quantifying littoral processes at a specific location through in situ measurement, Seymour et al, of the California Department of Navigation and Ocean Development, and the representatives of the Scripps Institute of Oceanography, developed a device for directly measuring the alongshore energy flux (sxy). This device was installed at Santa Cruz Harbor and values of sxy are being calculated routinely. Very preliminary results by Douglas Pirie et al of the San Francisco District of the US Army Corps of Engineers indicate that quantities dredged at Santa Cruz Harbor are related to the sxy values at Santa Cruz as calculated by Seymour.

CONCLUSIONS

Improved technology appears to have provided a path for a major breakthrough in quantifying the alongshore sediment movement which results in shoaling at harbor entrances. If the results of these improved methodologies are substantiated through longterm coastal measurements, a powerful new tool will have been provided coastal engineers.

ACKNOWLEDGEMENTS

The work summarized in this paper is financially supported through the programs of the California Department of Navigation and Ocean Development, and the US Army Corps of Engineers. The work effort on the project was accomplished through the efforts of Mr. Douglas Pirie et al of the US Army Engineer District, San Francisco; Mr. D. Lee Harris of the US Army Coastal Engineering Research Center, Washington, DC; Mr. Dick Sager and colleagues at the US Army Waterway Experiment Station in Vicksburg, Mississippi; Dr. Richard Seymour of the California Department of Navigation and Ocean Development and A. Higgins, M. Sessions et al at the Scripps Institute of Oceanography; Mr. Milton Millard of the US Army Corps of Engineers Office of the Chief of Engineers, Washington, DC; Mr. Donald C. Baer of the South Pacific Division of the US Army Corps of Engineers; and Mr. Jim Wolfe and Mr. Hank Pape of the US Army Engineer District, San Francisco. The leader for the Santa Cruz Harbor shoaling study was Dr. James (Kimo) Walker of Moffatt and Nichol, Engineers. Continuing cooperation was received by the Santa Cruz Harbor Port District and the California Department of Parks and Recreation.

Acknowledgement is gratefully made to the Corps of Engineers, US Army, for access and permission to use this study material. The views of the authors do not purport to reflect the position of the Corps of Engineers, Department of the Army, or Department of Defense.

CHAPTER 75

CASE STUDIES OF DELAWARE'S TIDAL INLETS: ROOSEVELT AND INDIAN RIVER INLETS

W. A. Dennis¹, G. A. Lanan² and R. A. Dalrymple³

ABSTRACT

Studies were undertaken to document the past and present characteristics and trends of Delaware's two major tidal inlets, Roosevelt and Indian River Inlets.

It was found that both inlet complexes are effective sediment traps causing considerable downdrift erosion. The major mechanism by which sand enters Indian River Inlet is by overtopping the impounded south jetty. At Roosevelt Inlet sediments are readily transported past the severed steel sheet pile jetties.

The results of a one-dimensional hydraulic model, as well as field measurements, predict the presence of a mean southerly flow through the canal and bay system which connects these two inlets. This flow is shown to have a substantial effect on the behavior and stability of these entranceways, causing major asymmetries on the depositional patterns at each location. Roosevelt Inlet was found to have a strong tendency to trap sediment within its throat; whereas, Indian River Inlet, on the opposite end of the system, was found to retain large quantities of sand on its developing ebb tidal shoal.

INTRODUCTION

The state of Delaware's coastline, along the shore of Delaware Bay and the Atlantic Ocean, features two major inlets which are coupled via the Intracoastal Waterway (Figure 1). These inlets, which were recently studied independently by Lanan and Dalrymple (1977) and Dennis and Dalrymple (1978), were shown to have various similar characteristics as shared with most tidal inlets as well as various contrasting features. Roosevelt Inlet, which serves as the northern entrance to the waterway, lies on the extreme southern edge of Delaware Bay, approximately 3 nautical miles west of Cape Henlopen. The inlet is bordered on the

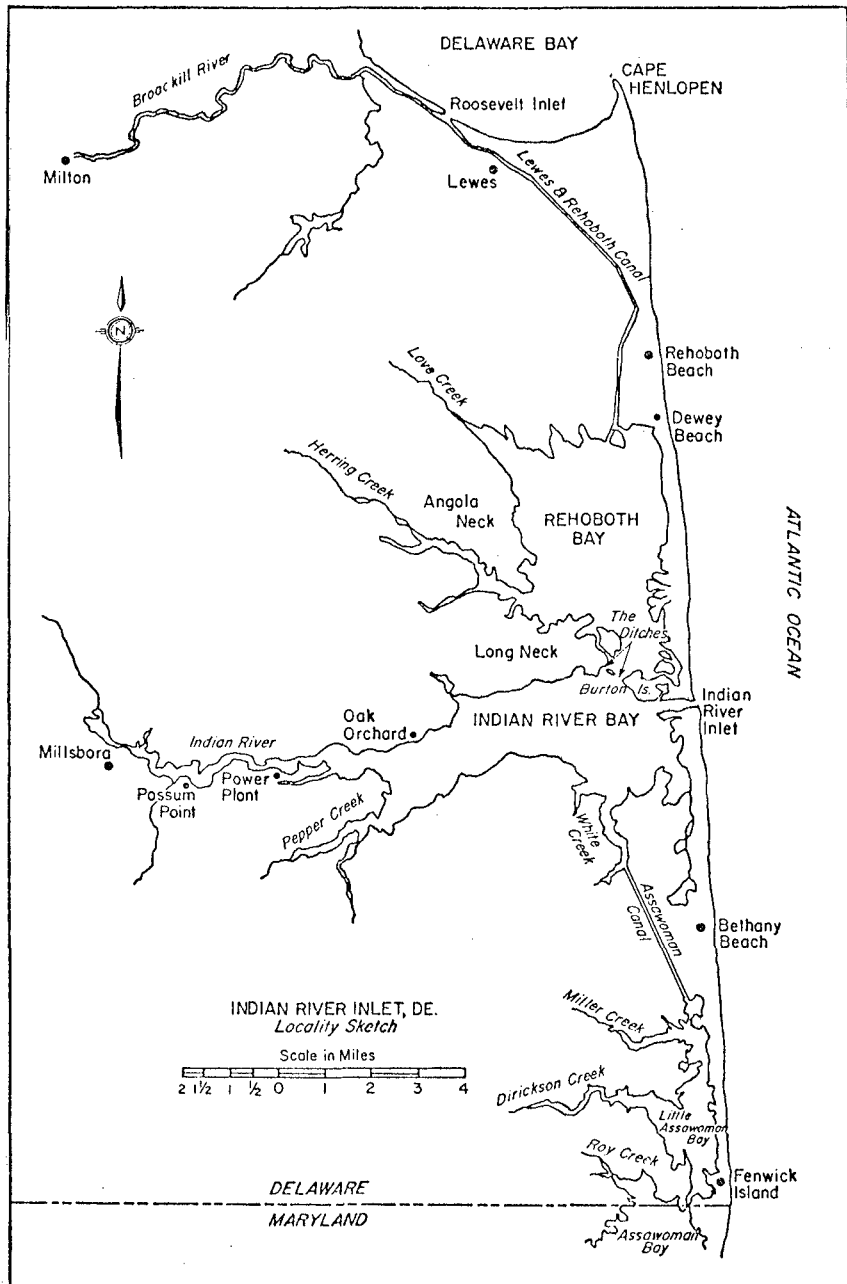

Figure 1 Locality Sketch of Indian River Inlet, Delaware

west by an undeveloped barrier beach known as Beach Plum Island and on the east by the small coastal community of Lewes Beach. Indian River Inlet lies about the midpoint of Delaware's Atlantic coast 11 nautical miles south of Cape Henlopen. The adjacent northern and southern barrier beaches are both contained in the Delaware Seashore State Park. These two inlets are connected by the Lewes and Rehoboth (L&R) Canal and the Rehoboth and Indian River Bays.

The wave climate in the vicinity of each of these inlets varies considerably due to the relative exposure of each location. Indian River Inlet, lying along the fully exposed Atlantic coast, is subjected to waves which average approximately a meter over the year; however, the possibility of two or three moderate-to-intense "northeasters" over that period, or the presence of a hurricane, are always a likelihood. The most effective wave energy arrives out of the southeasterly quadrant, driving the net littoral drift northward toward Cape Henlopen.

Roosevelt Inlet, on the other hand, is situated along a more sheltered shoreline. The wave climate is much less than that of the open ocean coast, with waves rarely exceeding a meter due to the limited fetch of Delaware Bay, particularly in the northeastern quadrant. Waves emanating from this direction are attenuated by the sheltering effect of the Cape as well as by the presence of two detached breakwaters at the southern entrance of Delaware Bay. Generally, the largest waves are generated along the major axis of Delaware Bay as a result of the sustained north to northwesterly winds. The biased wave climate results in an easterly net littoral drift along this reach, again toward Cape Henlopen.

BACKGROUND

Both of the inlets were stabilized about the same time. Roosevelt Inlet was established through the excavation of nearly 522,000 yd³ (399,300 m³) of mud, clay, and sand across the barrier beach commencing in the latter part of 1936. The construction of twin steel sheet-pile jetties followed the excavation and were completed by October 1937. The two structures were each 1,700 ft. (518.5m) in length extending bayward to the 6-foot (1.83m) depth contour, with a parallel spacing of 500 ft. (152.5m). This new inlet was to serve as a dependable and essential navigable northern entranceway of the recently completed L&R Canal after previous attempts at an alternate entrance (Broadkill Inlet), about 2 1/2 miles (4 km) to the west, had failed.

Unlike Roosevelt Inlet, Indian River Inlet occurred naturally, although its history has been one of migration, shoaling and closure. Repeated closure of the inlet in its natural state led to several pertinent problems, the most damaging of which was its effect on the local seafood industry. Not only did the inlet closure render vessel passage impossible, but normal fish migration into the feeding and spawning areas of the Rehoboth and Indian River Bays was disrupted. Furthermore, the large numbers of fish and shellfish trapped in the bays gradually died off as freshwater runoff reduced the salinity of the bay waters beyond tolerable limits. Many unsuccessful efforts were made to alleviate

these problems by both State and local interests through excavation and dredging until, finally, in 1937 a Federal project was approved to stabilize the inlet. Construction of two parallel stone jetties spaced 500 ft. (152.5m) apart was begun in 1938 and completed in 1940. Each structure extended seaward 1,556 ft. (474.6m) to the 14-ft. (4.3m) depth contour. The shoreward 904 ft. (275.7m) on the north side and 890 ft. (271.5m) on the south side were constructed of steel sheet piling for bank protection. For further historical details on Indian River Inlets, the reader is referred to Thompson and Dalrymple (1976).

INLET STABILIZATION AND RESULTING PROBLEMS

For both inlets office, as well as field studies, were undertaken to identify and document the various past and present coastal processes and associated problems. These studies included hydrographic surveys, beach profiles, current measurement, sand tracer experiments, collection and comparison of past and present charts and aerial photographs, as well as the documentation of all dredging and beach nourishment activities for each inlet. The following will present a discussion of the major problems and pertinent processes uncovered by these studies:

a. Downdrift Erosion. As with most tidal inlets along sandy coastlines, the presence of these inlets has resulted in significant erosion experienced by the adjacent beaches. Following the stabilization of Indian River Inlet, the south jetty began to trap sediment until the impoundment capacity was reached. Recent surveys of this area have revealed that approximately $319,000 \text{ yd}^3$ ($244,000\text{m}^3$) have been impounded since 1938 or an annual rate of $8,600 \text{ yd}^3$ ($6,580\text{m}^3$) per year. Presently, the sand passes rather freely around and over the south jetty entering into the confines of the inlet. At this point, the sand is entrained by the strong tidal currents reaching velocities as high as 6 feet/sec (1.8m/sec) and is ultimately deposited in either the flood or more extensive ebb tidal shoals. Thus the inlet complex acts as an effective sediment trap causing major erosion along the downdrift beaches. The shoreline response to the inlet stabilization is shown in Figure 2, which is based on comparison of aerial photographs, 1938 to 1975. In an effort to alleviate the sediment deficit, both the State and Federal governments have been nourishing the beach north of the inlet since 1957. To date, a total of $2,019,549 \text{ yd}^3$ ($1,544,955\text{m}^3$) have been placed along this reach.

The major mechanism by which the sand enters into Indian River Inlet and, to a lesser degree, Roosevelt Inlet, is by overtopping of the jetty. The beach berm crest along the reach adjacent to the south jetty at Indian River Inlet is generally one foot (0.3m) higher than the jetty crest. During periods of high tides, waves sweep up the beach, across and through the jetty, and into the channel, carrying large volumes of sand in the swash (Figure 3). At Roosevelt Inlet sediment occasionally overtops the shoreward portion of the east (downdrift) jetty during periods of northeasterly winds and high tides via a similar swash transport. The jetty at this location is essentially a low crested rubble revetment, primarily functioning as bank protection,

Figure 2 Shoreline Changes at Indian River Inlet

Figure 3 Sand Being Carried Over Indian River Inlet South Jetty by Ocean Waves

the crest of which varies 1-2 feet (0.3-0.6m) below the adjacent beach profile. A similar problem has also been noted to occur at Ocean City Inlet, Md., where the low and permeable inshore portion of the south jetty allows sand to flow downslope past the jetty and onto the northern tip of Assateague Island (Dean and Perlin, 1977).

b. Jetty Corrosion. A problem of greater impact which became apparent within two years after the jetty construction at Roosevelt Inlet was the corrosion and deterioration of the steel sheet-piling. At present no repairs have been made to the ailing structures which have deteriorated well beyond their effectiveness (most of the piling is only visible during low tide). As a consequence of the condition of the jetties, wave action easily moves sand through, around and over the severed sheet pile. Upon entering the inlet channel, the sand is reworked by wave and current action and is usually deposited in lobe-shaped shoals which build along both the east and west banks. The west lobe is usually larger, being on the updrift side of the inlet (Figure 4). Once the sand is worked within Roosevelt Inlet, there appears to be no effective mechanism to return the sand to the littoral regime other than by dredging. Therefore, in its present condition the inlet acts as an effective sink, trapping the gross littoral drift. The mechanism for this trapping will be explored more fully in the Section, Inlet Hydraulics. This trapping action has resulted in major erosion along Lewes Beach, which has again prompted both the State and Federal governments to provide remedial measures in the form of beach nourishment and the construction of nine groins.

FIGURE 4 Sand easily passing the deteriorated jetties at Roosevelt Inlet and depositing along the western bank.

c. Channel Bank Erosion and Channel Enlargement. Another major problem encountered following the stabilization of Indian River Inlet was the flanking of the jetties at the shoreward ends, causing erosion of the channel banks. The flanking probably was caused by the refraction of waves entering the inlet and striking the channel banks obliquely. Also, the expansion of the flood currents, upon exiting from the guides of the jetties, cause eddies to form which may result in scour of the unprotected banks. Following stabilization and the accompanying dredging, the unprotected channel banks began to widen dramatically. At a point about 650 ft. (198m) west of the present highway bridge, the channel widened 580 ft. (176.9m) during the following year and a half. In an effort to curtail the erosion, steel sheet-piling and riprap were extended along the channel banks in 1943 and again in 1963. However, each addition merely displaced the erosion pattern more westward. Today the erosion west of the protected channel banks is still continuing. The progressive widening can be seen by referring back to Figure 2.

Concomitant with the general widening of the unstabilized portion of Indian River Inlet was also a general deepening and thus a trend of increasing cross sectional area. This trend has caused the hydraulic characteristics of the inlet to change over time, including an increase in the tidal prism, enhancing the water quality of the adjoining bays. Comparison of past survey charts has revealed that the average cross sectional area has increased 15 fold since 1936. This increase has been manifested by a three-fold increase in the average width, 380 to 1,160 ft (116 to 354m) and a five-fold increase in the average depth of 3.5 to 18 ft (1.1 to 5.5m).

INLET HYDRAULICS

a. Development of Numerical Model. In order to gain a better understanding of the overall hydraulics, a one-dimensional numerical model was developed which encompassed all the bays and waterways from Indian River Inlet to Roosevelt Inlet. It provided a basis for simulating the tides and the cross sectionally averaged currents at any location within the system. The tides and currents (discharges) predicted by the model were compared with measured field data at specific locations and gave surprisingly accurate results. No effort was made to "fine tune" or calibrate the model to exactly predict the field data since the simplicity of the model would preclude such accuracy and also it was uncertain whether or not these measured data were representative of the average conditions.

The governing equations used in the model are the depth-integrated equations of motion and continuity. The effect of wind and the addition of freshwater inflow were neglected in the application and development of this model, although they are easily added. The vertically integrated differential equation of motion can be written in a semi-linearized form for flow in the x-direction as follows:

$$\frac{\partial q}{\partial t} = -g D \frac{\partial \eta}{\partial x} - \frac{\tau}{\rho} \quad (1)$$

where q = discharge per unit width in the x -direction

t = time

g = gravitational constant

D = total depth = $h + \eta$

h = depth at mean sea level

η = tide displacement above mean sea level

x = horizontal distance coordinate in flow direction

ρ = mass density of salt water

τ = frictional stress on the bottom of water column

$$= \frac{\rho f |q|}{8D^2}$$

f = Darcy-Weisbach friction factor

The continuity equation for one dimension is expressed as:

$$\frac{\partial \eta}{\partial t} + \frac{\partial q}{\partial x} = 0 \quad (2)$$

For computation these equations were cast into finite difference form, and the bays and waterways of the system were divided into finite segments. In the operation of the model a time and space staggered procedure is used in which the equation of motion is applied between mid-points of the adjacent segments (i.e., across segment boundaries) at full time steps, t , and the continuity equation is applied at each segment at half time step increments.

The finite difference form of Equation (1), expressed in terms of total discharge onto the n^{th} segment Q_n , follows, as:

$$Q_n' = \frac{Q_n - \overline{WD} g [\eta_n - \eta_{n-1}] \frac{\Delta t}{\Delta x}}{1 + \frac{\overline{W} \Delta t f |Q_n|}{8(\overline{DW})^2}} \quad (3)$$

where Δt = time step

Δx = space step

W = segment width

The primed quantities indicate unknown quantities whose values are determined at time $t + \Delta t$, from the unknown quantities on the right-hand side of the equation. The over-barred quantities represent averages based on the n^{th} and $(n-1)^{\text{th}}$ segments.

The continuity equation is expressed in finite difference form as:

$$\eta_n' = \eta_n + \frac{\Delta t}{\Delta x} \frac{1}{W} (Q_n - Q_{n+1}) \quad (4)$$

The segment characteristics used in the model are given in Table 1 and their locations, in Figure 5. Where small inlet segments connect two very large bodies of water, such as Indian River Inlet and "The Ditches", a Keulegan (1967) type inlet equation is used. The equation may be expressed as an example for Indian River Inlet as:

$$Q_2 = \frac{A_c \sqrt{2g} |\eta_1 - \eta_2| \text{sign}(\eta_1 - \eta_2)}{\sqrt{K_{en} + K_{ex} + f\ell/4R}} \quad (5)$$

where A_c = cross sectional flow area of Indian River Inlet

Q_2 = flow onto Indian River Bay from the Atlantic Ocean

η_2 = Indian River Bay tide

η_1 = Atlantic Ocean tide (specified)

K_{en} = entrance loss coefficient = 0.3

K_{ex} = exit loss coefficient = 1.0

R = hydraulic radius of the inlet

ℓ = length of the inlet

f = Darcy-Weisbach friction factor

The boundary conditions to be specified are the ocean and Delaware Bay tides at the mouths of Indian River Inlet (3.8 ft (1.2m) mean, 4.6 ft (1.4m) spring) and Roosevelt Inlet (4.4 ft (1.3m) mean, 5.2 ft (1.6m) spring), respectively (NOAA, 1977). The average time lag between each location was calculated to be 0.77 hours based on a month's tidal prediction, with the tides of Roosevelt Inlet lagging behind those of Indian River Inlet.

The development of the model was based on a similar study at Navarre Pass, Florida, (Coastal and Oceanographic Engineering Laboratory, University of Florida, 1973).

b. Results and Data Comparison. The results of the model were compared to tide and current measurements recorded at Roosevelt Inlet and the L&R Canal (Savannah Street Bridge - see Figure 5 for location) during June 1977, as well as with any other readily available source, such as the NOAA tide tables. Generally, the model showed good correlation with the field data but underpredicted the peak discharges and over predicted the peak tidal amplitudes. At Roosevelt Inlet the discharge peaks measured in the field were underpredicted by the model by as much as 40%.

Table 2 lists the predicted flow volumes for various locations in the system. The total volume passing the mouth of the Broadkill River $8.36 \times 10^7 \text{ ft}^3$ ($2.34 \times 10^6 \text{ m}^3$) was adjusted in the model by varying the dimensions of the "effective marsh" Segment No. 18 to match field measurements by DeWitt (1968).

The most apparent result indicated by Table 2 is the net southerly flow present throughout the system. The net volume pumped during each tidal cycle is approximately $6.3 \times 10^6 \text{ ft}^3$ ($1.76 \times 10^5 \text{ m}^3$) for mean tide conditions and $7.8 \times 10^6 \text{ ft}^3$ ($2.18 \times 10^5 \text{ m}^3$) for spring tide conditions. This net volume pumped is represented by a mean flow of 141 and 176 cubic feet (3.9 and 4.9 m^3) per second per tidal cycle for mean and spring tidal conditions, respectively (roughly 0.2-0.3 ft/sec (0.09m/sec) in the L&R Canal). The net volumes listed for all locations seem to indicate that mass is not conserved within the system (i.e., $6.3 \times 10^6 \text{ ft}^3$ enter through Roosevelt Inlet and $7.15 \times 10^6 \text{ ft}^3$ exit through Indian River Inlet for mean tide conditions). This error (18%) is a result of the computer accuracy in performing the integration routine for net volume over the complete tidal cycle and is not reflective of the time marching solution.

The current measurements recorded for this study also indicate the presence of a net southerly flow. For instance, a net southerly flow volume of $1.0 \times 10^7 \text{ ft}^3$ ($2.8 \times 10^5 \text{ m}^3$) was recorded at Savannah Street Bridge, which reduces to a mean flow of $230 \text{ ft}^3/\text{sec}$ ($6.4 \text{ m}^3/\text{s}$). This phenomenon has also been indicated in another set of recent field data (Jensen, 1977). More interestingly, a study dated back to the year 1930, undertaken to determine the effect of the Lewes and Rehoboth and Assawoman Canals on the behavior of Indian River Inlet, also revealed a net southerly flow out of the L&R Canal, which at this time was calculated to be $5.5 \times 10^6 \text{ ft}^3$ ($1.54 \times 10^5 \text{ m}^3$) (Indian River Inlet Commission, 1931).

The mean pumping to the south within the system is due to the combined effect of the mass transport of the two tidal waves entering each inlet, as well as the frictional characteristics of the system. A reasonable approximation of the net discharge quantity through the canal results, if one considers two separate tidal waves entering at each inlet and subtracts the respective mass transports for the net result. From long-wave theory the mass transport per unit width, M , is expressed as:

$$M = \rho q = E/C$$

(6)

TABLE 2. Predicted Flow Volumes* for Various Locations

Location	Mean Tide Conditions				Spring Tide Conditions			
	Volume Over One Tide Cycle $\text{ft}^3 \times 10^{-6}$		Net Volume $\text{ft}^3 \times 10^{-6}$	Mean Flow $\text{ft}^3/\text{s} \times 10^{-2}$	Volume Over One Tide Cycle $\text{ft}^3 \times 10^{-6}$		Net Volume $\text{ft}^3 \times 10^{-6}$	Mean Flow $\text{ft}^3/\text{s} \times 10^{-2}$
	North	South			North	South		
Roosevelt Inlet	59.1	65.4	6.3 S ⁺	1.41	66.6	74.4	7.83 S	1.75

* Numbers Rounded Off After Computation
 + S or N indicates direction

where

$$E = \text{wave energy} = \frac{\rho g H^2}{8} \quad (6)$$

$$C = \text{wave celerity} = \sqrt{g h}$$

with all other terms previously defined. Solving for q and expanding:

$$q = \frac{gH^2}{8 \sqrt{g h}} \quad (7)$$

Defining the net discharge per unit width as $q_{\text{net}} = q_c - q_o$ where the subscripts "c" and "o" refer to the canal and Atlantic ocean entrances, respectively, equation (7) may be cast in the following form:

$$q_{\text{net}} = \frac{g}{8} \left[\frac{H_c^2}{\sqrt{g h_c}} - \frac{H_o^2}{\sqrt{g h_o}} \right] \quad (8)$$

Substituting the appropriate quantities of $H_c = 4.4$ ft (1.34m) and $h_c = 10$ ft (3.05m) for the canal and $H_o = 3.8$ ft (1.16m) and $h_o = 16$ ft (4.88m) for Indian River Inlet into equation (8), we find $q_{\text{net}} = 1.77$ ft²/s (0.17m²/s). For the canal, which is approximately 100 feet (30.5m) in width, the net discharge would be 177 ft³/s (5.0m³/s). This estimate is reasonably close to that quantity predicted by the model of 141 ft³/s (4m³/s) for mean tidal conditions.

The effect of friction within the system can be evaluated from the following results. The model predicts that high tide occurs roughly about the same time in Indian River Bay and in the southern end of the L&R canal, with high tide occurring in Rehoboth Bay approximately 1.9 hours later, hence the tidal division line lies within Rehoboth Bay. In addition, low tide in Indian River Bay is predicted to occur nearly 1.4 hours before it occurs at the southern end of the canal. This indicates that Rehoboth Bay starts to drain through "The Ditches" into Indian River Bay long before it drains into the L&R Canal.

Therefore, in summary, it is felt that the mean pumping throughout the system is caused by the dominate southerly discharge, propagating completely through the canal into Rehoboth Bay on flood tide, whereupon during ebb tide Rehoboth Bay drains more favorably toward the south through a less frictionally resistant passage.

c. Effects of Net Flow. The amount of sediment carried into or out of an inlet is dependent on the power available in the ebb and flood flows to move the sediment plus the amount of sediment supplied to the inlet by littoral transport. When a mean flow is present over the tidal cycle, a bias in the tidal power exists, and this can materially affect the depositional characteristics of the inlet. A study by Costa and Isaacs (1975), using both a physical and numerical hydraulic model, showed that the superposition of a small current upon an unbiased tidal flow significantly altered the deposition pattern around the inlet. In fact, the results of their physical movable bed

model indicate that a secondary flow of one percent of the main flow directed in the ebb direction results in at least a twelve percent increase in sediment load being carried seaward.

Following the ideas and developments set forth by Costa and Isaacs, the effect of the anisotropic flow through the bay and canal system on the tidal power available for sediment transport was investigated. Within this development it is assumed that the work done in transporting sediment in the flood and ebb directions can be expressed as:

$$I_{f,e} \sim \int_{f,e} P(t)dt \sim \int_{f,e} \epsilon V^3(t)dt \tag{9}$$

where $I_{f,e}$ = work accomplished in transporting sediment in the flood and ebb directions

$P(t)$ = power utilized in sediment transport

$V(t)$ = velocity in the inlet as predicted by the model

ϵ = transport efficiency

The transport efficiency developed empirically by Costa and Isaacs after data presented by Inman is shown to be a function of the stream power as given by:

$$\epsilon = 0.01 \left[\left(\frac{V}{V_C} \right)^3 \right]^{1.86}, \quad V_C^3 < V^3 < 5V_C^3 \tag{10}$$

where V_C = velocity at which incipient motion begins

It was assumed that for the range of particle sizes present in the inlet, approximately 0.4mm to 1.0mm, that 20 cm/sec or 0.66 ft/sec would be representative of the critical velocity, V_C , based on a curve developed by Hjulström (1935) contained in Graf (1971).

The work done on sediment transport for both flood and ebb tide at Roosevelt Inlet was computed from the numerical integration of Equation 9 with the results given in Table 3.

TABLE 3 Sediment Transport Work Per Tidal Cycle at Roosevelt Inlet

Tide Condition	Available Work Per Tidal Cycle (ft-lbs)			Work Ratio Flood/Ebb
	Flood	Ebb	Net	
Mean	148	26	122 F	5.7
Spring	470	72	394 F	6.2

It is readily apparent that the mean pumping into the inlet results in a significant bias of the available tidal work to transport sediment into the inlet. In fact, the results show that the sediment transport work is approximately six times greater for flood than ebb. Although no investigation of the tidal power at Indian River Inlet was undertaken, it is clear that a similar, but opposite, (ebb to flood) bias exists.

The effects of the sediment transport bias should be reflected in the depositional characteristics of each inlet. At Roosevelt Inlet, the majority of the sediment that enters the channel deposits in lobe-like shoals along both banks (as mentioned previously), eventually clogging the rear of the entrance channel. In addition, strong evidence of the presence of an ebb-tidal shoal was not found (at least within the survey limits of this project). Both of these factors suggest a net flood transport as predicted in the model.

At the other end of the system, indications of a net seaward sediment transport should be evident. One indication of this has been the development of a rather extensive ebb tidal shoal currently estimated to contain 4,884,000 yd³ (3,763,260m³). Secondly, the sediment introduced to the system through erosion and scour of the inlet channel seems to have been dominated by ebb tidal flows since an overall loss within flood tidal shoals has been evident. Estimates of the material within the general vicinity of the flood shoals show slightly over one million cubic yards (7.65x10⁵m³) has been removed.

STABILITY ANALYSIS

In the preceding section it was surmised that the bias of tidal power can significantly influence the depositional patterns and hence the sedimentary stability of the inlets. At Roosevelt Inlet there was a tendency toward closure as sediment was continually trapped within its throat. On the other hand, Indian River Inlet is thought to be quite stable against closure with scour and enlargement present. In this section, the sedimentary stability of these two inlets will be further investigated by adopting the concepts developed by Escoffier (1940), O'Brien (1969) and Jarrett (1976).

A stability curve of maximum inlet velocity, V_{max} , versus the inlet cross sectional area, A_c , based on the concepts first developed by Escoffier, was generated for Roosevelt Inlet through the use of the numerical model discussed previously. Historic cross sections were fed into the computer, and a corresponding V_{max} was calculated using spring tidal conditions. Further cross sectional area data were generated, assuming the area could continually decrease with a minimum width of 200 ft (61m). The resulting curve is shown in Figure 6. It is seen that the inlet has always been in the stable portion of the curve. The change in cross section along this portion of the curve has been principally dominated by dredging activity. A closer look at the data indicates a general trend of increasing cross sectional area following dredging activity prior to June 1963. After this date, reductions in cross sections are evident following dredging activity.

Figure 6 Stability Curve for Roosevelt Inlet

This trend reversal has presumably been caused by the rapid deterioration of the jetties accompanying the devastating 6-8 March 1962 storm which, in turn, altered the nature and rate of deposition.

Other approaches to inlet stability by O'Brien and Jarrett have been based on empirical relationships between the inlet throat cross sectional area and the tidal prism. These relationships are mostly based on data of inlets that connect the ocean with a bay or bays; thus Roosevelt Inlet is a unique case. With this in mind the effect of the mean flow on the sedimentary stability of the inlet may somewhat supersede the prism area relationships at hand.

If it is assumed that the tidal prism can be closely represented by the following:

$$P = A_c \int_0^{T/2} V_{max} \sin \frac{2\pi t}{T} dt = \frac{A_c V_{max} T}{\pi} = \frac{Q_{max} T}{\pi} \quad (11)$$

where T is the semidiurnal period of 44,700 seconds. The tidal prism-area relationships of these investigators may be plotted with the stability curve. Where intersection occurs between the stability curve and the prism-area curve, the inlet is expected to reach an equilibrium satisfying both hydraulic and sedimentary properties. These curves are shown plotted in Figure 7. The figure shows that the stability curve lies below the prism-area curves for all cross sections, indicating a strong tendency for closure to occur. However, the exact position of the stability curve is open to question since: (1) The model used in generating the curve generally underpredicted the peak flows measured

Figure 7 Stability and Prism-Area Curves for Roosevelt Inlet

in the field and (2) the prism-area relationships were developed from inlets on fully exposed coasts unlike Roosevelt Inlet, and (3) the prism-area relationships are not directly applicable since they were derived mostly from inlets without net flows.

Similar curves were also generated for Indian River Inlet through analytical means. Historic average inlet cross sections were plotted, based on theoretical relationships presented by O'Brien and Dean (1972). These points are shown in Figure 8, marked with the appropriate date.

Additional points corresponding to cross sectional areas larger than the present were computed for the inlet deepening but not widening. The solid line was computed, based on a constant rectangular cross sectional shape, the width 20 times the channel depth. It is seen from the figure that the inlet has progressed from the unstable (frictionally dominated) portion of the curve, through the critical area and into the stable portion with a present cross sectional area of about 20,000 ft² (1,860m²).

The solid stability curve was also plotted with the various tidal prism area relationships as shown in Figure 9. All these prism-area curves intersect the stability curve near $A_c = 31,000$ ft² (2,883m³) and $V_{max} = 3.6$ ft/sec (1.1m/sec). As mentioned beforehand, the inlet could be expected to reach an equilibrium state when it suffices both relationships simultaneously. The present enlargement trend of the inlet channel may be an attempt to reach this equilibrium area.

Figure 8 Stability Curve for Indian River Inlet for Historical and Assumed Cross Sections

Figure 9 Stability and Prism-Area Curves for Indian River Inlet

Overall, the results of the stability and prism-area concepts reveal that neither of the inlets is presently in equilibrium. For Roosevelt Inlet a tendency for reduction in area is evident, mostly through a decrease in width from the developing sand lobes along the banks. At Indian River Inlet a tendency for cross sectional enlargement is expected to continue, mostly through a general deepening.

A true equilibrium will only exist if there is a zero mass transport through the system. The cross sectional enlargement at Indian River Inlet and decrease at Roosevelt Inlet are possibly natural adjustments to gradually alter the respective flow regimes at each inlet to reach a zero net flow condition.

CONCLUSIONS

1. Downdrift erosion is the major problem that developed after the stabilization of each inlet. In both cases sediments easily enter the inlet channel where they are transported to developing shoals with no apparent natural return to the littoral system. Sand primarily enters Indian River Inlet through the overtopping of the impounded south jetty. At Roosevelt Inlet sediments are readily transported past the badly deteriorated steel sheet pile structures.
2. The results of a one-dimensional hydraulic model, as well as field measurements, predict the presence of a mean southerly flow through the canal and bay system which connect Roosevelt and Indian River Inlets. This flow is believed to cause a major bias in the tidal power available for sediment transport at each inlet (6 to 1 at Roosevelt Inlet), thus significantly influencing the depositional characteristics at both locations.
3. The tidal power bias, as well as stability and equilibrium analyses, indicates that at Roosevelt Inlet a tendency toward closure is evident; whereas, Indian River Inlet seems quite stable against such an occurrence.

CHAPTER 76

NUMERICAL MODEL INVESTIGATION OF SELECTED TIDAL INLET-BAY SYSTEM CHARACTERISTICS

William N. Seelig (1)
Robert M. Sorensen (2)

Abstract

A spatially integrated one-dimensional numerical model of inlet-bay hydraulics has been combined with a simple sediment transport model to investigate selected tidal inlet-bay system characteristics. A parametric study has been performed using the models to determine the effect of various factors on the net direction and order of magnitude of inlet channel flow and sediment transport. Factors considered include astronomical tide type, storm surge height and duration, variation in bay surface area, time-dependent channel friction factor, and the addition of a second inlet connecting the bay and sea.

Introduction

The purpose of this study is to investigate selected basic flow and sediment transport characteristics of tidal inlets. A simple numerical hydraulic-sediment transport model applied to an idealized inlet-bay system is used to evaluate the time-dependent channel ebb and flood flow velocity and sediment transport rate as well as the net and gross sediment transport rate for a tidal cycle. The independent variables investigated are:

1. Common tidal types found on the Atlantic, Gulf and Pacific coasts of the United States.
2. A normalized storm surge of varying peak height and duration.
3. A water-level dependent variable bay surface area.
4. Time-dependent channel resistance specified by a variable Manning coefficient.
5. A second inlet of varying cross-sectional area.

Inlet-Bay System

The idealized inlet shape used in this study (Figure 1) was designed to have characteristics typical of tidal inlets, but excludes

¹Hydraulic Engineer, Coastal Structures Branch, US Army Coastal Engineering Research Center, Ft. Belvoir, Virginia 22060.

²Chief, Coastal Structures Branch, US Army Coastal Engineering Research Center, Ft. Belvoir, Virginia 22060

any ebb or flood tidal deltas. This idealized shape was developed during a classification study of many inlets throughout the United States.

The bay area is initially taken as independent of bay water level and the tidal wave length in the bay is assumed to be much longer than the longest axis of the bay.

Inlet Hydraulics

The numerical model of inlet hydraulics used in this study was reported earlier in Sorensen and Seelig (1976) and discussed in detail in Seelig et al. (1977). Important characteristics of the model are: (1) the continuity equation is used to relate rate of bay water level change, dh_b/dt to inlet velocity, V , by assuming that the surface water level is uniform throughout the bay at any time. That is

$$VA_c = A_b \frac{dh_b}{dt} \quad (1)$$

where A_b is the bay surface area and A_c is the inlet cross-sectional area. Storage of water in the inlet is neglected. (2) motion of water in the inlet is described by the one-dimensional equation of motion along the inlet channel axis:

$$-g \frac{d\eta}{dx} = \frac{fV|V|}{8R} + V \frac{dV}{dx} + \frac{dV}{dt} \quad (2)$$

where η is the water surface elevation, R is the channel hydraulic radius, x the distance along the channel axis from some reference point, f the channel friction factor, and g the acceleration of gravity. Eq. 2 relates the horizontal driving force due to the water surface slope to the channel frictional resistance, the convective acceleration caused by velocity variation along the channel axis, and the temporal acceleration (or inertia) caused by velocity variation with time.

In this numerical model the inlet is divided into a series of channels and cross-sections to produce a flow net grid. Each grid element is assigned a Manning's n , depth, width, and length. Eq. 2 is written in a finite element form. Equations (1) and (2) are then solved in a time marching procedure for solving differential equations with boundary conditions applied at each time step. Flow is assumed to follow the path of least resistance and the amount of flow in each grid element at each time step is determined accordingly.

This numerical model has been tested for a variety of inlets throughout the United States and found to be a reliable low-cost method for predicting the hydraulics of inlets.

The idealized inlet in Figure 1 was modeled using a semi-diurnal sinusoidal tide with an amplitude, a_o , of 61 cm and period, T , of 12.4 hours for various values of bay surface area. Figure 2 shows results of the hydraulic predictions where the phase lag and the dimensionless maximum velocity, V'_{max} , have been averaged for the flood and ebb portions

Figure 1. Idealized inlet

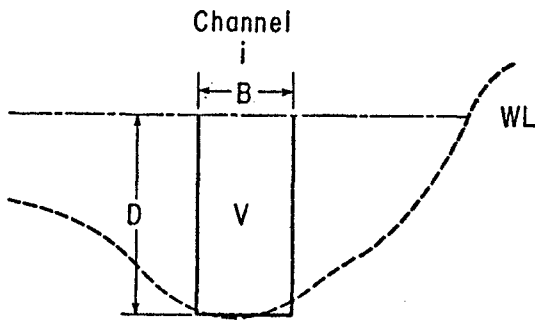

Figure 2. Inlet-bay hydraulic characteristics

Sediment Transport

$$Q_s = k \sum_{\text{cross section}} B (|V| - V_c)^3 \text{sg}(V)$$

Figure 3. Sediment transport calculations

of the tidal cycle. We define

$$V'_{\max} = V_{\max} T A_c / (2\pi a_o A_b) \quad (3)$$

where V_{\max} is the maximum channel velocity averaged across the throat cross section during a tidal cycle. Manning's n used in these calculations is taken as a weak function of channel water depth:

$$n = 0.038 - 0.0022 D \quad (4)$$

where D is the still water depth in meters for each grid.

Jarrett (1976) made a study of tidal inlets throughout the U.S. and presented a relationship between the cross-sectional area of the inlet at still water level and the tidal prism. This condition is satisfied for the idealized inlet where $A_b/A_c = 1.2 \times 10^4$. Conditions at this point are referred to as "the reference condition". For the reference condition the bay tide range is approximately equal to the tide range in the ocean.

Sediment Transport Model

The rate of sediment transport, Q_s , across the minimum cross-sectional area portion of the inlet is taken as:

$$Q_s = k \sum_{i=1}^N B (|V| - V_c)^3 \text{sg}(V) \quad (5)$$

where $\text{sg}(\)$ is the sign function, V is the velocity for a grid for a time step, $|V|$ is the magnitude of V , V_c is a critical velocity below which the sediment transport rate can be neglected (V_c is taken as 30 cm/sec in this study), N is the number of grid channels, and k is some unknown function influencing the transport rate (Figure 3) and B is the grid channel width. In this study k is taken as an unknown constant.

Figure 4 shows the predicted rate of sediment transport and average inlet throat velocity for the reference condition. Note that the maximum inlet velocity is slightly higher than 100 cm/sec, which is typical for natural tidal inlets. Changes in depth, cross-sectional flow area and frictional resistance throughout the tidal cycle produce asymmetries in water velocities that are magnified in the predicted rate of sediment transport. For example, the predicted rate of flood sediment transport for this case is higher but generally shorter in duration than for ebb.

The rate of sediment transport is integrated over the flood and ebb portions of the cycle to give volumes of transport, Q_f and Q_e . For the conditions in Figure 4 the flood transport is 20% higher than the ebb transport and the net transport volume is about one-tenth of the gross or total volume of sediment transport.

In the following sections, deviations from the reference conditions are systematically made and the predicted sediment transport volumes are compared to the reference condition.

REFERENCE CONDITION

$A_b/A_c = 1.2 \times 10^4$

$n = 0.038 - 0.0022D$

Figure 4. Hydraulic and sediment predictions for the reference condition

Influence of Tide Type

Astronomical tides are not strictly sinusoidal, as assumed in the reference condition, but are influenced by numerous astronomical and local affects. To obtain some idea of the effect of the astronomical tide type, tides were predicted for three locations (Wilmington, N.C., Galveston, Texas, and Los Angeles, California) using a computer program developed by D.L. Harris of CERC. Tides were predicted for the entire month of January 1981 and normalized by dividing by the root-mean-square of the water levels to give the tides the same energy. The relative amounts of calculated net and gross sediment transport and samples of the tide are given in Figure 5. These results suggest that for a fixed amount of tidal energy a semi-diurnal tide (top curve) produces the largest predicted gross transport with a relatively large net flood sediment transport, while a semi-diurnal tide with a strong inequality has lower gross transport and net transport in the ebb direction.

Storm surges investigated in this study are taken as having a normal shape with range in the ocean, R_0 . The period of the surge is characterized by four times the standard deviation of the normal shape. Figure 6 illustrates a surge of this type and shows the predicted hydraulic response. The inlet velocities are highly asymmetrical due to inertia and non-linear effects.

Predicted sediment transport volumes for storm surges are given in Figure 7 for surges with durations of one to eight hours and various surge amplitudes. The left portion of the figure shows the ratio of predicted flood to ebb sediment transport. For most conditions investigated, the value of this ratio is greater than unity, indicating that more transport occurs on the flood than ebb portion of the tidal cycle. In the right section of the figure the gross amount of sediment transport is normalized by the gross transport predicted for the reference semi-diurnal tide condition. (The superscript (')) indicates sediment transport has been normalized by conditions at the reference condition). The right portion of Figure 4 shows that the amount of transport during a surge can be an order of magnitude more than during astronomical tidal cycle.

The astronomical tide plus a storm surge produces a complicated pattern of sediment motion. The magnitude and direction of the sediment motion depends on the amplitude of the tide and are strongly influenced by the phase relation between the tide and surge. In conditions modeled, the gross transport for a surge plus tide reached as much as three times the value predicted for the surge and tide acting independently. Net transport was as high as one and one-half times larger.

Influence of Bay Surface Area

The bay surface area usually will not be constant with changing water level as was assumed in the reference condition. Flooding of tidal flats and sloping bay shores may dramatically change the bay surface area throughout the tidal cycle. A number of bay area variation models were tested and three are presented in this paper. First, bay area is assumed to be a linear function of bay level (Figure 8) and

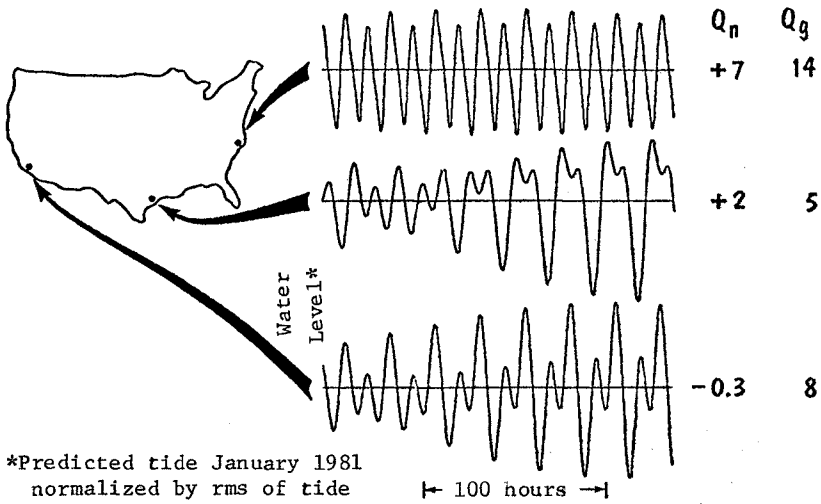

Figure 5. Influence of tide type on sediment transport

Figure 6. Inlet hydraulic response to a storm surge

Figure 7. Sediment transport caused by a storm surge

Figure 8. Effect of bay area variation on sediment transport

the amount of variation is characterized by the parameter, α_1 . If $\alpha_1 = 0$, there is no bay surface area variation and the reference condition is reached. As α_1 increases larger variations occur in surface area as the water level changes (upper portion of the figure).

As the rate of surface area change is increased (α_1 gets larger) the amount of gross sediment transport increases while the tidal prism remains approximately constant. Less flood dominance is present, as shown by the net transport, so that for $\alpha_1 = 0.25$ there is no net sediment transport predicted. For $\alpha_1 > 0.25$ net transport is in the ebb direction.

As a second form of bay area variation the bay surface area below the still water level is taken as constant and there is a linear variation above the still water level (Figure 9). This case could correspond to a bay with extensive incised channels and well-developed tidal flats at or above the mean water level. The pattern of trends in sediment motion is similar for this bay area change model to that for the linear case. No net motion occurs when $\alpha_2 = 0.58$.

Results for an exponential bay area variation model are given in Figure 10. The transition between net flood and net ebb sediment transport for this bay area variation model occurs at $\alpha_3 = 0.28$.

Influence of Channel Resistance

In the reference condition the Manning's friction factor, n , was made to weakly decrease with channel depth (Equation 3). This encourages higher flow rates in deeper portions of the inlet channel, so that predicted gross sediment transport is higher than for a constant value of n (Figure 11). Higher values of n decrease gross transport, but actually increase the amount of net transport because asymmetries throughout the flow cycle are enhanced (Figure 11).

Behrens et al. (1977) carried out a field study on Corpus Christi Pass, a tidal inlet dominated by frictional effects. Manning's friction factor was computed for the inlet as a function of time and found to vary strongly throughout the tidal cycle. For most cases studied, n steadily increased until it reached a maximum towards the end of a ebb or flood portion of the tidal cycle. In some cycles the opposite pattern was observed. Both cases were investigated in the idealized inlet (Fig. 12).

The case of the increasing n is characterized by a velocity that rapidly changes at flow reversal and reaches a high value that is retained throughout much of the cycle. The situation where n decreases during the cycle has larger variation in velocity with time (Figure 12). In spite of the differences in the shape of the velocity curves for these two cases, the gross and net amounts of predicted sediment transport are approximately the same. The volumes of sediment transport are approximately the same as if the mean value of n were used throughout the tidal cycle.

Figure 9. Effect of bay area variation on sediment transport

Figure 10. Effect of bay area variation on sediment transport

Figure 11. Effect of Manning's n on sediment transport

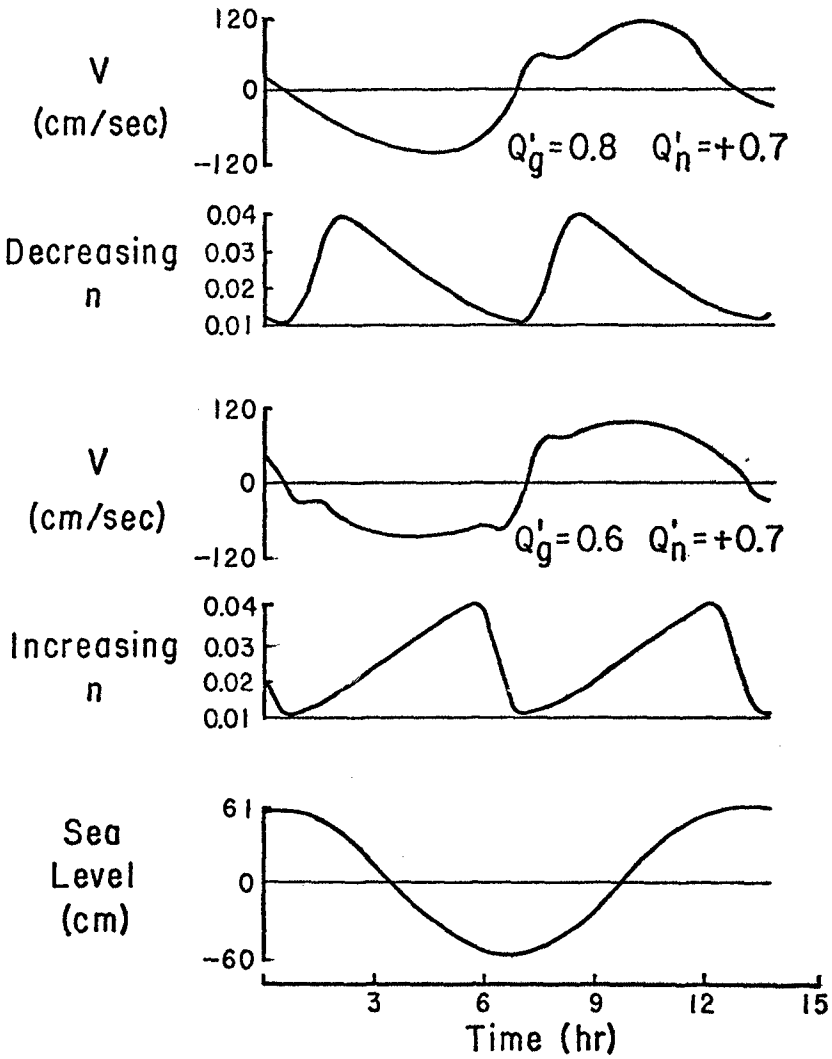

Figure 12. Effect of variable n on inlet hydraulics and sediment transport

Influence of a Second Inlet

A bay may be connected to an ocean by more than one inlet. The effect of a second inlet is examined by adding another inlet to the system with a length equal to the width of the barrier island. The second inlet is taken as prismatic with a width to depth ratio of 50, which was found as most typical for US inlets in an inlet classification study performed by Vincent (1978). Predicted transport volumes for the reference condition tide are shown in Figure 13.

As the size of the second inlet increases, the sediment transport in the idealized inlet rapidly decreases, so that when the cross-sectional areas are equal, $(A_{C1} + A_{C2})/A_{C1}=2$, the transport in the idealized inlet is less than ten percent of that at the reference condition. Total transport in the second inlet increases as its area increases until transport reaches a maximum when the cross-sectional area is approximately half of the idealized inlet. The sediment transport in the idealized inlet is generally larger than in the second inlet because the idealized inlet's deep gorge makes it more hydraulically efficient.

Summary and Conclusions

A numerical model investigation of the sediment transport in a realistic inlet shape shows that:

- (1) A semi-diurnal tide produces the largest amount of sediment motion and gives a net flood sediment transport, when several tides types of equal energy are compared.
- (2) Storm surges can move significantly more sediment than is moved during an astronomical tidal cycle. The phasing of a surge and tide is especially important in determining the amount and net direction of transport.
- (3) If the surface of the bay changes as the bay water level fluctuates there will tend to be less flood sediment motion and more ebb sediment motion than for the case of no bay area change.
- (4) High inlet friction enhances flow asymmetries so net sediment transport increases while gross sediment transport decreases. An inlet with a Manning's n friction factor that varies throughout the cycle produces approximately the same amount of sediment transport as the inlet with the mean value of n.
- (5) A second inlet may greatly reduce the amount of sediment transport in the primary inlet and the total transport of the two inlets can be smaller than if only the first inlet connects the bay and ocean.

ABSTRACT

Fast-response electromagnetic flowmeters were used in a marginal flood channel of an ebb tidal delta to assess the importance of wave contributions to the flood dominance of these channels. Measurements were made at a single point in the channel in both ebb and flood currents. The oscillatory motion of waves was a very significant feature of the velocity records, and its magnitude was comparable with the mean flow at all stages of the tide. This observation shows that flowmeters capable of responding accurately to wave velocities are needed to obtain accurate values of mean flow. Some earlier measurements made with slow response flowmeters are probably unreliable. Wave contributions to the mean flow were assessed by looking at the correlation between the low frequency ($>17.5s$) oscillations of the along-channel current and the low frequency envelope of the wave velocities. Surprisingly little correlation was found for any time lag, suggesting that wave effects were not important in the mean tidal currents in the channel studied. However, close to low tide on the ebb, conditions existed which appear to have been favourable for the "wave pump" mechanism suggested by Bruun and Viggisson (1973). Significant correlation between the wave envelope and low frequency fluctuations was observed at this time. It is therefore suggested that wave effects can be important to the mean flow in marginal channels with rapidly converging and shoaling mouths which are oriented towards the dominant incident wave direction.

INTRODUCTION

A tidal inlet is a complex region whose continually changing morphology is the result of the interaction of wave and tidal forces acting on the nearshore sediments. The most prominent feature of an

ebb-tidal delta is a broad relatively deep central channel, usually essentially at right-angles to the coastline, terminating on the seaward side with a deltaic fan of sediment often many kilometres offshore. This channel is flanked on either side by linear bars, and broad sheets of sand known as swash platforms on which shoreward migrating swash bars are commonly observed. On either side of the inlet, between the swash platforms and the beaches adjacent to the inlet, one usually finds marginal channels which are dominated by flood tidal currents (Hayes 1975).

Considerable understanding of the processes responsible for forming and maintaining the topography of these inlets has been gained from study of their morphology, and from measurements of the average tidal and wave parameters, but it is clear that more direct and detailed measurements of wave and tidal forces are needed to clarify some of the dynamic models inferred from these studies. The present investigation was designed as a preliminary look at the relative role of waves and tides in the hydraulics of the marginal flood channels of an inlet.

The dominance of flood currents in marginal channels is generally accepted, on the evidence of bedforms and a few direct measurements of tidal current (Brun and Gerritsen, 1959, Oertel, 1972, 1975, Fitzgerald et al 1977). Clearly the inertia of a jet-like ebb flow through the inlet mouth is likely to result in an asymmetry of the tidal currents on the seaward side, with mean current gyres on either side of the ebb channel tending to enhance flood currents in the marginal channels. Dean and Walton (1975) suggest that flood dominance may also be partly due to entrainment into the ebb jet from the marginal channels.

Fitzgerald et al. (1977) suggest that waves could also be important in contributing to the flood dominance of marginal channels. A longshore variation of the height of waves breaking on the seaward side of the bar which flanks the flood channel creates a longshore gradient of set-up along the bar. Fitzgerald et al. hypothesise that this set-up gradient may be felt over the bar into the flood channel where it could drive a flood-directed current. Waves clearly might also contribute to flood dominance in several other ways. For example, wave refraction over the delta system tends to cause waves to approach the shoreline obliquely towards the inlet throat, so that at breaking they should drive flood-directed longshore currents in a narrow surf zone at the shoreline. In the highly turbulent conditions of a marginal flood channel these surf-zone driven currents might spread beyond the surf zone and influence the overall mean flow in the channel. Similarly longshore currents generated in the surf zone on the seaward side of the outer bar may also spread over the bar into the marginal channel. Also possibly relevant in this context is the

description of a "wave pump" by Bruun & Viggisson (1973) and Brunn & Kjelstrup (1978). In their wave pump, some combination of mass transport and wave set-up in waves breaking in a converging shoaling channel drives a current (more than 1 m/s in large laboratory tests with 1.6m waves) into an open discharge channel ahead of the waves. In a tidal inlet these effects could be important, particularly for waves refracted to travel directly along the marginal flood channel.

As a preliminary test of some of these ideas, fast response flowmeters have been used in a marginal flood channel to measure accurately the wave and tidal currents during both ebb and flood flows.

THE FIELD MEASUREMENTS

The site chosen for this study was Price Inlet, South Carolina, about 15 km north of Charleston Harbour on the Georgian Bight coast of the Southeastern United States (figure 1). An aerial photograph of the inlet a few months before our study shows the general complexity of the region (figure 2). The southern flood channel region is particularly complex. An older flood channel has just been closed to form an isolated pond, and a new flood channel is forming offshore. The

Figure 1: Map showing location of Price Inlet

Figure 2: Price Inlet at Low Tide, March 1977

photograph in figure 2 was taken in March 1977, and by the time of our study in November 1977 the new flood channel had become considerably better defined by continued growth of the offshore bar. The measurements described in this paper were taken in this southern flood channel on November 20th and 21st, 1977.

The flowmeters used in this field study were two-component electromagnetic sensors with a nominal time constant (low pass) of 0.2 seconds (Marsh-McBirney Model 511 OEM). Three of these instruments were mounted on arms attached to an aluminum tripod 0.3m high. Two were mounted so as to measure simultaneously vertical (w) and along-channel (u) flow at 0.75m and 0.35m respectively above the channel floor. The third flowmeter was aligned to measure along-channel (u) and cross-channel (v) flow 0.52m above the channel floor. Figure 3 shows in plan view the location of the instruments and a cross-section showing the position of the flowmeters in relation to the offshore bar and marginal channel. The sensors appear to be well to one side of the channel, though this may be somewhat deceptive since at the tidal height necessary to cover the sensors this displacement would not be so apparent. In any case there was no evidence of spatial asymmetry in the flow at this point, so that flow past the sensors should be representative of the cross-sectional average. (This was not true for the northern marginal channel at this inlet where the strongest ebb current was displaced well towards the seaward side of the channel while the flood current dominated the landward side of the channel.)

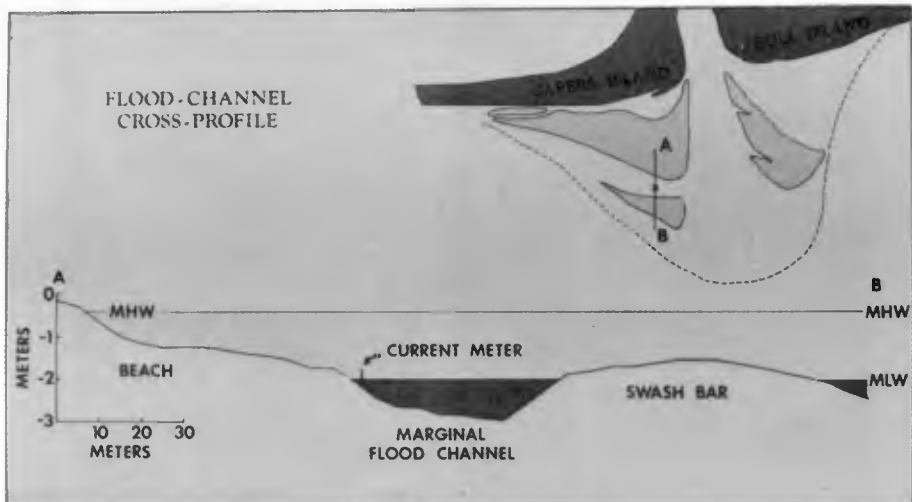

Figure 3: Plan and cross-section of marginal channel

The tripod mount holding the sensors was placed in this location near the time of low water and held onto the channel floor by lead weights placed in a cradle at the base of the tripod. Alignment of the sensor directions was achieved by sighting by eye along a range on the shore defined, from a theodolite survey, to be the across-channel direction; alignment accuracy was estimated to be approximately $\pm 5^\circ$.

Cables ran up the beach from the sensors to a telemetry system at the crest of the beach. This system consisted of a sealed aluminum canister about 2m high and 25cm diameter (designed also to be used as a surface buoy) containing batteries, an analogue multiplexing system for the six data channels and a low power transmitter. The buoy transmitted the data along line-of-sight to a receiving station and analogue data logger at some more convenient location. The receiving stations used in this experiment were either a hut with mains electricity about one km into the inlet or, more commonly for clarity of reception, a boat anchored in the channel throat on which car batteries were used as a power source. The analogue data were subsequently digitized at a sampling interval of 0.3 seconds for computer analysis.

An example of the velocity time series obtained with this system is shown in Figure 4. This record was taken during a flood tide, and a mean current of 62 cm/s in the flood direction has been removed from the along-channel velocity record. Positive velocities represent flood-directed, shoreward, and upward velocities respectively. The great irregularity in the flow is obvious from these records. The incoming waves broke at about 1m height on the margin of the swash platform but were reduced by multiple breaking over the platform to about 0.3m in height as they broke over the bar flanking the seaward side of the marginal channel. The larger of these waves, overtopping the bar, travelled obliquely shorewards in the channel with a large flood-directed component. These can be seen in the velocity records, for example between 38 and 50 seconds in Figure 4, as oscillations of both along-channel and cross-channel flow with a period of about 7 seconds. The time series of the product uv shows that these waves contribute large positive values to the flood-directed stress, for example at 38, 46, and 90 seconds. Superimposed on these waves are smaller higher frequency oscillations of velocity, probably caused by multiple wave crests refracted round the ends of the offshore bar and travelling in both ebb and flood directions along the channel. As is commonly observed in velocities from shoaling waves, the vertical velocity record appears much more spikey than the horizontal velocities, with a proportionally larger high frequency content (c.f. Huntley (in press)). This may in part be simply due to the smaller scale of the trace (peak of 0.25 m/s compared to 1.0 m/s and 0.75 m/s) but is also due to the sharp upward velocity peaks as the steep front of a shoaling wave passes. Notice also the presence of slow variations in the horizontal velocity records at periods much longer than observed wave periods.

Figure 4: An example of the velocity records

Table 1 summarizes the flow parameters measured in the southern marginal flood channel. The four runs numbered 12. were made between 17:40 hrs and 20:40 hrs local time on November 20th, 1977 during an ebb flow; the three runs numbered 13. were made between 12:50 hrs and 14:45 hrs on November 21st, 1977 during the flood flow. The elevation is relative to chart datum and was measured about 1 km inshore along the ebb channel by a U.S. Department of Commerce NOAA tide gauge. This gauge also was used to give the times of runs relative to high water shown in the second column of Table 1. A second tide gauge was also running on the seaward side of Bull's Island about 1km north of the sensor location. This gave a similar tidal record, with a time lead of only five minutes, so the horizontal distance between tide gauge and sensors was considered unimportant. For reference, the top of the flood channel bar was at about 0.95m above chart datum, so that overtopping was strong only for the records closest to high water. This is reflected in the values of standard deviation of the along channel flow shown in Table 1. The values are large only for runs 12.1 and 13.3. At lower mean water levels the standard deviation has become much smaller and surprisingly constant; these values are probably due predominantly to waves propagating along the channel.

Table of Flow Parameters, Southern Flood Channel, Price Inlet, S. C.

November 20/21, 1977

Run I.D.	Time from H.W. (Hrs Mins)	Elevation (m)	Mean Ebb Flow cm/s	Standard Dev. cm/s	Shoreward Horizontal Stress ₂ (cm.s) ²
12.1	+1h 30m	1.56	+ 60.5	72.4	-----
12.2	+2h 49m	1.07	+ 24.1	17.9	72.1
12.3	+3h 32m	0.84	+ 40.3	14.4	18.0
12.4	+4h 13m	0.60	+ 32.6	15.1	- 12.3
13.1	-4h 01m	0.69	-105.0	17.5	36.3
13.2	-3h 09m	0.98	- 70.5	18.8	109.4
13.3	-2h 25m	1.22	- 61.7	38.3	214.8

The mean flows shown in Table 1 are means over 15 minutes of record. Two things can be concluded from these means.

First, it is clear that they are all of the same order of magnitude as the standard deviations. Thus any current meter used to measure tidal flows at this point in the inlet, and presumably at other positions, must be capable of responding correctly to wave currents so that they can be averaged out of the velocity record properly. It is known that most slow response flowmeters cannot respond quickly enough to fluctuations, particularly of direction, under waves and will tend to rectify wave velocities, thus recording higher than true mean currents. This observation may therefore call into question previous measurements of flow in tidal inlets at locations where wave velocities are significant. In particular the large increase in wave velocities near the time of high water would cause slow-response flowmeters to overemphasise the skewing of maximum flood and ebb currents towards the time of high water (Fitzgerald et al 1977).

The second conclusion from these observed means is that, as expected from previous investigations, flood currents are very much larger than ebb currents at the same water level and time from high water. The tidal range for the ebb was 1.47m while that on the flood was 1.31m, suggesting that the difference in currents would be even greater for the same tidal ranges.

The last column of Table 1 shows the flood directed horizontal stresses uv due to the fluctuations, averaged over 15 minutes. Figure 5 shows these values plotted against tide height and it is clear that they are positive on both flood and ebb for most tide levels, which for these data ranged from about 0.3m to about 1.7m above datum. The radiation stress theory of longshore currents (Bowen 1969, Longuet-Higgins 1970) shows that these positive (flood directed) stresses, if interpreted as radiation stresses, would drive longshore currents in the flood direction in the narrow surf zone on the shoreward side of the flood channel. Estimates of the magnitude of these currents suggest that they reached about 1 m/s near high tide (c.f. Huntley 1977). We will see in the next section how we might estimate the importance of this predominantly surf-zone current to the mean flow in the main channel, seaward of the break point. The observation of larger values of stress on the flood than on the ebb is perhaps to be expected since refraction of incoming flood-propagating waves by the flood and ebb currents will cause this effect. It will not necessarily be reflected in larger longshore currents in the narrow shoreline surf zone where tidal currents are much smaller.

The observation of a negative value on the ebb tide is of some interest. Towards low tide the predominant wave activity in the channel was due to waves which were refracted around the ebb-channel end of the bar and which propagated up the channel in the ebb direction; flood-propagating waves were reduced by the longer shallow path around the opposite end of the bar. The presence of these ebb-propagating waves at this stage of the tide is of particular interest, as we shall see later.

WAVE EFFECTS ON THE MEAN FLOW

Clearly, with current data from a single point we are unable to study directly the importance of longshore variability of wave height in driving flood currents, although such variability clearly existed. Neither are we able directly to measure local mass transport effects since surface elevation measurements were not made along with the flow measurements.

In fact, separation of mean wave and tidal effects is in general going to be extremely difficult without extensive measurements covering a wide range of incident wave climates.

Figure 5:

Nevertheless, we might expect that any wave-driven component of the flow will show variations related to the "groupiness" of the wave record, i.e. to the envelope of wave velocities. This should be true in some sense for currents driven by a set-up gradient over the bar, for longshore current effects and for currents driven by non-local mass transport and set-up in waves propagating along the channel. We have therefore looked at the relationship between the low-passed portion of the along-channel flow and the time series of the envelope of the velocity fluctuations.

In spectral terms this involves dividing an initial spectrum of the alongshore flow (the upper trace of Figure 6) into two portions, using a Cartwright filter of 342 weights, with a half power point at a period of 15 seconds (Cartwright, personal communication). The lower trace in Figure 6 shows the same spectrum as the upper trace, but displaced downwards by an order of magnitude and divided into a low-passed and a high-passed portion. The high-passed portion contains, at each frequency, more than 99% of the spectral energy for periods shorter

than 12 seconds, and therefore includes the incident wave energy as well as the energy of higher frequency turbulent fluctuations. The low-passed portion, with the 99% level at 17.5 seconds, contains the longer period variability which may include wave-induced fluctuations as well as longer period turbulence. To obtain the wave envelope the high-passed time series was then squared and low-passed again with the same Cartwright filter.

Cross-correlation functions, the means of the product of two time series normalized by their standard deviations, were then calculated between the low frequency part of the original current record and the low frequency part of the wave envelope. These functions were calculated for different time lags between the two records to allow, in some average sense, for non-local forcing of the mean flow by the waves.

The result of these computations is, surprisingly, that all but one of the calculated cross-correlation functions have no significance at the 95% level for any time lag. Figure 7 shows an example of the cross-correlation function for run 13.1 and is typical of all runs except run 12.4. This result appears to suggest that wave forcing in the neighborhood of the sensors is of no importance in driving the mean flow under the wave conditions prevailing at the time of measurement. This does not, of course, preclude the possibility of purely local mass transport effects, but in view of the changing wave amplitudes along the channel this seems unlikely. Neither does it preclude the possibility that driving of the currents occurs at a location well removed from the sensor position and that wave breaking, dispersion and interaction destroys the relevant wave groups by the time they reach the sensors, but this too seems unlikely, particularly near high tide when the marginal channel is deep and relatively unobstructed.

Figure 6: Dividing a spectrum into low and high frequency parts.

Figure 7: --- Run 13.1
 ——— Run 12.4.

The one exception, showing significant correlation, is run 12.4. Figure 7 shows that the cross-correlation function has a correlation which rises to about 0.44 when the envelope of the waves leads the current by about 9 seconds. Pre-whitening of the time series before forming this function, in the manner prescribed by Jenkins and Watts (1968), reduces the correlation somewhat (to about 0.26), but does not effect the conclusion of significance at this time lag. Cross-spectra between the original time series and the envelope of the high frequency fluctuations were also calculated to see whether significant correlation existed over a broad low frequency band or was confined to a narrow band. Again significant correlation was only found for run 12.4 and at periods longer than about 40 seconds. Figure 8 shows a section of the time series for 12.4; although the calculated correlation coefficient is small, it is nevertheless possible to see correlation between the two lower records, as indicated by the fine diagonal lines.

Run 12.4 is the run at the low-tide end of the ebb current sequence which gave the ebb directed radiation stress shown in Figure 5. In fact, the positive sign of the correlation between wave envelope and current suggests that a large wave group, propagating in this case in the ebb direction, drives an enhanced current in the ebb direction, though the significance of the time lag is not known.

SI244 MEAN FLOW = 0.33 m/s EBB

Figure 8: Time series showing correlation between low frequency velocities and the high frequency envelope.

DISCUSSION

It is interesting that wave effects seem to be generally of negligible importance to the mean flow at the measuring point. The significant longshore currents suggested by the calculated stress values must presumably be confined to a narrow region in the vicinity of the surf-zone at the shoreline, and be of no importance at the sensors, except perhaps close to low tide. Surprisingly, the effect of a longshore gradient of wave set up along the outer bar is also probably small; no wave effect in the low-passed flow is observed even when the water level is sufficiently high for significant breaker energy to propagate over the bar into the marginal channel.

Laboratory tests of the "wave pump" effects of set-up and mass transport (Bruun and Viggisson 1973, Bruun and Kjelstrup 1978) show that they are critically dependent on the geometry of the channel along which the waves propagate and on the breaking or non-breaking of the waves. Largest currents are generated when waves propagate directly along a rapidly converging shoaling channel into a basin or channel of constant or increasing depth ahead, and when waves are near to breaking or are spilling. For most of our runs in the southern flood channel none of these conditions seem to have applied. For waves from the flood direction the marginal channel converges very slowly and, except at the entrance, has a relatively flat bed. In addition, since dominant waves approach from the north-east, waves entering the southern flood channel have been refracted a great deal and are therefore relatively small.

However, for the one run that does show some significant correlation, waves from the ebb-channel propagated into the rapidly converging and shoaling mouth of the marginal channel before passing over the sensors a short distance into the channel, and these conditions seem to fit those for wave pump effects quite well. Thus, despite the predominantly null results from these data, it does seem that waves might be important in the marginal flood channels of an inlet if the topographic and wave conditions were right. In fact, the northern marginal channel of Price Inlet has a rapidly converging and shoaling topography at its seaward end (Figure 2) and wave refraction diagrams (e.g. Fitzgerald et al 1977) suggest that waves would propagate much more readily into this channel. Wave effects on the flood dominance of this channel may therefore be much more significant than in the southern marginal channel. Further work is underway to test this idea.

ACKNOWLEDGEMENTS

The help of Rob Holman and Mendel Spencer from Dalhousie, and Tim Kana and others from the Geology Department of the University of South Carolina was vital to the success of this project. Logistic support was provided by the Coastal Research Division, Department of Geology, University of South Carolina, directed by Miles O. Hayes. Mrs. E Magwood and her family generously allowed us to use her home during the field work.

Financial support for the project came from grants from the Army Research Office, administered by the University of South Carolina (DN), and from the Canadian National Research Council (DAH).

CHAPTER 78

Periodic Flows from Tidal Inlets

by D.L. Wilkinson *

Introduction

A study was undertaken of the flow produced in the offshore region by tidal currents at the entrance of a coastal inlet. The gross features of the offshore flow structure were examined in an idealised two dimensional model in which a sinusoidally reversing flow was discharged from an open channel into a large stagnant basin. During each period of ebb flow, the discharge from the simulated inlet developed a structure very similar to that of a starting jet, and a vortex pair was observed to form and ultimately became the dominant feature of the flow. Although variable bottom topography and long shore currents will distort the flow pattern, the rotational motions observed in these experiments would be expected to persist.

The study was restricted to coastal inlets in which the sectional area of the entrance channel is several orders of magnitude smaller than the area of water surface inside the inlet.

Length and Time Scales of the Flow

The flow under study is shown schematically in Figure 1.

Figure 1: Schematic diagram of outflow from inlet

* Senior Lecturer, The University of New South Wales, Australia.

A periodically reversing flow passed through the entrance channel which joins to a large basin. The depths in the basin and the channel are uniform and the same. The flow per unit depth Q varies with time t according to the relationship

$$Q = Q_0 \sin \frac{2 \pi t}{T} \tag{1}$$

where Q_0 is the maximum flow rate and T is the tidal period.

It is well known that steady jets conserve axial momentum and that no characteristic length scale can be ascribed to them. However, if the strength of the jet is periodic with period T , it can be readily shown that a characteristic length scale exists for the motion. A periodic two dimensional jet at high Reynolds Numbers is fully defined by m_0 the maximum value of the momentum eflux, the period T , the width of the entrance channel w_0 , and the fluid density ρ . The momentum flux m_0 is given by

$$m_0 = \frac{\rho Q_0^2}{w_0} \tag{2}$$

The variables m_0 , T and ρ can be combined to give a characteristic length l which is now defined as

$$l = \left(\frac{1}{\rho} m_0 T^2 \right)^{1/3} \tag{3}$$

This is the appropriate length scale by which the structure of the flow may be described. Experiments have shown that l is of the order of the jet size, one period after the commencement of the ebb flow.

Any other flow parameter, for example the breadth b of the jet, at time t and distance x from the entrance, can be expressed non-dimensionally as

$$\frac{b}{l} = \text{fn} \left(\frac{x}{l}, \tau, \frac{w_0}{l} \right) \tag{4}$$

where τ is the normalised time t/T .

It is well established that the structure of steady jets is independent of the initial velocity structure at distances of 20 or more source widths downstream of the discharge point. Turbulence resulting from Kelvin-Helmholtz type instability in the shear zone, spreads in a direction normal to flow and destroys any initial structure. A similar situation can be expected to exist in the periodic jet provided the dimensions of the inlet are small compared with the size of the flow structures which develop. That is the ratio w_0/l must be small. This being so, it can be expected that periodic jets will have a general structural similarity at similar non-dimensional times.

Experiments

Experiments were conducted with three aims in mind:

- (i) To examine the basic structure of the flow and to check that the characteristic length as defined in Equation (3) was the appropriate scaling parameter.
- (ii) To examine the significance of the entrance width ratio on the normalised flow structure.
- (iii) To determine the proportion of the flow which returns to the inlet having been discharged on the previous ebb tide.

The experiments were performed in a tank 5m square and filled to a depth of approximately 100mm. The width of the entrance channel ranged from 25mm to 97mm and the maximum tidal velocities ranged from 30mm s^{-1} to 110mm s^{-1} in the different experiments. Reynold's numbers in the entrance were never less than 4000 at peak outflow. The periodic flow was achieved using the system shown in Figure 2.

Figure 2: Periodic flow generator

A constant flow Q_0 was discharged through a vertical manifold at b. A flow Q_a was drained from a location a and this flow was regulated by means of a motor driven valve to produce the flow $Q_a = Q_0(\sin 2\pi\tau - 1)$, that is, the withdrawn flow varied sinusoidally between 0 and $2Q_0$. The difference between the flows at a and b discharged into the model ocean and this flow varied sinusoidally between $-Q_0$ and $+Q_0$. The

tidal period used in the experiments was constant at 60s.

It will be noted with this system geometry, the ebb flow can only originate from Q_b and this flow was tabled with a very weak electrolyte solution so that concentrations of water originating from the inlet could be monitored in the ocean by means of conductivity probes. The addition of the electrolyte produced no detectable density stratification in any part of the model.

Structure of the Flow

The photographs in Figure 3 show the structure of the flow at dimensionless times $\tau = 0.25, 0.50, 0.75$ and 1.06 corresponding to

Figure 3: Structure of the flow at various phases

maximum ebb flow, low slack water, maximum flood flow and shortly after high slack water. The structure is revealed by means of streaklines observed by a stationary camera exposed for a time $\tau = 0.03$ (2 seconds). Water originating from the inlet was dyed in these experiments and shows as lighter coloured areas in the photo-

graphs. The grid scale consists of 200mm squares.

The entrance width ratio in this experiment was $w_0/l = 0.02$ which may be considered as small. The first photograph (a) shows the flow when the ebb current in the entrance is a maximum. It will be seen that a vortex pair has formed and is symmetrically placed about the entrance channel. Note that most of the circulation at this stage involves ocean fluid and is uncontaminated with water discharged from the inlet. This implies that the vortical motion is largely irrotational since vorticity can only be introduced from the shear layers at the boundary of the jet.

As time progresses, each vortex is spun up at a rate equal to the moment of momentum of the half jet and in photograph (b) taken at low slack water it will be observed that the areal extent of the vortices has increased and because of their mutual interaction they have moved further away from the entrance. Note also that because of the interaction, velocities are a maximum midway between the two vortices and that the symmetry observed in the previous photograph is no longer apparent. This results from the interaction of the present vortex pair with pairs formed during previous tidal cycles. In photograph (c), taken at maximum flood flow, the vortices are so distant from the entrance that the flow reversal has minimal effect on their motion. It can also be seen that the major portion of the fluid discharged from the inlet on the ebb cycle is now contained within the vortices which continue to move seawards. Photograph d was taken just after high slack water. The new ebb flow has just commenced to flow from the entrance and the vortices from the previous cycle are still clearly visible.

Profiles of the dyed inlet fluid normalised with respect to the characteristic length are shown at several stages of the tide in Figure 4. The physical value of the length scale was different in each of these experiments and the collapse of the data confirms that the scale formulation of Equation (3) is valid. Furthermore, the value of the inlet width ratio in each of these experiments was different but always less than 0.05. This suggests that like steady jets, the structure of periodic jets is independent of the entrance conditions provided the characteristic length of the flow is large compared with the dimensions of the entrance.

Figure 5 shows the normalised velocity structure of the flow at various tidal phases. The velocity maxima was found to always occur between the two vortices, and the distribution of the axial velocity component along a line joining the centres of the vortices at time $\tau = 0.5$ suggests that the flow could be modelled by a pair of interacting Rankine vortices.

It is not evident in the photographs; however, on the flood tide, the flow into the entrance was found to be very similar to that predicted

Figure 4: Normalised flow profiles for small values of $w_0/1$

Figure 5: Normalised velocity profiles of ebb flow

by potential flow theory. The flow was radially uniformly distributed about the entrance, and consequently the ocean area affected by the flood tide was very much less than that affected by the ebb tide.

Significance of the Inlet Width Ratio

It has been shown that provided the inlet width ratio is small (less than approximately 0.05), the structure of periodic jets is similar at any given value of the tidal phase. It remains to determine how valid this condition will be in real inlets. It is well established in many tidal inlets that the sectional area of the entrance channel, A , is in almost linear proportion to the mean tidal prism, P (O'Brien 1931). The constant of proportionality in the relationship is found to have a value of approximately $6 \times 10^{-5} \text{ m}^{-1}$ so that

$$A = 6 \times 10^{-5} P \quad (5)$$

In terms of the two dimensional model

$$\begin{aligned} A &\doteq w_0 \\ \text{and } P &\doteq \int_0^{T/2} Q \, dt = \frac{Q_0 T}{\pi} \end{aligned} \quad (6)$$

However, Equations (2) and (3) give

$$Q_0 T = (w_0 l^3)^{1/2} \quad (7)$$

which on substituting into Equation (5) gives

$$\begin{aligned} w_0 &= \frac{6 \times 10^{-5}}{\pi} (w_0 l^3)^{1/2} \\ \text{or } \frac{w_0}{l} &= 4 \times 10^{-10} l^2 \end{aligned} \quad (8)$$

Hence the entrance ratio can only be considered small for inlets with characteristic lengths of approximately 10km or less. This corresponds to tidal prisms of up to a maximum of $2 \times 10^7 \text{ km}^3$ where d is the mean depth of the entrance channel.

The effect of increased entrance width ratio can be seen in Figure 6 where normalised ebb profiles, as defined by dyed fluid emerging from the inlet, are shown for w_0/l ratios of 0.02 and 0.15 at dimensionless times $\tau = 0.25, 0.50$ and 0.75 . The breadth of the ebb discharge is appreciably greater for flows having higher entrance width ratios and this is particularly true in the immediate vicinity of the entrance channel. Therefore it is to be expected that the fraction of water returning to the inlet on the flood tide will increase as the entrance width ratio increases in value.

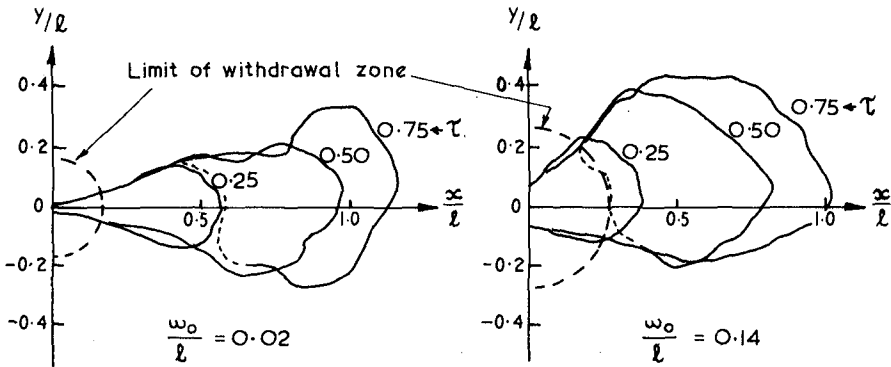

Figure 6: Effect of entrance width on the flow profiles

A further effect reinforces the above trend. The tidal prism P can be used to define a radius of withdrawal R at the channel entrance so that

$$\frac{\pi R^2}{2} = P \tag{9}$$

However, the tidal prism can be expressed in terms of l via Equations (6) and (7) to give

$$\frac{R}{l} = \frac{\sqrt{2}}{\pi} \left(\frac{w_0}{l} \right)^{\frac{1}{4}} \tag{10}$$

Thus the extent of the withdrawal zone increases as the entrance width ratio increases. The limits of the withdrawal regions for the two experiments shown in Figure 6 are indicated by the semi-circles encompassing the entrances.

It is apparent in Figure 6 that the fraction of water which returns to the inlet on the flood tide, having been discharged on the preceding ebb, will increase as the entrance width ratio of the inlet increases. This trend is clearly shown in Figure 7 where the fraction of returning water in the flood flow is plotted against tidal phase. These data were obtained by means of conductivity probes located in the entrance channel which detected the concentration of electrolyte labeled fluid in the incoming flow.

The flushing capacity of an inlet reduced as the entrance width ratio of the inlet increased. This is clearly demonstrated in Figure 8 which shows the fraction of water which returns to an inlet as a function of the entrance width ratio of the inlet. Equation (8) indicates that the flushing ability will reduce as the tidal prism increases for inlets con-

forming to the O'Brien relationship.

Figure 7: Fraction of water recycling on flood tide as a function of tidal phase

Figure 8: Fraction of inlet water returning on subsequent tide as a function of the entrance width ratio

Bottom Friction

It is to be expected that, in real estuaries, where the water depth would be relatively much less than in the experiments described here, the effect of bottom friction would be proportionately greater.

A measure of the importance of friction in real estuaries may be had by comparing the impulse (I), applied to the flow by bottom friction in one tidal period, with the total momentum M discharged from the inlet on the ebb tide. Thus

$$I = \int_0^T \int^A \frac{\rho g u^2}{C^2} dA dt$$

and
$$M = \int_0^{T/2} m d dt$$

in which C is the Chezy friction coefficient, A is the plan area of the flow associated with the discharge between times t = 0 and T = T, u is the axial velocity component within that area and d is the mean depth of the entrance channel.

Values of the impulse and total momentum can be expressed in terms of the characteristic variables, and the orders of magnitude of these two terms are

$$I = O \left[\frac{g}{10C^2} \left(\frac{1}{w_0} \right) \rho \frac{l^4}{T} \right]$$

and
$$M = O \left[\frac{d}{l} \frac{1}{w_0} \rho \frac{l^4}{T} \right]$$

Thus
$$\frac{I}{M} = O \left[\frac{g}{10C^2} \frac{1}{d} \right]$$

For a typical inlet in which

$$\frac{1}{d} = O [10^3]$$

and Chezy 'C' = 50 m^{1/2} s⁻¹

$$\frac{I}{M} = O [10^{-1} \text{ to } 1.0]$$

Thus substantial frictional effects could be expected in the prototype situation. These would be apparent in the far field (say for X/l > 0.5) where bottom friction will have done more work on the flow.

Conclusions

The off-shore flow structure at a tidal inlet resembles a starting jet during the period of ebb flow, and a potential flow during the flood half of the tidal cycle. The flow pattern is periodic and can be described non-dimensionally in terms of length and time scales based on the maximum value of the momentum flux emerging from the inlet and the tidal period.

The flushing capability of the inlet decreases as the normalised width of the entrance reduces in value.

Real inlets rarely conform to the idealised two dimensional conditions considered in this paper. Bottom friction will exert an appreciable influence on the flow particularly at distances of the order length scale. The offshore slope will also affect the motion tending to increase the angular speed of the vortices while diminishing their size. In spite of these influences, the basic structures observed in the experiments described here could be expected to persist in prototype situations.

Acknowledgements

The author would like to thank Mr. C.A. Miller for suggesting the means of obtaining the periodic flow and to Mr. R.B. Tomlinson for his assistance with the experiments.

THE EFFECT OF OFFSHORE DREDGING ON COASTLINES

W A PRICE J M MOTYKA
AND L J JAFFREY

1. Introduction

The South of England is well endowed with land deposits of river gravel and sand. Nevertheless, the demand for aggregate and the need to conserve agricultural land have increased to the point where in 1976 sea dredged aggregate was accounting for 11% of the total sand and gravel production. In addition to this annual home consumption of about 12 million tonnes of dredged aggregate a further 3.5 million tonnes was exported to Europe in 1976.

Understandably, authorities responsible for coast protection and sea defence view the increase in the removal of marine deposits with concern and a system of licensing by the Crown Estate Commissioners who are responsible for the sea bed from high water to the UK Continental shelf limit has been developed over the years. Dredging by port authorities within their area of jurisdiction, for navigational purposes, is outside this licensing system. Within the three mile limit local authorities have powers under the Coast Protection Act to regulate dredging.

In 1976 a report by an advisory committee to the Department of the Environment⁽¹⁾ recommended, among other things, that further studies should be carried out by HRS aimed at reviewing the existing constraints on marine dredging for gravel. In general, the material which is sought for construction purposes is a 60% shingle, 40% sand mixture, but sand is also needed for reclamation fill and for industrial purposes. The areas dredged at present are shown in Figure 1.

This paper deals briefly with the licensing procedure and at some length with the involvement of the Hydraulics Research Station in assessing how dredging might affect the coastline. The effect on fisheries, navigation, coastal ecology, and other interests is considered by other organisations.

Very little is known of the criteria applied to offshore dredging by other countries, apart from Germany, but with the increased exploitation of the sea bed it is important that information gained by other countries should be used to improve our existing criteria.

2. Consultation Procedure

The licensing system for offshore dredging in the United Kingdom started in 1963. It has now evolved to a stage where a licence is granted only after comprehensive consultations have taken place with many authorities.

After prospecting an area and proving the presence of suitable material the dredging company which is equipped with ships purpose built for gravel extraction submits an application for a licence to the Crown Estate Commissioners to dredge a defined area at a given rate. The Hydraulics Research Station is then asked to give an opinion on whether dredging at the stated rate is likely to effect the adjacent coastline. The questions to be considered and the studies which have assisted in providing some answers are dealt with later in the paper but if our opinion is unfavourable i.e. if damage may result, then the licence application is unlikely to proceed further.

Senior Principal Scientific Officer, Higher Scientific Officer and Principal Scientific Officer respectively at Hydraulics Research Station Wallingford UK

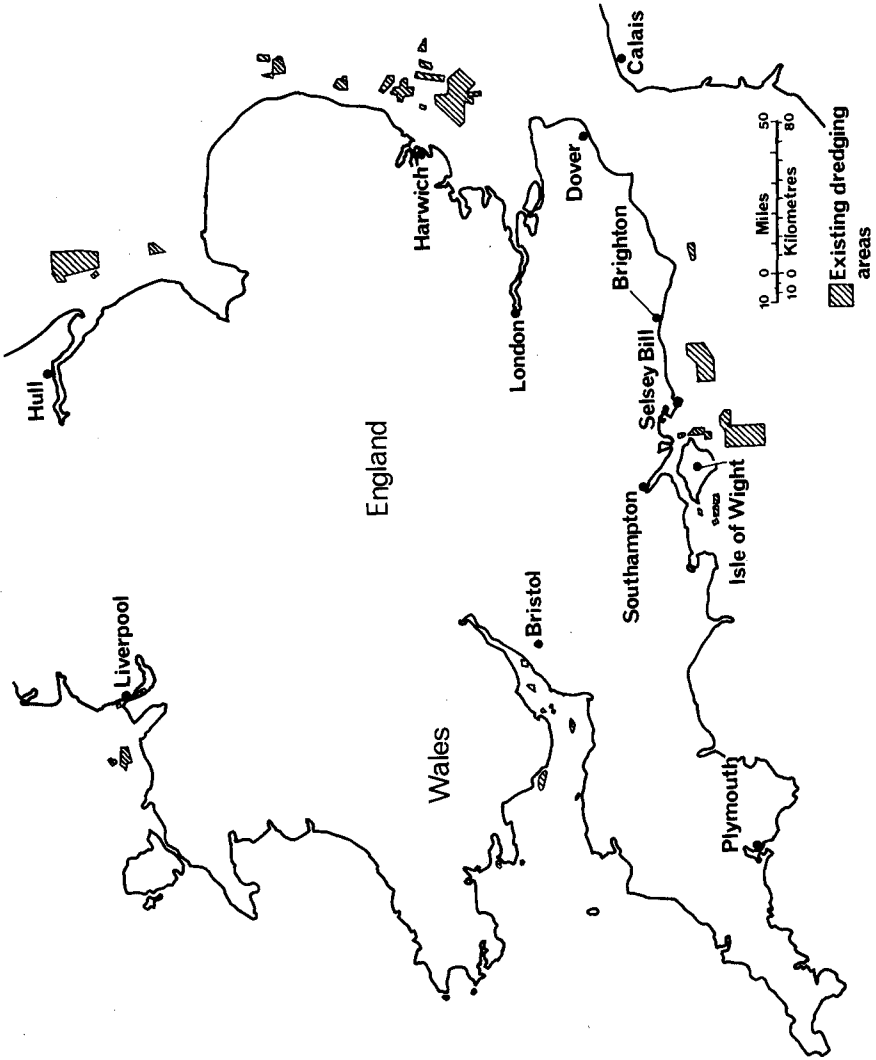

Fig.1 Map showing location of areas dredged

If, on the other hand, we consider that coastal changes will not take place then the following bodies are consulted:—

Department of the Environment (Coast Protection and Petroleum Division)
Ministry of Agriculture, Fisheries and Food (Fisheries Laboratory)
Department of Trade (Navigation)
Post Office (Marine Division)
Local coast protection authorities
Regional Water Authorities

These opinions are received by the Construction Industry Directorate of the Department of the Environment and a view on the issue of a licence is prepared after considering the interests of all parties. There is no right of appeal against a decision. In practice, now that the HRS guidelines are well known and with some measure of early discussion the submission of unreasonable applications is unlikely. Finally a licence is issued by the Crown Estate Commissioners who have the right to levy a charge on each ton of material landed.

3. Evaluation of Proposal by Hydraulics Research Station

In forming an opinion on a licence application HRS aims to answer the following questions:—

- (1) Is the area of dredging far enough offshore so that beach drawdown into the deepened area will not take place?
- (2) Is the dredging to be carried out in deep enough water so that it will not affect possible onshore movement of shingle?
- (3) Does the dredging area include bars and banks which might provide protection to the coast from wave attack?
- (4) Is the area to be dredged sufficiently far offshore and in deep enough water that refraction of waves over it will not cause significant changes in the pattern of alongshore transport of bed material?

Collection of data. A limited amount of information on sea bed levels and tidal currents is available from published Admiralty charts although various other sources are also used for additional information. However, unless an area has been the subject of particular study, the movement of bed material in the zone from low water to say, a depth of 20m, is difficult to quantify, although the general direction of movement can usually be inferred. Such measurements, particularly over a wide area and extending several kilometres offshore, would be extremely difficult to carry out and would almost certainly require time-consuming and high cost radio-active tracking techniques. It is possible that, if the demand for gravel continues to grow, areas where the effects of dredging are difficult to establish may have to be critically re-examined. In such cases a detailed investigation of material movement would be necessary for each particular licence application.

For most of the present applications that we receive, however, existing guidelines are adequate for assessing the effects of dredging on the coastline. These guidelines are

described below. The research carried out at the Station for the development of some of these guidelines is described in the next section, 4.

Beach Drawdown. This usually occurs during storms due to the action of high steep waves. Beach material is eroded from the upper foreshore and moved seawards. However, during periods of calmer weather the material is returned to the beach by long low swell. If the dredged area is too near the coastline then this dynamic equilibrium can be upset; in that material may be transported from the upper portion of the beach into the dredged hole and erosion of the foreshore may result. Some of the most comprehensive information concerning the seasonal offshore—onshore interchange of sand has been recorded by Inman and Rusnak off La Jolla, California⁽²⁾. Observations of sea bed levels were made by divers equipped with scuba who installed a series of rods at water depths of 1.8, 5.5, 9.1, 15.8 and 21.3 metres. The change in sand level at the reference rods was measured over a period of three years. The most inshore site provided very little useful information since the rod was usually completely buried. The rod at a depth of 5.5 metres showed large fluctuations in sea bed level but was lost after a short time, after a period of erosion. In water depths of 9.1 metres or more the vertical variation in level was only ± 0.03 metres or so. At the deeper stations, any seasonal trends were so small as to be masked by fluctuations of a shorter period. From this work it would appear that the active zone of offshore—onshore movement extends to 9.15m, say 10 metres, and beyond this depth seasonal movement takes place intermittently.

Most of the licences are issued for areas on the South and East coasts of the United Kingdom (Figure 1). The wave climate in these areas is certainly less severe than that at La Jolla, California and therefore we believe that dredging in water depths of 10 metres or more will not result in beach drawdown into the dredged hole due to seasonal changes in onshore—offshore movement.

In exceptional circumstances, even this criterion can sometimes be relaxed. For example in the case of beach nourishment from within the 10 metre contour, a redistribution of littoral material takes place but there is no actual loss incurred. Monitoring of beach nourishment projects by Watts, of the US Army Corps of Engineers⁽³⁾ has shown that dredging has been carried out as close inshore as 300 metres with no apparent detriment to the shoreline. Surveys of the borrow pits have shown a general infilling with silt sized material which normally would settle out further offshore. An increase in the proportion of fines can be undesirable from an amenity or fishery point of view and the Station recommends that dredging should not take place within twice that distance from the shoreline, namely 600 metres.

Thus, with respect to beach drawdown there are two criteria — a minimum depth of 10 metres and a minimum offshore distance of 600 metres. These considerations are applied usually to small scale or short term operations for winning sand for beach nourishment or for land reclamation purposes. For the majority of licences which involve longer term working of shingle deposits, a more severe criterion is applied. This is discussed under the next heading.

Interception of sediment. If the beach is being fed from offshore by current and wave action then dredging may trap a proportion of this material and interrupt the supply to the shore. It is very important therefore that dredging should be excluded from any deposits which are moving actively. Research into the threshold of movement of material by waves

and tidal currents forms an important and continuing part of the Station's programme. The first investigations were made using radio-active labelled shingle. The movement of this material was tracked at a number of water depths off Worthing, see next chapter. We concluded that shingle movement seaward of the 18 metre depth contour was negligible at all times. The present criterion therefore applied on the south and east coasts of the United Kingdom for the dredging of shingle is a minimum depth of water of 18 metres. Other ways of predicting the mobility of bed material are currently being pursued. Recently we have completed a study into the threshold of movement of shingle south-east of the Isle of Wight. Wave action and tidal currents here would appear to be strong enough to induce shingle movements in depths as great as 22 metres, see next chapter.

Protection by offshore banks. Offshore banks help to protect the coastline from wave attack either by dissipating wave energy as a result of bed friction, by partial breaking of the waves, by reflection or by any combination of these three. A permanent lowering of the crest of a bank due to dredging or indeed by natural means can result in changes of the wave refraction pattern and hence changes in the net angle of wave attack at the shoreline. Thus, under certain circumstances, dredging from offshore banks can alter the rate of littoral drift and hence affect the stability of the shoreline. Changes in wave refraction whether it be due to an overall lowering of the seabed or dredging from offshore banks are discussed under the next heading.

Where accretion on offshore banks has been well documented and where the coastline is sheltered from wave attack a limited amount of dredging is sometimes allowed. Dredging under such conditions is of course strictly controlled and is only considered on a short term basis. A desk study is first carried out to determine the wave height transformation by bed friction, refraction and shoaling using the method developed by Bretschneider and Reid⁽⁴⁾. The calculation of wave height is very dependent on the value of the friction factor f used in the calculation. Until the present time we have used the value of $f = 0.01$ adopted by Bretschneider for a sand seabed. The latest research from field work and model studies⁽⁵⁾ indicates that the value of the friction factor can be substantially greater than 0.01, and clearly further work is necessary before large values of f can be used with confidence.

Because of the uncertainty in the appropriate value of the friction factor to be used in wave height calculations, dredging of banks adjacent to the coastline is generally not allowed. The only exception to this rule is when the rate of accretion at the coastline is so high that any increase in wave activity and possible reduction in the rate of accretion would have no harmful effect on shoreline stability.

The effect of changes in wave refraction. As waves approach the shore they travel with a group velocity that is dependent upon their period and upon the depth of water. If the water depth increases locally, eg over a dredged hole, the velocity and wavelength change. The local increase in wave celerity due to the increased water depth causes changes in the angle of wave approach to the beach. Such changes result in a variation in the rate of littoral drift along the shoreline and can cause either accretion or erosion. An example of the result of such changes in wave approach took place in Botany Bay, Australia, where severe erosion followed a period of dredging within the Bay. Wave refraction diagrams were plotted showing the angle of wave approach to the beach. Changes in wave angle agreed closely with positions of beach erosion. A beach mathematical model has been developed by Hydraulics Research Station⁽⁶⁾ and is used to predict changes that could occur from offshore

dredging. Results have shown that, in general, the effects of wave refraction are insignificant when dredging takes place in water depths greater than 14 metres. The study is described in the next chapter.

4. Research by HRS

Tracer study off Worthing. In 1968 the Hydraulics Research Station began an investigation, for the Crown Estate Commissioners, into the movement of shingle by using radio-active tracers. This experiment was carried out on the south coast of England off Worthing, some 15 kilometres to the east of Brighton, see Figure 1. The object of the study was to obtain quantitative data on the mobility of shingle under wave action in water depths of 9 to 18 metres. The area was particularly suitable for such a study – firstly, because a number of firms wanted to dredge there and had already applied for licences, and secondly because the bottom topography was uncomplicated and wave conditions were fairly typical of those in British coastal waters.

Previous investigations carried out by Kidson and Carr⁽⁷⁾ off Orfordness on the East Anglian coastline failed to show any significant movement of shingle even under severe weather conditions. The duration of these experiments however was short, 8 weeks or less. The dispersal of radio-active pebbles over this period was small, a maximum of about 50 metres and a minimum dispersal of about 30 metres. It should be noted that the seabed in this area consists of sand, silt or mud and it is possible that the movement of the pebbles was hampered by burial within the soft surface layer.

In the HRS investigation the sea floor was first examined by divers and then radioactive tracer pebbles were placed at mean water depths of 9, 12, 15 and 18 metres.⁽⁸⁾ This operation was carried out in mid-September 1969 and the pebble movement was tracked over a period of 20 months. Wave observations from the Owers Light Vessel, situated off Selsey Bill, were used to relate the rate of movement of shingle to the prevailing wave conditions.

The results clearly demonstrated an increase in shingle mobility with decreasing water depth and also showed the existence of a small net landward movement of shingle inshore of the 12 metre contour. However, even at the inshore sites, in depths of water of 9 metres and 12 metres the quantities of shingle moved towards the shore were very small. The centroid shifts at these two sites indicated that the average pebble would take about 200 years to advance 3 kilometres shorewards from the 12 metre to the 9 metre contour.

It was concluded from the results of this study that the movement of shingle beyond the 18 metre depth contour on the South Coast will be negligible at all times. On this basis, therefore, the Station recommends that dredging of shingle should not take place in depths of water less than 18 metres below low water level.

Numerical model of shoreline changes due to wave refraction over dredged areas. A study financed partly by the Crown Estate Commissioners has been made on the effects that offshore dredging may have on shoreline changes. The Station's wave refraction computer program⁽⁹⁾ was linked to a beach mathematical model⁽⁶⁾. Predictions were made of changes in the plan shape of an initially straight shoreline due to changes in the height and the direction of the waves at breaking. The beach mathematical model is based on the reasoning that the alongshore sediment transport rate is a function of the wave height and

the angle between the breaking wave crest and the beach. For a given set of deep water wave conditions these variables can be easily calculated by the use of the wave refraction program. In the beach mathematical model the following operations are carried out:—

- (1) From the data obtained from the refraction program calculate the wave height and angle at breaking.
- (2) Calculate the rate of alongshore sediment transport rate using the Scripps equation as modified by Komar.⁽¹⁰⁾
- (3) Having determined a stable time step calculate the amount of accretion and erosion from changes in the rate of littoral drift. Distribute these changes over the inshore seabed.
- (4) Return to the wave refraction program to recalculate the input wave conditions i.e. go to (1).

Preliminary results from this study were presented at the 14th Coastal Engineering Conference in Copenhagen, Denmark⁽¹¹⁾. The model showed that the shoreline erosion decreased very rapidly as the area of dredging was moved offshore into deeper water. At this stage it was prudent to “err” on the safe side and we stated that the effects of wave refraction were insignificant in water depths greater than 18 metres in British Coastal Waters. However more work was needed to define the amount of shoreline erosion for different depths of dredging.

After further tests we now consider that the effects of wave refraction are insignificant in water depths of 14 metres or more. Our report to the Crown Estate Commissioners was published in April 1976⁽¹²⁾. This report shows that the mean shoreline erosion plotted against water depth is approximately an exponential curve with the asymptote occurring at 18 metres or so. However for all depths of dredged hole the difference in erosion due to dredging at 14 metres and at 18 metres is negligible. Inshore of the 14 metre depth, erosion was significant even for the shallowest depth of dredging tested (1 metre).

The effect of hole length was investigated for a 4 metre depth of dredging (dredging to greater depths is not generally considered). An increase in hole length, parallel to the shore resulted in a small but measurable increase in erosion. The shoreline recession was found to increase at the rate of about 1.4 metres for every kilometre increase in the length of the dredged hole. For depths of dredging shallower than 4 metres the effects of wave refraction were reduced and hence recession increased more slowly with increased length of hole. These tests were carried out inshore of the 14 metre depth contour. Beyond this depth, these effects can be considered insignificant.

All the results show that the water depth over the dredged area is the controlling factor for any particular wave climate tested. In British coastal waters dredging is not allowed shoreward of the 18 metre contour on sediment supply considerations. This mathematical study shows that a 14 metre depth limit is quite acceptable so far as wave refraction effects are concerned. At present we do not generally allow dredging between the 14 metre and 18 metre water depth. However, if all other criteria are satisfied then we might under some circumstances allow dredging closer inshore than at present.

Movement of shingle under waves and tidal currents. The studies with radioactive tracers off Worthing established a depth limit for no movement under wave action but with weak currents. There are areas where contractors would like to dredge, where currents as well as wave action contribute to the initiation of sediment movement. Such an area is off the Isle of Wight on the South coast of England. If the beaches at the adjacent coastline are being fed from offshore by current and wave action then material might be trapped in the dredged areas and the onshore supply of shingle interrupted. It is necessary to develop new criteria to help decide whether a dredging licence can be granted.

There were two parts to the studies designed to establish a criterion now to be described. A theoretical approach was developed to calculate the shear stress at the seabed due to the combined action of waves and tidal currents. The shear stress was then used to predict the threshold of movement of shingle using a modified form of the Shields curve. Also a field study was carried out to measure the strength of tidal currents south-east of the Isle of Wight — an area of high dredging potential. It was therefore possible to apply the criteria established theoretically to a practical case.

The shear stress due to tidal currents alone was calculated using the Karman–Prandtl velocity profile equations. Using Prandtl's mixing length hypothesis the velocity distribution can be written as:—

$$U = \left[\frac{\gamma_c}{\rho} \right]^{1/2} \cdot \frac{1}{K} \cdot \log_e \left[\frac{33y}{Ks} \right] \quad \dots (1)$$

where U = velocity measured at 0.4 of the water depth (m/s)

γ_c = shear stress exerted at the bed by the current flow (N/m^2)

ρ = density of sea water (kg/m^3)

K = Von Karman's constant, the value taken was 0.4

y = water depth at the height of the current velocity meter (m)

Ks = Nikuradse roughness parameter

The maximum bed shear stress due to wave action was calculated using Jonsson's wave friction factor $f_w^{(1,3)}$. The maximum shear stress being related to the wave conditions by the equation:—

$$\gamma_w = \frac{f_w}{2} \cdot \rho \cdot U_m^2 \quad \dots (2)$$

where γ_w = maximum bed shear stress (N/m^2)

f_w = wave friction factor, a function of the sea bed roughness and the wave conditions

ρ = salt water density (kg/m^3)

U_m = maximum horizontal wave orbital velocity (m/s)

The maximum orbital velocity was found from small amplitude sinusoidal wave theory, and was then used to calculate the water particle displacement at the seabed i.e.

$$A_m = \frac{U_m \cdot T}{2\pi} \quad \dots (3)$$

where A_m = maximum particle displacement (m)

T = wave period (s)

The value of f_w in equation 2 was found from the Jonsson friction diagram where it is plotted against the relative roughness of the seabed A_m/K_s .

So far we have considered the shear stress exerted near the seabed by tidal currents and wave action acting independently of each other. The combined shear stress was determined by considering the general formula for fully turbulent flow

$$\gamma = \rho L \left[\frac{\delta v}{\delta y} \right]^2 \quad \dots (4)$$

where γ = shear stress (N/m^2)

L = Prandtl's mixing length (m)

v = velocity at a small height y above the bed (m/s)

Rearrangement of the equation gave :-

$$\frac{\delta v}{\delta y} = \left[\frac{\gamma}{\rho} \right]^{1/2} \cdot \frac{1}{L} \quad \dots (5)$$

Hence the combined maximum velocity δv at the outer edge of the viscous sublayer with thickness δy is:-

$$\delta v = \left[\frac{\gamma_c}{\rho} \right]^{1/2} \cdot \frac{1}{L} + \left[\frac{\gamma_w}{\rho} \right]^{1/2} \cdot \frac{1}{L} \quad \dots (6)$$

And substituting back into equation (4) we have:-

$$\gamma = \gamma_c + 2 \sqrt{\gamma_c \cdot \gamma_w} + \gamma_w \quad \dots (7)$$

The combined instantaneous maximum shear stress is greater than the straight addition of the shear stress due to waves and tidal currents. Madsen and Grant⁽¹⁴⁾ found that the Shields curve predicted the threshold of movement by waves if the boundary shear stress was replaced by the maximum value of the oscillatory shear stress. It would therefore seem reasonable to use this curve to predict the threshold under the combination of the two and this is the approach used here.

The method has not been checked under prototype or model conditions and further experimental work will be carried out to refine the method.

The field study consisted of tidal current measurements in mean water depths ranging from 16 to 29 metres. The observations were made with a Plessey M021 current meter held at 0.4 of the mean water depth by means of a moored submerged float. This instrument translated the readings of current strength and direction at 10 minute intervals onto a self contained magnetic tape recorder. The data was fed into an HRS computer program which calculated a number of tidal current parameters e.g. magnitude, duration, direction, directional scatter of the velocity readings.

A desk study was then carried out using the tidal current velocity information together with wave data from the nearby Owers Light vessel. This data was used to calculate the threshold of movement of shingle under the combined action of waves and currents using the theoretical approach described above.

Preliminary results from this study show that off the Isle of Wight the mobility of shingle is significantly increased by the action of tidal currents. It is not possible at this stage to give definite recommendations about the minimum depth of dredging. It would appear however that 25mm shingle for example is likely to be mobile in depths of water up to 22 metres. Further research by the Station will indicate whether the existing criterion of 18 metres applicable in areas of weak tidal action needs to be strengthened, and by how much.

5. Conclusions

1. An increasing amount of shingle is being won from the sea. This source accounts for some 11% of the total sand and gravel production in the United Kingdom. In the procedure leading up to the granting of a licence by the Crown Estate Commissioners, the first to be consulted is the Hydraulics Research Station. We are asked to say whether there is a possibility that dredging could affect adjacent coastlines. If the answer is "yes" the application is usually turned down; if "no" then other authorities are consulted. We attempt to answer a number of questions:

- (i) Is the dredging far enough offshore that beach drawdown into the hole cannot take place? The approximate limit for onshore/offshore movement off the South Coast of England is considered to be about 10 metres below low water and this is usually taken as the minimum depth to ensure that beach drawdown will not take place into the hole. We also have a limit in terms of distance offshore of 600 metres. This criteria is hardly ever invoked because it is usually over-ridden by other considerations.
- (ii) Is dredging to be carried out in deep enough water so that the hole will not intercept the onshore movement of shingle? Field tracer studies have shown that for the south coast wave climate and in regions of weak tidal currents shingle will not move in depths greater than 18 metres. A method of including the effect of tidal currents has been developed. We believe it errs on the safe side. As an example, the 18 metre criterion changes to 22 metres for a tidal current of 1.1 m/s. However it is stressed that the method is at an early stage of its development.

- (iii) Does the dredging area include banks which if removed would increase wave activity at the shoreline? In this case it is usual for the application to be turned down. There are exceptions under special conditions. If for example it can be shown that the beach is well protected from wave attack, eg by a very wide fore-shore, then dredging of a limited quantity of material under controlled conditions may be allowed. For such special cases a desk study is carried out by HRS.
- (iv) Is the area sufficiently distant from the shore and in deep enough water so that changes in wave refraction over the dredged area do not lead to changes of littoral transport at the shoreline and hence changes in beach plan shape? A beach mathematical model developed at HRS has shown that in general the effects of wave refraction are insignificant when dredging takes place in water depths greater than 14 metres.

6. Acknowledgements

This paper represents years of effort on the part of many people working both on demanding field studies and physical processes. Although their names were not included as authors we would like to thank Dr A H Brampton, Mr M J Crickmore and Mr M W Owen for their considerable contributions to the studies. We appreciate the assistance of the Crown Estate Commissioners in sponsoring some of the studies and especially we wish to mention Mr John Edwards for his support and encouragement.

This paper is published with the permission of the Director of Hydraulics Research Station, Wallingford, England.

CHAPTER 80

SURF ZONE RESONANCE AND COUPLED MORPHOLOGY

JOHN CHAPPELL Department of Geography, School of General
 Studies, Australian National University,
 Canberra, A.C.T., Australia.

LYNN DONELSON WRIGHT Coastal Studies Unit, Department of
 Geography, University of Sydney, Sydney,
 Australia.

ABSTRACT The edge wave hypothesis for periodic inshore morphology and circulation is tested for five beaches and is supported by resulting wave-current spectral and cross-spectral data. Beach types range from a reflective, narrow surf zone, case through various dissipative medium to high energy beaches including some with inshore bar-trough morphology and one broad surf zone troughless one. In all cases beachface reflectivity is moderately high ($E < 2.5$) and inshore resonance occurs, indicated by strong spectral peaks at lower than incident frequency with wave-current co-peaks being 90° out of phase. Several different edgewave frequency and mode combinations are indicated. The reflective beach shows an $n = 0$ subharmonic edgewave (*i.e.* at half incident wave frequency) which Guza and Davis (1974) predict as the most likely case, *viz.* the (0,0) triad. The troughless dissipative case shows a (1,0) edgewave triad; the same occurs in some bar-trough dissipative cases but in other cases is supplanted by the (0,0) sub-harmonic wave and/or by a lower subharmonic wave at $\frac{1}{2}$ incident frequency. The likelihood of a given edgewaveset appears to be regulated by surf friction, and a change of edge wave set appears likely to explain observed changes of inshore circulation.

INTRODUCTION Several models exist for periodic morphology and associated cellular circulation on surf beaches. We present detailed wave and current data which support the edge wave model in the context of rip cells on high energy sandy beaches, and which indicate that inshore morphodynamic patterns change in response to discontinuous change of edge wave mode and frequency. In what follows, we discriminate between two categories of periodic phenomena, rip cells and beach cusp cells on the grounds that rip cells occupy broad dissipative surf zones and can exist in several different morphodynamic states, whereas cusps essentially are intertidal phenomena on reflective beaches and vary in scale rather than in form. We note that cusps frequently coexist with rips, especially where a steep beach face lies behind the inshore trough of a broad dissipative surf zone.

When inshore morphology is rectilinear, initiation of periodic patterns requires periodic variation longshore of wave

height, so that inshore radiation stress gradients can force cellular circulation. Periodic wave height variation has been suggested to be due:

(1) to intersection of two wave trains originating by refraction offshore (*e.g.* Dalrymple, 1975); or (2) to inshore wave edges interacting with the incident waves (*e.g.* Bowen and Inman, 1969); or (3) to a periodic deformation of water surface due to instability in the radiation stress field (Hino, 1975). The refraction hypothesis may have local application, but the widespread occurrence of beach cusps under shore-parallel swell conditions argues against this as a universal mechanism. On the other hand, the existence of edge waves on natural beaches has been supported by analysis of inshore current spectra by Huntley and Bowen (1975), and Guza and Inman (1975) show that beach cusps are coupled with edge wave development. Theoretical argument for edge wave initiation of rip cells was developed by Bowen and Inman (1969), but has been criticised by Hino (1975) - the proponent of the radiation stress instability theory - on the grounds that excitation of sufficiently large edge waves is improbable in a dissipative broad surf zone.

However, Guza and Davis (1974) show that edge wave excitation through resonance with incident waves is possible under reflective conditions when incident wave amplitude (a_i) is such that

$$a_i^2 > \gamma k(N_1, N_2)/\omega_i \quad \dots (1)$$

where γ is kinetic viscosity, ω_i is incident frequency, N_1 and N_2 are mode numbers of a possible edge wave pair, and $k(N_1, N_2)$ is a constant for given N_1, N_2 (note $K(N_1, N_2)$ values tabulated by Guza and Davis were subsequently found by Guza and Inman, 1975, to be too great by a factor of 4. It is debated whether excitation occurs in dissipative situations when the reflectivity parameter

$$\epsilon = a_i w^2/g \tan^2 \beta \quad \dots (2)$$

(where β is beach slope) is greater than about 2.0. This is important for the edge wave initiation of rips. Our results indicate resonance and edge wave existence in several morphodynamically different dissipative and reflective contexts, and indicate conditions where edge wave modes and periods change abruptly, depending on inshore bar morphology, incident wave conditions, and tide. In another paper in this volume (Wright *et al.* 1978) we discuss the morphodynamic associations between six commonly occurring morphologic types, different resonant frequencies, and different scales of inshore circulation. In the present paper we examine evidence for inshore resonance from five selected experiments.

EXPERIMENTAL METHODS

Several sandy surf beaches in N.S.W. Australia (Fig. 1) were chosen to represent a range of hydrodynamic and morphodynamic conditions, ranging from highly reflective steep beaches without a bar, through dissipative cases with either a rectilinear bar-trough system or a crescentic system, to dissipative cases where broad bars have accreted to the beach, forming long and broad inshore shoals (*e.g.* Wright *et al.* 1978; in press). The beaches experience medium to high wave energies, and experiments were done with mean breaker heights typically between .08 and 2 m.

Wave and current measurements were taken on a continuous basis, using pressure transducers for waves and fast-response directional flow meters for currents. Our standard instrument mount includes a pressure transducer plus orthogonal horizontal flow meters (shore-normal and shore-parallel), on a stable portable base, connected by cables to chart recorders, data logger, and a mini-computer in a mobile onshore van. Several instrument mounts can be deployed together. The system is described in detail by Bradshaw *et al.* (1978).

Measurements were made when waves essentially were normally incident (*i.e.* crests shore parallel). Spectral and cross-spectral analysis provide the key for edge wave identification. Standard spectral methods were used employing auto and cross covariance analysis, detrending and use of hanning or cubic filters, and Fourier transformation. Sampling intervals (Δt) of 1 or 2 seconds were used. Spectral and cross spectral analysis (*e.g.* Bendat and Piersol, 1971) are guided by the following points:

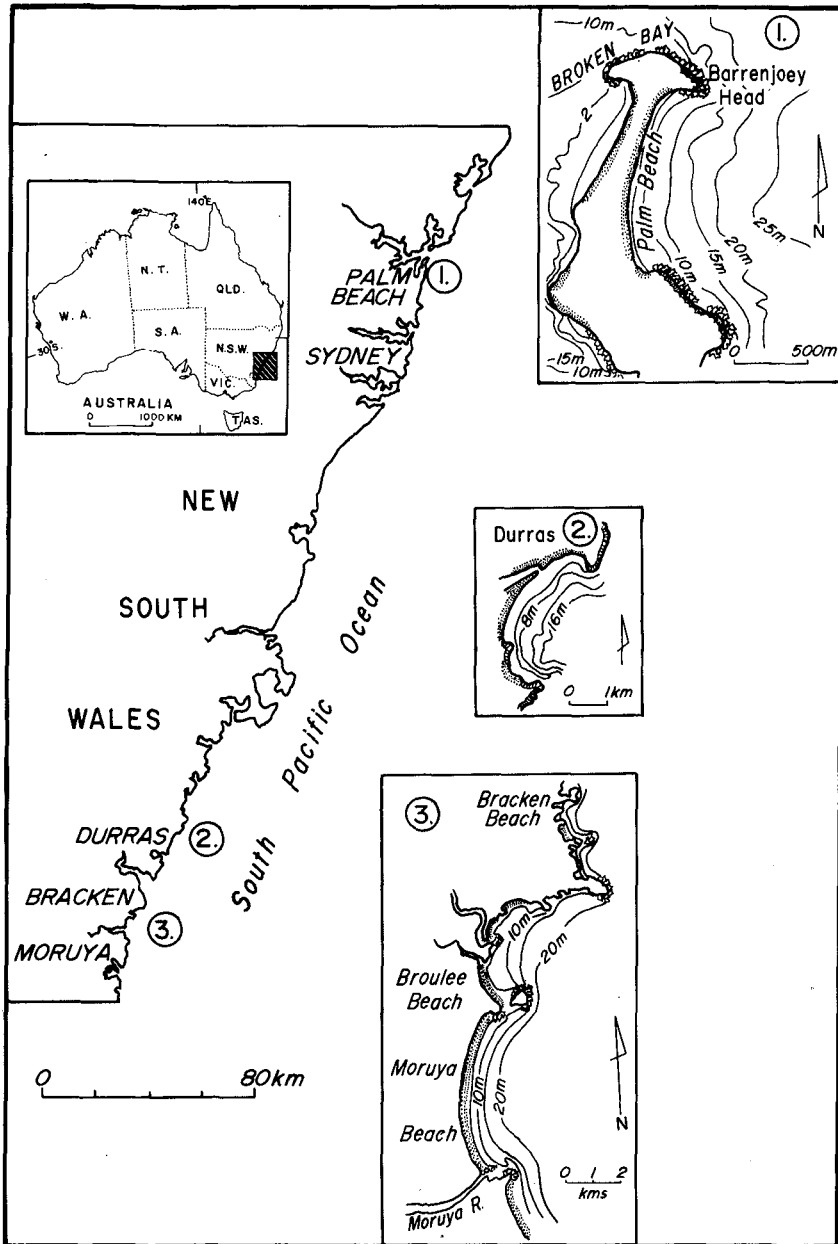

- (i) Auto or cross-correlogram reduction of primary data is repeated with different maximum lag numbers when preparing each spectrum, to establish stability of spectral peaks.
- (ii) We are concerned to identify oscillatory motions at incident wave frequency, subharmonics of this, or at surf beat frequencies, and consider only spectral peaks very significantly above the white noise spectrum.
- (iii) Cross-spectral coherence is a guide to usefulness of phase estimates of cross-spectral peaks, *i.e.* when coherence is low the phase estimate is judged unreliable.

We consider that an edge wave is indicated:

- (i) when phase difference between water surface and horizontal current is close to $\frac{\pi}{2}$, and (ii) when an inferred edge wave spectral peak diminishes in magnitude away from the shore (*i.e.* the same test as used by Huntley and Bowen, 1975).

Magnitude relationships of shorenormal and shore-parallel current components in a rip feeder channel usually differ from those predicted from the edge wave velocity potential (ϕ) field,

Figure 1 Locations of beaches used as experiment sites (Palm, Durras, Bracken, Moruya).

$(u, v) = \Delta\phi$, due to the presence of the current. At some of these sites we separate the bidirectional current time series into component left- and right-flow spectra to show that dominant drift is at edge wave rather than incident frequencies.

In the experiments which follow, not all results are final as some are based on measurements taken when field conditions precluded sampling at several sites, and for others the full analysis of data logs is still in progress.

FIELD EXPERIMENTS

We report from several dissipative beaches plus one reflective beach. The latter is included to furnish a connection between our work and that of Guza and Inman (1975) and others, and to provide a methodologic bridge to the dissipative cases. Locations and maps are shown in Figure 1. The dissipative beaches - Moruya, Durras, Palm Beach - have well sorted medium sand, dominantly quartz with variable but significant quantities of shell fragments. The reflective example - Bracken Beach - had bimodal sediment of coarse sand and gravel. The New South Wales coast experiences a variable wind-wave climate, with strong sea-breeze in summer, superimposed on persistent high energy swell from the southeast. Significant wave height exceeds 1.5 m for 50% of the time and 4 m for 1% of the time. Wave periods around 10 seconds are most common. Tides are semi-diurnal and have an average springtide range of 1.6 m.

Sites were chosen to sample a range of inshore morphologies. Measurements were made generally under swell conditions. Figure 2 shows site details for representative experiments discussed herein. The sites are briefly described in terms of the morphodynamic classification scheme of Wright *et al.* (1978). Primary morphodynamic data are listed in Table 1.

(i) A typical reflective experiment on Bracken Beach is shown in Figure 2a. Typical of reflective beaches (*e.g.* Wright *et al.* in press), Bracken Beach has a linear, low gradient nearshore profile (fine sand) which passes through a pronounced gravel step into the steep beach face of coarse sand. Beach cusps are well developed, the active cusps often being nested within much larger cusps high on the beach face, which are relict from storm waves. Waves break at the gravel step and surge up the beach face with high runup. Features such as transverse or crescentic bars, swash bars and inshore gutters invariably are absent.

(ii) Moruya experiment 1 (Figure 2b) took place in the presence of a long-shore bar-trough system with incipient periodic morphology and a moderately steep beach face. Topography was transitional between the parallel bar-trough system referred to by Wright *et al.* (1978) as Type 2 dissipative beach state, and the crescentic bar-

rhythmic shoreline situation of Type 3. The primary break typically was plunging with waves tending to reform as they traversed the trough.

(iii) Moruya experiment 2 (Figure 2c) was representative of a typical Type 3 state, where crescentic bars intermittently tie to the beach through transverse bars. Beach face and inshore wave conditions resembled Moruya experiment 1 (*cf* Table 1).

(iv) Palm Beach experiment (Figure 2d) represents an advanced stage in an accretionary phase where a broad shoal extending the full width of the surf zone had developed through shoreward bar migration (Type 5 of Wright *et al.*). The upper beach face was moderately steep; the lower portion flatter. Reflectivity varied accordingly with tidal stage. The entire surf zone was crossed by spilling bores.

(v) Durras experiment (Figure 2e) was conducted within a parallel bar-trough system. Topography approached Type 2 but was influenced by a nearshore reef at the northern end of the site. The trough is relatively shallow, and larger sets of waves developed spilling bores across the surf zone while small sets reformed inshore of the break. This experiment differed from the others in that measurements were taken at 5 sites alongshore, within the trough.

SURF ZONE RESONANCE

The results of each of the selected experiments described above reveal several distinctive resonant frequencies and modes which appear strongly dependent on the morphology prevailing at the time of the experiments. The resonant phenomena associated with each set of conditions are elucidated by spectral and cross-spectral analyses of the measured time series of water surface and inshore current oscillations.

(1) Reflective case - Bracken experiment (10 December, 1977)

The steep beach face showed pronounced cusps at 23 m spacing. Waves and currents were measured seawards of the shore break at three locations off a cusp horn, and near the step off a cusp bay (Figure 2a). Spectra (from the middle station off the cusp horn) reveal several important features some of which are shown in Figure 3).

(a) Wave spectra show sharp peaks at incident wave frequency (0.13 Hz) at all stations off the cusp horn although this peak weakens at the inner station and off the cusp. Water surface motion at this frequency is dominated by the incident waves, indicated by zero phase difference between horn and bay 0.13 Hz peaks. In this experiment, water surface elevation and currents were in phase at incident wave frequency at all stations.

(b) The shore-normal current spectra show strong peaks at the frequency of the first subharmonic (.067 Hz) at both the middle and inner stations. This peak is also expressed in water surface elevation spectra; it is present as a secondary peak in the middle station but becomes the dominant peak at the inner station. Flow is $\frac{\pi}{2}$ rds out of phase with water surface elevation at this subharmonic frequency.

(c) Segregation of current spectra into offshore and onshore components by separating the primary record into half series indicates that seaward flows had highest spectral energy at subharmonic frequency, while at incident frequency onshore and offshore energies are equal.

A subharmonic edge wave is inferred from the strong peaks at subharmonic frequency and from the $\frac{\pi}{2}$ current-wave phase relationship. Guza and Davis (1974) have shown that subharmonic edge waves are preferentially excited. Guza and Inman (1975) argue that cusp spacing should be one-half edge wave length, L_e :

$$L_e = (g/2\pi) T_e^2 (1 + 2_n) \tan \beta \quad \dots (3)$$

where n = mode number = 0,1,2,3 ... (Bowen and Inman, 1969). Bowen and Inman (1969) also suggest that dominant mode decreases with decreasing dimensionless surf zone width

$$\chi_s = \omega^2 X_s / g \tan \beta \quad \dots (4)$$

where $\omega = 2 / T_e$ and X_s is horizontal distance from the beach face to the break point. For edge waves to be trapped, χ_s must exceed a minimum value, χ_{min} , which Huntley (1976) estimates as

$$\chi_{min} = 3.5 n (n + 1) \quad \dots (5)$$

From χ_s values in Table 1, the cut-off mode at 0.067 Hz is $n = 0$ (from Eq. 5), corresponding to $L_e = 46$ for β values in Table 1 (Eq. 3). This is twice the measured cusp spacing.

(2) Dissipative bar-trough systems - Moruya experiments (ii) and (iii)

Spectra from two dissipative beach experiments on Moruya Beach are shown in Figure 3 from instruments located as shown in Figures 2b, 2c. Salient elements are as follows:

Figure 3 Representative spectra for reflective beach experiment (ref. Fig 2a for instrument locations).

Figure 4 Representative spectra for two dissipative bar-trough systems - Moruya experiments (ii) (25 May) and (iii) (27 May) (ref. figs 2b, 2c for instrument locations).

NORTH MORUYA RISING TIDE 27th MAY '77

FIGURE 4 (iii)

(a) Strong subharmonic components appear in current spectra on both occasions in addition to incident-frequency peaks, but at different multiples of incident wave period. For experiment (ii) the incident frequency is close to 0.1 Hz, and secondary current peaks appear at 0.05 Hz and 0.023 Hz, the 0.05 Hz being the stronger. Experiment (iii), with incident frequency again close to 0.1 Hz but a somewhat broader trough, shows only the lower frequency subharmonic current peak at 0.023 Hz, which is very near to $\frac{1}{4}$ the incident wave frequency. Phase determinations for experiment (iii) show that flow oscillations at .023 Hz are 90° out of phase with water surface oscillations at this frequency, whereas the strong incident-frequency flow is in phase. Progressive motion thus is indicated at incident frequency; standing motion at the $\omega/4$ frequency. The wave record for experiment (iii) at the same point in the trough, shows the same 0.023 Hz ($\omega/4$) peak; this peak is absent in the outer breaker record.

(b) Segregation of the current record from experiment (ii) into on-shore and offshore components shows a similar effect to the reflective beach case, *i.e.* offshore current substantially exceeds the onshore component at $\omega/2$ and $\omega/4$ frequencies.

(c) For the second experiment χ_g for the 0.023 Hz peak is 3.6, indicating that only the zero-mode edge wave is likely at this frequency. The corresponding L_e value is 190 m, which is very close to twice the observed spacing of transverse bars (90 m; data in Table 1). However, this does not constitute "proof" of edge wave determination of coupled circulation and topography: firstly, because several modes below cutoff are possible for resonance at $\omega/2$, and secondly, because estimates of L_e are very sensitive to values of β , which often varies down the beach face and over the surf zone. This allows too much freedom when finding a "fit" between L_e and rip or transverse bar spacing, especially when $\omega/1$ and $\omega/4$ peaks both are present as in the first Moruya experiment.

An interesting result is that the low frequency peak at $\frac{1}{4}$ of incident frequency, which is subordinate to the first subharmonic in Moruya 1, rises to dominance in the second experiment when energy conditions are 20% higher, the trough wider, and the surf zone broader (Table 1). This implies firstly that increasing dissipativeness inhibits excitation of higher frequency edge waves, which is consistent with Guza and Davis (1974) measure (D) of boundary layer dissipation per unit of longshore length, restated as

$$D = E\pi (2\gamma\omega_i)^{1/2}/L_e \tan \beta \quad \dots (6)$$

where E is total wave energy per unit longshore length. When dominant resonance shifts to $\omega/4$, L_g increases fourfold (relative to $\omega/2$) for a given mode (Eq. 3), and sensible dissipation for the edge wave decreases.

Guza and Davis argue that excitation of an edge wave of lower frequency and higher mode than the (0,0) subharmonic is possible only when $ai^2\omega$, $\gamma > 4 K(0,0)$. The corrected value of $K(0,0)$ is ≈ 50 (Guza and Inman, 1975), and from Eq. 1 the minimum incident amplitude at the beach face necessary for growth of higher mode, lower frequency edge waves for our case is $a_i \approx 6$ cm, which is about 1/7 of observed inshore wave amplitude.

Strong resonance at $\omega/4$ is not predicted by conventional edge wave theory and is generally inconsistent with the concept of resonant triad as set out by Guza and Davis (1974). For this reason and because thus far we have only found resonance at $\omega/4$ in situations of pronounced bar-trough topography, we infer that resonance at this frequency is a consequence of topography. In the cases studied the trough has been deep, the bar has been shallow with a steep (and potentially reflective) landward face and the beach face has been locally reflective. Estimated natural trough frequencies are close to the frequency of the first subharmonic ($\omega/2$) at times when $\omega/4$ peaks occur.

(3) Dissipative surf zone without trough - Palm Beach

An important question is whether edge waves occupying the inshore zone of dissipative systems will always be excited when beach reflectivity is high and the condition of Equation 1 is surpassed substantially. This is relevant to rip current initiation under Type 5 conditions when an inshore trough is absent; our observations indicate an absence of regular rip organization in these conditions (c. Figure 2d; see also Wright *et al.* 1978 and in press; Chappell and Eliot, in press). The broad troughless intertidal shoal fronting a moderately reflective high-tide beach ($\Sigma = 2.3$) was monitored for shore-normal currents at 3 sites - mid swag, and at points about 8 m and 20 m seaward of the shore break (Figure 2d). Wave record was obtained only from the inner surf zone site owing to failure of the outer transducer. Neglecting the swash zone record, spectra shown in Figure 5 indicate several interesting points.

The inner surf zone wave spectrum shows a strong incident peak and a minor subharmonic peak ($\omega/2$). This does not appear in the current record, however, which is dominated by a peak at 0.063 Hz with a second peak at 0.03 Hz. Both are close to 90° phase from the water surface oscillations although phase-significance is low. Both peaks exceed the incident-frequency peak at 0.1 Hz which is in phase with the incident wave peak. The mid-surf zone flowmeter shows the 0.063 Hz peak, at lesser amplitude than the

incident frequency peak. We interpret these results as indicating the edge wavepair (1,0) of resonant triad, which, according to Guza and Davis (1974) will have edge wave frequencies of (0.63, 0.3) ω_i *i.e.* very close to our observed frequencies. The (1,0) pair is consistent with χ_s values which indicate that mode 1 is possible at 0.63 Hz and only zero mode can exist at 0.03 Hz for the Palm Beach surf zone. Non-appearance of wave peak at 0.063 Hz suggests that the inner surf zone instruments were close to the mode 1 node. Profiles of edge wave surface, $\eta(x)$, and flow $u(x)$, calculated from $u = d\phi/dx$ and $\eta = (1/g)\delta\phi/\omega$ where $\phi = (ga/\omega)L_n(2Kx) \exp(-Kx)$, L_n is the Laguerre polynomial of mode n , in Figure 5, show that this interpretation is consistent, although the 0.03 Hz wave peak would have been expected.

This result, when compared with the Moruya cases, raises the question of why a particular set occurs. We suggest that answer lies with the dissipation parameter D (Eq. 6), and that the highest frequency, lowest mode set will occur which is consistent with the excitation condition (Eq. 1), and for which D is less than a threshold level D_c . Table 2 lists ω_e permitted modes and L_e values, and estimates of D for the Moruya and Palm Beach experiments. These D values are calculated using the surf zone gradient β_s rather than the beach-face β value. Empirically, it appears the D_c is about 1.0 for dissipative beaches. We note, however, that excitation of the first subharmonic ($\omega/2$), (0,0) set is significantly easier than the (1,0) set and suggest that a similar (0,0) set can be excited at $\omega/4$ in preference to the (1,0) : ($\omega/1.6$, $\omega/3.0$) set when a trough of sufficient width is present.

During the Palm Beach experiment, rips were virtually absent, allowing no test of possible edge wave - circulation relationships. To explore this last problem we turn to the final experiment.

(4) Multiple sites along a bar-trough system - Durras experiment

This experiment is potentially most interesting in that 5 sites at 20 m intervals in a parallel bar-trough system were measured, but unfortunately this was done prior to establishment of the full experimental system. A single instrument set of 2 flow meters and one transducer, logged by chart recorder, was moved to successive sites. This was a preliminary experiment and field work was done largely by a student, Mr E. Wallensky. Figure 6 shows spectral results and net (u , v) velocity components at each site. A longshore current feeding a rip is indicated clearly. There is no transverse or rhythmic topography to influence location of the rip catchment divide. In summary, results indicate a (1,0) edgewave set (0.06 Hz, 0.03 Hz) dominating, with a common node at the rip current and the 0.06 Hz component antinode about 30 m up-trough from the rip, while the 0.03 Hz component has its antinode about 40 m up-trough. These

Figure 5 Spectra for dissipative troughless surf zone, reflective beach face - Palm Beach (ref. fig. 2d). Theoretical edge wave surface and current profiles shown (normalised).

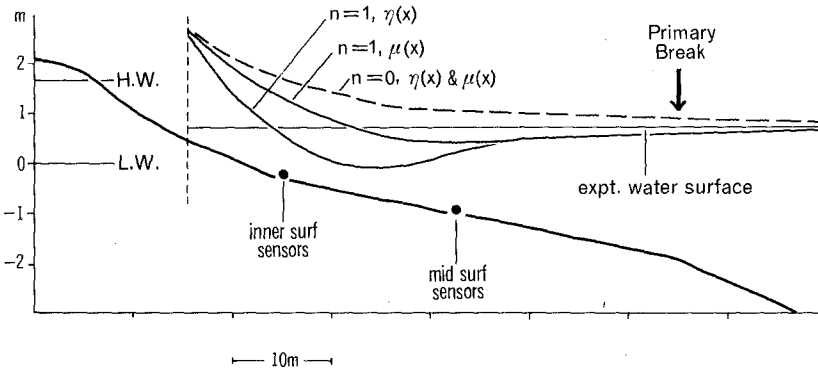

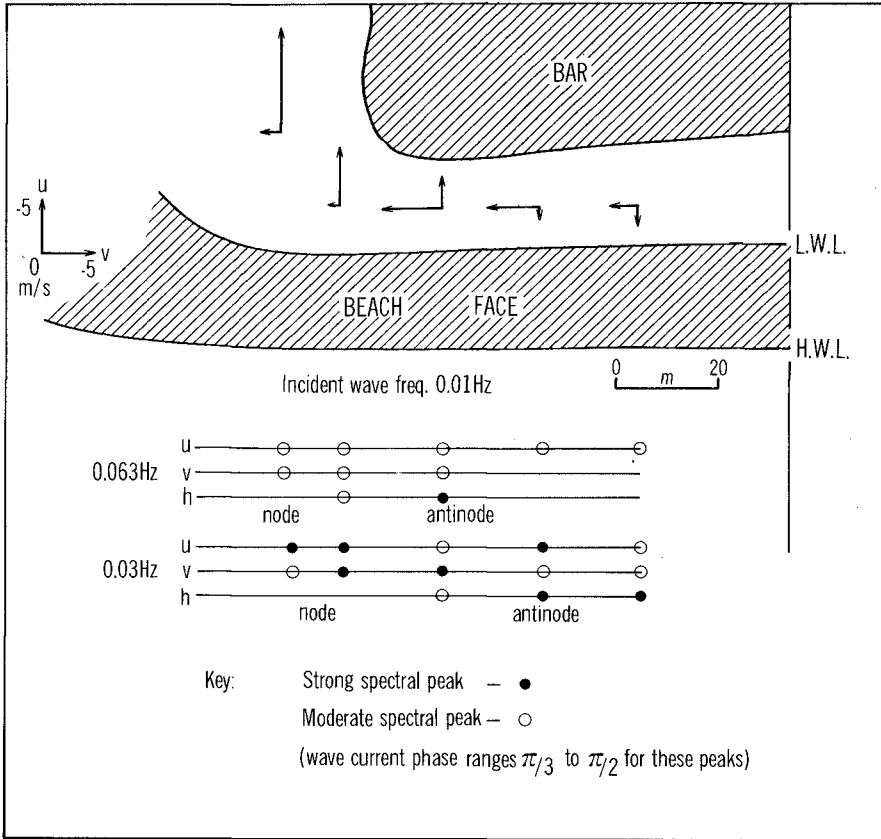

Figure 6 Multiple sites in parallel bar-trough system, showing longshore variation of inferred (1,0) triad spectral peaks and net currents (Durras Beach, ref. fig. 2e).

correspond quite well with predicted quarter-wavelengths (node to antinode) of the (1,0) components, *i.e.* 25 and 38 m.

CONCLUSIONS

The existence of edge waves appears confirmed for dissipative surf beaches, as well as for the simpler reflective case as previously has been argued. Our reflective example supports the hypothesis that beach cusps form from the influence of a stationary zero-mode edge wave at half the incident wave frequency, *i.e.* the first subharmonic. With varying degrees of dissipation it appears that a series of edgewave frequencies can exist with frequencies ω_j/j , where $j = 1, 1.6, 2, 3, 4 \dots$. We include $j = 1$ here to include possible edge waves at incident frequency (although these are less likely, especially as stationary waves: Guza and Inman).

Dissipative surf zones with steep beach faces show a greater range of inshore edge waves, in particular as resonant (0,0) or (1,0) pairs at frequencies of $\omega/2$, or $(\omega/1.6, \omega/3)$ respectively. Further, the single zero-mode form appears to occur at $\omega/4$. Although the zero mode wave at $\omega/2$ is more easily excited, by a factor of 4, the particular edge wave which occurs is limited by inshore dissipation, and that which exists is the lowest mode, shortest period wave for which inshore friction D (Eq. 6) is less than 1.0.

As far as our measurements go, edge waves appear to influence location of inshore circulation systems, with rips tending to locate at nodes. The fact that edge wave length increases discontinuously as inshore dissipation increases offers an explanation of the phenomenon - often observed - that new or secondary rips appear when wave energy conditions change.

ACKNOWLEDGMENTS

This study is supported by the Australian Research Grants Commission (ARGC). We are grateful to Mr M. Bradshaw, Mr. P. Cowell, and Professor B.G. Thom for co-operation and assistance in all facets of the study, and to Mr E. Wallensky for his major part in experiment 5.

CHAPTER 81

BEACH CUSPS AND EDGE WAVES

D. A. Huntley & A. J. Bowen

Department of Oceanography
Dalhousie University
Halifax, Nova Scotia
B3H 4J1, Canada

ABSTRACT

Beach cusps are very common, concave-seaward cusped patterns at the shoreline of a beach, which tend to occur with a regular longshore spacing, but which can have a wide range of longshore wavelengths from a few centimeters to several kilometers or more. Edge waves, resonant waves trapped at the shoreline by refraction, have been suggested as the cause of beach cusps but it has proved difficult to establish a definitive link on natural beaches. This paper describes field measurements of nearshore velocities, in all three orthogonal directions, that show the presence of edge wave motion just before the formation of beach cusps of the corresponding wavelength, and thus provides convincing evidence that edge waves are responsible for beach cusps. The magnitude of the observed edge wave oscillatory and drift velocities are found to be large and apparently well able to form cusps of the observed size. The observed edge waves are at the subharmonic of the incident wave frequency and thus are the field equivalent of the laboratory observations of Guza and Inman (1975) and Guza and Bowen (1977). It is not clear, however, whether the developing cusp topography enhanced or suppressed the edge wave motion.

INTRODUCTION

Beach cusps are cusped patterns in beach sediment formed at the shoreline, with longshore wavelengths which are generally relatively constant at a given location and time but which can vary with location and time from around 10 cms on lake shores (Komar 1973) to several hundred meters on long oceanic beaches. Dolan and Ferm (1968) have even suggested that the large-scale features of a shoreline, with capes and bays, may also be described as beach cusps with wavelengths of 100 km or more. The characteristic morphology of beach cusps is of seaward-facing concave embayments separated by relatively narrow seaward-pointing horns. Their relief varies typically from a few centimeters to several meters.

Considerable scientific and coastal engineering interest has centered on beach cusps, not only because of their very common occurrence and the wide scale of features they encompass, but also because they are

clearly the result of on/off-shore movement of sediment. As readily observable features of the shoreline, which are known to form remarkably rapidly where they occur, they may provide an important link in understanding the processes controlling the onshore and offshore movement of sediment on beaches.

Many mechanisms have been proposed to explain the existence of beach cusps, but the most plausible is that they are the response of the beach sediment to the presence of edge waves (Bowen 1969, 1973; Bowen and Inman 1967, 1971; Guza and Inman 1975). Edge waves are resonant waves trapped along the edge of water bodies by refraction. They vary sinusoidally along shore and have an amplitude which decays rapidly offshore. The existence of a regular longshore wave length for an edge wave, and the possibility of edge waves with a wide range of longshore wavelengths makes them very attractive as potential generators of beach cusps.

The laboratory experiments of Guza and Inman (1975) give clear evidence that, at least on reflective beaches where little or no breaking occurs and incoming waves are reflected seaward again, subharmonic edge waves (with period twice that of the incident waves) are generated and form cusped features at the shoreline on an erodable laboratory beach. Extensive laboratory experiments by Guza and Bowen (1977) show that subharmonic edge wave resonance occurs for low incident wave steepness but is suppressed, probably by the increased friction, for wave steepness large enough to produce pronounced plunging or spilling of waves in the surf zone.

In the field a definitive link between edge waves and beach cusps has proved elusive. Komar (1973) describes field observations which show that cusp formation is a result of motion in the water column which has its own intrinsic longshore wavelength, and is not a result of water/sediment feedback at some arbitrary perturbation wavelength. He made visual observations of small cusps of wavelength ranging, from day to day, between 11 and 58 cms on Mono Lake, California. Because of their small size he was able to destroy them by flattening the beach with a ruler. When this was done, cusps of the same wave length reformed on the beach within ten minutes under surging waves of height less than 2 cms. On the basis of their rapid formation, the co-existence of cusps and waves surging on the beach, and the consistency and magnitude of their longshore wavelengths, Komar concluded that the beach cusps were generated by edge wave motion. However, he did not make any direct measurement of the nearshore water motion to prove the existence of edge waves.

Direct observations in the field of edge wave motion, both at subharmonic and much longer periods, have been made on smooth beaches without obvious cusps or longshore rhythmic features, (Huntley and Bowen 1973, 1975a, Huntley 1976, Sasaki et al 1977) and on beaches with

pre-existing rhythmic topography (Huntley (in press), Chappell and Wright (in press)). However, the definitive experiment linking beach cusps to edge waves would be the observation of edge wave motion before and during the formation of beach cusps of the corresponding wavelength. This paper describes a field experiment in which, by good fortune, these conditions occurred.

THE FIELD OBSERVATIONS

Three electromagnetic velocity sensors (two Marsh-McBirney Inc. Model 711 and one Cushing Engineering Inc. Model 612) were used to measure the nearshore velocity fields. These two-component fast response (time constant 0.1 or 0.2 secs) instruments were mounted on an aluminum tripod 0.3m high which was dug into the seabed about 7 cms and held in position using lead weights (Huntley and Bowen 1975b). Two of the sensors, mounted 0.35m and 0.72m above sea bed, were aligned to measure the offshore and vertical components of flow and the third sensor, at 0.61m above the bed, was aligned to measure the offshore and longshore components of flow. In this way the three orthogonal components of flow were simultaneously measured essentially at a single location. Orientation in the horizontal plane was achieved by using a theodolite at the top of the beach to define a line perpendicular to the trend of the beach, and then aligning the offshore direction of the sensors by sighting along range poles placed on this line; accuracy of alignment was estimated to be about 2°. Cables ran up the beach from the sensors to a vehicle parked at the top of the beach which contained battery-powered electronics and a magnetic tape analogue data logger. The data were subsequently digitized at a sampling interval of 0.33s for computer analysis.

In addition, two 135 second time series of water elevation above the sensors were obtained by filming water level against a graduated range pole placed close to the sensor mount.

The field site was Queensland Beach, Nova Scotia, Canada (Figure 1). The beach is located at the head of St. Margaret's Bay, a large sheltered bay opening to the Atlantic. The beach itself forms a tombola about 300 m long facing directly towards the mouth of the Bay and the dominant incident wave direction. Figure 2 shows beach profiles measured at low tide in the vicinity of the instruments. A set of beach cusps remaining from the previous high tide were subaerial when these profiles were measured and gave the trough and cusp profiles shown, with an alongshore separation of about 3.5m. The sensors were placed on the cusp range. The mean sea level marked on Figure 2 gives the approximate level during the measurements of velocities, but a change of approximately 0.4m about this level occurred with the rising tide as measurements were taken.

Figure 1: Location map.

An example of the records obtained is shown in Figure 3. The upper time series shows the water elevation as measured by the movie film, and the elevation axis is given relative to the sea bed. The three horizontal lines mark the elevations of the three electromagnetic sensors. This time series shows the incoming waves to have a dominant period of about 7 seconds, but the period is clearly irregular. The sensors at this time were at the break-point for the largest plunging breakers (e.g. at 25 and 40 s) but outside the breakpoint for the smaller waves. The steepest breakers have a height of about 0.7m in a mean depth of 0.9m, in good agreement with the expected value.

The three lower records show the onshore and vertical velocities measured by the flowmeters at 0.72m and 0.35m height. Positive velocities are onshore and downwards respectively. The elevation record shows that the upper sensor came out of the water in wave troughs on several occasions, and the dotted lines in the velocity

Figure 2: Beach profiles.

Figure 3: An example of the time series records.

records show the measurements when this occurs. Except when this occurs, onshore velocities at the two flowmeters overlap, and the wave induced vertical velocities decrease with depth in a way consistent with the predicted linear decrease for shallow water waves.

The behaviour of the flowmeter as it comes out of the water and is re-immersed is interesting. The characteristics in the onshore record are most clearly shown in the second event at about 22s (Figure 3). As the flowmeter comes out of the water the sensor output settles rapidly, but with some ringing, to the zero-level (a zero-flow mean voltage equivalent to about 0.23 m/s was present for this sensor). On re-immersion a large spike occurs, either positively or negatively depending on the details of the immersion, followed by rapid recovery to a measurement of the true water velocity. Laboratory tests confirm this typical behaviour and show that, for an instrument with a nominal time constant of 0.2 secs, about 0.8 seconds of immersion are necessary before accurate measurements of water flow can be made. This time interval is clearly sufficiently small to allow the peak onshore velocities in breaking waves at this level to be measured, and further tests to measure the profile of onshore flow closer to the wave crest should be possible and will prove very interesting. For vertical velocities, however, the maximum upward flow occurs on the rising face of the breaker very close to the time of reimmersion and it is clear that the recovery time of the flowmeters is too long to measure this.

EDGE WAVES

The theory of edge waves has recently been reviewed in several papers (Bowen and Inman 1969, 1971, Huntley 1976, Guza and Inman 1975) and it is therefore only necessary here to point out features relevant to these measurements.

For a beach of linear slope angle β , Ursell (1952) finds a dispersion relation of the form

$$L = g \frac{T^2 \sin}{2\pi} (2n+1)\beta \quad (1)$$

where L is the longshore wavelength of the edge wave, T is the period and n is an integer, known as the mode number, which gives the number of zero crossings in the rapid decay of amplitude and velocity with distance offshore. This dispersion relation predicts a whole family of edge wave modes for any specified period, each mode having a distinct longshore wavelength. The work of Guza and Davis (1974), Guza and Inman (1975) and Guza and Bowen (1975, 1977) suggests that, for beaches with surging, collapsing or low plunging breakers, edge waves of subharmonic period (twice the incident wave period) dominate.

Bowen and Inman (1971) and Bowen (1973) show that edge waves which are not synchronous with the incident waves should generate beach cusps with a wavelength $L/2$. This was observed on an erodable laboratory beach by Guza and Inman (1975).

In distinguishing between edge waves and incident waves in near-shore velocity records, the relative phases between the orthogonal velocity components are important. Table 1 shows the phases for four cases based on gravity wave theory and Ursell's edge wave theory. Here "in phase" can mean a relative phase of 0° or 180° and "quadrature" a relative phase of 90° or 270° .

Table 1. Phase relationships between velocity components

Wave type	u	v	u	w	u	w
	offshore	vs longshore	longshore	vs vertical	offshore	vs vertical
Progressive Gravity	in phase		quadrature*		quadrature*	
Standing Gravity	quadrature		quadrature*		in phase	
Progressive Edge	quadrature		quadrature		in phase	
Standing Edge	in phase		in phase		in phase	

*Except near the sea bed where the velocity is linear and follows the bottom slope

In order to identify possible edge wave motion in the present velocity measurements spectra and cross-spectra were calculated, Figure 4 shows spectra for onshore and longshore velocities 0.61m from the bed and Figure 5 for onshore and vertical velocities 0.35m from the bed. For each of the spectra the most prominent peak occurs at about 0.145 Hz (period 6.9 secs) in good agreement with the estimated incident wave period. The fine vertical lines at higher frequencies mark the frequencies of the first, second, and third harmonics of this incident wave period and it is clear that structure is present in the spectra centered around these periods. In fact, for the onshore spectrum of figure 4 the bandwidths of the harmonic peaks increase approximately in proportion to the harmonic number, as might be expected. Of more interest in the present context however is the presence of a peak in each of the spectra at the first subharmonic of the incident wave frequency. Although this peak does not appear to be

Figure 4: Spectra and cross-spectra of onshore and longshore flows.

Figure 5: Spectra and cross-spectra of onshore and vertical flows.

significant at the 95% level in any individual spectrum, its persistence in all these and in the other spectra obtained from the present measurements suggests that it is a significant feature of the velocity field. A second low frequency peak also appears in both the onshore records at about 0.03 Hz but cannot be studied in detail with the short record lengths obtained during these measurements.

The significance of the low frequency peaks is confirmed by the calculated coherences between the velocity components. In figure 4 the coherence between the onshore and longshore velocities is well above the 95% confidence level for zero coherence at the incident wave frequency and at the first two harmonic and the subharmonic frequencies; in figure 5 the coherence is, rather surprisingly, higher for the first harmonic than for the incident wave peak, but is also well above the 95% level for the subharmonic (and 0.03 Hz) peak.

The phase plots show that the phase between the onshore and longshore components of flow is close to 180° throughout the frequency range shown; the expected 95% confidence limits for the phases of the incident peak and subharmonic peak are $\pm 12^\circ$ and $\pm 17^\circ$ respectively (Jenkins and Watts 1968) and the phases for each are well within this range about 180° . For the onshore and vertical velocities (Figure 5) the phase is close to 90° for the wind wave band of frequencies (0.1 - 0.9 Hz), though displaying an unexplained slight rise with increasing frequency. Below 0.1 Hz the phase changes dramatically, however, and at the subharmonic frequency has a value of about $+8^\circ$, insignificantly different, at the 95% confidence interval of $\pm 17^\circ$, from a phase of 0° .

When compared with the predicted phases shown in Table 1, the observed phases for frequencies above 0.1 Hz suggest that the spectral energy is predominantly due to the presence of progressive gravity waves approaching the beach, with little reflection occurring. Below 0.1 Hz, and specifically at the subharmonic frequency, the phases of 180° between onshore and longshore and 0° between onshore and vertical show that the subharmonic peak in the spectra is due to the presence of a standing subharmonic edge wave, with a period of around 14 seconds.

The confidence with which these identifications, based on phase, can be made depends to a large extent on accurate alignment of the sensors. For incident waves, which are refracted towards the shore normal as they propagate inshore, the longshore component of flow will be much smaller than the on/offshore, so that misalignment of the sensors in the horizontal plane may cause serious contamination to the assumed longshore record by on/offshore flows. For low mode edge waves, however, misalignment in the horizontal plane is not as serious since, in the offshore variation of amplitudes, away from zero-crossings onshore and longshore flows have comparable magnitudes so the distinction in phase between progressive and standing edge waves should be clear. Misalignment in the offshore/vertical plane may also seriously

contaminate the much smaller vertical velocities with horizontal flows. Thus there will be a tendency for offshore and assumed vertical records to be in phase for both incident waves and edge waves.

For the present data subharmonic edge waves are not predicted to have zero-crossings in either offshore or longshore flow near the sensors, except at high mode numbers, so the 180° phase between these components at the subharmonic frequency rules out the existence of low mode progressive edge waves; we will see later that the offshore variation of amplitude of this subharmonic peak also makes it unlikely to be due to a standing gravity wave. On the other hand, the observation of near 90° phase between onshore and vertical flow for frequencies above 0.1 Hz can only be due to progressive incident waves. This suggests that the sensors were aligned vertically to considerably better than 1° , which is surprising and probably fortuitous. The fact that the phase tends to drop below 90° for frequencies between 0.1 Hz and 0.3 Hz appears to be inconsistent with the possibility of some standing gravity wave energy being present at the incident wave frequency, since the phase between onshore and vertical velocities for standing waves of this frequency and at the offshore distance of the sensor is predicted to be 180° rather than 0° . The phase drop may therefore be the result of a slight shoreward dipping of the assumed on/offshore direction due to misalignment, or a tilt of the current ellipse so that its major axis is inclined slightly out of the horizontal towards the bottom slope.

In order to find the longshore wavelength of the observed subharmonic edge wave we need to know its mode number (equation 1). With the present data this can only be estimated from the offshore decay of the amplitude of the velocity components (e.g. Huntley 1976). The tidal excursion of the shoreline position changed the effective offshore distance of the sensor mount and this was used to map the velocity field for a narrow range of offshore distances, under the assumption that the edge wave velocity field remained essentially constant over the one hour of measurements. Figure 6 shows the result for the on/offshore velocities. Measured values have been scaled to give the best fit to the predicted variation for the mode zero edgewave of subharmonic period on a beach of the linear slope most closely matching the profiles (figure 2). The mode zero curve provides the best fit to the data, but the uncertainty in the levels of the observed velocities is sufficiently large that higher mode numbers would still provide a reasonable fit, despite a zero-crossing at around 14m. Unfortunately the longshore velocity records do not provide additional information. For the two inshore data records the longshore sensor, at 0.61m above the bed, came out of the water in wave troughs and satisfactory spectra could not be calculated. Nevertheless if we assume a mode zero wave and can accept an extrapolation to the shoreline based on a linear beach slope, the shoreline amplitudes shown in Figure 6 are obtained. In calculating these values a half-power band width of 0.035 Hz and a triangular peak shape were assumed for the subharmonic peak. Adjustment of the

velocity has also been made to allow for the fact that measurements were not made at an alongshore antinode of onshore velocity; the relative size of the longshore component suggests that measurements were made about 1.2m from an alongshore antinode. Higher mode numbers would give values within a factor of two of these shoreline values. The predicted total excursion (peak to peak) along the beach face is entirely consistent with observations of the longshore variability of run-up, though no precise observations were made.

Figure 6: Relative amplitudes of onshore velocity vs. offshore distance.

BEACH CUSPS

TABLE 2: Predicted Cusp Spacing

	wave period. s.	predicted cusp spacing m.		
		n=0	n=1	n=2
Synchronous	6.9	6.0	18.0	30.1
Subharmonic	13.8	12.0	36.1	60.2

Table 2 shows the predicted beach cusp spacings ($L/2$) for subharmonic standing edge waves of the first three mode numbers; for comparison the predicted spacings of cusps formed by synchronous edge waves (L) are also shown.

Two sets of cusps were observed at the beach site.

The first set of cusps, formed on the previous high tide, was found at the start of the field experiment (Figure 2). As the tide rose over the instrument mount, however, these cusps were destroyed and could not be seen by the time velocity measurements were begun. These pre-existing cusps had a longshore spacing, from measurement of 23 cusps, of 6.8m with a standard deviation of 0.7m. They may, therefore, have been formed originally by synchronous edge waves, but were not being actively formed during our measurements.

However, a second set of cusps began to form at the shoreline towards the end of the measurement period. Near the end of our final run, active formation of these cusps was first observed and within one hour the cusps appeared to have reached an equilibrium size. Measurement of the longshore spacings of eight of the cusps gave a mean spacing of 12.7m with a standard deviation of 1.4m, in good agreement with the predicted wavelength from a zero mode subharmonic edge wave.

The fact that subharmonic edge waves were measured in the water column before the formation of cusps of corresponding wavelength provides convincing evidence that beach cusps are the result of edge wave motion.

Unfortunately, the relief of the new cusps was not measured, but since they were of a similar size to the pre-existing cusps, the relief measured by the cusp and trough profiles in Figure 2 was used to provide a rough estimate of the amount of sediment moved in forming cusps of this scale. Based on a simple sinusoidal model of cusp topography, an estimate of about 1m^3 of sand per metre length of beach is obtained. Observations suggest that this amount of sand was moved in a period of about an hour.

The size of the observed edge waves, combined with the incident waves, would appear to be well able to move this sediment. The shoreline oscillatory velocity of the edge wave was about 1.8 m/s in mean amplitude (Figure 6). The maximum bottom drift velocity under the edge wave, calculated using Bowen and Inman (1971) equation 17, is found to be about 35 cm/s offshore.

The actual formation of the cusps seems to depend on having a reasonably steady shoreline position, since cusps did not form during the time of our velocity measurements, when there was a rapid rise of tide level. The shoreline was moving up the beach at a rate of about 6m per hour when our measurements began, but had slowed to 2m per hour by the time cusps began to appear.

A possible generation mechanism for subharmonic zero order edge waves on a plane beach has been shown by Guza and Davis (1974) and

Guza and Bowen (1975) to be the longshore instability of a reflected gravity wave. Guza and Bowen (1977) made a laboratory and theoretical study of the range of incident wave conditions for which subharmonic edge wave resonance was important, and found that a controlling parameter is

$$\epsilon_i = \frac{a_\infty}{gT^2} \left(\frac{2\pi}{\tan \beta} \right)^{5/2}$$

where a_∞ is the incident wave amplitude before shoaling. Subharmonic resonance was observed on their laboratory beach when ϵ_i was less than 9 or 10 but was suppressed for larger ϵ_i because of increased damping due to wave breaking. For our field data, we use the formula of Komar and Gaughan (1972) to estimate a_∞ from our measurements of breaking wave height, and hence find a value of $\epsilon_i \approx 7$ for the incident wave conditions. This value falls well within the range of ϵ_i for which maximum edge wave resonance was observed in the laboratory. Our field observations are therefore directly comparable with the laboratory observations of Guza and Bowen (1977) and Guza and Inman (1975) and confirm that subharmonic edge waves can form beach cusps in the field as well as in the laboratory.

CHAPTER 82

NEAR-BOTTOM VELOCITIES IN WAVES WITH A CURRENT

by W.T. Bakker¹⁾ and Th. van Doorn²⁾

0 Abstract

Bakker (1974) developed a mathematical model concerning the sand concentration and velocity distribution in an oscillatory turbulent flow, with or without resultant current.

The flow is assumed to be uniform in horizontal direction. The present paper reports on an experimental verification of this theory. Furthermore, the numerical accuracy of the model has been investigated and diagrams are presented which enable the computation by hand of global velocity profiles.

1 Introduction

This paper deals with a numerical theory on the near-bottom velocity pattern in parallel-directed waves and current and with the comparison of theory and measurements. The paper is a sequence to an earlier paper (Bakker, 1974); the numerical theory concerning the velocity field developed herein is further refined and, in some respects, revised. For the sake of physical understanding an additional paper, dealing with an approximate analytical theory is in preparation (Bakker, 1979).

Furthermore, a Report is in preparation (Bakker and Van Doorn, 1979) which comprises as well the analytical and the numerical theory, and which goes further into details. This study has to be placed in a general scope of investigations, mentioned in the preceding paper (Bakker, 1974).

The necessary assumptions are mentioned in Ch. 2; in Ch. 3 the mathematical formulation is given. Because several aspects differ from those in the earlier paper, most of the derivations from this paper are repeated for convenience. Ch. 4 deals with the investigations on numerical accuracy. In Ch. 5 experiments are described, carried out in the Delft Hydraulics Laboratory (DHL). Comparison between theory and experimental data is made in Ch. 6. The present theory and the theory of Lundgren (1972) are compared in Ch. 7. After the conclusions (Ch. 8) the acknowledgements (Ch. 9), the literature and the symbols are mentioned.

The theory was developed by the first author; the experimental verification was carried out by the second author, who also reported on this subject.

2 Assumptions

The following assumptions are made:

- a. Apart from turbulent fluctuations a horizontally directed and horizontally uniform current pattern is assumed. The current u is assumed to be only a function of the vertical coordinate z and the time t , but no function of the horizontal coordinate x .

1) Senior Scientific Officer, Technical University of Delft

2) Head of Study Dept. Vlissingen, Rijkswaterstaat, Netherlands

Project Engineer, Delft Hydraulics Laboratory, Netherlands

b. In the fluid a turbulent shear stress is assumed, according to the assumptions of Prandtl (1931) equal to:

$$\tau = \rho \ell^2 \frac{\partial u}{\partial z} \left| \frac{\partial u}{\partial z} \right| \quad (1)$$

in which τ is the shear stress, positive when acting in positive direction from the upper layer on the lower layer, ρ is the specific density of the fluid and ℓ is the mixing length.

c. A reasonable assumption on this mixing length and the distribution of the shear stress as a function of the height is obtained as follows. The equation of motion reads:

$$\rho \frac{\partial u}{\partial t} = \frac{\partial \tau}{\partial z} - \frac{\partial p_r}{\partial x} \quad (2)$$

in which p_r denotes the fluid pressure. A periodical water motion with period T is assumed. By Fourier analysis, one finds that the left-hand side of Eq. (2) will be zero when averaged over period T .

Then one finds from (2):

$$\frac{d\bar{\tau}_{\text{real}}}{dz} = \frac{\partial \bar{p}_r}{\partial x} \quad (3)$$

The bar above the symbol indicates the averaging over the wave period T ; the subscript "real" of τ serves as a distinction from the schematized τ , mentioned later on.

Assuming, that the mean pressure gradient is constant over the height h , one may write for $\bar{\tau}$:

$$\bar{\tau}_{\text{real}} = (h-z) \frac{\partial \bar{p}_r}{\partial x} \quad (4)$$

If only a stationary and no periodic motion would occur, according to well-known methods one finds a logarithmic velocity distribution, starting from a mixing length ℓ_{real} according to:

$$\ell_{\text{real}} = \kappa z \sqrt{1 - \frac{z}{h}} \quad (5)$$

where κ is the Von Karman constant.

For a stationary current, this logarithmic velocity distribution is found also, if the shear stress τ is schematized as a constant (i.e. uniform over the height):

$$\bar{\tau} = h \frac{\partial \bar{p}_r}{\partial x} \quad (6)$$

and the mixing length according to:

$$\ell = \kappa z \quad (7)$$

As the investigated features occur quite near to the bottom, where (4) and (6) on one hand and (5) and (7) on the other hand look very much the same, in the following the relationships (6) and (7) will be assumed.

d. Starting from a mixing length according to (7), generally it will be assumed, that the pressure gradient $\text{grad}(p_r)$ is horizontally directed, i.e. that the pressure is only a function of x and t .

e. The mean velocity, when averaged over the water depth and the wave period is called U_{mean} . It is further assumed that the water mass far from the bottom is in oscillatory motion according to:

$$U_{\text{osc}} = \hat{U}_1 \sin(\omega t - \psi_1) + \hat{U}_2 \sin(2\omega t - \psi_2) + \hat{U}_3 \sin(3\omega t - \psi_3) + \dots \quad (8)$$

\hat{U}_{mean} , \hat{U}_1 , \hat{U}_2 , \hat{U}_3 , ψ_1 , ψ_2 and ψ_3 can be arbitrary chosen. Connected with the solution, a small parasitary fourth harmonic is found, being 5 to 10% of the first one.

A solution with U_{mean} equal to zero can only be found, when also \hat{U}_2 is zero (as all higher even harmonics). In this case, a parasitary fifth harmonic of the order of 5 to 10% of the first one is found.

f. A hydraulically rough bottom is assumed. The velocity at a height z above the theoretical bottom level is assumed to be zero; it is assumed that z_0 equals 1/33 times the Nikuradse roughness r .

3 Computation of water velocities and shear stress

Define a rather arbitrary height z_{max} above the bottom, in this way, that the periodical changes of the shear stress are attenuated at that height. For $z \geq z_{\text{max}}$ the shear stress τ equals $\bar{\tau}$, being assumed constant over the height (assumption c). Thus one finds from (2):

$$\rho \frac{\partial u}{\partial t} = - \frac{\partial p}{\partial x} \quad \text{for } z \geq z_{\text{max}} \quad (9)$$

Let the velocity at $z = z_{\text{max}}$ be U . Thus Eq. (9) remains valid, when u is replaced by U ; let Eq. (9a) be Eq. (9) for $u = U$.

Define a "defect velocity" u_d as:

$$u_d = u - U \quad (10)$$

According to assumption d, subtracting Eq. (9a) from Eq. (9) yields:

$$\frac{\partial u_d}{\partial t} = 0 \quad \text{for } z \geq z_{\text{max}} \quad (11)$$

In (1), one may replace u by u_d , because U is no function of z . Thus, from (1) and (7) can be derived:

$$\bar{u}_d = \frac{\sqrt{\bar{\tau}/\rho}}{\kappa} \ln \frac{z}{z_{\text{max}}} \quad \text{for } z \geq z_{\text{max}} \quad (12)$$

Consider now the area where $z < z_{\text{max}}$. Subtracting Eq. (9a) from Eq. (2) and substituting u_d from (10) yields:

$$\frac{\partial u_d}{\partial t} = \frac{\partial(\tau/\rho)}{\partial z} \quad (13)$$

This equation can be transferred in an equation with the shear stress velocity p as independent variable.

Define p as:

$$p = \text{sign}(\tau) \cdot \sqrt{|\tau/\rho|} \quad (14)$$

Inversely, this implies:

$$\tau = \rho p |p| \quad (15)$$

From (1) and (7) it shows:

$$p = \kappa z \frac{\partial u}{\partial z} \tag{16}$$

In (16) one may replace u by u_d . Differentiation of (13) to z and multiplying with κz yields:

$$\frac{\partial p}{\partial t} = \kappa z \frac{\partial^2(p|p|)}{\partial z^2} \tag{17}$$

For method of computation of u from p is referred to Bakker (1974). The following mainly deals with deviations from this paper. From p , one can find u_d with the aid of (10), which can be written as:

$$u_d = - \frac{1}{\kappa} \int_z^{z_{\max}} \frac{p}{z} dz \tag{18}$$

Eq. (17) can be made dimensionless by introducing the following dimensionless variables:

$$\left. \begin{aligned} p^* &= p/\hat{p}_{b1} \\ t^* &= t/T \\ z^* &= z/Z, \text{ with } Z = \kappa \hat{p}_{b1} T \\ u^* &= u/\hat{p}_{b1} \quad (\text{see note } 1^1) \end{aligned} \right\} \tag{19}$$

in which \hat{p}_{b1} is the amplitude of the first harmonic of the shear stress velocity at the bottom (the index "b" refers to "bottom").

Thus one obtains from (17):

$$\frac{\partial p^*}{\partial t^*} = z^* \frac{\partial^2(p^*|p^*|)}{\partial z^{*2}} \tag{20}$$

As lower boundary condition is assumed:

$$p_b^* = \bar{p}_b^* + \sin 2\pi t^* + \hat{p}_{b2}^* \sin(4\pi t^* - \phi_2) + \hat{p}_{b3}^* \sin(6\pi t^* - \phi_3) \tag{21}$$

for $z^* = 0$

If U_{mean} equals zero, \bar{p}_b^* and \hat{p}_{b2}^* are assumed zero; to the choice of the variables \bar{p}_b^* , \hat{p}_{b2}^* , \hat{p}_{b3}^* , ϕ_2 and ϕ_3 will be referred.

The upper boundary condition is determined by the fact that $\bar{\tau}$ should remain constant over the height according to (6)²; Averaging Eqs. (13) and (17) over the wave period (in which case the left-hand side becomes zero, as can be seen by decomposing u_d and p in harmonics) one finds that

1) Generally, the velocities denoted by a symbol with an added star have been divided by \hat{p}_{b1} .

2) J. van Overeem drew the attention of the author to the fact, that this condition was not fulfilled by the solution for waves and currents, given by Bakker (1974). Therefore the solution in the present paper contains a revision of last-mentioned paper with respect to the case of waves with a current.

the solution of these equations fulfills this condition automatically, if the upper boundary condition is properly chosen. At the upper boundary the shear stress velocity p should be equal to $\sqrt{\tau}/\rho$:

$$p^* = \sqrt{p_b^* |p_b^*|} \quad \text{for } z^* = z_{\max}^* \quad (22)$$

In the case of an oscillatory flow without current (22) degenerates to $p^* = 0$ for $z^* = z_{\max}^*$. In the computer program, initially an approximation is chosen according to:

$$p^* = \sqrt{\pi p_b^* / 4} \quad \text{for } z^* = z_{\max}^* \quad (\text{initially}) \quad (23)$$

This approximation follows from analytical considerations (Bakker, 1979). In the course of the computations, the real value of the right-hand side of (22) is calculated; after each period the upper boundary condition is adapted. This condition changes, because after some periods \hat{p}_b^* , \hat{p}_{b2}^* , \hat{p}_{b3}^* , ϕ_2 and ϕ_3 are adapted by means of an iterative procedure¹⁾, in this way that the upper boundary condition (8) (in dimensionless shape) is fulfilled as good as possible.

In order to check the accuracy of this upper boundary condition, from the shear stress velocity p^* the value of U^* is calculated after some periods by means of numerical integration¹⁾ with the aid of (18), which clearly keeps its validity in the dimensionless shape.

In the following, some attention will be paid to the results with respect to the first harmonic and the mean velocity profile. This gives just a general scope: solutions, which fit rather closely to the wanted boundary conditions can be found by application of the computer program.

With respect to the first harmonic, the dimensionless relationship between \hat{u}_{d1}^* (the amplitude of the first harmonic of the dimensionless defect velocity) and z^* can be transferred into a dimensionless relationship between a kind of friction coefficient \hat{p}_{b1}/\hat{U}_1 and a_1/r , in which a_1 equals $\hat{U}_1 T/2\pi$ and r the Nikuradse roughness. This can be performed as follows.

Consider a certain defect velocity field u_d^* , which has been calculated, starting from certain bottom boundary conditions, defined by harmonics of p_b^* .

In principle every level z^* (at which u_d^* has been calculated) can be taken as a bottom boundary level z_o^* , where u^* is assumed zero. Therefore according to (10) the choice of z_o^* determines U^* , the dimensionless velocity far from the bottom (at $z^* = z_{\max}^*$). Thus one computation of u_d^* determines a great number of velocity fields u^* with various upper boundary conditions and various values of z_o^* . Neglecting (just for the general scope) non-linear interactions between the harmonics of p^* , in first approximation the relationship between dimensionless first harmonic U_1^* and z_o^* can be investigated by taking \hat{p}_b^* , \hat{p}_{b2}^* and \hat{p}_{b3}^* in

¹⁾ cf. Bakker (1974) and Bakker and Van Doorn (1979)

Fig. 1. Ratio \hat{p}_{b1}/\hat{U}_1 between the amplitudes of the first harmonics of the shear stress velocity and the velocity far from the bottom, respectively phase lag ψ_1 between \hat{p}_{b1} and \hat{U}_1 as function of the ratio a_1/r between the stroke length and the ripple height.

Fig. 2. Dimensionless amplitude \hat{u}_{d1}^* and phase ψ_1 of the defect velocity as function of the dimensionless height above the bottom: according to theory and measurements.

(21) equal to zero and calculating u_{d1}^* under these conditions.¹⁾ On the effect of non-linear interaction will be returned in Ch. 4.

From assumption \underline{f} and (19) the following relationship can be determined:

$$\frac{a_1}{r} = \frac{1}{66\pi\kappa} \cdot \hat{u}_1^* / z_o^* \quad (24)$$

which in turn can be written, using (10):

$$\frac{a_1}{r} = \frac{1}{66\pi\kappa} \hat{u}_{d1}^*(z_o^*) / z_o^* \quad (25)$$

where $\hat{u}_{d1}^*(z_o^*)$ denotes \hat{u}_{d1}^* at the height z_o^* .

Now the ratio \hat{p}_{b1} / \hat{u}_1 , relating the amplitude of the first harmonic of the bottom shear stress velocity to the amplitude of the first harmonic of the oscillatory motion U_{osc} far from the bottom, equals $1/\hat{u}_1^*$, according to (19) which in turn can be written as $1/\hat{u}_{d1}^*(z_o^*)$. According to a similar reason, the phase lag ψ_1 between p_{b1} and u_{d1} equals minus the phase lag between p_{b1}^* and $u_{d1}^*(z_o^*)$. Thus, from the computer results with the mentioned bottom boundary conditions, the choice of a value of z_o^* gives a relationship between a value a_1/r and the belonging values of \hat{p}_{b1}/\hat{u}_1 and ψ_1 . By using z_o^* as a parameter, the general relationship between a_1/r and the last mentioned parameters can be obtained; this is shown in Fig. 1. The same results are plotted in another way in Fig. 2, giving $\hat{u}_1^* (= \hat{u}_{d1}^* \text{ at } z_o^*)$ and ψ_1 as a function of z_o^* .

Now the attention will be turned to the mean velocity profile \bar{u} as function of z . From (10) and (18) for the upper part of the mean velocity profile is found:

$$\bar{u} = \bar{U} + \frac{\sqrt{\tau/\rho}}{\kappa} \ln \frac{z}{z_{max}} \quad \text{for } z \geq z_{max} \quad (26)$$

where \bar{U} is the mean velocity at $z = z_{max}$. Averaging (16) over the wave period and integrating, one finds in the vicinity of the bottom, where $\bar{p} \approx \bar{p}_b$:

$$\bar{u} \approx \frac{\bar{p}_b}{\kappa} \ln \frac{z}{z_o} \quad (\text{near the bottom}) \quad (27)$$

Therefore, plotting \bar{u} on the horizontal scale versus $\ln z$ on the vertical scale, the upper part will be a straight line with a gradient $\arctan(\kappa/\sqrt{\tau/\rho})$, where the curve tends to a straight line with gradient $\arctan(\kappa/\bar{p}_b)$ near the bottom. The last-mentioned gradient is larger than the first-mentioned one: the ratio $\bar{p}_b/\sqrt{\tau/\rho}$ will be called β_{op} and equals approximately $\sqrt{\pi\bar{p}_b^*/4}$ (for $\bar{p}_b^* \ll 1$); this follows from substitution of $\bar{p}_b = \bar{p}_b + \hat{p}_{b1}$ sin ωt into (15) and approximating in an analytical way²⁾³⁾.

1) This has been done earlier by Bakker (1974). In the present paper the conception is left of a coefficient " f_w ", occurring in the former paper, which relates the top-bottom shear stress to the top-orbital velocity. Because of the effect of higher harmonics, this coefficient obscures rather than enlightens the mechanism.

2) This result has already been used for the transition from (22) to (23).

3) Bakker (1979); Bakker and Van Doorn (1979).

Fig. 3a. Theoretical distribution of mean velocities.

Fig. 3b. Comparison with measurements.

Fig. 3. The mean velocity distribution according to theory and measurements.

Thus it shows, that the velocity profile consists of two logarithmic parts with a transition zone between.

With respect to this transition between the bottom and $z = z_{\max}$, an analytical approximation¹⁾ suggests the occurrence of a universal function $f(z^*)$ in this way, that for small values of z^* the following relationship holds:

$$\frac{\bar{\kappa} \bar{u}}{\bar{p}_b} = f(z^*) - f(z_o^*) \quad (28)$$

When z^* is plotted on a vertical, logarithmic scale and $\bar{\kappa} \bar{u} / \bar{p}_b$ on a linear horizontal scale so that 1 on the horizontal scale corresponds with $\ln e$ on the vertical scale, the lower part of the curve $f(z^*)$ degenerates to a line under an angle of 45° . Thus this part corresponds with the lower logarithmic part of the velocity profile mentioned before. The curve $f(z^*)$ also gives the transition zone; the upper logarithmic part of the velocity profile can be found by drawing the tangent to $f(z^*)$ with a gradient $\sqrt{\pi \bar{p}_b^* / 4}$ with the horizontal (inset Fig. 3).

From the computer results the curve $f(z^*)$ can be found. Starting from certain values of \bar{p}_b^* and assuming \bar{p}_{b2}^* and \bar{p}_{b3}^* equal to zero, the velocity field u_d^* , and thus \bar{u}_d^* , can be calculated; starting from a certain, rather arbitrary²⁾ value of z_o^* , one can find \bar{u}_o^* , and thus $\bar{\kappa} \bar{u} / \bar{p}_b^*$, equal to $\bar{\kappa} \bar{u} / \bar{p}_b$. Indeed it shows, that the lower part of the resultant curves for various values of \bar{p}_b^* coincide, and that the lower part gives a straight line under 45° , whereas the upper parts show a gradient $\sqrt{\pi \bar{p}_b^* / 4}$ (Fig. 3a).

The question remains how \bar{p}_b can be determined from U_{mean} , the velocity averaged over the period as well over the depth h .

Without an oscillatory motion, the relationship would exist:

$$\bar{p}_b = \frac{\bar{\kappa} U_{\text{mean}}}{\ln(h/ez_o)} \quad (\text{without oscillatory motion}) \quad (29)$$

which can be derived in the same manner as the Chezy relationship³⁾.

With oscillatory motion, an approximate calculation of U_{mean} from \bar{p}_b (or inversely: of \bar{p}_b from U_{mean}) could be made by neglecting the effect of the transition zone and the lower logarithmic curve on the mean velocity and extrapolating the upper logarithmic curve in downward direction (Fig. 4). However, this extrapolated line will intersect the (vertical) line of zero-velocity, in a point higher than $z = z_o$, say $z = \alpha z_o$ (Fig. 4). Thus it shows, that the effect of the oscillatory motion is an enlargement of the apparent roughness with a factor α . Furthermore, \bar{p}_b in (29) should be replaced by $\sqrt{\bar{\tau}} / \rho$, which makes a difference of a factor β_{ob} , as stated before in this Chapter. Thus, in case of oscillatory flow, (29) changes into:

$$\bar{p}_b = \frac{\beta_{ob} \bar{\kappa} U_{\text{mean}}}{\ln(h/e \alpha z_o)} \quad (30)$$

1) Bakker (1979); Bakker and Van Doorn (1979)

2) Only should be conditioned, that z_o^* is so small, that it gives a point on the lower straight section (under 45°) of the $f(z^*)$ -curve.

3) This can be easily seen by multiplying both sides of Eq. (29) with $(1/\bar{\kappa}) \ln(h/ez_o)$.

Fig. 4. Relationship between $\ln \alpha$ and \bar{u}_d^*

Fig. 5. The coefficient α as function of a_1/r and \bar{p}_b^* .

Fig. 6. Wave flume and artificial roughness.

in which $\beta_{ob} \approx \sqrt{\pi \bar{p}_b^* / 4}$ and in which α is derived with the aid of the computer program in the following way.

Analogous to the case with the first harmonic, each level z^* can be considered as a lower boundary condition z_o^* , which determines a_1/r . Fig. 4 shows that α can be found from the following relationship:

$$\ln \alpha = \ln \frac{z_{\max}^*}{z^*} - \frac{\beta_{ob} \kappa}{\bar{p}_b^*} \cdot \bar{u}_d^*(z^*) \quad (31)$$

where $\bar{u}_d^*(z^*)$ denotes \bar{u}_d^* at the level z^* . In this way, with one computer calculation—starting from a bottom boundary condition with a certain value of \bar{p}_b^* and assuming \hat{p}_{b2}^* and \hat{p}_{b3}^* equal to zero—one may find the value of a_1/r for a great number of values a_1/r . Fig. 5 shows α as a function of a_1/r and \bar{p}_b^* .

Now the following rough way of calculation of the mean velocity profile is advised:

- a. Determine a_1/r , using $a_1 = \hat{U}_1 T / 2\pi$
- b. Determine \hat{p}_{b1}^* from the ratio \hat{p}_{b1}^* / U_1 , found in Fig. 1
- c. Calculate \bar{p}_b^* from (30), which may be written as:

$$\bar{p}_b \approx \frac{\pi}{4} \cdot \left[\frac{U_{\text{mean}}}{(\hat{p}_{b1} / \kappa) \ln(h/\epsilon \alpha z_o)} \right]^2 \quad (\text{see note } 2) \quad (32)$$

Here α has to be determined iteratively: assuming for instance first $\alpha = 1$, finding \bar{p}_b^* from (32), finding a better estimation of α from Fig. 5 until the wanted accuracy of \bar{p}_b^* is reached.

- d. The lower part of the profile is a straight line on single-logarithmic paper under an angle $\arctan(\kappa / \bar{p}_b)$ through the point $(u, z) = (0, z_o)$
 - the upper part is a straight line on single-logarithmic paper under an angle $\arctan(\beta_{ob} \kappa / \bar{p}_b)$ or, approximately $\arctan(\kappa \sqrt{\pi} / (4 \bar{p}_b \hat{p}_{b1}))$
 - the transition can be found from Fig. 3a.

As mentioned, more accurate results can be obtained by using the computer program directly; in this case a first estimation of \bar{p}_b^* follows from (32).

4 Numerical accuracy

A number of computations has been carried out in order to check the numerical accuracy. For the details is referred to Bakker and Van Doorn (1979); here the following results may be mentioned.

- a. In the computer program an initial condition can be introduced, which may be different from the one, following from the periodical bottom boundary condition. After 4 periods running, the effect of this initial condition vanished up to 1°/oo of \hat{p}_{b1} ³⁾.
- b. The effect of the upper boundary condition on the ratio \hat{p}_{b1} / \hat{U}_1 is small, as long as z_{\max}^* is 1.5 at least.

1) For $\bar{p}_b^* > .5$ this approximation becomes inaccurate, in which case is referred to Bakker (1979) or Bakker and Van Doorn (1979).

2) In (32) the denominator between the brackets shows a hypothetical mean velocity over the profile, which would occur when the bottom shear stress velocity would have been \hat{p}_{b1} , instead of (a mean value of) $\sqrt{\pi} / \rho$. and when the roughness would have been α instead of r .

3) The ratio between \hat{p}_{b1} and \hat{U}_1 can be found from Fig. 1.

- c. The greatest traceable source of numerical error in the program is found to be caused by the fact, that the present iteration procedure does not extend up to the fourth and fifth harmonic; when the real fourth and fifth harmonic of U are zero, the error is of the order of 20% of \hat{p}_{b1} . Because of this error, the accuracy is not effectively enlarged by taking more than 6 grids (using $z_{\max}^* = 1.5$). The differences in U_1 between the use of respectively 3, 4, 5 grids compared with using 6 grids is respectively 4, 2, 1, 0.3% of \hat{U}_1 when $a_1/r = 129$ ¹⁾. The raising of the grid number by 1 increases the computer time about a factor 2.
- d. Considering the case without resultant current, the effect of a third harmonic of p_b (being so large, that \hat{U}_3 becomes zero) on the first harmonic U_1 is small (about 1% of \hat{U}_1).
- e. The effect of \bar{p}_b (i.e. resultant current) on the first harmonic u_{d1} is relatively small for large values of a_1/r (2.5% of \hat{U}_1 when $a_1/r = 129$ and $\bar{p}_b^* = .23$). For smaller values of a_1/r the effect is larger (6% of \hat{U}_1 when $a_1/r = 3.5$ and $\bar{p}_b^* = .23$).

5 Experiments

The bottom boundary layer under periodic progressive water waves, without and with a superimposed current has been investigated at the Delft Hydraulics Laboratory (DHL). The results of these experiments on the velocity distribution are compared with the present theory. In the theory, assumptions are made for the case of a horizontally oscillating flow such as can be realized in a horizontally pulsating water tunnel. The results of the present investigations, with free surface waves, will in future be compared with results from similar tests in the Oscillating Water Tunnel of the DHL.

Water surface elevation (η) and horizontal water velocity component in the direction of wave propagation (u) have been measured simultaneously in the same cross-section in a 30 m long, 0.5 m wide and 0.5 m high glass-walled flume of the DHL (Fig. 6).

Periodic waves were generated by a flat wave board oscillating horizontally with adjustable amplitudes at the lower and upper side. The wave trains applied in the experiments, obtained by starting the wave generator always from the same position were very well reproducible. In all experiments, the still-water depth (h) was 0.30 m, the wave period (T) with respect to a fixed point 2.0 s and the wave height (H) at the measuring station 0.12 m. Steady currents can be generated by circulating the water (Fig. 6). In view of the presence of secondary waves, the measuring stations were chosen so that the ratio of the amplitudes of the first and second harmonic components of the surface waves approximately showed a maximum. In order to obtain a turbulent boundary layer at the bottom, two-dimensional roughness elements (2 mm high at 15 mm centers) were applied (Fig. 6).

¹⁾ In the present program z_o^* may differ from Δz^* . This is a facility, plugged in the computer program after Appendix A of Bakker (1974) was written. In this way the value of \hat{U}_1^* belonging to an arbitrary value of a_1/r can be calculated, independent of the number of grids. For details, cf. Bakker and Van Doorn (1979).

The experimental study has been performed in two phases. In the first phase 1), waves without a current were considered. The inflow provision in the flume was covered. The artificial bottom roughness was applied only over a distance of 1.5 m at the measuring section. In the second phase of the experiments 2), roughness elements were applied over a distance of 15 m next to the water inlet and currents were generated in the same direction as the wave propagation. The mean current velocities (averaged over the height) were approximately 0.10 m/s (test code V10) and 0.20 m/s (test code V20). In this second phase, tests without a current (test code V00), but with open inlet were repeated for comparison.

For each condition, velocities in two verticals have been measured viz. in between two roughness elements (code RA) and just above one (code RB). In this way, tests series were performed with codes RA, RB (first phase) and VOORA, VOORB, VIORA, VIORB, V2ORA, V2ORB (second phase).

Figure 3b shows the distribution along the vertical of measured current velocities (time average values). It is noted that in the experiments the speed of the pump was the same for the current only and for current with waves, whereas the theory on oscillatory flow with resultant current starts from a given gradient of the mean water level which is supposed to be the same for "current only" and for "current with waves".

For the analysis, only the waves from a wave train were used after the start-up transients and before the first reflected wave reached the measuring station. Three wave trains were applied for every level at which velocities have been measured, from which as an average a more accurate orbital velocity could be determined. In the case of waves with a current, η and u are measured also without waves.

The water surface elevation was measured with a resistance-type wave gauge. The velocities were measured at a series of successive levels above the bottom with a laser-doppler velocity meter (LDV). The application of this technique with its general advantage of measuring accurately and contactless in very small measuring volumes, was highly satisfactory. The error in positioning the level of the LDV was less than ± 0.1 mm. The reference distance to the bottom, determined by means of a measuring rule is less accurate; the error is estimated less than ± 0.3 mm.

The signals from the wave gauge and the LDV were recorded simultaneously on paper and on an analog magnetic tape. From the tape recorder the signals have been processed in two steps:

- a. Digitization by synchronized sampling, exactly 72 times per wave period, i.e. a sampling frequency of 36 Hz. From every wave train, the measured signals have been sampled over the same time interval after the start of the wave generator, so phase relations between velocities measured at different levels could be maintained. In the first phase of the experiments, the accuracy of digitizing was ± 0.025 cm and ± 0.15 cm/s for the signals of the surface waves and the velocities respectively. In the second phase, these values were 10 times smaller.
- b. Harmonic analysis of the digital signals. The results obtained from harmonic analysis of the average wave (i.e. also velocities) of the three wave trains were used for comparison with theory.

Table 1 shows the most important parameters deduced from the tests.

6 Comparison between theory and measurements.

Comparison is made between the theory and the measured mean velocity profiles V1ORA and V2ORA. The results are plotted in Fig. 3b.

The theoretical curves (found from the computer program) differ from the ones which can be interpolated, using Fig. 3a, because of the effect of the strong second harmonic U_2 (about 1/3 of the first harmonic U_1) on \bar{U} , which is not taken into account in the derivation of Fig. 3a.

With respect to the comparison of the first harmonic, apart from the experiments, mentioned in Ch. 5, also the measurements of Jonsson (1963) (see also Jonsson and Carlsen, 1976) will be taken into consideration for the comparison between theory and measurements. The experimental data, as derived from the literature are added to Table 1.

For the various experiments, the dimensionless amplitude and the phase of the defect velocity have been calculated and plotted against the dimensionless height above the bottom. The results are shown in Fig. 2. With respect to the amplitude of the defect velocity there is a rather good agreement between measurements and theory, whereas the phases still show discrepancies.

The comparison between the instantaneous velocity profiles according to the theory and the measurements (starting from a given upper boundary condition) is given in Figure 7.

The general trend is rather well predicted, although the "overshoot" velocity tends to be higher according to the measurements than according to theory. Fig. 8 shows $\sigma(u) / \hat{p}_{b1}$ as function of the dimensionless distance z^* above the bottom for the various tests, $\sigma(u)$ being the standard deviation between the theoretical and measured values of the instantaneous velocities at a certain height. The mean value $\bar{\sigma}$ of $\sigma(u)$, averaged

Fig.9. Comparison of the velocity defect according to Lundgren and the present theory.

over the considered levels within the boundary layer, has also been given in Figs. 7 and 8.

7 The mean velocity profile according to the present theory and according to Lundgren

Lundgren (1972) defines a shear stress velocity "U_f" (Eq. (19) of his paper), equal to τ_{cw}/ρ, in which "τ_{cw}" is the period-average of the bottom shear caused by waves and current. Thus "U_f" equals \bar{p}_b/β_{ob} in the present notation.

Lundgren's equation ((23) of his paper) for the mean velocity profile reads, in the notation of the present paper:

$$\bar{u} = \frac{\bar{p}_b}{\beta_{ob}} \left(\frac{1}{\kappa} \ln \frac{z}{z_o} - A \right) \tag{33}$$

in which he calls A the "velocity defect".

In the present theory, the upper part of the velocity profile is given by:

$$\bar{u} = \frac{\bar{p}_b}{\beta_{ob}} \frac{1}{\kappa} \ln \frac{z}{\alpha z_o} \quad (z \gg z_o) \tag{34}$$

Therefore "A" equals (lnα)/κ. In his Fig. 2 Lundgren presents as result of his calculations the value of A as function of "τ_{cw}/ρU_b²", being in the present notation $\bar{\tau}/\rho\hat{U}_1^2$, or in dimensionless notation $(\bar{p}_b^*/\beta_{ob}\hat{U}_1^*)^2$.

In the computer program, \bar{p}_b^*/β_{ob} is known from the upper boundary condition (22). In the computer program for given values of \bar{p}_b^* as well A as $\bar{\tau}/(\rho\hat{U}_1^2)$ can be calculated as function of a₁/r; therefore Fig. 2 according to the lay-out of Lundgren may be reproduced according to the present theory. In Fig. 9 the lines of constant "A" as function of a₁/r and $\bar{\tau}/\rho\hat{U}_1^2$ according to Lundgren and the present theory are drawn together.

8 Summary and conclusions

- a. Bakker (1974) presented a numerical mathematical model of the turbulent bottom boundary layer in periodic waves with (or without) resultant current in the direction of wave propagation. This model starts from the Prandtl assumptions with respect to the relationship between shear stress and the instantaneous velocity gradient. Non-linear interactions are taken into account.
- b. In the present paper the mathematical model has been improved and has been compared with experimental investigations at the Delft Hydraulics Laboratory (DHL). Velocities at a series of successive levels above the bottom under free surface waves without, respectively with resultant current in a wave flume were measured with a laser-doppler velocity meter.
- c. The mathematical model predicts reality rather well although the phases of the first harmonic of the "defect velocity" in model and reality show discrepancies. With respect to the resultant velocity is referred to Fig. 3, with respect to the amplitude and phase of the first harmonic of the defect velocity to Fig. 2 and with respect to the instantaneous velocity profiles to Fig. 7. In Fig. 8 the standard deviation between measurements and theory is given as a function of the height above the bottom in a dimensionless graph. For this, \hat{p}_{b1} has been used as reference velocity (the ratio between \hat{p}_{b1} and the amplitude \hat{U}_1 of the first har-

monic of the velocity outside the boundary layer is given in Fig. 1) and $\kappa p_{bl} T$ as a reference height.

- d. The shear stress, exerted at the bottom according to this model and according to the investigation of Lundgren (1972) appears to be of the same order of magnitude (Fig. 9), although the problem is approached from a different angle.
- e. In the future, the mathematical model will be improved by including higher harmonics than the third in the upper boundary conditions; the measurements will be continued with similar tests in the Oscillating Water Tunnel of the DHL; a (less accurate) analytical theory will be presented, giving more insight in the physics of the matter.

e	basic number of neperian logarithms
$f(z^*)$	universal function, from which $\kappa \bar{u} / \bar{p}_b$ can be found (vide (28))
h	water depth
l	mixing length (schematized according to (7))
l_{real}	more realistic value of mixing length
p	internal shear stress velocity ($\sqrt{\tau/\rho}$) in the fluid
P_r	(instantaneous value of the) water pressure
r	Nikuradse roughness
t	time
T	wave period
u	horizontally directed water velocity (uniform in horizontal direction), after averaging turbulent fluctuations
U	velocity u at $z = z_{\text{max}}$
u_d	"defect velocity" $u - \bar{U}$
U_{mean}	mean velocity, averaged over both wave period T and water depth h
U_{osc}	oscillatory water motion above the boundary layer (assumed uniform over the height), i.e. $u - \bar{u}$ for $z \geq z_{\text{max}}$
x	horizontal coordinate
z	vertical coordinate
z_0	$r/33$, the theoretical level where the velocity is assumed to be zero
z_{max}	height, at which the variations of the internal shear stress are attenuated
α	multiplication factor of the apparent roughness, caused by the addition of the oscillation to the current
β_0	ratio between \bar{p} and $\sqrt{\tau/\rho}$ (about equal to $\sqrt{\pi \bar{p}_b^*}/4$ if $\bar{p}_b^* \ll 1$ and if $\hat{U}_2, \dots \ll \hat{U}_1$)
κ	Von Karman constant
ρ	specific density
τ	internal shear stress in the fluid
$\bar{\tau}_{\text{real}}$	more realistic approximation of the shear stress averaged over the wave period than $\bar{\tau}$ (vide (4))
$\phi_2, (3)$	phase angle of harmonics of the shear stress velocity p
$\Psi_1, (2), (3)$	phase angle of harmonics of the velocity U at height $z = z_{\text{max}}$ above the boundary layer
ω	angular frequency of first harmonic of oscillation ($2\pi/T$)

Other symbols added to a variable x :

\bar{x}	average value of x during period T
x^*	"dimensionless variable", i.e. velocity divided by \hat{p}_{b1} , or height divided by $\kappa \hat{p}_{b1} T$, or time, divided by T
x_b	value of x at the bottom ($z = 0$)
$x_1, (2), (3)$	subscript applies to first, (second), (third) harmonic of x
\hat{x}	amplitude of harmonic x (always in combination with subscript 1, 2 or 3)
$ x $	absolute value of x
$\text{sign}(x)$	"+1" if x is positive, "-1" if x is negative
$X(x)$	value of variable X at height x

CHAPTER 83

Rip Currents and Their Causes

by

Robert A. Dalrymple¹

Introduction

"The outworn dogmas of science seem to be particularly concentrated in the discussions of the ocean in geology books". Beginning with this controversial statement, F. P. Shepard in 1936 tried to lay to rest the concept of the undertow, which had been debated in the pages of Science for over a decade. At the same time, he introduced the term, rip current, to describe the rapidly seaward-flowing currents, which were well-known to lifeguards at that time, as these currents were responsible for carrying swimmers offshore at frightening speeds.

Subsequent studies by Shepard and his colleagues (Shepard, Emery and LaFond, 1941; Shepard and Inman, 1950a, 1950b) showed that rip currents (1) are caused by longshore variations in incident wave height, (2) are often periodic in both time and in the longshore direction and (3) increase in velocity with increasing wave height. The major reason put forth to explain the variation in wave height was the convergence or divergence of wave rays over offshore bottom topography (such as submarine canyons) or the forced wave height variability caused by coastal structures, such as jetties.

McKenzie (1958) and Cooke (1970) in their studies corroborated the findings of the Scripps Institution of Oceanography researchers and also pointed out the persistence of rip currents (once high energy waves in a storm had caused rip channels to be cut into the bottom) after the storm had abated. In fact it appears that on coastlines which are affected by major storms which build offshore bars, that the nearshore circulation may be dominated by the storm-induced bottom topography for long afterwards.

The researchers up to the late 1960's who attempted to theoretically model rip currents knew the importance of longshore wave height variability and the wave-induced set-up in the formation of rip currents, but it was not until Longuet-Higgins and Stewart (e.g., 1964) codified the wave momentum flux tensor that great strides were made in providing models for rip currents.

This paper is intended to categorize and review the more recent theories for rip current generation and to discuss a simple model for rip currents on barred coastlines.

¹Associate Professor, Department of Civil Engineering, University of Delaware, Newark, Delaware, U.S.A. 19711

Theoretical Approaches

The various mechanisms proposed to date to explain rip currents can be conveniently placed into two categories: (1) wave interaction and (2) structural interaction. The distinction between the two is that the first category mechanisms can occur on uniformly planar beaches (having no longshore variability), while the second group cannot. Table I lists the categories and the candidate theories within each.

Table I. Rip Current Mechanisms

<u>Wave Interaction Models</u>	<u>Primary Investigators</u>
Incident-edge wave	
Synchronous	Bowen (1969), Bowen and Inman (1969)
Infra-gravity	Sasaki (1975)
Intersecting wave trains	Dalrymple (1975)
Wave-Current Interaction	LeBlond and Tang (1974), Dalrymple and Lozano (1978)
<u>Structural Interaction</u>	
Bottom Topography	Bowen (1969), Noda (1974)
Coastal Boundaries	
Breakwaters	Liu and Mei (1976)
Islands	Mei and Angelides (1977)
Barred Coastlines	Dalrymple, Dean and Stern (1976)

Wave Interaction Models - The first theory in this category is the incident/edge wave interaction model proposed by Bowen (1970), Bowen and Inman (1970) and independently by Harris (1967). This model requires the intersection of synchronous edge waves (traveling along the shore) and the incident wave field to provide the longshore variability of wave heights. The synchronous edge wave forces a nearshore circulation with a longshore periodicity, L_r , equal to the edge wavelength, L_e ,

$$L_r = L_e = L_o \sin\{(2n + 1)\beta\} \quad (1)$$

where $L_o = gT^2/(2\pi)$, the deep water wavelength, g the acceleration of gravity, β is the beach slope and n is the offshore mode number of the edge wave. Clearly the rip current spacing depends strongly on the incident wave period. (Surprisingly, some of Harris' laboratory experiments (Mark II) show no period effects). The length of the rip spacing has a maximum of L_o , for the case of very steep

beaches and/or high mode edge waves. Often, however, for many beaches, such as Silver Strand (see Bowen and Inman (1970)) and the East coast of the U.S., L_r exceeds L_o , or else very high mode numbers are required for Eq. (1), Tait (1970). The origin of synchronous edge waves could be reflection of the incident waves by a structure or headlands or through a nonlinear resonance, but Guza and Davis (1974), theoretically, and Guza and Inman (1975) and Harris (1967), experimentally, showed that the most likely resonant edge wave is the subharmonic edge wave, which does not produce rip currents. A further restriction on the model is that the shoreline must be reflective, requiring the waves to be non-breaking. Guza and Inman (1975) have proposed the requirement for the existence of edge waves as

$$\epsilon = \frac{a_1 \sigma^2}{g \tan^2 \beta} = \left(\frac{2\pi H_o}{L_o \tan^2 \beta} \right) \leq 2 \quad (2)$$

Note that this parameter, ϵ , is directly relatable to the parameter proposed by Irribarren and Nogalles (see Battjes, 1974).

For surf zones, characterized as dissipative ($\epsilon > 2$), which would have a significant width, Bowen and Inman hypothesized that longer period edge waves and surf beat could perhaps interact to cause the longer rip spacings, $L_r > L_o$. Sasaki (1975), noting that there is significant energy in the surf zone at low frequencies (Suhayda, 1975; Huntley, 1976) recommended an empirical equation for the case of infra-gravity waves

$$L_r = 1.27 \times 10^{-2} \epsilon \quad (3)$$

For cases other than those used by Sasaki, Bruno and Dalrymple (1978) found an apparent linear trend with ϵ , but for small ϵ . Additionally the slope of the line was different than that in Eq. 3.

Dalrymple (1975) and Dalrymple and Lanan (1976) generalized the edge/incident wave model to show that rip currents and beach cusps are produced by intersecting synchronous wave trains. The periodic spacing of the rip current is

$$L_r = \frac{L_o}{(\sin \theta_o - \sin \zeta_o)}$$

where θ_o , ζ_o are the deep water angles of incidence made between the wave rays and the beach normal. This model has no theoretical maximum for L_r but has a minimum spacing of $L_r = L_o/2$, thus there is a small region of overlap between the edge wave and the intersecting wave model. While it is clear that this model will generate rip currents when the incident wave field is reflected back on itself or when refraction or diffraction is strong, it is not known what percentage of the time this mechanism is valid on a plane beach when two different synchronous wave systems would have to be present.

A third class in the wave-interaction category is the wave-current interaction models, which have been stimulated by the observations of Arthur (1950, 1962), Harris (1967) and others that rip currents can cause strong refractive effects on the incident wave field.

The concept is that for normally incident waves, the basic state is one of uniform setup along the beach with no nearshore circulation; however, as the investigators of this class of models have discovered, there are other modes that are also possible, which do yield rip currents. LeBlond and Tang (1974) investigated the possibility that the interaction of the nearshore currents and the wave energy would cause a feedback mechanism and a preferential spacing for rip currents. Iwata (1976) used a similar approach; but, as pointed out recently by Dalrymple and Lozano (1978), these models did not predict rip current spacings. Mizaguchi (1976), unable to get rip currents with a fixed bottom friction, introduced an arbitrary variation in the friction coefficient and was able to predict rips; however, the assumed variability in f was somewhat arbitrary. Dalrymple and Lozano (1978) showed that only when the effects of incident wave refraction by the outgoing rip currents are included can a model similar to LeBlond and Tang's predict a rip current spacing. The non-dimensional rip current spacing, $\lambda X_b \cong 2\pi X_b / L_r$, (where λ is the longshore wave number for the circulation and X_b is the surf zone width) is expressed as a function of the parameter $A_D = (\tan \beta \kappa \pi / 8f)$ where κ is the breaking index, $0(1)$, which relates the breaker height to the water depth and f is a Darcy-Weisbach (constant) friction coefficient. This result can be approximated as

$$\lambda X_b \cong \frac{1}{A_D} + 2.8 \quad (4)$$

Note that this result yields an increase in L_r with wave height as X_b directly proportional to H_b , the breaking wave height. The solution obtained by Dalrymple and Lozano was for a beach characterized by a flat sloping surf zone bottom and a flat offshore; the discontinuity in slope at the breaker line caused the development of two circulation cells, one wholly contained within the surf zone and one which extends across the breaker line. Despite this, the results appear to follow the trend of LEO observations, taken by the Coastal Engineering Research Center, with a great deal of scatter (Bruno and Dalrymple, 1978).

A key assumption included in these theories is the manner in which energy dissipation is modelled in the surf zone at each order of the perturbation. For the above studies it was assumed that the form of energy dissipation corresponds to that necessary to give $H = kd$ at the basic state (LeBlond and Tang, 1974), that the relationship between H and d is true for all order of perturbations (Dalrymple and Lozano, 1978) or there is no dissipation beyond the basic state (Iwata, 1976). Recently Miller and Barcilon (1978) have used a hydraulic jump analogy to develop a form for energy dissipation. Their results yield an approximate formula (for their $B = 32$ case)

$$\lambda X_b = 0.03/A_D + 0.6 \quad (5)$$

This result is far smaller than most field observations. Until more studies are made for energy dissipation in the surf zone, no real progress can be made using these techniques.

Another problem that hampers this area of research is the inability to study the instability mechanisms; for example, a small perturbation in the basic state. Since the governing equations have been time averaged (over a wave period), only slowly evolving instabilities can possibly be studied. As yet, even this problem has not been solved.

Finally, Hino (1974) has proposed a model for coastal instability based on a feedback between the deforming bottom and the flow field. His model yields approximately a constant spacing

$$\lambda_{x_b} \cong \pi/2 \quad (6)$$

Significant work still needs to be done in this area.

Boundary Interaction Models - This category of models probably accounts for the majority of rip currents observed on coastlines. As mentioned, the early researchers discerned that longshore variability in the bottom topography would cause rip currents to form. If the bottom variability is periodic in the longshore direction, then periodic nearshore circulation cells may form. The first theoretical model for this case was put forward by Bowen (1969). Numerical and analytical extensions of his work to various bottom bathymetries have verified the basic forcing of the nearshore circulation due to the bottom topography's effect on the wave field, e.g., Sonu (1972), Noda (1974), Noda *et al.* (1974), Birkemeier and Dalrymple (1974) and Mei and Liu (1975). All of these models have utilized linearized models in the sense that the wave field has been characterized by linear water wave theory and the mean equations for the nearshore currents do not include the convective acceleration terms.

In addition to bottom topography, the presence of man-made or natural lateral barriers influence the nearshore circulation also. Dalrymple, Eubanks and Birkemeier (1977) studied the circulation interior to rectangular basins, such as a harbor or, in particular, laboratory wave basins. Liu and Mei (1976) in a series of two papers examined the wave field and the nearshore circulation in the vicinity of breakwaters both shore-connected and detached. Mei and Angelides (1977) examined the wave-induced flow around a circular island, considering refractive effects alone. This problem of circulation around structures is still one that requires a significant amount of study, particularly in determining the wave field in the regions surrounding structures, that not only partially reflect and diffract the waves, but also serve as significant energy sinks. Laboratory studies of structures and the effect on the nearshore circulation have been conducted by Gourlay (1976).

The case of incident waves encountering longshore bars and the associated nearshore current field has been largely neglected in the literature. While the presence of rip channels in bars has been

recognized in longshore current formulae, e.g. Inman and Bagnold (1963) and Bruun (1963), efforts to develop nearshore circulation models in this case are hampered by an inability to correctly predict the wave field over the longshore bar. Recently, Dalrymple, Dean and Stern (1977) indicated that, in addition to the usual continuity assumptions (that is, the mass transport of water over the bar must equal the flow in the rip current), wave reflection from the submerged sand bar provides an important forcing for the circulation system. Since that work has not been clearly expounded upon, a similar approach is presented here for normally incident waves on a bar.

Currents on a Barred Shoreline

The model primarily is presented to examine mean currents behind a longshore bar, including the effect of wave reflection from the bar. There are three equations necessary for the model. The first is the continuity equation, which relates the onshore flow over the bar to the increase in flow in the longshore trough, between the bar and the beach.

$$U h_b = h_t w_t \frac{\partial V}{\partial y} \quad (7)$$

where U is the vertically and time-averaged in-flow, including the mass transport, h_b is the mean depth over the bar, h_t and w_t are the mean depth and the width of the trough, and $V(y)$ is the cross-sectionally and time-averaged longshore current. Figure 1 illustrates the geometry. The second equation is the equation of motion within the trough.

$$v \frac{\partial V}{\partial y} = -g \frac{\partial \bar{\eta}}{\partial y} - \frac{f_t U_m V}{4\pi h_t} \quad (8)$$

where $\bar{\eta}(y)$ is the mean water level within the trough measured from the still water level. The bottom friction term is of the form developed by Longuet-Higgins (1970) for weak currents (see Liu and Dalrymple, 1978, for a generalization for strong currents), U_m is the wave-induced water particle velocity over the trough.

$$U_m \approx \frac{H_t \sqrt{gh_t}}{2 \cdot h_t} \quad (9)$$

and f_t is the Darcy-Weisbach friction factor in the trough.

The final equation is the onshore/offshore momentum equation, which includes the mean excess momentum flux due to the presence of the waves (the radiation stresses), denoted S_{xx} , as well as the force exerted on the submerged bar by the waves. The basic premise here is that the portion of the incident wave reflected by the bar induces a force as its momentum flux has been reversed. This force is provided by the reaction force of the bar but also by a set-up of water inside the bar (Longuet-Higgins, 1967) or bottom friction across the bar. The set-up of water, which only exists where the bar is reflecting waves and which is much smaller where the rip channel exists, provides the longshore variation in water level to drive the longshore flow. Therefore, the force balance on each side of the bar is

ELEVATION

PLAN

Fig. 1

$$S_{xx,I} + S_{xx,R} + \frac{1}{2} \rho g h_t^2 - F = S_{xx,T} + \frac{1}{2} \rho g (h_t + \bar{\eta})^2 + \tau_b \omega_b \quad (10)$$

where the subscripts on the radiation stresses denote incident, reflected and transmitted, F is the mean wave force on the bar and $\tau_b \omega_b$ is the shear force exerted on the bar.

If the longshore bar is uninterrupted by rip channels, then the set-up, $\bar{\eta}$, would be uniform in the longshore direction and will be denoted as $\bar{\eta}_p$, where the subscript p indicates the potential set-up. For this case the friction term would be absent (no flows over the bar) and F can be determined (Longuet-Higgins, 1976). If, on the other hand, rip channels exist and $\bar{\eta}$ is drawn down below the $\bar{\eta}_p$ level necessary to provide the force balance, then a shear stress is developed by an in-flow across the bar. Therefore, if we define

$$\bar{\eta}_D = \bar{\eta}_p - \bar{\eta} \quad (11)$$

where $\bar{\eta}_D$ is the deficit in the set-up between the maximum potential set-up and the actual set-up, η , and substituting into the previous equation, we have remaining,

$$\rho g h_t \bar{\eta}_D = \tau_b \omega_b \quad (12a)$$

or

$$\rho g h_t \bar{\eta}_D = \frac{f_b U_m}{2\pi} (U - \bar{u}) \omega_b \quad (12b)$$

where the mean flow is reduced by mass transport velocity, \bar{u} , which does not contribute to the bottom friction (Iwata, 1970).

Using the last equation and the continuity equation, $\bar{\eta}_D$ may be eliminated from the longshore equation of motion, with the assumption that the geometry is fixed and all second order terms may be neglected (including the convective acceleration terms), leaving

$$\frac{d^2 v}{dy^2} - \gamma^2 v = 0 \quad (13)$$

and

$$\gamma^2 = \left(\frac{f_t U_m h_b}{2f_b U_m h_t \omega_b \omega_t} \right) \quad (14)$$

A solution to this equation, which is zero at $y = 0$, the midpoint between two rip channels, is

$$v = v_m \frac{\sinh \gamma x}{\sinh\left(\frac{\gamma b}{2}\right)} \quad (15)$$

where V_m is the maximum of V which is assumed to occur at $l/2$, the location of the rip channel. The distance l is the longshore length of the bar.

The deficit, $\bar{\eta}_D$, can be found from the linearized Eq. (8), subject to the condition that $\bar{\eta}_D = 0$ at $x = 0$.

$$\bar{\eta}_D = \frac{f_t U_m V_m (\cosh \gamma x - 1)}{4\pi g h_t \gamma \sinh\left(\frac{\gamma l}{2}\right)} \quad (16)$$

and also, from the continuity equation,

$$U = \frac{\gamma h_t \omega_t V_m \cosh \gamma x}{h_b \sinh\left(\frac{\gamma l}{2}\right)} \quad (17)$$

The V_m can be found from the bottom stress, Eq. (12b), to yield

$$V_m = \left(\frac{h_b}{h_t \omega_t}\right) \frac{\bar{u}}{\gamma} \sinh\left(\frac{\gamma l}{2}\right) \quad (18)$$

Thus

$$V = \frac{\bar{u} h_b}{\gamma h_t \omega_t} \sinh \gamma y \quad (19)$$

For small y , the longshore current V can be approximated as

$$V = \frac{\bar{u} h_b}{\omega_t h_t} y \quad (20)$$

which indicates initially the longshore current increases due to the inflow over the bar by mass transport. However, as the mean water level drops from its potential value at $y = 0$, the inflow U increases above the \bar{u} value.

$$U = \bar{u} \cosh \gamma y \quad (21)$$

Further

$$\bar{\eta}_D = \frac{f_b \omega_b U_m \bar{u} (\cosh \gamma y - 1)}{2\pi g h_t} \quad (22)$$

The flow out of the rip channel is

$$U_r = \frac{2V \omega_t h_t}{\omega_r h_r}$$

by continuity considerations, where the r subscripts refer to rip variables.

It is expected that the maximum upper limit for $\bar{\eta}_D$ is $\bar{\eta}_p$; that is, $\bar{\eta} = 0$, which would occur at $y = \ell/2$. With this upper limit, an estimate may be made for ℓ . For the case of no wave breaking over the bar, Longuet-Higgins (1965) showed

$$\eta_p = \frac{\alpha E}{\rho g h_t}$$

where $\alpha = (1 + K_r^2 - K_T^2)$, where K_r and K_T are the reflection and transmission coefficients. For other cases, where breaking occurs on the bar, $\bar{\eta}_p$ would be larger.

Since $\bar{u} = E_b / (\rho C_b h_b)$ and $U_{m_b} = \kappa \sqrt{g h_b} / 2$, we can write Eq. (22) as

$$\frac{2\pi g h_t \bar{\eta}_p}{f_b \omega_b U_{m_b} \bar{u}} = \cosh\left(\frac{\gamma \ell}{2} - 1\right) = 2 \sinh^2\left(\frac{\gamma \ell}{4}\right) \quad (23a)$$

or

$$\frac{\pi \alpha h_b}{f_b \omega_b \kappa \beta} = \sinh^2 \frac{\gamma \ell}{4} \quad (23b)$$

where β relates E_b to E_{incident} .

$$\text{Finally} \quad \ell = \frac{4}{\gamma} \sinh^{-1} \left(\sqrt{F \frac{h_b}{\omega_b}} \right) \quad (24)$$

where F is a constant, of order (125).

$$F = \frac{\pi \alpha}{f_b \kappa \beta}$$

Now, h_b can be related to H_b by the breaking index κ and ω_b is presumed to be a fixed fraction of the wavelength $\omega_b \sim \mu L$, therefore

$$\ell = \frac{4}{\gamma} \sinh^{-1} \sqrt{\frac{F}{\mu \kappa} \left(\frac{H_b}{L} \right)}$$

Recall from Eq. (14)

$$\gamma = \sqrt{\frac{f_t}{2f_b} \frac{U_{m_t}}{U_{m_b}} \frac{h_b}{h_t} \frac{1}{\omega_b \omega_t}} \approx \varepsilon \frac{1}{L}$$

where

$$\epsilon = \left(\frac{f_t}{2f_b} \frac{\omega_b}{L} \frac{\omega_t}{L} \left(\frac{h_b}{h_t} \right)^{1/2} \right)^{1/2}$$

assumed to be a constant.

From the preceding results and assumptions, it is logical to expect the dimensionless rip spacing (ℓ/L) to be related to the wave steepness, H/L , with some effects due to sediment characteristics (f). It remains to be proven whether this is in fact true; however, laboratory experiments to date have shown (1) gaps in bars to produce longshore and rip currents and (2) there is a longshore gradient in water surface slope as predicted by the theory.

A significant assumption is the neglect of the convective acceleration terms which certainly play a role, particularly in the deceleration in the base of the rip current. Another critical assumption is the neglect of wave-current interaction which plays an important role in varying the wave direction offshore of the rip channel and in the longshore trough.

Conclusions and Recommendations

In the fifty years that rip currents have been the study of coastal engineers and scientists, numerous theories have been proposed to explain their occurrence. Most of these theories have appeared in the last ten years and yet, owe their origin to different mechanisms. These theories can be grouped into two broad generic categories, the wave-interaction models and the boundary interaction models. Of the various theories within each group, it is not yet entirely clear during which percentage of time they may occur for a particular coastal type or wave climate, if they occur at all. This question, which, of course, bears on the validity of the various theories, must be addressed by field observations of nearshore circulation for many coastal types. Some work has been undertaken in this area (Sonu, 1972, Fox and Davis, 1974 and Allender, et al. in this volume), yet more detailed and thorough studies remain to be conducted, to include all relevant variables and many coastal geometries.

Significant research needs to be conducted to provide a general model for the shoaling, refraction and diffraction of water waves, so as to provide a unifying basis on which a general model can be built.

Finally the hydrodynamics must be melded to the sediment transport, in order that the feedback mechanism of bottom topographic changes can be incorporated into the models. This development would provide the bridge between the two classifications of rip currents, thus allowing a model of the wave-interaction category to develop perturbations in a previously planar bottom, which would then force a reinforcing circulation of the boundary interaction type.

Acknowledgments

This research was supported in part by funds from the Office of Naval Research, Geography Programs, and the National Sea Grant Program. This paper was written while the author was a sabbatical visitor at the Scripps Institution of Oceanography's Shore Processes Laboratory and their hospitality is appreciated.

ABSTRACT

This paper evaluates, through the use of a stepwise multiple regression procedure, whether parameters descriptive of the surf-zone wave field adequately explain the variability in longshore current velocities, or if the inclusion of additional physical environmental parameters could significantly improve the ability to predict such currents. The data set consists of 250 LEO - observations, collected on a seasonal basis over one year, at Debidue Island beach, South Carolina.

A regression analysis was performed both on linear combinations of all measured wave parameters, and on non-linear parameter combinations proposed in various semi-empirical predictive equations. Invariably, in all the regression analyses, the longshore component of the wind velocity proved to be the independent variable explaining most of the observed variance in the current velocity. Therefore, the statistical data analysis presented in this paper strongly suggests that wind stress can be a most significant factor in surf-zone current generation.

INTRODUCTION

Longshore current velocities measured in the surf-zone at Debidue Island, South Carolina, are the vector resultant of velocity components due to the oblique approach of the

breaking wave, the nearshore cell circulation system, currents generated directly in the nearshore zone by wind stress and, perhaps, components of a regional circulation system. It is generally assumed that the dominant factor in the generation of longshore currents is the oblique approach of the breaking wave. Accordingly, the two most important parameters determining the longshore current velocity are the wave height and the angle between the wave crest and the shoreline (U.S. Army, Corps of Engineers, Coastal Engineering Research Center, 1973). A number of theories explain the generation of such currents and predict their magnitude. These theories are grouped according to their considerations of (a) conservation of mass, (b) conservation of energy flux, or (c) conservation of momentum flux (Galvin, 1967). Empirical equations, based on statistical analysis of parameters describing the breaking wave, have also been constructed (Harrison, 1968; Fox and Davis, 1972), though such equations are generally of limited value outside the specific area of formulation.

The objective of this study was to evaluate, through the use of a stepwise multiple-linear regression procedure, whether parameters descriptive of the surf-zone wave field adequately explain the observed variability in longshore currents, or if the inclusion of additional environmental parameters could significantly improve the ability to predict such current velocity. Linear combinations of breaker parameters and four proposed equations for prediction of longshore current velocity were used in the evaluation.

Galvin (1963), basing his model on the continuity of water mass, arrived at the following equation

$$V = k \cdot g \cdot m \cdot T_b \cdot \sin 2\alpha_b \quad (1)$$

where V is longshore current velocity, g is the acceleration of gravity, m is beach slope, α_b is breaker angle, T_b is breaker period, and k is a parameter of the breaker form, here taken as 1.0 (Galvin and Eagleson, 1965).

Longuet-Higgins (1970) derived an equation by considerations of the conservation of momentum flux for breaking waves. The U.S. Army, Corps of Engineers, Coastal Engineering Research Center (1973) empirically determined the proportionality constant in Longuet-Higgins' equation by fitting it to laboratory data by Galvin and Eagleson (1965)

and field data from Putnam et. al (1949). Thus, the "modified" Longuet-Higgins equation reads:

$$v = 20.7 \text{ m } (g H_b)^{\frac{1}{2}} \sin 2\alpha_b \quad (2)$$

Fox and Davis' (1972) empirical equation for their Lake Michigan data set is:

$$v = 2.98 \frac{H_b}{T_b} \sin 4\alpha_b \quad (3)$$

Another empirical equation, derived by Harrison (1968) from analysis of surf-zone data at Virginia Beach, reads:

$$v = 0.17 + 0.037 \alpha_b + 0.032 T_b + 0.24 H_b \quad (4)$$

Equations 1 through 4 formed the basis for the statistical evaluation of the role of breaker parameters in explaining the observed variability in the longshore current.

MEASUREMENTS

Descriptive summary statistics for all longshore current velocity readings obtained between July 1974 and March 1976 are presented in Table 1. The mean longshore current is stronger to the south (35.8 centimeters per second versus 23.8 centimeters to the north). Extreme variability in current velocities is demonstrated by the fact that the standard deviation almost equals the mean. Inman and Quinn (1952) also found in their study of longshore current variability on the Pacific coast that the standard deviation often equalled or exceeded the mean. There is an indication in the data that fall current velocities are slightly higher than those at other seasons.

The data set includes only those velocity readings which were obtained at least 3 hours after sudden reversals in wind direction. It was determined that there was a lag of about 2 to 3 hours between reversals in the longshore wind component and corresponding reversals in the current.

¹Current direction along shoreline. N is to the north, S to the south.

²Number of observations.

³No reading.

All measurements were made by observers on the beach in accordance with specifications set forth in the Littoral Environments Observation program by the Coastal Engineering Research Center. As demonstrated in figure 1, the southern end of Debidue Beach, where the measurements took place, is characterized by a straight, gently sloping beach. Bathymetric profiles (Humphries, 1977) demonstrate that

the nearshore region has straight shore-parallel depth contours. Although the North Inlet tidal delta is only about 2 km south of the study site, no measureable influence of tidal currents was detected.

Fig. 1. Oblique aerial view to the south along the shore of Debidue Island

ANALYSIS

Three regression procedures were utilized in this data analysis:

(1) Simple correlation was used to test for linear relationships between any pair of variables. The Pearson correlation coefficient is a measure of the degree of proportionality between two variables.

(2) Stepwise regression enters one independent variable at a time until all are entered simultaneously. Their order of inclusion is determined by the computer - the independent variable which explains the largest amount of variance in the dependent variable is entered first. The others are then entered in order of decreasing variance explained. The proportion of the total variance in the dependent variable explained by an independent variable, or a combination of variables, is expressed by the multiple correlation coefficient, r^2 .

(3) Multiple regression enters one independent variable at a time in any order specified by the investigator. Thus, the amount of variance explained by any independent variable of particular interest can be assessed.

The variable names used in the computations and the following analysis are defined in Table 2.

Table 2. Variable names used in multiple regression analysis of littoral processes.

Name	Definition
VEL	Observed longshore current velocity (in centimeters per second). (+) indicated current to the right (south); (-) indicates current to the left (north).
HGT	Breaker height (in centimeters).
PER	Breaker period (in seconds).
WINDL	Longshore component of wind velocity (m.p.h.)
WAVL	Sine of the breaker angle.
VGAL	Velocity calculated by Galvin's (1963) formula (eq. 1), (centimeters per second).
VELH	Velocity calculated by Longuet-Higgins (1970) formula (eq. 2)
VEFD	Velocity calculated by Fox and Davis' (1972) formula (eq. 3)
VHAR	Velocity calculated by Harrison's (1968) formula (eq. 4).

Table 3 is a matrix of the Pearson product-moment correlation coefficients for these 9 variables for the 1975-76 data set of 250 observations.

Table 3. Pearson correlation coefficients between littoral variables defined in Table 2.

	VEL	HGT	PER	WINDL	WAVL	VGAL	VELH	VEFD
VEL	--							
HGT	0.37	--						
PER	-0.11	-0.06	--					
WINDL	0.83	0.36	-0.07	--				
WAVL	0.68	0.27	-0.09	0.68	--			
VGAL	0.64	0.27	-0.01	0.66	0.97	--		
VELH	0.69	0.38	-0.07	0.70	0.97	0.95	--	
VEFD	0.70	0.46	-0.12	0.69	0.88	0.81	0.93	--
VHAR	0.68	0.39	0.05	0.69	0.98	0.97	0.97	0.88

Bivariate data plots produced by computer give further information on the nature of these correlations. The plots of wave height and period versus current velocity show hardly any discernible trend. Clearly, these parameters do not exert any dominant control on the current velocity. The sine of the breaker angle shows a moderate correlation with the current velocity. The scatter is particularly large for small angles of breaker approach. Wind velocity shows a moderate correlation with the current velocity, again scatter is at a maximum for relatively moderate winds. By far the best correlation is that between the longshore component of the wind velocity and the observed current velocity. The correlation coefficient equals 0.83 and the scatter is small, and uniform, over the entire range of the independent variable. If the surf-zone wave parameters are combined as suggested in equations (1), (2), (3) and (4), the predicted and observed longshore velocities show correlations ranging from r equals 0.64 for Galvin's (1963) formula to r equals 0.70 for Fox and Davis' (1972) formula.

If the longshore component of the wind is considered to be the only independent variable, one can write a simple regression equation for the longshore current velocity as:

$$VEL = 3.42 \cdot WINDL + 6.3 \quad (5)$$

This is a wholly empirical equation, and all parameters affecting the longshore current velocity are lumped into WINDL. Equation (5) does not indicate how much is due to the oblique breaking of the wind-generated waves. However, the equation is of predictive value for longshore currents off Debidue Island (and probably elsewhere under similar environmental conditions).

The correlation coefficients between observed current velocity and that predicted by the tested equations are all reasonably high. This indicates proportionality. However, the magnitude of the predicted velocity generally differs substantially from that observed, as evidenced by the proportionality factors in the following regression equations (all velocities are in centimeters per second).

$$VEL = 0.33 VGAL + 5.18, r = 0.64 \quad (6)$$

$$VEL = 0.45 VELH + 4.6, r = 0.64 \quad (7)$$

$$VEL = 2.0 VEFD + 4.1, r = 0.70 \quad (8)$$

$$VEL = 0.71 \overline{VHAR} - 14.4, \quad r = 0.68 \quad (9)$$

Galvin's (1963) and Longuet-Higgins' (1970) equations are both semiempirical, both predict current velocities higher than those observed at Debidue Island. The empirical equation of Fox and Davis (1972) predicts current velocities which are generally too low by a factor of $\frac{1}{2}$. Harrison's (1968) equation predict currents of essentially the correct magnitude.

To test for the relative importance of the independent variables in explaining the variance in the dependent one, a stepwise regression analysis was used. The test was performed both for the pooled annual data and for each seasonal data set. Results are summarized in Table 4.

Table 4. Percent of the variance in VEL explained by each of four independent variables entered successively in a stepwise regression analysis.

Variable	Annual	1975		1976	
		June	Sept.	Jan.	Mar.
WINDL	70	81	63	57	69
VGAL	1	0	0	2	2
VELH	2	0	1	2	4
VEFD	4	0	7	1	6

For all data sets, the longshore component of the wind velocity, WINDL, proved to be the independent variable explaining most of the observed variance in current velocity, VEL. The multiple correlation coefficient (r^2), for VEL versus WINDL ranged from 0.81 for the June 1975 data set to 0.57 for the January 1976 data. Expectedly, data noise was at a maximum in January and minimum in June because of the different weather conditions under which the field observers had to operate. It is quite significant to note that for the data set which was expected to be the most reliable, (June 1975), WINDL alone explained 81 percent of the variance. For this data set, the inclusion of breaker parameters combined into the predictive equations of Galvin (1963), Longuet-Higgins (1970), and Fox and Davis (1972), does not improve the multiple correlation coefficient. For the other data sets, these variables add a few percents of explained variance.

A series of regression equations can be developed depending on which variables or combinations of variables are included. Table 5 summarizes the two types of equations derived in this study; the first (equation 10) is the regression equation derived by treating each measured environmental parameter as an independent variable; the three subsequent equations (equations 11, 12, 13) are derived by combining the pertinent breaker parameters as suggested in Galvin's (1963), Longuet-Higgins' (1970), and Fox and Davis' (1972) predictive formulas. Breaker parameters not accounted for in the predictive formulas are included as independent variables. The amount of variance in VEL explained by each parameter combination is constant, about 72 percent. Typically, the longshore component of the wind speed, WINDL, alone explains 70 percent of the variance. All other parameters combined can improve the predictability by a mere two percent.

Based on a similar analysis, Harrison (1968) derived a regression equation for longshore current velocity at Virginia Beach, Virginia. However, simultaneous wind measurements were not obtained in his study, and the question of wind stress or breaking wave dominance in longshore current generation could not be assessed.

Table 5. Multiple regression equations for measured longshore current velocities. The equations are all based on the same data set, but utilize different combinations of independent parameters.

$$VEL = 2.78 WINDL + 44.2 WAVL + 0.12 HGT - 0.85 PER + 5.94 \quad (10)$$

$$VEL = 2.73 WINDL + 0.69 VEFD + 4.72 \quad (11)$$

$$VEL = 2.83 WINDL + 0.13 VELH - 0.94 PER + 13.28 \quad (12)$$

$$VEL = 2.91 WINDL + 0.06 VGAL + 0.12 HGT - 1.15 \quad (13)$$

CONCLUSION

Based on measurements of longshore currents at Debidue Island beach, South Carolina, it appears that the parameters descriptive of the surf-zone wave field do not explain a significant amount of observed current variance. In fact, the longshore component of the wind velocity explains more of the observed current variance than any

single parameter, or combination of parameters, descriptive of the breakers.

ACKNOWLEDGMENTS

Financial support for this study was obtained from the Coastal Engineering Research Center through contract no. DACW 72-74-C-0018 to the University of South Carolina (M.O. Hayes, principal investigator). Stan Humphries contributed valuable assistance in both data collection and analysis.

Ibaraki 300-31, Japan*
Kiyoshi Horikawa *Department of Civil Engineering, University of
Tokyo, Tokyo 113, Japan*

ABSTRACT

By use of a synchronized camera system, multiband black-and-white photographs and conventional color photographs were taken respectively with the purposes of testing filters available for shallow-water photographic bathymetry, and of checking the availability of low-cost process imagery for the study of coastal processes. Kodak Wratten filters 29, 58, and 90 were employed for the multiband photography. A Wratten 90 filter provided the best correlation between water depth and the photographic density. The low-cost imagery, obtained in a laboratory from the color photographs by applying ordinary filters without using any expensive image processing devices, proved to be useful.

INTRODUCTION

Since minimum attenuation of light in water occurs in the visible region of electromagnetic spectrum, i.e., 400-700 nm in wavelength, the remote sensors available in this region are effective for the aerial investigation of nearshore waters, especially of underwater environments. The photographic sensors covering the visible region are (1) black-and-white photographs, (2) color photographs, and (3) multiband or multispectral photographs; these sensors have been widely used in the field of coastal engineering (Stafford, 1972).

The feasibility of nearshore bathymetry using multiband photographs has recently investigated (Stafford, 1972), and several studies have been conducted to explore optimum film/filter combinations for the bathymetric use (e.g., Lockwood et al., 1974; Magoon and Pirie, 1972; Pestrong, 1969). However, sufficient data on this point are unavailable. One of two purposes of the present study is to furnish a basic data on filters used for the multiband

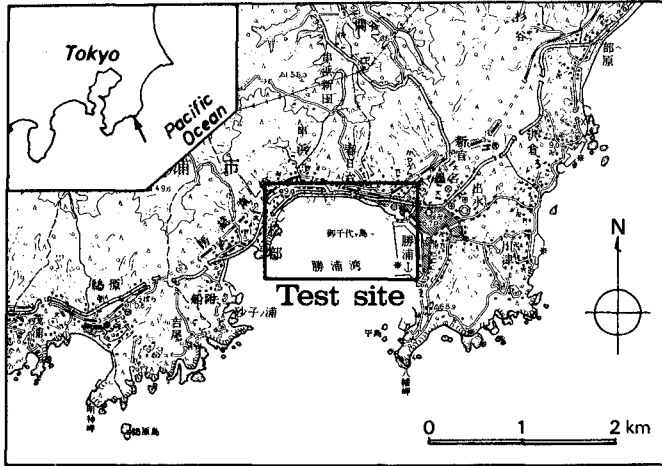

Figure 1 Test site.

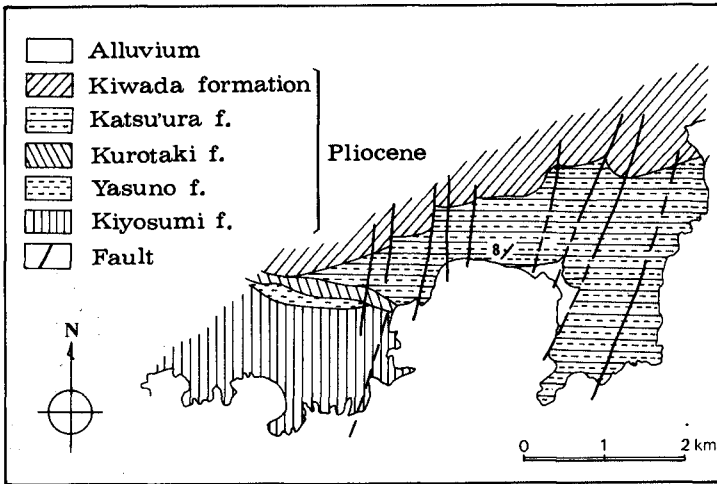

Figure 2 Geology around the test site.

photography with the aim of sounding a shallow-water area.

The process imagery through the image enhancement or processing devices has been widely used to extract various information from photographs (American Society of Photogrammetry, 1975, pp. 611-813). However, these devices are expensive. The imagery processed from conventional color photographs by applying only filters without using any expensive equipment is also considered to be useful. But, the availability of this low-cost process imagery has not yet been tested with the exact sea or ground truths. The second purpose of the present study is to examine this availability from the view point of the data acquisition for coastal processes studies.

TEST SITE

The test site is a shallow-water area at the head of the Katsu'ura Bay located on the Pacific coast of Japan (Fig. 1). The bay is a semicircular shape bordered by coastal cliffs made of Pliocene sedimentary rocks (Fig. 2). The alternation of sandstone and siltstone strata of Katsu'ura formation (strike: N40-50E, dip: 5-10N) forms the cliff at the test site. A narrow bay-head beach develops with an alongshore distance of 1.3 km. The direction of wave approach is nearly normal to the beach. Approximate tidal range at spring tide is 1.5 m, while at neap tide is 0.7 m.

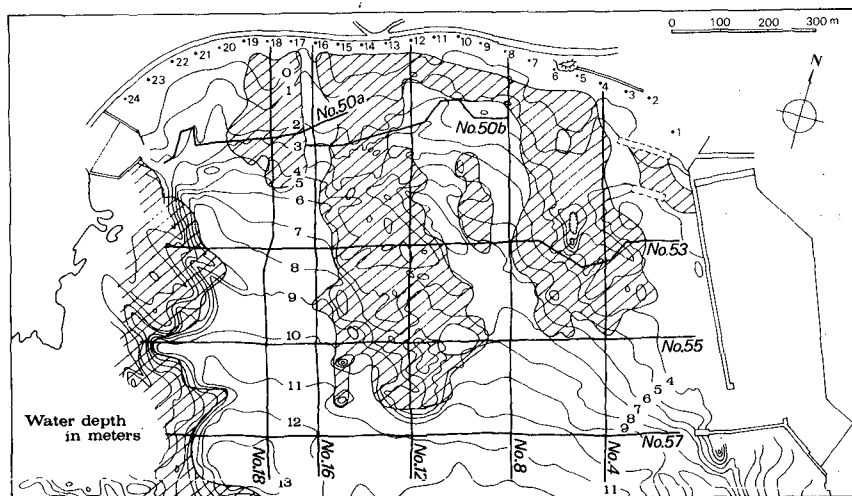

Figure 3 Submarine topography and the area of exposed bedrock (hatched area).

Underwater topographical and geological characteristics of the test site are that (1) the seabed consists of portions made of medium sand and of exposed bedrock (Katsu'ura formation) (Fig. 3), and (2) the bedrock region is located higher than the adjacent sand bottom, forming an abrasion platform (Fig. 4). The higher bedrock-region induces the convergence of wave energy (Sunamura and Horikawa, 1976); the energy convergence produces breaking waves even in a calm sea.

The main reasons for the selection of this area as the test site are that (1) water is clear, and (2) both the bedrock and the sandy areas have no regional color variations, respectively.

AERIAL PHOTOGRAPHY

The flight plan was made paying much attention to the exclusion of the sun's glitter on aerial photographs. Along the flight lines (Fig. 5), the test site was photographed by using a Cessna aircraft at an altitude of about 1,000 m during three days from November 27 to 29, 1974, under different wave conditions. Approximately 60 per cent overlap along the flight lines and 30 per cent side lap were obtained.

A synchronized camera system consisting of four Hasselblad cameras was employed. One of them was used for color photographs, and the remaining three cameras were used for multiband photographs, i.e., 3-band black-and-white photographs applying Kodak Wratten filters 29, 58, and 90, respectively (Fig. 6). Films for the color and the multiband photographs were Kodak Aerocolor Negative 2445 and Kodak Tri-X Aerographic 2403, respectively. Table 1 shows the film/filter/camera combinations and additional photographic data.

GROUND AND SEA TRUTH MEASUREMENTS

Prior to photographing, two kinds of work were made for the water depth determination test: (1) a bathymetric survey and (2) submarine installation of white targets. The former was done along 32 ranges 25 m apart, set up perpendicularly to the shoreline; the inshore region including the backshore and foreshore was measured by using a transit, staff, and tape, while the offshore region up to a water depth of several meters was surveyed with the aid of an echo sounder. The latter was done by using five squares with a length of 1.8 m each (Fig. 7), which were placed at a water depth of 1 to 5 m with a vertical interval of 1 m (Fig. 8). The location of the target installation is shown in Fig. 9.

Figure 8 Schematic diagram showing underwater installation of targets.

Table 2 Wave and tidal conditions at the time of photography.

Time and date	Waves		Tide level
	Breaker height	Period	
	H_b	T	
12:00-13:00 Nov. 27, 1974	ab. 1 m	9 - 10 sec	0.4 - 0.5 m above MSL
12:00-13:00 Nov. 28, 1974	ab. 2	10 - 11	0.4 - 0.5 above MSL
12:00-13:00 Nov. 29, 1974	ab. 1.5	ab. 10	0.35-0.45 above MSL

The wave condition during the aerial photography is summarized in Table 2. The test site is characterized by the existence of an alongshore variation in the height of breaking waves: higher breakers are observed in the bedrock region compared to the adjacent sand area. The "breaker height" in Table 2 denotes a time-averaged value in the bedrock region.

DATA ANALYSES AND RESULTS

(1) Filter Test for Water Depth Determination

Two methods have been developed concerning the quantitative photographic bathymetry (American Society of Photogrammetry, 1975, pp. 1574-1584): (1) photogrammetric method using stereoscopic (three-dimensional) measuring techniques, and (2) transparency method using photographic-density measuring techniques. The present study applied the latter method for the availability check of the filters used in the multiband photography. Photographs with no influence of suspended material are needed for the quantification of the photographic density-water depth relation. The photographs of November 27 were used here, because the degree of sediment suspension was the lowest due to the calmest sea during the three-day investigation (see Table 2). The photographic density was measured by applying a micro-densitometer (Rhesca Model PPA-250) on the positive transparencies. The density output was expressed in terms of volts.

Figure 10 shows a linear relationship between water depth and the photo-density on the submerged targets; this relation was obtained from the photographs with a Wratten 90 filter. Results from the Wratten 29- and 58-filtered photographs presented the similar relation to Fig. 10, although a considerable scatter of the data

points was seen.

Two measuring lines, C-16 and C-30 (see Fig. 9), were sorted out from the 32 survey ranges for the photo-density measurement over the natural submarine bottom: C-16 traverses the bedrock area, while C-30 the sandy area. Both lines have little influence of sediment suspension. The correlation between the density and water depth becomes worse in order of the Wratten 90-, 58-, and 28-filtered photographs. Figure 11 is the best result, obtained from the Wratten 90-filtered photographs, showing some scatter of the data points. The lack of data points in the bedrock region shallower than a water depth of 1.5 m is due to the presence of surf zone. The result of the natural seabed shows the exponential relation (Fig. 11), while the target test presents the linear one (Fig. 10). The reason for this difference is unknown.

The light transmission characteristics of coastal water show that maximum transmittance occurs with the 500-600 nm (green) range of electromagnetic spectrum (Duntley, 1963; Lockwood et al., 1974). Therefore, one can expect that a Wratten 58 filter having a bandwidth of 460-620 nm (see Fig. 6(b)) could be optimum for the bathymetric use. However, the present study indicates that a Wratten 90 filter was the best. The possible reason for this is as follows:

In the visible-region electromagnetic spectrum, the shorter wavelength radiation is more sensitive to the scattering by fine particles suspended in the atmosphere and the ocean than the longer wavelength radiation. A Wratten 58 filter transmits wavelengths of 460-500 nm (a part of blue region), allowing the record of the atmospheric and oceanic scattering; this masks the underwater information recorded by the green-region electromagnetic waves. Therefore a perfectly blue-cut filter like a Wratten 90 filter would produce the best result.

(2) Availability Check of Low-Cost Process Imagery

Three kinds of images were processed in a laboratory from the color photographs by utilizing blue (Kodak Wratten filter 94), green (93) and red (92) filters, respectively (see Fig. 12). In this processing, was used a separation film whose sensitivity covered a wavelength range of 400-700 nm. The imagery, printed on the separation film at first, was finally printed out on the ordinary printing paper. This was black-and-white negative imagery. Figure 13 shows one example of the process imagery.

Figure 13(a) shows a low-contrast image, produced by the atmos-

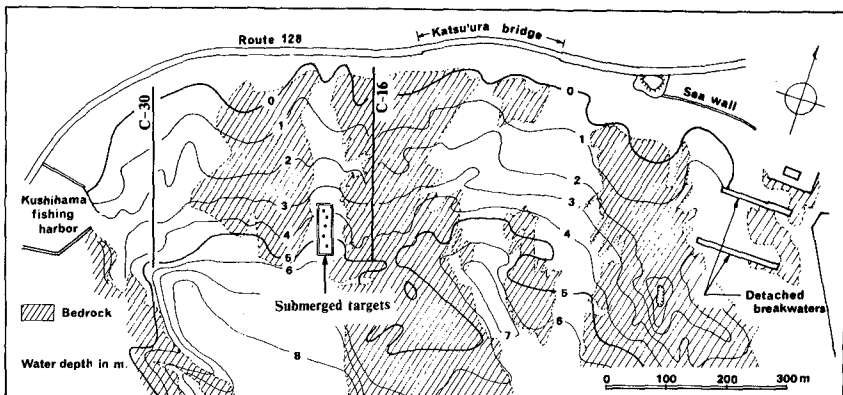

Figure 9 Locations of the submerged targets and the survey lines (C-16 and 30), used for water depth determination test.

 from the color photographs.

pheric and oceanic scattering of the 400 to 500 nm-length waves. This indicates that blue-filtered photographs are not available for use in the interpretation of a shallow-water environment.

Figure 13(b) allows the visualization of submarine bedrock features, because the green filter transmits wavelengths of 510 to 580 nm, which have the capability of recording underwater details to maximum depth. Since wave breaking and sediment suspension deteriorate the underwater information, the photographs taken under the calmest sea condition should be used for the submarine investigation. The green-filtered images of November 27 were applied for the delineation of the linear features on the exposed bedrock; the result is shown in Fig. 14.

Figure 13(c) exhibits a clear image of rip current pattern, i.e., flow pattern of water discolored by suspended material. In

Figure 15 Schematic diagram showing a possible transportation pattern of suspended matter captured by rip currents.

the red region of electromagnetic spectrum, the degree of water penetration is inferior as compared to the green-region wavelengths. This means that the red-filtered imagery supplies shallower-water information than the green-filtered imagery does. The material transported offshore by rip currents would probably be suspended to a certain height over the seabed (Fig. 15). Therefore the red-filtered imagery is preferable for tracing the pattern of sediment-laden rip currents. Figure 16 shows the rip current patterns depicted from the red-filtered images of the three-day data; the solid lines indicate certainty and the dashed lines show uncertainty as to the delineation of the flow pattern. The degree of rip current development increases with increasing breaker height.

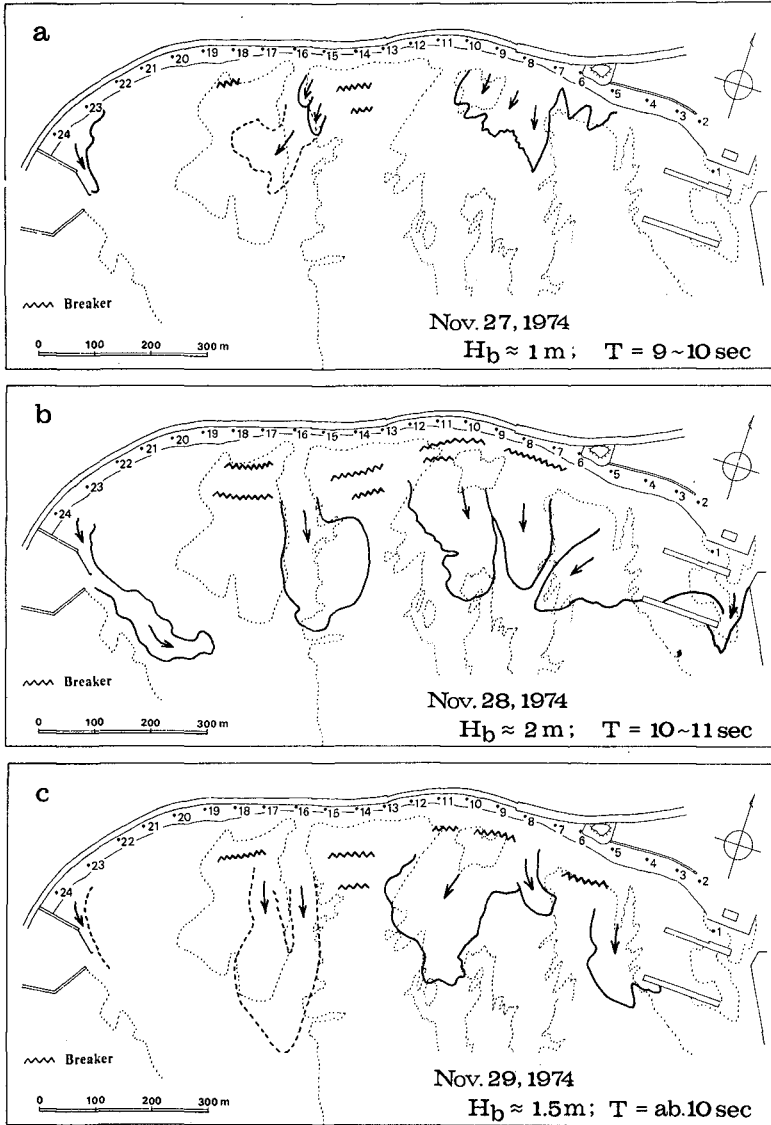

Figure 16 Rip current patterns depicted from the red-filtered imagery.

CONCLUSIONS

A perfectly blue-cut filter is useful for the multiband photography having the purpose of shallow-water bathymetry by the transparency method. However, there is a limitation that the photographs should be taken under calm sea conditions, because suspended material and surf zone make it difficult to read accurately the photographic density.

The low-cost process imagery from conventional color photographs by using pertinent filters is available for use in the study of coastal processes.

CHAPTER 86

UNDULATED BOTTOM PROFILES AND ONSHORE-OFFSHORE TRANSPORT

Madhav Manohar*

ABSTRACT: Underwater bars, the characteristic features of oceans and lakes occur singly or in a series along the coast. Nearest bar to the shore, namely the break-point bar moves shoreward in summer, joins the coast and is replaced by another bar in its original place. The other seaward bars are storm bars, more or less permanent though they may shift slightly in orientation, position and shape depending upon the wave climate and state of the coastal processes. With the sediment and bottom profiles changing constantly with differing wave characteristics and beach exposure, a rigorous mathematical analysis for long range variability of profiles and therefore coastal processes is not possible. Therefore, the concept of medium depth and steepness characteristics is introduced to distinguish the profiles and their major dimensions.

Onshore-offshore sediment motion is sometimes far in excess of longshore transport mostly confined in the breaker zone. When submarine bars are present, such motion is considerable mainly as a result of the hydrodynamic reaction between the rotating eddies generated over the bars and the bar surface. By means of dimensional analysis, it is possible to relate the quantity of onshore-offshore motion to the bar dimensions, wave period, water depth and transport direction by profile steepness characteristics.

The above two concepts are then applied to the Nile Delta coastal processes with satisfactory results.

INTRODUCTION: Longshore bars, are a series of submerged sand bars which often form parallel or nearly parallel to the coast. They occur either singly or in a series in the nearshore and offshore zones extending many kilometers into the sea or lake. They develop in both tidal and tideless seas, moving back and forth in the former depending upon the water level fluctuations and are more or less stationary in the latter. A common feature of both is a breakpoint bar - a well developed high and narrow bar at the point of breaking. Offshore of this bar, one, two or three storm bars also develop depending upon the wave climate and they are more or less low in height and wide at base. Lake Michigan (Hands, 1976) and Chesapeake Bay (Ludwick, 1972) areas manifest bars belonging to the tidal seas, whereas Nile Delta coast of the Mediterranean Sea (UNESCO et al 1973) is a typical example having more or less stationary bars of a sea of small tides.

*Visiting Professor, Civil Engineering Department, Pahlavi University, Shiraz, Iran.

Waves are known to be the main agents for bar development. Longshore currents may modify them but are not essential for their formation (Keulegan (1948)). The shape of bars depends greatly on wave, beach and sediment characteristics. Overnourished profiles (accretion areas) have flat slopes and fine sediment, whereas undernourished profiles (erosion areas) are steeper with coarser sediment. The bars on the former have wide base unlike the latter. Bars on equilibrium profiles (a stable profile with maximum steepness - Bruun and Manohar, 1963) have features similar to the undernourished profiles. The number of bars is greater on flatter profiles. Generally, the break-point bars and storm bars can be considered as independent features supposedly related to separate events. Further bars over accretion profiles are highly variable in shape, position, orientation and stability whereas those on erosion profiles are known for their regularity.

Whereas within the breaker zone, longshore transport is the predominate transport mode, seaward of the breaker zone, longshore currents unless external, are negligible and therefore in such cases longshore sediment motion may be insignificant. However, in areas where fine sediment and considerable swell and storm activity exist, intense onshore-offshore motion with consequent formation of submarine bars, and they (bars) acting as focus, and area between them acting as transport zone, can be expected. In many coastal area devoid of source nourishment for longshore motion, onshore-offshore transport seaward of the break-point bar is several times larger than the longshore movement landward of it.

One of the first laboratory experiments (Manohar, 1955) on onshore-offshore sediment motion emphasized on the nature of the boundary layer at the bottom, the type of bars generated by oscillatory motion at the bottom, and the sediment transport mechanism and the resulting rates. Subsequent laboratory research (Rector, 1954; Eagleson, 1961; Nayak, 1970) showed beach profile characteristics to be functions of wave steepness, height and sediment characteristics. Sitarz (1963) analyzed swell built profiles without bars theoretically and found the shape to be parabolic. Swarts (1974) in his laboratory studies on offshore barless profiles, obtained from regular waves and uniform sand, found them (called D-profile) to be functions of deep-water wave characteristics and sediment size. He found all such transport from his studies, to be offshore. Unfortunately in nature, every variable involved in the generation of profiles, bars and in onshore-offshore motion changes continuously and even for short term variability, no two analyses seem to agree as to the exact relationships between the variables (Saville, 1957). Therefore, these and other similar laboratory studies, though useful for an understanding of the mechanisms involved in the coastal processes, are not of much value in the study of natural beach profiles.

Assuming that onshore-offshore motion is considerable, it is necessary to know its direction. According to Carter et al (1973), some degree of beach reflection is always present and it is related to the foreshore slope and offshore topography which in turn depends upon the profile type existing in the area. For flat slopes with bed sediment being smaller than the boundary layer thickness, net sand transport

is mainly onshore because of weak reflection. If reflection coefficient is large (Moraes, 1970) as on steep slopes or with low amplitude waves, sand movement may occur offshore eventually stopping in sufficiently deep water when mass transport becomes negligible at the bottom.

Keulegan (1948), in his experimental study of submarine sand bars, found the following: Water depth remaining constant, depth of bar base and consequently bar position formed by a singly system of waves, is a function of wave height and wave steepness. If the water depth and wave steepness are constant, an increase in wave height will move the bar seaward. If the water and wave height are constant, an increase in wave steepness will move the bar shoreward. If the wave height and wave length are constant, any increase in water depth will move the bar seaward.

VARIABILITY OF PROFILES: Beach profiles being variable in character can be studied by repeated observations over time spans of varying duration. But to interpret the variations one must know the variables causing the changes namely the characteristics of waves, currents, sediments and other interrelated quantities which themselves vary from time to time. Further the controlling processes are different in the nearshore and offshore zones. No doubt statistical analysis of waves may indicate a pattern in its behavior but, such analysis will need many years of data rarely available. Thus analysis on short-term variability basis (Zeigler and Tuttle, 1961; Harrison, 1969), though useful to a limited extent may not be of much help in the analysis of coastal changes on long term basis.

PROFILE VARIABILITY ON LONG TERM BASIS: As already stated, a dynamic equilibrium gradient of a natural beach continuously adjusts itself to the changing variables on which it depends. But, it is safe to assume that its dynamic state will fluctuate within some inner, outer and mean limits for a long term time span. The same may be said to occur on over-nourished and under-nourished beaches also. The concept of medium depth and steepness characteristics of profiles used to define beach steepnesses of the North Sea coast (Bruun, 1954) may be used with advantage to determine the nature of the profiles.

Consider two profiles, namely one of erosion (under-nourished) and another of accretion (over-nourished) (Fig. 1) with the distance of the outer depth limit from the shoreline being the same in both cases. In the former, medium profile depth ($d_m = A/Z$) will be larger than in the latter and the profile steepness s_t ($s_t = A/Z^2$) defined as the medium depth divided by the distance from the shoreline will be larger also. For an equilibrium profile, it will have a constant value.

The importance of these two parameters is that when the analysis of profiles in the field which fluctuate continuously with even a small change in wave and sediment characteristics is difficult, they (the two parameters) give a valuable insight in the dynamic nature of the profiles on a long term basis. Their advantage lies in the fact that changes within area "A" need not be taken into consideration except

a) Overnourished profile

b) Undernourished profile

$$\text{Medium Profile Depth} = d_m = \frac{A}{z}$$

$$\text{Profile Steepness} = S_t = \frac{A}{z^2}$$

FIG.1: PROFILE DEPTH AND STEEPNESS DEFINITION

the knowledge as to whether they are eroding or accreting which in turn can be determined from a few hydrographic surveys. This approach, therefore, avoids the analysis of profile changes as functions of wave and sediment characteristics. The latter analysis will result in so many numbers of profile shapes (mostly smooth shapes without bars) that it will be difficult to interpret the results for long term analysis. No doubt, each coast will have its own limiting medium depth and profile steepness characteristic but, these can be obtained from a few surveys.

NEARSHORE SEDIMENT MOVEMENT: In the analysis of nearshore processes, as stated earlier, it is preferable to study the changes within and beyond the breaker zone separately. It is also necessary to determine the influence of the various bars on sediment transport and its direction.

Out of the two or three bars developed on beach profiles, the nearest one (break-point bar), frequently joins the shore in summer since swells with longer periods and smaller wave steepnesses cause a net shoreward sediment transport. When this bar joins the coast, a new bar is formed at its previous location and the process is repeated. This onshore sediment in motion trapped between the break point bar and the shore is the primary sediment source for alongshore transport unless external sources such as river sediments are available. Further, the nearshore circulation systems being more regular in summer than in winter, localize the coastal processes. Also the alongshore transport is much less in summer than winter, the major summer process being the shoreward transport.

With relatively large waves of the winter (large wave steepness), angle between the breaker line and shoreline in the breaker zone becomes the controlling factor for longshore current direction. Similarly, there is greater turbulence in the surface zone which keeps the sediment in suspension particularly in the shallow water zone. With mass transport from high waves being greater, substantial translation waves are also generated on wave breaking resulting in shoreward flow of water at the surface and seaward current at the bottom. Thus in winter, these flow systems cause formation of undulations, large and small, at the bottom.

Seaward of the break point bar, the onshore-offshore sediment exchange is likely to be as follows: When deep water waves travelling towards the shore start feeling the bottom (approx. when $d/L < 0.5$), ripples are formed which eventually become large size bars in the nearshore zone orienting themselves parallel to the wave crests. With the passage of waves, sediments will move from one side by the bar crest to the other (Fig. 2). When depth decreases, bottom velocity distribution with time changes from approximately sinusoidal to one that has a high shoreward component associated with the brief passage of wave crest and smaller seaward velocities associated with the longer time interval of the trough passage (CERC, 1973). When the shoreward velocity decreases with the crest passage and begins to reverse direction, sediment is placed in suspension from the landward side of the bar and this is transported with the seaward flow under the trough. Generally landward flow drops material shoreward as bed load and suspended load

FIG. 2: ONSHORE-OFFSHORE EXCHANGE
AROUND BARS

goes seaward. Thus in areas having coarser sand and lesser fines, net shoreward movement may be higher. Vice versa is likely to occur for more fines and less coarse material. Further, most storms move large amounts of sediment from the beach offshore but after each storm, the smaller waves which follow, tend to restore this loss shoreward to some extent unless another storm intervenes in the process. Successive storms in the same area may generate sufficient transport in the opposite directions causing insignificant net coastal changes whereas if the transportation direction before, during and after the storms is the same, changes can be considerable.

FACTORS AFFECTING ONSHORE-OFFSHORE TRANSPORT OVER BARS

In his classical analysis of onshore-offshore sediment transport over the bars, Keulegan (1948) showed that correlation exists between the sediment transport rate and total displacement of water surface during the passage of a wave. Using dimensional analysis, it can be shown that:

$$\frac{QT}{\rho_s g d^2} = f \left(\frac{\Delta H}{d}, \frac{\rho_w}{\rho_s}, \frac{\sqrt{gd} D}{\nu}, \frac{d}{gT^2}, \frac{D}{d}, m, \sigma_\phi \right)$$

defining the laws of sediment motion. In this,

Q = sediment transport rate

ρ_w & ρ_s = densities of water and sediment resp

ΔH = total displacement of water during the passage of a wave

d = depth of water at the seaward toe of the bar

T = wave period

D = characteristic grain size

ν = kinematic viscosity of water

m = bed slope

σ_ϕ = sand dispersion coefficient

Assuming other quantities to be constant for a given wave condition,

$$\frac{QT}{\rho_s g d^2} = f \left(\frac{\Delta H}{d} \right).$$

Since the total displacement ΔH is composed of the maximum elevation of the surface above the undisturbed water level and the corresponding maximum depression during the passage of a wave, it may be further approximated, to be the breaking wave height over the bar. Further assuming the breaking wave height = depth of water at the point of

breaking, ΔH is equal to the depth H on top of the bar. In other words

$$\frac{QT}{\rho_s g d^2} = f \left(\frac{H}{d} \right)$$

The significance of this equation (as confirmed by model experiments) can be understood if one looks at each of the quantities in the equation. The wave period T , specifies the type of waves, density ρ_s , the weight characteristics of the sediment; d , the depth seaward of the bar; and H , the depth of water over the bar. These basic variables govern the sediment transport rate. The term $(d-H)$ namely the height of the bar governs the hydrodynamic reaction between the rotating eddies between the bars and the sediment surface of the bars.

DIRECTION OF ONSHORE-OFFSHORE TRANSPORT: The influence of water depth, wave height, and wave steepness in moving the sediment seaward or shoreward has already been mentioned. Unfortunately, because of their continuous variability, their use for long range interpretation of direction of transport is impractical. One likely solution to this problem is again the use of medium depth and profile steepness concept. If the value of the steepness characteristic decreases as compared to its previous value, the predominant transport will be onshore and vice versa will occur for offshore transport. Similar use of medium depth is possible.

APPLICATION TO FIELD DATA

The above concepts were applied by the author on the Nile Delta coastal studies spanning from 1971 to 1977. During that period, annual and semi-annual hydrographic surveys were conducted, waves and currents were measured, and erosion and accretion trends of the 240km long coastal stretch (Fig. 3) were monitored and continuously analysed.

BAR ANALYSIS: The characteristic feature of the Nile Delta coast of the Mediterranean Sea is that it has a series of longshore bars, typical of a tideless sea. In general, there are three bars, one nearest to the shore being the break-point bar in one to two meter depth, with the middle one (in three to four meter depths) and the outer one (in five to six meter depths) being the storm bars. The breaker zone bar is mobile and shifts landward during summer accretional processes, joins the coast and is replaced by another similar bar. The other two bars are permanent features adjusting back and forth consistent with wave climate. Field observations confirm that the first bar is formed by the short steep waves and swells with the middle and outermost bars being formed by storm waves. As regards to their heights, there is no regular pattern. They may be as high as one meter and sometimes wide at base and low. Generally, greater heights cause greater onshore-offshore motion. Typical barred profiles are shown in Fig. 4.

UNDERWATER PROFILES: All three types of profiles, namely undernourished, equilibrium and overnourished profiles exist on the Nile Delta coast (Fig. 5), though equilibrium profiles are found only on very short stretches.

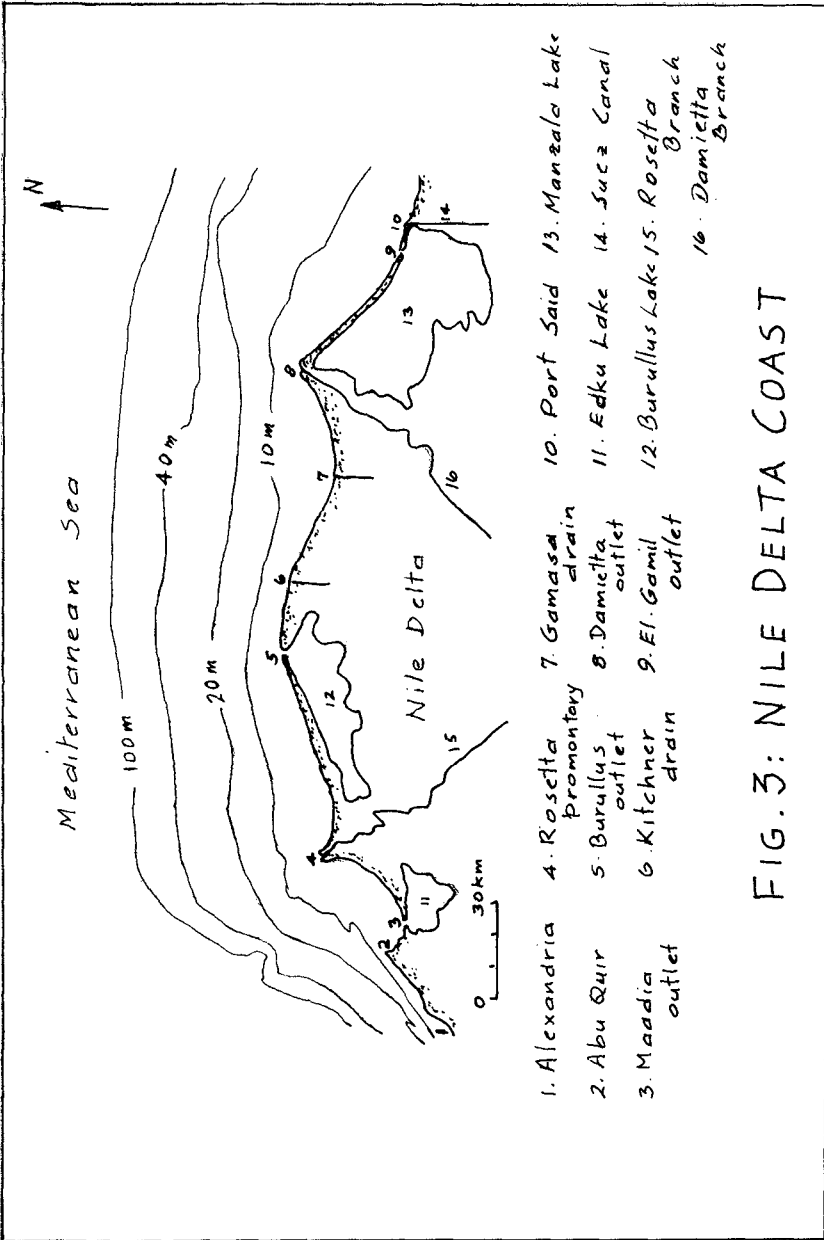

FIG. 3: NILE DELTA COAST

FIG. 4: TYPICAL PROFILES WITH BARS

FIG.5: TYPES OF PROFILES

Analysis based on medium depth and steepness criteria shows that the limiting value of profile steepness represents equilibrium profiles with a value of $A/Z^2 = 0.0049$ with accretion profiles having lower values and erosion profiles having higher values (Fig. 6). Medium depth criterion for different types of profiles is shown in Fig. 7. Fig. 6 is also useful for preliminary determination of area A and type of profile from a measurement of depth d beyond the bars and the corresponding distance from the shoreline. Fig. 8 shows the status of the Nile Delta coast profiles based on profile steepness.

SEDIMENT TRANSPORT: Continuous monitoring of the coast for six years, analysis of yearly and semi-annual hydrographic surveys, calculation of gross volume and net volume changes, determination of alongshore transport by actual measurements and refraction analysis in the breaker zone, and analysis of sediment movement patterns by T-X diagram (a 3-dimensional representation with time on the vertical axis and baseline distance along the shore on the horizontal axis) indicate the following:

- i) alongshore transport in the breaker zone is small compared to the total sediment in motion;
- ii) bottom changes do not follow any set pattern or alongshore direction;
- iii) there is no predominant direction in which the sediment moves;
- iv) net volume changes appear independent of time, that is, volume changes in an interval of four to five years is not anywhere equal to the volume change per year multiplied by time even if overall change in wave climate is insignificant;
- v) movement is compartmentalized in various stretches (physiographic units) and;
- vi) changes beyond the breaker zone in the onshore-offshore direction within the physiographic units are several times more than the alongshore changes.

Using the already described dimensional analysis as the tool and assuming the sediment trapped between the bars is mainly the result of onshore-offshore transport, quantity Q , in movement between the bars was calculated as a function of height of the bars ($d-H$), wave period T and depth d seaward of the bars. Figs. 9, 10, and 11 show that relationships do exist between them. Fig. 9 also shows that beyond a certain increase in bar height, the rate of increase in quantity trapped, drops considerably because under those conditions, waves are liable to break on the bars and the transport mechanism becomes different. The quantities so calculated, agree well with the erosion and accretion rates calculated from hydrographic surveys using the bar steepness criterion for finding the transport directions.

FIG. 7: PROFILE MEDIUM DEPTH FOR N.D. COAST

WILKINSON

FIG.10: ONSHORE-OFFSHORE Q AS FUNCTION OF T, d, & H

CONCLUSIONS

1. Characteristic features of majority of coasts facing seas with moderate or no tidal action are the existence of one or more submarine bars beyond the breaker zone and a break point bar in the breaker zone.

2. Underwater profiles with or without bars can be divided into three categories, namely, undernourished profiles in erosion areas, equilibrium profiles in dynamically stable areas and overnourished profiles in accretion areas.

On long term basis, they can be distinguished by medium depth and profile steepness criteria which will have certain limiting values for different types of profiles for a particular coast.

3. Though alongshore transport may predominate in the breaker zone, onshore-offshore transport beyond may be many times more influencing the coastal processes on a far bigger scale than has been anticipated at present. Submarine bars influence such motion to a considerable extent. Using dimensional analysis as the tool, onshore-offshore motion or vice versa can be calculated as functions of bar height, sediment density, wave period and depth behind the bars.

4. The methods described in 2. and 3. are applied to the Nile Delta coast where a comprehensive study of coastal processes has been in existence since 1971.

5. The fact that the coastal processes beyond the breaker zone especially in the onshore-offshore direction influence the erosion and accretion patterns much more than the alongshore transport, emphasizes the view held by many coastal engineers that the engineering project study of a coast should be extended far into the offshore zone.

ACKNOWLEDGEMENTS

This study is based on the field data taken by the author and his colleagues during his assignment as UNESCO expert on Nile Delta coast studies. The author wishes to thank the UNESCO, UNDP and Academy of Scientific Research and Technology, Egypt for the opportunity given to him.

CHAPTER 87

ONSHORE-OFFSHORE SEDIMENT MOVEMENT ON A BEACH

P. Nielsen¹ I. A. Svendsen² C. Staub³

ABSTRACT

A theoretical model is developed for the movement of loose sediments in oscillatory flow with or without a net current. In the present formulation the model is two-dimensional, but may readily be extended to three dimensions.

It is assumed that all movement of sediments occurs in suspension, and exact analytical solutions are given for the time variation of the concentration profile, the instantaneous sediment flux and the net flux of sediment over a wave period. The model requires as empirical input a diffusion coefficient ϵ and pick-up function $p(t)$, for which experimental data are presented. Two examples are discussed in detail, illustrating important aspects of the onshore-offshore sediment motion.

1. INTRODUCTION

The motion of loose sediments perpendicular to the coastline is one of many unsolved problems in sediment transport due to waves and currents. Yet it is generally agreed that this particular phenomenon plays a vital part in the sorting of sediments on a coast and hence has important bearing on the question of which grain sizes are present in the surf zone, where the bulk of the longshore transport takes place.

In nature the lateral sediment transport depends strongly on three-dimensional effects which are responsible for the often significant net water motions that occur in particular in the surf zone. Here the net water flux is shorewards in areas where the bottom configuration creates heavy breaking, and seawards (sometimes as rip-currents) in the often deeper areas where the breaking is weak or absent, moving as a longshore current between these regions. Also appreciable time variations occur over some minutes and may even dominate the spatial variations.

Though obviously crucial for the net movement of sediments it is beyond the scope of the present paper to analyse this water motion further. In the following we shall assume that the water motion is known. This is further justified by the observation that the processes involved in the local movement of sediments, which we are going to analyse, are almost exclusively governed by the local flow conditions. The purpose of the present paper is to formulate a theory that as closely as possible models the important part of the processes which can be observed to occur in sediment motion under waves.

2. PHYSICAL DESCRIPTION

To do so it is important first to describe the nature of the phenomenon.

Bottom configuration

One of the basic aspects is the bottom configuration generated by the water motion. It is well known that for a wide range of wave and sand parameters ripples are formed on the bed. The size, steepness and shapes of these have been measured by numerous authors (see e.g. Inman (1957) and Dingle (1974)), and lately Nielsen (1977) showed that the steepness of the ripples (measured ratio between height η from trough to crest over distance λ between two successive crests) is almost constant (0.15 to 0.20) for a value of the Shields' parameter θ' less than about 0.4, where θ' is defined as

$$\theta' \equiv \frac{1}{2} a^2 \omega^2 f_w / (s-1) g d \quad (1)$$

with a the amplitude of water particle motion at the bottom, $\omega = 2\pi/T$, T being the wave period. f_w is a friction factor, s and d are specific gravity and mean diameter, respectively, of the sand grains. g is the acceleration of gravity.

For θ' increasingly larger than 0.4 the steepness of the ripples decreases rapidly, and for $\theta' > 1$ the bed is virtually plane with relatively gentle undulations.

These are general trends subject to considerable scattering in the individual cases, in particular when field conditions in irregular waves are considered. Nevertheless it shows that except for very high storm waves, the sand on natural beaches (most often having $d \approx 0.2 - 0.3$ mm) will yield θ' -values not larger than 1. (A wave height $H = 10$ m, say, on a water depth $h = 15$ m yields $\theta' \sim 5$), which again implies that most often the bed will be covered by ripples.

Since it turns out that the ideas presented later in this paper can readily be adopted to a plane bottom, we first focus on the flow over a ripple bed.

Oscillatory flow over a ripple bed

The ripples formed by the oscillatory particle motion under waves are entirely different from the bed forms known from steady flow (see e.g. Allen (1968)). Also the oscillatory flow itself and the mechanisms by which the sediment is moved show little resemblance with unidirectional flow patterns.

This is due to the strong pressure gradients associated with the oscillatory flow which create strong lee eddies during the phase where the main flow is retarded, i.e. twice every wave period. Successively at the turn of the flow these eddies are 'washed' out into the main flow, thus yielding dominant contribution to the general turbulence level, and carrying appreciable amounts of sediment out in suspension (Fig. 1). Excellent photos showing details of the development of the eddy and a description of the process were presented by Bijker et al. (1976). Also Nakoto et al. (1977) describe the sequence.

One of the important features is the large velocities in the lee eddy. In fact the adverse velocity is of the same magnitude as the

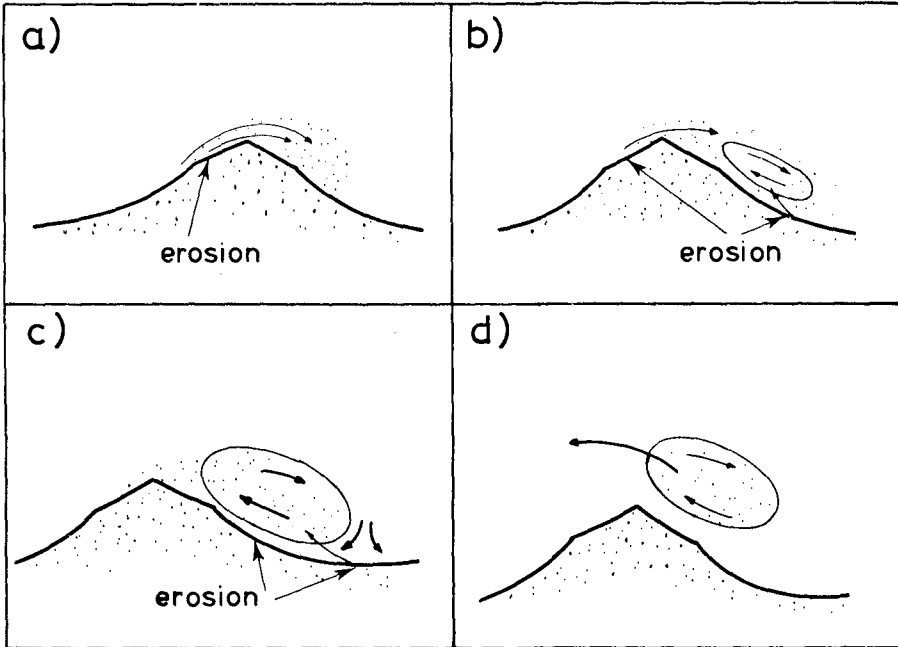

Fig. 1 Pick-up mechanism over a rippled bed. a) Velocity increasing, no separation, no effective pick-up. b) Velocity decreasing, separation started, sand accumulation in vortex. c) Water velocity vanishing, the vortex is fully developed. d) Water velocity reverses, the vortex is lifted out. This is when the effective pick-up takes place.

velocity in the main flow outside (Tunsdall and Inman (1975)), in contrast to the back flow in lee eddies in a steady unidirectional flow, which is usually only a fraction of the velocity in the main flow.

Another point is worth mentioning. The total excursion of the main water flow is often less than twice the ripple length.

Thus the flow pattern above the level of the ripple crests does not, as one might expect, attain the character of an oscillatory boundary layer in the known sense with the ripple height as a measure of the bed roughness. In fact the flow structure is entirely dominated by the regular eddies, their interaction and decay into turbulence.

Finally direct visual observations and high speed movies of the motion of the sand particles indicate that actual bed load transport as known from unidirectional flow hardly occurs. In fact one gets the impression that once a sand grain has started to move it goes into suspension (often via the eddy) before it settles again. This is also in disagreement with Longuet-Higgins (1972, p. 213) who (quoting Inman) claims that 'most of the weight of sediment is indeed in bed load, and not in suspended load.'

3. OUTLINE OF A THEORETICAL MODEL

We assume on the basis of these observations that *all* sediment is moved in suspension. The sediment is brought into suspension by a pick-up mechanism (as described above), which is further discussed in § 6. In the model it is described by the amount of solid sediment $p(t)$ being picked up per unit area of bottom per second, and the mean value of $p(t)$ over one period will be determined experimentally.

We further assume that the balance between the agitating processes tending to keep the sediment in suspension, and the settling of sediment (described by settling velocity w) has the nature of a diffusion process (irrespective the above mentioned regular nature of the eddy motion) with a diffusion coefficient ϵ , which is independent of time and horizontal coordinate x . (In fact the latter corresponds to averaging over a ripple length.) Thus the concentration $c(z,t)$ of suspended sediment satisfies the diffusion equation

$$\frac{\partial c}{\partial t} - w \frac{\partial c}{\partial z} - \frac{\partial}{\partial z} \left(\epsilon \frac{\partial c}{\partial z} \right) = 0 \quad (2)$$

z being the vertical coordinate.

The assumption of a pick-up mechanism $p(t)$ implies that the process of bringing the sand into suspension is independent of the settling of the sediments. In the mathematical formulation this function acts as the source for the diffusion equation (2), thus representing the boundary condition at the bottom level z_b

$$- \epsilon \frac{\partial c}{\partial z} = p(t) \quad \text{at} \quad z = z_b \quad (3)$$

One advantage of this formulation is that it is considered easier to suggest physically realistic descriptions for the pick-up function $p(t)$ (which could e.g. be proportional to the bottom shear stress) than for e.g. the bottom concentration c_b , often used as a boundary condition in suspension models.

As the second boundary condition in z is used $c(z) \rightarrow 0$ for $z \rightarrow \infty$ (though the water depth is h), and the system is closed in time by a periodicity assumption

$$c(z, t+T) = c(z, t) \quad (4)$$

When $c(z,t)$ has been determined the instantaneous flux $Q(t)$ of sediment through a vertical section is readily determined from the horizontal water velocity $u(z,t)$ by

$$Q(t) = \int_0^h u(z,t) c(z,t) dz \quad (5)$$

and the net sediment flux then follows from

$$\bar{Q} = \frac{1}{T} \int_0^T Q dt \quad (6)$$

At this point the model is more detailed than e.g. the approach used by Madsen and Grant (1976) who only consider the net motion of sediments. A closer inspection of the system shows that the clear separation of the pick-up and settling processes yields a memory effect in the model which implies that the maximum of sediment in motion occurs later than the

maximum of p , and also that the sediment motion does not vanish with p , which may itself show a phase difference relative to the fluid motion. This is a generalization of the idea of a phase lag between shear stress and sediment motion introduced by Kennedy (1963), and used in waves by Kennedy and Falcon (1965). It will be shown that this effect is crucial for the understanding of the onshore-offshore transport.

4. GENERAL SOLUTION

In the general solution the pick-up function $p(t)$ is considered in terms of its fourier series, which is assumed to have the form

$$\left. \begin{aligned} p(t) &= \sum_0^N P_n \cos n(\omega t - \psi_n) \\ p(t) &= \text{Re} \left\{ \sum_0^N P_n e^{in(\omega t - \psi_n)} \right\} \end{aligned} \right\} (7)$$

The z coordinate is zero at the level of the ripple crests which is also chosen as the level for the boundary condition (3), i.e. $z_b = 0$.

The phase angle ψ_n in (7) accounts for the phase difference between p and the water motion which will be assumed to vary as $e^{in\omega t}$.

The equation is solved by separation of variables, and to facilitate the calculations the physical concentration is considered to be the real part of the complex function

$$c(z,t) = \sum_0^N C_n e^{in\omega t} \zeta_n(z) \tag{8}$$

where for simplicity we assume

$$\zeta_n(0) = 1 \tag{9}$$

Inserting (8) in the diffusion equation (2) leads to

$$\zeta_n'' + \left(\frac{w + \epsilon'}{\epsilon} \right) \zeta_n' - i \frac{n \omega}{\epsilon} \zeta_n = 0 \tag{10}$$

where $\epsilon' = d\epsilon/dz$. The experiments presented later show that ϵ does not vary with z in non-breaking waves. If this is introduced into (10), an equation with constant coefficients results

$$\zeta_n'' + \frac{w}{\epsilon} \zeta_n' - i \frac{n \omega}{\epsilon} \zeta_n = 0 \tag{11}$$

which can be solved by standard methods.

Invoking (11) and the boundary condition $\zeta_n \rightarrow 0$ as $z \rightarrow \infty$ we get

$$\zeta_n(z) = e^{-\frac{w}{\epsilon} \alpha_n z} \tag{12}$$

where

$$\alpha_n = \frac{1}{2} + \sqrt{\frac{1}{4} + i \frac{n \omega \epsilon}{w^2}} \tag{13}$$

The complex coefficients C_n in (8) are determined by the boundary condition (3), which using (8) becomes

$$-\epsilon \frac{\partial}{\partial z} \left(C_n e^{in\omega t} \zeta_n \right) = P_n e^{in(\omega t - \psi_n)} \tag{14}$$

from which we get

$$C_n = \frac{P_n}{w \alpha_n} e^{-in\psi_n} \tag{15}$$

For $n = 0$ this yields a relation between the steady part of $c(o,t)$ and the steady part of $p(t)$

$$C_o = \frac{P_o}{w} \tag{16}$$

which enables us to determine P_o from measurements of $C_o = \overline{c(o,t)}$, where the bar denotes mean value over a wave period.

Thus the complete solution for the concentration profile as a function of time becomes

$$\left. \begin{aligned} c(z,t) &= \sum_0^\infty \frac{P_n}{w \alpha_n} e^{in(\omega t - \psi_n)} e^{-\frac{w}{\epsilon} \alpha_n z} \\ \alpha_n &= \frac{1}{2} + \sqrt{\frac{1}{4} + i \frac{n \omega \epsilon}{w^2}} \end{aligned} \right\} \tag{17}$$

We note that $\epsilon\omega/w^2$ is an important parameter, which represents the ratio of the response time for the concentration profile ϵ/w^2 over the wave time scale $T/2\pi$. This information could, of course, also be extracted directly from (2) by non-dimensionalization.

The physical concentration is obtained as the real part of (17), which is

$$c(z,t) = \sum_0^\infty \frac{P_n}{w |\alpha_n|} \cos n \left[\omega t - \psi_n - \frac{1}{n} \left(\arg \alpha_n + \frac{wz}{\epsilon} \text{Im}\{\alpha_n\} \right) \right] e^{-\frac{wz}{\epsilon} \text{Re}\{\alpha_n\}} \tag{18}$$

Fig. 2 shows the variation of α_n , and Fig. 3 that of $|\alpha_n|$, $\arg \alpha_n$, $\text{Re}\{\alpha_n\}$, and $\text{Im}\{\alpha_n\}$.

Finally the sediment flux Q is determined from (5). Here we assume that the ripple length λ is small, i.e. $\lambda \ll L$, where L is the wave

Fig 2
The position of α_n
in the complex plane.

Fig. 3
The magnitude of $|\alpha_n|$, $\text{Re}\{\alpha_n\}$, $\text{Im}\{\alpha_n\}$ and $\text{arg } \alpha_n$ versus $n\omega\epsilon/w^2$.

length, so that the horizontal water velocity is approximately constant over λ , and the averaging over a ripple length introduced earlier can be executed with a constant $u(z,t)$. Thus for convenience we assume that u has the form

$$u(z,t) = \sum_0^N u_n(z) \cos n \omega t \tag{19}$$

which include a term $u_0(z)$ constant in time. Substituting this and (8) into (6) yields

$$\bar{Q} = \frac{1}{T} \int_0^T \int_0^T \sum_0^N c_n(z,t) u_n(z,t) dz dt \tag{20}$$

which is a general expression for Q . To get practical results from this expression we must specify the value of the diffusion coefficient ϵ , a problem which is discussed in § 5. We must also know the form of the pick-up function p (i.e. the fourier-coefficients P_n in (7) and the phase angle ψ_n). This is discussed in § 6. And finally $u_n(z)$ is required. However, the formulation above is actually too general for detailed discussion, and a number of useful conclusions can be obtained from studying special examples. This will be discussed in § 7.

5. PREDICTION OF THE DIFFUSIVITY

One of the basic assumptions behind this model is that the upward flux of sediment at any level is due to diffusion as expressed by the term $-\epsilon \partial c/\partial z$.

To test this assumption and to obtain results for ϵ , the sediment concentrations were measured over a sand bed subjected to waves in a 60 cm wide wave flume with a water depth of about 40 cm. The water/sand mixture was sucked out through thin pipes (1,5 mm diameter) at different levels, and the concentration determined from the sample. Thus all measurements represented mean values over several wave periods. In addition to these results, measurements published by Nakato et al. (1977), and some unpublished results performed in the pulsating water tunnel described by Lundgren and Sørensen (1958), have been used in the following analysis.

The value of ϵ for each experiment was determined graphically from a semilogarithmic plot of the measured concentrations versus the vertical coordinate z . Fig. 5 shows examples of such plots which clearly illustrate that ϵ is nearly constant under non-breaking waves, and also may be taken as a support of the assumption that the phenomenon may be approximated by a diffusion process with $\epsilon = \text{constant}$.

The results thus obtained for ϵ have been analysed in several ways. First it is worth to notice that Svendsen et al. (1977) analysed the motion of suspended particles in accelerated flow and found that sand grains would follow the oscillatory water motion practically identically (apart from the settling due to gravity). From their results for sinusoidal oscillations may be deduced that even in the relatively low frequency turbulence in the flow in question, the grains must very nearly follow the water flow, from which we can conclude that the diffusivity ϵ is equal to the turbulent eddy viscosity ν_T .

ϵ or ν_T are often considered as the product of a typical length scale l_ϵ and a typical velocity u_ϵ .

A natural length scale (of vertical motion) in the flow over a ripple bed is the ripple height η .

When no ripples are present, the scale is $\kappa \delta$, where κ is Von Karman's constant and δ the boundary layer thickness. δ may then be calculated from the equation

$$\delta/a = 0.072 (2.5 d/a)^{0.25} \quad (21)$$

as given by Jonsson and Carlsen (1976).

For the characteristic velocity u_ϵ , is normally used the friction velocity $u_f = \sqrt{\tau_{\max}/\rho}$. One might then conjecture a simple relation like

$$\epsilon = F(u_f[\eta + \kappa \delta]) \quad (22)$$

where $\kappa \delta \ll \eta$ in situations with noticeable ripples.

In fact it turns out that the best empirical correlation in the results for ϵ is obtained if we use

$$\frac{\epsilon}{(\eta + \kappa \delta) g T} = f\left(\frac{U_m}{w}\right) \quad (23)$$

as shown in Fig. 4. The physical background, however, of this correlation is not clear, and the subject obviously needs further consideration.

The diffusivities mentioned above are all determined in non-breaking waves and from measurements of concentrations within about 5 ripple heights from ripple crest level. Above this level there is hardly any bed material in suspension.

If, however, the waves are just gently breaking as spilling breakers, the turbulence generated by the breaking will reach the bottom after 4 - 6 wave periods, and significantly change the shape of the concentration profile, down to a few ripple heights (centimeters) above the bed. As a result the suspended material is spread from surface to bottom. The effect is surprisingly strong, particularly for fine materials with large u/w , and indisputable as shown in Fig. 5, where the concentration profile from under a spilling breaker is shown together with that of an unbroken wave with the same height. It also forms a remark-

Fig. 4 A plot for semi-empirical determination of ϵ from U_1/w and the vertical length scale $(\eta + \kappa \delta)$.

Fig. 5 The distributions of suspended sediment under breaking and non-breaking waves of equal heights. Breaking gives much larger diffusivities but slightly smaller concentrations at the bed level.

able illustration to the ideas about the turbulence conditions in spilling breakers presented by Peregrine and Svendsen (1978).

It should be noticed that the concentrations at the bed level are nearly unchanged by the breaking, and the measurements show that the total amount of sediment in suspension is practically unchanged too. This indicates that the pick-up process is only moderately affected by the surface turbulence, which has been decaying over 4 - 6 wave periods before it reaches the bottom. On the other hand, the relative change in turbulent intensity is large from the surface down to about 5 times the ripple height above the bed, and the already suspended sand is easily spread over a whole depth of water.

6. ANALYSIS OF PICK-UP FUNCTION

The pick-up function $p(t)$ is always non-negative and therefore has a positive time mean value P_0 . In the following we divide the discussion between P_0 , which is determined experimentally, and the time variation of $p(t)$ (i.e. the rest of fourier-coefficients in (7)).

The time mean value of $p(t)$

In the solution for $c(z,t)$ we found in § 4 that the true mean value P_0 of $p(t)$ was equal to wC_0 where C_0 is the time mean value of the concentration at $z = 0$. This means that P_0 can be determined directly from the measurements described in the previous paragraph.

A closer analysis of these shows that C_0 depends on the horizontal position of the measuring point relative to the ripple. C_0 is larger over the crest than over the trough. We find that $C_{0,crest} \approx 1.8 \cdot C_{0,trough}$.

However, the net transport \bar{Q} must be the same through any vertical section. And since we have chosen our reference level $z = 0$ at the level of the ripple crest to be consistent, we must also in the calculations use the C_0 values obtained over the ripple crest.

Fig. 6 shows the measured values of $C_{0,crest}$ as a function of the Shields' parameter θ' (i.e. the non-dimensional shear stress) given by (1), in which we have used Swart's (1974) empirical fit to the experimental results for f_w in an oscillatory boundary layer, i.e.

$$f_w = \exp\{5.213 (2.5 d/a)^{0.195} - 5.977\} \quad (24)$$

It is important here that f_w is based on grain-roughness, not on the ripple-height, say.

As we see from the figure, the results for C_0 varies fairly consistently with θ' .

The time variation of $p(t)$

As mentioned in § 2 most of the sediment grains that move over a rippled bed are ripped off the upstream side of the ripples, pass over the crest into the lee eddy, and are then washed out into real suspension with that eddy. Thus we must expect the pick-up function $p(t)$ to show significant peaks twice every wave period. No measurements are available to quantify this, but observations in a wave flume or on a beach clearly show strong puffs with high concentration of sediments

Fig. 6 The steady part of the concentration at ripple crest level is a function of θ' .

emerging in the general 'pea soup' over each ripple, and at the right time. Often the puffs occurring right after the wave crest has passed (i.e. after the highest velocities) are more significant than those produced after the weaker return flow in the wave trough.

Tentatively this can be modelled by a pick-up function of the form

$$p(t) = \frac{P_0}{1+\beta} \frac{(2m)!!}{(2m-1)!!} \left[\cos^{2m} \frac{1}{2}(\omega t - \psi^+) + \beta \cos^{2m} \frac{1}{2}(\omega t - \psi^-) \right] \quad (25)$$

where m is a positive integer,* and β is accounting for the difference between crest and trough velocities. β may be determined as

$$\beta = \left(\frac{u_{\text{trough}}}{u_{\text{crest}}} \right)^2 \quad (26)$$

with the u 's as maximum values of the bottom velocities in the water motion (notice that weak currents may be included here).

According to the description above the phase angles ψ^+ and ψ^- are determined as the phases where the velocity in the main flow is changing direction. Notice that this choice, however surprising, may also be expected to apply as an approximation to the case of a plane bed. Then the thin boundary layer adhering to the bottom separates shortly before the time of velocity shift, yielding a situation similar (though less pronounced) to the release of eddies over the ripple bed.

* $(2m)!! = 2 \cdot 4 \cdot \dots \cdot 2m$; $(2m-1)!! = 1 \cdot 3 \cdot 5 \cdot \dots \cdot (2m-1)$.

Thus ψ^+ and ψ^- depend on the wave motion considered. In the examples in the following paragraph $\psi^+ = \psi^- - \pi = \pi/2$ for sinusoidal waves (example (1)), whereas $\psi^+ < \pi/2$ and $\psi^- > 3\pi/2$ for second order Stokes waves with zero mass flux (example (2)).

Fig. 7 The time-variation of the pick-up function for different values of the power $2m$.

The exponent $2m$ gives the shape of the pick-up function. For $m \rightarrow \infty$ (25) corresponds to two δ -functions at $\omega t = \psi^+$ and ψ^- , respectively. Fig. 7 shows some examples for different choices of m . The important point, however, how much the choice for m is influencing the results for \bar{Q} is analysed in more details in example (2).

7. EXAMPLES

(1) Sinusoidal wave motion

The simplest example one can think of is that of a sinusoidal wave, where

$$u(t) = U_1 \cos \omega t \tag{27}$$

Here $p(t)$ must have two peaks, equal in height and with a phase difference of π , i.e. $\beta = 1$ in (25), so that $p(t)$ is

$$p(t) = P \cos^{2m}(\omega t - \psi) \tag{28}$$

Without loss of generality we can take $m = 1$ to obtain

$$p(t) = P_0 (1 + \cos 2(\omega t - \psi)) \tag{29}$$

Fig. 8 shows the variation of the pick-up function and the concentration at the bed level in this case.

We see from (15) that the phase shift is $\frac{1}{2} \arg \alpha_2$, and that $c(o,t)$ does not go to zero as $p(t)$ does. Hence this important property of

the suspension mechanism is modelled correctly because of the separation between the pick-up and settling process.

Equation (20) shows that $\bar{Q} \approx 0$ because of the symmetry of the problem. Note that this result is independent of ψ and of the power $2m$ in (28).

Fig. 8 The variation mode of $p(t)$ and $c(o,t)$ when $u(t)$ is simple harmonic. Note that $c(o,t)$ is not in phase with $p(t)$, and that $c(o,t)$ does not go to zero as $p(t)$ does.

Fig. 9 The choice of m is not critical for $Q_1 + Q_2$. (Q_o is independent of m).

(2) Second order Stokes' wave

In the second example we assume a second order Stokes' wave motion, i.e. a velocity u at the bottom given by

$$u = U_0 + U_1 \cos \omega t + U_2 \cos 2\omega t$$

with

$$U_1 = \frac{\pi H}{T \sinh kh} \quad U_2 = \frac{3}{16} c \frac{(kH)^2}{\sinh^4 kh} \quad \left. \vphantom{U_1} \right\} (30)$$

i.e. we neglect the z -variation of u . Notice that U_0 can represent a 'return flow' corresponding to a zero net mass transport (i.e. (30) will represent a pure wave motion), if

$$U_0 = -\frac{1}{8} \frac{gH^2}{ch} \quad (31)$$

If (30) is substituted into (20) together with (25), we get the following expression for the net sediment flux

$$\begin{aligned} \bar{Q} &= \frac{U_0 P_0 \epsilon}{2w^2(1+\beta)} \left[2(1+\beta) - \sum_{n=1.2} \frac{a_n U_n}{U_0 |\alpha_n|^2} \left(\cos(n\psi^+ + 2 \arg \alpha_n) + \beta \cos(n\psi^- + 2 \arg \alpha_n) \right) \right] \\ &\equiv Q_0 + Q_1 + Q_2 \end{aligned} \quad (32)$$

The parameters of this expression are the wave data H/L and $T\sqrt{g/h}$, the grain diameter d , and m . Fig. 9 shows for a particular wave the influence on the oscillatory part of \bar{Q} (i.e. $Q_1 + Q_2$) of three choices for m in the range, which is considered realistic. $m \rightarrow \infty$ yields less than 10% change in \bar{Q} relatively to $m = 32$. The dependence on m is moderate, and we choose $m = 12$ in the following.

The results for the ripple height η required for evaluation of ϵ from Fig. 7 have been obtained from the mean curve shown in Fig. 10, which gives η/a (a being the water particle amplitude at the bottom determined from linear theory) versus $U_1^2/(s-1)gd$, s being the relative density of the sand.

Figs. 11 through 14 show the variation of $Q_1 + Q_2$, Q_0 and the net discharge \bar{Q} for waves with $T\sqrt{gh} \approx 10$ and height up to 4 metres (0.4 times depth of water), and four typical grain diameters $d = 0.1, 0.2, 0.4$ and 1 mm. In these calculations U_0 has been determined from (31), i.e. the \bar{Q} represents zero net transport in the water motion. Some characteristic values of ϵ and θ' obtained in the computations are shown in the figures too.

The figures show that under these conditions the sediment will move seawards under almost all wave conditions ($\bar{Q} < 0$).

A number of other observations and conclusions may be extracted from the results.

(i) The rather sharp decrease in the numerical value of all Q -curves corresponds to the region between $\theta = 0.4$ and $\theta = 1.0$, where the ripples suddenly disappear and ϵ , as given by Fig. 4 and Fig. 10, consequently decreases by a factor of 10.

(ii) For the larger grains sizes the oscillatory contributions are positive (shoreward movement) for high waves, and of the same order of magnitude as Q_0 . Thus if Q_0 had been less negative (or even positive) -

Fig. 10 Semi-empirical plot for determination of the ripple height η for instance due to three-dimensional effects, vide the introduction — \bar{Q} might well have been positive.

(iii) The finer the material, the less important the oscillatory part, and for $d = 0.1$ mm net sediment discharge is entirely dominated by Q_0 , i.e. U_0 . Then the net sediment flux may be determined by

$$\bar{Q} \approx Q_0 = U_0 P_0 \epsilon / w^2 \tag{33}$$

and this corresponds to situations where the variation of c over a wave period is small.

(iv) The values obtained for ϵ by the procedure described above appear in a wide region without ripples to be close to $1/4 \kappa U_f \delta$ (κ von Karman's constant, U_f friction velocity, δ boundary layer thickness). This esti-

mate can in fact be inferred from Kajiura (1968) (Jonsson, private communication). Since part of this region is outside the region where measurements for ϵ are available, this is taken as an indication that our extrapolations in the computations are reasonable.

Finally it is emphasized that all these results apply to non-breaking waves only.

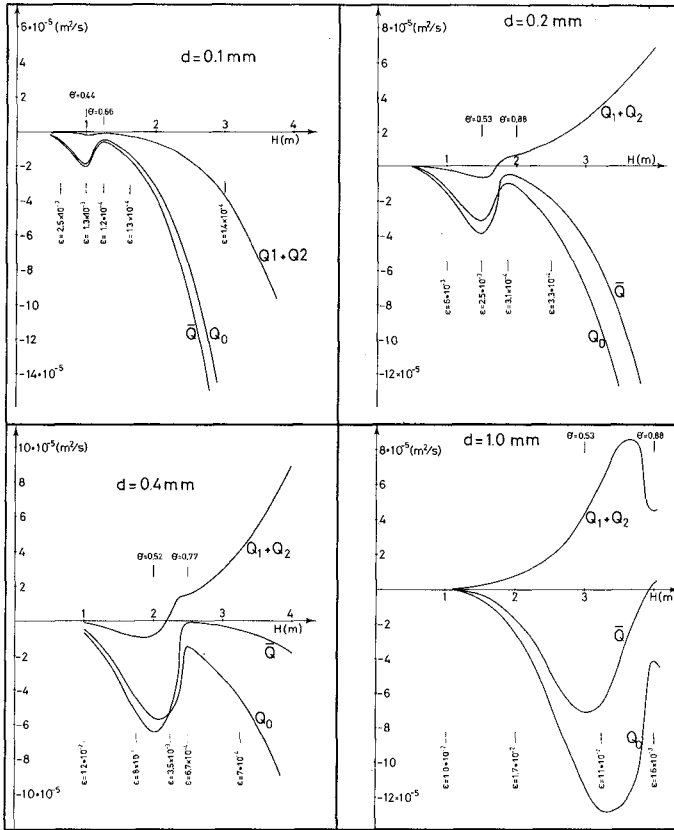

Fig. 11 - 14 Transport versus wave height for different grain diameters. ($U_0 = -gH^2/8ch$).

Comparison with experiments

The model has also been compared with measurements in a wave flume. Fig. 15 shows measurements of \bar{Q} obtained on a horizontal bottom from the changes in bed elevation over a recorded number of waves. Fig. 16 shows the corresponding measurements of the mean water velocity U_0 . When this is used in the calculation of \bar{Q} , we get the value shown by the dotted line in Fig. 15. (The straight line approximation in Fig. 16 was used for U_0).

Fig. 15 - 16 Calculated and measured transport for a flume experiment. (ISVA, 1978).

8. CONCLUSIONS

A theoretical model has been developed which yields analytical results for the instantaneous distribution of sediment concentrations $c(z,t)$, when the oscillatory water motion (the wave) and the net mass flux (the current) is prescribed. The result for c is given by (17). Also the sediment flux (instantaneous and time mean) is determined (Eqs. 5 and 6).

Experiments are used to determine the diffusion coefficient ϵ (§ 5) required as input to the model (Fig. 4), and the results indicate that it is reasonable as done to assume the suspension of sediment can be approximated by a diffusion process. The actual physics of the sediment motion is described and discussed in detail in § 2.

In the solution a pick-up function $p(t)$ occurs. Mathematically it acts as the boundary condition at the sea bed for the diffusion equation (§ 3-4). Physically it accounts for the process (also described in § 2) of picking up the sand and bringing it into suspension. The mean value of $p(t)$ is determined experimentally in § 6 where also the time variation of this process is discussed, and equation (25) is a heuristic suggestion for $p(t)$ and further discussed in example (2) in § 7.

In § 7 two examples are analysed, showing the consequences of the model for the onshore-offshore sediment flux in two different wave motions. The first (a simple sinusoidal wave) always yields zero net sediment movement.

In the second example a second order Stokes' wave with specified mass flux is considered. Here the results are far more complicated. For a wave motion with zero net mass flux, the net sediment motion \bar{Q} is always against the wave direction. The balance, however, is delicate, and in a pure oscillatory flow (no return flow) the motion may go in either direction (Figs. 11 through 14).

Finally the model is compared with a measurement of \bar{Q} in a wave flume with zero net water flux, using a second order Stokes' wave model and a measured mean water velocity profile (Fig. 16). In Fig. 15 the computed and measured values of \bar{Q} are shown to compare within the accuracy of the measurements.

CHAPTER 88

USES FOR A CALCULATED LIMIT DEPTH TO BEACH EROSION

by

Robert J. Hallermeier

Oceanographer, U.S. Army Coastal Engineering Research Center,
Fort Belvoir, Virginia 22060

Abstract. A sediment entrainment parameter is used to calculate maximum water depth for intense bed agitation by shoaling linear waves of given height and period. Calculated limit depths agree with available laboratory measurements of water depth at an erosive wave cut into slopes of quartz and other fine sediments. Ignored variables have small effects on the agreement between calculations and laboratory measurements. On natural seasonal beaches, available measurements of seaward limit to appreciable sand level changes agree with limit depths calculated for extremely high waves expected 12 hours per year. The apparent accuracy and lack of scale effect in the calculated limit depth justify several applications in field and laboratory projects.

THE CALCULATED LIMIT DEPTH

In considering sediment transport by water waves on a beach, it is useful to divide the onshore-offshore profile into zones related to physical processes. The simplest division distinguishes two zones: a nearshore or littoral zone; and an offshore zone. In the offshore zone, wave shoaling is the dominant process and bed agitation remains relatively moderate. The littoral zone is characterized by increased bed stresses and sediment transport, caused by waves near breaking and induced fluid circulations.

The hypothetical boundary between these two zones is the seaward limit of intense bed agitation by shoaling wave action. Hallermeier (1977) proposed that the onset of intense bed agitation might be described as a critical value of a sediment entrainment parameter. This parameter has the form of a Froude number:

$$\phi = U_b^2 / \gamma' g \epsilon d \quad (1)$$

where U_b is maximum horizontal water velocity near the bed, g is the acceleration of gravity, d is water depth, ϵ is a number less than unity, and γ' is the ratio of the density difference between sediment and fluid to fluid density. This Froude number is peak near-bottom wave energy per unit sediment grain volume, divided by the energy needed to raise an immersed grain a distance $(\epsilon d/2)$. Two order-of-magnitude choices, $\epsilon = 0.03$ and $\phi = 1$, are taken to describe the onset of intense wave agitation for fine sands (diameter, D , between 0.06 and 0.5 mm).

With these assumptions and linear theory for shoaling waves, equation 1 can be written as

$$\xi \sinh^2 \xi \tanh^2 \xi \left(1 + \frac{2\xi}{\sinh 2\xi} \right) = (329 H_o^2 / \gamma' L_o^2) \quad (2)$$

where H_o and L_o are wave height and wavelength in deep water, and $\xi = (2\pi d_s / L_s)$ gives the limiting water depth, d_s , in a form normalized by local wavelength, L_s . For a certain γ' , H_o and $L_o = (gT^2/2\pi)$, where T is wave period, the ξ solving equation 2 can be conveniently computed using either a graph or an iterative root-finding procedure on a programmable calculator. The maximum water depth for intense bed agitation is $d_s = (\xi \tanh \xi)(L_o/2\pi)$.

The primary evidence for the usefulness of the calculated d_s is provided by laboratory tests with constant waves on an initially plane slope of sediment. The many published profiles developed in such tests provide a data base on sediment transport towards an equilibrium profile in controlled wave conditions. A common profile feature with fine sediment is a submarine cut by erosive waves into the initial slope, with sediment deposition offshore. The well-defined water depth at this wave cut, d_c , is the limit depth to the erosive action of the surface waves. The wave cut sometimes lies on the landward side of a bar, but more commonly is on a gently sloping terrace.

Figure 1 shows the good agreement of measured d_c with calculated d_s for 46 laboratory tests of profile development with an initially plane sediment slope. The filled points in Figure 1 denote tests with sediments having γ' appreciably different from quartz in water. The Appendix gives references and test conditions for the 46 profiles,

Figure 1. Measured profile cut depth, d_c , versus calculated limit depth, d_s . Conditions for 46 laboratory tests from 13 studies are presented in the Appendix.

selected as ideal cases of a wave cut. In each case, there is only sand deposition on the initial slope offshore of the cut depth.

Table 1 presents results of linear regressions on the Figure 1 points. For each regression line (including those of the data set halves discussed in the following section), the correlation coefficient, r , is large enough to reject the possibility of no linear relationship between d_c and d_s with at least 99.99% confidence, presuming the data points are random samples from a bivariate normal population (Freund, 1962). In each case, the intercept of the fit line is fairly near zero and the slope is near unity. The agreement between measurement and calculation is most ideal for the 38 tests with quartz sands. With the sediments of other densities (glass, coal, bakelite, maselite, and oolitic aragonite), agreement is still good, providing additional confidence that the calculated d_s is the limit depth to the erosive action of various waves causing offshore deposition of various fine sediments.

The footnote to Table 1 emphasizes the fact that d_s is approximately a linear multiple of incident wave height, for any given γ' . The measured d_c is well described by a linear dependence on H_o , but the fit is considerably better with the exact calculated d_s , which includes a slight effect of wave period.

It may be noted that a similar physical viewpoint is involved in the d_s calculated using the equation 1 consideration of sand entrainment energetics and in a limit depth arising in the empirical eroding-profile schematization of Swart (1974). That work considers an "equilibrium D-profile" geometry, with offshore water depth, d_1 , at the lower limit stated to be related to the first occurrence of suspended-load transport. For the 6 tests considered in Figure 1 and in Swart (1974), $0.69d_1 < d_s < 0.78d_1$; this narrow range helps confirm a similar phenomenon is involved in d_s and d_1 .

EFFECTS OF IGNORED VARIABLES

The laboratory data base was divided into approximate halves to isolate effects of larger or smaller: tank water depth; number of waves; initial slope; Stokes number, describing the nonlinearity of the

* Also, $d_c = 1.97 \text{ cm} + 1.70 H_o$, with $r = 0.875$, for quartz sands

waves; and sand diameter. The separation criteria are given in Table 1 along with the linear regression results; data subsets of nearly equal size facilitate comparison of results. In Table 1, the relative tank depth is given in dimensionless form as $(d_t / L_t) / (d_s / L_s)$, where d_t is maximum water depth and L_t is linear wavelength in that depth for the

given T ; this form seems more appropriate than (d_t/d_s) for considering wave geometry effects. The Stokes number is $S = (H_s L_s^2 / 2d_s^3)$, where H_s is calculated wave height at d_s , according to linear theory for wave shoaling. Ignoring sand size is thought to be a significant assumption in the calculation procedure, so the influence of sand diameter was examined using four parameters: D directly; (H_s/D) , suggested by Bagnold (1940) as a similarity parameter for beach profile development; and two useful parameters from dimensional analysis of oscillatory-flow interaction with a sediment bed (Lofquist, 1978), $\phi = (U_b^2 / \gamma' g D) = (\epsilon d_s / D)$ and $(a_s / D) = (H_s / 2D \sinh \xi)$, where a_s is near-bottom horizontal fluid orbit amplitude.

There are differences in the fit lines and the correlation coefficients between each data subset of the eight pairs in Table 1. The quantity r^2 measures the amount of variance in d_c attributable to the derived linear dependence on d_s . This ranges between 73% and 95%, and differs somewhat between the two members of each of the eight pairs. In seven of the eight cases, the larger r occurs for the fit line in better agreement with the present model, i.e., α nearer zero and β nearer unity. (Results with gentler and steeper slopes show practically the same agreement with the model.)

For each of these eight cases, a nonparametric statistical test was applied to assess the parallelism of the two regression lines. This test (Hollander and Wolfe, 1973) compares two sets of slope estimators from pairs of points within each data base half, using the Wilcoxon signed rank test, with no assumptions about the distribution of deviations from linearity. Inferences from repeats of this test may differ slightly because a random pairing of slope estimators is involved.

The tank water depth was found to affect the slope at the 0.13 level of significance. This result implies there is a 0.13 probability that the parallelism of the fit lines has been rejected, when in fact they are parallel. With relatively large water depth, $(d_t L_s / d_s L_t) > 1.7$, the $(d_s d_c)$ data shows better agreement with the present model. Because 6 of 8 tests with non-quartz sands were done with relatively small water depth, these 8 points were deleted from the further analyses.

The number of waves was found to affect the slope at the 0.04 level of significance. More waves result in a better agreement between calculated and test results. For 25 of the 38 quartz-sand tests, the profile development in time was available, and d_c is found to oscillate somewhat but generally to increase slightly with running time. On the average, it is clear that d_s provides a useful estimate for the limit depth on an eroding profile approaching equilibrium.

The statistical test gave no conclusive indications of effects of initial slope and of Stokes parameter on the regression line slopes. Initial slope appears to have insignificant consequences for the present consideration, considering the large and nearly equal r for these two data subsets. However, the lack of a discernible effect of the Stokes parameter on the fit between d_c and d_s requires comment. Linear wave theory can be valid only if correction terms arising in second-order theory are negligible compared to the linear solution; an approximate form for this requirement is that the Stokes parameter be much less than about 50 (Madsen, 1976). The stream function results in Dean (1974) show that for $(HL^2/2d^3)$ greater than about 10, the calculated U_b is appreciably greater than that given by linear wave theory, although the difference is not monotonic with the Stokes parameter, clearly depending on (d/L) . These results are for waves over an ideal immobile bed, and the present data base includes only $S > 11$. These facts might account for lack of a definite effect with larger Stokes parameter for the calculation procedure to underestimate U_b and thus d_s (equation 1), as the wave condition becomes increasingly non-linear.

The examinations of sand size effects gave some interesting results. Splitting the data base directly according to reported D was found to affect the regression-line slope at the 0.18 level of significance; finer sands result in slightly better agreement between the model and measurements. When the data base is split using either (H_s/D) , $(U_b^2/\gamma'gD)$ or (a_s/D) , the parallelism of the two regression lines cannot be rejected even at the 0.4 level of significance.

The separation of the data base according to (H_s/D) appears to be the least constructive, because the fit line for each data subset shows

relatively poor agreement with the present model. Bagnold (1940) suggested the change of bed material behavior from shingle to sand takes place for (H_s/D) on the order of 2,000, but the present consideration suggests the transition value is on the order of $(H_s/D) = 200$, if this is the proper descriptive parameter. A limited range of relatively fine sands are represented in the present data base. Bagnold (1940), Rector (1955), Popov (1960), and van Hijum (1974) have reported laboratory tests with waves acting on coarse quartz sediments: $3 \leq D \leq 7$ mm. A near-horizontal shelf or wave cut commonly occurred at water depth ranging from $(0.7 H_o)$ to $(2 H_o)$. These tests with coarse sediments all have (H/D) on the order of 40, but no clear conclusion is possible on the limit depth to the wave's erosive action. However, it seems clear that the calculated d_s should be an upper bound to the actual limit depth with erosive waves acting on coarser, less mobile sediments.

Although results are not too decisive when the data base is separated according to $(U_b^2/\gamma'gD)$ or (a_s/D) , it is somewhat paradoxical that measurements appear in better agreement with the model for relatively small $(U_b^2/\gamma'gD)$ and for relatively large (a_s/D) , because these two parameters are strongly and positively correlated in the present data base. Others of the ignored variables might cause this. $(U_b^2/\gamma'gD)$ roughly measures the intensity of sand motion, and the values of $(U_b^2/\gamma'gD)$ and (a_s/D) in the present data base indicate that $\phi = 1$ may correspond to the onset of intense bed agitation as revealed by the decline of bed forms with increasing bed agitation (cf. Figure 32 in Lofquist, 1978).

In summary, the variables ignored in calculating the limit depth appear to have small or negligible effects. Emphasizing the non-negligible effects, d_s has been seen to agree better with the limit depth of equilibrium profile erosion for fine sands and unconstrained water depth. Each data subset gives less ideal agreement between d_c and d_s than the entire data base for quartz sands. The excellent agreement between d_c and d_s in the larger data base evidently results from an averaging of effects of ignored variables.

YEARLY LIMIT DEPTH TO PROFILE ACTIVITY ON SEASONAL BEACHES

Because d_s is calculated from a critical value of a Froude number, this limit depth should pertain to eroding natural beach profiles of fine sand, with comparable (H_o/L_o) and Φ , as well as to profiles developed in smaller-scale laboratory tests. This is partially confirmed by several profiles obtained by Saville (1957) in large-scale laboratory tests, as discussed in Hallermeier (1977). However, application of this calculated limit depth to natural beaches must consider complicating effects occurring in nature, including changing wave action.

For natural sand beaches, one limit depth useful in coastal engineering is the yearly limit to the very active nearshore profile, beyond which repetitive surveys reveal little sand level change throughout the seasonal wave climate changes. This profile close-out depth can be estimated using the cut depth calculated for a yearly extreme wave condition. Such high waves erode the nearshore and deposit sand offshore; the estimated yearly extreme cut depth should be a minimum limit to water depth for appreciable sand level changes. An appropriate extreme wave condition is proposed to be that exceeded for 12 hours per year (0.137%). This duration should permit moderate adjustment towards profile equilibrium and moderate quantities of sand deposited beyond the limit depth. Also, Maksimchuk (1976) stated the beach profile in varying wave action is dominated by a similar wave condition, that having a cumulative frequency of 0.2% (0.73 days per year).

To calculate limit depth for such extreme waves, an accurate approximation for equation 2 is convenient:

$$d_{se} = 2.28 H_e - 68.5 (H_e^2 / g T_e^2) \quad (3)$$

Here γ' has been taken as 1.6 (quartz sand in salt water), H_e and T_e are nearshore significant height and period of the extreme wave condition, and g is acceleration of gravity in appropriate units.

H_e is the dominant input in calculating d_{se} . Thompson and Harris (1972) reported measured nearshore wave heights for a complete yearly cycle occur according to a modified exponential distribution, and

height of extreme waves is best estimated using the mean height, \bar{H} , and standard deviation of height, σ , defined by a full year of at-least-daily nearshore wave measurements. According to the exponential distribution, the 12-hour-per-year height is

$$H_e = \bar{H} + 5.6 \sigma \quad (4)$$

T_e should be taken to be the typical period of measured high waves.

Any near-bed velocities above those caused by linear waves are ignored in calculating the limit depth in equation 3. Use of linear wave theory is warranted because of its simplicity and agreement with available field measurements of peak near-bed velocity (Grace (1976)). However, any flows superposed on surface waves must increase the peak near-bed fluid kinetic energy, the numerator of equation 1, and thus increase the calculated limit depth in the denominator. To counteract this, it is proposed that the calculated d_{se} be used as a minimum estimate of profile close-out depth with respect to mean low(er) tide level.

Table 2 presents estimated profile close-out depths along with recorded close-out depths from published field studies including repetitive nearshore profile and wave measurements. The estimated water depths are calculated using equations 3 and 4, and measured depths are for profile superposition throughout a yearly cycle to within 1 foot, a typical resolution for nearshore surveys. In each case, the estimated close-out depth is quite close to and usually less than the measured depths. There is about the same agreement with measurement if limit depth is calculated using, rather than equation 3, the exact form of equation 2 ignoring shoaling wave height change (given in Hallermeier, 1977). Each field study in Table 2 was done on a different sea coast, with very different extreme wave conditions, increasing confidence in the usefulness of the calculated yearly limit depth. Agreement between calculated and measured depths is best for the most ideal data set, Torrey Pines Beach, where three profiles were surveyed monthly over a two-year interval.

On the other hand, Table 2 summarizes a very small amount of field investigation, and the present treatment has ignored several possibly important factors in considering only two-dimensional wave action.

Table 2. Comparison of estimated and measured profile close-out depths from field studies reporting repetitive nearshore profiles and wave measurements. Water depths are with respect to local mean low(er) tide level, and sand sizes are near estimated limit depths.

* Profiles superpose to within ± 0.5 ft; depth is average of two yearly cycles, except for Balsillie (1975).

Swart (1974) considered the effects on the onshore-offshore equilibrium beach profile of wave-induced longshore and rip currents; in erosive waves, each effect theoretically deepens the profile due to increased bed shear. Bijker (1967) reported the measured increase of bed shear in a uniform current due to wave action could be expressed as an empirical function of: angle between wave and current; the ratio of their peak near-bed speeds; and the bed roughness. These factors must be considered in predicting alongshore and onshore-offshore sediment transport within the nearshore beach zone.

However, the beach profile near d_{se} ($\approx 2 H_e$) should be beyond the influence of intense wave-induced nearshore circulations. Wave breaking usually occurs at water depth on the order of wave height, i.e., in water appreciably shallower than d_{se} . Beyond wave breaking, the seaward extent of the induced currents seems a useful way to define the extent of the nearshore zone. Available theory and experiment on the wave-generated alongshore current give maximum current speed on planar fixed beds within the breakers, with monotonically decreasing current speed offshore of the maximum (Longuet-Higgins, 1970; James, 1974; Jonsson et al., 1974). The onshore-offshore profile of the longshore current evidently depends on wave condition and on the mechanisms of energy dissipation and lateral fluid mixing. There remains considerable uncertainty about the seaward extent of significant near-bed alongshore currents and rip currents, especially in extreme events, but the water depth d_{se} seems a reasonable estimate for the extreme extent of the nearshore zone, intensely active due to wave action.

At such water depth, tidal or wind-induced currents may significantly add to wave-induced velocities. Interaction of water waves and currents is a complex topic (Peregrine, 1976), and available results on bed agitation and suspended sediment provide no guidance on modifying equation 1 to account for the combined effect of wave action and a current. For this reason, the simple geometric correction has been proposed for the effect of tidal action: d_{se} is to be taken with respect to mean low(er) tide level for estimating minimum limit depth to the very active profile on natural seasonal beaches.

APPLICATIONS TO FIELD PROJECTS

The yearly limit depth from equations 3 and 4 has several applications in coastal engineering:

a. Any nearshore hydrographic survey should extend further seaward than the estimated limit depth, to ensure coverage of the very active zone of a sand beach. Minimum definition of conditions at a seasonal beach requires two such surveys, conducted when the beach shows maximum summer-wave accretion and winter-wave erosion.

b. For subaqueous beach nourishment, suitable material should be placed landward of the estimated limit depth to the active seasonal profile during the summer-wave accretionary beach phase. This guidance is consistent with field offshore nourishment attempts judged successful (Vera-Cruz, 1972; Mikkelsen, 1977; Schwartz and Musialowski, 1977) and unsuccessful (Harris, 1954; Hall and Watts, 1957; Wiegel, 1964). Nearshore wave measurements (Thompson, 1977) indicate average summer-wave height is about $(0.8 \bar{H})$, and the estimated yearly limit depth is about half the maximum water depth for motion initiation with fine sands, summer waves, and the motion threshold criterion of Komar and Miller (1974).

c. For effective offshore disposal, material should be placed far seaward of the limit depth to the very active beach profile, so that it does not enter the nearshore system.

The estimated limit depth to the nearshore zone might also find applications in the design of coastal structures in sandy regions. It seems an offshore mound-type breakwater must be situated in water deeper than this limit for the nearby region, if it is to provide wave shelter while minimizing its effect as a littoral barrier. Also, it seems that dual jetties at a navigation channel extending to the limit depth may be expected to intercept almost all the littoral drift during a typical yearly cycle of waves. However, regions near navigation channels and structures are three-dimensional and have significant currents in addition to waves (Liu and Mei, 1975), factors not considered in the present treatment. Also, coastal structure design must consider the economics of construction and maintenance, as well as functional performance. Further research is needed before the

estimated limit depth can be applied with confidence to structure design.

APPLICATION TO LABORATORY TEST DESIGN

Laboratory investigations of nearshore sediment transport can potentially provide valuable information for coastal engineering, since regulated experiments on sand response to controlled hydraulic forces are permitted in the laboratory. Interpretation of laboratory results requires consideration of scale effects in replicating prototype processes (Bijker, 1967; Kamphuis, 1975), and obtaining meaningful experimental results requires that laboratory effects, e.g., constrained geometry, be minimized (Chesnutt, 1978).

The previously discussed results (Table 1) on parameters influencing the cut depth by erosive waves clarify one requirement for unconstrained geometry in laboratory experiments on nearshore processes: water depth must be adequate to accommodate an equilibrium nearshore profile. The wave cut in laboratory sand slopes is a distinct geometrical feature with erosive waves, and the elevation of this feature on a two-dimensional profile approaching equilibrium is generally better explained by d_s from equation 2 with relatively large tank water depths: $(d_t L_s / d_s L_t) > 1.7$. Some profiles obtained by Monroe (1969) and by Masuda and Ito (1975) indicate untypical forms are associated with dimensionless water depths much less than this. Using typical laboratory values of $d_s = 2H$ (quartz sand) and $(L_t/L_s) = 1.5$, it seems water depth should be at least five times generated wave height for vertically unconstrained tests with fine quartz sand in water. For sediments of lower density, larger water depth is required (equation 1) for meaningful tests.

The laboratory requirements for a horizontally unconstrained beach profile remain somewhat uncertain, but appear harder to accommodate in general. Two-dimensional profiles developed by erosive waves commonly have a gently sloping terrace centered at the cut point in the initial slope. The profile developments in time reported by Sunamura and Horikawa (1974) and by Chesnutt (1978) show an approximately logarithmic increase in the length of this terrace with running time. The

terrace slope is on the order of 1° (comparable to offshore slopes on natural beaches), and an equilibrium eroding profile must be very long, because the terrace should extend to a depth where sediment movement ceases, to include the entire active beach profile.

A practical alternative is to truncate the offshore profile, while including the entire nearshore zone in the laboratory situation. Kemp (1960) has noted that dynamic similarity between laboratory test and prototype is more likely within the turbulent breaker zone than offshore. In designing the profile truncation, provision must be made for the offshore-zone function as a source or sink of nearshore sands, in various wave conditions. Also, the truncation cross-section should be shaped to minimize wave reflection, which has deleterious effects on laboratory beach studies (Chesnutt, 1978). Available laboratory results on perched beach designs (Chatham et al., 1973) provide a data base for further research on offshore profile truncation.

SUMMARY

The sediment entrainment parameter (equation 1) does not figure in any reported research results on wave propagation or interaction with sand beds. However, with linear wave theory, and two coupled order-of-magnitude assumptions, this parameter can be used to calculate a limiting water depth to the erosive action of waves causing offshore deposition of fine sands (equation 2). This calculated depth agrees well, over a wide range of conditions, with the elevation of the wave cut commonly occurring on eroding laboratory sand slopes (Figure 1). Also, for extremely high waves expected 12 hours per year, the estimated limit depth (equations 3 and 4) agrees well with recorded close-out depth to significant profile activity at seasonal beaches on several sea coasts (Table 2). The calculated limit depth has several types of application in field and laboratory projects, although further analysis and tests are clearly required.

ACKNOWLEDGEMENTS

For kindly providing beach profiles, I thank J. Nicholson, National Research Institute for Oceanology, South Africa; T. Sunamura, University of Tokyo, Japan; C.H. Hulsbergen and J.J. Vinje, Delft Hydraulics Laboratory, Netherlands; and S. Masuda and M. Ito, Meijo University, Japan.

Also, I thank C.B. Chesnutt and C. Mason for review of this manuscript, and K.L. Jacobs and M.W. Leffler for assistance in data analysis. Results presented herein, unless otherwise noted, are based on research conducted at the Coastal Engineering Research Center under the Coastal Engineering Research Program of the U.S. Army Corps of Engineers. The findings reported are not to be construed as an official Department of the Army position unless so designated by other authorized documents. Permission to publish this information is appreciated.

CHAPTER 89

DEPTH OF DISTURBANCE OF SAND IN SURF ZONES

Michael K. Gaughan¹

ABSTRACT

A coring technique employed during wave action allowed accurate measurement of the depth of vertical mixing b_m of fluorescent sand tracer grains within the surf zone of a gently sloping Pacific Ocean beach (beach slope tangent $s = 0.012$). The depth b_m is the distance from the sediment surface to the lower limit of observed tracer grains within the inner portion of the core. Although this definition is only strictly applicable to a rectangular distribution of tracer concentration with depth, the b_m results were quite similar to those using concentration-weighted depth averages of Crickmore (1967). For one winter regime experiment, vertical cross-sectional contour maps of tracer concentration normalized by the local core maximum were drawn with concentrations computed for each 0.4cm slice. Trends present are (1) in the onshore-offshore direction the maximum concentration is at the bed surface shorewards of the mid-surf position and 0.4 cm to 1.2 cm below the bed seaward of the mid-surf position, and (2) in the longshore direction (at the mid-surf position) the maximum concentration lies 0.4 cm to 1.6 cm below the bed surface. For spilling breaker heights H_b between 75 cm and 150 cm, histograms of b_m were clearly different for spring/summer and fall/winter experiments: the mean and standard deviation (in parenthesis) are 0.5 cm (0.5 cm) and 1.1 cm (0.5 cm), respectively. These results are substantially less than both the 3.0 cm and the 20 cm to 40 cm disturbance depths per 100 cm of H_b reported by King (1951) and by Otvos (1965) and Williams (1970). The discrepancy with Otvos and Williams is due to the much different breaking process; in their experiments small breakers ($H_b = 5$ cm to 30 cm) plunged directly onto steep beach slopes ($s = 0.1$) causing large b_m . The tracer grain's longer exposure to bottom stresses of passing surf bores may explain King's greater disturbance depths. Her sampling interval was one semi-diurnal tidal period T versus the span $0.02 T$ to $0.32 T$ in this study.

INTRODUCTION

It is well accepted that waves breaking on a beach are the prime mechanism for transporting sand. However, quantitative measurements of the waves and moving sand are scarce

¹CICESE, 843 Espinoza Ave., Ensenada, Baja Calif., Mexico

(e.g., Komar, 1969). Several methods of measuring the volume of moving sand are available (e. g., sand tracers, bedload and suspension traps, periodic surveys). Because of the successes of the sand tracer technique in estimating sand transport in rivers (Crickmore, 1967) and in narrow surf zones (10 m) with large tidal ranges (8 m) (Komar, 1969), the present study investigates its usefulness in wide surf zones (100 m) with moderate tidal ranges (2 m) typical of many Pacific Ocean beaches. A few experiments of this nature were also carried out by Komar (1969).

For non-steady, two-way transport the spatial integration method is to be preferred over both the time integration and steady dilution methods when using sand tracer to calculate sediment transport (Crickmore, 1967); these are essentially the conditions normally present within surf zones. Following Komar (1969) the mean velocity of transport is calculated from the tracer concentration distribution by taking moments of the tracer concentration in the direction of interest. For example, the mean longshore velocity of the tracer centroid is given by

$$V = \frac{\sum_{x=0}^{x_b} \sum_{y=-\infty}^{\infty} y C_{(x,y)} / t}{\sum_{x=0}^{x_b} \sum_{y=-\infty}^{\infty} C_{(x,y)}} \quad (1)$$

where $C_{(x,y)}$ is the concentration at a longshore distance y from the injection line and at an offshore distance x , and t is the time between release and sampling. The bulk volume sand transport is then

$$S_1 = b \cdot X_b \cdot V_1 \quad (2)$$

where b is the depth of disturbance and X_b is the surf zone width. Preliminary field studies of the depth of disturbance are described in this report.

FIELD SITE AND METHODS

Because much of the surf zone remains covered with water at low tide on the beach of interest, a method was devised of obtaining samples under these conditions. It consists of a coring pipe with a transparent sampling tube inserted into the bottom end (Figure 1). This beveled transparent tube is then forced into the sand by leaning on and rotating the coring pipe. The coring pipe is withdrawn slowly, and once the transparent tube holding the sand sample surfaces, it is immediately inspected for sand movement. If there is any, the sample must be retaken. Although the method is not extremely rapid, the cores provide accurate measurements of the depth of disturbance and the tracer concentration.

Figure 1.- Sand coring apparatus.

The beach is 15 km long with a lagoon entrance located midway between the rocky headlands at both ends (Figure 2). It is backed by small sand dunes along most of its length. At the site of interest the foreshore sand is relatively fine-grained (Figure 3) with the beach slope tangent $s = 0.012$. Most of the time the waves form spilling breakers, with the larger waves occurring from fall through spring. Waves from the south are blocked by Punta Banda and Todos Santos Island. Several sampling intervals and grid sizes were tested to gain familiarity with the surf zone time and length scales. During all nine of the field studies a single point source of tracer sand (20 kg to 50 kg) was injected at an estimated mid-surf position.

RESULTS AND DISCUSSION

A comparison was made of three definitions of the depth of disturbance. (1) b_{max} is the maximum depth below the sand surface of tracer grains observed in the sample. (2) A second disturbance depth b_2 is given by

$$b_2 = h(c_1 + c_2 + c_3 + \dots) / c_{max} \quad (3)$$

where h is the core slice thickness (0.4 cm), c_1, c_2 are the concentrations of core slices, 1,2 where 1 denotes the top slice, c_{max} is the maximum concentration in the core under study. This equation is only directly applicable when the concentration/depth distribution has a continuous negative gradient, with the concentration decreasing sequentially with depth (Crickmore, 1967). The more irregular tracer distributions were first simplified to eliminate any positive gradients and then treated as above (Crickmore, 1967). Figure 4 illustrates this procedure for various forms of concentration distributions (Crickmore, 1967), and it also defines the types of distributions. (3) A third definition of the depth of disturbance b_3 is computed from equation (3) by using the mean concentration (averaged over the number of cores) for each slice where c_{max} is the maximum of these averages. For 60 core samples from the 9DEC experiment the results are

$$\begin{aligned} \bar{b}_{max} &= 1.1 \text{ cm} \\ \bar{b}_2 &= 1.0 \text{ cm} \\ \bar{b}_3 &= 1.2 \text{ cm} \end{aligned}$$

where $\bar{}$ indicates mean value. Since there is less than ten percent difference between b_{max} and the concentration-weighted disturbance depths, b_{max} is used throughout the remainder of this paper.

Figure 2.- Study area near Ensenada, Baja California, Mexico.

$$b_2 = h (C_1 + C_2 + C_3 \dots) / C_{max}$$

where

h = core thickness (mm)

c = tracer concentration in number of grains per gram of sand

CONCENTRATION

Figure 4.- Calculation of depth of mixing from core distribution. A. Abrupt decrease. B. Continuous negative gradient. C. One positive gradient. D. Two positive gradients (Crickmore, 1967).

The most frequently occurring concentration distribution type is Type C, which has the maximum concentration in the slice one layer below the surface. It is predominant offshore of the mid-surf position, while Types A and B, which have maxima at the surface slice, occur in nearly half of the samples shoreward of the mid-surf position (Figure 5). The near-to-shore occurrence of Types A and B may be due to sand deposition in the upper swash zone which is continually receding seaward during the ebbing tide. In addition, although the distribution type and b_{max} may be a function of bedform, in this case the vertical scale of the bedforms was very similar. The ripple height of both the usual sand ripples and the backwash ripples was approximately 0.5 cm to 1.0 cm. For the sheet flow-flat bed conditions the depth of the mobile layer was likely less than 0.5 cm, but it is possible some grains mixed to greater depths.

The apparent independence of the disturbance depth on time for wave exposures of 15 min to 240 min is seen in Figure 6. These samples were within 5 m of the mid-surf release site. The 18MAR data have two b_{max} greater than 2.0 cm, and these may be due to sampling within the dyed sand patch before it has had time to disperse; indeed after 80 min the release site still contained much of the tracer sand below a thin moving surface layer (0.3 cm) of undyed sand. The 26MAR samples ($b_{max} = 0.8$ cm) were cored under very strong current conditions ($H_b \approx 2$ m) resulting in a very rapid dispersion of tracer sand. On this occasion the bed was always flat. Careful measurements of stake heights within 20 m of the release site showed erosion of less than 0.5 cm. Unfortunately the coring technique had not been sufficiently mastered and only 19 cores were acceptable for analysis. The 31MAY data also display very little trend of increasing burial with time.

Figures 7 to 11 are the results of sampling 3 hours after tracer release. Again the tracer sand was exposed to breakers during an ebbing tide. Due to the approximate nature of the mid-surf position, it was considered inappropriate to combine data from separate field studies. Individually some of the measurements do show b_{max} to vary with distance from the injection site; the 25NOV data show a slight tendency to decrease with distance from the injection site.

The disturbance depth seems to show a marked dependence on the incident wave conditions (Figure 12). These histograms represent two classes of field experiments; (1) the spring/summer regime and (2) the fall/winter regime. As yet unprocessed wave measurements may generate a hypothesis attempting to explain these observations.

Vertical cross-sectional contour maps were drawn to study the horizontal variation of the tracer concentration versus depth. Figure 13 demonstrates the effectiveness of this presentation as shorewards of the release site, the maximum con-

centration is clearly at the bed surface, while seaward of the release site, it is below the surface. The maximum concentration is nearly always below the bed surface along a line parallel to the shoreline located at the mid-surf position (Figure 14).

SUMMARY

All field experiments involved sand tracer exposure to waves in the surf and swash zones during an ebbing tide. For these conditions some important observations are:

1. For breaker heights between 75 cm and 150 cm, the disturbance depth b_{max} averaged much less than in previous experiments of King (1951), Otvos (1965), and Williams (1970).
2. A comparison of b_{max} to concentration-weighted disturbance depths showed less than 10% difference for 60 cores from one field study.
3. Maxima of tracer concentration were located at the bed surface shoreward of the mid-surf release site and just below the bed seawards of the release site. The indication of deposition in the receding upper swash limit leads to hypothesis regarding the calculation of the longshore transport. Obviously, as this tracer sand leaves the longshore transport zone, the longshore transport would be underestimated if these samples were included in the calculation of the moments about the injection line.
4. b_{max} did not show any strong trends either with time near the release site nor with distance from the release site three hours following injection.

CHAPTER 90

SCALE RELATIONS FOR EQUILIBRIUM BEACH PROFILES

Hideaki NODA*

ABSTRACT

The scale relation for modeling natural beach profiles in the laboratory and selecting size of model sediments is examined. The results are shown for relating scale law to the dimensionless fall velocity and the model law for selecting sand size is proposed.

INTRODUCTION

There are many practical problems related to coastal engineering, which may be solved by using movable bed scale models of the coastal zone. The scale model must obey the laws of sediment transport in order to obtain satisfactory results. However, sediment transport in the coastal zones is so complex that the mechanism is not fully understood.

Some authors have attempted to find a model law relationship for equilibrium beach profiles. Yalin¹⁾ derived a scale law for the offshore zone using a bed velocity based on laminar boundary conditions. Brebner, Kamphuis and Paul²⁾ have performed extensive experimental tests on movable-bed models using light weight sediment, and Le Méhauté³⁾ presented a scaling law for coastal movable-bed models in the breaker zones.

The purpose of this study is finally to determine the scale law relationship for coastal movable-bed model. As first step, this paper concerns itself with the derivation of proper scale laws for modeling of equilibrium beaches.

DIMENSIONAL ANALYSIS AND SCALE RELATIONS

The depth of beach profiles, h may be expressed as a function of

$$H_0, T, D, \rho, \rho_s, g, \nu, x$$

where H_0 the deepwater wave height, T the period of waves, D the representative diameter of sediments, ρ the fluid density, ρ_s the sediment density, i_0 the initial slope of the beach, g the acceleration of gravity, ν the kinematic viscosity of fluid, and x the horizontal distance measured from the initial shoreline as shown in Figure 1.

The beach profile may be expressed as

$$h = f (x, H_0, T, D, \rho, \rho_s, i_0, g, \nu) \dots\dots\dots(1)$$

By using the relation of $L_0 = gT^2/2\pi$ and neglecting the fluid viscosity,

* Professor, Department of Civil Engineering, Faculty of Engineering, Tottori University, Tottori, Japan

Equation (1) may be rewritten in the dimensionless form as

$$\frac{h}{L_0} = f \left(\frac{x}{L_0}, \frac{H_0}{L_0}, \frac{H_0}{D}, \frac{\rho_s}{\rho}, i_0 \right) \dots \dots \dots (2)$$

Figure 1 Definition sketch

The author⁴⁾ previously indicated that the deepwater wave steepness H_0/L_0 and the ratio of the deepwater wave height to the median diameter of sediment H_0/D_{50} are important parameters governing generation of longshore bars. It appears that these two parameters also are useful to describe the equilibrium beach profiles formed in the simplified conditions of onshore-offshore sediment motion due to wave action.

From Equation (2), the following scale laws may be derives as

$$\left. \begin{aligned} n_h &= n_{L_0}, n_x = n_{L_0}, n_{i_0} = 1 \\ n_{H_0} &= n_{L_0}, n_{D_{50}} = n_{H_0}, n_{\rho} = n_{\rho_s} \end{aligned} \right\} \dots \dots \dots (3)$$

where n is the scale expressed as model value over prototype one. Equation (3) implies that the horizontal and the vertical scales of beach profiles must be identical with those of wave motion, that is, the models cannot be distorted, and that $n_{\rho} = n_{\rho_s} = 1$, i.e. the density of model sediment must be selected so as to be identical with that of prototype one, since it is necessary to use water in model, while particle sizes must be scaled down geometrically.

By taking the effect of the fluid viscosity into account, the another expression of the beach profiles was presented by Brebner and others²⁾ as

$$\frac{h}{L_0} = f \left(\frac{x}{L_0}, \frac{H_0}{L_0}, \frac{H_0}{D_{50}}, \frac{D_{50}\sqrt{gH_0}}{\nu}, \frac{\rho_s}{\rho}, i_0 \right) \dots \dots \dots (4)$$

As pointed out by them, the effect of $D_{50}\sqrt{gH_0}/\nu$ is negligible when the value of $D_{50}\sqrt{gH_0}/\nu$ is large enough to ensure a turbulent flow around the grain in both prototype and model. However, it will be shown that

the effect of the Reynolds number cannot be negligible in the scale of laboratory. On the other hand, scale laws on H_0/L_0 and $D_{50}\sqrt{gH_0}/\nu$ yield conflicting values for n_{D50} , i.e. the former is $n_{D50} = n_{H_0}$ and the latter $n_{D50} = n_{H_0}^{-0.5}$. Therefore, both conditions of similarity cannot be satisfied concurrently.

Dean⁵⁾ presented a model for the shift from a storm to a swell profile and found that the dimensionless parameter $\pi w_f/gT$, where w_f is the fall velocity of grains, is important in governing the equilibrium beach profiles. Therefore, an equation of the equilibrium beach profiles is expressed as

$$\frac{h}{L_0} = f \left(\frac{x}{L_0}, \frac{H_0}{L_0}, \frac{\pi w_f}{gT}, i_0 \right) \dots\dots\dots (5)$$

From Equation (5), the following scale laws may be derived as

$$\begin{aligned} n_{H_0} = n_{L_0}, \quad n_{w_f} = n_T = n_{L_0}^{1/2} \\ n_h = n_{L_0}, \quad n_x = n_{L_0}, \quad n_{i_0} = 1 \end{aligned} \dots\dots\dots (6)$$

The fall velocity of a grain w_f is expressed as

$$w_f = \left\{ \frac{4}{3} \left(\frac{\rho_s}{\rho} - 1 \right) \frac{gD}{C_D} \right\}^{1/2} \dots\dots\dots (7)$$

where C_D is the drag coefficient of sphere grain and a function of Reynolds number $w_f D/\nu$. If it is assumed that

$$C_D = \alpha \left(\frac{w_f D}{\nu} \right)^{-m} \dots\dots\dots (8)$$

the fall velocity w_f is given by

$$w_f^{2-m} = \frac{4}{3\alpha} \left(\frac{\rho_s}{\rho} - 1 \right) \frac{g}{\nu^m} D^{1+m} \dots\dots\dots (9)$$

where α and m are constants. Substituting Equation (9) into dimensionless parameter $\pi w_f/gT$, this quantity may be rewritten as follows:

$$\frac{\pi w_f}{gT} = \beta \left(\frac{\rho_s}{\rho} - 1 \right)^{1/(2-m)} \left(\frac{D_{50} g H_0}{L_0} \right)^{m/(2-m)} \left(\frac{H_0}{L_0} \right) \left(\frac{H_0}{D} \right)^{1/2} \dots\dots (10)$$

where $\beta = \sqrt{\pi/2} \cdot (4/3\alpha)^{1/2-m}$.
 If $D = D_{50}$, the dimensionless parameter is a function of $(\rho_s/\rho)-1$, H_0/L_0 , H_0/D_{50} and $D_{50}\sqrt{gH_0}/\nu$. Therefore it is evident that the application of Equation (5) for the scale law coordinates the contradiction mentioned above.

EXPERIMENTAL EQUIPMENT

Laboratory experiments of the equilibrium beach profiles were made using a steel wave tank 20m long, 0.5m wide and 0.6m deep at the Hydraulic Laboratory, Tottori University. Waves were generated by a

flatter type generator with a 2 HP electric motor. Incident wave heights were measured by a capacitance type wave gage which was installed at the part of constant water depth, $h = 0.4\text{m}$.

Two kinds of the well-sorted sand were used in the experiments and the median diameters of these sands were 0.3mm and 0.6mm, respectively.

All tests were carried out in the initial slope of 1:10, for sufficient time to form an equilibrium beach. The equilibrium beach profiles were measured with a point gage along the flume centerline.

EXPERIMENTAL RESULTS

with their corresponding prototype beach profiles, and Table 1 indicates the test conditions and the scale relations represented by Equation (3). Since the tests were carried out using natural sand in both prototype and model, the scale was selected in values of $n_{H_0} = n_{L_0} = n_{D_{50}} = 1/2$, in order to avoid the use of the cohesive range for the model sand.

The comparisons in the test results indicate a closer similarity between prototype and model of foreshore berm in No. 4, but significant differences still exist beyond wave breaking zone. Furthermore considerable differences are observed for the other test results. Therefore, it is evident that the scale laws based on Equation (3) cannot be adopted.

It seems that the differences between comparable profiles depend upon the influence of fluid viscosity. The values of H_0/L_0 and H_0/D_{50} are same for each comparable profiles, but the model value of $D_{50}\sqrt{gH_0}/\nu$ cannot be equivalent to prototype one for each test. From the test results of No. 4, 5 and 6, it is apparent that the lower limit of model beaches, which is related to beginning sand movement due to wave motion, makes a considerable difference from that of prototype beaches. This fact shows that the difference is related to Reynolds number $D_{50}\sqrt{gH_0}/\nu$.

(b) Scale relations based on Equation (6)

Figure 3 shows model and prototype beach profile data plotted in the dimensionless form x/L_0 versus h/L_0 , and Table 2 indicates the test conditions and the scale ratios of H_0 and D_{50} . These results were obtained by using the scale laws represented by Equation (6). The comparisons between the test results indicate a closer similarity. From these figures, however, a few differences of profiles between prototype and model are observed. The reason is due to a few difference of the value of $\pi\omega_f/gT$ as shown in Table 2. Therefore, it should be noted that the dimensionless parameter $\pi\omega_f/gT$ must be severely preserved in model tests.

Figure 4 shows that the various model beach profiles are compared with a prototype beach profile (DP) in order to clarify the effect of

DM-3	5.83	1.07	0.28	0.0326	0.0099	1/2.27	1/2.14

size of model sediment. From this figure, it is evident that the upper model profile (DM-1) is coincident with the prototype one (DP), but the middle (DM-2) and the lower (DM-3) model profiles do not reproduce the prototype profiles correctly. In the upper case of Figure 4, it is apparent that the value of $n_{D_{50}}$ is less than that of n_{H_0} . From these test results, sand size used in model may be chosen so as to reproduce prototype beach profiles.

Figure 5 Relationship between n_{H_0} and $n_{D_{50}}$

Figure 5 indicates the relationship between n_{H_0} and $n_{D_{50}}$ to be recommended when using the sand in model. In this figure, it is apparent that the test results of DM-2 and 3 do not reproduce the prototype beach profiles.

(c) Possibility of distorted movable-bed models

Figure 6-a indicates dimensionless comparison between equilibrium beach profiles obtained by Watts⁶⁾ (prototype) and Iwagaki and Sawaragi⁷⁾ (model), and their test conditions are presented in Table 4. From Table 4, it is evident that the horizontal and the vertical scales with respect to wave motion are $n_{H_0} = 1/4$ and $n_{L_0} = 1/8$ respectively, and $n_{D_{50}} = 1/2.14$. Therefore, $N_w = n_{H_0}/n_{L_0} = 2$, where N_w is the model distortion of wave motion. On the other hand, model scale of distortion with respect to beach profile, N is expressed as

$$N = n_x/n_h \dots\dots\dots(11)$$

where n_x and n_h are the horizontal and the vertical scales of the beach profiles, respectively.

Figure 6-b shows that the model beach profile is coincident with the prototype one, if $N = N_w^{0.7}$. The relationship among N , N_w and $n_{D_{50}}$ is not clear and therefore no general conclusion can be drawn as to validity of the distorted models. However, it is recognized that it is possible to use the distorted models in practical purpose.

CONCLUSIONS

The following conclusions may be derived from the laboratory test results developed in this paper:

- 1) Two dimensional equilibrium beach tests, based on the scale laws preserving the parameters H_0/L_0 and H_0/D_{50} , indicate that it is impossible to obtain closer similarity between prototype and model beach profiles.
- 2) Closer similarity between the profiles are obtained when dimensionless fall velocity is preserved and the sediment size may be modeled by Figure 5 when using the sand in model.
- 3) Based on the experimental results, it is found that the coastal movable-bed model may be distorted. However, no general conclusion can be drawn as to the validity of the distorted models.

CHAPTER 91

TRACKED VEHICLE FOR CONTINUOUS NEARSHORE PROFILES

Richard J. Seymour*
Alan L. Higgins**
David P. Bothman***

INTRODUCTION

The measurement of nearshore profiles has been the traditional method for evaluating on- and offshore transport of beach sand by waves. The measurement on that portion of the beach face which is dry at low tide presents no particular problems and can be effectively accomplished with conventional rod and level surveying techniques. Once the measurement location moves into the wet part of the foreshore, however, the problems rapidly increase. In general, it requires an extremely dedicated rod man to remain on position in breakers larger than a meter, although measurements in breakers up to 2 meters in height have been accomplished on a nonroutine basis. When waves exceed this height, or when the water depth exceeds the ability of a man to stand and hold the rod, this method must be abandoned. In deeper water, and well outside the surf zone, a boat and fathometer approach is normally employed with considerable loss in vertical and horizontal accuracy. In particular, the vertical resolution is decreased by the uncertainties in knowledge of the instantaneous sea level because of the combination of tides, waves and storm surge. If the tides are large and the waves small, it is possible to achieve an overlap between the boat survey and the shore survey. When the wave height exceeds the ability of the boat to operate, this method also must be abandoned. Although larger boats can operate in larger waves, they are generally also restricted to deeper water.

The result of all of the restrictions described above is that profiles can be measured with reasonable accuracy only during periods of low waves. Unfortunately, the episodes of greatest interest are the rapid cutting back of the beach face and the accompanying offshore bar building which occur during times of high waves. The technology to measure the storm waves has been available for many years. The ability to correlate wave parameters with offshore transport rates requires the ability to make accurate profiles from the dry beach through and beyond the breaker line under storm wave conditions. This paper describes a vehicle that was developed to meet this need.

***Scripps Institution of Oceanography

PROFILER VEHICLE

The approach selected to obtain storm wave profiles was to use a remotely controlled tracked vehicle capable of traversing to a sufficient distance offshore to pass well beyond the breaker line. Design limits were set at 450 meters maximum offshore excursion and 10 meters maximum operating depth.

The basic vehicle is a small tractor originally used for light construction work. The 7.5 horsepower internal combustion engine was replaced by an electric motor of the same power which is powered from an umbilical cable. The motor is run totally immersed in the reservoir of hydraulic fluid to protect it from sea water. This reservoir is maintained at ambient pressure by a large flexible diaphragm. The electric motor drives the hydraulic pump in the tractor which in turn powers the tracks through a hydraulic motor driving through a transmission and mechanical clutches and brakes on each tread. The manual controls for steering the tractor were replaced by hydraulic rams controlled by solenoid valves.

The profiler is shown in Figure 1. The mechanism above the tractor provides for cable tension control when the profiler is returning to shore. The simplest maneuver is for the profiler to be stopped at the end of the profile and then returned on the same line. Eliminating turns avoids any concern with running over the cable in the case where strong longshore currents may exist and also provides for a second realization of the profile. Since the cable drag over the bottom is large, it dominates the tension at the land end so that the winch operator cannot tell if the cable is slack at the profiler from measuring tension on shore. A cable tension measuring system is provided utilizing a hydraulic cylinder and a pressure measuring transducer as the load sensing element. This tension is displayed onshore on a meter and is used to adjust the winch takeup speed. The cable, which contains 16 conductors, is jacketed in plastic and uses Kevlar strength members to reduce weight. Its diameter is 2.5 cm and its length is 450 meters.

SUPPORT EQUIPMENT

The profiler is transported on a military surplus ten-wheel-drive truck capable of traversing sandy beaches. This truck also mounts a 75KVA diesel powered generator which delivers 220 v, 3 phase power to the electric motor and 110V current to the instruments and controls. Two aluminum ramp sections are stored below the truck bed and are used to load and unload the profiler. Also mounted on the truck bed is a winch powered by a 3HP variable speed direct current

motor which is used to unwind and wind the umbilical cable. The truck and other support equipment is shown in Figure 2.

INSTRUMENTATION

Consideration was given initially to using a stadia rod on the profiler so that conventional surveying methods could be extended into deeper water. However, it was decided that the poor visibility associated with flying spray from heavy wave breaking, plus the great distance offshore, would make optical tracking very difficult. Therefore, the decision was made to utilize onboard instruments that would not require any penetration of the surface.

Horizontal position as well as vertical profiles are obtained from the on-board instrumentation. A two-axis vertical gyroscope, a flux gate compass, and an odometer for each tread are sampled once per second. These data are multiplexed, converted to serial format, and transmitted by cable to the beach. The on-board instruments are contained in a waterproof enclosure.

The shielded cable used for data transmission is jacketed together with the power cable. All conductors of both cables are connected to slip rings to allow rotation of the winch. Double rings are provided for data conductors. At the stationary slip rings, the power conductors leading to the diesel generator and control box branch away from the data lines.

The serial multiplexed data are transmitted asynchronously over a single line. On the beach, it is immediately recorded on a digital cassette tape recorder. An electronic monitor box decodes the data, either as it is recorded, or from tape recorder playback. Any channel can be selected for binary display on LED panel lights. The control box used for vehicle control and data recording is shown in Figure 3.

Motions of the profiler are calculated relative to its starting position, which is a fixed point on the beach of known position. Distance traveled along the path is obtained from the odometers, assuming a constant, empirically determined slippage rate. At each observation, the odometer and compass azimuth readings form the magnitude and direction of a displacement vector. Horizontal position is updated by adding this vector to the previous position fix.

Vertical excursions are tracked in the same manner. The two-axis vertical gyro measures pitch and roll. The sine pitch angle is integrated with respect to odometer output to obtain profiles. Roll

angle is not used in position calculations but is valuable for construction of topography between transects.

$$x(t) = \sum_{i=1}^t l_i \cos \theta_i \cos \phi_i$$

$$y(t) = \sum_{i=1}^t l_i \sin \theta_i \cos \phi_i$$

$$z(t) = \sum_{i=1}^t l_i \sin \phi_i$$

l_i = distance traveled in i^{th} observation period

θ = azimuth

ϕ = pitch

Since the profiles will ideally be measured along a straight line, the course is plotted in printer-plot style with a compact thermal printer. A commercial programmable calculator has been modified so that data can be entered remotely. An interface circuit is used to bypass the buttons. Program steps required to calculate and plot the course are stored on a magnetic card. Each time the tractor moves a fixed distance, its new position is approximated from the reported azimuth and plotted. Although the plotted position is not exact, it indicates to the operator when course corrections are necessary. The control console is shown in Figure 3.

After the beach experiment is over, the cassette tape is played back through an interface circuit, into an IBM 1800 computer. This interface, like the decoder box on the beach, converts the data back to parallel form and generates synchronization pulses as external interrupt. Computation of courses and profiles and interpolation of topography is done after the data are transferred.

PERFORMANCE

Initial evaluations have been performed on the handling characteristics and profile measurement capabilities at Scripps Beach, California. Figure 4 shows the profiler entering the ocean on a calibration run. In order to provide verification of the actual profile traversed, a mast was added temporarily to support a standard surveyor's stadia rod. A base line was set up on the beach with a surveyor's level on the profile range line and a transit for measuring angles at the other end of the base line. The tractor was stopped at approximately 5 m intervals to allow recording of the position and elevation. Observations have shown that no track slippage occurs, even on steep and soft beach slopes. Further, no vertical elevation changes occur even when the tractor remains stopped for long periods under breakers greater than one meter in height as illustrated in Figure 5 and Figure 6.

The results of one of the calibration runs at Scripps Beach is shown in Figure 7. The agreement between the measured and computed profiles is excellent, with a maximum error of only a few centimeters. The actual slope measurement record is also depicted to illustrate how the apparently noisy slope signal integrates to a smooth profile.

Figure 8 shows the profiler returning on a calibration run.

ACKNOWLEDGEMENTS

The development of this profiler was undertaken with financial support from the Nearshore Sediment Transport Study (described by Seymour and Duane in these proceedings) and from the Naval Ocean Systems Center, San Diego, California.

CHAPTER 92

THE NEARSHORE SEDIMENT TRANSPORT STUDY

Richard J. Seymour*
David B. Duane**

INTRODUCTION

The models for predicting longshore transport of sediment along straight coastlines that are presently in general use were derived empirically from very sparse measurements of both the forcing function (waves and currents) and the response function (sediment motions). A detailed treatment of these data sets is contained in Greer and Madsen (1978). In addition to the generally unsatisfactory nature of the basic measurements upon which they were based, the models may be deficient because they fail to employ such potentially significant factors as wind stress, sediment size distribution, bottom slope and spatial variations in waves and currents, including the effects of rip currents. Although these models have served certain engineering needs, there is a strong measure of uncertainty in the coastal engineering community about their general applicability. Certainly, because they are empirical rather than physically reasoned models, there is no rational means for extending their usefulness to predicting transport where coastlines are not straight -- such as the case of a tidal inlet.

The economic impact of sediment transport in the nearshore regime is enormous and the need for improved predictive tools appears to be universally accepted. To be most useful, these improved models must be globally applicable. This implies very strongly that they must be based upon a thorough understanding of surf zone dynamics and the details of the response of the sediment. The surf zone flow fields are highly complex and nonlinear, implying an equally complex and difficult system of sediment responses. Characterizing the entire forcing and response functions simultaneously requires large and expensive field measurement programs that greatly exceed the present state of the art of measurement and analysis. The approach of the last two decades of single investigators working at laboratory scale or in the ocean with a few single point measurements would not appear to ever meet these needs. However, the present costs for coastal dredging and shoreline protection, which can be measured in billions of dollars on a world scale, argue for a major undertaking to develop better predictive tools.

In an attempt to satisfy these needs, an ad hoc group was formed at the Fifteenth Coastal Engineering Conference in Honolulu to plan a large scale and coordinated series of investigations leading to improved sediment transport predictive models. Less than a year later, the Nearshore Sediment Transport Study was initiated under the sponsorship of the Office of Sea Grant. The program began as a focused

*California Dept. of Navigation and Ocean Development, Scripps Institution of Oceanography, UCSD, La Jolla, California
**Office of Sea Grant, Washington, D. C.

cooperative effort among four Sea Grant universities and several government agencies. With the advent of new legislation authorizing national Sea Grant projects to meet national needs, the NSTS program has recently been designated as the first such national program.

OVERALL OBJECTIVES

The major objective of the NSTS program is to produce improved engineering models for predicting the motion of sediment along straight coastlines under the action of waves and currents in the nearshore regime. From its inception, the program has been directed towards the development of models that can be simply employed, without recourse to large computers, and which will depend upon measurements or observations that can be obtained at reasonable cost.

PROGRAM ORGANIZATION

Management of a technically complex program and the effective coordination of a large and diverse group of investigators required the creation of a management concept substantially different from existing Sea Grant programs. The program employs a two tier management structure which is shown schematically in Figure 1. The Sea Grant Director has appointed an advisory group referred to as the NSTS Review Committee. This group, all experienced in nearshore processes, reviews proposals and makes funding recommendations to the Director, formulates overall program direction and reviews the progress of the investigators. A second tier group, known as the NSTS Steering Committee, is formed of the senior investigators. The chairman of this group functions as the Project Manager and is an ex officio member of the Review Committee. The Steering Committee formulates the details of the project program, plans and executes cooperative field programs and conducts workshops to promulgate the findings of the study to the coastal engineering community.

The NSTS program will have a duration of five years and is anticipated to cost more than \$4 million. During this period, four major functional elements will be completed. These are:

1. The development of necessary instruments and measurement and analysis techniques.
2. The determination by field investigation of the parameters which are significant to nearshore sediment transport and the collection of sufficient data to allow characterization of these significant parameters.
3. The formulation of models to characterize the forcing and response functions and overall engineering models for predicting transport.
4. The verification of these models using field data obtained in this program.

These functions, although they are logically sequential, will be undertaken with a certain level of concurrence as indicated by their schedule in Figure 2.

NSTS PROGRAM MANAGEMENT

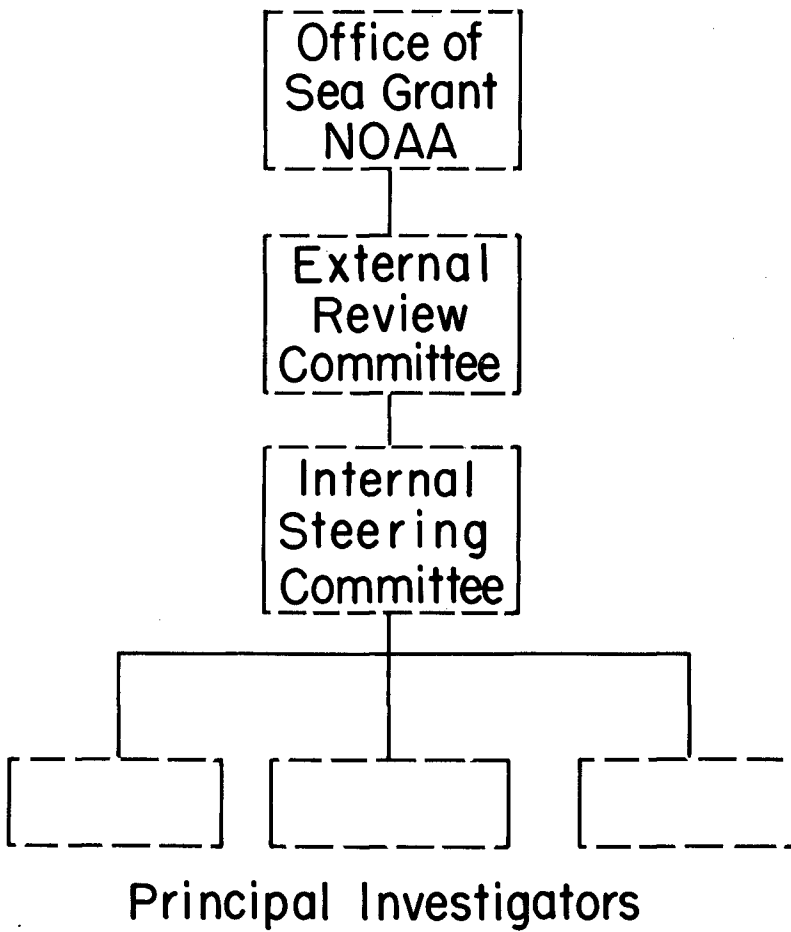

FIGURE 1

FUNCTIONAL SCHEDULE

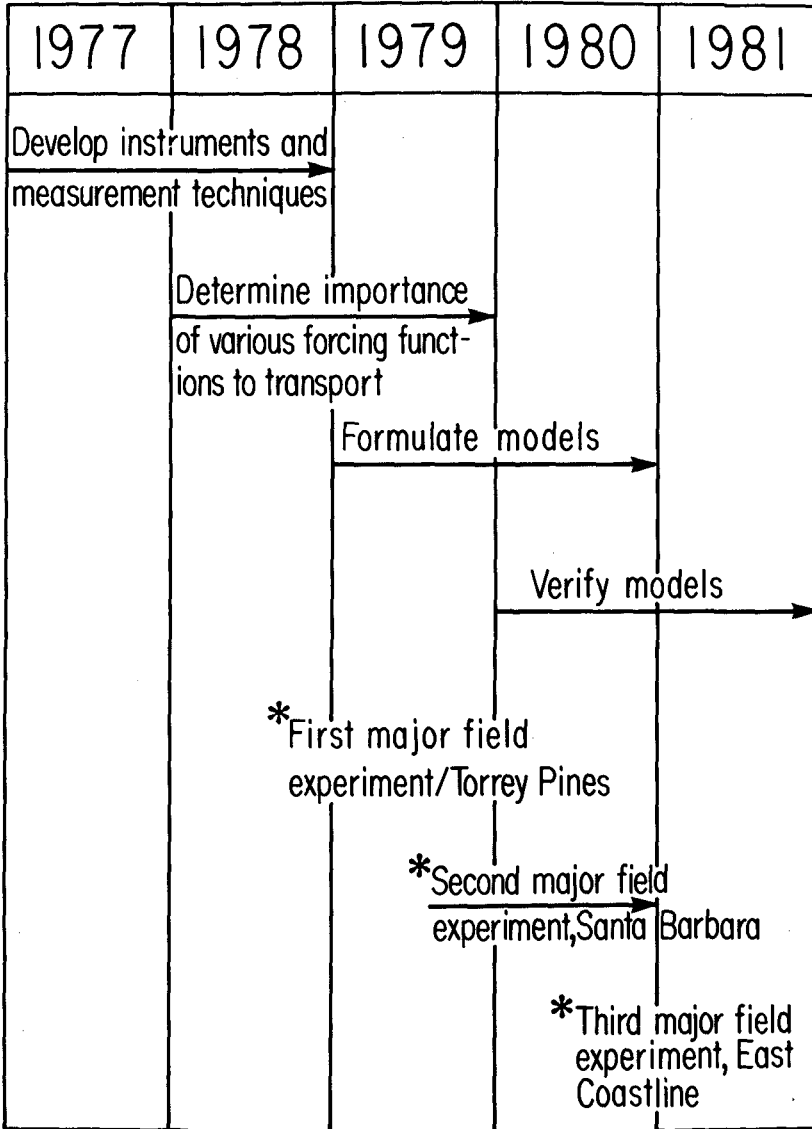

FIGURE 2

PROGRAM ATTRIBUTES

To accomplish the NSTS objectives, it was understood from the earliest planning sessions that the program must contain certain attributes which would set it apart from many prior efforts. Among the most important of these attributes are:

1. NSTS is a broad-based program with many investigators from a large number of institutions. It is an attempt to bring together many experienced practitioners to plan and execute a series of major experiments which would vastly exceed the capabilities of a single investigator.
2. NSTS is a field-oriented program. Laboratory or numerical modeling are not foreseen as significant elements of the project.
3. The NSTS field experiments will attempt to measure, simultaneously, the details of both the velocity field within the surf zone and the sediment response to these velocities. This is in recognition of the fact that there are significant spatial variations in sediment transport within the nearshore regime and that the ability to understand and predict these variations is a prerequisite to developing a universally applicable engineering model.
4. The NSTS measurement program will encompass a large number of parameters that are potentially significant to a predictive model.
5. The NSTS predictive model is intended to be two-dimensional. That is, it will predict on-offshore movement as well as longshore movement of sediment.

TASK ORGANIZATION

The overall NSTS program is composed of a large number of tasks, each one of which addresses a major element in the project and which is under the direction of one or more principal investigators. In the following sections, the tasks which were funded in 1977 and 1978 will be described followed by those which are anticipated to be funded in 1979 and subsequent years.

TASKS PRESENTLY FUNDED

.....Field Investigation of Currents and Surface Elevation Within the Surf Zone. This task is under the joint direction of R. T. Guza of Scripps Institution of Oceanography and E. B. Thornton of the Naval Postgraduate School. Guza and Thornton (1978) describes the type of measurements and analyses undertaken in this task. A typical instrumentation plan is shown in Figure 3. The major objective of this task is to characterize the three-dimensional velocity field within the surf zone and to relate this to the observed incident wave climate.

.....Field Investigation of Rip Currents, under the direction of R. A. Dalrymple of the University of Delaware. This task is concerned with the measurement and characterization of rip currents, determination of

TYPICAL PLAN FOR INSTRUMENT PLACEMENT IN A LARGE FIELD
EXPERIMENT TO DEFINE SURF ZONE DYNAMICS
FIGURE 3

the mechanism for their formation and their correlations with the incident wave climate. A general treatment of the approach is contained in Dalrymple (1978).

.....Development of a Model Characterizing Surf Zone Dynamics. This task, under the direction of O. S. Madsen of Massachusetts Institute of Technology, will undertake the synthesis of a simplified model for predicting the surf zone velocity field from known incident wave and wind characteristics. This model will then be verified using the data sets from Guza and Thornton, and Dalrymple.

.....Field Investigation of Longshore Sediment Transport, under the direction of D. L. Inman of Scripps Institution of Oceanography. This task has as its major objective the characterization of longshore transport using fluorescent tracers, point samplers of suspended concentrations and continuous measurement of bedload transport with monitoring instruments.

.....Field Investigation of Suspended Sediment, under the direction of R. W. Sternberg at the University of Washington. This is a complementary project to the Inman task and is concerned with the development and deployment of monitoring instruments to obtain continuous measurements of suspended sediment concentrations.

.....Field Investigation of On-Offshore Transport, under the direction of R. J. Seymour of Scripps Institution of Oceanography. This task is concerned with the characterization of on-offshore transport by means of precision profiling. Seymour, Higgins and Bothman (1978) describes a remotely controlled profiling tractor developed in this task.

.....Evaluation of Candidate Experimental Sites, under the direction of R. G. Dean of the University of Delaware. This task is concerned with identifying and ranking potential sites along the United States coastlines for large scale field experiments.

1978 FIELD EXPERIMENT

The first major experiment under the NSTS program is scheduled for October - November 1978 at Torrey Pines Beach in Southern California. All of the field investigations described above will be undertaken jointly in this one-month-long effort. Approximately 90 channels of data will be sampled at 16 Hz for at least four hours each day for the 30-day period.

TASKS TO BE FUNDED IN 1979 AND SUBSEQUENT YEARS

.....Field Investigation of Tidal Currents. In this task, long-term (on the order of months) measurements of longshore current will be made at locations through the surf zone and correlated with surface tides. The objective is to determine if tidal current is a significant factor within the surf zone.

.....Field Investigation of the Effect of Winds. In this task, the wind stress on the surf zone will be characterized and correlated with the surface elevation and velocity fields measured in other tasks. The objective is to determine under what conditions the wind is a significant parameter in nearshore transport.

.....Field Investigation of the Interactions with Periodic Planform Changes. In this task, rhythmical changes in beach contour in the longshore direction will be measured and correlated with changes in the velocity field measured by others. The objective is to determine if these planform shapes must be accounted for in the transport model.

.....Field Investigation of Three-Dimensional Velocity Structure. This task is a continuation of the present effort associated with characterizing the nearshore velocity field.

.....Field Investigation of the Incident Directional Wave Field. In this task, directional arrays will be employed to characterize the incident wave field. These data will form the basis for models that predict velocity or transport rates from known wave data.

.....Field Investigations of Longshore Transport. This task is a continuation of the two present programs on longshore transport with increased emphasis on the use of continuously monitoring instruments.

.....Field Investigation of On-Offshore Transport. This is a continuation of the present program using beach profile data with emphasis on rapid offshore movement under storm waves.

.....Develop an Improved Engineering Model for Nearshore Sediment Transport. This is the task in which all of the other findings of the program are synthesized into a single model.

FUTURE FIELD EXPERIMENTS

The major field experiment for 1979 will occur at Leadbetter Beach, west of the harbor at Santa Barbara, California. The experiment sites for 1980 and beyond are presently under study. However, it is planned that one East Coast site will be selected.

AVAILABILITY OF DATA

Under the NSTS management plan, data are exchanged freely between investigators. The investigator collecting the data has proprietary publishing rights for a period of one year. After that time, all data becomes available to the public. In addition to the normal papers, texts and reports, all of the raw data will be archived through the National Oceanographic Data Center and will be available on magnetic tape.

CHAPTER 93

LONGSHORE SEDIMENT TRANSPORT DATA: A REVIEW

by

Matthew N. Greer⁽¹⁾ and Ole Secher Madsen⁽²⁾

INTRODUCTION

Siltation rates anticipated at harbor entrances, in navigation channels and at inlet structures as well as possible adverse effects caused by these and other coastal engineering constructions are often assessed based on considerations of longshore sediment transport rates. The ability to predict the longshore sediment transport rate is consequently of considerable importance in many coastal engineering problems. The engineering need for an ability to predict longshore sediment transport rates is evidenced by the fact that the development of empirical relationships preceeded, by decades, any attempts at rigorous analyses of the mechanics of sediment transport processes in the surf zone.

A predictive relationship for longshore sediment transport rates, which enjoys considerable popularity in the United States, is the empirical relationship suggested by the U.S. Army (1973), Coastal Engineering Research Center (CERC) in their Shore Protection Manual (SPM-73). This relationship suggests the longshore transport rate, Q_{ℓ} , to be proportional to the wave energy flux factor, $P_{\ell S}$, and is given by the formula

$$Q_{\ell} = 7.5 \cdot 10^3 P_{\ell S} \quad (1)$$

in which Q_{ℓ} is in cubic yards per year and $P_{\ell S}$ is evaluated based on the significant wave characteristics in the ft-lb-sec system. The wave energy flux factor is given by

$$P_{\ell S} = \frac{1}{16} \rho g H_b^2 C_{g,b} \sin 2\theta_b \quad (2)$$

in which ρ is the fluid density, g is gravity, H , C_g and θ are the wave height, group velocity and angle of incidence, respectively, all evaluated at breaking as denoted by the subscript b .

(1) Grad. Res. Assist., MIT-WHOI Joint Program in Oceanographic Engineering, R.M. Parsons Lab., Dept. of Civil Engineering, MIT, Cambridge, Massachusetts

(2) Doherty Associate Professor in Ocean Utilization, R.M. Parsons Lab., Dept. of Civil Engineering, MIT, Cambridge, Massachusetts

Earlier versions of the CERC formula suggested Q_{ℓ} to be proportional to some power of $P_{\ell s}$. Arguments based primarily on dimensional considerations (Bagnold, 1963) have, however, been used to justify the linear relationship suggested by Eq. (1). The absence of sediment characteristics (grain size), beach characteristics and the sole dependency of the longshore sediment transport rate on wave characteristics suggest the limited validity of Eq. (1). The data used in establishing Eq. (1) were obtained in three independent studies (Watts, 1953; Caldwell, 1956; Komar, 1969) covering a relatively wide range of conditions (grain sizes from 0.175 mm to 0.6 mm) and using quite different techniques for the determination of Q_{ℓ} as well as $P_{\ell s}$. Although some justification for the type of relationship suggested by Eq. (1) has been given, it should be regarded as a purely empirical relationship established by plotting points of Q_{ℓ} versus $P_{\ell s}$ on log-log paper. Such a plot is presented in SPM-73, and reproduced in Figure 1. Considering the fact that we are dealing with the problem of sediment transport, the data points show a remarkably low degree of scatter around the relationship given by Eq. (1). In fact, it is reported in SPM-73 that "the average difference between the plotted points from field data and the prediction given by Equation (1) is at least 28 percent of the value of the prediction". Even in the context of the much simpler problem of sediment transport in unidirectional open channel flow such an agreement between predictions and observations would be considered extremely good. Thus, one is left with the impression that Eq. (1) is a reasonably accurate relationship. Being empirical it can, however, be no more accurate than the data on which it is based. To assess the degree of confidence one can have in the data points used to establish Eq. (1) it was therefore decided to critically review the methods used by Watts (1953), Caldwell (1956) and Komar (1969) for the determination of Q_{ℓ} and $P_{\ell s}$.

The review emphasizes a critical evaluation of the different methods used for the determination of the longshore sediment transport rate. The assumptions underlying the use of a particular method are discussed and the degree to which these assumptions are violated or not is investigated from the reported data. It is realized that there are several unanswered questions regarding the validity of the significant wave concept as an equivalent representation of a random sea. This problem is not addressed in the review of the manner in which the wave energy flux factor was determined. Comments on the determination of wave characteristics are therefore limited to comments on how the significant wave characteristics were obtained and used to determine the wave energy flux factor.

REVIEW OF THE DATA BASE

WATTS (1953)

In this study a sediment trap north of the jettied South Lake Worth Inlet on the east coast of Florida was assumed to catch the long-

Figure 1: Plot of Data Points and Empirical Relationship for Longshore Sediment Transport Rates. (From U.S.Army, Shore Protection Manual, 1973)

shore sediment transport during periods of waves out of the north. The rate of southerly transport was estimated from pumping rates reported by a sand by-passing plant at the inlet. Wave heights and periods were obtained at 4-hour intervals from a wave gage located in 17 ft. of water some 10 miles north of the study area. Wave directions were determined twice daily by sighting from the top of a hotel 3.5 miles north of the study area using an engineer's transit. The estimated pumping rate over a given time interval, Q_ℓ , was related to the southerly wave energy flux, P_ℓ , during the same interval. Both short term ("daily" averages) and long term ("monthly" averages) were reported. Only the monthly averages (4 points) are used in SPM-73 to establish Eq. (1).

The use of a sand trap to determine longshore sediment transport rates is, in principle, appealing. The method does, however, rely on several assumptions some of which are discussed in the following.

For waves out of the north the

- (A) sand trap must be 100 percent effective and catch only the longshore transport.

In general it appears to be extremely difficult to ascertain whether or not this assumption is violated. During Watts' experiment wave heights were quite moderate (2 ft. or less) which may justify assumption (A) provided the trap caught only the longshore transport.

For waves out of the south the

- (B) sand trap should not catch any significant amount of material.

If significant amounts of sediment are caught by the sand trap during periods of waves out of the south this is indicative of the sand trap catching not only longshore transport. Presumably, this would also be the case during periods of waves out of the north, thus violating assumption (A). In the analysis of the data averaged over long periods Watts correlated the total pumping rate with the wave energy flux factor computed from wave observations including only the energy flux during times of waves out of the north. This clearly makes the monthly average data meaningful only if assumptions (A) and (B) are satisfied.

Erosion north of the jetty during periods of waves out of the south

- (C) does not affect the longshore transport rate when waves are out of the north.

If it is assumed that the jetties act as a littoral barrier for waves out of the south, the beach north of the inlet is deprived of sediment during periods of waves out of the south. To the north of the jetty there would be a stretch of beach along which the longshore sedi-

ment transport would be increasing with distance from the jetty until it attains its equilibrium value. This would cause some erosion to take place north of the jetty during periods of waves out of the south. Once the wind and waves swing around to be out of the north, a southerly transport would be initiated. If this southerly transport is affected by the erosion which took place during waves out of the south, by repairing the damage done, the sand trap would not catch the southerly longshore transport until equilibrium conditions were re-established. It appears to be extremely difficult to ascertain to which extent assumption (C) is violated; however, the use of sand traps for the determination of longshore sediment transport rates relies heavily on this assumption.

To examine the degree to which the assumptions discussed above are violated in the field experiment performed by Watts the complete tabulation of wave data given by Das (1971) as well as the pumping rate reported by Watts (1953) have been plotted in Fig. 2. The sign convention for angles of incidence, θ , is that $\theta > 0$ for waves out of the north. At the start of the experiment, it is seen that the waves were quite high (H^2) as were the pumping rates (Q). During the period of March 7 to 9 waves were out of the north ($H^2 \sin\theta > 0$) but swung around to be out of the south from March 10 to 15. From the ideal behavior of the sand trap discussed in conjunction with assumption (B) it is noted that the change in wave direction, somewhat disturbingly, is practically unnoticeable in the reported pumping rate during this period. Similar evidence of significant transfer of sediment into the sand trap during periods of waves out of the south is observed around March 23, April 10, and April 24. The conclusion reached from the presentation of Watts' data in Fig. 2 is that assumption (B) is violated, thereby invalidating the manner in which the data points corresponding to monthly averages were obtained. Furthermore, the results presented in Fig. 2 suggest that the sand trap may catch sediment not considered to be part of the longshore sediment transport during periods of waves out of the north. Thus, the daily averages, obtained over the periods indicated in Fig. 2, may not represent the short term longshore transport. In addition, the short term average pumping rates are more sensitive to errors arising from pumping rates not corresponding exactly to the amount of material deposited in the sand trap.

The wave data (height and period) were obtained in 17 ft. of water. No specific mention of the depth of water where the wave direction was obtained can be found in the original report. Since the direction was observed visually it would be tempting to assume that the direction was the angle of incidence at breaking. Several directional observations, however, report values of θ in excess of 20° (up to 49°). Since waves of 5 sec. period breaking in 1.5 ft. of water will have an angle at breaking less than 15° , it does not appear reasonable to assume that the reported angle of incidence corresponds to the angle at breaking. Examining the nature of Eq. (2) this may be written in the form

Figure 2: Plot of Wave Intensity (H^2), Pumping Rates (Q), and Directional Wave Intensity ($H^2 \sin \theta$) During Watts' (1953) Experiments.

$$P_{\ell s} = \left\{ \frac{1}{8} \rho g H_b^2 C_{g,b} \cos \theta_b \right\} \sin \theta_b \quad (3)$$

The bracketed terms represent the shore normal energy flux and assuming Snell's Law to be valid this quantity is customarily assumed to remain constant. Thus, the bracketed terms may be evaluated in any water depth, for example, corresponding to $h = 17$ ft. where H and T were obtained. The uncertainty about the location where θ , as reported by Watts, was obtained is of relatively minor importance in the evaluation of the bracketed term in Eq. (3). It is, however, of extreme importance that the angle at breaking be used to evaluate $\sin \theta_b$. It is evident that Watts evaluated Eq. (3) using a water depth of 17 ft. and assuming all wave parameters to correspond to this water depth. If the reported value of θ does indeed correspond to $h = 17$ ft. Watts' evaluation of $P_{\ell s}$, which is used in SPM-73, could potentially be off by a factor of the order 5.

CALDWELL (1956)

In this study the erosion rate "downdrift" of a littoral barrier was determined by surveying 21 transects spaced at 500 ft. intervals. Surveys were repeated every 2 to 3 months. The net amount of sediment volume change within the study area between consecutive surveys was used to determine an average daily net sediment transport rate at the transect furthest away from the littoral barrier. Wave characteristics were determined from a combination of wave gage records, obtained 6 miles away in 20 ft. of water, and from hindcasts. Wave direction was obtained from refraction diagrams based on hindcast deep water wave characteristics. This study produced six points of Q_{ℓ} versus P_{ℓ} ; however, one of these points showed a negative relationship between Q_{ℓ} and P_{ℓ} and it was consequently discarded.

Using the erosion or deposition rate "downdrift" of a littoral barrier to quantify the longshore sediment transport rate is based on the assumptions that

(D) The littoral barrier is 100 percent effective.

No transport out of or into the
(E) study area through its offshore boundary.

The longshore sediment transport
(F) through the downdrift boundary of the study area is unaffected by the presence of the littoral barrier.

As discussed in conjunction with the discussion of assumption (C), the longshore transport rate requires some distance downdrift of a littoral barrier to achieve its equilibrium value. The same applies for sedi-

ment transport towards the littoral barrier. The spatially varying longshore sediment transport rate in the vicinity of the littoral barrier suggests an erosion or deposition pattern which approaches a zero volume change between transects close to the "downdrift" boundary of the study area. This required behavior of the erosion pattern appears self-evident since the net volume change within the study area and hence the inferred longshore transport rate otherwise would depend on the location of the "downdrift" boundary.

The observed volume changes within the study area of Caldwell are plotted in Fig. 3 for the six survey periods. It is evident that the erosion patterns for all survey periods conform rather poorly to the expected ideal pattern discussed above. Only the erosion and deposition patterns during the survey periods Nov. 9 to Jan. 25 and Jan. 25 to April 8 exhibit the features resembling those required. The two data points corresponding to these survey periods, with $P_{\ell S}$ evaluated in the manner to be discussed, happen to indicate a significant decrease in Q_{ℓ} with increasing $P_{\ell S}$, hardly a comforting result.

The wave characteristics (height and period) were determined from a combination of wave gage measurements in 20 ft. water depth and hindcasts, used whenever results from the wave gage were unavailable. A comparison between hindcast and measured wave characteristics is reproduced in Table 1.

Table 1: Comparison between hindcast and observed (wave gage) wave heights (from Caldwell, 1956, Table 4).

H_{gage} (ft.)	3.6	0.5	2.0	1.1
H_{hindcast} (ft.)	1.4	1.5	1.5-1.8	1.5

Recalling that the wave height enters the determination of $P_{\ell S}$, Eq. (2), essentially to the $5/2$ power, it is seen from the comparison of measured and hindcast wave heights that $P_{\ell S}$ obtained from hindcast wave characteristics may deviate considerably from the values obtained from measured wave characteristics.

Refraction diagrams were used to determine the wave directions in 12 ft. water depth for waves out of the west to northwest and for waves out of the south. For waves out of the west to northwest hindcast directions varying between 4° to 15° were obtained, and an "average" value of $\theta = 9^{\circ}$ was used for all waves from this direction. For hindcast waves out of the south an average direction of 21° , representing a directional spreading of $16^{\circ} < \theta < 23^{\circ}$, was used for all waves.

The value of the wave energy flux factor was evaluated from Eq. (2) using the hindcast or observed wave height and period corre-

Figure 3: Plot of Volume Changes Observed During Caldwell's (1956) Experiments.

sponding to 20 ft. water depth with the angle θ taken as the constant average value determined from refraction diagrams and corresponding to a water depth of 12 ft. Thus, the values obtained by Caldwell for $P_{\ell S}$ are not based on breaking wave characteristics, and Caldwell's values can readily be imagined to be off by factors of 10 or more. Nevertheless, the values for $P_{\ell S}$ obtained by Caldwell (1956) are the values used in the SPM-73 plot of Q_{ℓ} versus $P_{\ell S}$.

KOMAR (1969)

In this study sand tracers (fluorescent) were injected on the beach face (El Moreno Beach) or across part of the surf zone (Silver Strand Beach). Sampling at some time following injection gave contours of equal tracer concentration from which the centroid movement of the tracers was determined. From the distance traveled, $\Delta\ell$, and the time, Δt , the average centroid velocity, $V = \Delta\ell/\Delta t$, was obtained and used as the average velocity of moving sediment. The longshore transport rate was then obtained from the formula

$$Q_{\ell} = V b X_B \quad (4)$$

in which b is the thickness of the moving layer of sediment and X_B is the width of the surf zone. The thickness of the moving layer was taken to be the burial depth of tracers as obtained from core samples taken close to the injection line. Wave characteristics were determined from a wave gage array located some distance seaward of the surf zone. Breaking wave characteristics were either predicted by shoaling the measured waves until breaking or by direct observation of the breaker characteristics.

When applying tracer techniques for measuring sediment transport a number of assumptions are made.

(G) The tracer should behave as the native material.

This is most readily satisfied by coating material from the study area as done by Komar.

(H) The transporting system is stationary.

This basically requires conditions to be steady during the experiment. Clearly, conditions are far from steady in the surf zone. However, one may view the transport process in the surf zone as consisting of a series of events, each event corresponding to the passage of a breaking wave. The stationarity requirement therefore does not apply to the time scale of the wave motion. Rather it should be interpreted to mean that wave conditions do not change during the experiment. At Silver Strand Beach injection was made in the surf zone around high

tide and sampling was performed 1 to 3 hours after injection. Although the tide introduces some changes during the duration of an experiment of this type, it appears that this lack of stationarity is minimized by conducting the experiments in the manner used by Komar at Silver Strand Beach. At El Moreno Beach, the experimental procedure was, however, somewhat different. Here the tidal range is considerable (about 20 ft.) so the steep beach face was exposed during low tide. Tracer was injected in a trench on the beach face during low tide. As the tide came in the surf zone would move across the injection site. The same would happen as the tide went out. When the beach face was exposed again sampling was performed. It is evident that the conditions during experiments at El Moreno Beach hardly can be considered to have been stationary. We are not aware of any investigations which allow us to assess the possible effects of lack of stationarity on results obtained from tracer experiments. All we can say is that the crucial assumption (H) was violated for Komar's experiments on El Moreno Beach and the quality of his data on sediment transport rates obtained at this location is therefore somewhat uncertain.

An additional assumption is that

- Sufficient time following injection should
(I) be allowed to ensure that the tracer behavior is
independent of the manner in which it was introduced.

If one models tracer dispersion based on the diffusion equation the spatial integration method used by Komar was shown by Lean and Crickmore (1963) to be applicable at any time following injection. The dispersal patterns observed by Komar are, however, not indicative of a transport system which is adequately modeled as a simple advective diffusion process. If this were the case the region of high tracer concentrations would move downdrift and at the same time spread out. Contrary to this behavior many of Komar's dispersal patterns show that the area of high tracer concentrations, at the time of sampling, had remained at the location of the initial injection. Such a behavior of tracer dispersal following an instantaneous line injection is to some extent modeled by a simple model which considers the transporting system to consist of two layers. In this two-layer model the top layer is a transporting layer and exchanges particles with an immobile bed layer. Based on a model of this type tracer particles would appear in the bed layer downdrift of the injection site because they had been "picked up" by the transporting layer and subsequently deposited in the bed layer. This two layer model predicts that the area of high tracer concentration in the bed would remain at the injection site for some time following time of injection. It also predicts that the centroid velocity immediately following injection is zero and with time approaches a constant value. If the centroid velocity obtained by Komar corresponds to this equilibrium value the two layer model suggests that the transport indeed may be obtained from Eq. (4). The only change from a diffusion model is that b , rather than being inter-

puted as the thickness of moving sediment, should be interpreted as the thickness of the non-moving bed layer which exchanges tracer particles with the moving layer. It is not possible to ascertain whether or not the time between injection and sampling used by Komar at Silver Strand Beach was sufficient to satisfy assumption (I). The determination of V obtained from a single measurement of $\Delta R/\Delta t$ can therefore not be accepted without some reservation.

Since the longshore transport rate represents the transport across the entire width of the surf zone it is, of course, necessary that the entire surf zone participates in the dispersal of the tracer particles. A certain distance must therefore be allowed downdrift of the injection site for complete mixing to take place, if the injection covers only part of the width of the surf zone. Komar (1969) comments on this point in conjunction with a discussion of the uncertainties associated with his experiments at Silver Strand Beach.

A final requirement, when tracer techniques are used in sediment transport studies, is that all the tracer particles initially injected must be accounted for. In the context of Komar's longshore sediment transport study this translates into the assumption that there can be

(J) No transport of tracer particles out of the sampling area.

The degree to which this assumption was satisfied in Komar's experiments was assessed by evaluating the amount of tracer accounted for by the sampling program. It is, however, difficult to interpret the significance of a tracer mass balance which accounts for, say, 80 percent of the tracer initially injected. Is the discrepancy experimental error or did tracer particles leave the sampling area? And, if the latter explanation is adopted, to which extent does this loss of tracers affect the results obtained?

The quantity b in the transport equation, Eq. (4), was obtained by Komar from core samples. The values obtained for b in a single experiment were reported to vary greatly with location of the core sample relative to the initial injection line. Thus, Komar reports that fairly large burial depths of tracers could be observed near the injection site whereas tracers were found only near the bed surface further away from the injection. This observed variation in b necessitates a choice of which value to use in the evaluation of Eq. (4). The larger burial depth observed close to the injection site is explained by Komar to be associated with the relative abundance of tracers in this region over a relatively long period of time. Thus, near the injection site tracers are more likely to have sufficient time to "diffuse" vertically into the bed. This explanation does appear very plausible indeed. It does not, however, appear to justify Komar's use of the large values of b obtained close to the injection site when Eq. (4) is evaluated. It is our feeling that the determination of b

represents one of the major difficulties in sediment transport studies using tracer techniques.

Komar's determination of the wave energy flux factor, as defined by Eq. (2), appears to be quite accurate when one accepts the equivalent wave concept without detailed considerations of the influence of directional wave characteristics.

CONCLUSIONS

The data base used by the U.S. Army (1973) in their SPM-73 to establish the empirical longshore transport relationship given by Eq. (1) has been reviewed.

The review revealed that the data points obtained from the studies by Watts (1953) and Caldwell (1956) are of questionable quality. Fundamental assumptions regarding the methods used for the determination of the longshore sediment transport rates appear to have been violated to the extent that one can have no confidence in the values of Q_{ℓ} reported in these studies. The values obtained for the wave energy flux factor should, according to Eq. (1), correspond to breaking wave conditions. The values of the wave energy flux factor reported by Watts (1953) and Caldwell (1956) are used in SPM-73 as if they corresponded to breaking wave conditions whereas they in fact do not. It is not possible to quantify the errors associated with each of the data points obtained by Watts and Caldwell. However, they appear to be sufficiently uncertain in terms of both Q_{ℓ} and $P_{\ell s}$ to justify their exclusion from any analysis aimed at establishing empirical longshore sediment transport relationships.

Removing Watts' and Caldwell's data from Fig. 1 leaves the data points obtained by Komar (1969) and removes the comfort of the argument that Eq. (1) is based on data from three independent studies. The degree of confidence one can have in the accuracy of Eq. (1) is therefore intimately related to the accuracy of the methodology used by Komar in his experiments. The critical review of Komar's use of tracer technology for the determination of longshore sediment transport rates revealed that several of the basic assumptions underlying the use of tracers in sediment transport studies appear to have been violated in this study. The lack of stationarity of the transporting system during the experiments at El Moreno Beach renders the quality of these data points uncertain. The uncertainty about whether or not sufficient time was allowed between injection and sampling to make the determination of the centroid velocity meaningful during the experiments at Silver Strand Beach casts doubts on the accuracy of these data points. In all experiments the ambiguity in the determination of the "thickness of moving sand" introduces a significant uncertainty in the results obtained. It does not appear possible to quantify the magnitude of the errors resulting from the noted violations of the

basic assumptions. The fact that several basic assumptions were violated does, however, suggest that it is unjustified to rely too heavily on the accuracy of the sediment transport rates obtained in Komar's investigation.

The conclusion of our review is therefore that coastal engineers using Eq. (1) for the calculation of longshore sediment transport rates should regard their results as no better than order of magnitude estimates.

ACKNOWLEDGMENT

The present investigation is part of ongoing studies of Longshore Sediment Transport and Surf Zone Hydrodynamics carried out at the R.M. Parsons Laboratory, Department of Civil Engineering, MIT, and the Ocean Engineering Department, WHOI, as part of the MIT Sea Grant Program, supported by NOAA's Office of Sea Grant, U.S. Department of Commerce under grant number 04-7-158-44079. CHAPTER 94

SEDIMENT MOTION CAUSED BY SURFACE WATER WAVES

by

A G DAVIES* AND R H WILKINSON*

Abstract

This paper describes an experimental study of sand motion on the seabed caused by surface water waves. The observations were made close to a beach, but outside the breaker zone and in a location where steady currents were small. Measurements of water velocity components were made at various heights above both rippled and flat beds, together with measurements of the pressure gradients at the seabed, in order to examine the threshold of motion of the natural coarse sand ($D_{50} \approx 1.4\text{mm}$). This motion was monitored with an under-water television system. The flow conditions were predominantly laminar and no flow separation occurred above the lee slopes of the ripples.

Sediment motion was of 'bed load' type and was confined to the crests when the bed was rippled. This motion has been found to be caused by waves having an orbital velocity amplitude (measured in the free stream flow) of about one half of that required to cause motion on a flat bed of the same material. Wherever possible the threshold measurements have been compared with results obtained in the laboratory.

The relative importance of forces on the seabed induced by velocity and pressure gradients has been assessed. It appears that the latter effects are of little or no importance in situations of the kind described, as suggested elsewhere in the literature.

1. Introduction

Most previous experimental work on the threshold of sediment motion by waves has been carried out in the laboratory. Typically, this has involved the definition of 'critical waves' of single frequency which are just capable of causing sediment motion on a flat bed, such waves being defined by their velocity amplitudes and periods, and the bed material by its size and density. Sediment motion arises primarily as a result of the near-bed velocity field; however, a secondary influence which must be investigated is the possible role of pressure gradients at the bed surface. The velocity induced bed shear stresses are expected to lead the oscillation in the free stream in phase, on account of bottom boundary layer effects; whereas the additional forces on the grains due to the direct action of the fluid pressure field are expected to be in phase with the pressure

*Institute of Oceanographic Sciences, Crossway, Taunton, Somerset, UK,
TA12DW

gradients in the free stream outside the boundary layer. Unfortunately, in laboratory work little attention has been given to these phase relationships and, in particular, to the phase angles in the wave cycle between which to- and fro- motion of sediment has been observed. This makes the interpretation of field observations difficult.

A study of incipient sediment movement requires ultimately an understanding of the shear stress distribution in the flow, accompanied by a knowledge of the instantaneous velocity profile in the boundary layer through a wave cycle. Both of these quantities will depend upon the seabed topography; the development of ripples complicates the flow pattern close to the bed, alters the amount of sediment in motion and causes the breakdown of the 'critical wave' formulae derived for flat beds in the laboratory. An important part of such a study involves determining whether the flow in the boundary layer is laminar or turbulent. The transition from laminar to turbulent flow occurs near the threshold of motion for sands and, furthermore, differs for flat and rippled beds (see Davies and Wilkinson (1977)).

In this paper we are concerned with the relevance of laboratory formulae for threshold motion, when applied in the sea where the bed is normally rippled; also with the secondary problem of whether forces induced by pressure gradients in the flow are important at the threshold of motion. We make no attempt here to model the bottom stress and the resulting sediment transport directly. Instead we concentrate on studying the causal link between observations of sediment motion on the seabed and measurements of the flow parameters in the free stream outside the boundary layer. In particular, an attempt has been made to identify the critical conditions which exist instantaneously in the free stream flow at the threshold of motion of coarse sand.

2. Field Studies

Two experiments have been carried out at Blackpool Sands, Start Bay, Devon, England: the first on 22 March 1975 (Davies, Frederiksen and Wilkinson (1977)); the second on 25 - 26 March 1976. Measurements were made at positions close to the beach but well outside the breaker zone (Fig 1). Tidal currents and the effects of shoaling were shown to be of secondary importance at the experimental site, and the flow near the seabed was due primarily to an incoming ocean swell on both occasions. The bottom slope at the position of the rig was about 1 : 17 and the mean water depth was about 5m (Fig 2).

In the first experiment measurements of velocity were made above the crest of a ripple of height about 10 cms, and wavelength about 100 cms; and in the second above the crest of a ripple of height 12 cms and length 85 cms, as well as above an artificially flattened bed. When the bed was rippled, the to- and fro- motion of grains was always confined to the region of the ripple crests, and was of bed load type only. The bed features were almost certainly fossil ripples in both experiments, not in equilibrium with the existing flow field but formed by some previous more active wave-induced flow conditions.

BLACKPOOL SANDS, START BAY.

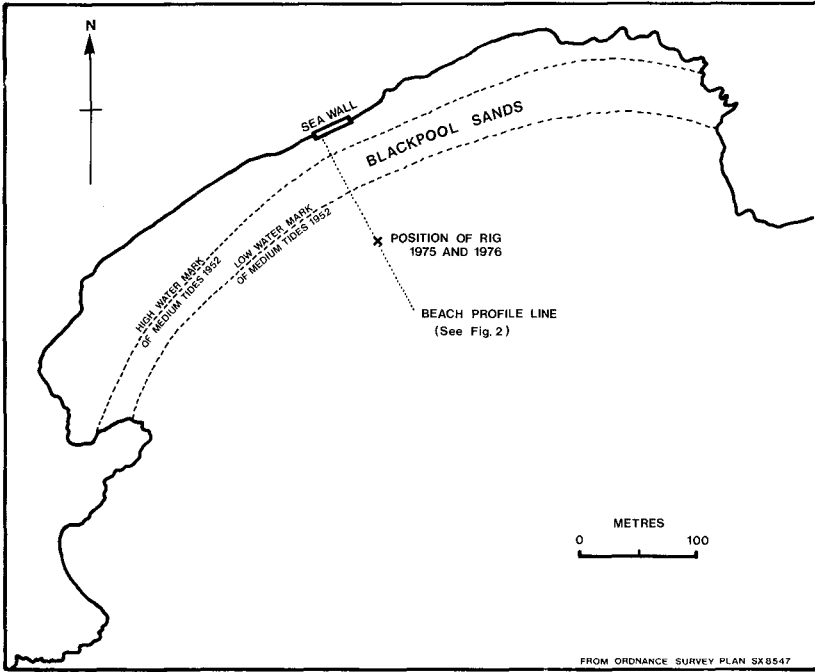

Fig.1

Fig.2 BEACH PROFILE AND NEARSHORE BOTTOM TOPOGRAPHY.

No flow separation was observed above the lee slopes of the ripples, judging from the behaviour of visible particulate matter in the water, nor was there any obvious sign of turbulent exchange in the flow. Indeed conditions, at least well away from the bed, appeared to be predominantly laminar in both experiments. When the bed had been flattened, grain motion occurred more generally over the bed surface, and again the flow appeared to be laminar.

In both experiments, the surface bed material was a coarse sand on the ripple crests and an even coarser material in the troughs, see Fig 3. In the second experiment, the material on the surface of the artificially flattened bed was predominantly of crest type.

The deployment of the apparatus was carried out by divers; its layout on the seabed is shown in Fig 4, together with the definition of axes and the symbols adopted for the flow parameters. Velocity measurements were made using two electromagnetic flowmeters with 10cm diameter Colnbrook measuring heads, mounted on a tetrahedral frame. These were positioned to measure the horizontal and vertical components of velocity in the vertical plane in the direction of wave advance; one flowmeter was at a height of 1m above the seabed, and the other at a height of 30cms in the first experiment and at a variable height between 15 and 60cms in the second. It was possible also to position the 'lower' flowmeter in a horizontal plane above the rig; this was done before and after runs in the second experiment in order to monitor the directional characteristics of the waves. In this paper, we concentrate for the most part on measurements of the horizontal velocity made with the 'upper' flowmeter.

Also attached to the rig was an underwater television camera, with which an area of the seabed about one half a metre square vertically below the flowmeters was viewed. The resolution of the camera was such that individual sand grains could be detected clearly and, when the bed was rippled, a view along a crest was obtained (as shown schematically in Fig 4). At distances of 5m on either side of the rig, in the direction of wave advance, FM-pressure transducers were positioned in order to obtain a direct estimate of the pressure gradient in the flow. The separation of the transducers was less than one quarter of the expected surface wavelength in order to avoid spatial aliasing.

The velocity and pressure signals were logged on a Bell and Howell FM-tape recorder. In addition, a synchronous video record showing the sediment motion was made with the underwater television system. The first experiment provided continuous data over a two hour period, while, in the second, four forty-minute runs were made on each of two consecutive days.

Before and after the experiments, the FM-flowmeters were calibrated in a towing tank. However, in the second experiment, zero points on the velocity scales were also determined in the field by placing shrouds over the measuring heads; this enabled the drift in the system to be corrected for. The noise of the flowmeter system was equivalent to a pk-pk velocity of about 1 cm/sec, and the pressure transducers could each resolve to about 1 cm of water.

ARRANGEMENT OF EQUIPMENT ON SEABED AND DEFINITION OF AXES

3. The Sediment Threshold Analysis

One of the main objectives of the experiments was to determine the values of the measured parameters at the instants when sediment motion started and stopped in both shoreward and seaward directions. This aspect of the investigation required the times of occurrence of grain motion to be obtained from the video records, and these times were then used to obtain critical velocities from the FM-flowmeters, as well as critical pressure values from the two FM-pressure recorders.

The method adopted was to replay the video tapes to three observers, each of whom recorded automatically an opinion as to whether sediment movement was taking place (for details, see Davies, Frederiksen and Wilkinson (1977)). The three sets of opinions were then averaged in such a way that a series of times was obtained at which sediment motion was considered to have either started or stopped, in both shoreward and seaward directions. These times were used to obtain critical instantaneous values of velocity and pressure from the synchronous analogue data. The means and variances of the critical values were calculated and, due to the subjective nature of the sediment threshold analysis, it was not surprising to find that they contained a considerable amount of scatter. It has been shown that the distribution of the critical values around their means was Gaussian for each parameter.

Under the experimental conditions, the sand on the ripple crest and, even more so, the sand on the flattened bed, remained stationary for most of the time. Sediment movement was observed only occasionally and it was usually associated with a group of higher amplitude surface waves. The number of instances of sediment motion in both shoreward and seaward directions, together with the percentage of the total time that sediment was in motion are shown in Table 1. The most striking feature here is the almost complete inhibition of sediment motion which was brought about by flattening the bed, even though the wave conditions were essentially the same.

For the first experiment, the number of instances of motion has been broken down into values for succeeding intervals of duration 10 minutes. In this form they display a considerable variability which can be associated with the changing wave conditions which were experienced during the experiment. To illustrate this, the number of instances of motion in an interval has been plotted against the variance of u_x , the horizontal velocity at a height of 30 cms, in that interval (see Fig 5). There is clearly an increase in the number of instances of motion with variance as expected; the scatter in the results indicates merely that variance is a crude measure of wave intensity for the present purpose and does not bear any direct relationship to sediment transport. Similar results were obtained by taking the variances of u_v , p_x and w_x (see Fig 4).

4. Energy Spectra and Probability Density Functions

The analogue velocity and pressure data recorded on the magnetic tape, having been filtered and then digitized at a rate of 5 Hz, was examined from a general statistical point of view. Firstly, the energy content of the signals was investigated by computing variances over intervals of duration 10 mins, and then the frequency composition of these variances was studied using standard spectral analysis techniques

BED TYPE	EXPERIMENT 1		EXPERIMENT 2

Fig. 5

Fig. 6

based on the use of a Fast Fourier Transform. In forming energy spectra, adjacent harmonics were grouped such that spectral estimates were obtained every $1/120$ Hz in the frequency domain.

Typical energy spectra of u_x for the two experiments are shown in Fig 6. For the first experiment, the spectrum is dominated by a single peak centred on 0.088 Hz, corresponding to a wave of 11.4 secs period. For the second, in addition to the main peak at 0.080 Hz, a smaller peak can be seen in the range (0.17, 0.19)Hz; this was typical during the experiments on both the rippled and flattened beds. Relatively little activity was measured at frequencies above 0.3 Hz. Thus conditions in both experiments can be seen to have been dominated by a low frequency swell, with a higher frequency contribution also present in the second experiment.

For the purpose of further classifying the observed phenomena, the digitized data from a 10 minute interval is presented in Fig 7 in the form of normalized probability density functions for both u_x and u_y . The normalized Gaussian curve is included for comparison and, since the distributions for both velocity components shown are approximately Gaussian, the signals can be classified as narrow band random noise. This is consistent with the wave group behaviour noted in the velocities and pressures measured during the experiment.

5. Results of Threshold of Motion Studies

(i) The instantaneous threshold of sediment motion

After critical values of the measured velocities and pressures at the times of sediment threshold motion had been established (as described in Section 3), these were sorted into four groups of starting (α) and stopping (Ω) of motion, in the shoreward (+) and seaward (-) directions. Mean values and standard deviations were calculated for each group. Threshold results from the two experiments for u_x , the horizontal velocity measured at a height of 1m above the ripple crest, are shown in Table 2. At threshold the critical velocities in the '+' and '-' directions were approximately equal, and the large standard deviations show that the differences between the magnitudes of the threshold values in the two directions have no statistical significance. Also the results suggest that the asymmetry introduced by an overall beach slope of 1 : 17 did not significantly enhance sediment motion seawards. However smaller critical speeds occur at termination of motion than at initiation. This suggests the persistence of grain motion after the current speed had fallen below the initiation threshold value, possibly as a result of the inertia of the grains in motion. Differences between results for the two experiments can be accounted for in terms of differences in ripple steepness.

The same procedure was carried out on sets of data reduced in such a way that instances of motion were retained for analysis only if the time interval (ΔT) between the initiation of one motion and the cessation of the previous motion exceeded some specified value. This was aimed at studying possible differences in threshold values caused by a "settling of the bed" during a period of no grain motion. It was thought that the longer the interval, the more time the bed would have to "settle out" and become increasingly resistant to subsequent erosion. Results for an interval $\Delta T = 5$ secs are given in Table 2. These show an increase in the initiation threshold values of u_x in both directions, as anticipated. Different values of the interval, ΔT , have been taken for

the case of u_w , for motion in the (-) seaward direction during the first experiment (Fig 8). For critical current speeds at the initiation of motion (α), a sharp increase can be seen in the range $0 \leq \Delta T \leq 3$ secs but, thereafter, no further statistically significant increase occurs. Standard errors are indicated by vertical bars, and the t-Test for the Two Sample Case (Dayton and Stunkard (1971)) has been used to show that the mean values obtained for u_w with $2 \leq \Delta T \leq 15$ secs, are different from the overall mean value ($\Delta T = 0$) within 95% confidence limits. On the other hand the mean \bar{u}_w -values, indicating termination of motion, display no such trend as ΔT is varied; for these values, the t-Test indicates that none of the mean values in $1 \leq \Delta T \leq 30$ secs has arisen from a population having a different mean value from the overall mean at $\Delta T = 0$ again within 95% confidence limits. From these typical results (similar results being obtained in the shoreward direction, as well as in u_v) it does seem possible that a sand bed takes a certain length of time to "settle out". However the subjective nature of the sediment threshold analysis might have had a bearing here; in particular, the possibility must be admitted that the longer the grains on the bed surface remained stationary, the slower were the reactions of the observers watching the TV-replay when they eventually moved.

(ii) The critical wave analysis

The critical times indicating the occurrence of sediment motion were used also for a wave by wave analysis. In this case, the aim was to classify individual wave half-cycles in a record according to their velocity amplitudes and periods, noting which waves moved sediment and which did not. This analysis was performed to enable direct comparisons to be made with laboratory findings, and the results described in this section are based on the horizontal velocity data obtained at the 1m height above the bed.

Typical results from the second experiment for the rippled and artificially flattened beds are shown in Figs 9 and 10 respectively, in which the peak velocity (U_m) achieved in a wave half cycle has been plotted against the number of half cycles during the record which had U_m falling within each unit range. The full histogram indicates the distribution of U_m for all waves in the record, and the shaded one is a subset of this indicating only those waves which moved sediment. Positive values indicate the shoreward direction. Fig 9 shows results for a 110 minute data collection period on a rippled bed, and Fig 10 for a 120 minute period on a flat bed.

It can be seen from Figures 9 and 10, firstly, that there is a marked difference between threshold conditions on rippled and flat beds, the measured threshold velocity amplitudes in the latter case being higher by a factor of about two than in the former. Secondly, as expected, the figures show that the waves having high free stream orbital velocity amplitudes moved sediment, and those with low velocity amplitudes did not. Less predictable is the existence of the "transition ranges" between these two situations, in which only a proportion of the waves achieving a particular value of U_m moved sediment. In the case of the rippled bed, the transition range was (-7, -21) cms/sec in the - direction, and (6, 23) cms/sec in the + direction. For the flattened bed, the wave conditions measured in the free stream during the experiment were such that very little motion occurred, despite the

fact that these conditions were essentially the same as those during the experiment with the rippled bed; however the start of a transition range can be seen in Figure 10.

Also shown in Fig 10 for the case of the flattened bed are some typical threshold velocity amplitudes obtained on flat beds in the laboratory. The values shown are from the formulae of Bagnold, Manohar, and Komar and Miller (see Table 3). In the calculations the sand grain size has been varied through the range 1 - 2mm, the D_{50} value in the second experiment being 1.4mm. The wave period has been taken equal to 9 seconds, which was a representative mean value obtained from an analysis of zero crossing periods (see Fig 11); in fact, each of the formulae shown is relatively insensitive to wave period, and Manohar's is independent of it. The observed sediment motion can be seen to have occurred at slightly lower values of velocity amplitude than predicted by the three formulae, even allowing for the uncertainty as to which grain size in the range shown was actually moving. It should be realized however that, although an attempt was made to achieve a consistent sediment threshold criterion in the present experiment, it is not possible to compare this criterion objectively with those adopted by the other workers. Nevertheless it can be seen that the parameter U_m does go a considerable way towards explaining the sediment threshold observations on the flattened bed.

(iii) Discussion of the sediment threshold results

The main questions emerging from the critical wave analysis were, firstly, why did the change from a rippled to a flat bed inhibit sediment motion; and, secondly, what was the explanation for the existence of the transition regions, which were particularly evident in the rippled bed results and in which only a fraction of the waves achieving a particular U_m moved sediment.

A quantitative explanation of the apparent discrepancy between the threshold values on flat and rippled beds has been achieved by performing an analysis of the frictionless flow over both real and idealized finite amplitude ripple shapes, assuming a non-separating deep oscillatory flow over the prescribed bed surface. The results of this work have indicated that the measuring height of 1m was well outside the zone of (frictionless) influence of the ripples, and the velocities at this height can, therefore, be said to have been obtained in the unperturbed free stream flow. Calculations of the velocity at the surface of the ripple crest have shown that, for the real sand ripples over which the measurements were made in the second experiment, almost a doubling of the velocity in relation to the unperturbed flow is to be expected (Davies, in prep). This would explain the apparent discrepancy in the sediment threshold findings.

A number of explanations can be proposed for the appearance of the transition regions in the histograms, involving factors of secondary importance in the problem:

- (a) the subjective nature of the sediment threshold analysis;
- (b) sedimentological considerations of various kinds:- the uncertainty about the grain size in the range (1, 2)mm which was moving at any one time, possible effects of the "settling" of the bed, and changes in the threshold velocity due to the continual changes occurring in the ripple shape during an experiment;

TYPICAL SEDIMENT THRESHOLD FORMULAE FROM THE LABORATORY FOR OSCILLATORY FLOW OVER A FLAT BED

BAGNOLD (1946) $\frac{\omega^{1/4} U_M^{3/4}}{\gamma^{1/2} D^{0.325}} = 21.5$ (c. g. s. units)

MANOHAR (1955) $\frac{U_M}{(\gamma g)^{0.4} (vD)^{0.2}} = 8.2$

KOMAR AND MILLER (1973) $\frac{\omega^{1/4} U_M^{7/4}}{\gamma g D^{3/4}} = 1.45$ (for $D > .05$ cms.)

where

- U_M = velocity amplitude in the free stream
- ω = wave frequency = $(2\pi/T)$
- D = representative grain diameter
- $\gamma = (\rho_s - \rho_f) / \rho_f$
- ρ_f = density of water
- ρ_s = density of sediment
- g = acceleration of gravity
- v = viscosity of water

TABLE 3

Fig. 11

MEAN PERIOD BETWEEN ZERO-CROSSINGS OF WAVE HALF CYCLES DEFINED BY VALUES OF U_m (IN INTERVALS OF UNIT WIDTH)

- (c) slight changes in wave direction - in particular, the transverse velocity component in the direction normal to the plane of the measuring head has been assumed small compared with u and this may not always have been the case;
- (d) finally, and probably most important of all, the forces at work at threshold are not being considered directly in concentrating attention on U_m . In particular, an analysis involving bed shear stress is more likely to yield a solution to the problem than one based on the velocity amplitude U_m . However, another possible secondary perturbing influence at threshold is the fluid pressure field, which will give rise to forces on the grains on the bed over and above those forces caused by the fluid velocity field. The discussion in the next section is concerned with the importance of the spatial pressure gradient $\partial p / \partial x$ in the direction of wave advance.

6. The Importance of Pressure Gradients in the Fluid at the Threshold of Sediment Motion

The role of spatial pressure gradients in the fluid acting on individual grains at the initiation of sediment motion is likely to be of secondary importance only and depends, essentially, on whether or not fluid molecular viscosity is an active agent in determining the nature of forces on the exposed sand grains on the bed surface. Davies, Frederiksen and Wilkinson (1977) in discussing a related topic have shown that, depending upon whether fluid momentum is transferred to sand grains on the bed by dynamic pressure effects or by skin friction acting on the exposed top surfaces of grains, the role of pressure gradients is likely to be negligible or of small secondary importance respectively. In deciding which case is relevant in the present problem, it is possible to look for guidance at the comparable and well documented situation of uniform fluid flow past a single sphere; however, unfortunately, the Reynolds number of the flow past the sphere equivalent to the sand grains in question, lies in the intermediate region between linear and quadratic drag law behaviour. The nature of the forces on grains of mixed size on a sand bed is also unclear, and for this reason the data analysis described in this section has been pursued.

In examining the importance of forces resulting from the fluid pressure field at threshold, the analysis of the data has again been carried out both on a wave by wave basis and on the basis of an examination of instantaneous values of the relevant parameters at the initiation of sediment motion.

(i) Further results of the critical wave analysis

The aim in performing this analysis was to determine from the measured parameters whether any decisive difference could be found in the transition regions, between the waves which did and did not move sediment at each value of U_m . Before the measured pressure field was examined, consideration was given to the fluid acceleration. This was done on account of the presence in certain of the laboratory threshold formulae (Table 3) of the wave frequency, in addition to the velocity amplitude, indicating the possible importance of accelerative effects at threshold. In carrying out the analysis, it was assumed

that the behaviour of the velocity field in individual wave half cycles in the transition range was approximately sinusoidal, and that a measure of acceleration in a particular wave half cycle could thus be obtained by noting the interval between zero crossing values of velocity. The purpose of proceeding in this way was to see whether the waves in the transition ranges which moved sediment were, on an overall basis, those which displayed shorter periods (and, therefore, greater accelerations) between zero crossings at each value of U_m . It was not possible to seek directly peak values of acceleration itself during half cycles defined by zero-crossing times of measured velocity, due to the quadrature phase relationship between these quantities.

The results of the investigation are shown in Fig 11, in which average values of the interval are plotted against U_m for the rippled bed data in the second experiment. It can be seen that there was no systematic difference of the type sought, the waves moving sediment in the transition regions having a similar interval between zero-crossings to the assembly of all waves in the record. In other words, the examination of the transition regions has revealed that, at a particular U_m , the mean period of the waves causing sediment motion was not significantly different from that of the waves which did not cause motion. In addition, Figure 11 shows that the waves in the transition regions had a half-period of approximately $\frac{1}{2}$ seconds, or period of 9 seconds.

As argued above, a direct examination of the peak acceleration in each wave half cycle was not possible on account of the phase relationship between u and $\partial u / \partial t$. Clearly, the same phase relationship exists between u , the horizontal velocity measured in the free-stream flow, and $\partial p / \partial x$, the spatial pressure gradient in the direction of wave advance, since, in a frictionless zone and on a linearized analysis, the fluid acceleration is proportional to the pressure gradient. This was approximately so in the field, as can be seen in the typical scatter plot shown in Figure 12. The 3000 points plotted are pairs of digitized values of $\partial u / \partial t$ and $\partial p / \partial x$ from a 10 minute period during the second experiment. Although a general linear relationship is clear in these results, there was thought to be sufficient scatter about the mean line to justify an examination similar to the one described above, but now taking the peak pressure in each wave half cycle instead of the period between zero crossings of u . This was possible on account of the approximately in-phase behaviour of u and p , the waves measured being predominantly of progressive wave type; the pressure was taken as the mean value $\bar{p} = \frac{1}{2} (p_1 + p_2)$. Then, again at each U_m in the transition regions, the mean peak pressures of the waves which moved sediment were compared with peak pressures for the assembly of all waves in the record.

Figure 13 shows the results obtained for the rippled bed data in the second experiment. It is apparent that the waves which moved sediment were associated at certain values of U_m with higher than average peak pressures through the transition ranges in both shoreward and seaward directions. However, to argue from this that pressure gradients in wave half cycles associated with sediment motion were also generally greater than average, requires further assumptions; these relate both to the sinusoidal nature of individual wave half

Fig.12 A SCATTER PLOT OF ACCELERATION AGAINST SPATIAL PRESSURE GRADIENT

Fig.13

cycles, but more importantly to whether the flow can truly be regarded as two-dimensional. For it is possible that the degree of correlation between β and the total horizontal velocity may have been better than that between β and u ; no suitable experimental evidence was obtained to test this. Thus, on the basis of Figure 13, it cannot be shown that pressure gradients were a significant perturbing influence at threshold, and to resolve this area of ambiguity an analysis of the instantaneous sediment threshold data has been carried out.

(ii) Further results of the instantaneous threshold of motion study

Corresponding to the instantaneous threshold values of u_0 , quoted in Table 2 for the case of the rippled bed in the second experiment, mean values of the pressure gradient $\partial p / \partial x \approx (\bar{p}_1 - \bar{p}_2) / \Delta x$ were found to be -0.75 and $+0.81$ cms of water/metre, at the initiation of motion in the shoreward and seaward directions respectively; the standard deviations were 0.76 and 0.69 cms of water/metre respectively.

In order to assess the importance of pressure gradients at threshold, an attempt has been made to reduce the considerable amount of scatter in the critical values of u_0 and $\partial p / \partial x$ on a systematic basis, by combining pairs of critical values to form empirical expressions for the total force on the bed surface, firstly of the type

$$F_1 \Big|_{\nu} = C_1 u_0 \Big|_{\nu} + C_3 \frac{\partial p}{\partial x} \Big|_{\nu}$$

and secondly,

$$F_2 \Big|_{\nu} = C_2 \{ u_0 | u_0 | \} \Big|_{\nu} + C_3 \frac{\partial p}{\partial x} \Big|_{\nu}$$

where the subscript ν indicates the ν th data value at threshold. The expressions relate to the cases of linear and quadratic velocity drag law behaviour respectively, and C_1 , C_2 and C_3 are appropriate force coefficients. The aim of this exercise was to determine whether the scatter in $F_{1,2}$ could be shown to be significantly smaller than the scatter in the critical values of $F_{1,2}$ with $C_3 = 0$, by adopting some optimum value of the ratio $C_1 : C_3$ or $C_2 : C_3$ respectively. The method used was a perturbation procedure to determine values of these ratios according to the criterion that the variance in $F_{1,2}$ over all ν , should be minimized.

The investigation was carried out for the rippled bed data in the second experiment, over successive data collection periods of 10 minutes. Occurrences of motion in the shoreward and seaward directions were examined separately. The results showed that, although the variance in $F_{1,2}$ could be reduced substantially in almost all the data portions examined by a particular choice of the ratios $C_1 : C_3$ and $C_2 : C_3$, no systematic behaviour was evident in these ratios. In particular, the general trend in the results was for the minimization of variance to be accomplished by a pressure gradient force acting always in one direction regardless of the direction of grain motion. In other words, while the minimization of variance was of numerical significance, it had no physical significance. It is thought that this offers

substantial evidence that the pressure gradients in the present problem were of no importance in mobilizing grains on the seabed, despite a weak suggestion in Section 6(ii) to the contrary.

7. Discussion and Conclusions

From the critical wave by wave analysis, two main conclusions have been drawn. Firstly, that for the real sand ripples in the present experiment there was an apparent doubling in the threshold velocity amplitude (measured in the free stream) for sediment motion on a flat bed compared with motion on the crest of a sand ripple. However, a quantitative explanation for this has been obtained from a model of the potential flow over real sand ripple shapes.

Secondly, there was not found to be just one value of velocity amplitude associated with the initiation of grain motion; rather, a wide (transition) range of velocity amplitude values has been identified in which only a fraction of the measured waves moved sediment. Sedimentological considerations, the somewhat subjective nature of the sediment threshold analysis and possible effects of three-dimensionality in the flow, have been proposed as factors of secondary importance in the problem which may go some way towards explaining the presence of the transition regions. Accelerative effects in the flow do not appear to provide an explanation. However more recent work has suggested that a significant narrowing of the transition regions can be accomplished by working a critical wave by wave analysis in terms of bottom stresses at threshold, rather than velocity amplitudes measured in the free stream flow. Despite the improvement in an understanding of the phenomenon which can be achieved in this way, it is thought encouraging that the measured critical velocity amplitude values in the present experiment (when the bed was flattened, or when allowance was made for the effect of ripples) were in reasonable agreement with various well known laboratory threshold results.

The instantaneous threshold of motion study has been used to isolate the critical instants in time at which sediment motion started or stopped, with a view to understanding in more detail the processes at work at the initiation of sediment motion. The study conducted on the importance as a perturbing influence at threshold, of pressure gradients in the flow, has led to the conclusion that pressure induced forces on the surface grains on the bed are of little or no importance in the transport of coarse sands by swell waves. The same may not be true during and after the breaking of waves, where the pressure gradients are much higher at certain instants in each wave cycle. However, outside the breaker zone, it appears that sediment movement by waves is capable of explanation in terms of the near-bed velocity field alone.

Acknowledgments

The authors would like to thank the electronics engineers and the diving team at IOS Taunton for the essential part they played in performing the experiments. Dr K R Dyer is thanked for his comments during the preparation of this paper.

CHAPTER 95

DISTRIBUTION OF SAND TRANSPORT RATE ACROSS A SURF ZONE

Toru Sawaragi

Research Associate of Civil Engineering
Osaka University, Osaka, Japan

ABSTRACT

The distributions of longshore and on-offshore sediment transport rates in a surf zone were measured by an apparatus which was able to separately record both components of the sediment transport rate. The characteristics of their distributions were discussed from the bottom shear stresses which were measured by the shear meter under the same wave conditions as the laboratory experiment of the sediment transport.

The maximum bottom shear stress took place at the depth between the breaking depth of waves and the depth where the velocity of the longshore current showed a maximum. On the other hand, the maximum on-offshore and longshore sediment transport rates occurred at the depth slightly shallower than the depth where the maximum bottom shear stress took place. What's more, the longshore sediment transport rates were represented by the longshore current velocity and the bottom shear stress generated by waves and the longshore current. However, the distribution of the on-offshore sediment transport rates showed more complicated profile than that of the longshore sediment transport rates because there were no eminent unidirectional flow in the direction normal to the shore line. Therefore, the on-offshore sediment transport rates could not be formulated by the bottom shear stresses.

1. Introduction

In the problems of the coastal sediment, the sediment transport is usually considered to be divided into the longshore and the on-offshore components for convenience. The longshore sediment transport rate has been investigated from an energy principle approach, and the on-offshore sediment transport has been investigated in the process of equilibrium beach profiles. However, the sediment in the surf zone do not move in the directions normal and parallel to the shore line independently. Although some investigations concerning the distribution of the longshore sediment transport rate in the surf zone based on both energy and force principle approach have been proposed (Thornton(1972)

and Komar(1977)), those theories have not been verified thoroughly by fields or model beach experiments because of the lack of information about wave deformations and wave-induced flow conditions, and the difficulty of the measurement of the longshore sediment transport rate in the surf zone.

The authors devised an apparatus which was able to separately record the longshore and the on-offshore sediment transport rates, the distributions of each component of the sediment transport rate along a line normal to the shore line across the surf zone were measured by using this apparatus in a field as well as in a laboratory model beach. Furthermore, the distribution of bottom shear stresses, which directly cause sediment movements on a sea bottom, along a line normal to the shore line was also measured by a shear meter on a fixed bed in a laboratory under the same wave conditions as the laboratory experiment of sediment transport rates.

The characteristics of a bed load caused by waves and wave-induced longshore current were discussed with respect to the distribution of the bottom shear stress and the formula on the rate of longshore sediment transport was proposed.

2. Equipments and procedures to measure the sediment transport rate.

In the surf zone where the wave-induced longshore current occurs, sediment particles at the bottom are moved by the water-particle-motion combined waves and the longshore current. As a results, the directions of sediment movements change with time according to the phase of the wave motion or the relative velocity of the water particle due to waves to the velocity of currents. The authors devised the method to analyze the longshore and the on-offshore sediment transport rates by measuring the sediment volume which are moved by uprush and downrush separately, by using a sand trap as shown in Fig.1. During the measurement, this sand trap was buried in the sea bottom till the upper part of the trap and its surrounding sea bottom were on the same level. Pebble stones were also put around the trap to prevent local scouring due to waves in the field. In Fig.1, the following symbols are used:

a : the diameter of the sand trap

$|\vec{q}_u|$ and $|\vec{q}_d|$: the sediment transport rates per unit length per unit time when sediment are moved by uprush and downrush,

Fig.1 Sand trap

respectively.

θ_1 and θ_2 : the angles between a line normal to the shore line and the directions of the sediment movement (the clockwise position being positive), respectively.

where q_{u1} and q_{d1} are defined by assuming the following model of the sediment transport:

a) When the sediment moves toward the shore line, the volume of the sediment which can be transported by any current per unit area at the bottom is q_{u1}^* and the velocity of the sediment transport is $|\vec{u}_{s1}|$, the direction of which makes an angle θ_1 with the normal to the shore line. Hence the sediment transport rate per unit length per unit time when the sediment is moved by uprush equals $|\vec{q}_{u1}| = q_{u1}^* \cdot |\vec{u}_{s1}|$ and the longshore and the on-offshore components of the velocity of the sediment transport equal $|\vec{u}_{s1}| \sin \theta_1$ and $|\vec{u}_{s1}| \cos \theta_1$, respectively.

b) When the sediment is moved toward offshore by downrush, the volume of the sediment which can be transported is q_{d1}^* and the velocity of the sediment transport is $|\vec{u}_{s1}|$, the direction of which makes an angle θ_2 with the normal to the shore line. Here, the sediment transport rate when the sediment is moved by downrush equals $|\vec{q}_{d1}| = q_{d1}^* \cdot |\vec{u}_{s1}|$ and the longshore and the on-offshore components of the velocity of the sediment transport equal $|\vec{u}_{s1}| \sin \theta_2$ and $|\vec{u}_{s1}| \cos \theta_2$, respectively.

Based on these assumptions, the longshore and the on-offshore sediment transport rates per unit length per unit time, q_x and q_y , are given as follows:

$$\begin{aligned} q_x &= q_{u1}^* |\vec{u}_{s1}| \sin \theta_1 - q_{d1}^* |\vec{u}_{s1}| \sin \theta_2 = |\vec{q}_{u1}| \sin \theta_1 - |\vec{q}_{d1}| \sin \theta_2 \\ q_y &= q_{u1}^* |\vec{u}_{s1}| \cos \theta_1 - q_{d1}^* |\vec{u}_{s1}| \cos \theta_2 = |\vec{q}_{u1}| \cos \theta_1 - |\vec{q}_{d1}| \cos \theta_2 \end{aligned} \quad (1)$$

In these equations, $|\vec{q}_{u1}|$, $|\vec{q}_{d1}|$ and θ_1 , θ_2 can be calculated volumetrically from the sediment which were trapped in the individual compartments of the sand trap by using the following relations:

For $0 < \theta_1, \theta_2 < \pi/4$

$$\begin{aligned} q_1 &= |\vec{q}_{u1}| \sqrt{2} \cos \theta_1, \quad q_2 = |\vec{q}_{u1}| a (1 - \cos(\theta_1 + \pi/4)) + |\vec{q}_{d1}| a (1 - \cos(\pi/4 - \theta_2)) \\ q_3 &= |\vec{q}_{d1}| \sqrt{2} \cos \theta_2, \quad q_4 = |\vec{q}_{d1}| a (1 - \cos(\theta_2 + \pi/4)) + |\vec{q}_{u1}| a (1 - \cos(\pi/4 - \theta_1)) \end{aligned} \quad (2)$$

For other values of θ_1 and θ_2 , similar relations as eq. (2) are used to calculate $|\vec{q}_{u1}|$, $|\vec{q}_{d1}|$ and θ_1 , θ_2 except when $-\pi/2 < \theta_1 < -\pi/4$, $\pi/4 < \theta_2 < \pi/2$ and $\pi/4 < \theta_1 < \pi/2$, $-\pi/2 < \theta_2 < -\pi/4$. In these case, the velocity of the longshore current is greater than the water-particle velocity due to the wave, and the on-offshore sediment transport can be neglected.

3. Field measurements of the sediment transport rate in the surf zone.

The authors conducted the measurements with this sand trap in the two natural beaches shown in Fig. 2. Isonoura Beach looks out on the Pacific Ocean and has a straight beach of about 1 km, the slope of which is about 1/80. The median grain size of the beach materials is about 0.2 mm. The incident wave steepnesses are usually flat and wave heights are relatively high. Matsuho Beach is located at the southern end of Awaji Isl. and has a convex beach of about 50 m, the slope of which is about 1/15. The median grain size of the beach materials is about 2.0 mm. The incident wave steepnesses are usually steep and wave heights are

Fig.2 Sites of field measurements of sediment movements.

relatively small. The diameter of the sand trap used in these field experiments was 50cm and the depth was 30cm – 40cm . 10 sand traps were buried equi-distance between the wave run-up height and about 3.0m below the mean water level. The incident wave characteristics were also recorded by the pressure-type wave gauge.

Figs.3 and 4 show examples of the distributions of the longshore and the on-offshore sediment transport rates along beach profiles measured in these two beaches.

Figs.3(a) and (b) indicate the results obtained at different times in Isonoura Beach. This beach has a large surf zone of about 100m width because of the gentle slope and flat and high incident wave height. The distribution of the longshore and the on-offshore sediment transport rates shown in Fig.3(a) indicates one peak slightly seaward from the shore line. While the profile of the distribution of the longshore sediment transport rate shown in Fig.3(b) indicates two peaks near the shore line and a location slightly shallower than the breaking depth of the significant incident wave.

Figs.4(a) and (b) indicate the results obtained in Matsuho Beach. Since Matsuho Beach has a steep beach slope which consists of relatively large beach materials, and furthermore, since the incident wave heights are usually small, the length of the surf zone is small (about 5m). So, as shown in Fig.4, the longshore and the on-offshore sediment transport were concentrated in a narrow range near the shore line. And the profiles of the distribution of the longshore and the on-offshore sediment transport rates indicated one keen peak which was sometimes above the shore line.

Fig. 4 Distribution of sediment transport rate measured at Matsuho Beach.

Fig. 3 Distribution of sediment transport rate measured at Isonoura Beach.

4. Measurements of the sediment transport rate and bottom shear stresses on a model beach.

It appears very difficult to find the general characteristics of the sediment transport from the field data as shown in Figs.3 and 4 because of the irregularities of incident waves and the changes of the still water level due to tides. Therefore, the authors conducted measurements of the sediment transport rates in the surf zone on a model beach with a movable bed. In addition, bottom shear stresses which directly cause sediment movements on a fixed bed were measured in order to make more detailed investigation of the mechanism of the sediment transport in the surf zone.

4-1. Measurements of the sediment transport rate on a model beach.

Movable bed experiments were conducted by using a wave basin of 20^m width, 30^m length and 0.6^m depth. At one end of the basin was equipped a straight 12^m long model beach with a slope of 1/20. At the other end of the basin was installed a flap-type wave generator which generated an incident wave making an angle 30° with the shore line of the model beach at the water depth of 38^{cm}. Three kinds of waves of which the steepness in a deep water were about 0.02, 0.04, and 0.06 were propagated. Two kinds of beach materials, median grain size d_{50} being 0.34^{mm} and 0.68^{mm}, were used. However, the wave height in deep water was kept constant at about 6^{cm}.

Sediment transport rates were measured by 10 sand traps buried between the shore line and at the depth of 10^{cm}. The diameter of the sand trap was 10^{cm} with a depth of 7^{cm}. Wave height distributions in the surf zone were measured by capacitance-type wave gauges, and the longshore current velocity and the wave direction were recorded by 16^{mm} high-speed cine camera equipped at a height of 4^m above the wave basin.

4-2. Equipments and procedures to measure bottom shear stresses.

The bottom shear stress was measured by a shear meter which is shown in Fig.5. In Fig.5, a shear force acting on the shear plate ① is measured by converting the force into a moment of the supporting shaft ②. The shear plate is subjected to a resultant force due to wave pressure gradient force and the shear force. Thus, the shear force is calculated by subtracting pressure gradient force, measured by the pressure tube ③ equipped at both ends of the shear plate, from the resultant force measured by the shear plate.

Fig.5 Shear plate

However, in the experiments, the bottom shear stresses were caused by waves and currents and the direction of their respective water-particle-motion made an angle of about 90° . Therefore, it was assumed that the water-particle movements normal to the direction of the shear stress do exist. Then the authors made many concave gratings under the shear plate to prevent these water-particle movements. And the bottom shear stress was measured as the longshore and the on-offshore components separately at about the same point as the measurement of the sediment transport. Hereafter, these components of the bottom shear stress are represented by τ_x and τ_y , respectively.

5. Experimental results.

5.1 Distributions of q_x and q_y .

The distributions of averaged q_x and q_y measured twice within 10^{min} after wave propagation in the experiments of $d_{50} = 0.34^{\text{mm}}$ and $d_{50} = 0.68^{\text{mm}}$ are shown in Figs.6 and 7, while Fig.8 shows the distributions of the velocity of the longshore current U and wave height H . In these Figs., q_{xm} and q_{ym} indicate the maximum value of q_x and q_y . And U_m is the maximum longshore current velocity and H_b is the breaking wave height. Y is the distance from the shore line and Y_b is the distance from the shore line to the breaking point.

When $d_{50} = 0.68^{\text{mm}}$ ($H_0/d_{50} = 88$) as shown in Figs.6 and 8(a), the maximum q_x and q_y occurred at $Y/Y_b = 0.6$ which was slightly seaward than the point where the velocity of the longshore current showed a maximum value regardless of H_0/L_0 . Besides, the direction of the on-offshore sediment transport was almost offshore. According to the continuous equation for the sediment transport, the distribution of q_y as shown in Fig.6(b) causes the following modes of beach deformation as erosion in the range of $Y/Y_b < 0.6$ and accretion in the range of $Y/Y_b > 0.6$ and these modes of beach deformation were confirmed in our experiments.

On the other hand, in the case of $d_{50} = 0.34^{\text{mm}}$ in Fig.7(a), maximum q_x took place at $Y/Y_b = 0.8$, which was more toward the seaward side than the former case and the profiles of the distribution showed saddle shapes in the region of $Y/Y_b < 0.6$, while the distribution of q_y shown in Fig.7 (b) indicates complicated figures, maximum q_y occurring at the same point as q_x . Furthermore, it can be seen from Fig.7 that a fair amount of sediment transport occurred in the region of $Y/Y_b > 1.0$.

5-2. Profiles of the distribution of τ_{xm} and τ_{ym} .

Fig.9 shows an example of the distribution of measured maximum bottom shear stresses in nondimensional form by dividing by $\rho g H_b$ along a beach profile together with the distribution of the velocity of the longshore current and the wave heights measured at the same time, where ρ is the density of the water and g is the acceleration due to the gravity.

In the region of $Y/Y_b > 0.8$ in Fig.9, both $\tau_{xm}/\rho g H_b$ and $\tau_{ym}/\rho g H_b$ increase monotonously as Y/Y_b decreases. And in the region of $Y/Y_b < 0.8$,

Fig.6 Distribution of sediment transport rate.

Fig.7 Distribution of sediment transport rate.

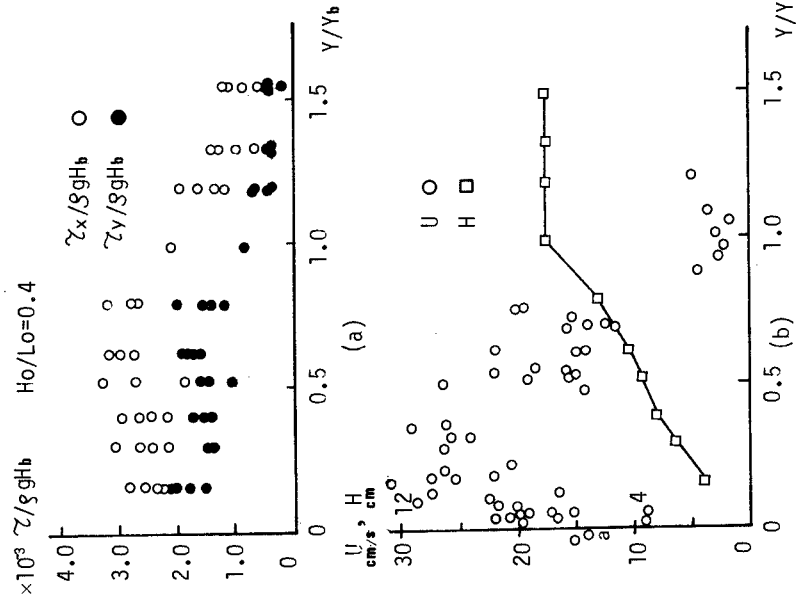

Fig. 9 Distribution of bottom shear stress, longshore current velocity and wave height.

Fig. 8 Distribution of longshore current and wave height.

$\tau_{ym}/\rho g H b$ indicates almost constant values. On the other hand, the distribution of $\tau_{xm}/\rho g H b$ in this region is minimum at $Y/Y_b=0.6$ and maximum at $Y/Y_b=0.3$ where the velocity of the longshore current became significant as shown in Fig.9(b).

Bijker(1966) studied the problem of the bottom shear stress due to a combined wave and current action when they were given independently. In his theory, the bottom boundary layer was mainly determined by a current. So, when his results were applied to our experiments τ_{xm} surpasses τ_{ym} ($\tau_{xm}/\tau_{ym}>5$) in the whole range of the surf zone. However, because the longshore current is caused by waves, it can be thought reasonably that the boundary layer in the surf zone is determined almost by the wave characteristics and Bijker's theory can not be applied in the surf zone.

Therefore, the authors assume the effects of the longshore current on the bottom shear stress as follows:

Consider the water particle velocity which is composed of the wave and the longshore current just outside the bottom boundary layer as shown in Fig.10. In this figure, the following symbols are used:

U : the velocity of the longshore current.

u_{bm} : the maximum water-particle velocity by waves.

θ : the angle between the direction of wave propagation and a line normal to the shore line.

V : the composite water-particle velocity of the wave and the longshore current.

β : the angle between the direction of the composite bottom shear stress and a line normal to the shore line ($=\tan^{-1}(\tau_{xm}/\tau_{ym})$).

and \rightarrow indicates a vector. It is now assumed that the maximum bottom shear stress acts in the direction of the vector sum of the longshore current and the maximum water-particle velocity by the wave, which makes an angle $(\pi/2-\theta_m)$, and is expressed by the following relation,

$$\tau_m = \rho f |\vec{V}_m|^2$$

$$\text{where } |\vec{V}_m|^2 = (u_{bm} \cos \theta_m)^2 + (u_{bm} \sin \theta_m + U)^2 \quad (3)$$

and f is the friction factor. In this case, the longshore and the on-off-shore components of τ_m become

$$\tau_{xm} = \tau_m (u_{bm} \cos \theta_m) / |\vec{V}_m|$$

$$\tau_{ym} = \tau_m (u_{bm} \sin \theta_m + U) / |\vec{V}_m| \quad (4)$$

and the following relation can be obtained,

$$\frac{\tau_{xm}}{\tau_{ym}} = (\tan \theta_m + \frac{U}{u_{bm}}) \sec \theta_m \quad (5)$$

Now, let $(\tau_{xm}/\tau_{ym})_0$ be the ratio when there is no current ($U=0$), $(\tau_{xm}/\tau_{ym})_0 = \tan \theta_m$ from eq.(5), and eq.(5) can be written as

$$\left(\frac{\tau_{xm}}{\tau_{ym}} - \left(\frac{\tau_{xm}}{\tau_{ym}} \right)_0 \right) \cos \theta_m = \frac{U}{u_{bm}} \quad (6)$$

Fig.11 shows the relation of eq.(6) where u_{bm} was calculated from the relation

$$u_{bm} = \sqrt{g(h+H)} (H/2h) \quad (7)$$

and H in eq.(7) was obtained from the experimental results.

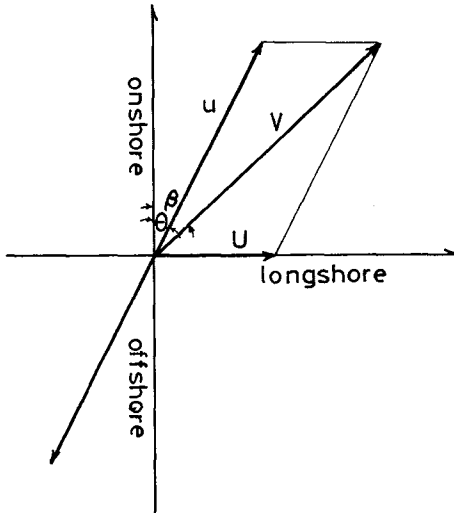

Fig.10 Composite water-particle velocity

Fig.11 Increase of the longshore component of bottom shear stresses due to longshore current.

It can be seen from Fig.11 that $(\tau_{bm}/\tau_{gm} - (\tau_{bm}/\tau_{gm})_0)\cos\theta_m$ increase linearly as U/u_{bm} increase regardless of H_0/L_0 . However, the gradient of the straight line drawn in Fig.11, which indicates the approximate relation between the two quantities of eq.(6), is about 1/2. From this fact, the velocity of the longshore current just outside the boundary layer assumes a value about half of the velocity at the surface and the following expression for τ_{bm}/τ_{gm} and τ_{bm} can be obtained,

$$\frac{\tau_{bm}}{\tau_{gm}} = \frac{U}{2u_{bm}\cos\theta_m} + \tan\theta_m \quad (8)$$

$$\tau_{bm} = (\tau_{bm}^2 + \tau_{gm}^2)^{1/2} = \left\{ \left(\frac{U}{2u_{bm}\cos\theta_m} + \tan\theta_m \right)^2 + 1 \right\}^{1/2} \tau_{gm} \quad (9)$$

However, there are some complexities involved calculating these components of the bottom shear stress according to eqs.(3) and (4), and the authors tried to express τ_{gm} by using the wave characteristics only as defined by

$$\tau_{gm} = \rho f_y u_{bm}^2 \quad (10)$$

Fig.12 shows the relation between f_y calculated from eq.(10) and the Reynolds' number $Ret = u_{bm}^2 T/\nu$, where T is the wave period, ν is a coefficient of the kinetic viscosity of the water, a_s is an amplitude of the water-particle movement just outside the boundary layer and k_s is the equivalent roughness element. The full line in this figure indicates the relation obtained from the laminor theory and the dotted line indicates the limit of the transitional range from laminor to turbulent flow condition obtained by Reidel et.al.(1972). It can be seen from Fig.12 that f_y calculated from our experiments are a few times larger than those in the laminor boundary layer.

From the results mentioned above, it can be seen that bottom shear stresses can be calculated easily from Fig.12 and eqs.(8),(9) and (10).

5-3. Relations between q_x and the bottom shear stress.

As shown in Figs.6.7 and 8, there exists a certain relation between q_x and the bottom shear stress. Therefore, the authors investigated the distribution of the longshore sediment transport rate along the beach profile, based on the measured results of the bottom shear stress by considering the velocity of the longshore current as a velocity of the sediment transport. However, since the bottom shear stress was measured on a smooth-fixed bottom, there still remains some questional problems as to whether the same bottom shear stress as measured on a fixed bed can be applied to a movable bed or not. According to Kajiura(1968), the flow condition in the bottom boundary layer in the surf zone was laminor or smooth-turbulent when the bottom was flat, and rough-turbulent when sand ripples were formed in a movable bed. However, in the surf zone, large turbulence was brought into the water from the surface by breaking. And it was estimated that the wave energy loss in the surf zone was some hundred times the amount of energy dissipated due to the bottom shear stress(Sawaragi et.al.(1974)). Therefore, the flow condition in the surf zone seems to determined by the intensity of the turbulence by wave breaking regardless of the bottom configurations. Hence, the application of the results in a fixed bed to the movable bed is justified. Figs.8 and 9(b) may verify the above-mentioned consideration to some extent.

Fig.12 Friction factor calculated from the on-offshore component of the bottom shear stress and water-particle velocity.

Fig.13 Distribution of u_x/W_o

That is, the conditions of the wave attenuation in the surf zone are similar and there seems to be no significant difference between the distribution profiles of the velocity of the longshore current of various bottom configurations. Therefore, the authors considered that the bottom shear stresses, as measured on the fixed bed, acted with almost the same intensity on the movable bed in the surf zone. Hence the longshore sediment transport rate can be expressed as a function of the bottom shear stress and the velocity of the longshore current.

Based on the above-mentioned way of thinking, the maximum longshore sediment transport takes place at the same location regardless of the size of the beach materials. However, this fact is different from the experimental results in that the location where the maximum longshore sediment transport of $d_{50} = 0.68^{mm}$ took place was shallower than that of $d_{50} = 0.34^{mm}$.

The sand trap shown in Fig.1 was used in our experiment for the purpose of recording the volume of the sediment which were transported as the bed load. In the region where the turbulence at the bottom is strong enough to bring the sediment into suspension from the bed, this kind of sand trap does not function effectively. Therefore, it is worthwhile to clarify the region where both bed materials of $d_{50} = 0.34^{mm}$ and 0.68^{mm} in the model beach experiments could be suspended in the surf zone.

It has been recognized that the criterion for the start of the suspension is determined by the ratio u_* / w_o where u_* is the bottom shear velocity and w_o is a falling velocity of the sediment and the region where the suspended load surpasses the bed load is also determined by u_* / w_o in the field of the open channel flow. For example, these limits concerning the suspension are given by Engelund(1965) and Shinohara (1959) as follow:

$$\begin{aligned} u_* / w_o > 1.0 & \dots \text{the start of suspension} \\ u_* / w_o > 1.7 & \dots \text{suspended load surpasses bed load} \end{aligned} \quad (11)$$

Fig.13 shows u_* / w_o against Y/Y_b calculated from the bottom shear stresses measured on a fixed bed and Rubey's formula for w_o with the parameter d_{50} and H_o/d_{50} . As can be seen from Fig.9, measured bottom shear stresses were scattered, u_* were calculated by using the averaged values of τ_{zm} and τ_{ym} at the same Y/Y_b from the relation

$$u_*^2 = \tau_m / \rho = (\tau_{zm}^2 + \tau_{ym}^2)^{1/2} / \rho$$

The criterions given by eq.(11) are indicated in Fig.13 by the dotted and the chain lines. According to these criterions, it is clear that when $H_o/d_{50} < 125$ ($d_{50} > 0.5^{mm}$), no suspension of the sediment can occur in the whole range of the surf zone, while in the case of $H_o/d_{50} > 200$ ($d < 0.3^{mm}$) the sediment is suspended in the surf zone and in the case of $H_o/d_{50} > 300$ ($d_{50} < 0.2^{mm}$), the volume of the sediment transported in suspension is larger than the volume of the sediment transported as bed load at the phase of the maximum bottom shear stress taking place. From these considerations, it can be assumed that in our experiments of the measurements of the sediment transport rates, sediment were transported almost as the bed load. However, a certain amount of the sediment

particles, which can not be predicted by the informations the authors have, were suspended in the region of $Y/V_b < 0.8$ in the case of $d_{50} = 0.34^{mm}$.

Taking account the above-mentioned considerations about the sediment transport, the authors tried to obtain the relationship between nondimensional longshore sediment transport rates q_x/Ud_{50} and nondimensional force of the sediment transport, $F = (u_*^2 - u_{*c}^2) / (\rho/\rho_s - 1)gd_{50}$, as shown in Fig.14, where u_* is given by eq.(12), ρ_s is the density of the sediment particle and u_{*c} is given by Iwagaki(1956) as follows:

$$\begin{aligned}
 u_{*c}^2 &= 80.9d_{50}^3, & \text{for } d_{50} > 0.303^{cm} \\
 &= 134.6d_{50}^{3/4}, & \text{for } 0.303^{cm} > d_{50} > 0.118^{cm} \\
 &= 55.0d_{50}, & \text{for } 0.118^{cm} > d_{50} > 0.0565^{cm} \\
 &= 8.41d_{50}^{1/2}, & \text{for } 0.0565^{cm} > d_{50} > 0.0065^{cm} \\
 &= 226d_{50}, & \text{for } 0.0065^{cm} > d_{50}
 \end{aligned}
 \tag{13}$$

Fig.14 Relation between non-dimensional longshore sediment transport rate and nondimensional force of sediment transport.

Although the data shown in Fig.14 are somewhat scattered, they can be approximately represented by the following two straight lines:

$$\begin{aligned} \frac{q_x}{U_{d50}} &= 86F^{3.7}, & \text{for } F \geq 0.3 \\ &= 23F^{4.5}, & \text{for } F < 0.3 \end{aligned} \quad (14)$$

In eq.(14), u_* in F can be predicted by eqs.(9) and (10). Therefore, the distribution of q_x can be calculated if the velocity of the longshore current is given.

The predicted distribution of q_x calculated from eq.(14) are compared with the measured distribution of q_x in the case of $H_0/L_0=0.04$ in Fig.15. Here, the longshore current velocity was calculated by the theory of Longuet-Higgins(1970). The parameter p defined by Longuet-Higgins in his theory was fixed at 0.4 based on the consideration that the location where the longshore current shows the maximum is at about $Y/Y_b=0.4$ as shown in Fig.9(b). In Fig.15, the predicted q_x is indicated as a non-dimensional quantity by dividing by the predicted maximum value. From Fig.15, it is found that the distribution of the measured q_x in the case of $d_{50}=0.68^{mm}$ where any suspension did not occur in the entire region of the surf zone coincides fairly well with the distribution predicted by eq.(14) and the longshore current velocity presented by Longuet-Higgins. However, the distribution of q_x in the case of $d_{50}=0.38^{mm}$ differs from the predicted distribution in the profile. In such conditions of the sediment transport as in the case of $d_{50}=0.38^{mm}$, a certain amount of sediment was brought into suspension in the surf zone and it seems necessary to clarify the mechanism of suspension of the bed materials in the surf zone and take account of the quantity of the sediment in suspension in eq.(14)

Fig.15 Comparison of the predicted and the measured longshore sediment transport rate.

6. Conclusion

The method to separately record the longshore and the on-offshore sediment transport rates, as the bed load, in the surf zone is developed, and the characteristics of the sediment transport in the surf zone are discussed from the bottom shear stresses measured on a fixed model beach.

The following conclusions are drawn from the foregoing study:

1. The distribution of the longshore sediment transport rate as the bed load shows a steep profile compared with the distribution of the longshore current and the maximum longshore sediment transport occurs at the place between the breaking point of incident waves and the location where the velocity of the longshore current shows the maximum value.

2. The maximum on-offshore sediment transport takes place at about the same place as the longshore sediment transport. However, the distribution of the on-offshore sediment transport rate shows more complicated profiles than that of the longshore sediment transport rate; the direction of the on-offshore sediment transport at any location changes with wave characteristics and beach slope from offshore direction to onshore direction.

3. The locations where the maximum longshore and on-offshore sediment transport take place are mainly controlled by the sediment size relative to the wave height.

4. The longshore current has less influence on the on-offshore component of the bottom shear stress than the longshore component, and within the range of the measurements where the wave directions at the breaking points are less than 20° , the on-offshore component of the bottom shear stress is greater than the longshore component of the bottom shear stress. This result differs from the result obtained by Bijker under the condition where waves and currents are given independently. However, the magnitude of the longshore component of the bottom shear stress is not so small as assumed by many investigators in the theory of the longshore current.

5. The longshore sediment transport rate when there are no suspended sediment can be represented by the function of the maximum bottom shear stress and the velocity of the longshore current. However, the estimation of the on-offshore sediment transport rate can not be represented by the maximum bottom shear stress. Further, there still remain some problems with regards estimating the on-offshore sediment transport rate and suspended load quantitatively.

CHAPTER 96

LITTORAL DRIFT ALONG BAYSHORE OF A BARRIER ISLAND

Yu-Hwa Wang* and T.H. Chang**

INTRODUCTION

A barrier island is an easily recognized geographical land feature along the south-east Atlantic and Gulf of Mexico coasts of the United States. It is characterized by a large ratio of length to width. It has a bay on one side and an ocean on the other. The inlets, on the ends, connect the bay to the ocean. The sand movement along the bayshore side is subjected to steeper and shorter waves which respond to local wind conditions. The physical boundary constraint of a bay is also different from open coast shorelines. Virtually no information exists with regard to the littoral drift rate on a bay shoreline. This paper tries to answer the question of whether or not the drift on the bay shoreline is different from that of the open coast since it is under different wave climates and physical constraints.

STUDY AREA

Santa Rosa Island is a barrier island situated on the west end of the Florida panhandle. It has the Gulf of Mexico on its south side and Santa Rosa Sound to its north. This barrier island has 48 miles of sand beaches on its Gulf and bay shores, which stretch eastward from Pensacola Beach to Fort Walton Beach. The average width, however, is approximately 1.5 miles. Santa Rosa Sound is 44 miles long and 2 miles wide. The study area was a highly-developed recreational community. A location map of the study area is given in Figure 1.

FIELD MEASUREMENTS

The breaker height, breaker angle and the longshore current were measured during the sampling operation (Wang et al, 1977). They are shown in the following table.

TABLE I

Date Mon./day	Breaker height (cm)	Breaker angle (degree)	mean longshore current u(cm/sec.)
2/15	15.2	11	7.4
2/15	12.7	10	7.0
2/16	10.2	9	7.4
2/16	11.4	10	6.2
2/17	8.9	12	10.5
2/17	10.2	7	5.7
2/18	15.2	10	5.1
2/18	12.7	12	8.8
2/19	15.2	13	7.2

The sand tracing method was used for determining the littoral transport rate. Sand was collected from the study site shortly before the tracing operation. This sand was coated with four colors of fluorescent dye in the Coastal and Oceanographic Engineering Laboratory (COEL), University of Florida. One hundred pounds of each of the four colored tracers were then injected back into the shoreline. A dredge-type sand sampler was used for collecting the samples, and the sampling stations were according to the predetermined coordinate system shown in Figure 2. Each sample was put into a sampling cloth bag with the station number marked on the label, and then sorted into sample sets for shipping to COEL for tracer counts in Gainesville. A series of equal concentration contour maps were produced. Figure 3 shows equal concentration contours for the blue tracer. The centroids of each contour map were calculated, and their longshore co-ordinates $(y_{\ell})_i$ were determined. $i = 1, 2, 3, \dots$

A tide gage and a wind anemometer were installed near the study area. Tidal curves and wind roses can be found in the report by Wang et al, 1977.

ESTIMATION OF LITTORAL TRANSPORT RATE

The water depth at the study site was shallow. The shoreline slope was rather flat with transverse bars at an angle with the shoreline (Wang et al, 1977). Wave conditions and currents at the study area correspond directly to the local winds. In order to account for the wind and tide induced currents it is considered that Bagnold's (1963, p. 518) formulation would be more appropriate for the present study,

$$I_{\ell} = K' w \frac{u}{u_m} \tag{1}$$

where the immersed transport rate is I_{ℓ} , the wave power $w = (EC)_b \cos \alpha_b$, E is the wave energy density, C the wave group velocity, α the breaking angle, subscript b meaning at wave breaking condition; the maximum orbital velocity $u_m = \sqrt{(2E/\rho h)}$; ρ is the water density; h , the water depth, and u is the average longshore current in the surf zone. The quantity $w(u/u_m)$ may be calculated from the field measurements in Table 1. I_{ℓ} is determined through the sand tracing technique. The longshore component of the advective velocity of the beach sand (considered same as the tracer sand) is calculated as

$$v = \frac{(y_{\ell})_2 - (y_{\ell})_1}{t} \tag{2}$$

where t is the time between sampling operations. The active depth d of the moving layer of beach sand was obtained by examining the eroding depth of a buried tracer column. It was determined to be 1/8 of an inch for the study area. The volume transport rate S_{ℓ} is then,

$$S_{\ell} = v d B$$

where B is the surf zone width. This volume transport rate S_{ℓ} is related to I_{ℓ} by $I_{\ell} = (\rho_s - \rho) g \beta S_{\ell}$. ρ_s and β stands for the density and the porosity correction of sand respectively.

The transport coefficient K' in equation (1) was determined by the data which were derived from the four color tracers; each color consisting

of nine sample sets. Only the blue tracer is presented here in Table 2.

TABLE 2

Sample sets	Date Mon/day/year	Time EST (hour)	I_s NT/Sec.	$W(u/u_m)$ Joules/Sec. M	K'
1	2/15/77	14:00	1.64	7.25	0.23
2	2/15/77	21:00	0.44	4.75	0.09
3	2/16/77	10:00	0.69	3.25	0.21
4	2/16/77	15:00	0.24	3.40	0.07
5	2/17/77	10:00	0.29	3.60	0.08
6	2/17/77	16:00	0.28	2.50	0.11
7	2/18/77	10:00	0.77	5.10	0.15
8	2/18/77	16:30	1.46	6.08	0.24
9	2/19/77	12:00	1.39	7.00	0.20

I_s 's for the blue tracer in Table 2 as well as for other three colors were then plotted against the quantity of $w(u/u_m)$. A regression line through the data points was drawn and shown in Figure 4. The regressional transport coefficient was determined to be $K' = 0.18$. The statistical analysis of the data, including the test of fit of the data, may be found in Chang (1978), Chang and Wang (1978).

DISCUSSION OF RESULTS

1. The calculated regression coefficient $K' = 0.18$ is approximately 36% smaller than the value 0.28 for open coast given by Komar in 1969.
2. There are, in general, two difficulties involved in a sand-tracing operation. First, the conservation of the tracer within the sampling area is often violated due to (a) loss of tracer seaward of the surf zone, (b) tracer moving out of the sampling area and (c) tracer loss due to burials. Secondly, the determination of the active moving layer depth and its vertical variations are uncertain. However, these were not the problems in the present study. Following a single injection of 100 pounds each of the four colors of fluorescent tracer; there were nine consecutive sampling operations covering a time span of five days. The nine equal concentration contour maps of the blue tracer (the other 3 colors as well) have shown that much of the tracers remain in the sampling region after 5 days. The depth of active moving sand layer on the bayshore was small (1/8 inch), and therefore there was very little or no loss of tracer due to burial.
3. The tide and wind induced currents were taken care of by using Bagnold's formula for sediment transport rate calculations.
4. The tracer dispersal pattern was characterized by closed loops and islands in the equal concentration contour maps. These peaks and valleys on the maps correspond to the bathymetry configurations. The low transverse bar tends to collect tracer on its troughs and less tracer on its broad crests (Wang et al, 1977).
5. The concentration of tracers in the injection area were noticeably increased in Figure 3. i, from the previous contour map. This indicated a strong onshore movement which may have been induced by an onshore wind-driven current.
6. All nine centroids of equal concentration contour maps were collected and plotted in Figure 5. The centroids are marked with letters which correspond to the sequence of the contour maps in Figure 3. A study of the movement of these centroids revealed the following interesting observations.
 - (a) The tracers were injected 25 feet from the water's edge (see Figure 3). Four hours after the injection the centroid #a moved out a distance approximately 80 feet from the water's edge.
 - (b) Several reversals of the drift direction during the five day period were clearly observable. The sand transport was longshore dominant. The on/off shore transport was relatively small compared to their longshore component.
 - (c) All nine centroids were in the region approximately 65 to 80 feet from the water's edge. This peculiar character may be explained by the fact that the coating of the local sand with fluorescent dye resulted in an increase of sand particle volume, consequently, a decrease of the specific gravity. When tracers were injected back in to the shoreline they were subjected to a wave-sorting process and moved bayward

Figure 5. A Collection Of The Centroids From Figure 3

because the tracers were lighter than the local sand at the injection point. This may raise a question concerning the accuracy of the convective velocity V defined in equation (2). Perhaps the distance between the injection point and the centroid of the first contour map should be adjusted to account for the wave sorting effect. It is however not clear how one can perform this adjustment properly.

ACKNOWLEDGEMENT

The field data collection work was sponsored by Corps of Engineers, Mobile District, Alabama. The analysis was supported by Engineering and Industrial Experimental Station, University of Florida. Their financial assistance is gratefully acknowledged.

CHAPTER 97
SEDIMENT LOAD UNDER WAVES AND CURRENTS

by

D.H. Willis
Associate Research Officer
National Research Council of Canada

ABSTRACT

A technique is proposed for calculating sediment load, the mass concentration of sediment in motion, under combinations of waves and currents. The technique is based on the unidirectional flow method of Ackers and White, Ref. 1. The calibration of the technique against measurements of sediment load under waves has only just begun.

SEDIMENT LOAD

Sediment load is not sediment transport. It is an essential part of sediment transport, the concentration by mass of sediment in motion, but it requires the presence of a current to transport it from one place to another.

Although I will primarily deal with sediment load under waves, or waves and currents, the concept is best grasped for the case of currents alone. In this case there is, of course, always a current and therefore always a sediment transport. Sediment load is then the mass rate of sediment transport divided by the mass rate of current discharge.

The sediment load concept is however most useful when there are only very small currents, for example the mass transport associated with water waves. Here the sediment load due to the oscillatory wave motion may be quite high, but because of the very small currents involved, sediment transport calculations frequently fail. It is still handy to know how much sediment is available to fill in your navigation channel, even if you remain unsure of the rate at which infilling takes place.

We, at the Hydraulics Laboratory of the National Research Council of Canada, have therefore undertaken a program to develop a technique for calculating sediment loads under combinations of waves and currents, covering the range from currents only to waves only. We are initially aiming for a technique applicable seaward of the breaker line, but will not be at all disappointed if it turns out to be useful in the surf zone as well.

Like Swart in Ref. 13, I chose as a basis the method of Ackers and White, Ref. 1, for calculating sediment load in currents only. Their method has proved to be very

successful in predicting sediment loads in rivers, see for example Fleming and Hunt, Ref. 3. The theoretical modification of the Ackers and White method for the presence of waves is virtually complete. But in making that modification, I added a new empirical coefficient, the calibration of which has only just begun. This then is a report on work in progress.

ACKERS AND WHITE METHOD

The technique of Ackers and White, see Ref. 1, was developed for calculating the sediment load in unidirectional flow over an alluvial bed. Ackers and White take a transporting power approach: the work done in moving sediment is the product of the power available to move the sediment and the efficiency of the system.

Despite its being a total load concept, their derivation does make a distinction between bed load and suspended load. But the distinction is made, not on the basis of position in the water column, but rather on dimensionless grain size,

$$D_{gr} = D \left(\frac{g(s-1)}{v^2} \right)^{\frac{1}{3}} \quad (1)$$

Coarse material, $D_{gr} \geq 60$, is considered to be moved as bed load. Grains are rolled along the surface of the bed by the component of bed shear parallel to the local bed surface,

$$\tau_{cg} = \rho \frac{V^2}{C_{hcg}^2} \quad (2)$$

$$\text{where } C_{hcg} = 5.75 \log \frac{11d}{D} \quad (3)$$

Fine material, $D_{gr} \leq 1$, is moved as suspended load. The turbulence which keeps the grains in suspension is a function of the total shear on the bed,

$$\tau_{fg} = \rho \frac{V^2}{C_{hfg}^2} \quad (4)$$

$$\text{where } C_{hfg} = 5.75 \log \frac{11d}{r} \quad (5)$$

The total shear includes components both parallel and normal to the local bed surface

The power per unit area available to move sediment then becomes

$$\begin{aligned} P_{cg} &= \tau_{cg} V \\ \text{and } P_{fg} &= \tau_{fg} V \end{aligned} \quad (6)$$

It is not my purpose to repeat the derivation by Ackers and White here. You are instead referred to Ref. 1. It will I hope suffice to say that they develop two sets of relationships, one for coarse grains and one for fine grains. Transition sizes, $1 < D_{gr} < 60$, are handled by mixing the relationships using an exponent, n . This is illustrated by the Ackers and White mobility number,

$$F_{gr} = \frac{u_{*fg}^n u_{*cg}^{1-n}}{\sqrt{gD}(s-1)} \quad (7)$$

where the shear velocity is as usual,

$$u_* = \sqrt{\frac{\tau}{\rho}} \quad (8)$$

An important feature of the method, and one which makes it almost unique, is the inclusion of a criterion for the beginning of sediment motion, the threshold of movement. This is expressed as a critical value of the mobility number, F_{gr_c} , below which no sediment motion takes place. They then derive the following expression for sediment load:

$$X = C \left(\frac{F_{gr}}{F_{gr_c}} - 1 \right)^m \frac{sD}{d} \left(\frac{\rho^{\frac{1}{2}} P_{fg}}{\tau_{fg}^{\frac{3}{2}}} \right)^n \left(\frac{P_{cg}}{\tau_{cg} V} \right)^{1-n} \quad (9)$$

In the currents only case of Ackers and White, this reduces to

$$X = C \left(\frac{F_{gr}}{F_{gr_c}} - 1 \right)^m \frac{sD}{d} C_{hfg}^n \quad (9a)$$

At this point, the values of C , F_{gr_c} , m and n are still undefined. Ackers and White considered them to be empirical coefficients and calibrated them against over 1000 field and laboratory measurements of sediment load, obtaining

$$\log C = 2.86 \log D_{gr} - (\log D_{gr})^2 - 3.53, \quad (10)$$

$$2.95 \times 10^{-4} \leq C \leq 0.025$$

$$F_{gr_c} = \frac{0.23}{\sqrt{D_{gr}}} + 0.14, \quad 0.17 \leq F_{gr_c} \leq 0.37 \quad (11)$$

$$m = \frac{9.66}{D_{gr}} + 1.34, \quad 1.5 \leq m \leq 11.0 \quad (12)$$

$$n = 1 - 0.56 \log D_{gr}, \quad 0 \leq n \leq 1 \quad (13)$$

MODIFICATION FOR WAVES

My principal criterion in modifying the Ackers and White method for the presence of both waves and currents, was that the basic method as set out in Ref. 1 should remain intact

when no waves were present. Ackers and White have, after all, calibrated their method against more than 1000 measurements, and such a wealth of data can not be lightly tossed aside.

Vector addition of wave and current velocities produces a shear relationship which meets that criterion. Shear is proportional to the instantaneous velocity squared:

$$V_{TOT}^2 = (V + u_o \sin \frac{2\pi t}{T} \cos \alpha)^2 + (u_o \sin \frac{2\pi t}{T} \sin \alpha)^2 \quad (14)$$

Averaging V_{TOT}^2 over a wave period,

$$\overline{V_{TOT}^2} = V^2 + \frac{u_o^2}{2} \quad (15)$$

which is independent of direction.

If we assume that the unidirectional Chézy friction factor can be applied to the unidirectional term only, the Jonsson wave friction factor, $f_w/2$ see Ref. 6, to the oscillatory term only, and that f_w is independent of wave phase, we obtain for the combined bed shear

$$\tau = \rho \left(\frac{V^2}{C_h^2} + \frac{f_w}{4} u_o^2 \right) \quad (16)$$

Power is a scalar, and therefore we only need obtain an expression for the wave power available to move sediment and add that to the unidirectional term, Equation (6). The wave power per unit area, available to move sediment is

$$P_w = E \frac{dC_g}{dx} + C_g \frac{dE}{dx} \quad (17)$$

Since a locally horizontal bed is assumed in the Ackers and White method, C_g does not vary with distance and

$$P_w = C_g \frac{dE}{dx} \quad (17a)$$

There are a number of factors affecting the wave energy attenuation, dE/dx : bed friction, bottom percolation, surface contamination, to name a few. But we are only interested in that part of dE/dx available to move sediment, the part due to bottom friction or bed shear. Therefore

$$P_w = C_g \rho \frac{f_w}{4} u_o^2 \quad (17b)$$

The total power per unit bed area under waves and currents then becomes

$$P_w = \rho \left(\frac{V^2}{C_h^2} V + C_g \frac{f_w}{4} u_o^2 \right) \quad (18)$$

Subscripts have been dropped from Equations (16) and (18) but there are fine grain and coarse grain versions, analogous to Equations (2), (4) and (6). In both Equations (16) and (18), the first term is that for currents only, as in the Ackers and White method, with the second term adding the wave effect.

One further modification is necessary to compensate for the fact that the threshold of sediment motion is different under waves than under unidirectional flow. If the expression for F_{grc} , Equation (11), is modified, as Swart has done in Ref. 12, then it ceases to be a function of D_{gr} alone; it also becomes a function of the flow conditions. However, the flow conditions are already contained in the mobility number, F_{gr} Equation (7), by way of the modified shear stress of Equation (16). I therefore decided to leave the threshold of movement criterion alone, and further modify the shear stress to compensate for differences in wave and current thresholds. A new empirical coefficient, W_c , was added to the wave terms of Equation (16) and (18), which become respectively:

$$\tau = \rho \left(\frac{V^2}{C_h^2} + W_c^2 \frac{f_w}{4} u_o^2 \right) \quad (19)$$

$$P = \rho \left(\frac{V^2}{C_h^2} V + W_c^2 C_g \frac{f_w}{4} u_o^2 \right) \quad (20)$$

THRESHOLD OF MOVEMENT

Equations (19) and (20) not only reduce to their unidirectional flow forms when no waves are present, but when no currents are present they also reduce to their wave terms. It should therefore be possible to calibrate W_c against measurements of sediment load under waves alone.

Twenty-seven suitable measurements of sediment load under waves were found in the literature, 4 field measurements of which one included a current velocity, and 23 laboratory measurements. "Suitable" simply means that enough data were presented to allow an Ackers and White calculation of sediment load to be made and a value of W_c to be determined. Even for such "suitable" measurements, it was usually necessary to make one or more of the following assumptions:

1. Mass density of sea water, 1020 kg/m^3 , or of fresh water, 1000 kg/m^3 .
2. Mass density of sand, 2650 kg/m^3 .
3. Kinematic viscosity of laboratory water, $1 \times 10^{-6} \text{ m}^2/\text{s}$ (20°C), or of sea water $1.3 \times 10^{-6} \text{ m}^2/\text{s}$ (10°C).
4. Ripple dimensions given by the design curves of Mogridge, Ref. 10.

The 27 measurements are summarized in Table I. In all cases, sediment load was presented as a plot of concentration vs. depth. I integrated these plots, either analytically or numerically, from water surface to bed to obtain the total load, X , shown on Table I. The column headed " F_{grC} Required" is the value of the threshold of movement necessary to make the computed sediment load agree with the measured, and "Equivalent W_c " is the adjustment required to the wave shear.

The computed thresholds are plotted on Fig. 1 as Shields parameter, θ , against dimensionless grain size, D_{gr} . The Shields parameter is simply the square of the Ackers and White mobility numbers, F_{gr} or F_{grC} . The following are also plotted on Fig. 1.

1. The Shields curve, Ref. 11, for threshold of movement under unidirectional flow over a plane bed. Threshold was determined by observation and is somewhat subjective. It may be useful to note that, plotted in this way with D_{gr} as the abscissa rather than shear Reynolds Number, the Shields curve can be used without iteration to determine a critical shear stress for a given sediment.
2. The Ackers and White threshold of movement criterion, Equation (11), for unidirectional flow over a rippled bed. This criterion has been inferred from measured rates of sediment transport, and may therefore be more objective than the Shields curve.
3. Thirty-five points presented by Komar and Miller, Ref. 8, for threshold of movement under oscillatory flow. These points come from a variety of sources, but in general are the result of observation of the initiation of motion on a plane bed.

Most of the oscillatory flow points lie above the two curves for unidirectional flow. However, the data of Bhattacharya, Ref. 2, which forms the majority of my 27 calibration points, seems to require a significantly lower threshold of movement than either the unidirectional criteria or the rest of the oscillatory flow data. Thirteen of the 21 points from Ref. 2 fall below both the Shields and the Ackers and White curves, while only one of the remaining 41 points does so. This may be a bed slope effect, Bhattacharya did his measurements on a laboratory beach, but whatever the reason, it was with some regret that I decided to ignore his data for the rest of the analysis.

The remaining oscillatory flow points on Fig. 1 show no clear trend, other than that there appears to be a higher threshold of movement under oscillatory than under unidirectional flow. Madsen and Grant, Ref. 9, concluded that the Shields curve adequately described the threshold in oscillatory flow. Certainly for large grains, $D_{gr} \geq 100$, the Shields

FIG.1 THRESHOLD OF MOVEMENT

curve is a better lower envelope to the oscillatory flow threshold than the Ackers and White curve. The value of W_c needed to make the two curves coincide here is 0.76. However, at the lower end, $D_{gr} \leq 10$, the Ackers and White criterion is a better lower envelope, implying $W_c = 1$. Perhaps overall W_c varies inversely with D_{gr} , but as an interim measure, I have taken it as a constant, $W_c = \sqrt{0.6}$, in Equations (19) and (20), making them

$$\tau = \rho \left\{ \frac{V^2}{C_h^2} + 0.6 \frac{f_w}{4} u_o^2 \right\} \quad (21)$$

$$P = \rho \left\{ \frac{V^2}{C_h^2} V + 0.6 C_g \frac{f_w}{4} u_o^2 \right\} \quad (22)$$

FUTURE WORK

There is clearly a need for more data, in particular for a consistent set of sediment load measurements covering the full range of dimensionless grain sizes. We at the National Research Council of Canada are presently collecting that data in a wave flume, varying grain size and density, water depth, and height and period of the regular waves. Sediment load is determined by counting particles in the narrow column illuminated by a vertical laser beam.

I must emphasize again that the work reported here is still very much in progress. The quoted value of $W_c = \sqrt{0.6}$ must be regarded as a temporary measure until either confirmed or replaced by something better as a result of the on-going flume tests.

ACKNOWLEDGEMENTS

I particularly want to thank Dr. C.A. Fleming for pointing out that what really needed modification for waves in the Ackers and White method was the threshold of movement criterion.

My thanks also go to Ir. J. Moes and Dr. G.R. Mogridge for their day-to-day help and advice, and for their critical reading of this paper.

APPENDIX II

SUMMARY OF METHOD

1. Calculate D_{gr} from Equation (1)
2. Calculate empirical coefficients, C , F_{grc} m and n from Equations (10), (11), (12) and (13)
3. Calculate the dimensionless Chézy coefficients Ch_{cg} and Ch_{fg} using Equations (3) and (5).

4. Calculate the Jonsson wave friction factors,

$$f_{w_{cg}} = \exp(-5.98 + 5.21 \left(\frac{d_o}{2D}\right)^{-0.19}) \quad \left. \vphantom{f_{w_{cg}}} \right\} f_w \leq 0.30 \quad (23)$$

$$f_{w_{fg}} = \exp(-5.98 + 5.21 \left(\frac{d_o}{2r}\right)^{-0.19}) \quad (24)$$

These approximate formulae are from Swart, Ref. 13.

5. Calculate bed shears, τ_{cg} and τ_{fg} , using Equation (21) and convert to shear velocities, u_{*cg} and u_{*fg} , with Equation (8).
6. Calculate powers, P_{cg} and P_{fg} , using Equation (22).
7. Calculate the mobility number, F_{gr} , using Equation (7).
8. Calculate sediment load by Equation (9).

CHAPTER 98

SEDIMENT TRANSPORT AND RIPPLES DUE TO WAVES AND CURRENTS

Zbigniew PRUSZAK* and Ryszard B. ZEIDLER**

ABSTRACT

Water velocities and shear stresses have been determined for a laminar boundary layer of a progressive wave travelling over a regular series of ripples. The Lavrentiev variational method was used to transform conformally the water area with ripples into a strip with flat bottom, while the Lin approach permitted solution of the boundary layer equation.

The theoretical prediction of the bed friction was verified experimentally with a new mechanical apparatus.

By coupling the theoretical shear stress at the rippled bed with laboratory data for ripple parameters one can expose the friction conditions that control the growth and decay of ripples. If waves develop higher values of shear stress, the rippled bed becomes gradually washed out. For known shear stresses, basing on the Frijlink-Bijker formula one can compute sediment transport rates. In the respective diagram, a curve of s.t. rate versus bottom friction consists of two branches. The stages of the growth and decay of ripples are reflected in the lower and upper branches of the curve. For identical ripple height there are two values of s.t. rate, for two different wave intensities, likely to differ by as much as 25 per cent.

Three-dimensional ripples have been analyzed with regard to bed friction and compared with two-dimensional conditions.

BOUNDARY LAYER ON RIPPLES

The dynamics of sediment and ripples depends on the characteristics of boundary layer. In order to analyze this dynamics it is reasonable to map conformally the area of motion over ripples, solve equation of motion in the basic flow region, use this solution as a background for a boundary layer equation, and determine motion inside the boundary layer. The following assumptions were made in the analysis :

- 1 Regular series of impermeable sinusoidal ripples preserve their form during motion
- 2 Ripples are exposed to regular progressive small-amplitude waves with wave height h and period T
- 3 Oscillatory boundary layer is laminar
- 4 Regular eddies are generated by waves in ripple troughs.

As shown by experiments, laminar flow at rippled bed under oscillatory motion is fairly stable. The assumption on eddies is an outcome of the studies by Sleath [6] .

A method derived by Lavrentiev [3] has been employed in our conformal mapping. The method is particularly suitable for cases with slightly different original and mapped areas of motion. Two subsequent stages of mapping, from original area with ripples, of depth H , to an elementary strip with flat bottom, are presented in Fig.1.

In the dimensionless form, the formula of mapping reads

$$w=f(z) \approx \left[\bar{x} + \frac{\eta}{2} \coth\left(\frac{2\pi H}{\lambda}\right) \sin\frac{2\pi\Delta x}{\lambda} \cosh\frac{2\pi\Delta y}{\lambda} \right] + \dots 1$$

$$+ i \left[\bar{y} + \frac{\eta}{2} \coth\left(\frac{2\pi H}{\lambda}\right) \cos\left(\frac{2\pi\Delta x}{\lambda}\right) \sinh\left(\frac{2\pi\Delta y}{\lambda}\right) \right] = u(x,y) + iv(x,y)$$

in which $z = \bar{z} + \Delta z$ with the following intervals of variation

$$\begin{array}{ll} -\infty < \bar{x} < \infty & - \eta/2 \leq \Delta y \leq \eta/2 \\ 0 < \bar{y} < H & - \lambda \leq \Delta x \leq \lambda \end{array}$$

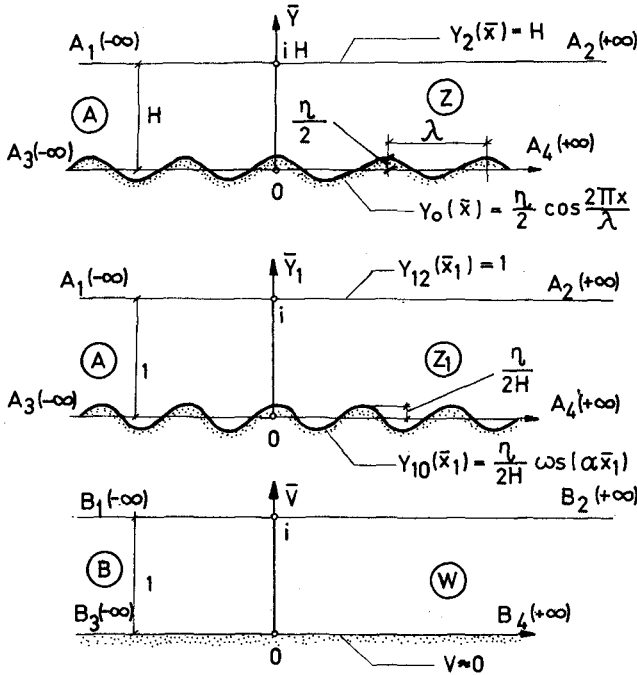

Fig.1 - Conformal Mapping

The complex velocity potential in the strip w can be chosen as

$$W(w) = \phi(u, v, t) + i \psi(u, v, t) = \frac{h \omega \cosh kv}{2k \sinh kH} \sin(ku - \omega t) + \dots 2$$

$$+ i \frac{h \omega \sinh kv}{2k \sinh kH} \cos[ku - \omega t]$$

By substituting (1) in (2) and assuming $v \approx 0$ for the lower boundary in the strip w , or $\sinh^2 kv(x, y) \approx 0$, one obtains the following velocity at the upper limit of the boundary layer

$$\begin{aligned}
 u_1(x,y,t) = & \frac{\cosh kv(x,y)}{\sinh kH} \cos[ku(x,y) - \omega t] \left\{ 1 + 2\pi \frac{\eta}{\lambda} \coth\left(\frac{2\pi H}{\lambda}\right) x \right. \\
 & \times \cos\left(\frac{2\pi \Delta x}{\lambda}\right) \cosh\left(\frac{2\pi \Delta y}{\lambda}\right) + \pi^2 \left(\frac{\eta}{\lambda}\right)^2 \coth^2\left(\frac{2\pi H}{\lambda}\right) \cos^2\left(\frac{2\pi \Delta x}{\lambda}\right) \times \dots 3 \\
 & \left. \times \cosh^2\left(\frac{2\pi \Delta y}{\lambda}\right) + \pi^2 \left(\frac{\eta}{\lambda}\right)^2 \coth^2\left(\frac{2\pi H}{\lambda}\right) \sin^2\left(\frac{2\pi \Delta x}{\lambda}\right) \sinh^2\left(\frac{2\pi \Delta y}{\lambda}\right) \right\}^{1/2}
 \end{aligned}$$

One can now proceed to solution of a boundary layer equation. In 1957 Lin presented the following approximation for an unsteady laminar boundary layer:

$$\frac{\partial u}{\partial t} = \frac{\partial U}{\partial t} + \nu \frac{\partial^2 u}{\partial y^2} \dots 4$$

The well-known boundary conditions are

$$u = 0 \text{ at } y = 0 \text{ and } u = U \text{ at } y \rightarrow \infty \text{ (or } y \rightarrow \delta \text{)}$$

It is possible to determine the error of the linearization inherent in Eq.4. Using Eq.3 and by comparison of the nonlinear term $U \frac{\partial U}{\partial x}$ to $\frac{\partial U}{\partial t}$ one can find the linearization errors for various values of ripple steepness. They are shown in Fig.2, for the most inaccurate situation with U_1 , at the upper limit of the boundary layer.

Fig.2 - Linearization Error

In general, the Lin method proves to be acceptable for fairly small bed microforms, under the studied conditions with wave periods from 1 to 2.5 (5) seconds.

The following solution [4] can be obtained from Eq.4

$$u(x, y, t) = U_{max}(x) \left\{ \cos[ku(x, y) - \omega t] - \exp(-\beta y_1/X) \cos[ku(x, y) - \omega t + \beta y_1/X] \right\} \quad \dots 5$$

in which

$$U_{max}(x) = \frac{h\omega}{2} \frac{\cosh kv(x, y)}{\sinh kH} \times \sqrt{1 + 2\pi \frac{R}{\lambda} \coth\left(\frac{2\pi H}{\lambda}\right) \cos\left(\frac{2\pi \Delta x}{\lambda}\right) + \cosh\left(\frac{2\pi \Delta y}{\lambda}\right) + \pi^2 \left(\frac{R}{\lambda}\right) \coth^2\left(\frac{2\pi H}{\lambda}\right) \cos^2\left(\frac{2\pi \Delta x}{\lambda}\right) \cosh^2\left(\frac{2\pi \Delta y}{\lambda}\right) + \pi^2 \left(\frac{R}{\lambda}\right)^2 \coth^2\left(\frac{2\pi H}{\lambda}\right) \sin^2\left(\frac{2\pi \Delta x}{\lambda}\right) \sinh^2\left(\frac{2\pi \Delta y}{\lambda}\right)} \quad \dots 6$$

and X is the vortex-effect parameter introduced by Sleath. By analogy, one can suggest the following formula for the bed friction

$$\tau_o^* = \frac{2\sqrt{2}}{\omega h} \frac{U_{max}}{X_o} \cos\left[ku(x, y) - \omega t + \frac{\pi}{4}\right] \quad \dots 7$$

in which $X_o \neq X$.

In order to determine the parameter X_o we used the data measured by Kalkanis [2]. From the comparison of this data and the results predicted by formula (7) it follows that X_o depends on $R = U_{max} \cdot \eta^2 \cdot \beta \cdot \nu^{-1}$

$$X_o \approx 0.3 R^{0.165} \quad \dots 8$$

An example of the computed velocity profiles is presented in Fig. 3. From analysis of the velocity fields it is clear that both velocities and their gradients above

Fig.3 - Velocity Profiles in Boundary Layer

the ripple crests increase with decreasing depth of water and increasing height of water waves. The magnitudes above ripple troughs are much lower than those over the crests. The local excess of u over U , for $1.5 \leq y_1 \cdot \beta \cdot x^{-1} \leq 4.0$, is likely to be caused by the eddies generated about ripples.

The distribution of computed bed friction on ripples, both in time and space, is shown respectively in Figures 4a and 4b. In Fig.4a it can be seen that the maximum bed friction is shifted by $\omega t = \frac{\pi}{4}$ with regard to the wave crest. The values drawn in the diagram correspond to strictly defined instants, different for various points on the ripples, as if independent of the conditions in their neighborhood. On the other hand, presented in Fig.4b is the distribution generated over a certain section with ripples, as if the

Fig.4a - Temporal Variation of Bed Friction During Consecutive Wave Phases ωt

Fig.4b - Distribution of Maximum Bed Friction (for $\omega t = \frac{\pi}{4}$)

wave crest occurred at each ripple. In reality, the distributions vary in time and space, and both figures have to be combined.

EXPERIMENTAL VERIFICATION

The theoretical prediction of the bed friction on ripples was checked experimentally with a new device shown in Fig.5.

Fig.5 - Apparatus for Measurement of Bed Friction

The apparatus consists of an organic-glass cylinder, mostly sheltered in its body, the latter being flush with the crest of a ripple. The forces induced by waves are exerted in a narrow upper part of the cylinder, in the slit of the concrete ripple segment. The principle of operation consists in an angular displacement of the cylinder under the action of water. The mass of the cylinder is distributed so accurately that it moves even if minute forces are applied to its surface and returns very fast to its original position after the force is removed. Owing to a system of transverse scratches, the roughness of the exposed surface of the

cylinder is identical with that of the concrete ripples. At present, measurements of displacements of the cylinder are conducted by visual means; the calibration curve permits translation of displacements into forces. The bearing friction and the drag forces acting on the working surface of the cylinder are deducted from the total force measured with the apparatus.

The measurements of the bed friction were carried out in a wave flume with the rippled bed, a section of which is depicted in Fig.5. The waves generated in the flume had periods from 1.5 to 2.7 seconds. Because of technical difficulties, it was only a few ripple-and-wave combinations that corresponded to each other: the concrete ripple segments had forms identical with those generated by their water wave counterparts. Other pairs were incoherent, so that the results obtained for them should be treated with caution. In Table 1 they are marked with asterisks. - As can be seen from the comparison in Table 1, the computed bed friction exceeds the measured values by 10 to 40 per cent. These figures are yet smaller, below 30 percent, if one takes into account the resistance at the bearings of the measuring device. Thus, it can be claimed that the theoretical prediction of the bed friction presented in the previous section is close to reality and that the apparatus, even in its prototype version, is a promising tool in laboratory investigations.

BED FRICTION AND SEDIMENT TRANSPORT ON RIPPLES

By coupling the theoretical bed friction at rippled bed with laboratory data for ripple parameters one can expose the friction conditions that control the growth and decay of ripples. The findings for ripple height are shown in Fig.6. Four different zones, separated by three critical lines of bed friction, can be distinguished. For bed friction lower than τ_{1c} it is only the movement of single sand grains, on a flat bed, that is possible. The zone of the generation of eddies and single ripples (whichever come first) stretches

between τ_{1cr} and τ_{2cr} , while series of ripples are formed between τ_{2cr} and τ_{3cr} . The line of τ_{3cr} marks the conditions under which the growth of ripples is completed. If waves generate higher stresses at the ripples, the latter become gradually washed out. For the sand used in our wave flume (with $D_{50} = 0.025$ cm and density of 2.65 gram per cubic cm) the ripples created by lower waves are unable to withstand (without irreversible deformations) shear stresses over 0.005 to 0.006 $\text{kg cm}^{-1}\text{s}^{-2}$. It can be assumed that ripples become completely destroyed if shear stresses at the bed reach 0.01 $\text{kg cm}^{-1}\text{s}^{-2}$. Under these conditions, with reconstructed flat bed, water carries suspended sediments of high concentrations.

One of the opportunities offered by the theoretical prediction of shear stresses consists in the computation

Fig.6 - Ripple Height Versus Bed Friction

of sediment transport rate, one of the most important quantities in the coastal dynamics. The computation can be based on the Frijlink formula (which is also used by Bijker [1]). Some results are presented in Fig.7 for various wave periods and velocities of longshore currents. The latter have been included in order to generalize the findings, but they are not necessary to draw the conclusions presented below. The picture illustrates general trends only, because the values of s.t. rates are local, as they were computed for the crest of the "first" ripple (where the boundary layer begins to develop). The s.t. rates averaged over the ripple length are smaller by three orders of magnitude. For comparison, analogous rates are also given for flat bed (dots for D_{50}). It should be mentioned that higher s.t. rates for rippled bed (than for flat bed) are not paradoxical: higher ripples

Fig.7 - Sediment Transport Rate Versus Ripple Height

bring about more resistance to motion of water but it must be remembered that, at the same time, they are produced by stronger waves.

The stages of the growth and decay of ripples are reflected respectively in the lower and upper branches of the curves. From a similar trend observed in the wave tank it can be inferred that sediment transport sometimes differs considerably for seemingly close bed roughness conditions. For the same ripple height there occur two different values of the sediment transport rate. Depending on the strength of wave motion, which is coupled with shear stresses at the bed, a given ripple with a certain height can be in the stage of growth or washout, and the corresponding s.t.rates can differ by as much as 25 per cent.

In many existing formulas for sediment transport rates (for example, those derived by White and Ackers, Engelund and Hansen, and Bijker) the rippled bed is represented by the equivalent roughness height r . The results of this study can be used to substantiate the choice of this parameter and to revise the assumptions on r made hitherto.

THREE - DIMENSIONAL EFFECTS

Under complex conditions of coastal zones, with various systems of currents and waves and diversified configuration of beach, bed microforms are usually three-dimensional (Fig.8).

Fig.8 Three-dimensional Bed Forms in PAS-IHE Wave Tank

It is interesting to determine the origin and transformation of these forms and expose general relationships of the type $\eta, \lambda = f(\tau)$, as shown for two-dimensional forms.

Parameters of three-dimensionality can be chosen in a dozen of ways. In our analysis of the results obtained in a wave tank for two angles of wave incidence, 45° and 0 to 5° , we confined ourselves to three parameters: ripple height η , ripple length λ and the angle between ripple and local wave crest (Fig.9), Δ .

Fig.9 Ripple Misalignment Angle versus Shear Stress

The three parameters have been investigated as functions of shear stresses computed as if the ripples were two-dimensional. Thus, our definition of three-dimensionality is fairly arbitrary : 3-D conditions differ from 2-D configurations mostly by oblique layout of ripples. The angles $0 \leq \psi \leq 5^\circ$ are usually linked with 2-D ripples, provided however that coastal currents are secondary (although the reverse is encountered most often).

As can be concluded from Fig.9, small angles of wave incidence (normal attack) are connected with minor misalignment of ripples, but even small changes in the layout of ripples induce considerable increase in shear stress. These situations embody local gradential currents. For oblique incidence of waves, with more pronounced longshore currents, the misalignment

angle Δ increases much stronger as the waves approach beach, and shear stress at the bed also increases. Both curves in Fig.9 merge at the abscisae axis about the shear stress $\tau = 0.006 \text{ kg}\cdot\text{cm}^{-1}\cdot\text{s}^{-2}$. This marks the limit at which three - dimensional ripples begin to appear in the wave tank.

Fig.10 Height of 3-D and 2-D Ripples

Fig.11 Length of 3-D and 2-D Ripples

Figures 10 and 11 present heights and lengths of three-dimensional ripples; 2-D ripples are also shown for comparison. The curves suggest that the processes of the generation and decay of ripples are similar for 2-D and 3-D forms. The shift of 3-D curves, with regard to 2-D curves, is partially caused by cementing of sediments in the open-air wave tank, attacked by plankton and silt.

Three-dimensionality of bed microforms in the presence of waves and currents becomes more pronounced with higher angles of wave incidence, Ψ . Even though the shift of curve (2) with regard to (1) in Fig.10 can be attributed to cementing, the discrepancies of curves (2) and (3) are due to different Ψ . It should be noted that the scatter of the measured results around curve (3) depends on the ratio of oscillatory and longshore velocities, $U_{max} : V$. For the ratios smaller than 1 the scatter is considerable, while for $U_{max} : V > 2$ the results lie close to the curve, especially at its apex.

The three-dimensional effects in the ripple length (Fig.11) are reflected in relative increase in the length, for a given shear stress. The differences of the lengths of 2-D and 3-D ripples increase with higher shear stress. The 3-D length also increases with higher Ψ .

An important role in the generation of 3-D microforms is played by interrelations of waves and currents in the coastal zone. The effect of these factors is inherent in the angle Ψ , which determines, among others, the longshore current due to wave breaking. The variation of ripple parameters with the velocity of longshore current depends on local vectors of longshore current and wave motion. Thus, the angle Ψ determines the ripple length λ on greater depths, seawards of the breaking zone, where refraction of waves and ripples is similar, so that their directions are parallel. In the surf zone, where the effect of currents is pronounced, the three-dimensional effects become significant. Fig.12 illustrates the influence of Ψ and Δ on the increase in the length of 3-D ripples, compared to 2-D forms.

Fig.12 Relative Increase in Length of 3-D Ripples

CHAPTER 99
A MODEL STUDY OF ALONGSHORE SEDIMENT TRANSPORT RATE

by

J.W. Kamphuis
Queen's University
Kingston, Canada

and

J.S. Readshaw
Western Canada
Hydraulics Laboratories
Vancouver, Canada

ABSTRACT

Alongshore sediment transport rate was studied in a 3-dimensional mobile bed coastal model and was found to depend on the beach profile and rate of wave energy dissipation in addition to the normal wave and sediment parameters. Alongshore sediment transport rate was found to be strongly related to the surf similarity parameter, a single parameter simplistically describing beach profile and breaker type.

INTRODUCTION

Tests have been performed at Queen's University for a number of years using the concept of "dynamic equilibrium profiles" (6,7,8) denoting the profile response to a simply simulated annual wave climate. A detailed description of "dynamic equilibrium" may be found in Ref. 6.

The earlier tests were concerned with beach profile formation, application of artificial beach nourishment and redistribution of grain sizes. This particular paper deals with littoral drift rates.

SIMPLE EXPRESSIONS

Many expressions have been developed to relate littoral transport to wave conditions. The simplest of these are based on either energy or momentum principles.

The energy approach in its simplest form relates littoral transport to alongshore energy flux

$$Q_s = K_p P_{ab} \quad (1)$$

where Q_s is the littoral transport rate, K_p is a constant and P_{ab} is the alongshore component of wave power in the breaking zone in N-m/s/m of beach.

$$P_{ab} = \frac{1}{2} n_b C_b E_b \sin 2 \alpha_b \quad (2)$$

Here C is the velocity of wave propagation, E is the wave energy density, α is the angle of wave approach and

SEDIMENT TRANSPORT RATE

$$n = \frac{1}{2} \left[1 + \frac{4\pi d/L}{\sinh 4\pi d/L} \right] \quad (3)$$

while the subscript b denotes the breaking zone. This approach is described in detail in Shore Protection Manual (11) and is often referred to as the CERC formula. The constant K_p is dimensionless if Q_s is expressed as weight flux (N/s). In this paper Q_s will be expressed as mass rate of transport and thus K_p has the dimensions of (1/g) or, defining a new constant K'_p ,

$$Q_s = K'_p \left(\frac{P_{ab}}{g} \right) \quad (4)$$

The momentum approach uses the concept of "radiation stress", the excess momentum flux resulting from the presence of waves (10). The stress component of interest is the alongshore component

$$S_{xy} = n E \sin \alpha \cos \alpha \quad (5)$$

If an onshore gradient in this component exists, an alongshore force is present:

$$F_a = - \frac{\partial}{\partial x} (S_{xy}) dx \quad (6)$$

Such an onshore gradient only exists in the breaking zone, where the wave energy is dissipated. Assuming the radiation stress at the shore to be zero the total lateral thrust available to move sediment is

$$F_a = (S_{xy})_b = \frac{1}{2} n_b E_b \sin 2 \alpha_b \quad (7)$$

Sediment transport may be related to wave thrust in its simplest form as:

$$Q_s = K_t F_a \quad (8)$$

where K_t is not dimensionless but has units of time. Some experimental evidence in support of an equation such as Eq. 8 is presented by Bruno and Gable (2). It is to be noted that

$$P_{ab} = F_a C_b \quad (9)$$

and thus Eqs. 4 and 8 are very similar. Equation 8 is easier to use since F_a does not include a difficult estimate value of C_b

DIMENSIONAL ANALYSIS

Sediment transport is a function of water, wave and beach parameters

$$Q_s = f(\mu, \rho, g, H, T, \alpha, \rho_s, D, t, n) \quad (10)$$

where μ and ρ are the viscosity and density of the water,

g the gravitational acceleration, H the wave height, T the wave period, α the angle of wave approach, ρ_s and D the density and size of the sand, t is time and η is the beach shape. The quantity η is included simply as a reminder that beach shape is important.* In a later section it will be seen that η is a complicated combination of many geometrical parameters.

Dimensional analysis yields:

$$\frac{Q_s}{\rho H^2 \sqrt{gH}} = \Phi \left(R, \frac{H}{L_o}, \alpha, \frac{\rho_s}{\rho}, \frac{D}{L_o}, \frac{t}{T}, \eta^* \right) \quad (11)$$

where
$$R = \frac{\hat{u}_\delta a_\delta}{v} = \frac{\pi H^2}{4\sqrt{T}}$$

the maximum amplitude Reynolds number (4), while η^* denotes the dimensionless version of η .

During the present tests, α , ρ_s/ρ and D/L_o were not varied.

The effect of using light weight (or heavy weight) material has been discussed earlier in detail (5) and consequently sand was used in the model. This introduces scale effect in the model since the initiation of motion and sediment transport characteristics have now changed (5). This scale effect will be denoted by m_ρ . The scale effect resulting from improper scaling of the material size has also been discussed (5) and it is expected that a scale effect (m_η) is present in this model.** Since tests were only performed with one generated angle of approach of the waves the effect of α has been assumed to be as shown in Eqs. 2 and 7. This assumption is based upon the experimental results of Refs. 2 and 11. Thus Eq. 11 may be rewritten for purposes of this study as:

$$\frac{Q_s}{\rho H^2 \sqrt{gH}} = m_\rho m_D \sin 2\alpha_b \Phi_1 \left(R, \frac{H}{L_o}, \frac{t}{T}, \eta^* \right) \quad (12)$$

The value of C_b in Eq. 2 is difficult to determine and may be expressed as

$$C_b = \sqrt{\kappa g d_b} \quad (13)$$

* In a strict dimensional analysis sense, the quantity η should not be included here since η is not independent of D and ρ_s , hence the term "reminder".

** Note that these are scale effects in addition to the influence of different profiles as a result of using incorrectly scaled ρ_s and D. The effect of profile differences is included in η^* .

$$\text{where} \quad 1.0 < \kappa < 1.78 \quad (14)$$

depending on whether linear, cnoidal or solitary wave theory is used. A careful interpretation of Iversen's (3) and Battjes' (1) results would indicate that both H_b/d_b and κ may be approximated by unity, yielding:

$$\frac{Q_s}{\rho H_b^2 \sqrt{g H_b} \sin 2 \alpha_b} = \frac{Q_s}{P_{ab/g}} = K'_p = m_\rho m_D \Phi_1 \left(R, \frac{H}{L_0}, \frac{t}{T}, \eta^* \right) \quad (15)$$

and what was assumed constant in Eqs. 1 and 4 is seen to be a function of the wave Reynolds number, the wave steepness, the time and the beach shape.

The effect of R is small in a turbulent flow region such as near the breaking zone and thus the investigation concentrated on wave steepness, time and beach shape.

EXPERIMENTS

The experiments were carried out in the wave basin shown in Fig. 1, essentially the same as used by Kamphuis and Myers (7) except that the generator was placed further away from the beach to improve re-reflection patterns. Circulation was allowed to take place in the breaker zone and under the generator to achieve an "infinitely long beach". The sediment feeder was placed on a track to facilitate dropping the feed material in the breaker zone at all times. The sediment trap was suspended with 3 load cells to allow continuous weighing of the trapped material. The material entered the traps through narrow slots. The end of the beach was supported by a template which had approximately the same shape as the profile line in the middle of the beach. Sediment was pumped from the trap to the feeder at the end of each test using a diaphragm slurry pump.

The tests performed are summarized in Table 1. The wave climates for tests 1 through 4 are the same as used by Bridgeman and by Myers (6,7). In tests 5 through 7 the summer waves were 20% larger but with the same steepness and the winter waves were 5% smaller and somewhat steeper. In test 8, the winter wave period was substantially reduced to produce a very steep wave.

A distinction must be noted in Table 1 between series types S and D, denoting steady state and dynamic equilibrium tests. In the steady state tests a number of summer (or winter) storms were repeated immediately following each other.

TEST RESULTS

The rates of sediment feeding and trapping were carefully measured and matched. A sample plot is included in Fig. 2. A number of

discrepancies occurred which were corrected as the tests progressed and with respect to modelling of beaches the following was learned:

1. If the model study is meticulously controlled, *it is possible* to investigate alongshore sediment transport in a model which is carefully set up to simulate an infinitely long beach.
2. The *model boundary conditions* affect the measured littoral transport rate.
 - a. The *end (downdrift) template* must closely match the existing beach profile. If the template is too high, the beach will accrete locally at the downdrift end and with time will turn and decrease the breaking angle. If the template is too low, an alongshore beach gradient will be formed as the beach erodes near the template. This will increase the littoral transport rate as the sand is removed and with time will cause the breaking angle to increase.
 - b. Small variations in the *feed rate* had a negligible direct effect on the littoral transport rate. Dissimilarities between the littoral transport rate and the feed rate did, however, cause the beach profile to change. This in turn changed the nature of the interaction between the beach profile and the breaker and changed the littoral transport rate.
 - c. The *feeder position* must be continuously adjustable so that the feed material is always introduced at the breaker point. Only then are the sand grains distributed over the entire width of the surf zone.

With respect to sediment transport rates it was learned that:

3. Sediment transport rates are *not the same* for steady state and dynamic equilibrium tests (Table 1) and are also different for component storm waves when paired with different storm waves (Table 1, tests 6S and 8S).
4. The rate of sediment transport for the *steady state equilibrium profiles* increased slowly until it reached a constant value for the smaller summer storm waves. For the large winter storm waves, a constant sediment transport rate was reached almost immediately after startup.
5. For the *dynamic equilibrium tests* the transport rate was

constant throughout the winter storm portion of the cycle (Fig. 3). For the summer storms, the transported volume exhibited an S curve indicating a small "initial" transport rate, followed by a large "transitional" transport rate, followed by a smaller "equilibrium" transport rate (Fig. 4). Tangents may be drawn to the curve (Fig. 5) and these tangential sediment transport rates have been recorded in Table 1 for the dynamic tests 3, 6 and 8.*

In order to understand the mechanism that results in the S-curve of sediment transport a test series was run in which the beach profiles were measured at short intervals. It was found that:

6. *Beach profiles* and equilibrium transport rates are very closely related and the transport rate responds rapidly to changes in beach profile.
 - a. The transport rate for the steep *winter storm waves* (Fig. 3) was constant because the profile resulting from summer storms was rapidly reshaped into a bar profile by the first few waves and subsequently only small adjustments took place to achieve more complete equilibrium.
 - b. For the *summer storm waves* (Fig. 4), the first stage of the reshaping cycle consisted of removing sand from the offshore bar into the trough and into the swash zone. This resulted in a long, flat shelf, a very gentle breaking wave and a low initial transport rate. The material was subsequently remoulded into a summer step and during this "transitional" stage a violent breaker and large littoral drift rate was evident. Eventually, the summer step increased in length to its ultimate equilibrium length and an equilibrium beach with "equilibrium" transport rate resulted.

BEACH PROFILE AND BREAKER

Further study was made of the beach profile and its important influence on sediment transport rate as outlined in conclusion 6 above. In the dimensional analysis, the term η was used. This

* Note that for waves of small steepness, "equilibrium" littoral transport rate cannot be measured accurately unless the material transported is trapped and weighed continuously. The average transport rate \bar{Q} for the summer storm waves is meaningless since it depends on when the test is completed. In Fig. 5 two such rates corresponding to test durations t_1 and t_2 are shown.

FIGURE 4 MASS OF SAND TRAPPED vs TIME WITHIN SEASON 86

FIGURE 5 TRANSPORT RATE DEFINITIONS

η is a combination of a number of levels and distances on the beach profile and nomenclature for the beach profile is introduced in Figures 6 and 7. The beach is divided into a turbulent zone and a swash zone and several geometrical distances are defined as shown in Fig. 7 where S refers to beach slope, initially (S_0), on the foreshore (S_{FS}) and offshore (S_{OS}), λ is the length of the summer step (λ_s) or the distance to the bar (λ_w) - defined as distances between tangents S_{FS} and S_{OS} , Σ is the depth of water over the summer step and β the depth of water over the bar.

In the following, Q_s refers to the equilibrium sediment transport rate both for the steady state and dynamic equilibrium tests.

Whenever a beach profile and a sediment transport rate were measured simultaneously, comparisons were made between the sediment transport rate and the individual beach parameters of Fig. 7. Figures 8, 9, 10 and 11 indicate little relationship between Q_s and S_{FS} , S_{OS} , Σ and β . This leaves λ , the length of the summer step or distance to the bar. A measurement of the evolution of λ_s for test 3S (Fig. 12) indicates an S curve somewhat similar to Figure 4 and when Q_s is plotted against λ there is a definite relationship as shown in Fig. 13. The scatter is a result of simultaneous variation of the other parameters. Figure 13 indicates that as λ lengthens, the sediment transport rate decreases and this corresponds with observation as well as with conclusion 6b above. This also explains why the dynamic equilibrium tests produced higher sediment transport rates in summer than the identical steady state tests and why there was a discrepancy between tests 6S and 8S.

It was also noticed that as λ increased, the breaker type became less violent, tending to change from plunging to spilling characteristics.

Extensive work on breaker types on a plane slope has been done by Battjes (1) who relates breaker type to the surf similarity parameter

$$\xi_b = \frac{\tan \theta}{\sqrt{H_b/L_0}} \quad \text{or} \quad \xi_0 = \frac{\tan \theta}{\sqrt{H_0/L_0}} \quad (16)$$

where θ is the slope of the plane beach. This parameter combines beach slope, essentially a simplification of beach profile and of η , with wave steepness. Obviously if this parameter were to be used in the present study, it should include λ and thus for this study

$$\xi_s = \frac{\Sigma/\lambda_s}{\sqrt{H/L_0}} \quad \text{and} \quad \xi_w = \frac{\beta/\lambda_w}{\sqrt{H/L_0}} \quad (17)$$

where Σ/λ_s and β/λ_w are simplifications of η^* and are estimates of the beach slope of the active portion of the beach, i.e. in the turbulent zone and the swash zone for summer and winter respectively.

The rate of sediment transport is plotted against ξ_b in Fig. 14 and it may be seen that there is a strong relationship indicating that the replacement of η^* in Eq. 11 by ξ_b is a valid step, especially since Σ and β can be shown to be independent of λ_s and λ_w . Introducing the above simplification, it is now possible to plot the dimensionless sediment transport $Q_s/\rho H_b^2 \sqrt{gH_b}$ against ξ_b as was done in Fig. 15. Breaking wave heights were used in the formulation of dimensionless sediment transport to correspond to ξ_b . Use of deep water wave heights and ξ_0 introduced further scatter in the results. Figure 15 indicates a single, very strong relationship, suggesting that the variation with R , H/L_0 and α for equilibrium values of $Q_s/\rho H_b^2 \sqrt{gH_b}$ is small. In a further step, K'_p of Eq. 15 was plotted against ξ_b using values of α_b obtained by refraction analysis and checked by overhead photography. It may be seen from Fig. 16 that the K'_p is not a constant but is strongly related to ξ_b .

The straight line shown in the diagram indicates that

$$K'_p \approx 0.7 \xi_b \quad \text{for} \quad 0.4 < \xi_b < 1.4 \quad (18)$$

with a correlation coefficient, $r^2 = 0.73$. This correlation is an improvement over Fig. 15 where a similar line would yield $r^2 = 0.56$. Thus Eq. 15 improved upon Eq. 11 and the term $(\sin 2 \alpha_b)$ removes a considerable portion of the variance present in Fig. 15.

The constant K'_p as determined by Komar and Inman (9) has also been shown on Fig. 16. It may be seen that the test results and the constant value of K'_p correspond very well for high values of ξ_b . Indeed, Komar and Inman state that the breakers at their most intensively studied beach (El Moreno) were violently plunging and that the beach was steep. This would indicate a high value of ξ_b for these tests. Their other beach (Silver Strand) was much flatter, but the measurements were made for swell of small height, thus again indicating possibly high values of ξ_b . The fact that for lower values of ξ_b , K'_p is a function of ξ_b may be why Komar and Inman's work and the CERC formula overestimate littoral transport rate for many situations, especially those involving gently sloping beaches and low swell.

Equation 8 surmises that littoral transport rate may be presented as a simple function of wave thrust. Figure 17 indicates this proportionality also to be a function of ξ_b . The straight line in the figure is

$$K_t \approx 0.08 \xi_b \quad \text{for} \quad 0.4 \xi_b < 1.25 \quad (19)$$

with a correlation coefficient $r^2 = 0.62$ indicating that this relationship contains more scatter than Eq. 18. Field results obtained by Bruno and Gable (2) have not been shown on Figure 17 since no wave and beach profile data were available from their paper and since their field results for K_t showed much more scatter than the experimental results in Fig. 17.

Figures 14 to 17 yield the following conclusions:

7. The rate of littoral transport was closely related to the beach shape, the type of breaker and the rate of energy dissipation in the breaking zone. These quantities may be simply represented by the surf similarity parameter and the dimensionless littoral transport was found to increase linearly with the surf similarity parameter over the range $0.4 < \xi_b < 1.4$.
8. The CERC formula can be used to estimate littoral transport rate only for beaches where the breakers are violently plunging or surging. For gently sloping beaches or for low swell, resulting in spilling to plunging breakers, the beach profile must be taken into account using the surf similarity parameter and the CERC formula overestimates littoral transport rate.

DISCUSSION

It is worthwhile to note the following points:

Sediment transport rate is closely related to the rate of energy dissipation in the breaker zone, i.e. breaker type, which in turn is related to beach shape. The surf similarity parameter may therefore be estimated either by inspection of the beach shape or by inspection of the breaker type. This yields two estimates of ξ_b and should facilitate determination of this parameter and hence of sediment transport rate on more complex beach profiles with multiple bar systems.

Recently much discussion has centred on the usefulness of the CERC expression and the dependence of its "constant" on grain size and density. This paper has shown that the CERC expression is valid for simple model conditions, but that the "constant" is a variable. The value of K_p' was shown to be strongly related to ξ_b , but ξ_b in turn depends strongly on grain size and density. Thus, although m_D and m_ρ explain some of the dependence of K_p' on ρ_s and D , most of the dependence on ρ_s and D is taken care of via ξ_b .

Finally, although out of experimental necessity equilibrium values of Q_s and ξ_b were used to define Figs. 16 and 17, the relationships are general and can be used for beaches which are not in equilibrium, except for short-term storm durations where a transition sediment transport rate can occur which is several times the equilibrium rate.

CHAPTER 100

EFFECT OF WAVES ON SAND TRANSPORT BY CURRENTS

by

Michael W Owen* and Michael F C Thorn*

The effect of waves on the transport of sand in suspension by currents can be especially important in the outer regions of estuaries and tidal inlets. Two series of field experiments are therefore being carried out to investigate the transport of sand under the combined action of waves and currents.

In the first series of tests, measurements were taken from a specially constructed tower located just off the Maplin Sands in the outer Thames Estuary, England, (Fig.1). The tower stands in about 1.5m of water at lowest tide levels, and the mean spring tidal range is about 4.5m. Average tidal velocities are about 0.6m/s, with peak values up to about 0.9m/s. The tower has a completely open structure (Fig.2) below the water line, with the exception of the four corner piles penetrating the sea bed, and a vertical trackway which stops approximately 1m above bed level. A series of instruments were fixed to a trolley which could be winched up and down the trackway, thus allowing measurements at any height above bed level. The annual wave climate at a waverider buoy position some 900m from the tower is summarised in Fig.3: Fig.3a shows the percentage occurrence of different wave heights, and it can be seen that the tower is at a fairly sheltered site, with less than 2 per cent of the waves exceeding 1m in significant height. Fig.3b shows the percentage occurrence of given wave periods which, as one would expect, are correspondingly short, with less than 2 per cent exceeding 4.5s mean-zero crossing period.

The second series of field tests are presently being carried out at the seaward end of Boscombe Pier, located in Poole Bay, England, (Fig.4). Water depths at this site are about 2.5m at low tide, with a mean spring tidal range of about 1.7m. Maximum tidal velocities are only about 0.3m/s, although during prolonged storms the tidal currents are enhanced by strong wind-induced currents. This site is significantly more exposed than Maplin, which was the reason for the choice of this second location. Annual wave statistics are not available for Boscombe Pier itself, but a waverider buoy some 3000m from the pier (Fig.4) has been operated by the University of Southampton for several years, and Fig.5 shows the percentage occurrence of given wave heights for the year 1977. Some 17 per cent of waves were greater than 1m significant height, and 2 per cent greater than 2m. Fig.6 shows the percentage occurrence of given wave periods: 5 second waves are the most common, but with periods of longer than 10 seconds being recorded. Despite initial appearances, Fig.7, Boscombe Pier is a relatively open structure below the water line, with only vertical columns 0.4 x 0.4m, spaced at 5.5m centres. As at Maplin, a vertical trackway is provided, and an instrument trolley can be winched up and down.

*Principal Scientific Officers, Hydraulics Research Station
Wallingford, England.

The actual instrumentation used at Maplin and Boscombe was very similar, (Fig.8). To measure time-averaged and also instantaneous velocities an electro-magnetic current meter was mounted in the horizontal plane, giving the two horizontal velocity components. A sampling nozzle connected to a pump enabled large-volume samples of the suspended sediment to be taken. On its delivery side the pump was connected to a pressure filter which separated off all sediment coarser than $40\mu\text{m}$ (microns), with the volume flow rate being measured by flow-meter. At Maplin these two instruments were augmented by a Braystoke propeller current meter to give time-averaged velocities during the first few months of the experiment when the electro-magnetic current meter was unavailable. At Boscombe the two basic instruments were augmented by a light-extinction turbidity meter, which it was hoped would give a qualitative indication of instantaneous sediment concentrations. At both Maplin and Boscombe wave heights were measured by bottom-mounted pressure recorders. Output from all the instrumentation was recorded in digital form on magnetic tape, and also in analogue form on paper chart.

The experimental procedure at both sites is first to lower the instrument trolley until a bed sensor locates the seabed. At this position the instruments were 0.05m above the bed. Velocities were then measured at this level over a 100s period, and a 20 litre sample of the suspension taken and filtered. The filtered sand was then removed ready for return to the laboratory where it was to be sub-divided into 5 size fractions by dry sieving. The trolley was then unclamped from the trackway and moved up to place the instruments at 0.1m above seabed level. Measurements were then repeated at this level and also at 0.15 , 0.25 , 0.5 , 1 , 2 , 3 and thence every metre up to the water surface. Measurement of the complete profile of velocity and sediment concentration generally takes about 20 minutes. Profiles are taken at about 30 minute intervals during typical calm conditions, and also an attempt was made to man the experiments during periods when storms were forecast. All the field measurements have been completed at Maplin Tower, and the equipment has been removed and transferred to Boscombe Pier. Here a good number of measurements were obtained during the winter of 1977/78 but at the time of writing analysis of these results has hardly begun. The results presented in this paper are therefore based almost entirely on the Maplin measurements.

Each data set consists essentially of vertical profiles of time-averaged velocities of the root-mean-square of the velocity fluctuations and of the suspended sediment concentrations of each of 6 size gradings. For the earlier readings at Maplin, when the electro-magnetic current meter was not available, the rms velocity was calculated from the recorded wave spectrum. When the e.m. current meter finally became available a comparison between the measured and calculated rms velocities could be made: the agreement was remarkably good as the example in Fig.9 shows, indicating that the velocity fluctuations were primarily due to the orbital motion of the waves. Altogether some 250 complete sets of good data were obtained at Maplin: faced with this quantity of information the decision was first taken to sub-divide the data into groups corresponding to the range of the tide during which the particular measurements were taken. Secondly it was decided to try a simple "bulk -flow" analysis of the data. For this purpose a classical

logarithmic expression was fitted to the velocity profile and the profile integrated from bed to water surface to give the depth-averaged velocity. An exponential expression of the Rouse type was then fitted to the sediment concentration profiles for each sediment size grading. The product of the fitted velocity and sediment concentration expressions was then integrated numerically from bed to surface to give the sediment discharge in each size grading. The total discharge of sand-sized sediments ($> 40 \mu\text{m}$) was then obtained by summation. This sand discharge was then plotted against depth-averaged velocity, with the rms of the velocity fluctuations at 0.05m above the bed as the third variable. One plot was prepared for each of the tidal range groups of data, and on each plot it was found that for small values of the rms velocity the sand discharge T (g/s/m width) was uniquely related to the depth-averaged velocity V (m/s) by the expression

$$T = 1400 V^4$$

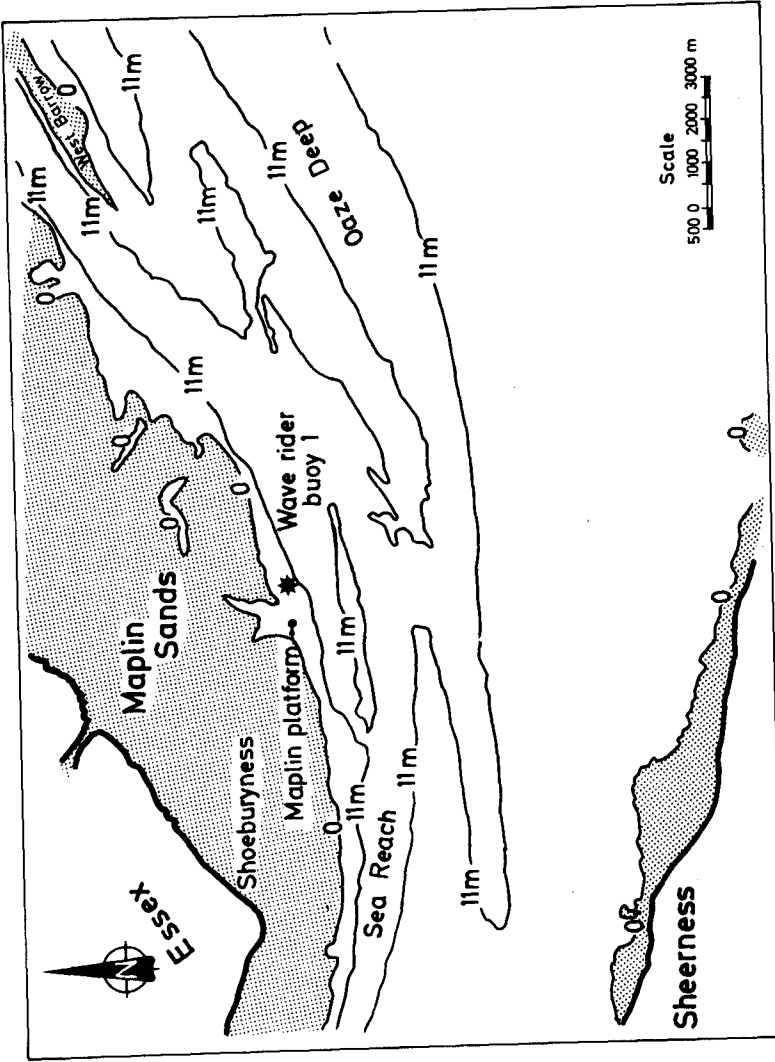

Fig.10 shows the plot for Group A tides - these having a tidal range of about 4.5m and a peak tidal velocity of about 0.8m/s. Neither tidal range, water depth nor rms velocity affected this expression provided that the rms velocity was less than about 50mm/s. Altogether some 210 sets of good data fell within this range of rms velocities. Although there were, inevitably, significantly fewer sets of data with rms velocities greater than 50mm/s it was evident that the sand discharge was substantially increased when there was pronounced wave activity. When lines were drawn on the sand discharge/depth-averaged velocity plot joining points of equal value of rms velocity it was found that they were broadly parallel to the base or 'no-waves' line, Fig.11. In other words, the expression relating sand transport to velocity was still of the basic form $T = \text{const} \times V^4$, but with the constant as a function of the rms orbital velocity. By plotting this constant derived from the various plots against the corresponding rms orbital velocity, Fig.11 it appears that the sand transport can be expressed as

$$T = 1400 \left(\frac{U_{\text{rms}} - 0.05}{0.05} \right)^2 V^4$$

where U_{rms} is the rms value of the velocity fluctuations at 0.05m above the bed, V and U_{rms} are in m/s, and T is in g/s/m width.

It is evident that although such a simple analysis of the data gives a usable expression for sand discharge at the Maplin site, it gives little insight into the actual effect of the waves, for example in possibly enhancing suspended concentrations or in distorting the velocity profile. In addition the analysis does not make use of the data on each size of sediment. Further detailed analysis of the results is therefore presently underway to obtain a better understanding of the processes involved.

The work described in this paper is being undertaken as part of the research programme of the Hydraulics Research Station, Wallingford, England, and is published with the permission of the Director of Hydraulics Research.

CHAPTER 101

FIELD EXPERIMENT ON BEACH GRAVEL TRANSPORT

by

Masataro Hattori* and Takasuke Suzuki**

* Department of Civil Engineering

** Institute of Geoscience

Chuo University
Bunkyo-ku, Tokyo, Japan

Abstract

To examine the longshore transport processes of beach gravels under wave action, a field experiment was performed by tracing the dacite blocks injected on Fuji Coast, Shizuoka Prefecture, Central Japan.

The mean dislocating velocity of the tracer was 2 to 3 m/day under normal sea conditions, while under storm conditions it reached about 400 m/day. This velocity was fairly proportional to the longshore component of incident wave energy flux.

The longshore variations of the size and shape of beach gravels were mainly resulted from the progressive attrition and impact breakage of beach gravels rather than from the selective transport.

INTRODUCTION

This paper describes a field experiment carried out to obtain a better understanding of the littoral transport of beach gravels under wave action.

The mechanism of littoral transport of sand by waves and wave-induced currents has been extensively investigated and the beach processes have also been discussed by many researchers (1)*. On the other hand, our knowledge of the processes of beach gravel transport seems to be very limited in comparison with that of the sand transport, because it is very difficult to study the gravel transport by the laboratory experiments.

* : The figure in parentheses represents the reference cited at the end of this paper.

The transport processes of beach gravels have been studied by the tracing experiment using marked beach materials (2,3,4). According to previous studies, the transport processes are controlled by the size of gravels and the location of the zone in which the transport occurs.

Some researchers have inclined to the view that the longshore variation in beach gravel size can be produced by the selective transport processes. On the other hand, a number of field studies (5) demonstrates that beach gravels decrease in size, and change in shape due to the progressive attrition during their travel.

The present writers suggested in the previous paper(6) that the predominant direction and intensity of littoral sediment transport were more easily determined from longshore variations of beach gravel properties than from those of sand properties. More detailed informations on this subject are required to substantiate the writers' concept.

The principal purposes of this experiment were as follows:

1. To examine the longshore dislocating velocity of beach gravels,
2. To obtain the relation between the dislocating velocity and the longshore component of incident wave energy flux.
3. To elucidate the processes of the size and shape changes of beach gravels during their travel.

OUTLINE OF THE STUDY AREA

The experiment was performed on Fuji Coast located at the head of Suruga Bay, Shizuoka Prefecture, Central Japan (Fig.1). The study beach is the eastern reach of Fuji Coast which extends about 15 km from Tagonoura Port on the west to Numazu Port on the east.

The beach is about 150 m in width and is composed of sand and gravels. They are derived mostly from Fuji River on the west and slightly from Kano River on the east.

Suruga Bay is extremely deep and faces the Pacific Ocean in the south-west direction. Since the head of a submarine canyon is located near the coastline, the near-shore slope is so steep, up to about 1 on 10, that breaking waves plunge and form an intense swash with a narrow surf zone. The longshore current is not strong under normal wave conditions.

According to the tide observation of Fuji Coast (7), the tidal range during a spring tide is about 1.5 m, and the greatest resultant velocity of tidal current in the east-west direction is about 9 cm/day.

The littoral drift is in the east direction, which is the dominant one along Fuji Coast, and it has been intercepted by a navigation channel at Tagonoura Port. This has

Fig. 1 Location of the study area.

I: Tracer injection site, W: Hara Wave Observatory, Q: Dacite block quarry, P.T.: Tagonoura Port, N: Numazu City, F: Fuji City, F1, F2 and F3: Outlet works.

resulted in severe beach erosion on the up-drift side of the study beach.

To prevent further beach erosion, wave defense works, a kind of offshore breakwater system, have been constructed along the shoreline in the vicinity of the Tagonoura Port. There are no other coastal structures on the beach, except for three diversion outlet works, whose locations are denoted by F1, F2 and F3 in Fig.1. Their effect on the shoreline configuration is not so large.

Figure 2 shows the two-dimensional bottom profile

Fig.2 Two-dimensional bottom profile along the study coast.

along the study beach from the west to the east. Figures attached to the profile represent the bench mark number.

Due to the submarine topography of Suruga Bay, swells and huge waves generated by typhoons often attack the beach. The predominant wave direction is almost constant with respect to seasonal changes. The wave energy level along the study beach is considered to be almost constant, except for the vicinity of Numazu Port.

METHODS OF FIELD EXPERIMENT

Various labelling techniques of beach materials for the tracing experiment have recently developed to examine the nature and dislocating velocity of sediment transport (8). In this experiment, dacite blocks from a quarry, Q in Fig. 1, were used as the tracer.

This dacite is whitish yellow in color and homogeneous in texture, and have the physical and mechanical properties as shown in Table 1. This type of dacite gravels are not found on the study beach and also on the bed of Fuji and Kano Rivers. Therefore, the dacite blocks could be easily distinguished from the indigenous beach gravels, most of which are sandstone, granite, slate and basalt. The tracer is slightly softer and lighter than these indigenous gravels.

Table 1 Physical and mechanical properties of dacite blocks.

Initial Tracer Properties	Water Condition	Number of Specimen	Mean	S.O.
apparent specific gravity		5	2.68	0.01
dry bulk weight (gr/cm ³)	dry	10	2.41	0.02
porosity (%)	dry	5	10.1	0.80
maximum water content (%)	wet	10	3.8	0.17
P-wave velocity (km/sec)	dry	5	3.2	0.06
	wet	5	3.3	0.07
S-wave velocity (km/sec)	dry	5	2.5	0.1
	wet	5	2.5	0.2
dynamic modulus of elasticity (x10 ⁵ kg/cm ²)	dry	5	3.5	0.6
	wet	5	3.1	0.7
compressive strength (kg/cm ²)	dry	5	615	41

tensile strength (kg/cm ²)	dry	5	70	4.5
	wet	5	29	3.8
weight loss percentage by Los Angeles test (%/500gr)	wet	1	18.3	-----

Some 7000 dacite blocks were injected on the beach face from the shoreline at low tide-level to the backshore berm line in the shape of a jetty 42 m long, 3 m wide and 0.3 m high. The injection site, I in Fig. 1, was about 1.5

km east of Tagonoura Port. The initial size and shape indices of the injected blocks are shown in Table 2. The injected blocks were larger in size and more angular in shape than the indigenous beach gravels.

Table 2 Initial size and shape indices of the injected blocks

Initial tracer parameters	maximum	minimum	mean
long diameter : a (cm)	85	10	26.0
intermediate diameter : b (cm)	40	7	19.2
short diameter : c (cm)	29	4	13.2
nominal volume : $V_n(=axbxc)(cm^3)$	6.4×10^4	2.8×10^2	5.8×10^3
flatness : axb/c^2	16.1	1.2	2.7
elongation : a/c	5.0	1.2	2.0
Krumbein's roundness	0.5	0.3	0.32

Surface sampling of the tracer was carried out across the entire beach profile along the beach every field survey. Every sampled block of tracer was measured for its long, intermediate and short diameters, and its sampling location on the beach was recorded in terms of the longshore distance from the injection site and the seaward distance from the bench mark. Its picture was also taken to determine the roundness on the basis of Krumbein chart of roundness. After measurement, the tracer was returned to its sampling point.

The tracer recovery rate was two or three percent for every field survey. In the discussion of the experimental results, it is assumed that the distribution of sampled tracer on the beach surface represents that of the whole transported tracer.

Wave data at Hara Wave Observatory, W in Fig. 1, were obtained from a pressure wave gage placed on the sea bottom at a depth of 20 m and lined to an analogue recorder on land. The measurements were made for twenty minutes every two hours.

Figure 3 shows a temporal change in wave height using the data for the first 70 days after injection. Two typhoons, Nos.5 and 6, attacked the beach 11 days and 17 days after injection. The greatest wave height of 11.6 m was recorded during Typhoon No.6.

Figure 4 shows the distributions of wave height and period. From these histograms, prepared using the data

during the experiment, the significant wave height and period are read as 0.5 m and 8 seconds, respectively.

Fig. 3 Temporal change of wave height during the first 70 days after injection.

Fig. 4 Distributions of wave height and period.

DISLOCATING VELOCITY OF TRACER

Figure 5 shows the distribution of displaced blocks three days after injection. At that time, three quarters of the injected blocks still remained at the injection site. The drift piling zone, indicated by a thin dotted line, is considered to represent the upper limit of uprush at high tide-level.

Asymmetrical distribution indicates that the beach drift direction is eastward. Most of displaced blocks are distributed in the median zone between the top of foreshore and the upper limit of uprush.

Fig. 5 Distribution of displaced blocks three days after injection.

The mean longshore distance of transport was calculated from the longshore distribution of displaced blocks by taking the first moment of the tracer distribution in the longshore direction about the injection site.

The greatest or maximum distance was estimated from the sampling location of the furthest travelled block.

The mean longshore dislocating velocity was calculated by dividing the mean transport distance by the elapsed time during which the transport occurred. The maximum velocity was also obtained in the same manner.

Experimental results of the longshore transport distance and the dislocating velocity are summarized in Table 3. Figure 6 shows the time changes of the greatest and mean longshore distances of tracer transport.

It is noticed from these results that the predominant direction of littoral transport was westward and the exceptional displacements occurred during the two typhoon attacks on the beach. The furthest blocks reached 14 km east of the injection site in about a half year after

Fig. 6 Temporal changes of the longshore distance of the tracer transport.

injection.

The dislocating velocities under various sea conditions are estimated from these results as follows:

The mean dislocating velocity was between 2 and 3 m/day under normal sea conditions, while under storm conditions it reached about 400 m/day. The maximum velocity under normal sea conditions was estimated to be 50 to 60 m/day, and during Typhoon No.6 it produced about 1 km/day.

Table 4 shows that the mean velocity seems to increase with tracer-size decrease. Phillips (9) also reported a similar tendency, whereas, Evans (10) and Kindson and Carr (11) stated that the larger gravels were transported faster than the small. However, the problem is very complicated, because in the present experiment the tracer decreased in size due to the progressive attrition and impact breakage, as discussed later. Hence, the result shown in Table 4 does not necessary imply the size effect on the dislocating velocity.

Table 4 Relation between the tracer size and mean dislocating velocity.

Mean Diameter (ϕ -scale)	- 8	- 7	- 6	- 5	- 4
Mean Velocity \bar{V} (m/day)	6	14	19	--	23

The relation between the mean dislocating velocity and the longshore component of incident wave energy flux is shown by Fig. 7, which was prepared using the data collected during the first 89 days after injection.

This shows a fairly good linear relationship between the two quantities. A similar relationship between the rate of sand transport and wave energy flux has also been reported (12).

From Fig. 7, an empirical relation is obtained as

$$\bar{V} = 0.0025 \bar{E} - 3.75,$$

where \bar{V} is the mean dislocating velocity in m/day, and \bar{E} is the longshore component of incident wave energy flux in ton·m/day·m.

Using this relation, the threshold wave height for the tracer movement is calculated to be about 0.2 m, for which the wave period is assumed to be 8 seconds.

Fig. 7 Relation between the mean dislocating velocity and the longshore component of wave energy flux.

CHANGES IN TRACER SIZE AND SHAPE

Figure 8 shows the temporal changes of the mean long and short diameters and the mean nominal volume of the tracer. Figure 9 is the cumulative curves of the tracer nominal volume for each field survey.

These figures indicate the following facts:

1. During the two typhoon attacks, there occurred considerable volumetric decreases, reaching about 70 percent of the initial mean volume (Fig.8), and all fraction of blocks seemed to lose volume uniformly (Fig.9).
2. Over the 70 days after the typhoons, the tracer size seemed to be almost constant (Fig.8), because the sea conditions during this period were very calm.
3. Over the 275 days between 89 days and 364 days after injection, only the small size fraction of the tracer decreased in volume (Fig.9).
4. The whole fraction of tracer decreased in volume in the next year (Fig.9).
5. The rates of decreases of the long and intermediate diameters were slightly greater than that of the short diameter (Fig.8).

Fig. 8 Temporal changes of the mean long and short diameters and the mean volume.

Fig. 9 Cumulative curves of tracer volume.

Figure 10 shows the longshore variations of the long and short diameters 36 days, 89 days and 364 days after injection. Abrupt decreases in diameters are found about 3 km east of the injection site. The location of the abrupt decrease moved progressively eastward with the elapsed time.

Fig. 10 Longshore variations of the long and short diameters.

Figure 11 shows the longshore variations of the mean nominal volume of the ten largest blocks. In comparison with Fig. 10, it is found from this figure that the abrupt decrease in the tracer volume also occurs at almost the same location as the case of the long and short diameters.

The temporal changes of the elongation and flatness of the tracer are shown in Fig. 12. These shape indices increased progressively with the elapsed time. After attaining their maximum values about 100 days after injection, they tend to decrease. The increases in these indices suggest also that the short diameter decreased faster than the long and intermediate diameters.

Fig. 11 Longshore variations of the ten largest tracer blocks.

Fig. 12 Temporal changes in the elongation and flatness of the tracer.

The evidences deduced from the experimental results suggest that the large blocks tended to be displaced by sliding motion, and that as the blocks became smaller in size, they tended to be rolled and tossed by waves.

Figure 13 shows the typical longshore distributions of the elongation and flatness of the tracer 36 days after injection. These distributions indicate that the two indices increase with longshore distance until a point about 2 km east of the injection site. Beyond this point they abruptly decrease, and then again increase gradually. Based on these longshore variations, it is concluded that the abrupt decreases in the shape indices of the tracer are caused by tracer breakage due to collisions with beach gravels.

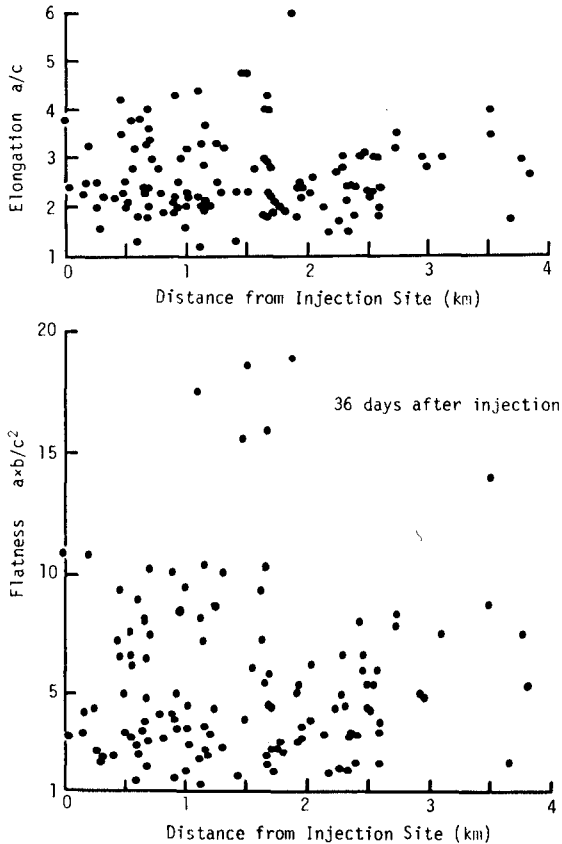

Fig. 13 Longshore distributions of the elongation and flatness 36 days after injection.

Figure 14 shows the longshore variations of the tracer roundness. The upper figure indicates that the injected blocks having sharp edges were soon rounded due to the grinding with the indigenous gravels and sand. As shown in the bottom figure, the roundness of about two thirds of the tracer 364 days after injection is more than 0.7.

Fig. 14 Longshore variations of the roundness.

In conclusion, a possible process of the size and shape changes of the tracer can be inferred from the results of the present experiment, as follows:

Over initial period after injection, the blocks are displaced through sliding motion due to wave action. Then, the blocks decrease in size and become rounder, flatter, and more slender through sliding abrasion.

When their shape indices attain certain values, for example, 4 to 5 for elongation and 10 to 15 for flatness, the block must be broken into two pieces by collisions with beach gravels. As a result, the elongation and flatness become about a half of these values before the impact breakage occurs.

As the blocks decrease in size due to both attrition and breakage, they are rolled and tossed by waves and thus they experience wearing on all sides.

Figure 15 is a comparison of the longshore variation of the mean nominal volume of the tracer with that of the main indigenous beach gravels. Abrupt changes in the indigenous gravel volume were observed at almost the same location as that giving abrupt decreases in tracer volume.

The tracer became smaller rapidly than the indigenous beach gravels. This fact depends on 1) the weaker resistance of the dacite blocks to the attrition and breakage, 2) the initial angularity of the tracer, and 3) the limited supply of the tracer.

Fig. 15 Longshore variations of the mean volume of tracer and beach gravels.

Ss: sandstone, Gr: granite,
Sl: slate, Ba: basalt.

CONCLUSIONS

The mean dislocating velocity of the tracer was 2 to 3 m/day under normal sea conditions, while under storm conditions it reached about 400 m/day. This velocity was fairly proportional to the longshore component of incident wave energy flux.

The longshore variations of the size and shape of beach gravels were mainly resulted from the progressive attrition and impact breakage of beach gravels rather than from the selective transport.

CHAPTER 102

SHINGLE¹ TRACING BY A NEW TECHNIQUE

Peter Wright, J.S. Cross and N. B. Webber
Department of Civil Engineering
University of Southampton, England

Abstract

A major drawback of all existing tracer techniques for monitoring shingle movement, except that of labelling with radioactive isotopes, is that tracer recovery rates are invariably low, (commonly less than 15% of the total injected) because recovery is limited to the beach surface. Investigations were made into the possibilities of developing a new tracer that might overcome this problem.

The paper describes the results of, and the conclusions drawn from two trial field experiments carried out using metal tracer pebbles. These had specific gravities, size and shape similar to the indigenous beach pebbles, and were recovered both on and beneath the beach surface using metal detectors. By assessing the relative merits and drawbacks of the technique it was concluded that the use of metal pebbles as tracers for shingle beaches is more practical than other methods for most tracing purposes. At present the technique is best suited to investigations ranging in length from a few days to a few months and requiring small to medium-scale injections of 5000 tracer pebbles or less. The considerable scope for the further development and application of the technique is discussed.

Introduction

Most techniques for investigating shingle transport on beaches depend either on some method of marking the indigenous beach material, on the introduction of beach pebbles and cobbles of a different petrological type or pebble and cobble substitutes and monitoring their movement after injection. The relative merits and drawbacks of existing tracer techniques are well documented in the literature by Kidson and Carr (1962). A more recent but less comprehensive review of shingle tracing is contained in Hails (1974).

A major drawback of all existing tracer techniques except that of labelling with radioactive isotopes, is that tracer recovery is limited to the beach surface. Consequently tracer recovery rates are seldom

SHINGLE¹ - used here in the context defined by Carr (1971), that is as encompassing all sediment particles whose long diameter, 'a', lies within the range 4-256mm, and as such includes the pebble and cobble categories of the Wentworth Scale.

greater than 30% and commonly less than 15% of the total quantity of tracer injected. This situation in which tracer recovery rates are low and little, if anything, is known of the tracer distribution beneath the beach surface is clearly unsatisfactory for seeking a detailed understanding of the behavioural patterns of shingle beaches.

Investigations were made into the possibilities of developing a new tracer for shingle beach studies that might overcome these difficulties.

Metal Pebbles: A New Type of Tracer for Shingle Beaches

The potential merits of using metal pebbles as a new type of tracer for shingle beaches were considered to be:

1. With the use of metal detectors it would be possible to detect the tracer pebbles beneath the beach surface which would not only increase tracer recovery rates but also provide information on the vertical distribution of the tracer.
2. Metal tracer pebbles could be manufactured to reproduce the specific gravity, size and shape of the indigenous beach pebbles.
3. Of importance when investigating beaches which are popular with the general public, they would be unobtrusive and present no health risk.

The specific gravity of the indigenous pebble-sized material found on the beaches to be investigated directly governed the metal used for the manufacture of the tracer pebbles. The pebble and cobble fractions of these beaches are composed of 90+% of flint and chert, both have specific gravities of 2.7. Aluminium was chosen as the metal most suitable for the purpose, not only because it has a specific gravity of 2.7, but also because it is easy to work with. The tracer pebbles used in the first trial field experiment were manufactured using the "full mould" or "cavityless" method of casting (Waring, 1965). Those used in the second trial field experiment were manufactured using a "sand-casting" technique (Fig.1).

Full details of the manufacturing procedures and the methods of tracer pebble detection and recovery in the field, including a discussion of the relative merits of the various types of metal detectors and search procedures, are contained in Wright, et al (1978).

Field Trials of the New Tracer

Aims of the field trials

1. To establish estimates of "expected" tracer recovery rates when using aluminium tracer pebbles.

Fig.1. Aluminium tracer pebbles manufactured using a "sand-casting" technique (first and third columns). Indigenous beach pebbles used as patterns (second and fourth columns).

2. To gain a clearer insight into the practicalities of undertaking a larger-scale field investigation using this tracer technique.
3. To ascertain the purpose and scale of tracer experiments to which this new tracing technique would be best suited.
4. To assess the corrosive and corrasive qualities of the aluminium tracer pebbles under field conditions.

It was hoped to assess whether or not the behaviour of the aluminium pebbles differs significantly from that of the indigenous beach pebbles by releasing simultaneously with the aluminium tracers, and at the same site, marine-painted or fluorescent-coated beach pebbles. However, due to financial restrictions this was not possible.

Conduct and results of the field trials

Field trials were undertaken at Hengistbury Long Beach, Poole Bay, Dorset (Fig.2), during the periods 9/5/77 - 25/5/77 and 20/2/78 - 11/3/78.

In both experiments the tracer pebbles were injected at one-pebble depth (40-50mm) on the upper foreshore at the seaward foot of the shingle scarp face of the backshore zone. The background indigenous pebble population incorporated the full size range of the artificial aluminium pebbles. The dimensions of the tracer pebbles injected in the two experiments are given in Table I.

Wave orientation is expressed as the angle which the orthogonals of waves approaching the shore make with an imaginary line drawn at right-angles to the same shoreline. Angles measured to the west of the line are prefixed +, and those measured to the east, prefixed -.

During the first field trial the tracer pebbles were subjected to movement under three distinct sets of wave conditions. During the second experiment however conditions were much more varied. Wind and wave conditions during the two field trials are summarized in Table II. During the first field trial tracer recoveries of 41% (no lower foreshore search), 63%, 59% and 61% were made on the four days of full sweeping of the tracer-spread area. During the second trial tracer recoveries of 38%, 27%, 28%, 30%, 34% and 43% were made. Tracer recovery rates for both field trials are fully tabulated in Table III.

TABLE III

27	34*	42	44	30	34	34	22
37	43	54	54	32	43	41	33

* - No lower foreshore search possible

The lower rates of tracer recovery made during the second field trial were attributed to three main causes. Firstly, only on the occasion of the final full sweep of the backshore and foreshore zones was the lower foreshore sufficiently exposed for an adequate search to be made. Secondly, the area of beach through which the tracer spread was 18540m², four times greater than that during the first field trial (Table IV). Consequently, with the limited personnel available, searches of the beach were insufficiently thorough. Finally, the depth of beach through which the tracer spread was 1.3m, 2.5 times greater than that during the first field trial (Table IV). Consequently, a high proportion of the tracer pebbles were buried at depths exceeding the maximum penetration depth of 0.4m of the metal detectors. The validity of the latter explanation is illustrated by the data presented in Table V. Although tracer recoveries during any one search of the beach averaged only 30-35% of the total quantity injected, the majority of the remaining tracer pebbles had not been "lost" either longitudinally or transversely beyond the search area. After only two tides the tracer pebbles were thoroughly distributed through the backshore and foreshore zones. Subsequent reworking of the beach material by wave action successively returned tracer pebbles to within 0.4m of the beach surface, where they could be readily detected. Table V shows that in this way an overall average of 72% of the tracer pebbles injected had been recovered at least once since injection (The tracer pebbles were number stamped so that the movement of individual pebbles could be monitored).

TABLE IV

Comparison of tracer recovery rates with the volume of beach through which the tracer had spread.

37	43	18510	1.2

TABLE V

Cumulative percentage of tracer pebbles within each batch recovered at least once since injection.

No. of tides after injection	Tracer recoveries						
	<u>Total</u>	<u>Pebble Batches</u>					
		LA	MA	SA	LR	MR	SR
<u>Field Trial 2</u>							
2	28.1	39	21	24	34	29	21
6	40.8	46	46	44	43	36	30
8	49.6	61	54	56	46	43	38
17	55.3	67	61	59	51	49	44
27	59.0	73	64	61	59	51	46
37	66.8	74	77	69	67	60	53
57	69.3	77	79	72	67	64	57
97	71.7	80	80	76	69	66	60

During both field trials recovery rates for the larger size tracer pebbles were, for the most part, greater than that for the smaller pebbles because the former have a greater surface area than the latter and are consequently detectable at greater depths. Further discrepancies in the recovery rates of tracer pebbles of differing size and shape were attributable to pebble sorting by wave action. For example, angular tracer pebbles, irrespective of size, tended to be carried up on to, and remain on, the upper foreshore and backshore zones, whereas rounded tracer pebbles under the same wave action were more likely to be returned with the backwash to the lower foreshore.

The use of metal detectors better suited to the conditions of operation should result in higher recovery rates.

Conclusions

From our investigations carried out to-date the application of metal pebbles as a tracer for shingle beaches offers the following merits:

1. The most valuable capability of the new technique is the ease of detection of the tracer beneath the beach surface. This provides:
 - a) a direct, and consequently more reliable means of studying beaches as three-dimensional features.
 - b) a higher rate of tracer recovery upon which to base statistical inferences.
2. The ability to manufacture tracer pebbles with similar specific gravity, size and shape to that of the indigenous beach pebbles is a considerable advantage over many previously devised artificial tracers.
3. Number stamping the tracer pebbles can provide a means of tracking the movement of individual pebbles.
4. Of prime importance when investigating beaches which receive use by the general public are the considerations that:
 - a) aluminium pebbles present no health risk. Whilst the use of radioactive isotopes provide a means of tracer pebble detection and recovery from beneath the beach surface they should not be used on popular public beaches.
 - b) they are also unobtrusive, and as such are unlikely to arouse public interest in the same way that painted pebbles might. Therefore losses and redistribution due to interference should be minimal.
5. The new technique provides a means of pebble detection, although not necessarily recovery, in the unexposed swash zone.
6. Tracer contamination of the beach is no particular problem because pebbles used in successive experiments can be colour-coded with small resin plugs poured into holes, either cast or drilled, in the individual pebbles. Tracer contamination

is a problem when using mass injection of "foreign" beach pebbles, because the range of pebbles of different petrological types which have similar specific gravity, size and shape characteristics to that of the indigenous beach pebbles is normally very limited.

7. Tracer pebbles recovered at the end of an experiment are reusable in subsequent investigations.

Four possible drawbacks of the technique can be identified:

1. Cost. At current British prices 1000 tracer pebbles 50x40x35mm in size can be manufactured, using a "sand-casting" technique, at a cost of £200 sterling (380 U.S. dollars). This cost may be considered high by researchers working on a low budget. However, the cost of using aluminium tracer pebbles compares favourably with that of other tracer techniques when one considers that:
 - a) in order to achieve comparable results, the number of tracer pebbles required using the new technique is less than that by any other method because of the higher recovery rates one can normally expect
 - b) the tracer pebbles are reusable on recovery.
2. Tracer pebbles not recovered at the end of an experiment are liable to be unnecessarily detected in subsequent experiments carried out on the same length of beach. However, in the normal sequence of events the longer the tracer pebbles remain on the beach the more diffused they become, i.e. spread longitudinally beyond the limits of later experiments and buried to depths exceeding the maximum penetration depth of the metal detectors.
3. The background metal content of the beach can be a problem if the beach being investigated is highly contaminated with metal objects.
4. Losses and redistribution of the tracer during field experiments due to public interference arising from the fact that treasure hunting using metal detectors has become a popular minority pastime in Britain in recent years. The majority of these treasure hunters are members of regional clubs, which when approached, are very pleased to co-operate and even give assistance during field experiments.

Summary

By assessing the relative merits and drawbacks of the technique, we have concluded that the use of metal pebbles as tracers for shingle beaches is more practical than other methods for most tracing purposes. At present the technique is best suited to investigations ranging in length from a few days to a few months and requiring small to medium-scale injections of 5000 tracer pebbles or less. It is of particular value when a knowledge of the movements of individual pebbles is required.

Refinements to the efficiency of the technique would greatly increase its value. The efficiency to be gained from improvements to the field application of the technique are small compared to that attainable by improvement to the detection equipment. Two such improvements to the latter are of prime importance and both are within the bounds of present technology. There is a need to increase the depth of sensitivity of the search heads, and to increase the reliability of metal discrimination devices that are currently built into detectors. There is a future need for a detector capable of differentiating between various grades of tracer pebbles on the basis of size and/or shape differences. This might be achieved in one of two ways, either with a programmable detector in which the differentiation could be carried out internally or with a detector with an inbuilt display panel upon which it could display an outline of the detected metal object which could then be classified by the operator.

There is considerable scope for the further development and application of the technique both for use on beaches and in the near-shore and offshore zones.

CHAPTER 103

A NUMERICAL MODEL FOR SEDIMENT TRANSPORT

by

J.P. LEPETIT and A. HAUGUEL*

ABSTRACT

We introduce here a numerical two dimensional model for sediment transport which permits to compute the impact of a coastal structure on the bottom evolution.

The introduction of current disturbance and some assumptions using difference of time scale between current and bottom evolutions permits to obtain a propagation equation driving the bottom evolution. The model has been calibrated in the case of the local scour around a jetty. At last, it has been applied to the bottom evolution in the vicinity of the new port of Dunkerque.

INTRODUCTION

One of the impacts of a large coastal structure is its effect on current pattern in the vicinity of the structure. These changes in current conditions will induce changes in the sediment transport pattern and may disturb an existing equilibrium thus causing large changes in bottom topography in the vicinity of the structure. To assess the severity and extend of topographical changes induced by the structure the interaction of the resulting fluid motion with the bottom evolution must be properly reproduced.

The study of sediment drifting and movable bed evolution is a difficult problem from a physical and mechanical point of view. But the sediment transport relationship admitted, the problem is reduced to the study of a conservative phenomena.

An other problem is the difference of time scale between current and bottom evolution. It is impossible (because of cost), to compute simultaneously the bottom evolution and the current by the classical way. Nevertheless, the interaction between the two is fundamental for the bottom evolution.

This paper presents a two dimensional mathematical sediment transport model taking into account the influence of the bottom evolution upon the current pattern and shows how this particular aspect of the interaction drives the ripples propagation.

THEORETICAL ANALYSES

Bed continuity equation and sediment transport relationship

Let \vec{T} be the sediment transport vector and ξ the bottom elevation ; the bed continuity equation may be expressed as

* Division Hydraulique Maritime. Laboratoire National
d'Hydraulique. Electricité de France. Chatou. France.

$$\frac{\partial \xi}{\partial t} + \text{div } \bar{T} = 0$$

How express \bar{T} as a function of the velocity? That is a real problem. Many relations can be found taking into account waves or not. For ourselves we have used the Meyer-Peter relationship for the sediment transport vector \bar{T} which is supposed in the direction of the current bottom shear stress which is evaluated using Chezy's relationship.

So the bed continuity equation can be transformed into :

$$\frac{\partial \xi}{\partial t} + T_{Xu} \frac{\partial u}{\partial x} + T_{Xv} \frac{\partial v}{\partial x} + T_{Yu} \frac{\partial u}{\partial y} + T_{Yv} \frac{\partial v}{\partial y} = 0$$

with

$$T_{Xu} = \frac{u}{W} \frac{\partial T}{\partial u} + T \frac{v^2}{W^3}, \quad T_{Yu} = \frac{v}{W} \frac{\partial T}{\partial u} - T \frac{uv}{W^3}$$

$$T_{Xv} = \frac{u}{W} \frac{\partial T}{\partial v} - T \frac{uv}{W^3}, \quad T_{Yv} = \frac{v}{W} \frac{\partial T}{\partial v} + T \frac{u^2}{W^3}$$

$$T = \left. \begin{array}{l} 8\sqrt{\frac{g}{\varpi}} \frac{1}{\varpi_S - \varpi} (\tau - \tau_C)^{3/2} \text{ if } \tau > \tau \\ 0 \text{ if } \tau < \tau_C \end{array} \right\} \text{ sediment transport}$$

$$\tau_C = A (\varpi_S - \varpi) D_M \quad (0,02 < A < 0,06 \text{ Shields}). \text{ Critical bottom shear stress}$$

$$\tau = \varpi \frac{W^2}{C^2} \text{ bottom shear stress}$$

u, v are the two components of the depth averaged current

$$W^2 = u^2 + v^2$$

ϖ, ϖ_S specific weight of water and sediment

D_M mean diameter of sediment.

Influence of bottom evolution upon the current pattern

With the initial bottom shape ξ_0 and the new geometric conditions the depth averaged flow pattern is (u_0, v_0) .

This current modifies the bottom shape which in turn modifies the current by $(u_1(t), v_1(t))$.

At time t , the current pattern is given by $(u_0 + u_1(t), v_0 + v_1(t))$ and the bottom level by $\xi(t)$ ($\xi_S = \xi - \xi_0$ is the bottom evolution).

The resulting disturbance (u_1, v_1) is assumed to be without effect upon the surface elevation z_0 . This assumption is equivalent to neglect the characteristic response time of the surface wave propagation compared to the characteristic response time of the bottom evolution.

The resolution of the fluid continuity equation shows that the current disturbance (u_1, v_1) can be written in two different terms :

- the first one (\bar{u}_1, \bar{v}_1) comes directly from the bottom elevation ξ and expresses the flow conservation along the stream lines of the undisturbed field of currents (u_0, v_0)

$$\bar{u}_1 = u_0 \frac{\xi - \xi_0}{z_0 - \xi} = u_0 \frac{\xi_s}{h} \quad \bar{v}_1 = v_0 \frac{\xi - \xi_0}{z_0 - \xi} = v_0 \frac{\xi_s}{h}$$

- the second one (\tilde{u}_1, \tilde{v}_1) is a deviation of the flow due to the bottom slope. It is governed by :

$$\frac{\partial}{\partial x} \left[\tilde{u}_1 (z_0 - \xi) \right] + \frac{\partial}{\partial y} \left[\tilde{v}_1 (z_0 - \xi) \right] = 0$$

Bottom equation

These two terms are introduced in the bed continuity equation (1) which can be written :

$$\frac{\partial \xi_s}{\partial t} + C \left(\frac{u}{W} \frac{\partial \xi_s}{\partial x} + \frac{v}{W} \frac{\partial \xi_s}{\partial y} \right) = - T_{Xu} \left[\frac{\partial}{\partial x} (u_0 + \tilde{u}_1) + \xi_s \frac{\partial}{\partial x} \left(\frac{u_0}{h_0} \right) \right]$$

$$\begin{aligned} & - T_{Xv} \left[\frac{\partial}{\partial x} (v_0 + \tilde{v}_1) + \xi_s \frac{\partial}{\partial x} \left(\frac{v_0}{h_0} \right) \right] \\ & - T_{Yu} \left[\frac{\partial}{\partial y} (u_0 + \tilde{u}_1) + \xi_s \frac{\partial}{\partial y} \left(\frac{u_0}{h_0} \right) \right] \\ & - T_{Yv} \left[\frac{\partial}{\partial y} (v_0 + \tilde{v}_1) + \xi_s \frac{\partial}{\partial y} \left(\frac{v_0}{h_0} \right) \right] \end{aligned} \quad (2)$$

with $C = \frac{1}{h} \left(u \frac{\partial T}{\partial u} + v \frac{\partial T}{\partial v} \right)$

Equation (2) governs a ripples propagation in the direction of the initial current pattern with the celerity C. This phenomena comes directly from the adaptation of current disturbance (\bar{u}_1, \bar{v}_1). By neglecting the disturbance it is impossible to reproduce the ripples propagation.

The second member can be divided in two different parts :

- contribution of the initial current pattern which is conserved at time t
- contribution of the deviation of the flow (\tilde{u}_1, \tilde{v}_1) which drives a ripple deformation.

Fluid equation

To determine the current disturbance (u_1, v_1) an other assumption is required; an irrotational current disturbance pattern ($\hat{u}_1 + \hat{u}_1, \hat{v}_1 + \hat{v}_1$) is assumed. So \hat{u}_1 and \hat{v}_1 are obtained from the three-dimensional stream function ψ , which yields a Poisson type equation (3).

So the actual current pattern is defined by :

$$u = u_0 + u_0 \frac{\xi_s}{h} + \frac{\hat{u}_1}{h} \frac{\partial \psi}{\partial y}$$

$$v = v_0 + v_0 \frac{\xi_s}{h} - \frac{\hat{v}_1}{h} \frac{\partial \psi}{\partial x}$$

$h = z_0 - \xi$ actual depth and ψ obtained from

$$\Delta \psi = + h \frac{\partial}{\partial x} \left(v_0 \frac{\xi_s}{h} \right) - \frac{\partial}{\partial h} \left(u_0 \frac{\xi_s}{h} \right) + \hat{u}_1 \frac{\partial h}{\partial y} - \hat{v}_1 \frac{\partial h}{\partial x} \quad (3)$$

NUMERICAL MODEL

A finite difference scheme is used to solve equations (2) and (3). The computational grids ψ and u, v, ξ are shifted. The initial conditions (u_0, v_0, z_0, ξ_0) are obtained with an other numerical model or recorded on a scale model.

Each time step involves two stages :

- computation of the bottom level ξ ; equation (2) is solved by the characteristic method. All functions are explicit but the scheme is stable.
- computation of the new velocities ; only \hat{u}_1, \hat{v}_1 have to be computed. Equation (3) is solved by an iterative process.

NUMERICAL EXAMPLESLocal scour around a jetty

Several numerical examples have been computed. In figures 1 and 2, the local scour around a jetty, and the flow pattern evolution are shown. The conditions are : flat initial bottom, far field mean velocity = 41 cm/s, water depth = 20 cm, width = 46 cm, ratio jetty length over flume width = 1/3 and particle diameter 4,5 mm. The initial current pattern has been computed with an other numerical model. In figure 3, comparison between computed and measured scour is shown.

Study of new port of Dunkerque

The Port Autonome of Dunkerque has built a new port able to receive 22 metters draught ships. Many studies have been

Fig.1_EROSIONS AFTER 1,2 AND 3 HOURS

Fig.2_ CURRENT PATTERN AFTER 1,2 AND 3 HOURS

EXPERIMENT

COMPUTATION

Fig.3 _COMPARISON BETWEEN MEASURED
AND COMPUTED EROSIONS

carried on during ten years. Particularly, a movable bed model have been built to study the bottom evolution due to tidal currents near the new port.

The numerical model has been used in this particular case, but to decrease the cost of computation the second kind of disturbance has been neglected. Only equation (2) was solved. The initial current pattern used for the computation was recorded on the scale model.

The comparison between the computed and mesured erosions and accretions is presented on figures 4 and 5. The main difference takes place near the jetties and it probably comes from the initial current pattern which was not conservative because of the precision of measurements on the scale model.

CONCLUSION

A simple kinematical study of the sediment transport equation has shown how can the ripples propagation be obtained. It has also allowed a numerical integration on a computer. The characteristic response time of the surface wave propagation compared to the characteristic response time of the bottom evolution put a stop to any sort of computation of the disturbed current in the classical way. The introduction of current disturbance and several assumptions permit the computation of the bottom evolution during a long time. This kinematical and mathematical aspect almost understood, studies are going on a more physical and dynamical point of view to determine the influence of the different parameters in transport relationship and to find a best dynamical approximation of the current disturbance. In the same time, a mean of averaging the tide in tidal problems is investigated.

CHAPTER 104

SURF ZONE MEASUREMENTS OF SUSPENDED SEDIMENT

Timothy W. Kana¹

ABSTRACT

Suspended sediment concentration was measured in approximately 250 breaking waves on undeveloped beaches near Price Inlet, South Carolina, U.S.A., using portable *in situ* bulk water samplers. As many as 10 instantaneous 2-liter water volumes were obtained in each wave for a total of 1500 samples. Concentrations of suspended sediment were determined at fixed intervals of 10, 30, 60 and 100 cm above the bed for various surf zone positions relative to the breakpoint. The majority of waves sampled during 22 days in June and July, 1977 were relatively long crested, smooth, spilling to plunging in form, with breaker heights ranging from 20 to 150 cm. Surf zone process variables measured included breaker height and depth, breaker type, wave period, surface long-shore current velocity, wind velocity and direction.

Scatter plots of mean concentration against various process parameters indicate the amount of sediment entrained in breaking waves is primarily a function of elevation above the bed, breaker type, breaker height and distance from the breakpoint. Concentration ranged over 3 orders of magnitude up to 10 gm/l, but varied less than 1 order for samples collected under similar conditions with regard to elevation and breaker type. Plunging breakers generally entrain 1 order more sediment than spilling breakers equal in height. Despite considerable scatter, these data indicate concentration decreases with increasing wave height for waves 50 to 150 cm high, suggesting that small waves can be important in the transport of sand on gently-sloping open coasts.

INTRODUCTION

Over 1500 instantaneous suspended sediment concentrations have been determined from water samples collected in the surf zone near Price Inlet, South Carolina, U.S.A. The purpose of this study was to determine the spatial distribution of suspended sediment near the breakpoint under various wave conditions in order to identify the wave parameters which control the amount of sediment entrained from the bed. This work represents one of several experiments conducted by the Coastal Research Division of the University of South Carolina designed to increase our understanding of sediment entrainment and transport processes in waves and eventually to construct a predictive model of suspended sediment concentration in the surf zone.

METHODS FOR MEASURING SUSPENDED SEDIMENT CONCENTRATION

Only a few workers have attempted to measure concentration of suspended sediment in breaking waves, undoubtedly due to the relative difficulty of sampling in a high energy environment. Three basic methods for measuring concentration in oscillatory flows have been used: pump systems for obtaining a time-integrated sample of water and sediment (Watts, 1953; Fairchild, 1972, 1977; and Coakley, *et al.*, 1978, this volume); *in situ* collecting traps for obtaining relatively instantaneous bulk water samples (Kana, 1976; Inman, 1977); and indirect measures which relate turbidity to light attenuation, back scatter of light, or gamma absorption (Homma, *et al.*, 1975; Hattori, 1969; Horikawa and Watanabe, 1970; Kennedy and Locher, 1972; Basinski and Lewandowski, 1974; Brenninkmeyer, 1976a; and Leonard and Brenninkmeyer, 1978, this volume). There are obviously certain disadvantages to any of these techniques, most important of which is the influence of the sampling apparatus on the flow field. Any device which remains fixed to the bed, or utilizes a supporting structure or pier, is likely to monitor artificially-induced suspensions (Inman, 1977).

Pump samplers were not suitable for the present study because they provide time-averaged water samples making it difficult to determine the effect of a single wave on sediment suspension. Since concentration generally fluctuates at a period approximating that of the incident wave field, relatively instantaneous values were required.

Indirect monitors of concentration, such as the almometer (Brenninkmeyer, 1976a), have the advantage of providing detailed time series information on turbidity changes, but most of these devices are difficult to calibrate for field use. Such external conditions as cloud cover, air entrainment in the surf zone, and the presence of varying amounts of organic matter in the water column, affect turbidity and, therefore, the output of these devices. Also, in some cases, the threshold for detecting sediment bursts from the bed is significantly higher than the typical concentrations found in the surf zone by Watts (1953) in California, or Kana (1977) in South Carolina.

According to Inman (1977), the best way of overcoming the limitations of presently available suspended sediment samplers is by using portable *in situ* samplers activated by swimmers in conjunction with remote recording turbidity sensors. This combination may be ideal, but it is difficult to coordinate and expensive to deploy. However, for the past 3 years, we have used a portable *in situ* water sampler which has proven to be an efficient and inexpensive means of obtaining suspended sediment samples in the surf zone under a variety of wave conditions. Concentrations obtained directly from *in situ* water samples have been combined with littoral observations to estimate suspended sediment transport rates along two undeveloped beaches (Kana, 1977).

The apparatus used in the present study collects several closely spaced simultaneous water samples in a vertical array above the bed (Kana, 1976). It consists of a 2 meter-long mounting pole, support brackets and several 2-liter cast acrylic bottles closed off by hinged

doors (Fig. 1). To ready the sampler for use, the operator opens the bottle doors and attaches them to a trigger assembly on the mounting pole, similar to rigging a Van Dorn-type water sampler. Then as the bottles are held open, the device is carried into the surf zone and positioned vertically above the bed until the sampling instant. At the desired sampling time, the apparatus is thrust into the bed, forcing the trigger open and allowing the bottles to shut simultaneously, trapping each sample. The device has a relatively fast response time of less than one-half second, remaining off the bed until the sampling instant. Tests have shown that the collecting bottles are drawn shut before sediment thrown up by the apparatus reaches each sampling position. The typical array of samples collected in this study were centered at 10, 30, 60 and 100 cm above the bed. Because of the relatively broad, stubby shape of each collecting bottle, the lowermost sample obtains sediment suspended between 4 and 16 cm above the bottom. Inman (1977) has recently developed a portable device for "coring" the water column to obtain a similar vertical array of instantaneous water samples; however, detailed results were not available in time to be included in this report.

PREVIOUS RESULTS

It is generally recognized from laboratory studies that in oscillatory flow, suspended sediment concentration decreases exponentially above the bed (Hattori, 1971; Kennedy and Locher, 1972; and MacDonald, 1977). Field measurements in the surf zone by Inman (1977; Fig. 5) and Kana (1977; Figure 5) tend to confirm this relation. A relatively constant suspension wash load of fine-grained particles exists throughout the water column in the nearshore. However, in the breaker and swash zones, intermittent suspensions of relatively coarse bed material are thrown up by waves to cause the observed vertical distribution of concentration. The frequency and magnitude of these intermittent suspensions are of primary interest because of their importance in the transport of sand on beaches. In general, the timing of bursts of sediment from the bed corresponds to the time of wave breaking, with some delay as the particles lag behind the water motion (Hattori, 1969; Brenninkmeyer, 1976b).

Fairchild (1972), working from ocean piers at Ventnor, N. J. and Nags Head, N. C., has measured a slight increase in concentration with breaker height and a decrease away from the breakpoint for time-integrated pump samples. Additionally, he has shown that concentration increases with the ratio of breaker height to breaker depth and is more variable with low waves than high. His samples were collected in waves ranging from 40 to 120 cm, yielding concentrations up to 4.0 parts per thousand. The sampler intake was varied between 8 cm and 75 cm above the bed. Since most of the samples were pumped over a 3 minute time period, it is difficult to isolate the effect of a single wave and establish any quantitative relationships from these data. However, Fairchild was apparently correct in concluding that suspended sediment concentration is a function of elevation above the bed, wave height and position in the surf zone.

Brenninkmeyer (1976b), using arrays of photoelectric sensors in the surf at Point Mugu, California, found that the zone of maximum suspension occurs near the stillwater level in the swash zone. He reported that suspensions of sand more than 15 cm above the bed are rare in the outer surf zone and appear to be influenced by the stage of the tide and the elevation of the ground water table. Bursts of sediment from the bed or "sand fountains" have durations of the order 2 to 10 seconds, apparently corresponding to the period of incident waves.

Kana (1977) reported a dependency of concentration on elevation above the bed and breaker type, based on instantaneous in situ bulk water samples collected along two South Carolina beaches. Using a visual classification, he reported that plunging-type waves entrain almost one order more sediment than spilling breakers.

None of these studies is complete enough to establish a quantitative relationship between suspended sediment concentration and commonly measured surf parameters. However, they provide a basis to continue research designed to isolate and identify the important factors controlling the entrainment of sediment in the surf zone. The present paper is, at most, an attempt to describe some relations of common surf parameters to suspended sediment concentration under a variety of moderate wave conditions. As such, it applies to a relatively specific wave climate, beach morphology, sediment size and bed packing.

STUDY AREA

The field measurements for this study were obtained at two beach sites, each approximately 2 km from Price Inlet, on Bulls Island and Capers Island, South Carolina (Fig. 2). This portion of the South Carolina coast is under the influence of dominant waves from the northeast, causing net longshore transport to the south (estimated rate is $1.2 - 1.5 \times 10^5 \text{ m}^3/\text{yr}$; Kana, 1977). Wave energy is moderate with breaker heights ranging from 20 to 160 cm under non-storm conditions, with a mean of 60 cm. The beaches at these two sites are composed of well-sorted, fine sand (mean diameter = 0.22 mm) and are gently sloping and relatively featureless (mean beach face slope = 0.018). During average swell conditions, the surf zone is approximately 50 meters wide, but due to the mean tide range of 1.5 meters, a much wider portion of the beach face is periodically exposed to the impact of breaking waves. The bed in the active surf zone is tightly compacted and rarely exhibits small scale bedforms. Slope changes along the beach face are minor and generally controlled by the formation of low amplitude ridges or bars parallel to shore.

EXPERIMENTAL DESIGN

During 22 sampling days in June and July, 1977, multiple arrays of water samples were collected in the littoral zone near Price Inlet, South Carolina, during a variety of swell conditions using the sampler in Figure 1. Up to three arrays providing as many as 10 water samples were used in the same wave to detect suspended sediment concentrations

Figure 1. Apparatus used to collect water samples in the surf zone. A 2 m-long pole supporting several 2 l. bottles is emplaced vertically in the surf zone. When thrust into the bed, a foot pad moves the trigger assembly up, simultaneously tripping each bottle. Top two bottles are rigged for sampling. Bottom bottles are in the tripped position.

Figure 2. Study area near Charleston, South Carolina, U.S.A. Suspended sediment samples were collected at stations located along two undeveloped beaches near Price Inlet (arrows).

across the surf zone and along individual wave crests. A four-to six-man field team was required in order to simultaneously collect the water samples, make littoral process observations, and photograph each wave sampled.

Two ranges were established at the experiment sites and periodically surveyed to the low tide breaker line to establish the beach slope at each sampling point. Each day, stakes were set throughout the surf zone as reference points for sampling location and wave position. Each suspended sediment sample was positioned in relation to: 1) the bed, by means of the sampling apparatus, 2) a bench mark on land, by means of the reference stakes, 3) the wave breakpoint, by measuring the distance seaward or landward to each array, and 4) the time of passage of each wave sampled. Figure 3 is a sketch of a typical sampling arrangement.

Figure 3. Sketch of the sampling arrangement showing samplers in place. Operators stood downdrift from sample point holding apparatus above bed until sampling instant.

In order to minimize the number of variables affecting the distribution of concentration, sampling was performed during swell conditions with wind velocities less than 5 m/s. Generally at these beach sites, waves are more "classically" formed and long crested in the morning before the diurnal sea breeze is established. As onshore wind velocity increases, wave crests become shorter and more irregular, making it difficult to distinguish the breakpoint. The beaches at these two sites were chosen for the experiment because their profiles are generally featureless, small scale bed forms are essentially nonexistent, and they are away from any artificial structures which may influence turbidity.

All samples reported herein were collected approximately 2 seconds after the passage of the wave bore by each sampler. Previous results indicate that, in general, the maximum concentration at a point occurs just after the passage of a wave (Kana, 1977). Thus, with 3 operators, it was possible to follow one wave toward shore and, to some extent, determine the change in concentration across the surf zone. Multiple arrays were also collected along individual wave crests to determine the range of variability of concentration within a single wave. Each wave sampled was photographed at several positions during breaking to maintain a record of wave types and provide a means of checking visual estimates of height and depth. A typical photographic sequence is shown in Figure 4.

The following surf parameters were measured for each sample array:

1. Breaker height (H_b) and water depth at breaking (d) - visually, by means of a graduate staff held in place at the breakpoint and checked by scaling photographs taken during sampling. Limit of error ± 10 cm.

2. Wave period (T) - by averaging the time of travel between the wave crest prior to, and the crest following, the wave sampled. Limit of error ± 1 second.

3. Surface longshore current velocity at mid-surf position (V) - by timing the travel of small floats between range markers set 10 m apart in the alongshore direction.

4. Breaker angle (α_b) - visually, by means of a protractor, sighting the acute angle between wave crest and shoreline. Limit of error ± 2 degrees.

5. Breaker type - qualitatively, by visual observations in the field, verified by photos taken while sampling and checked against various breaker-type parameters (e.g., Galvin, 1968; Battjes, 1974).

6. Wind velocity and direction - by means of a hand-held anemometer.

Suspended sediment samples were processed by normal filtration techniques to determine concentration as a weight per unit volume (gm/l).

Using up to 3 samplers in each wave, over 250 individual waves were sampled during the study yielding approximately 1500 concentration values. Over 1000 of the samples were collected at 10 and 30 cm above the bed.

Table 1 summarizes the range of surf conditions and number of samples by wave type and wave height collected during the experiment.

Figure 4. Four successive photographs of one of the breaking waves sampled at 3 positions inside the surf zone. Arrays of suspended sediment samples taken 3 m, 7 m, and 10 m landward of A. the breakpoint. Concentrations are listed below.

A. Wave beginning to break 3 m seaward of sampler operator #1.

$H_b = 90$ cm; $d = 95$ cm; $T = 8$ s; $V = 0$ cm/s; $m = 0.011$; breaker type: spilling; Time = 0 s.

B. Wave fully broken, bore at Operator #1.

Bore height = 70 cm; Depth under bore = 90 cm; Time ~ 1 s.

C. Bore approaching operator #2.

Bore height = 60 cm; Depth = 65 cm; Time ~ 2½ s.

RESULTS

Previously reported field results by Watts (1953), Fairchild (1972) and Kana (1977) have shown that the concentration of suspended sand in the surf zone can vary by several orders of magnitude. Therefore, it is necessary to compare samples collected under similar conditions with regard to wave position and height above the bed in order to determine the effect of individual waves. By grouping samples according to elevation, breaker type or distance from the breakpoint, it is possible to eliminate much of this variation. As a first attempt at establishing the relation between common surf parameters and concentration, it was decided that a comparison of mean values obtained under similar conditions was the best (and perhaps only) way of isolating any trends. There will be no attempt in this paper to rigorously test these relationships. Instead, they are presented as a description of a given set of field conditions.

Plotted on a log scale, suspended sediment concentration is normally distributed by sample elevation for the data set reported herein (Fig. 5). From Figure 5, it can be seen that the mean concentration 10 cm above the bed is approximately 2 times higher than the mean concentration at 30 cm. The range of concentrations at each sample elevation spans roughly 2 orders of magnitude.

Figure 6 shows mean suspended sediment concentration by elevation for three breaker types classified by visual and photographic interpretation. Two dominant wave types, plunging and spilling, occur at the experiment sites. However, we identified and plotted an intermediate type exhibiting characteristics of both spilling and plunging

Figure 5. Normal probability plot of concentration for all samples collected 10 cm and 30 cm above the bed irrespective of breaker types.

Figure 6. Suspended sediment distribution in the outer surf zone between 1 and 10 m landward of the breakpoint. Mean concentrations are plotted by elevation above the bed for spilling and plunging type breakers. An intermediate wave type exhibiting characteristics of spilling and plunging waves is also plotted (triangles).

waves. The visual classification of wave types tends to agree with Galvin's (1968) breaker classification, which is given by a dimensionless parameter, (B_b), based on wave steepness and beach slope*. Galvin reports a cut off from spilling to plunging waves at $B_b = 0.068$ versus 0.070 for these data. The depth at breaking generally decreases from spilling to plunging waves, and this agrees with mean values of the ratio breaker depth to height, (d/H_b), listed in Fig. 6. Note that plunging waves, on average, entrain almost one order more sediment than spilling breakers. Concentration decreases exponentially up to 60 cm above the bed, then appears to reach a constant value, reflecting the type of suspension: intermittent close to the bed, resulting from periodic bursts of coarse, bed material; continuous near the surface, due to the dominance of suspended wash load.

Since breaker type is an important factor controlling the magnitude of intermittent bursts of sand from the bed, it is desirable to test concentration against parameters which quantify the variation in wave type. No universally accepted breaker classification exists, but several have been proposed. Probably the most widely known are Galvin's (1968), which was already mentioned, and Battjes' (1974), which is also based on wave steepness and beach slope. Based on laboratory waves, Galvin has determined cutoffs between spillings and plunging waves at $B_b = 0.068$ and for plunging and collapsing waves at $B_b = 0.003$. Galvin's inshore parameter is plotted against mean suspended sediment concentration for samples collected 10 cm above the bed (Fig. 7). There is a general trend of increasing concentration from spilling to plunging waves, but due to considerable scatter, and the relatively flat slope of the regression line, this relation is not satisfactory as a predictor of concentration for these data.

The poor fit of the data to Galvin's breaker classification may be due to the dependence of B_b on wave period (T). A plot of concentration versus period shows essentially no dependence of suspended sediment on T (Fig. 8). This suggests that the periodicity of waves has little effect on sediment entrainment for this range of waves. This is not surprising, considering the characteristics of waves as they are transformed at breaking. Munk (1949) recognized that wave length, a function of T , has little to do with the shape of waves near the breakpoint since waves in very shallow water commonly have long, shallow troughs and steep, sharp crests. Consequently, he recommended applying solitary wave theory for describing waves near breaking. This theory differs from the classical Airy or Stokes

* B_b is Galvin's inshore parameter given by $B = H_b / (gmT^2)$, where H_b is breaker height; g is acceleration of gravity; m is beach slope; and T is wave period.

Figure 7. Mean concentration at 10 cm above the bed versus Galvin's (1968) inshore breaker type parameter ($B_b = H_b / (gT^2)$). The defined cut off between spilling and plunging waves is 0.063. Although there is a trend toward high concentrations in plunging waves, this parameter is not an adequate predictor for these data.

Figure 8. Mean concentration at 10 cm above the bed versus wave period for plunging and spilling breakers. Bars on each point represent the range in concentration values to ± 1 standard deviation. Suspended sediment appears to be independent of wave period for moderate wave conditions.

Figure 9. Mean concentration at 10 cm versus the ratio of breaker depth (d/H_b). Bars on each point are ± 1 standard deviation. This parameter, independent of wave period, is useful for distinguishing breaker types and predicting concentration.

wave theories because it contains only one fundamental parameter independent of wave length: relative wave height, or the ratio, H_b/d .

In Figure 9, d/H_b has been plotted against mean concentration for the 10 cm above the bed samples. There is still considerable scatter in the plot, but the data show better separation of breaker types by this parameter alone. Relative wave height, which is independent of wave steepness, appears more useful for classifying the present set of waves. Bars on each data point represent the range of variation in concentration to ± 1 standard deviation.

It would be useful to establish a relation between wave height and suspended sediment concentration for purposes of prediction, since H_b is a commonly measured surf parameter. Fairchild (1972) reported an increase in concentration with wave height, and it is commonly believed that sediment suspension increases directly with wave energy. The data in Figure 10, breaker height versus concentration by wave type, do not support this contention. The means for samples collected 10 cm above the bed show a clear distinction between breaker types, but the shape of each curve is different. Figure 10 shows an increase in concentration for spilling waves up to approximately 90 cm, then a significant decrease for higher waves up to 150 cm. This suggests a concentration maximum in wave heights between 50 and 90 cm for moderate swell conditions. Plunging waves, on the other hand, show a generally continuous decrease in concentration with increasing breaker height. It is not clear why this unexpected result occurs, but it may be related to the increased interaction of the wash uprush and backrush with smaller waves. The width of the surf zone is a function of breaker height such that higher waves tend to break in deeper water considerably seaward of the zone of maximum backrush. This is especially true for relatively flat beaches similar to those in South Carolina. If concentrations corresponding to waves less than 50 cm in height are not considered, there remains a trend of decreasing concentration with H_b for both breaker types.

Concentration is plotted against distance from the breakpoint in Figure 11, showing the variation in mean values across the surf zone. Again, there is a clear distinction between breaker types, with plunging waves entraining higher amounts of sediment. Spilling waves show a sudden increase in concentration within 1-2 m landward of the breakpoint and then appear to maintain a relatively steady suspension across the surf zone. Plunging waves similarly show a rapid increase in concentration just landward of the breakpoint, then a gradual decrease with distance toward shore. The shapes of these distributions seem reasonable if one considers that plunging waves dissipate their energy more rapidly (Führbötter, 1970), and, consequently, should show a peak close to the breakpoint.

Other parameters tested against concentration included wind velocity, longshore current velocity and beach slope; however, none was found to be a useful predictor for these data. This is due in

Figure 10. The variation in concentration with wave height for spilling and plunging waves. In general, suspended sediment decreases with increasing wave height during moderate wave conditions on gently sloping ($m = 0.018$), fine-grained beaches. Plunging waves entrain approximately 1 order more sediment than spilling waves equal in height.

Figure 11. Distribution of mean concentration at 10 cm above the bed, relative to wave breakpoint. Suspended sediment increases sharply 1-2 m landward of the breakpoint, then remains relatively constant in spilling waves. Plunging waves tend to peak close to the breakpoint then gradually decrease due to more rapid energy dissipation.

Figure 12. Suspended sediment concentration appears to be independent of longshore current velocity for these data. Samples were collected during a variety of moderate wave conditions over 22 days.

part to the moderate weather conditions prevailing during the study and the attempt to sample only during swell conditions. Beach slope remained relatively constant during the experiment, and surface wind velocity never exceeded 5 m/s. Longshore currents were variable, but as shown in Figure 12, they do not explain concentration variability for these data. This is probably due to the imprecision of our current measurements, as much as the relatively low velocities recorded. It is probable that wind and longshore current velocity become very important during storms.

DISCUSSION

Despite the lack of measurements during storms (a perennial omission with experiments in the surf zone), a major problem in the present study is the range of variability of wave conditions even during relatively ideal swell conditions. To isolate the effect of a single process variable on concentration, repeat sampling under identical conditions is necessary. This may be an impossible task, since not only do successive waves vary in form on a given day, but individual waves exhibit considerable variation along their crests. This is further magnified by small scale changes in bottom topography. It was the intention in this experiment to sample well formed, swell waves with easily definable breakpoints to minimize the influence of such secondary effects as surface wind stress or small scale bedforms. Obviously, these external factors can be important. Even under controlled situations in the laboratory, suspended sediment can be as variable as turbulent flows.

Although concentration varies by several orders of magnitude in the surf zone, these data show that samples taken under similar conditions with respect to elevation, breaker type or wave height vary by much less. As indicated by the ranges in each figure, the standard deviation around the means is significantly less than one order of magnitude for most of these samples. Thus, with increased control over sampling, it should be possible to define a smaller range of concentration values for a given set of wave and beach conditions.

These results tend to confirm several widely held notions concerning sediment suspension in the surf zone, including the dependence of concentration on elevation above the bed and breaker type. But at the same time, they present relations which are not easily explained based on our present understanding, especially the decrease in concentration with breaker height. A possible explanation for the results reported herein may be found in the laboratory studies of Miller (1976), who photographed the entrainment of air in breaking waves. Figure 13, reproduced from Miller's work, shows the distribution of air bubbles entrained in plunging and spilling waves. Note that in spilling breakers, bubbles remain near the surface; whereas, in plunging waves, air is entrained all the way to the bed. Since this distribution of bubbles is an indication of turbulence, it is evident that plunging waves

will effect sediment entrainment from the bed more readily than spilling breakers. The concentration data of the present study verify this.

Figure 13. Cross-sectional contour diagrams of bubble concentration in plunging (A) and spilling (B) breakers. Numbers represent percentage estimate of the number of 1 mm scale units containing one or more bubbles (on a scale of 1 to 10). A 5 means 50% of the scale units contain bubbles, a 10 represents 100% bubble concentration. Note that bubbles penetrate to the bed in plunging waves but remain close to the surface in spillers. This suggests more turbulence reaches the bed in plunging waves contributing to the observed higher concentrations of suspended sediment for this breaker type (Miller, 1976).

Miller's diagrams may also explain lower concentrations with increasing breaker heights. If one considers that waves generally break at a depth approximately equal to wave height, turbulence in higher waves must penetrate deeper water to impact the bed. Just as the air bubbles in Miller's spilling waves remain near the surface, the energy to suspend sediment may move away from the bed as water depth increases with higher waves. Although wave energy increases with breaker height, it may be counteracted by the absorbing "cushion" of water which increases with trough depth. Also, on gently sloping coastlines like South Carolina, the largest waves tend to spill, gradually dissipating their energy over a wider surf zone.

An important implication of these results is the apparently significant role of smaller waves on sediment suspension. During moderate swell conditions, there may be less sediment moved by the largest waves breaking in the outer surf zone than is moved by small secondary waves close to the swash zone. And, as Brenninkmeyer (1966) suggests, sediment suspension may be the dominant mode of transport only in the inner surf zone.

Inman (1977) has stated that studies of suspended sediment in the surf zone are generally deficient due to the lack of simultaneous measurements of the velocity and turbulence fields. While this is certainly true, the problem will remain until better measurement techniques are developed. Obtaining simultaneous, accurate measurements of the suspended load and velocity field is a formidable and expensive proposition. The techniques used in the present study offer a less rigorous but efficient and inexpensive method of studying suspended sediment in moderate wave conditions.

CONCLUSIONS

Based on the above results for plunging and spilling waves, under moderate swell conditions, the following conclusions are offered:

1. Suspended sediment concentration in the breaker zone is primarily dependent on elevation above the bed, breaker type, wave height and distance from the breakpoint.
2. Concentration decreases exponentially above the bottom to approximately 60 cm elevation as a function of the intermittent suspension of coarse sediment from the bed.
3. Relative breaker height (d/H_b) is useful for quantifying breaker types and predicting concentration at a given elevation.
4. Concentration decreases with wave height in the range 50 to 150 cm for spilling and plunging waves, but the relationship for waves less than 50 cm is not adequately resolved.
5. In spilling waves, concentration rapidly increases inside the breakpoint, then remains relatively constant under the bore as it propagates toward the beach. In plunging waves, concentration peaks within a few meters of the breakpoint, then decreases gradually toward shore.

ACKNOWLEDGEMENTS

Support for this study was provided by the U.S. Army Research Office Grant No. DAAG-29-76-G-0111 (Miles O. Hayes and Dag Nummedal, principal investigators). Dan Domeracki, Jerry Sexton and Robert Logan provided enthusiastic and efficient assistance in the field. Pris Ridgell and Nanette Muzzy helped prepare the manuscript. I'm indebted to Dag Nummedal, Miles Hayes and members of the Coastal Research Division for their continued help and advice.

CHAPTER 105

STORM INDUCED PERIODICITIES OF SUSPENDED SAND MOVEMENT

JAY E. LEONARD¹

AND

BENNO M. BRENNINKMEYER, S.J.²

SUMMARY

An array of electronic sensors was installed on Nauset Light Beach, Cape Cod, Massachusetts, U.S.A., in order to provide a description of the sediment movement during storm conditions. These sensors included two sediment concentration indicators (almometers) which monitor sediment movement as a function of elevation and time, one bidirectional electromagnetic current meter, and a resistive wave staff.

Prior field studies performed during "normal" conditions have indicated that surf-zone suspended sediment movement is a low-frequency phenomenon, with the relatively high-frequency component (normal wave period) contributing little to the amount of total sediment transported. Development of a computational technique based upon discrete Fourier analysis and digital filtering called *Spectrally Filtered Integration* (SFI) provides the calculation and filtering of true units of sediment change in grams-per-liter. Moreover, the SFI technique eliminates the possibility spurious sediment information created by the presence of air bubbles in the water column.

Generally, higher-frequency sediment movement is more common during storm conditions than during normal non-storm conditions. This movement is controlled not by the prevailing wave and swell periods, but by a longer period which may be due to water interactions below the surface.

INTRODUCTORY REMARKS

The nature and periodicity of sedimentation during storm conditions

in the nearshore zone is virtually unknown. At no other time do the processes of erosion, transportation and deposition operate with such a degree of efficaciousness. Therefore, the relationships among storm waves and currents to the movement of sedimentary material is one of the major problems prevalent in the nearshore zone.

A major limitation, however, in understanding these relationships is the lack of reliable storm-garnered quantitative field data. This dearth of data has led workers to rely upon models based on mechanics, hydrodynamics, flume studies and empirically derived non-storm data. Therefore, the ability to make real-time field measurements during storm conditions is essential. The purpose of this report is to present results and interpretations concerning the periodicities of sediment movement based upon a series of five-experiments performed during the rising tide of a coastal storm.

FIELD TECHNIQUES

Instrumentation

To measure nearshore sediment movement and processes, an array consisting of two almometers, a bidirectional electromagnetic current meter and resistance wave-staff was utilized. The almometer (Brennk-meyer 1973, 1975, 1976) is a series of electro-optical sensors which instantaneously and continuously measure the change in opacity of the lower one meter of water column caused by sediment concentration. A sealed fluorescent bulb at a distance of one meter provides constant illumination. This distance prevents the coalescing of scour pits around each almometer. Each photoresistor was fitted with a 1.5 cm copper tube internally darkened so that its field of "vision" was limited and controlled (see Table 1). The data were recorded on a FM and direct seven-channel analog tape recorder operating at 3.75 ips. The data were gathered between 2400 and 0600 hours so that sunlight could not affect the incident light on the photocells.

Study Area

The instrumentation was emplaced as shown in figure 1 at low tide on Nauset Light Beach in late October of 1975. Nauset Light Beach, located on outer Cape Cod, Massachusetts, U.S.A., trends northerly and faces the open Atlantic Ocean. The major storms are "noreasters" since their principal direction is from the northeast. The tides on the outer Cape are semi-diurnal and have a mean range of 2.3 m and a spring range of 2.7 m. Although the outer Cape has an erosion rate slightly less than 1 m/y (Marindin, 1889; Zeigler, 1964), the beaches are relatively narrow indicating that a large amount of sediment is transported along-shore (Leonard and others, 1976).

Sea State

The original intention of the study was to measure sediment movement during "normal" sea conditions; however, during the latter part of the study a severe storm arose so quickly that the equipment could not

Table 1

removed from the water. During the storm, the primary breakers were approximately 500 m from shore. Breaker height was estimated to be 4 m, with long-period variations caused by at least two principal swell directions. The array usually stood in the area of secondary and/or tertiary breakers which were considered normal to the beach. These breakers coupled with short-period wind-chop, translational-bores and turbulent-surf defined an extremely confused nearshore hydrodynamic condition. The largest peak in the unusually noisy wave spectra occurred at about 8 seconds.

Zones

Most authors follow the ideas of Shepard and Inman (1951) in dividing the water motion on the foreshore and offshore regions of a beach into three dynamic zones: swash, surf and breaker zones. Schiffman (1965) added another, "the transition zone," between the swash and surf. This zonal concept is valuable in placing a complex environment into a logical reference framework. These dynamic zones, however, are only well-defined during fair-weather conditions. In the conditions extant during a storm, with different period waves arriving at a shore simultaneously from different angles, the boundaries between the zones become indistinct and may even be absent. During this study the breaker zone was relatively far out to sea, and the nearshore was a mass of turbulence caused by the interaction of locally derived wind waves, swell, as well as bore-surf and backwash. In this paper, the operational definition "time zones" will be used. Each zone (Fig. 2) represents a one hour time slice of a rising tide. During this time the array went from partially underwater to completely underwater.

Figure 1. The configuration of the sensor array, onshore conversion station and the recording station (not to scale). W is the wave staff attached to the light source. C is the electromagnetic current meter. A₁ is the onshore/offshore almometer. A₂ is the longshore almometer. The distance of A₁ and A₂ from the light source is one meter.

Figure 2. A schematic of the sensor array and its relative position to the time zones described in the text. I-V refer to the approximate still water elevation of each time zone.

ANALYTICAL METHODSAnalog to Digital Conversion

Conversion of the analog data to a digital form was performed subsequent to the field experiments. Each data point of all sensors was twelve-bit resolution at a frequency of 2 kilohertz. Brenninkmeyer (1975) digitized four different key almometer concentrations: 40, 75, 135, and 365 grams-per-liter of sediment at their corresponding elevation in the water column. Each point was sampled at a 5-Hertz interval, thereby showing a time-history of the elevation of a particular sediment concentration. He then Fourier-transformed each concentration's elevation to find its individual spectrum. This method offers information on both the geometry of sand suspension events, and the frequency of particular concentrations of suspension as a function of elevation. A major drawback to this technique is that the mode of digitizing was such that the almometer record was scanned for these key concentrations from the top of the water column to the bottom. If a sediment concentration inversion occurs, the digitizing records only the highest point of this event and indicates a continuous sand fountain.

By contrast, the almometer information for this study was digitized in a different manner. Each discrete elevation above the bottom was recorded with respect to changing sediment concentration, in order that the fluctuations of concentration, not the fluctuations of elevation, could be Fourier-transformed. Although this technique provides little immediate information on the geometry of sand suspension events, it gives an excellent appraisal of the time-history of a discrete elevation. One can, therefore, see the frequency of all sediment concentration as a function of elevation.

A major drawback is inherent in this technique: one must make assumptions as to the location of the dynamic bottom and constantly update these assumptions since the elevations must remain discrete. However, sediment concentration inversion can be found and analyzed.

Time Series Analysis Applied to Experimental Data

The data chosen for Fourier analysis included the wave record and the two current meter records for the five time zones. In addition, 30 elevations above the bottom were selected for the analysis of periodic sediment movement. In all, 2079 points, or 13.86 minutes, of real-time data from each elevation in each time zone were transformed. The Fourier routine used in the analysis was a modification of the FORTRAN program, FILTRAN (Cohn and Robinson, 1975). FILTRAN is based upon the Fast Fourier Transform of the Gentleman and Sande (1966) algorithm as modified from Good (1958) and Cooley and Tukey (1965). This algorithm provides faster and more accurate manipulation of the data arrays and is considered as a significant advancement over the standard Cooley-Tukey techniques.

Digital Filtering and the SFI Technique

Filtering is a process by which a portion of a signal is removed by

suppressing amplitudes of certain frequencies. Filtering in the time-domain is defined as convolution (Blackman and Tukey, 1959). In one-dimension this operation can be expressed as:

$$O(x) = \int_0^{\infty} I(x-\lambda)S(\lambda) d\lambda \quad (1)$$

where $I(x)$ is the input function, $S(\lambda)$ is the lagged filter, and $O(x)$ is the filtered output. The Fourier-Transform of the convolution integral is:

$$O(\omega) = I(\omega) \cdot S(\omega) \quad (2)$$

where $I(\omega)$ is the input function in the frequency-domain, $S(\omega)$ is the filter, and $O(\omega)$ is the filtered output. Filtering in the frequency-domain requires only that the components of the filter be multiplied by those of the input function, whereas filtering in the time-domain is more complicated in that it requires folding, multiplication, shifting and summation (Cohn, 1975).

The actual filtering process, whether convolution in the time-domain or multiplication in the frequency-domain, simply changes the amplitudes of some of the component sinusoids. Digital filtering enhances the interpretation of a particular waveform by suppressing the amplitudes of conflicting sinusoids that fall outside the desired frequency range. This process is analogous to the action of an automobile suspension, where the springs and shock absorbers filter out the short-period undulations while passing long-wavelengths bumps and hills without change (Robinson, 1968).

For digital filtering in the frequency-domain, all that is necessary is to compute the one-dimensional Fourier-Transform, delete undesired frequencies (noise) by multiplying by zero, then return to the time-domain through the inverse-transform (Cohn and Robinson, 1975).

Because filtering in the frequency-domain is achieved with much greater speed and efficiency than its time-domain convolution counterpart, a technique utilizing both numerical integration and digital frequency-domain filtering was developed. This method called the *Spectrally Filtered Integration* technique (SFI) (Leonard, 1977), is used to differentiate the true "unit-valued" amount of sediment moved by various process agents at given frequencies.

Simply, given a function $f(t)$ (in this case, grams-per-liter of sediment movement versus time), the total amount of sedimentation over a particular time span or zone can be expressed as:

$$\int_a^b f(t) dt \quad (3)$$

which is step (A) in Fig. 3.

Taking Fourier-Transform of this function and deleting the mean value (Fig. 3, B) produces the function $f(\omega)$ or the frequency-domain spectrum of the original amount of grams-per-liter of movement (Fig. 3, C).

By deleting the amplitudes at various frequencies (Fig. 3, D) and substituting zeros in both the real and imaginary coefficients, one in effect places a filter on the data. Figure 3, D, shows a simple band pass filter that is applied to the frequency spectrum.

Next (Fig. 3, E) one applies the inverse-transform to this data and reassesses the effect of the deleted D.C. component while reordering the data matrix and considering the effects of the imaginary components. This operation results in $f'(t)$, or the filtered reconstruction of the original data (Fig. 3, F).

Since the units are maintained as an end-product, the integration:

$$\int_a^b f'(t)dt \quad (4)$$

gives the amount of transported material at all frequencies except the ones filtered.

By mere subtraction the residual area of the filtered frequencies is calculated (Fig. 3-G). This is the spectrally filtered integration method. In other words, the contribution of periodic stimuli (i.e., waves, edge waves, and other processes) to the sediment movement can be selectively removed and the resulting sediment concentrations can be calculated.

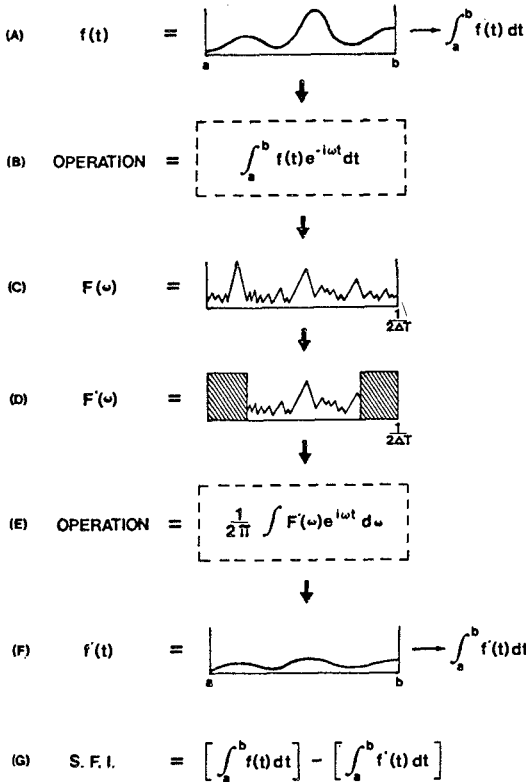

In this study it was chosen to determine and quantify the amount of sediment moved at low-frequencies (<0.01 Hz. or >100 seconds). The stimulus for this came from Brenninkmeyer (1975) who observed low-frequency movement in his data. The SFI analysis of this data included the application of a bandpass filter. The periodicities greater than 100 seconds were nulled along with the higher-frequency "noise." This "noise" included all frequencies greater than 0.5 Hertz (2 seconds). The variance within this high-frequency band can be attributed to the random variations of air bubbles present in the water column. This effect can be shown through visual observations of the almometer oscilloscope record where bubbles and surface foam exhibit a high-frequency variation. Another cause of high-frequency fluctuations is the vibration of the almometer and the anchoring auger in the presence of waves. We believe the construction of the 0.5 Hertz cutoff will eliminate all but a small portion of the error caused by the presence of air bubbles and vibrations. Therefore, the filtered data should contain only information on sediment movement.

Figure 3. The SFI technique in schematic form (below):

- A. The second order integration of the time-domain function $F(t)$.
- B. The Fourier Transformation of the function $F(t)$.
- C. The transformed function $F(\omega)$ to $F(\omega)$.
- D. The frequency-domain filter applied to the function $F(\omega)$.
- E. The inverse-transform of the function $F(\omega)$.
- F. The resultant time-domain function $F'(t)$ after frequency-domain filtering and the second-order integration of this function $F'(t)$.
- G. The determination of the residual amount of time-domain data, represented by the contribution of the filtered frequencies.

Note $1/2 T =$ the Nyquist frequency.

This diagram implies continuous functions; however, the analyses for this study were performed with discrete functions. Implicitly, the complex conjugant of the Fourier transform must be included in the SFI technique.

RESULTS

In order to determine sediment concentration as a function of elevation, the position of the bottom (datum) must be monitored. Bottom is defined, operationally, as that elevation which attained a time-averaged concentration of greater than 500 grams per liter. Bottom changes not only occur dynamically at high-frequencies, but also may exhibit an established trend. Figure 4 shows the changing absolute position of the bottom as a function of time zones during the increasing tide. At first glance, a disproportionate amount of burial appears in the onshore/offshore almmometer at Zone IV. This is interpreted as a sand bar created from the eroding berm.

By performing the Fourier transformation of the autocorrelation function of the time-domain records for the various changing sediment concentrations, information on the frequency or its reciprocal periodicity can be determined at elevations of high concentration variance throughout each time zone. A precise breakdown of contributions appears in Appendix I, A-E, which shows percentage contribution to the total variances (power) of selected bandwidths. The bandwidths chosen include: greater than 120 seconds, 120 to 60 seconds, 60 to 30 seconds, 30 to 15 seconds, 15 to 12 seconds, 12 to 10 seconds, 10 to 8 seconds, 8 to 6 seconds, and 6 to 4 seconds.

The bandwidth of greater than 120 seconds indicates the long periodicities of sediment movement. This change can perhaps be characterized as transient suspension events occurring within the sampling period. Some of these may be due to shelf waves (Munk, 1962). This band may also indicate the long term change of data string (i.e., fluctuations in bottom topography).

Figure 4. Depth of burial of the bottom of the almmometer in both the longshore and onshore/offshore for each zone.

The bandwidth between 60 and 120 seconds represents movement or changes that may be caused by surf beat (Munk, 1949; Tucker, 1950). Surf beat is the systematic low-frequency fluctuation in wave height created when two sets of small waves arrive simultaneously from two different storm sources. The constructive and destructive interference of these wave trains gives the impression of rhythmically varying wave heights on the beach.

The 60-to-30 second bandwidth input during storm conditions is difficult to explain. The processes that contribute to this moderately low-frequency may include the following: (1) The shore face is reflecting surging water. (2) The variations in the components of both standing and progressive edge waves (Bowen and Inman, 1969; and Huntley and Bowen, 1973, 1975). Huntley and Bowen (1973, 1975) measured edge waves in the field and found them to be subharmonic of the incoming waves. In the case of storm conditions, the various wave trains arriving may cause variations in these subharmonic edge waves. (3) Finally, the input process to this bandwidth may include the phase difference or time lag between the incoming bore (swash) and the returning backwash. Emery and Foster (1948) have observed this phenomenon, and suggest that it may be attributed to the interaction with the ground water table. Waddell (1976) also sees this relationship.

The possible causes of the remaining moderate-frequencies which are also the middle-periods of 30 to 4 seconds, may include combinations of the previously mentioned process with the addition of the major swell, breaker, and wave periods. The 10-to-8 and 8-to-6 second bands indicate the periods of the major wave and water velocity variance as indicated by their respective spectra.

Zonal Periodicity

Zone 1. The sediment power spectra for Time Zone 1 show similar characteristics, and generally appear in one form. Appendix I-A indicates a breakdown of percentage contribution of the total power to the various bandwidths. Generally, in the onshore/offshore direction, a majority of the variance of sediment movement occurs within the large band between 60 and 120 seconds. Just (0-5 cm) above the bottom, a major portion of the movements occur every 60 to 30 seconds with the highest peak at 40 seconds. This peak represents a contribution of slightly over 6 percent. As the elevation increases, the frequency of movement also increases with the preponderance of power residing in the 30-to-15 second bandwidth. At 10 centimeters and above, the 15-to-12 second band shows some activity, but not nearly as much as the 30-to-15 second band. Also, from 5 to 25 centimeters (above the bottom), approximately 30 percent of the remaining variances occur between 10 and 4 seconds. Seemingly, the major factor contributing to sand movement in this zone is the interaction of wave surges, which are exhibited as a subharmonic of the wave period.

In the longshore direction, the same trend can be seen with a majority of the power residing in the 30-to-15-second bandwidth. The bottom

sediment here also moves at a lower-frequency than the material in the water column.

Little information could have been gained from the wave and current records because of the noisy spectra created by instruments' poor response in alternating wet and dry conditions.

Zone II. During Time Zone II, the power spectra (Appendix I-B) reveal a general trend toward low periodic sediment movement. In the onshore/offshore direction, the strongest peaks are all longer than 120 seconds. Above 1 minute, approximately 30 percent of all the variances (power) for all the onshore/offshore elevations can be explained (Appendix I-B). Approximately 40 percent of the remaining variances lie within a band between 15 and 60 seconds, indicating some long-period water interaction creating sediment suspension events. Very little contribution came from the normal wave period (10 to 8 seconds).

The same trend exists for the longshore direction, except that it is more magnified. Approximately 50 percent of the sediment movement is explained at a frequency of greater than 120 seconds. No major contributions occur at a period of less than 15 seconds.

In contrast, the current and wave instruments show their strongest peaks at a band between 8 and 4 seconds. Therefore, the contribution to sediment movement by the normal wave and current activity in this zone is minimal.

Zone III. The spectra of Time Zone III (Appendix I-C) indicate peculiar properties. In the onshore/offshore direction at the 5 centimeter level, more than half the power is located in the greater than 120-second band. This is due to the long-term burial of the lower sensors. The resulting bands at this (5 cm) elevation are virtually undifferentiated. At the 15 centimeter elevation, however, the greatest contribution lies between 30 and 12 seconds, indicating that at this height, movement is still controlled by an interaction of the translational bore with the seaward returning water. At 25 centimeters, the greatest power is in the greater than 120-second band, but a strong peak is present in the 30-to-15 second interval.

In the longshore direction almost 80 percent of the contribution exists in the greater than 120-second band.

Zone IV. In Time Zone IV, the power spectra appear to take on diverse forms. In the onshore/offshore direction less contribution (Appendix I-D) comes from the greater than 120-second band than for the previous time zones. Generally, in upper elevations, more power is concentrated between 8 and 4 seconds, indicating the frequencies of waves and currents. Strong peaks do occur, however, in the water interaction band of 30 to 15 seconds. At 5 and 10 centimeters, the greatest contributions lie in the low-frequencies, with major peaks at greater than 120 seconds. Some sediment movement variance is seen in the 30 to 15 second band, as a response of translational water interaction. A small (10.8 percent) peak is found at the 5 centimeter level, showing that near the bottom normal

wave activity contributes to sediment movement.

In the longshore direction, the near bottom elevations of ≈ 0 and 5 centimeters show movement occurring at low-frequencies. A major break exists at 10 centimeters where the frequency of the major contributors occurs in the 8 to 4 second band. Only 5 centimeters above this level however, at 20 centimeters, sediment movement periodicities increased to between 60 and 5 seconds. At present no explanation can be given for this 10 centimeter anomaly.

Zone V. In the onshore/offshore direction of Time Zone V, the sediment power spectra (Appendix I-E) indicate generally low-frequency movement. At all elevations, approximately 20 percent of the contribution can be placed in the wave and current bandwidth. The water interaction band of 30 to 15 seconds shows greater than 10 percent contribution at elevations of 10 and 15 centimeters.

The longshore direction spectrum at 5 centimeters indicates approximately 75 percent of the contribution occurring above 30 seconds. The current and wave sensors spectra indicate that the strongest peaks occur between 10 and 4 seconds.

Amount of Sediment Moved

The integration of the time-domain records of sediment movement provides a reasonable estimate of the total sediment moved during each time zone. Figure 5 illustrates the total amount of sediment moved in the onshore/offshore direction as a function of near bottom elevation for each time zone.

In Time Zone I, the expected pattern of decreasing sediment movement with increasing elevation is present. Total movement on the bottom is over 350 kilograms per 13 minutes of "almometer-sensed" water volume (Table 1), whereas at an elevation of 25 centimeters, only 75 kilograms of sediment move. The decrease from bottom to top is linear, except at 15 centimeters, where the slope steepens, and movement decreases at a lower rate.

Zone II indicates the same trend in movement, although less movement is present at the bottom and at 5 centimeters than in Time Zone I. Interestingly, greater amounts of sediment were moved at the 10 centimeter level in Time Zone II than in Time Zone I, perhaps due to the presence of minor sediment concentration inversions at this level.

Zone III shows a peculiar divergence from the previous zones. At an elevation of 25 centimeters, approximately 250 kilograms of material moved, whereas below this level at 15 centimeters, only 170 kilograms moved. This phenomenon probably occurs because of sediment concentration inversions. Generally, more material was moved in Zone III than in Zones I and II.

In Time Zone IV, the total amount of movement decreases significantly and follows a pattern of decreasing quantity with increasing elevation.

Zone V also indicates less movement than the previous zones, except for a concentration inversion at 10 centimeters. This inversion may be the response of the oceanward flow of water present in a rip-current observed at this time by the array.

In the previous section, it was stated that the low-frequency, long period bands normally contained the most power contribution. It should be mentioned, however, that phase relationships play an extremely important role in determining what the percentage contributions really mean in terms of total material moved. If, for example, a band contains two large power spikes, the percentage contribution would also be large, but if these two peaks were 180 degrees out of phase, the resulting movement would be zero. This reasoning led to the development of the SFI method.

Utilizing the SFI technique, Table 2 presents a summary of the "time-averaged" quantity of sediment moved in each of the respective time zones. The "O" column represents the integrated total quantity (in grams corrected to one liter of water) seen by a photocell in respect to the volume of its particular field of "vision" (Table 1). In other words, these numbers are the grams of sediment per liter of water, one would statistically expect to find in any given second.

Table 2. Various parameters derived from the SFI technique

A. O equals the "time-averaged" total amount of sediment moved expressed in grams-per-liter per second.

B. F equals the "time-averaged" quantity of material moved at a periodicity greater than 100 seconds.

C. O-F equals the "time-averaged" quantity of sediment moved at periodicities between 2 and 100 seconds.

D. The ratio of F to O.

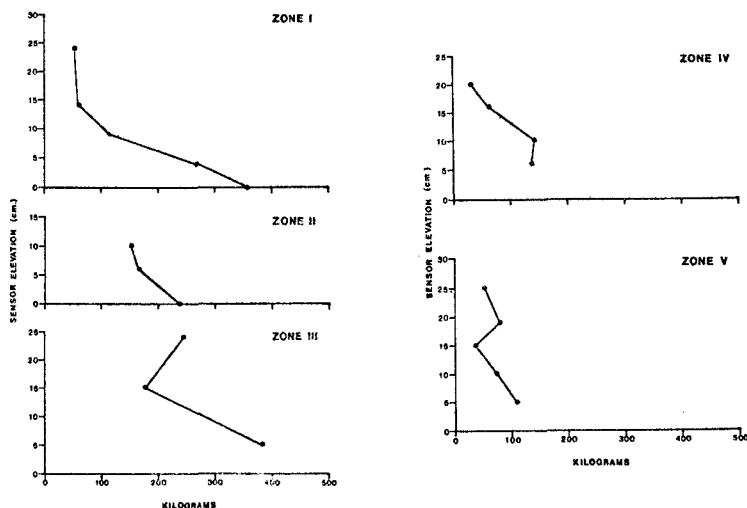

Figure 5. Corrected total amount of sediment movement in the onshore/offshore direction as a function of elevation for each zone.

The data taken from elevations in excess of 10 cm above the bed are in reasonable agreement with values of surf-zone sediment suspension measurements reported by other workers (Komar, 1978, Table 1); utilizing more direct measurement techniques. Those values include .13 g/l at Torrey Pines, California (Thornton, 1977), 0.26 g/l in spilling breakers at Price Inlet, South Carolina (Kana, 1976), 0.39 g/l at Nags Head, North Carolina (Fairchild, 1973), 0.53 g/l at Ventnor, New Jersey (Fairchild, 1973), 0.68 g/l at Pacific Beach, California (Watts, 1953) and 1.09 g/l at Price Inlet in plunging breakers (Kana, 1976).

Below 10 cm, however, the values of sediment concentration increase by several orders of magnitude. This is not surprising, since our data were obtained close to the bed in storm conditions. The "F" value is the amount of sediment moved at a periodicity greater than 100 seconds. Various other derived parameters contained in these tables are explained in the figure captions.

Low Period Contribution to Sediment Movement

Figure 6 illustrates the relationship between the percentage-ratio of the material moved at a periodicity greater than 100 seconds to the total amount of material moved. It can be seen that for the onshore/offshore direction for Zone I, the high-frequency contribution decreases with increasing elevation. This relationship is expected because sediment movement in the higher elevations should be less common than in the lower. In the longshore direction, the low frequency contribution seems to be undifferentiated as a function of depth.

Onshore/offshore sediment movement in Time Zone II indicates high-to mid-frequency motion on the bottom, with increasingly low-frequency

contribution to an elevation of 5 centimeters. This trend then reverses, and the contribution of lower-frequency decreases to an elevation of 10 centimeters. The longshore direction shows that low-frequency increases with increasing elevation.

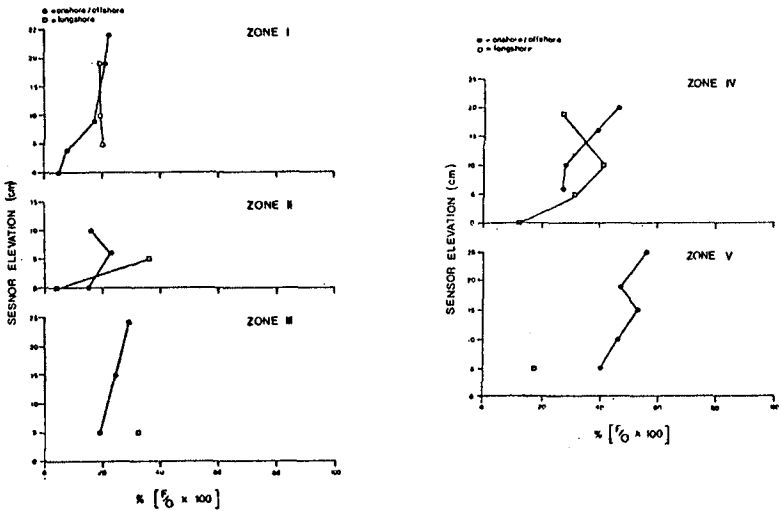

Figure 6. The ratio between the sediment moved at periodicities greater than 100 seconds (F) and the total sediment moved (O) for the five zones, as a function of elevation (in cm), in both the onshore/offshore and longshore directions. Note: Dark circles indicate onshore/offshore.

Zone III (onshore/offshore) also shows the expected relationship with 20 percent of sediment movement accounted for by the greater than 100-second periods at 5 centimeters above the bottom. This figure then increases to 30 percent at 25 centimeters.

As the water deepens, the low-frequency contributions tend to become more important. In Time Zone IV, the onshore/offshore direction reflects this expected relationship, but the total curve shifts to the right, indicating a generally more significant contribution by the low-frequencies. An anomalous trend occurs, however. In the longshore direction of Zone IV, at above the 10 centimeter elevation, the lower-frequencies become approximately a factor of 2 less significant. This reduction may be explained by sediment shedding off a sand bar, which buried the onshore/offshore sensors, but not those of the longshore.

In Zone V, the curve shifts further to the right, indicating a greater lower-frequency contribution in deeper water. A small shift to the left (higher-frequency contribution) can be seen at the 20 centimeter elevation, and is probably due to sediment "jetting" from the higher bar

elevation bounding the throat of a rip current.

In contrasting the five time zones for the onshore/offshore direction with the contribution of low-frequency movement, Figure 7 illustrates the relationship between the total sediment moved (expressed in decibels) and the ratio of sediment moved at low-frequencies (expressed in decibels). The decibel scale [$10 \log (\text{ratio})$] was chosen since it compacts both data sets to the same scales of the same order of magnitude. For the total sediment movement (TdB), the ratio was determined by contrasting the total amount moved in kilograms to a nominal movement of 1 kilogram, hence eliminating division by zero.

Figure 7. Relationship between the ratio of the total sediment moved (TdB) and the ratio of the total amount moved at low frequencies (dB O/F) for the onshore/offshore direction.

The zonal grouping shown indicates that, during storm conditions, high-frequency sediment movement decreases as the tide rises. This diagram also indicates that as time progresses, this relationship is virtually constant, i.e., it shows little if any differentiation due to the traditional dynamic zones.

CONCLUSIONS

Some general impressions can be extracted from the analysis of data concerning the nature and periodicity of sediment movement in the nearshore zone during storm conditions. A summary of the more salient conclusions follow:

(1) Standard time series analysis is insensitive to the study of quantitative periodic sediment transport in the nearshore zone. A technique has therefore been developed (the SFI method) which will isolate certain sediment movement frequencies caused by explained and inferred stimuli; wave period, edge waves, surf beat, shelf waves and interference of uprush and backwash. This method allows an analysis of the absolute amount of material moved by each of these inputs.

(2) During severe storm conditions sediment suspension and resuspension is more prevalent through the five time zones than during times

of milder wave conditions.

(3) The power spectra of sediment movement throughout various elevations, various zones and different directions exhibit diverse forms. Typically, however, during severe storm conditions, throughout all time zones, the power contained in the lower-frequencies is not as strong as that during normal (non-storm) conditions. If one were to characterize the most common process based upon the spectra, it would be the frequency of the water collision and interaction of two opposing velocity distributions. This is substantiated by current meter measurements. However, this relatively higher-frequency movement decreases as water deepens and lower frequency contributions tend to become more important to sediment transport. Nevertheless, contrasted to non-storm conditions sediment movement during storms is at a much higher-frequency.

Because these experiments represent only conditions which occurred during one storm event, much more data of this type must be acquired in order to characterize the processes interacting with the dynamic beach environment. This study is, therefore, more of a starting point than an end in itself.

ACKNOWLEDGMENTS

Many people and institutions have contributed to the fulfillment of the project. We thank the National Park Service, Cape Cod National Seashore, the computer centers of Boston University, Bryn Mawr College, Haverford College and Rensselaer Polytechnic Institute. Many thanks to B. Cohn, J. Filor, G. Hoffman, C. James, A. Niedoroda, and C. Rouleau. Financial support was provided by the Office of Naval Research Geography Program and the National Oceanographical and Atmospheric Administration (NOAA).

CHAPTER 106
SLED SYSTEM FOR PROFILING SUSPENDED
LITTORAL DRIFT

by

J. P. Coakley¹, H. A. Savile², M. Pedrosa², and M. Larocque²

INTRODUCTION

There are many factors which suggest that littoral zone processes in the Great Lakes differ substantially from those of the marine coasts described in the existing coastal research literature. Among these factors are the lack of an appreciable tidal cycle; the predominance of relatively short, steep, waves; the virtual absence of swell waves; and the presence of shore fast ice in winter. As a result, many of the empirical relationships derived for marine coasts might be of questionable applicability to Great Lakes coasts. The present study, which represents only one phase of a long-term project designed to develop more specific littoral transport relationships, is aimed at obtaining accurate, direct estimates of the actual littoral transport at an experimental site located at the western end of Lake Ontario.

This paper will describe a mechanical system designed to collect a series of time-averaged samples of suspended sediment for concentration determinations as well as flow velocity and water depth at locations across the surf zone. Some preliminary results of the field program using the system will also be presented and discussed.

BACKGROUND

A number of researchers in the U.S.A. (Watts, 1953; Fairchild, 1972; Brenninkmeyer, 1974), Japan (Hom-ma and Horikawa, 1962; Noda, 1967), and other countries (Aibulatov, 1957; Jensen and Sorensen, 1972; and Kilner, 1976) have published techniques for measuring suspended sediment transport in the nearshore zone. Because of the variety of process factors operating there and the presence of breaking waves, this is usually not an easy task. From an operational point of view, the two most common problems involved in such measurement are the physical spanning of the zone (usually more than 100 m in width), and the designing of a measurement platform rugged enough to withstand the highly turbulent conditions that typify this area. Most of the work cited above has involved the use of pump samplers manipulated along a pier or a specially constructed tramway, or cumulative samplers such as the moored bamboo samplers used in the Japanese research. From an interpretation point of view, the main problem lies in the unsteadiness of the phenomenon both in time and space, due to the periodic or oscillatory nature of the driving processes in sediment suspension. This unsteadiness contributes to making the establishment of theoretical models of the process very difficult.

¹Hydraulics Research Division

²Scientific Support Division
National Water Research Institute
Canada Centre for Inland Waters
Burlington, Ontario

Nevertheless, the concept of relating quantitatively the total suspended sediment transport to the total littoral transport rate is generally recognized to be a valid one (Dean, 1973) and has the potential of improving considerably on previous direct techniques such as sand tracers. Simply stated, the concept entails the determination of the suspended sediment volume along a transect normal to the longshore currents of the littoral zone. By coupling these data with concurrent measurement of the flow velocity of the water column in a manner analogous to river discharge measurements, it should be possible to obtain a good estimate of the rate and direction of littoral transport. The word "estimate" is deliberately chosen since the unknown proportion of total transport in the form of bed load is not taken into account. Our experience with profile changes in the Great Lakes, however, leads us to believe that the dominantly bed load transport which occurs between storms is relatively minor, so by concentrating on storms when most of the material transported is suspended above the bed for some period of time at least, we feel that the estimate we obtain still represents an improvement on other techniques described to date in the literature. Three important factors, however, must be taken into account. One; the unsteady nature of the process means that the suspended sediment concentrations at a given location vary with time at a frequency related mainly to the orbital motions of the water particles under the waves (Brenninkmeyer, 1974), so care must be taken to obtain measurements over a period long enough for these variations to be averaged out. The variation produced by unsteadiness should also be significantly reduced if measurements were taken during fully developed turbulent conditions, i.e. during storms of moderate intensity. Two; the distribution curve for both sediment concentration and flow velocity with respect to the vertical (or depth) axis is well-known to be of a quasi-exponential form with values for both changing rapidly in the lower part of the curve, and becoming more uniform in the upper part. This makes it essential that measurements be biased toward obtaining sufficient readings near the bed. Finally; studies by Komar (1971) and Aibulatov (1957) demonstrate that the littoral transport rate varies across the surf zone as well. Thus, measurements must be spaced at intervals along the surf zone transect so that this horizontal distribution can be taken into account. Furthermore, since a proper measurement of instantaneous depth values is critical in a zone where rapid bottom topographical changes are occurring continually, the system must be designed to also measure depth, or height of the water column.

In summary, if the above constraints are successfully met, then the estimated total longshore sediment flux (Q_{long}) could be expressed as:

$$Q_{long} = \int_{j=0}^x \int_{i=0}^z (C_{ij} V_{ij} dz) dx$$

where: x = width of transect; V_{ij} = longshore component of the flow at level i and horizontal position, j ; z = vertical axis (or depth); C_{ij} = concentration of suspended sediments at level i and position j ; and dz, dx = vertical and horizontal gradient, respectively.

It is evident that, in such an experiment, onshore-offshore sediment transport would at best be only qualitatively indicated, mainly from the flow direction measurements. Also, variations in longshore transport rate parallel to the shore would require additional transects. Such a three-dimensional approach is beyond the scope of this experiment.

DESIGN OF THE PROTOTYPE SYSTEM

After a thorough investigation of all the techniques described in the literature, we finally chose the profiling system described below. The system consists of a low-slung, rugged sled towed and positioned along a fixed cableway by a shore-based winch (Figure 1). The system was designed and constructed at the National Water Research Institute and was used for the first time during a program of field measurements carried out in late 1977. The main components of the system are:

1. The Surf Sled Instrument Platform

The Surf Sled, shown in Figure 2, was adapted from a similar concept described in Reimitz and Ross (1971) and Teleki *et al* (1976). It measures 2.84 m in length, 1.68 m in width, and stands approximately 30 cm high. Because of its open-work frame and welded 0.5 cm gauge aluminium plate construction, its total displacement in water was only 340 kg. The sled was fitted with wide (35 cm) runners or skis to minimize excess loading and penetration into the sand substrate. Hinged towing yokes are attached to both ends for towing the sled out and in. The flat, open-work top surface carries the sampling accessories, power and electronics packages, and recorder cylinders.

Protruding forward from one of the corners of the sled, and aligned parallel to its length, is a 1.5 m long rigid boom, framed in the shape of an elongated parallelogram, and articulated at the base. At the end of this boom is located the two-axis current sensors and the intake for the sampler pump. During field operations, the sled was intended to be configured with the boom pointing lakeward or in front of the sled body.

At each sampling position the boom is programmed to move to three vertical sampling/sensing positions: 10 cm, 30 cm, and 100 cm above the lake bottom. The lake bottom is defined as being 5 cm above the forward projection of the sled runners, to allow for some settling of the sled into the sand substrate. The power and switching systems for moving the boom are described in a later section.

2. Sampling System

The sampling pump used presently, a Jabsco 12 V D.C. Mini Puppy model, is mounted inside the power distribution box and draws through a sample intake at the end of the boom. The intake is equipped with a 2 mm mesh strainer to remove large objects which might damage or clog the system. From the pump, which provides twice the desired flow, the sample goes to a flow splitter. One half goes to waste and the other goes to the distribution valve. This is a rotary, 60 position, valve driven by a commercially available, air operated rotary table. This table is operated via a solenoid valve operated by a momentary, 0.1 second, 12 V pulse from the sequencer through a monostable circuit. The valve output is divided alternately into 30 waste and 30 sample positions. In operation the valve is held in the waste position for 15 seconds while the pump purges the lines and is then shifted to a sample position to fill a sample bag in the rack at the stern of the sled. The sample bags are slightly modified urinary

catheterization bags, cutter Resiflex #950-19, with the air vent heat-sealed off. Sample size ranges from 1200-1800 ml of sand/water suspension.

3. Sensing and Recording Sub-System

The sensing of water flow is performed by two (Bendix B10 ducted impeller type) flow sensors mounted orthogonally, one above the other, at the end of the sled's 1.5 m moveable boom. The sensors have their central axes parallel to the horizontal plan and sense the water flow bidirectionally at the three preprogrammed boom positions, while suspended sediment samples are taken automatically just beneath them. The impellers of the sensors rotate and produce five pulses for each revolution. These pulses are converted to analog output which is 1 mV per 5.14 cm/s.

The sensing of instantaneous water depth is performed by a sensitive and fast (<.1 s response) pressure transducer (Gould PA 822-15) mounted on the sled platform 32 cm above the bed. The amplifier output is 18.4 mV/m.

The analog recording of water flow (two bidirectional axes "x" and "y") and the depth of the sled track is carried out by two Rustrak Potentiometric recorders (Model 3400 - dual channel for the x and y flow components, and model 400 - single channel for depth).

Two event markers are also used to record each boom position at a station on the x-y recorder and the arrival at each station on the depth recorder.

4. Programmable Sequencer and Control System

This apparatus controls, via timed electronic impulses to the various solenoid or on-off switching units, the sequence of functions performed by the sled during a sampling/sensing traverse of the surf zone. In brief, the system is activated on the beach prior to immersion and after a pre-determined time lapse (sufficient to enable it to reach the first station), goes through the following sequence:

- i) Pump is switched "on" at the exhaust mode; sampler arm is lowered by solenoid-controlled pneumatic action of both air cylinders to the lowest position (position 1-0.10 m above the bed). At this position, a switch on the moveable boom closes and causes an event mark to be made on the recorder chart. Exhaust mode lasts for 15 seconds exactly. This time is sufficient to purge the lines of water/sediment from the previous sample.
- ii) Sampler is then switched (by solenoid impulse) to the sample mode and collects a sample over a period of 44 seconds.
- iii) Solenoid switches sampler to exhaust mode; sampler arm rises to position 2 (0.30 m above the bed). This event is marked again on recorder. Exhaust cycle lasts for 15 seconds.
- iv) Sampler is switched to sample mode, and collects a sample over a period of 44 seconds.

- v) Sampler is switched to exhaust while the arm moves to position 3 (1.0 m above the bed); exhaust time - 15 seconds.
- vi) Event marker indicates arrival at position 3 and sample mode is activated. Sample collected over a period of 44 seconds.
- vii) Sequence ends and pump is shut off; event marked on both pressure and current records; sampler arm stays in "up" position; sampler itself switched to exhaust mode but this is not activated until the arrival at the next station when the pump is switched on again.
- viii) Sled is towed to the next station where the above sequence is repeated. After the last station (up to 10 stations possible), all systems are shut down and the sled is returned to the beach for unloading and reactivation for the next run.

5. Power Supply Systems

- i) The 12 V D.C. supply consists of two 150 A lead acid batteries arranged in parallel. The tops of the batteries are potted with polyester to electrically insulate all connections. Venting and pressure compensation are achieved by manifolding together all the battery vents and running the common vent line to the top of a sealed reservoir which is open at the bottom. The power is supplied through "E.O." connectors to the distribution box.
- ii) The 115 V A.C. supply consists of an inverter, "Abbott KNGT-115-60, which draws 12 V D.C. from the terminal bus in the power distribution box and outputs up to 60 VA of 115 V 60 Hz sine wave power for driving the chart recorders.
- iii) The compressed air supply consists of a pair of 224 m³ capacity "SCUBA" cylinders and associated reducing valves. One cylinder is used to pressure compensate the power distribution box. The other provides air at 0.83 M Pa to move the sampling arm and the distribution valve via the solenoid valves.

6. Winch and Cableway

The sled is moved by means of a cableway extending 100 m out into the surf zone. The shore end terminates above the maximum wave runup point on the beach. Both ends of the cableway are secured to jettied-in piles which penetrate 5 m into the soil. The piles are in two parts joined with a bolted flange connection at ground level. A middle pile is located at the top of the beach 1 m away from the centreline of the cableway and carries an arm with sheaves to lift the cable over the abrupt change in slope at that point. The winch is housed in a sheet metal garden-type shed on shore and is of the friction wheel type having a 2.2 KW S.C.R. controlled motor through reduction gearing. The winch is free to move fore and aft on teflon sliders and tension is applied to the system by means of a counterweight and multiple purchase. The tension in each leg of the 9.5 mm diameter wire rope is approximately 7.8 KN which is sufficient to provide traction on the winch drive wheel and to avoid whipping caused by wave action yet provide an adequate safety factor.

The offshore pile is guyed to eight anchors jettied into a depth of 5 m and the two onshore piles are unguyed. Grease nipples and bronze sleeves are fitted to all sheaves.

An electronic meter wheel indicates the position of the sled to the nearest 1 m. The cable is also marked to give an emergency stop point should the meter wheel fail.

FIELD OPERATIONS

The system described above was tested and used in littoral drift studies during the fall of 1977. The field operations were located at Hamilton Beach at the western end of Lake Ontario (see inset, Figure 1). Length of the surf zone transect was approximately 100 m (cableway length was 135 m) and the transect terminated in roughly 3.5 m of water.

During the period October 21 - December 5, 1977, a total of 16 experiments, covering moderate to storm-wave conditions, were carried out. In spite of breaking waves as high as 3 m, the system suffered no structural damage. Seven of the runs yielded complete data sets, i.e. full sample bags and complete depth/flow records.

PRELIMINARY RESULTS

1. Reproducibility

In order to test the reproducibility of the measured data, the sled was positioned at a station roughly midway across the transect (depth 1.4 m) over a full cycle. Figure 3 shows the plotted results from a series of seven complete vertical profiles taken at that location. In spite of the small sample size, the results show reasonable internal consistency.

2. Effect of Sled on Flow and Suspension

Two tests of this effect were carried out. One involved the visual inspection of the sled operation by divers. This test was, of necessity, carried out in moderate wave conditions. However, the divers noted no resuspension phenomena that were obviously related to the presence of the sled in the oscillating flow field caused by the waves.

The second test was carried out during a storm and involved the reversing of the sensor/sampler boom position with respect to the sled, i.e. the sled's normal confirmation was altered so that these components were on the landward side. This placed them in the lee of the propagation direction of the wave bore. The discharge results obtained in this configuration were more than double those of a run immediately preceding it, in which the normal forward configuration of the sensor/sampler head was used (1050 m³/hr versus 440 m³/hr). This indicates clearly that there is a sled effect on the discharge quantities calculated, and that the reversed configuration clearly overestimates the actual discharge. However, we do not yet know whether there is an appreciable sled effect on discharge values obtained using the normal configuration during storms. Experiments are presently being planned to investigate this further using a scale model and simulated wave conditions inside the HRD wind/wave flume.

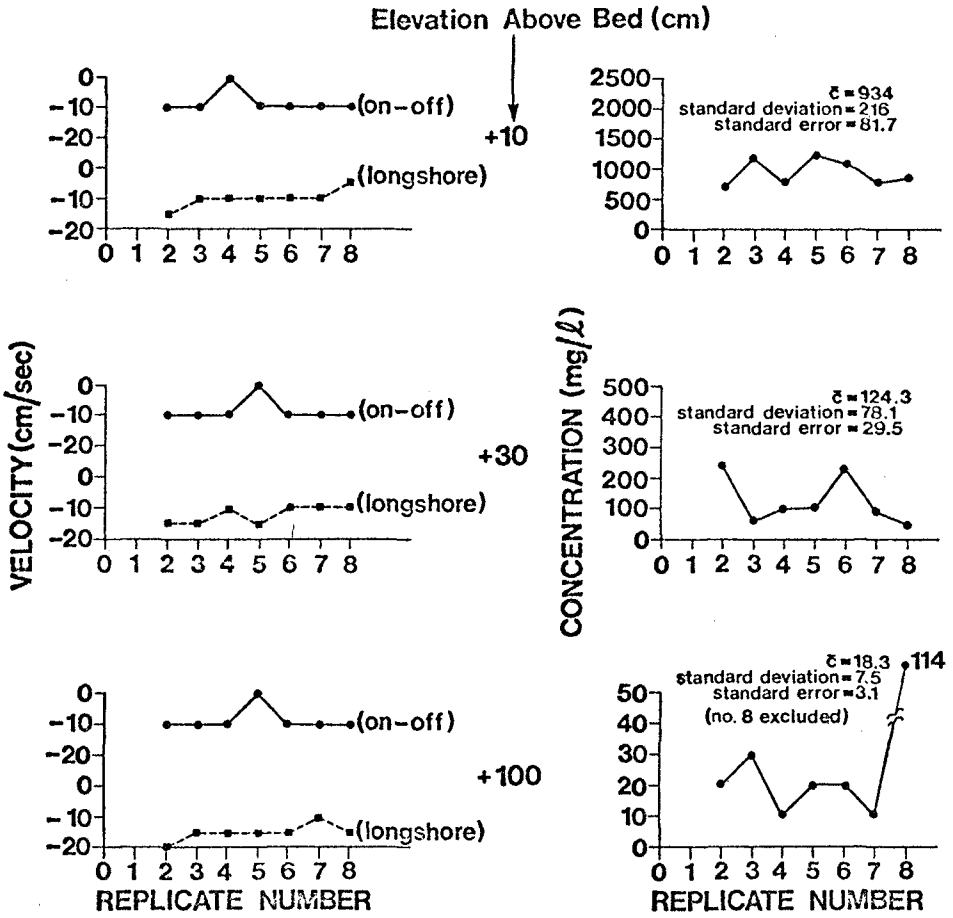

Figure 3 Plot of replicate measurements of two-axis flow velocity and concentration at a single station along the surf zone transect. The station was located 50 m from the shoreline at a depth of 1.4 m. Wave parameters during the run were: significant wave height - 0.8 m, and period - 2.5 s. For the flow values, negative indicates on-shore (on-offshore component) or toward the North (longshore component).

3. Magnitude and Distribution of Suspended Sediment Discharge

As stated previously, the number of complete data sets (flow velocity/suspended sediment concentration couples) is at this time too small to allow any broad statement on transport rates to be made. Furthermore, due to the fact that dry-weight/volume concentrations were used, we might want to revise the analysis procedure at some later date to make it more comparable with other studies. Nevertheless, in order to illustrate the final results of the system, we present a plot of the variables (concentration, longshore component of flow, calculated discharge versus distance along the surf-zone transect for a single experiment conducted during a severe storm on December 5, 1977 (Figure 4). Wave statistics were as follows: H -186 cm, T -6.1 sec, and wave angle -1.8° . These wave data were measured during the experiment at a three-staff wave array just outside the breaker zone in 5 m of water (Figure 1). Waves at the time were mostly of the plunging type. The value shown for discharge is based on a dry weight-to-volume conversion factor of 1600 kg to 1 m³.

The data appear to have an expectedly high variability both in time and space, so any further discussion of the results ought to await the collection of a more statistically valid data base. To this end, we are continuing our data collection into at least the winter of 1978 and spring of 1979.

CONCLUSIONS

The system described above was designed and constructed to collect profile data on suspended sediment concentration and flows velocity across a transect spanning the surf zone of western Lake Ontario. Experiments carried out to date have demonstrated that the system functioned well under conditions which at times exceeded the design criteria.

Because of the small data base compiled thus far, a full data analysis is still in the initial stages. However, preliminary analysis indicates that the figures obtained are reasonable and internally consistent.

CHAPTER 107

ON THE GEOMETRY OF RIPPLES DUE TO WAVES

by

M.S. YALIN¹ and E. KARAHAN²

ABSTRACT

The present paper is an attempt to determine a single curve for the prediction of the length of ripples forming due to wind waves in shallow waters. The curve is revealed by normalising the field and laboratory data supplied by various authors. The concept of the unified plot embodied by the single curve mentioned is developed by using dimensional methods and by considering the fact that the specific weight and the density of the cohesionless bed material do not affect the length of ripples in a detectable manner. It is shown that the present formulation of the length of ripples due to waves satisfies the requirement of transition into the corresponding formulation of the unidirectional flow ripples when the period and the amplitude of the oscillatory motion increase indefinitely, while their ratio (implying "the velocity") remains finite.

INTRODUCTION

The occurrence of ripples alters the roughness of the movable bed and thus exerts a considerable influence on the mechanical structure of the flow and on sediment transport. Hence it is not surprising that the formation of ripples has attracted the attention of many researchers for many years. In spite of this, however, our knowledge of the origin of ripples and our methods of predicting their dimensions is far from complete, and therefore some further contributions on the topic cannot be regarded as superfluous. The present paper concerns the prediction of the length (Λ) of ripples generated by short waves (wind waves) in shallow waters. It is assumed that the initial surface of the horizontal movable bed is flat, that the granular material is cohesionless, and that the oscillatory motion of the two phases (transporting fluid and transported sediment) is two-dimensional. Furthermore, it is assumed that this oscillatory motion is completely symmetrical, i.e. that no "not drift" is present.

DIMENSIONLESS FORMULATION OF RIPPLE LENGTH

If the internal geometry of a granular material (i.e. the shape of its grains and the shape of its sieve curve) is specified, then, under the conditions stated above, the oscillatory two-phase

¹ Professor of Hydraulics, Queen's University, Kingston, Canada.

² Tech. Univ. Istanbul, Post Doctoral Fellow, Queen's University, Kingston, Canada.

motion in the vicinity of the bed is determined by the following dimensionless variables (Refs. [1] and [2])

$$X = \frac{\gamma_s D^3}{\rho \nu^2} \quad Y = \frac{\rho D}{\gamma_s T^2} \quad Z = \frac{a}{D} \quad W = \frac{\rho_s}{\rho} \quad (1)$$

Here	$\rho =$ fluid density $\nu =$ kinematic viscosity $\rho_s =$ density of grains $\gamma_s =$ specific weight of grains in fluid $D =$ typical grain size (usually D_{50}) $T =$ period of the oscillatory fluid motion $a =$ orbit length of fluid motion at the boundary layer level] fluid] granular material] fluid kinematics
------	--	--

The dimensionless variables (1) ensure the possibility of determining any quantitative property of the oscillatory two-phase motion. This, however, does not mean that all four of these variables must necessarily be present in the expression of every property. The number of variables that must be present and the form of their appearance vary depending on the property under consideration.

The graphs produced to date for the prediction of ripple length Λ , or of its dimensionless version Λ/D , are in the form of a family of curves plotted versus the orbit length a or $Z = a/D$. (See e.g. Figs. 1 and 2 reproduced from Ref. [3] and [2] respectively.) Thus, contemporary practice is to treat Λ/D as a function of two variables, i.e. as

$$\frac{\Lambda}{D} = f(Z, \theta) \quad (2)$$

say, and to plot it by using Z as the abscissa and θ as a parameter differentiating individual curves (each curve corresponding to a constant value of θ). There is general agreement that Z is the most important variable in the expression of Λ/D . There is, however, no agreement yet as to what is exactly the "parameter θ ", i.e. how it should be expressed in terms of the remaining variables X , Y and W ; (see e.g. from Figs. 1 and 2 that in Ref. [2] the parameter θ is identified with the variable Y , whereas in Ref. [3] the curves are classified simply by using the grain size D). The next section is an attempt to reveal the expression of θ .

Fig. 1

Fig. 2

PARAMETER Θ

Consider the information supplied by experiment.

In Ref. [4] the measurements of the ripple length were carried out for three different granular materials: quartz ($\gamma_s/\gamma = 1.65$); coal ($\gamma_s/\gamma = 0.50$) and steel ($\gamma_s/\gamma = 6.6$). No influence of γ_s or ρ_s was detected in the behaviour of the curves representing the variation of the ripple length Λ with the orbit length a . (See e.g. the three curves corresponding to the same grain size $D = 0.36$ mm in Fig. 1 of Ref. [4]).

Similarly from Fig. 3 of Ref. [1] it can be seen that the variation of Λ/D with Z for sand ($\gamma_s/\gamma = 1.65$) and perspex ($\gamma_s/\gamma = 0.19$) is almost the same if the period is the same ($T = 1.82s$) and if their grain size is comparable. (Compare e.g. the patterns of the points corresponding to $D = 0.52$ mm sand and $D = 0.48$ mm perspex in Fig. 3 of Ref. [1] (last two lines in the table on this graph)). These are only a few of the examples which indicate that the length Λ of ripples does not depend on the nature of the granular material, i.e. on its specific weight γ_s and density ρ_s . But the quantities γ_s and ρ_s can only disappear from the expression of Λ if W is excluded, while X and Y appear in the form of the product

$$X \cdot Y = \left(\frac{\gamma_s D^3}{\rho v^2} \right) \cdot \left(\frac{\rho D}{\gamma_s T} \right) = \frac{D^4}{v^2 T^2} \quad (3)$$

(or any power thereof). Accordingly, the relation determining Λ/D can be expressed in the form

$$\frac{\Lambda}{D} = f\left(Z, \frac{vT}{D}\right) \quad (4)$$

From the comparison of (4) and (2) it follows that

$$\Theta = \frac{vT}{D^2} = (X \cdot Y)^{-1/2} \quad (5)$$

DISCUSSION

(i) The parameter Θ which reflects the influence of T in conjunction with v is, at the same time, an indicator which shows how the viscous effect (at the bed) compares with that of turbulence. Indeed, let δ_v and δ_t be the boundary layer thicknesses of viscous and fully turbulent flows respectively. If the flows are oscillatory and the bed is flat, then

$$\delta_v \sim \sqrt{\nu T} \quad (6)$$

$$\text{and} \quad \delta_t \sim K_s \sim D \quad (7)$$

Fig. 3

Thus

$$\theta \sim \left(\frac{\delta v}{\delta t} \right)^2 \quad (8)$$

(If the "geometry" of the oscillatory motion over the flat (initial) bed is given (by $Z = a/D$) then the subsequent wave-like deformation of this bed appears to be dependent only on the comparative degree of turbulence.)

(ii) In the field of unidirectional flows it is well known that the length (Λ) of sand waves does not depend on γ_s or ρ_s . Indeed, none of the expressions produced to date for the length of ripples, dunes or antidunes contain γ_s or ρ_s ; (these quantities affect only the speed of their development). In particular the length of ripples forming in a (two-dimensional) unidirectional flow is determined only by the parameters v_* , D and v (Ref. [5]):

$$\frac{\Lambda}{D} = \phi \left(\frac{v_* D}{v} \right) \quad (9)$$

Consider now an oscillatory flow having

$$(a \rightarrow \infty, T \rightarrow \infty) \quad \text{but} \quad \left(\frac{a}{T} \text{ finite} \right) \quad (10)$$

Suppose that the (finite) mean orbital velocity $U = 2(a/T)$ of this flow is as sufficiently large as to induce the transport of sediment and consequently to generate ripples. Clearly the ripples generated by such an oscillatory flow must be virtually the same as those of a unidirectional flow. But if so, then the function (4) (of two variables) must in the limit (10) reduce into the function (9) (of one variable). In other words, the function (4) must possess the property

$$\lim_{\substack{a \rightarrow \infty \\ T \rightarrow \infty}} \left[f(Z, \theta) \right] = \phi \left(\frac{v_* D}{v} \right) \quad (11)$$

If a and T are very large, then their individual influence vanishes and they affect the phenomenon in the form of the ratio a/T meaning "the velocity" ($u \sim a/T$). But the ratio a/T can only appear in the expression of Λ/D if two variables Z and θ of the function (4) merge into a single variable Z/θ , which means that

$$\lim_{\substack{a \rightarrow \infty \\ T \rightarrow \infty}} \left[f(Z, \theta) \right] = \phi \left(\frac{Z}{\theta} \right) \quad (12)$$

must also be valid. From comparison of (11) and (12) it follows that the necessary expectation in the limit (10) can only be satisfied if Z/θ has the same meaning as the Reynolds number $v_* D/v$. Observe that this is indeed so

$$\frac{Z}{\Theta} = \frac{(a/D)}{(\sqrt{T/D^2})} = \frac{(a/T) \cdot D}{v} \sim \frac{UD}{v} \sim \frac{v_* D}{v} \tag{13}$$

(An analogous transition into the Reynolds number $v_* D/v$ (which does not contain γ_S or ρ_S) cannot be achieved by any other expression of Θ (other than (5)), as any combination of X , Y and W (other than $(X Y)^n$) will inevitably contain γ_S and/or ρ_S).

NORMALISED PLOT

When the values of Λ/D corresponding to a constant value of Θ are plotted versus Z , then the experimental points first follow a common 45°-straight line S , then they diverge from it and form some curves (Figs. 1 and 2). These curves (point patterns) are rather similar to each other and it is very likely that each of them is in fact "the same curve shifted in the 45°-direction". Let m be the point (location) where an individual curve diverges from the common straight line S , and a_0 and Λ_0 be the coordinates of m (Fig. 1). If the individual curves are indeed the shifted versions of each other, then one can normalise the curve family (i.e. one can make all the curves collapse into a single unified curve) by plotting Λ/Λ_0 versus a/a_0 . Estimating the locations m from the data available (Refs. [2], [3], [4], [6], [7]) such a normalised plot was produced and it is shown in Fig. 3. The scatter is considerable (especially that due to the field data) and yet the points (symbols) do not tend to form some patterns of "their own". Thus the idea of a normalised plot appears to be feasible. It would certainly be desirable if some further (laboratory) measurements were carried out in the range

$$\approx 2 < \frac{a}{a_0} < \approx 20$$

(in order to reveal more clearly the position of the curve in this region).

The graph in Fig. 3 can only be used for the prediction of Λ if one knows the values of a_0 and Λ_0 . Since the divergence points m lie on the straight line S (Figs. 1 and 2) a_0 and Λ_0 are interrelated by the simple proportion

$$a_0 = (\text{const}) \cdot \Lambda_0 \tag{14}$$

$$\text{where} \quad \approx 0.75 < (\text{const}) \leq \approx 1 \tag{15}$$

(In fact it is only the curve family of Ref. [2] which yields $(\text{const}) \approx 0.75$. The curve families of the rest of the authors quoted yield $(\text{const}) \approx 1$, and therefore with regard to practical purposes it would be only reasonable to adopt simply $a_0 \approx \Lambda_0$).

Thus it remains to reveal the value of Λ_0 . Since the

divergence point m is displaced together with the curve (Figs. 1 and 2), and since the position of each curve is determined only by the parameter Θ , the value of Λ_0/D must also be determined by Θ only.

$$\frac{\Lambda_0}{D} = \psi(\Theta) \quad (16)$$

Plotting the ordinates Λ_0/D of the points m (estimated from the data available) versus the corresponding values of $\Theta = \sqrt{T/D^2}$ one arrives at the graph in Fig. 4. (Note from this graph that the points corresponding to different γ_s and ρ_s do not tend to form different patterns).

Hence, knowing D , v and T (and consequently Θ) one determines from Fig. 4 the value of Λ_0 , and then from Eqn. (14) the value of a_0 . Knowing a (and thus a/a_0) one can predict Λ/Λ_0 (and thus Λ) from Fig. 3.

Fig. 4

LIST OF SYMBOLS

ρ	fluid density
ν	kinematic viscosity
ρ_s	density of grains
γ_s	specific weight of grains in fluid
D	typical grain size (usually D_{50})
T	wave period
a	orbit length of the oscillatory fluid motion due to waves at the boundary layer level
$U = 2a/T$	mean orbital velocity at the boundary layer level
K_s	height of the granular roughness of the (initial) flat bed
v_*	shear velocity of the unidirectional open channel flow
Λ	ripple length
δ_v	boundary layer thickness of the viscous oscillatory flow
δ_t	boundary layer thickness of the fully turbulent oscillatory flow
X, Y, Z, W	dimensionless variables of the two dimensional oscillatory two-phase motion at the mobile bed, as defined by Eqns. (1)
$\Theta = \nu T/D^2$	dimensionless combination reflecting the influence of period (in conjunction with viscosity)
a_o and Λ_o	upper limits of the proportionality between a and Λ which correspond to a given $\Theta = \text{const}$

CHAPTER 108

THE INFLUENCE OF DUNE AND FLOW PARAMETERS ON THE FRICTION FACTOR

by

J. Sündermann¹

H. Vollmers²

W. Puls³

Taking for example the flow over a ripple, some results of a hydrodynamic numerical model are presented and compared with experimental results. Special importance is attached to the pressure. On the basis of the used equations the physical reason for the horizontal pressure gradient is investigated. The influence of some dune and flow parameters on the friction is examined.

Introduction

Less is known about tidal bedforms than there is known about bedforms in unidirectional flow. Therefore, a project having in mind the investigation of tidal bedforms must at first be sure to give a good description of the simpler conditions. The investigation, a part of which is presented here, is divided into two branches: a hydraulic and a numerical one. The following only concerns the numerical model.

For sediment transport over dunes a special model has been formulated and some calculations of bed deformations have been performed (/1/, /2/). Before tackling the bed, there must be a good knowledge about the flow over this bed. The major work until now was concentrated on this subject.

Numerical model

The numerical model is two-dimensional (horizontal (x)-vertical(z)). It calculates the pressure p , the horizontal

2. Prof. Dr.-Ing., Hochschule der Bundeswehr München, FRG

3. Dipl. Phys., SFB 79 Hannover, Fed. Rep. of Germany

velocity u and the vertical velocity w . There is a free surface, and the natural bed is approximated by a rectangular polygon (Fig. 1).

Fig. 1 Grid and approximated bed

There are about twenty grid points in a vertical section. Near the bed, the grid is refined. The grid is rigid, whereas the bed can move within the grid. A variation of the bed, caused by flow-induced sediment transport, in turn leads to a variation of the flow.

The flow is calculated from the primitive equations ($\zeta = 1$)

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + w \frac{\partial u}{\partial z} - \frac{\partial}{\partial z} \left(A_v \frac{\partial u}{\partial z} \right) + \frac{\partial p}{\partial x} = 0 \quad (1)$$

$$\frac{\partial w}{\partial t} + u \frac{\partial w}{\partial x} + w \frac{\partial w}{\partial z} + \frac{\partial p}{\partial z} = 0 \quad (2)$$

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0 \quad (3)$$

The eddy viscosity A_v is calculated from a turbulence model (/3/). It is variable both in the horizontal and in the vertical direction. The turbulence model is a two-equation model; the calculated quantities are the turbulent kinetic energy k and the dissipation rate ϵ . A_v is a function of k and ϵ . The turbulence model has not only the task to calculate A_v . The knowledge of turbulence is an important tool for the determination of sediment transport.

Verification of calculated results

In order to be sure that one has a productive model for the flow, one has to compare the calculated results with measurements. For this comparison several experiments were carried out in the hydraulic model and data from literature was also used. The basis for the following comparison is an experiment that was performed by Raudkivi (/4/, /5/).

A short description of the experiment: There is a chain of ripples (length $\Lambda \approx 38\text{cm}$, height $\Delta \approx 3\text{cm}$) in a rather narrow flume (mean water depth $H \approx 13\text{cm}$). The flow is stationary (mean velocity $u_m \approx 30\text{cm/sec}$). The topography of the rippled bed as well as the measured quantities have been taken from drawings. This, of course, can be a source of error. Another point producing discrepancies is the fact, that there are periodic conditions in the numerical model (also a question of costs), which is not totally true for the experiment.

The comparison of measured and calculated quantities is shown in Fig. 2, 3, 4, and 5.

Fig. 2 Comparison of horizontal velocities

In Fig. 2 a measured profile at $x \approx 23\text{cm}$ could not be

taken, because the drawn values were obviously wrong (/5/, Fig. 12.13). The agreement of the other profiles in Fig. 2 is quite good, except perhaps at $x \approx 15\text{cm}$ and $x \approx 30\text{cm}$, where the calculated velocities near the bed are too small.

Fig. 3 Comparison of turbulent kinetic energy

Fig. 3: The measured quantities are $\overline{u'^2}$ and $\overline{w'^2}$, whereas the corresponding calculated quantity is $k = (\overline{u'^2} + \overline{v'^2} + \overline{w'^2}) \cdot 0.5$. For the comparison, it was supposed that $\overline{v'^2} = \overline{w'^2}$. For the turbulent quantities, a quantitative agreement can hardly be expected (due to both insufficiencies in measurements and calculations). So a difference of 50% in some places is not surprising. The good qualitative agreement must be emphasized, however.

The same is true for Fig. 4, with the additional difficulty, that the identification of $-\overline{u'w'}$ with $A_v \frac{\partial u}{\partial z}$ is problematic (turbulent viscosity concept of Boussinesq). It is interesting to see that near the bed there is a

decrease of $-\overline{u'w'}$, contrary to the behaviour over a flat bed.

Fig. 4 Comparison of shear stress

Fig. 5 Comparison of pressure

Fig. 5: The agreement of pressures is satisfying. At $x \approx 33\text{cm}$ the measured and the calculated surface pressures were set to zero. Both for the water surface and for the bottom pressure there are the same tendencies: the amplitude of the calculated pressure is too small and there is a shift to the right. Above all, this can be noticed for the bottom pressure. The influence of the walls of the flume had to be separated for the experimental curves.

On the whole, the comparison of the calculated and the measured quantities show, that the model is able to reproduce sufficiently the flow over dunes. Other flows, like that over a block or the flow behind a negative step have also been calculated. They too were found to be in acceptable agreement with experimental results.

Analysis of the pressure gradient

In principle, there are two methods to determine the pressure gradient S of the flow over a periodic bed:

1.
$$S = \frac{p(x_1 + \Lambda, z_1) - p(x_1, z_1)}{\Lambda} \quad (4)$$

(x_1, z_1 arbitrary within the fluid)
2. Measuring tangential and normal stresses at the bed; subsequent determination of S .

In the case of a stationary flow, the two methods must lead to identical results for S (principle of actio and reactio). This was also a test for the correctness of the model.

Knowing S , one is usually content. In this view-point, however, the flow is like a black box. One knows S , but one doesn't know it's origin. An advantage of computer calculations is the possibility to look at what happens in detail in the flow.

The flow is a result of the equations (1), (2), (3) (apart from boundary and initial conditions). We are interested in $\partial p / \partial x$ which appears in (1). Every term A, B, C, D in (1) represents a positive or negative horizontal acceleration of the fluid. The spatial distribution of the effects of the terms A and B can be taken from Fig. 6 and 7. Acceleration means an acceleration in the positive x -direction. The

dotted lines indicate the regions where the effect is highest.

Fig. 6 Effect of term A

Fig. 7 Effect of term B

Fig. 6: The predominant effect of A is a deceleration of the flow which comes from the trough between the ripples. At the lee slope u is small, whereas at the luff slope u is large. Apart from the eddy, the flow transports small u into a region of large u , which means deceleration. In the main flow we have both acceleration and deceleration; the net effect in this part is relatively small.

Fig. 7: In the lee of the ripple crest w has a great negative and $\partial u / \partial z$ a great positive value. Thus the vertical velocity transports large u into a region of small u , which means acceleration. The opposite effect is found in the luff region. On the whole, acceleration is the predominant effect of B.

The influence of the diffusion term C can be imagined from Fig. 4. Due to C, there is a deceleration of u in the most part of the flow and an acceleration near the bed. These two effects nearly compensate each other.

Because $A_v \partial u / \partial z = 0$ at the water surface, we have the following pressure gradient due to C over one ripple length ($h(x)$ = actual water depth):

$$S_c = \frac{1}{\Lambda} \int_0^{\Lambda} \frac{1}{h(x)} \left(A_v \frac{\partial u}{\partial z} \right)_{Bd} dx$$

As can be seen from Fig. 4, $(A_v \partial u / \partial z)_{Bd}$ is small everywhere. S_c is the value that is expected theoretically. Because of numerical influences the model gives a value S_c^{model} , that is different from S_c . This difference can reach about 50%, which is relatively large. But assuming the absolute smallness of S_c , it is not so bad. In the following, we will use S_c , so we have to put up with a small error.

Now we want to pass over to quantitative examinations. For this we take equation (1) and integrate it vertically. Now the single terms in (1) depend on x only. Expressing the influences of the integrated terms A, B, C, D with pressure gradient terms $\partial \bar{p}_A / \partial x, \dots, \partial \bar{p}_D / \partial x$, the curves $\bar{p}_A(x), \dots, \bar{p}_D(x)$

give an impression of the effect of the single terms (Fig. 8). The pressure gradient due to A for one ripple length Λ is

$$S_A = \frac{\bar{p}_A(\Lambda) - \bar{p}_A(0)}{\Lambda}$$

The corresponding is valid for the other terms. It is $S_D \approx -S_A - S_B - S_C$ ("≈" because $S_C \neq S_C^{\text{model}}$).

Fig. 8 Representative pressures due to the terms of (1)

The vertical integration of (1) leads to an additional difficulty. This can be seen from Fig. 9 (compare with Fig. 1).

Fig. 9 For the explanation of effect E

The numerical integration of p in column j gives $\tilde{p} := \frac{1}{5} \sum_{n=1}^5 p_n$. \tilde{p} acts on the u -points in column i . The u -points in column k , however, are only affected by $\hat{p} := \frac{1}{3} \sum_{n=1}^3 p_n$.

If $\tilde{p} \neq \hat{p}$, the gradients $\partial \tilde{p} / \partial x$ for the u -points in i and k have not the same "basis" in j . This effect (which we call E) leads to a difference between S from equation (4) and S_D . E is no physical effect, but a consequence of vertical integration. In accordance with S_A etc., S_E is the pressure gradient due to E for one ripple length. Then we have:

$$S = S_D - S_E$$

$$\text{and } S \approx -S_A - S_B - S_C - S_E$$

The total and the partial pressure gradients for Raudkivi's conditions are given in the first column of the table. There is also given the friction factor (Darcy-Weisbach), taken from the law

$$|u_m| = \sqrt{\frac{8}{f}} \sqrt{\frac{1}{5} H |S|}$$

The results of the numerical model can be compared with theoretical considerations of Yalin (/6/). Yalin gives expressions for the pressure gradients due to skin and form effects. Deducing the formula for the form drag, he says, that the pressure gradient over a dune is mainly due to the

expanding part (lee slope), the effect of the contracting part (luff slope) being negligible.

This seems to be too rough. From Fig. 8 we see that both the expanding and the contracting zones are influencing the behaviour of pressure. It is the net effect that represents S . Compared with this net effect, the single contributions of the expanding and the contracting zones are considerably large.

Yalin's formula for the form drag is:

$$\left(\left| \frac{\partial p}{\partial x} \right| \right)_{\text{form}} = \frac{1}{2} \frac{\Delta^3 u_m^2}{H^2 \Lambda} \quad (5)$$

For Raudkivi's conditions this gives $0.62\text{g}/(\text{cm}^2\text{s}^2)$. Our corresponding value is $S_A + S_B + S_E$, which is also $0.62\text{g}/(\text{cm}^2\text{s}^2)$.

Yalin's formula for the skin friction gives a pressure gradient of $0.11\text{g}/(\text{cm}^2\text{s}^2)$, whereas we get $S_c = 0.085\text{g}/(\text{cm}^2\text{s}^2)$. A remark: Yalin assumes constant skin friction over the luff slope. In the numerical model, the skin friction is about zero in the lower part of the luff slope (reattaching and developing zone), whereas it is relatively high near the crest (see the curve for \bar{p}_c in Fig. 8).

Influence of the flow and bed parameters

The effects of the parameters u_m , H and Λ were investigated in the numerical model: Case I includes the original conditions of Raudkivi; there are six variations of case I, that can be taken from the table (all values of S in $10^{-2}\text{g}/(\text{cm}^2\text{s}^2)$).

The table gives the total pressure gradient S , the partial pressure gradients S_A , S_B , S_C , S_E and the friction factor f for the different cases.

In case II, u_m gets a factor of 1.25 compared with case I. As a result, every pressure gradient gets a factor of about $(1.25)^2$; f remains nearly constant. This is well known, of course also (5) gives this dependance. Case II can be thought to be a test for the model.

The cases III-V include three calculations where only H differs from case I. Yalins formula (5) gives a proportionality to H^{-2} . This can be noticed here too, though it is not unequivocal. Approximately we have $S_A \sim H^{-2}$, $S_B \sim H^{-1.5}$, $S_E \sim H^{-1}$.

Case	I	II	III	IV	V	VI	VII
$u_m \left[\frac{\text{cm}}{\text{s}} \right]$	28.7	35.9	28.7	28.7	28.7	28.7	-28.7
$H \text{ [cm]}$	13.2	13.2	9.2	17.2	28.7	13.2	13.2
$\Delta \text{ [cm]}$	2.95	2.95	2.95	2.95	2.95	4.43	2.95
S	-66.8	-102.1	-132.0	-42.6	-17.8	-102.7	130.8
S_A	73.1	111.1	149.6	44.4	16.5	95.0	-25.6
S_B	-33.2	-50.5	-58.4	-22.2	-10.2	-19.1	-42.5
S_C	8.5	12.4	17.3	5.4	2.2	2.3	-18.1
S_E	22.0	34.8	30.7	17.5	10.7	28.5	-53.9
$r \text{ [} 10^3 \text{]}$	8.6	8.4	11.8	7.1	5.0	13.2	16.8

Compared with S_A however, the effect of the sum $S_B + S_E$ is small, and thus the final result is nearly due to the effect of A alone. Of course this is a rough approximation, usable perhaps as a rule of thumb.

A variation of Δ is only examined for one case (VI). Compared with case I, the bed height (see Fig. 5) gets the factor 1.5. As a result, the sum of S_A , S_B , S_E is nearly proportional to Δ . The tendencies for the single terms, however, is quite different: $|S_A|$ and $|S_E|$ become larger, $|S_B|$ becomes smaller. This behaviour is a result of the expansion of the lee eddy. For the same reason (expansion of the recirculating and the developing zone) the skin friction has decreased in case VI. From this comparison of only two cases one cannot say that $S_A + S_B + S_E \sim \Delta$ is valid, but it is a reference point. Yalin's formula (5) gives a different result: a proportionality to Δ^2 .

On the whole, from the numerical experiments we get the rough formula for the friction factor (the influence of skin friction produces an additional uncertainty):

$$f \sim \frac{\Delta}{H} \quad (6)$$

The versions II-VI are more or less small variations of Raudkivi's original experiment. The dominating influence always comes from A. This is not true if we take the same geometry, but a reversed direction of the flow (case VII). Here the effect of B has the same sign as A, C, E, and together with E it is dominating.

This investigation does not take into account variations of the length and the shape of a ripple. A tidal dune, for instance, can lead to totally other results, which is indicated by case VII. Thus the "law" (6) can be thought to be valid for conditions like Raudkivi's only. What about the dependence $S \sim \Delta$, which is contrary to Yalin, this work can perhaps give an impuls for further investigations concerning this point.

CHAPTER 109

TIME-LAG OF DUNES FOR UNSTEADY FLOW CONDITIONS

by

Horst Nasner*

1. Introduction

Many publications based on theoretical considerations or model tests, give utterance to the demand that there should be unequivocal relations between hydraulic conditions and bed form characteristics which should be generally applicable. These relationships determined for steady conditions and limited water depths should be handled with care when being applied to natural rivers. The bed configurations do not immediately fit themselves to the varying flow conditions. The bed forms need a certain reconstruction time in case of a changing discharge. The time-lag of dunes was observed on numerous rivers, in the past. A general review of investigations made in this field is given by ALLEN (1976 b).

In the following contribution, an attempt is made to describe the magnitude of the time lag of bed forms for unsteady flow conditions.

2. Bed forms and flow conditions

The formation and migration of the different bed forms which may occur, were investigated in many basic theoretical studies and laboratory tests for stationary conditions and restricted water depths. The terms for different bed configurations are explained by the graph in Fig. 1 (ENGELUND and HANSEN, 1967). For the relation between bed shear stress and flow velocity it shows the bed forms which occur for an increasing velocity of flow.

* Head of Hydraulic Engineering, Engelbrecht Consult, Hamburg /Germany

Fig. 1 Bed Shear Stress, Flow Velocity and Bed Forms

(ENGELUND and HANSEN, 1967)

In the lower regime, with streaming flow, ripples or dunes are formed when a certain velocity is exceeded. For a further increase of the flow velocity in the transition zone, the dunes are drawn out.

In the upper regime, standing waves or antidunes may be observed which move against the direction of flow. The upper regime is apparent for Froude numbers $Fr > 1$ (shooting flow).

Deep water rivers and tidal channels are characterized by low Froude numbers. Following the preceding example, large dunes should be formed with increasing flow velocities.

For unsteady conditions, the maximum dune dimensions should appear with a time-lag, after the maximum flow.

3. Change of bed forms with tidal motion
- 3.1. Shifting during the tide

From model tests with tidal currents it is known, that the shape of the current ripples adapts itself to the prevailing flood - or ebb-current direction - within a short time (DILLO, 1960).

TERWINDT analyzed on 923 dune fields in tidal channels of the Netherlands (1970) up to what height the tidal dunes change their general shape with the alternating currents.

These observations led to the following result: "The asymmetry of the ripples ($H = 30 - 100$ cm) may change with the turn of the tidal currents, but this is not always the case. The asymmetry of the ripples ($H = 100 - 200$ cm) most times does not change with the turn of the tides." From this result it may be concluded that the adaption time or time-lag of the smaller forms is less than one flood - or ebb current phase - which are shorter than 6 hours as the tides at the North Sea coast are semidiurnal. The general shape of the larger dunes ($H > 1$ m) is not affected by tidal motion, that means the time-lag exceeds 6 hours. There are only local redistributions in the crest area due to the tidal currents (NASNER, 1974 a).

- 3.2. Fresh-water flow and dune height

In the upper part of a tidal river, the mean current velocities are influenced by the fresh-water discharge. Analyses of many years on four significant dune fields in the navigation channel of the River Weser between Bremen und Bremerhaven (Fig. 2), proved that the height and migration of the ebb predominant sand waves are influenced significantly by the long-term change of the mean ebb-current velocities as a consequence of the change of the fresh-water discharge Q_0 (NASNER, 1974 a, 1974 b). The characteristics of the bed forms are not influenced by the tidal motion. The mean wave length is in the order of 50 m, the mean height reaches values of more than 2,5 m in mean water depths of about 10 m. The semidiurnal tides are quite regular with a tidal range of approximately 3,5 m.

Fig. 2 German North Sea Coast

4. Phase diagrams

4.1. Preliminary remark

A possibility to determine the time-lag between the change of the flow parameters and the adaption of bed form characteristics is given by phase diagrams (ALLEN, 1973; 1976 a; 1976 b; JACKSON II 1976). This can be done by plotting, for example dune height against fresh-water discharge, where both parameters are also functions of the time. Such graphs are loops which ideally are closed, whereas the time may run clockwise or anticlockwise.

4.2. Dune height discharge diagram for the River Weser

By way of example the mean dune height \bar{H} (about 40 dunes are analysed) was plotted as a function of the fresh-water discharge in a phase diagram for the River Weser, from September, 1966 till October, 1967 (Fig. 3). The time-lag between maximum discharge and maximum dune height is extremely large for the River Weser with values up to 7 - 9 months (ALLEN, 1976 b). However, this result is not relevant to the behaviour of dune characteristics and discharge, as the following explanations will show.

Fig. 3 Mean Dune-Height Discharge Curve for River Weser

According to the preceding description of possible bed forms (Fig. 1), the river bottom of the Weser is far-off the transition zone, as the Froude number compares with $Fr = 0,1$. For the water depth of approximately 10 m the Froude number obviously is no longer the determinative factor. The dune height H is governed by the mean ebb-current velocity over the dune crest. A state of equilibrium is given, when the flow velocity over the crest reaches a limiting value, which is a function of the sediment characteristics. For the dunes in the River Weser, the limiting velocity is about 1,0 m/sec (NASNER, 1974 a; 1974 b).

The conditions for the River Weser are represented ideally in Fig. 4. Due to the unsteady situation, there are no unique relationships between dune height and fresh-water flow. One value of discharge ($Q_{a,b}$) corresponds to two values of dune height (H_a ; H_b) and inversely.

Fig. 4 Schematic Dune-Height Discharge Curve for River Weser

With increasing fresh-water discharge, the limiting ebb-current velocity is exceeded and erosion is caused. The dunes are higher than they should be (lag of erosion). With decreasing discharge, dunes are smaller than they should be (lag of sedimentation). It is mentioned elsewhere that a state of equilibrium is reached in the River Weser, when there is a quasi steady fresh-water discharge for about 30 days.

As a result, the tidal dunes of the River Weser are to be assigned to the transition zone in Fig. 1. This may be seen from the shape and time sequence of the diagram in Fig. 4. The smaller dunes thus are related to the higher discharge. The assumption that higher bed forms are built up with a higher discharge, is refuted by the preceding descriptions.

The adapting of the dunes to the fresh-water discharge in the River Weser is clearly given in the time-series in Fig. 5. For the hydrological years 1966 to 1972, the daily fresh-water discharges Q_0 of the River Weser are compared with the mean dune heights \bar{H} . The example shows the continuous creation-destruction process to which the bed forms are subjected.

The model tests carried out by Simons and Richardsor. (1960) are quite interesting in this connection. Fig. 6 shows the flow velocities, water depths and different bed forms as functions of the Froude number. Even for water depths of only 0,3 m the beginning of transition was measured for a flow velocity of about 1,0 m/sec. Similar results were found by model tests in a circuit flume with water depths of approximately 1 m and sand from the River Weser (ZANKE, 1976). As the prototype investigations have shown, the limiting value for the flow velocity may be extrapolated to greater water depths.

Fig. 5 Progress Line of Discharge Q_0 and Mean Dune Height \bar{H} for River Weser

Fig. 6 Flow Velocity, Water Depth and Bed Form (SIMONS and RICHARDSON, 1960)

5. Comparison with other rivers

The results found for the River Weser, can be generalized as they also apply to other rivers, where with raising water levels due to the increasing flow velocities, there occur smaller dunes (phase of erosion) than with falling water levels (phase of sedimentation). Examples are given for rivers without tidal motion by the investigations of NEDECO (1959) on the River Niger and of STÜCKRATH (1969) on the Rio Paraná (Fig. 7 and 8).

In a 40 km river stretch of the River Niger, soundings were performed by NEDECO. In Fig. 7 the frequencies of dune heights at low water and at high water are plotted. The dunes are smaller at the raising stage (A) than at the falling stage (B).

Fig. 7 Dune Heights on the Niger at Low Water and at High Water (NEDECO, 1959)

STÜCKRATH analyzed soundings on the Rio Paraná from May, 1967 up to December, 1968 (Fig. 8). The time progress is indicated by the arrows in Fig. 8. In general, there is a decrease in dune height with an increase of the water level and flow velocities. The Froude number is smaller than $Fr = 0,1$. The range of the mean flow velocities, which is between 0,9 and 1,1 m/sec comparable with those in the River Weser, is of special interest. It can be stated from Fig. 8 that the dunes on the bottom of the Rio Paraná are in transition.

Fig. 8 Mean Dune Height, Flow Velocity and Water Levels in the Rio Paraná (STÜCKRATH, 1969)

Mean water level and dune height

In Fig. 9, besides the progress line of the daily fresh-water discharge and the measured dune heights, the monthly mean tide levels are plotted. Again the continuous adaption of the dunes to the changeable discharges is shown as well as the fact that the time-lag is a short-term event.

A remarkable result is the circumstance that the fixed boundary (dune height) reacts to changed flow conditions in a more sensitive way than the free surface. The fluctuation of the mean tide is significantly smaller than the variation of the dune height. The height variation is caused mainly by erosion and sedimentation in the crest area with a nearly constant through level (NASNER, 1976 a). The significant parameter is the flow velocity to which the river bottom adjusts itself. It is of interest, in this connection, that in many formulas on sediment transport, the bed-form contribution is considered by an additional friction factor.

The stability of a dune-covered bed against discharging is subject to the transport mechanism of the bed forms, by which the bed load is considerably reduced in comparison with a flat bed (FÜHRBÖTER, 1967). Investigations in the prototype have proved that the sand transport in a dune field is effected essentially through a local redistribution of the bed material corresponding to about the migration velocity of the dunes (NASNER, 1976 b).

Fig. 9 Progress Line of Discharge Q_0 , Mean Dune Height \bar{H} and Mean Tide Level $MT \frac{1}{2} w$ for River Weser (1966-1967)

7. Concluding remarks

In this paper, the time-dependent behaviour of dunes as a function of the governing hydraulic conditions have been described. The results can be summarized as follows:

- It has been proved that it is difficult to apply the results from experiments on models, to natural rivers. A clear-cut relationship between bed form properties and flow conditions may be given for steady circumstances. In nature where unsteady flows prevail, the bed configuration adjusts itself to the changing hydraulic conditions with a time-lag. However, also for significant dunes in deep-water rivers, this is a short-term process.
- The knowledge gathered from laboratory tests, according to which for low Froude numbers and increasing velocities, higher dunes will be established, obviously applies to limited water depths only. The governing parameter for rivers of greater depths is the flow velocity which determines the limiting dune height - depending on the sediment characteristics. In spite of the low Froude numbers, the river bottom may be situated in the transition zone. The dunes become smaller by erosion, for increasing discharges and flow velocities. In case of falling water levels and lower current velocities, the bed forms may be enlarged again by sedimentation.
- The investigations revealed that the river bottom shows a very sensitive reaction to changed discharge and flow conditions. The variations of the dune height are of a remarkably greater order of magnitude than the fluctuations of the mean water level. On principle, the dunes cause a stabilization of the bottom so that the sediment removal is reduced. Compared with a flat bed, the sand transport is considerably reduced by the merely local redistribution of the bed material. In this respect, the dune height is of minor significance, as the height as well as the migration velocity of the bed forms is governed by the mean velocity of the flow and not inversely.

CHAPTER 110

PREDICTION OF BEACH PLANFORMS WITH LITTORAL CONTROLS

by

Marc Perlin⁽¹⁾ and R. G. Dean⁽²⁾

ABSTRACT

Three numerical models representing shoreline response are described and applied to a number of problems of coastal engineering interest. Included are: (1) a one-line explicit model, (2) a one-line implicit model, and (3) a two-line explicit model. Simplified refraction and diffraction schemes are incorporated into the models. The models allow grid elements to be activated and deactivated as sand is initially deposited in or the last sand removed from a grid at a jetty inclined to the shoreline. The one-line explicit model and two-line explicit model are similar to those described by Bakker, Breteler and Roos⁽³⁾. The one-line implicit model offers the advantage of stable computations for much longer time steps.

Example applications of shoreline response are presented to illustrate the utility of the model including: permeable versus impermeable jetties, shoreline perturbations caused by jetties which are aligned with the incoming waves versus jetties perpendicular to shore, shoreline response inside a groin compartment and the effect of a littoral barrier. In addition, the one-line implicit model is applied to predict the shoreline response in the vicinity of an offshore breakwater at Channel Islands Harbor, California where sediment is accumulated and dredged periodically. In this case, excellent shoreline response data are available from the prototype; however, only visual wave observations were available for this comparison and it was found necessary to increase the sediment transport relationship fourfold to achieve even approximate correspondence.

Numerical models offer a powerful means which, when combined with good judgement, should strengthen the coastal engineer's ability to predict the effects of a coastal engineering design. The research needs to improve numerical modeling capabilities are presented.

INTRODUCTION

In considering the installation of a coastal structure it is important to know the impact of the structure on shoreline fluctuations. Theoretical solutions are available for idealized cases of simple littoral barriers, unidirectional waves and linearized transport. Most actual conditions are considerably more complex due to reversals

(1) Hydraulic Engineer, Evaluation Branch, Coastal Engineering Research Center, Fort Belvoir, Virginia 22060.

(2) Professor, Department of Civil Engineering and College of Marine Studies, University of Delaware, Newark, Delaware 19711.

of longshore transport, a time-varying wave height and possibly more than one structure present. Numerical modeling has been developed to a fairly high degree of reliability for some applications such as tidal wave propagation in estuaries. Conversely, the numerical modeling of shoreline evolution must be considered in a relative state of infancy, however, it does appear to offer the potential of providing a substantial improvement to existing design and assessment capabilities. Moreover, it is anticipated that the use of numerical models will identify those critical sediment transport mechanisms requiring improved understanding and will provide the framework which, when applied in conjunction with well-designed and instrumented laboratory and/or field experiments, will allow these mechanisms to be better defined.

In this paper, three numerical models to represent shoreline evolution will be described and examples illustrating their application presented. Two of these models are quite similar to those developed and described by Bakker, Breteler and Roos⁽³⁾ and by Hulsbergen, Bakker and van Bochove⁽⁹⁾. The third utilizes an implicit approach and allows much longer time steps to be utilized. Additionally, the latter model is applied to several interesting coastal engineering problems not previously treated by this approach.

REVIEW OF PREVIOUS WORK

Analytical Approaches

Previous efforts to predict shoreline evolution include both analytical and numerical approaches. The earliest approach was that of Pelnard Considère⁽¹³⁾ in which the linearized longshore sediment transport equation and conservation of mass equation were combined to yield the diffusion equation in terms of a shoreline coordinate, y

$$\frac{\partial y}{\partial t} = A \frac{\partial^2 y}{\partial x^2} \quad (1)$$

and where A incorporates the wave and beach characteristics. Eq. (1) has been solved for a number of conditions including that of a long littoral barrier, the spreading out of a deposit of sand on an otherwise straight shoreline, etc.

Bakker, Breteler and Roos⁽³⁾ have extended the theory of Pelnard Considère by representing the beach profile by two contours, say y_1 and y_2 . In this case, there are two governing equations which incorporate the effect of the onshore or offshore motion between the two contours due to a non-equilibrium beach slope. Bakker has solved these equations for a number of interesting cases including those of single and multiple groins along a shoreline. Accumulation occurs at a groin until the accretion of the shoreline results in a profile that is so steep that the offshore gradient causes the sand to be diverted to the offshore contour where it is transported around the tip of the groin.

There have been a number of laboratory experiments^{(3) (4) (9) (16)} of shoreline evolution; the results of these experiments are generally in good agreement with the analytical solutions.

Numerical Approaches

In order to avoid the assumptions and limitations associated with the analytical approaches, a number of studies (2) (3) (9) (15) (16) (18) have been carried out to investigate the application of numerical models to shoreline evolution problems. The advantages of numerical modeling include the capability to readily incorporate many features, including: changes in wave conditions, the full (nonlinear) equations, complicated structure geometry, wave diffraction, structure permeability, crest elevation, etc. Almost any feature or mechanism for which a relationship is known (or is suggested) can be incorporated into the numerical model.

METHODOLOGY

Three numerical models will be described and illustrated by examples. These include: (1) a one-line explicit model, (2) a one-line implicit model, and (3) a two-line explicit model.

One-Line Explicit Model

This type of numerical model has been applied by a number of investigators to the problem of shoreline response. The governing equations include the sand transport equation and the conservation of mass equation.

Sand Transport Equation. The relationship governing the transport of sand along a straight shoreline as expressed by Inman and Bagnold⁽¹⁰⁾ is

$$I = K P_{\ell s} \quad (2)$$

in which I is the immersed weight transport rate, K is a dimensionless constant (≈ 0.8) and $P_{\ell s}$ is the longshore component of wave energy flux at the breaker line, given by

$$P_{\ell s} = \rho g \frac{H_b^2}{8} C_{G_b} \sin \delta_b \cos \delta_b \quad (3)$$

in which ρ is the mass density of water, g is the gravitational constant, H_b is the breaking wave height, C_{G_b} is the group velocity at the breaker line and δ_b is the breaking wave crest angle relative to the shoreline,

$$\delta_b = \beta_B - \beta' - \alpha_b$$

and α_b is the azimuth from which the waves propagate, β_B is the azimuth of the outward normal of the baseline and β' is the inclination of the shoreline relative to the baseline. One advantage of Eq. (2) over other forms is that I and $P_{\ell s}$ have the same dimensions. The immersed weight sand transport rate, I , and the volumetric sand transport rate, Q , are related by

$$Q = \frac{I}{\rho g (S-1) a} \quad (4)$$

in which S_s is the specific gravity of the sediment relative to the fluid and a is the complement of the porosity ($a \approx 0.6$ to 0.7).

Conservation of Mass Equation. The conservation of mass equation, considering only longshore transport is

$$\frac{\partial \Psi}{\partial t} + \frac{\partial Q}{\partial x} = 0 \tag{5}$$

in which x is the longshore coordinate and Ψ represents the total volume of the beach profile per unit length.

Solution. The one-line explicit model utilizes a time-marching space and time-staggered procedure in which the shoreline orientation is held fixed for one time step (from $n\Delta t$ to $(n+1)\Delta t$) and the sand transport calculated, and the transport held fixed over a time step (from $(n+\frac{1}{2})\Delta t$ to $(n+\frac{3}{2})\Delta t$) and the changes in shoreline position are determined. The finite difference equations are

$$Q_i^{n+1} = K \left(\frac{H_b^2}{8} \right)^n \frac{C_b^n}{(S_s - 1)a} \sin \delta_b^{n+\frac{1}{2}} \cos \delta_b^{n+\frac{1}{2}} \tag{6}$$

$$y_i^{n+\frac{3}{2}} = y_i^{n+\frac{1}{2}} - \frac{\Delta t}{D\Delta x} \left[Q_{i+1}^{n+1} - Q_i^{n+1} \right] \tag{7}$$

where the superscripts denote the time level at which the variable is evaluated and D represents the total depth of the "active" beach profile which is assumed to be displaced landward or seaward without change of form. The shoreline orientation β' relative to the baseline is determined by

$$(\beta'_i)^{n+\frac{1}{2}} = \tan^{-1} \left(\frac{y_{i+1}^{n+\frac{1}{2}} - y_i^{n+\frac{1}{2}}}{\Delta x} \right) \tag{8}$$

Figure 1 presents the grid system for the one-line model.

Wave Refraction. The orientation of the deep water waves is considered known. The waves are then refracted to the breaking depth in accordance with Snell's Law, where the orientation of the contour at breaking is assumed to be the same as that of the shoreline for the same grid.

Wave Diffraction. An approximate diffraction procedure is incorporated in the model, based on the results of Penny and Price⁽¹⁴⁾. The reader is referred to Perlin⁽¹⁵⁾ for greater detail on the manner of representing diffraction in the model.

Figure 1. Shoreline Representation for One-Line Numerical Model.

One-Line Implicit Model

The one-line implicit model is based on the same equations (Eqs. (5) and (6)) as the one-line explicit model; however, for the implicit model they are solved simultaneously and thus greater numerical stability results. The main features of the implicit model will be described in detail, since this type of model does not appear to have been applied before for shoreline evolution.

Sand Transport Equation. The sand transport equation is the same as introduced earlier and is written below in abbreviated form as

$$Q = \Gamma H_b^{5/2} \sin 2\delta_b \quad (9)$$

where

$$\Gamma = \frac{K\sqrt{g}}{16(S_s - 1)\sqrt{k} a}$$

in which the shallow water approximation $C_{G_b} = \sqrt{gh_b}$ and the usual spilling breaking assumption $H_b = kh_b$ have been introduced. The quantity h_b

represents the breaking depth. Considering that the appropriate sand transport value for establishing changes between the n^{th} and $(n+1)^{\text{th}}$ time step as that at $(n+\frac{1}{2})\Delta t$, expanding Eq. (9) and accounting for first order effects of changes in y

$$Q_i^{n+\frac{1}{2}} = \Gamma(H^{\frac{5}{2}})^n \left[\sin 2(\beta_B - \alpha_{b_i})^n \cos(2\beta_i')^n - \cos 2(\beta_B - \alpha_{b_i})^n \frac{y_i^{n+1} + y_i^n - y_{i-1}^{n+1} - y_{i-1}^n}{\sqrt{(\Delta x)^2 + (y_i^n - y_{i-1}^n)^2}} \right] \quad (10)$$

Other forms for $Q_i^{n+\frac{1}{2}}$ could be equally valid or more valid.

Conservation of Sand Equation. The equation for the conservation of sand is

$$y_i^{n+1} = y_i^n - \frac{\Delta t}{D\Delta x} \left[Q_{i+1}^{n+\frac{1}{2}} - Q_i^{n+\frac{1}{2}} \right] \quad (11)$$

Solution to Equations. Prior to describing the equations to be solved, they will be rewritten in the following forms

$$A_i y_i^{n+1} + Q_i^{n+\frac{1}{2}} - A_i y_{i-1}^{n+1} = D_i \quad (12)$$

$$B_i Q_{i+1}^{n+\frac{1}{2}} + y_i^{n+1} - B_i Q_i^{n+\frac{1}{2}} = E_i \quad (13)$$

where

$$A_i = \Gamma(H^{\frac{5}{2}})^n \frac{\cos 2(\beta_B - \alpha_{b_i})^n}{\sqrt{\Delta x^2 + (y_i^n - y_{i-1}^n)^2}} \quad (14)$$

$$D_i = \Gamma(H^{\frac{5}{2}})^n \left[\sin 2(\beta_B - \alpha_{b_i})^n \cos 2(\beta_i')^n - \cos 2(\beta_B - \alpha_{b_i})^n \frac{y_i^n - y_{i-1}^n}{\sqrt{\Delta x^2 + (y_i^n - y_{i-1}^n)^2}} \right] \quad (15)$$

$$B_i = \frac{\Delta t}{D\Delta x} \quad (16)$$

$$E_i = y_i^n \quad (17)$$

and Eqs. (12) and (13) represent the sand transport and conservation of sand equations respectively.

Eqs. (12) and (13) are solved by the so-called double-sweep method⁽¹⁾⁽¹⁶⁾ in which it is assumed that the adjacent Q and y values are related linearly, i.e.

$$Q_{i+1}^{n+\frac{1}{2}} = G_i y_i^{n+1} + H_i \quad (18)$$

$$y_i^{n+1} = G_i^* Q_i^{n+\frac{1}{2}} + H_i^* \quad (19)$$

It is clear that if the G , G^* , H and H^* values were known for all i and if either y or Q were also known at one boundary, it would be possible to calculate all Q and y values from Eqs. (18) and (19). The double-sweep method proceeds by substituting Eq. (18) into Eq. (13) and solving for y_i^{n+1} , which results in

$$y_i^{n+1} = \frac{B_i}{B_i G_i + 1} Q_i^{n+\frac{1}{2}} + \frac{E_i - B_i H_i}{B_i G_i + 1} \quad (20)$$

and substituting Eq. (19) into Eq. (12) yields

$$Q_i^{n+\frac{1}{2}} = \frac{A_i}{A_i G_i^* + 1} y_{i-1}^{n+1} + \frac{D_i - A_i H_i^*}{A_i G_i^* + 1} \quad (21)$$

Comparison of Eqs. (20) and (21) with (18) and (19) establish a relationship between the unknowns, G_i , H_i , G_i^* and H_i^* and the knowns A_i , B_i , D_i and E_i as

$$G_i = \frac{A_{i+1}}{A_{i+1} G_{i+1}^* + 1}, \quad H_i = \frac{D_{i+1} - A_{i+1} H_{i+1}^*}{A_{i+1} G_{i+1}^* + 1} \quad (22), (23)$$

$$G_i^* = \frac{B_i}{B_i G_i + 1}, \quad H_i^* = \frac{E_i - B_i H_i}{B_i G_i + 1} \quad (24), (25)$$

As an example, the solution proceeds from the right-hand boundary ($i = I$) where either Q_I or y_I is specified. If Q_I is known, then $H_{I-1} = Q_I$ and $G_{I-1} = 0$. If y_I is specified, then $H_I^* = y_I$ and $G_I^* = 0$. To illustrate the process further, suppose Q_I is specified, then H_{I-1} and G_{I-1} can be determined, and from Eqs. (24) and (25) it is possible to establish G_{I-1}^* and H_{I-1}^* . Continuing in a stepwise fashion, from Eqs. (22) and (23), G_{I-2} and H_{I-2} are calculated, etc. Considering that Q_I is the value stated at the left-hand end of the grid system the determination of G_1^* and H_1^* complete the first "sweep" from right to left. The second "sweep" is from left to right and comprises the establishment of the sand transport values $Q_i^{n+\frac{1}{2}}$ and y_i^{n+1} for all i using Eqs. (18) and (19). This completes the procedure for one time step and the process is repeated for subsequent time steps.

Unless otherwise stated all examples presented subsequently will be based on the implicit model.

A M-Line Model

A M-line model is an extension of the similar two-line explicit model presented by Bakker, Breteler and Roos⁽³⁾. The displacements of M contours are calculated at each time step including onshore-offshore transport due to the beach slope being milder or steeper than the equilibrium, respectively, see Figure 2. A multi-line model provides a much better representation of shoreline response in the vicinity of structures where, for example, the steepening of the profile on the updrift side causes offshore transport and bypassing of the structure before the mean water level contour has advanced to the tip of the structure.

Figure 2. Beach Profile and Transport Representation For Multiple-Line Numerical Model.

Sand Transport Equations. The longshore sand transport equation for the m^{th} line is

$$Q_{x_{i,m}} = \mu_m Q$$

where Q is the value given by Eqs. (2) and (4) and μ_m is the proportion of the transport associated with the m^{th} line and it follows that

$$\sum \mu_m = 1 \tag{26}$$

The equation for offshore transport per unit beach length, q_{y_m} from the $(m-1)^{th}$ to the m^{th} contour is

$$q_{y_m} = K_{y_m} (y_{m-1} - y_m + W_m) \tag{27}$$

in which K_{y_m} is a transport coefficient for the m^{th} contour line and W_m is the equilibrium separation distance for the $(m-1)$ and m contours. It follows that if the profile is steeper or milder than the equilibrium the transport will be offshore or onshore respectively. In the two-line

model utilized here, the equilibrium distance, W , was based on an analysis of equilibrium profiles by Dean⁽⁸⁾ and the sand transport coefficient, K_y , was based on wave tank tests by Saville⁽¹⁷⁾.

Conservation of Sand Equation. The sand conservation equation, for the m^{th} contour, including the effects of onshore-offshore transport, is

$$\Delta h_m \frac{\partial y_m}{\partial t} + \frac{\partial Q_x}{\partial x} - q_{y_m} + q_{y_{m+1}} = 0 \quad (28)$$

Solution to Equations. In the present study, the equations for the two-line model were solved explicitly; however, there should be no difficulty in utilizing a mixed (explicit-implicit) procedure.

APPLICATIONS

As with any model, a complete evaluation requires comparison with as many other analytical and physical model results as possible. First a comparison between explicit and implicit one-line models will be demonstrated to provide confidence in the implicit solution followed by a comparison between the numerical model and the theory of Pelnard Considère, using two different transport equations in the numerical model. This is followed by specific applications which demonstrate the utility of the model.

In addition to intercomparison of numerical and analytical models, the model developed here is compared with the results from two physical model tests. Finally, the model predictions are compared with the results of a field measurement program.

Explicit Versus Implicit Schemes

To evaluate the implicit scheme, comparisons were carried out with results obtained from the explicit model. The wave conditions used in both models were a breaking wave height of 5 ft., an angle of wave approach of 45° from the north, and a duration of 1.39 days. The jetties were 1500 ft. long, and both the north jetty and the south jetty were oriented at angles of 20° to the shoreline. The time step in the explicit and implicit models are 600 and 6000 seconds, respectively. Because the differences between predicted shoreline changes by the two methods are small, rather than presenting plots, the results are tabulated in Table 1. The accretion is represented as a positive change and the erosion as negative. Both the x-distances (distance from shore end of the jetty at the baseline) and the y-coordinates have been rounded to the nearest tenth of a foot. Also, y-coordinates which did not change due to being outside the region of jetty influence are not presented in Table 1.

The distances proceed outwards in both directions from the jetty. Note that grid point 50 has a value of 176.2 ft. which is less than the value at grid 48. The explanation is simply that 176.2 ft. is the distance from the baseline to the jetty at grid 50 (i.e., the jetty is impounded with sand at this point). It is also worth noting that the south beach is affected for a larger distance from the jetty because

the diffraction changes the wave heights along this stretch of beach and, therefore, the transport rate is not uniform even for the straight beach condition until the beach is out of the diffraction shadow zone.

TABLE 1
COMPARISON OF EXPLICIT AND IMPLICIT ONE-LINE MODELS
SHORELINE CHANGES ADJACENT TO JETTIES AT AN INLET

Grid Point	Distance From Base of Respective Jetty (ft.)	Shoreline Changes		Percent Difference (Explicit vs. Implicit)

78	2023.7	21.1	22.9	-8.5
80	2261.8	13.1	12.9	1.5
82	2499.8	5.1	5.1	0.0
84	2737.9	16.0	1.6	0.0
86	2976.0	0.4	0.4	0.0
88	3214.1	0.1	0.1	0.0

The last column on the table, which gives percent differences demonstrates that the two methods are reasonably close. The error in the explicit procedure is due to the fact that the y values are computed using Q values determined at previous time steps whereas in the implicit scheme, they are solved simultaneously. As a summary statement of this comparison, the two approaches yield results which are in generally good agreement.

Theory of Pelnard Considère, Numerical Model With Pelnard Considère Transport Equation, and Comparison to Both With One-Line Implicit Scheme

The solution of Pelnard Considère has been plotted on Figure 3 for the following conditions: $\alpha_0 = 22^\circ$, $A = 1.045 \text{ ft}^2/\text{sec}$, $t = 86,400 \text{ sec.} = 1 \text{ day}$.

As a check of the numerical model, the linearized transport equation of Pelnard Considère was introduced into the numerical model and the solution obtained as indicated by the dash-dot line in Figure 3. Also presented on Figure 3 is the solution resulting from the one-line implicit model. As expected, the shoreline has not accreted as far as with the other two models because the angle of wave attack is modified along the beach such that the sine of twice the difference between the wave angle and the shoreline decreases, thereby reducing the sediment transport. This exercise demonstrates that the finite-difference equations approach the analytic solution.

Figure 3. Comparison of the Three Predictions for Sand Accumulation Against a Littoral Barrier

Jetties Oriented Directly Into the Dominant Waves Versus Jetties Perpendicular to the Original Shoreline, With and Without Permeable Jetties

It appears that shoreline fluctuations adjacent to jetties could be minimized by orienting the jetties into the dominant wave approach, rather than perpendicular to the shoreline. In order to examine this problem, particular waves and jetty orientations were selected for modeling. The breaking wave height was 5 ft. incident on the beach at a +20° angle, with a period of 8 seconds and a duration of 1 day. Then, the wave angle was shifted to -20° for another day, +20° for a third day and finally back to -20° for the fourth and final day. First, these conditions were run with the 1500 ft. jetties perpendicular to the original baseline, and then the 1500 ft. jetties were oriented inward, each at an angle of 20°, i.e. into the incoming waves.

Figure 4. Comparison of Shoreline Response Due to Jetties Perpendicular to the Shoreline Versus Jetties Oriented Into Oncoming Waves.

The results of the simulation are presented graphically in Figure 4. Note the significant differences in magnitude in the shoreline changes for the two cases. With the angled jetties (the dashed lines in the diagram), the disturbance is considerably less, i.e., the shoreline changes for the perpendicular jetty case is modified more by the presence

of the jetty. This is due to the redistribution of wave energy caused by the diffraction, or lack of diffraction in the perpendicular and angled jetty cases, respectively. Because each of the two wave directions causes shadow zones on the instantaneous downdrift beach, the sand is displaced on both sides and once the fillets have developed the waves are not able to transport the sand readily; therefore, the fillets remain.

In nature, waves are not monochromatic, nor do they originate from two directions, however, this simulation suggests that a structure should be designed considering the perturbations that different jetty orientations would cause to adjacent beaches.

Another application of the numerical model is to represent jetties which are not sand tight (i.e., permeable). The permeability characteristics of a particular barrier are, by far, not easy to determine. However, for the purpose of the model, a jetty with a permeability of 20% was selected. The definition of permeability, as used here, is that 20% of the sand which arrives at the grid adjacent to the barrier is carried through and lost to the system. In the case of two jetties, the sand is only carried through the respective jetty during periods when the wave conditions are such as to transport sediment toward that jetty.

Using the same wave conditions as were used for the comparison of perpendicular jetties and angled jetties, and a permeability for both jetties of 20%, the resulting beach in planform is shown in Figure 5.

Figure 5. Effect of Permeable Versus Impermeable Jetties Oriented Perpendicular to Shore.

The difference between the total sand accumulation in the impermeable and permeable simulations for 1 day is 16%. The explanation of the difference between the permeability (20%) and the 16% difference is that only the grid adjacent to each jetty allows sand through it. As the beach accretes in the fillets, the transport rates in the adjacent grids to the jetty decrease due to the angle changes which occur. Therefore, a difference of 4% seems reasonable.

The effect of permeability on accretion of the fillets is of interest. Examining the south jetty, it is seen that the impermeable barrier impounded sand extending out from the original shoreline a distance of 112.5 ft., while the permeable barrier's beach extended out to approximately 92.5 ft. This is a change of slightly less than 18% which again seems reasonable.

The Physical Model of Barceló as Compared With the Numerical Model Prediction

One of the few physical models presented in the literature which contains sufficient information to model is that of Barceló⁽⁴⁾. Numerical model predictions for this hydraulic model test have been presented by Hulsbergen, Bakker and van Bochove⁽⁹⁾. In Barceló's model, two groins were present on each side of a beach which measured slightly less than 45 ft. in length. The updrift groin was approximately 18 ft. from his original shoreline with the downdrift groin approximately 7 ft. The beach was composed of pumice stones.

In order to simulate his model conditions, several of the constants had to be calculated and many other parameters had to be scaled from the figures in his article. The beach slope used was 8%, the length of the first jetty which caused the diffraction and was perpendicular to the original beach was 18.27 ft., the total beach length (including groin compartment) was 88.58 ft., and the length of time the model was run was 35 hours.

The depth, D , of the active profile was not given explicitly in the paper, however, examining the offshore profiles suggested an approximate value of 0.33 ft. with very small changes occurring for depths greater than 0.20 ft. For reasons to be discussed later, runs were carried out with $D = 0.33$ ft. and $D = 0.72$ ft.

The constant used in the sediment transport equation was changed because the mass density of pumice stone is different than quartz.

The results of the runs are shown in Figure 6. The most obvious differences are that for $D = 0.33$ ft. the numerical model predicts more rapid changes than measured in the physical model and it is noted that the beach in the immediate vicinity of the jetty adjacent to the eroded portion of the beach has a slightly different shape than the numerical model. The first difference is expected because different D values can be interpreted as different time scales (or transport proportionality factors) and laboratory data fall significantly below the field data on the curves used to establish the transport constant, see the Shore Protection Manual, 1973. Since the value of K used in the model ($K = 0.77$), was determined from field data, it is reasonable that the

numerical model would predict higher degrees of erosion and accretion.

Figure 6. Comparison of One-Line Numerical Model Predictions with Hydraulic Model Tests by Barceló. Groin Compartment.

Comparison of a Two-Line Physical Model and the Two-Line Numerical Model

In order to evaluate the ability of the two-line numerical model to predict shoreline changes, the two-line physical model of Hulsbergen, Bakker and van Bochove⁽⁹⁾ was simulated. Test "T22" was the run chosen to model because it was stated in the article as one of their best runs. The length of the beach was approximately 106.6 ft. and the duration of the test was 50 hrs. The beach material was comprised of dune sand and was fed into the model at the updrift boundary.

A list of the constants used is presented in Table 2. The sediment transport constant, T , was taken as 0.326 and the other required input data were taken or scaled from the article. It should be noted that a plane beach was not used in this model, but rather the idealized beach profile (Dean⁽⁸⁾) discussed earlier. Also, the value of "w" used in the numerical model was obtained by scaling from Figure 14 of the paper by Hulsbergen, Bakker and van Bochove. "w" represents the equilibrium distance between the two lines and the lines in this figure at $t = 0$ are supposed to be at equilibrium (the model was first run without the

groins to reach equilibrium). The value scaled from the diagram was an average value of 5.97 ft., this being the value used in the numerical model.

TABLE 2

<u>Constants</u>	<u>Value Used in Two-Line Model</u>
Length of Groin	13.78 ft.
Length of Beach	106.63 ft.
Angle of the Groin	0°
Shape Factor for Equilibrium Profile Dependent on Bed Material, see Reference 8	0.0778 ft ^{1/3}
Reciprocal Depth of Closure	0.802 ft ⁻¹
Constant of Proportionality, Γ , in Sediment Transport Equation	0.326
Equilibrium Distance Between Two Lines	5.97 ft.
Height of Breaking Wave	0.246 ft.
Wave Period	1.55 sec.
Direction of Wave Attack	5°
Time Step	0.5 min.
Duration	6000 iterations (= 50 hours simulated)

The values input as "y₁" and "y₂" initial conditions were scaled from an enlarged version of Figure 14 of their paper. The only other change made in the numerical model was the boundary condition at the groin. The only way in which sand would be moved in the model with a wave height of only 0.246 ft. was by onshore/offshore sediment motion because breaking waves only occurred inshore of Line 2. This seemed to be realistic except at the boundary (groin) between the two beaches. Here, the amount of transport across the boundary was computed in the following manner. The distance from the tip of the groin to the y₂ grid point was divided by the total distance between the two lines, y₁ and y₂. This portion of the total offshore transport at the groin became the value of sediment transported around the barrier (i.e., at Line 2) and the remaining portion resulted in a seaward advancement of the first line, y₁. The sediment transported around the end of the barrier is used as the transport at the second line. This sand is then moved onshore accordingly.

Results of the comparison between the physical model tests and the numerical model tests are shown for the test duration of 50 hours in Figure 7. The prediction seems quite good with the exception of the smoothing that took place as expected. Certainly, the magnitude of the changes are approximately the same along with the general shapes. As noted in Reference 9, some of the perturbations apparent in the physical model could be due to rip currents which are not included in the numerical model.

Figure 7. Comparison of Two-Line Numerical Model Predictions With Hydraulic Model Tests of Hulsbergen, Bakker and van Bochove.

Channel Islands Harbor Simulation

As a final application/evaluation of the model, it is desirable to compare model predictions with field data. Channel Islands Harbor was selected because concurrent wave data and planform change data exist. The wave data available at the time of writing this paper are LEO (Littoral Environmental Observational) visual data collected by the Coastal Engineering Research Center (CERC). The Channel Islands Harbor area of interest consists of two entrance jetties and an overlapping offshore breakwater. This structure system was idealized as shown in Figure 8. Two modeling efforts were carried out. The first utilized the recommended K value (c.f. Eq. (2)) of 0.77 and it was found that the amount of sediment accumulation behind the jetty was much too small. The second modeling was with a fourfold increase in K ($= 3.08$) and the results shown in Figure 8 were determined, which still indicates that not enough sediment is being transported and deposited behind the breakwater.

The Channel Islands Harbor study is being conducted by the Coastal Engineering Research Center as a full-scale sediment trap to attempt to determine the value of the constant, K (c.f., Eq. (2) of this paper). To date, it has been the general finding of that study that the constant ($K = 0.77$) is too small and perhaps should be increased by as much as twofold, Bruno and Gable⁽⁵⁾. There are various possibilities for the differences noted. The constant in the sediment transport equation could be too small for the transport at Channel Islands Harbor. Also, it is possible that on ebb tide a cell circulation is set up such that sand is transported toward the jetty by forces other than just those of the waves. The wave data were observed visually and a consistent underestimate in

wave height by 25% would result in a sand transport which was too low by 51%. The effect of the dredged area would be to cause sand transport behind the breakwater, a three-dimensional effect not accounted for in the present sand transport relationship.

Figure 8. Comparison of Calculations With Field Surveys at Channel Islands Harbor, California. Longshore Transport Constant, $K = 3.08$.

SUMMARY

The governing equations and solution algorithms are presented for three types of numerical models developed to represent shoreline response to coastal structures. The models include: (1) a one-line explicit model, (2) a one-line implicit model, and (3) a two-line explicit model. This appears to be the first application of the implicit model for shoreline representation. In addition, the one-line models allow for activation and deactivation of grids adjacent to a structure oriented at an angle to the shoreline.

A number of problems of relevance to coastal engineering are investigated by the models including: permeable jetties, shoreline effects due to jetties aligned with the incoming waves compared with jetties perpendicular to the beach, shoreline response inside a groin compartment, and the effect of a littoral barrier. In addition, the one-line implicit model was applied to predict the shoreline response at Channel Islands Harbor, California where sediment is accumulated and dredged periodically from behind an offshore breakwater. Although in this case, only visual wave observations were available, it was necessary to increase the proportionality factor in the sediment transport relationship by a factor of four to obtain even approximate agreement between measurements and predictions.

The results of this paper are in accordance with those of other investigators of numerical models (3) (9) (12) (16) (18), namely that the potential is good for predicting shoreline response. Particular research needs to improve numerical modeling are:

- (1) An improved understanding of the distribution of longshore sediment transport across the surf zone,
- (2) An improved understanding of the mechanics of onshore-offshore sediment transport as affected by beach slopes milder and steeper than the equilibrium slopes, respectively,
- (3) The effects of longshore bottom slopes such as would exist in the vicinity of a dredged hole, and
- (4) Quantification of the sand transport processes in close proximity to structures. Of particular interest is the transport over a sill which is lower than the natural equilibrium profile elevation, and the transport through a permeable structure.

There appear to be no major difficulties in developing a "m-line" model and this should allow a more detailed description of shoreline response in the vicinity of structures.

CHAPTER 111

ESTIMATION USING A MOVABLE BED MODEL OF SHORELINE CHANGE CAUSED BY A RECLAMATION PROJECTED INTO THE SEA

by

Shoji SATO and Hiroaki OZASA
Port and Harbour Research Institute, Ministry of Transport,
1-1, 3-chome, Nagase, Yokosuka, Japan

INTRODUCTION

Recently, many local airports in Japan are considering to extend their runways, so accomodating passenger traffic. But most airports are obliged to extend their runways into the sea on account of the shortage of land and complaints from their neighbors about jet-plane noise. Tokushima Airport is one of such local airports, which is situated on the coast along the Kie-Suido Channel as shown Figure 1. The length of the runway of Tokushima Airport is 1500 m at present, so a plan to extend the runway by 600 m into the sea has been proposed by the local government. However, Matsushige beach, where the airport is located, is now so seriously eroded that offshore breakwaters are being constructed in the south and the northern part is used for sea-bathing. Therefore, it is necessary to estimate the change of beach profiles, especially of the shoreline, caused by the extension of the runway, and to find countermeasures against unfavourable change.

A movable bed model was constructed to estimate such changes, because no numerical simulation using a computer has been developed to estimate changes of a complicated beach topography. Of course, the universal dynamic similarity does not hold for model studies on sand transport problems. Therefore, the characteristics of sand transport at the site are first clarified through analysis of the field observation data, and then the model scale, bed material, and test waves are determined in such a manner that the topographic variation in the model sea bed will become similar to that in the prototype. But, in general, it is difficult to make all of the variations of the sea bed in the model similar to that in the prototype. In this model experiment, the long term changes of the shoreline has been taken as the most important phenomena to be reproduced in the model.

CHARACTERISTICS OF LITTORAL SEDIMENT TRANSPORT

The Matsushige coast, where the airport is located, is a sandy beach of 4000 m long bounded by the breakwaters of Imagiri and Awazu Ports. Waves from SSE-SE are overwhelmingly predominant, as seen in Table 1 which shows the deep water wave energy from each direction based on wave hindcasting using weather maps during the period from January 1971 to December 1975. Their wave heights, however, are usually less than 1.5 m as seen in Table 2, which shows waves of significant height more than one meter recorded on a wave recoder in 15 meters of water, from November 1975 to November 1976. Waves of more than 2 m high occur only when the typhoon passes near by the coast. Northerly waves occur

13 SEP. 1976	1.31	7.0

Table 2. Observed waves of $H_{1/3}$ 1 m at the 15 m contour (nov. 1975 to Nov. 1976)

mostly in winter, but their height is usually less than one meter.

From the above wave characteristics, it is clear that the sand is predominantly transported along the coast from south to north. The Matsushige coast is located on the delta formed by the material discharged from the Yoshino River, the mouth of which is at about 2 km south of Imagiri Port. At present, however, littoral material transported into the coast from the south and transported out northward from the coast is very small in volume, on account of the construction of dams in the upstream areas of the Yoshino River and the completion of the breakwaters of Imagiri and Awazu Ports. So, the coast can be considered to be a nearly isolated beach from the standpoint of littoral sediment transport.

Figure 2 shows a contour map of the coast. At present, there is no sand beach within 1600 m from Imagiri Port, but from there it gradually appears, becoming 100 m wide at Awazu Port. Looking at the contours, 5 m line runs parallel to the coast from Awazu Port until the center of bay, and then turns seaward, and reaches the tip of the breakwater at Imagiri Port. Shallower contours tend to be parallel to the beach for a greater part of the bay, those less than 2 m being parallel all along it. Longshore bars occur only in the half of the bay near Awazu Port and are between 2 and 3 m deep. These contours also prove that the littoral transport is overwhelmingly northward in direction as mentioned above. The median diameter of the bed material is 0.3-0.36 mm on the beach, 0.2-0.24 mm on the bed at 5 m deep, and 0.1-0.13 mm on the bed at 10 m deep, as shown in Figure 2. A sea dike with crest height of 7 m above the datum level exists along all this stretch of the coast.

PRELIMINARY TEST

Method of The Preliminary Test

The waves for the main test which are able to cause littoral transport similar to that in the prototype clearly have SSE-direction in deep water, as seen in Table 1. Waves from SSE in deep water become SE in direction on 15 m contour owing to the refraction shown in Figure 1. Therefore, the bottom topography from the sea dike to the 15 m contour between Imagiri and Awazu Ports was produced in a wave basin with a scale of 1/200 horizontal and 1/50 vertical. The model area is shown in Figure 2. The part between 10 and 15 m contours was a fixed bed of concrete and the shallower part was made as a movable bed of sand with median diameter of 0.29 mm. The grain size distribution of the sand is shown in Figure 3.

This model test aim was to estimate long term changes of the bottom topography, especially of shoreline, caused by the extension of the runway. Past data on the long term changes of the bottom topography near the shoreline, therefore, are necessary in order to determine the wave condition for the main test. Unfortunately, no field surveys of the beach have not conducted in the past, except for a three years in recent, so that the past changes of the shoreline have been investigated using aerial photographs taken in different years. Figure 4 shows the shorelines in May 1964 and May 1969 which were found by that method.

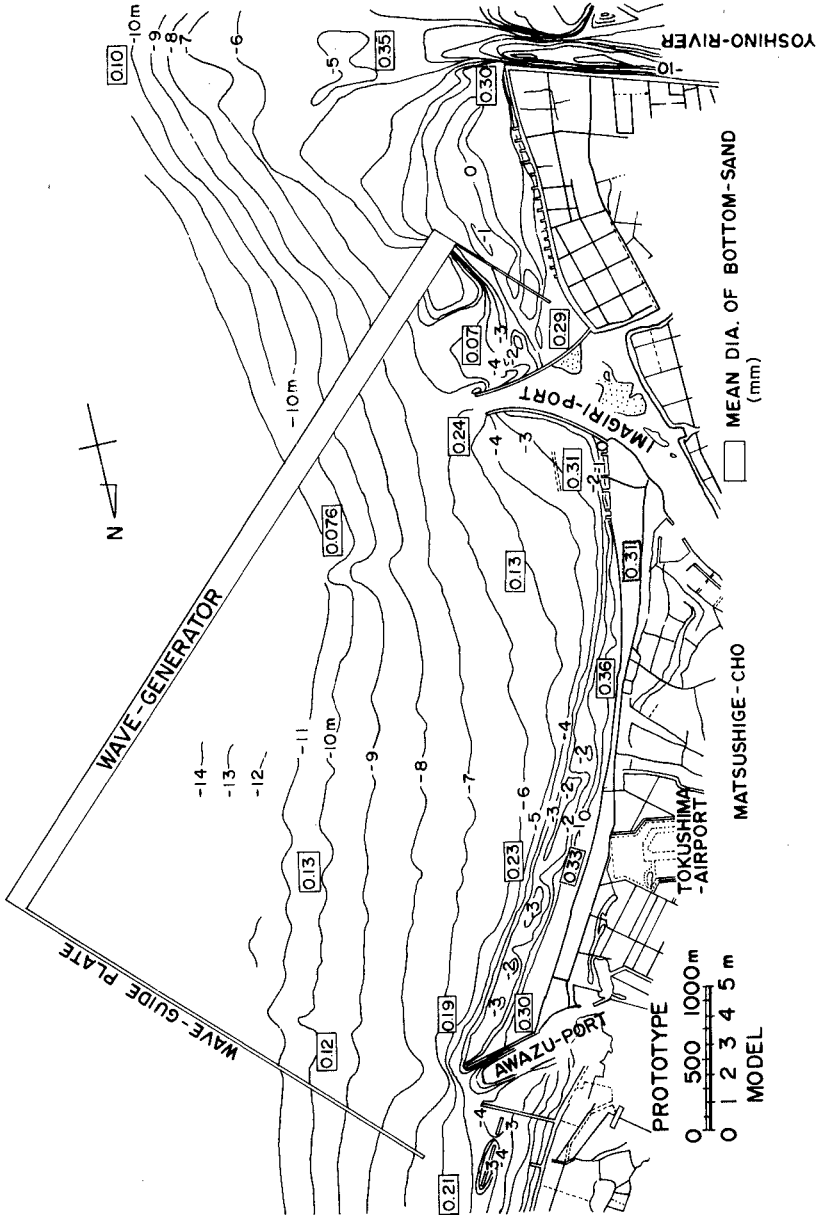

Figure 2. Contour map and the area of hydraulic model

The breakwater of Imagiri Port had already been completed in May 1964, while the the south breakwater of Awazu Port was extend by 400 m, from 150 m long in May 1964 to 550 m long in May 1969. During those 5 years, the beach disappeared in the 1000 m nearest Imagiri Port and widen near Awazu Port.

The preliminary test was conducted by a trial and error method to find the most suitable SE-wave to produce the shoreline changes shown in Figure 4. Each wave, as shown in Table 3, was generated in the model where the bed topography was made to correspond to that of May 1964. The structures such as breakwaters were modeled to correspond to their state in May 1969. The bottom topography of May 1964 was obtained by the method shown in Figure 5, that is, the position of the shoreline investigated by using the aerial photograph of May 1964 was plotted with the beach profile of May 1975. Then the profile near the shoreline was drawn so that the same shape should be similar to that of May 1975. In order to check how the plan shape of the beach in the model approached that of the profile in May 1969 after wave action, the standard deviation of the former against the latter was calculated by the method shown in Figure 6. The position of the model was measured at 50 cm intervals (100 m in the prototype). The test was conducted at the level of M.W. which is one meter above the datum level. The scale of the wave period was taken as the square root of the vertical scale.

Result of The preliminary Test

Figure 7 shows changes of the above mentioned standard deviations during the experiment. The standard deviations, for all cases, decreased with the duration of the wave action, reaching a minimum value after some hours, then increasing. Among these cases, the standard deviation reached its smallest value for the case of waves of 5.3 cm in height and 1.13 sec period and its second smallest value for the case of the wave of 8.5 cm and 1.41 sec. Figure 8 shows the relation between H_o/L_o and H_o/d_{50} for each case, where H_o is the deep water wave height and d_{50} the median diameter of sand. The boundary lines between storm and normal beaches of Johnson (1949)¹⁾ and Iwagaki-Noda (1963)²⁾ are also shown in the figure. Comparing the test data with these boundary lines, it is found that Cases 1 and 5 which have the smaller minimum values of standard deviation are nearly on the boundary lines, but Cases 2 and 6, having larger values are a long way from them. Figure 9 shows the shorelines for each case at the time when it approached nearest the position of the prototype in May 1969. Cases 1 and 5 coincide with the shoreline of May 1969 fairly well, but Cases 2 and 6 deviate respectively seawards and landwards. The waves of Cases 2 and 6 are considered to be respectively accumulative and erosive waves.

In order to determine the wave condition for the main test, it is also necessary to the quantity of sand movement in the offshore zone as well as the comparison of the shorelines as mentioned above. In Case 5, which has waves of 5.3 cm in height and 1.13 sec period, sand ripples were not seen in some areas of the offshore zone deeper than about 16 cm (8 m in the prototype). On the other hand, in Case 1, which has waves of 8.5 cm in height and 1.41 sec period, they were seen in all area of

the movable bed.

The critical water depth h , where all sand particles of the surface layer of the sand bottom are moved collectively in the direction of the wave propagation on the open sea without strong currents, is expressed by Sato-Ijima-Tanaka (1962)³ as follows:

$$\frac{H_o}{L_o} = 1.35 \left(\frac{d}{L_o}\right)^{1/3} \left(\sinh \frac{2\pi h}{L}\right) \left(\frac{H_o}{H}\right) \quad (1)$$

Where H_o and L_o are the height and the length of deep water waves, H and L are the height and the length of the waves at the critical water depth h , and d the diameter of bottom sand. The calculation diagram of Equation (1) is shown in Appendix. The length of the deep water wave of $T = 1.41$ sec is

$$L_o = 1.56 \times (1.41)^2 = 3.10 \text{ m}$$

Using small amplitude wave theory, the dimension of the deep water wave for $H = 8.5$ cm and $T = 1.41$ sec at 30 cm deep is obtained to be $H_o = 9.13$ cm. Using $d = 0.29$ mm in the model,

$$\frac{H_o}{L_o} = \frac{0.0913}{3.10} = 0.0295, \quad \frac{d}{L_o} = \frac{0.29 \times 10^{-3}}{3.10} = 9.35 \times 10^{-5}$$

According to Figure (A-3) in Appendix, $h/L_o = 0.038$. So,

$$h = 0.038 \times 310 = 11.8 \text{ cm}$$

The critical water depth $h = 11.8$ cm corresponds to $h = 5.9$ cm in the prototype. The critical wave height H_o for $T = 10$ sec, $h = 5.9$ m, and $d = 0.23$ mm in the prototype is calculated as follows:

$$\frac{d}{L_o} = \frac{0.23 \times 10^{-3}}{156} = 1.47 \times 10^{-6}, \quad \frac{h}{L_o} = \frac{5.9}{156} = 0.038$$

By the same figure in Appendix, $H_o/L_o = 0.0075$ is given. So,

$$H_o = 0.075 \times 156 = 1.2 \text{ m}$$

That is, the waves of Case 1 nearly correspond to a significant wave of $H_o = 1.2$ m and $T = 10$ sec in the prototype from the standpoint of the sand movement in the offshore zone. Also, it is found that the critical water depth for Case 5 is 6 cm and that the waves of Case 5 nearly correspond to a significant wave height of $H_o = 0.7$ m and period of $T = 10$ sec in the prototype from the same standpoint.

On the other hand, according to the observation data shown in Table 2, the wave height in the normal storm would be expected to be 1.0–1.5 m. Therefore, the wave for the main test was determined to be the wave from SE of 8.5 cm height and 1.41 sec period. This wave reproduced the shoreline change from 1964 to 1969 after 120 minutes of the run, as shown in Figure 7; the time scale for the shoreline changes would be approximately 120 minutes in the model to 5 years in the prototype.

MAIN TEST

Test Cases

The determined wave condition was generated for 6 hours on each of the following four cases:

- Case 1: The present bottom configuration which was surveyed in 1975
- Case 2: Reclamation for the runway extension is added to Case 1
- Case 3: A single line of offshore breakwaters along the coast south of the runway reclamation and a long offshore breakwater along the north coast are added to Case 2

Case 4: Double lines of offshore breakwaters along the southern part of the coast and three short offshore breakwaters along the northern part are added to Case 2

The models of offshore breakwaters are rectangular boxes of wire netting filled by small gravel, so they are permeable. The crest height is 8 cm (4 m in prototype) above the datum level, though that of the prototype actually is 2.5 m. This is because the model wave height is larger than 1/50 of the prototype wave height for a normal storm as mentioned before. Where the beach was eroded so severely that waves struck directly on the sea dike, same gravel was placed in front of it. The sea wall around the runway reclamation was faced by wave absorbers of gravel. The water level was set at the mean water level, the same as that in the preliminary test.

Changes of The Shoreline

The lines of the mean water level are shown in Figure 10 for before the wave action and after 360 minutes of it. Not that longitudinal and lateral scales are different. Using the time scale obtained in the preliminary test, 360 minutes of wave action nearly corresponds to 15 years in the prototype. The following changes of the shoreline can be deduced from the figure.

(1) The coast between the runway reclamation and Imagiri Port
From the result of Case 1, it can be seen that the coast will carry on eroding if it remains in the present state without any countermeasures; the beach above M.W.L. would disappear moreover over a stretch of about one kilometer after 15 years. But, if the runway reclamation is carried, the coastal erosion would be cease in some areas; the loss of the beach above M.W.L. after 15 years only occurs over half the stretch affected in Case 1. Moreover, if the offshore breakwaters are added as in Case 3, the distance over which the beach would disappear reduces to 300 m. In Case 4 with the double lines of offshore breakwaters set in zigzag-pattern, the beach would be formed to the south of the present one.

(2) The coast between the runway reclamation and Awazu Port
From the result of Case 1, the beach is clearly going to continue accreting if it remains in the present state. On the other hand, if the runway reclamation is constructed, the width of the beach would increase near the breakwater of Awazu Port and the reclamation, and decrease a little between them. As a result, the shape of the beach line would become concave. Though such a concave shoreline was not considered to be inconvenient for sea-bathing, measures to keep the shoreline straight were researched in Cases 3 and 4. In Case 3 with a long offshore breakwater, the beach erodes near Awazu Port and accumulates elsewhere. In Case 4 with three short offshore breakwaters, the beach accumulates throughout, keeping an almost straight shoreline. The distance between the offshore breakwaters and the shoreline, however, becomes so small as to be inconvenient for sea-bathing.

Changes of The bottom Topography

Figure 11 shows the contours for Case 1. (a) in the figure, which

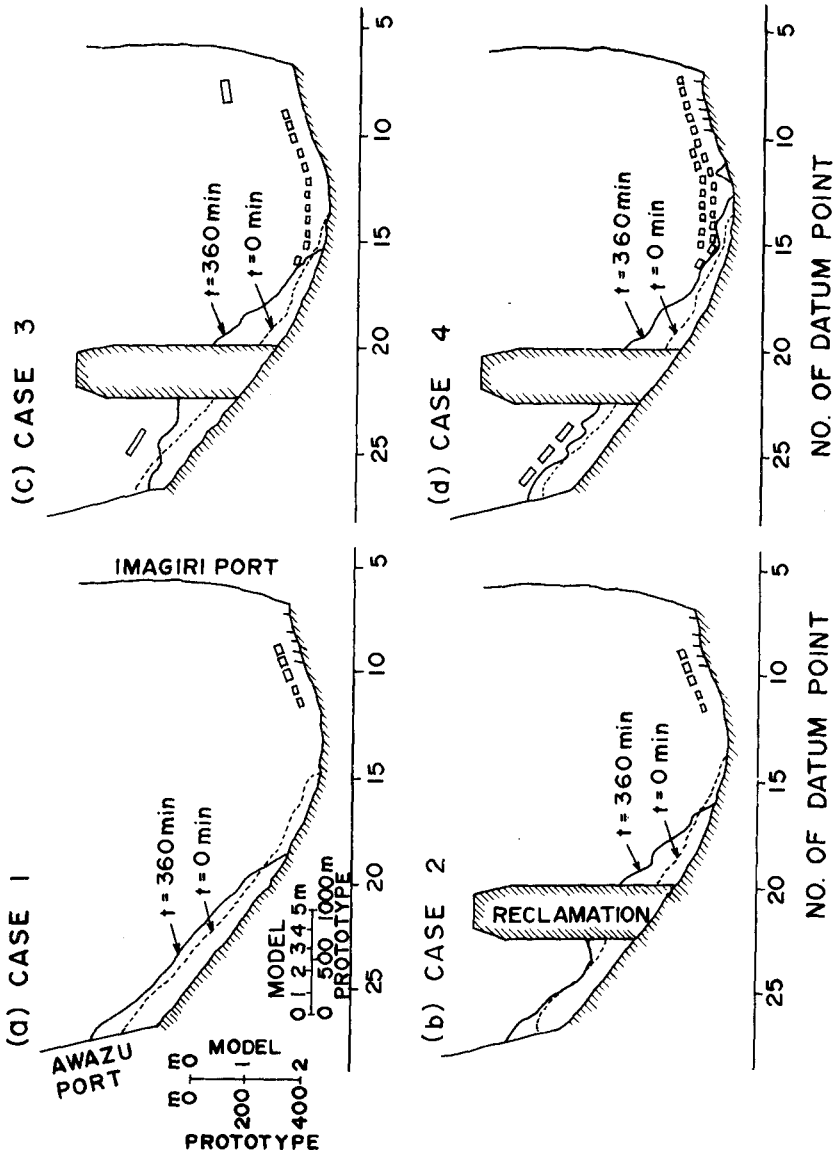

Figure 10. Changes of the lines of m.w.l.

Figure 11. Changes of the bottom topography

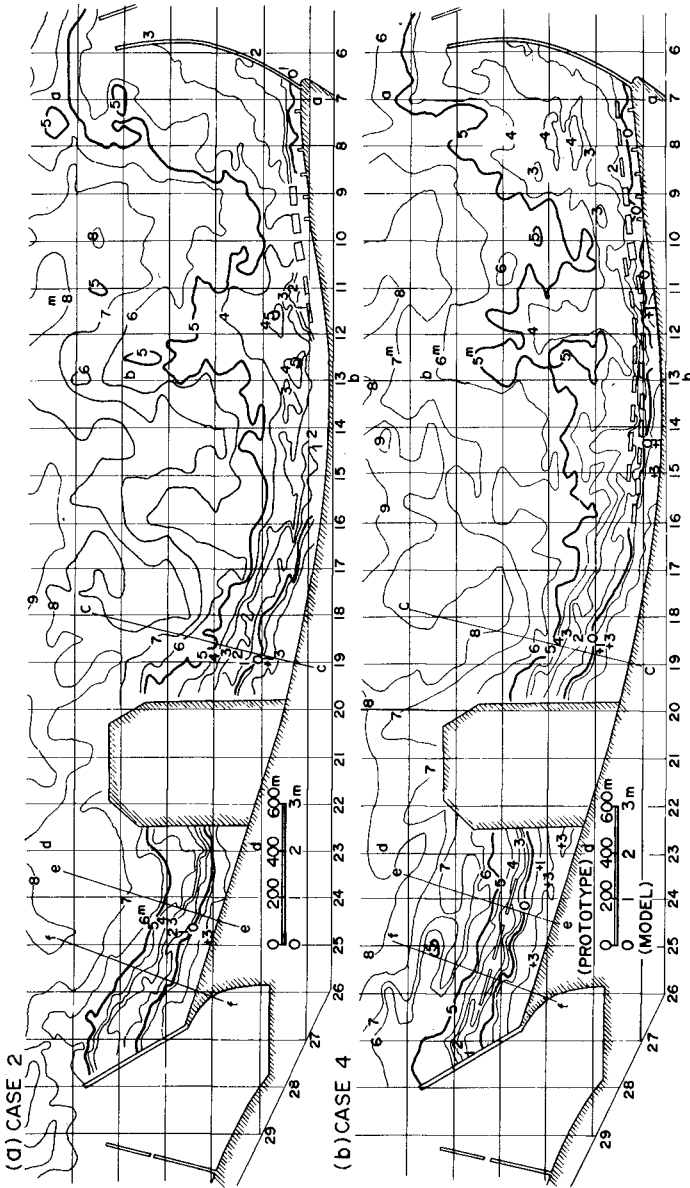

Figure 12. Contours after 360 minutes of wave action for Cases 2 and 4

is before wave action, is the bottom topography of 1975. The beach above 0 m is not exposed over a stretch of 1100 m near the south end of the bay and has a width of 100 m at the north end. In the contour map after 360 minutes of the run shown in (b) of the figure, the 5 m contour recedes landwards considerably in the areas near datum points Nos. 9-10 and 13 at the south end and Nos. 16-18 in the central part. It advances seawards considerably at the area of points Nos. 11-12 and 22-23. The contour of 5 m also advances seawards in the vicinity of the tips of the breakwaters of Imagiri and Awazu Ports. In the area near the shoreline, there is clearly a tendency of erosion in the south and of accumulation in the north; the beach above 0 m is not exposed for a stretch of 2200 m near Imagiri Port but increases to 200 m in width in the vicinity of Awazu Port.

Figure 12 shows the contours after 360 minutes of the run for Cases 2 and 4. Needless to say, the contours before the run for the both cases are the same as (a) in Figure 11. The followings can be deduced from (a) of Figure 12 in comparison with (a) of Figure 11:

(1) The 5 m contour recedes landwards in the area of Nos. 9-10 and advances seawards in the area of Nos. 11-12 as remarkably as in Case 1 but does not recede in the areas of Nos. 13 and 16-18. It, in fact, advances seaward in the vicinity of the runway extension.

(2) In the vicinity of the shoreline, a wide beach appears just at the south side of the runway reclamation, and the width of the beach between the reclamation and the south breakwater of Awazu Port becomes a littil narrower than in Case 1.

(3) The 5 m contour recedes landwards a littil at the tip of the south breakwater of Awazu Port, which is different from Case 1.

Comparing (a) and (b) in Figure 12, the points of difference points between Cases 2 and 4 are as follows:

(1) In the area between the runway reclamation and Imagiri Port, a beach above 0 m appears in front of the sea dike almost along its length in Case 4 and the contours between 1 and 5 m recede a littil further landwards in Case 4 than in Case 2.

(2) In the area between the runway reclamation and Awazu Port, the line of 0 m advances further seawards in Case 4 than in Case 2, though it runs in a rather straighter line.

Figure 13 shows the changes of the beach ploffiles after 360 minutes of wave action for Cases 1, 2, and 4. The profiles shown in the figure are along the lines a-a, b-b, c-c, d-d, e-e, and f-f of Figure 11 and 12. The profile a-a, which is near Imagiri Port, accumulates most in Case 1. The profile b-b, which is about 1300 m from the north breakwater of Imagiri Port, erodes in Cases 1 and 2, but accumulates at the shoreline of Case 4. The profile c-c accumulates in all cases, but more so in Cases 2 and 4 as a result of the runway extension. The profiles d-d, e-e, and f-f accumulate more in Case 1 than in Cases 2 and 4, and, comparing Cases 2 and 4, the area in the vicinity of the shoreline accumulates more in Case 4 than in Case 2.

The Rate of Littoral Sediment Transport

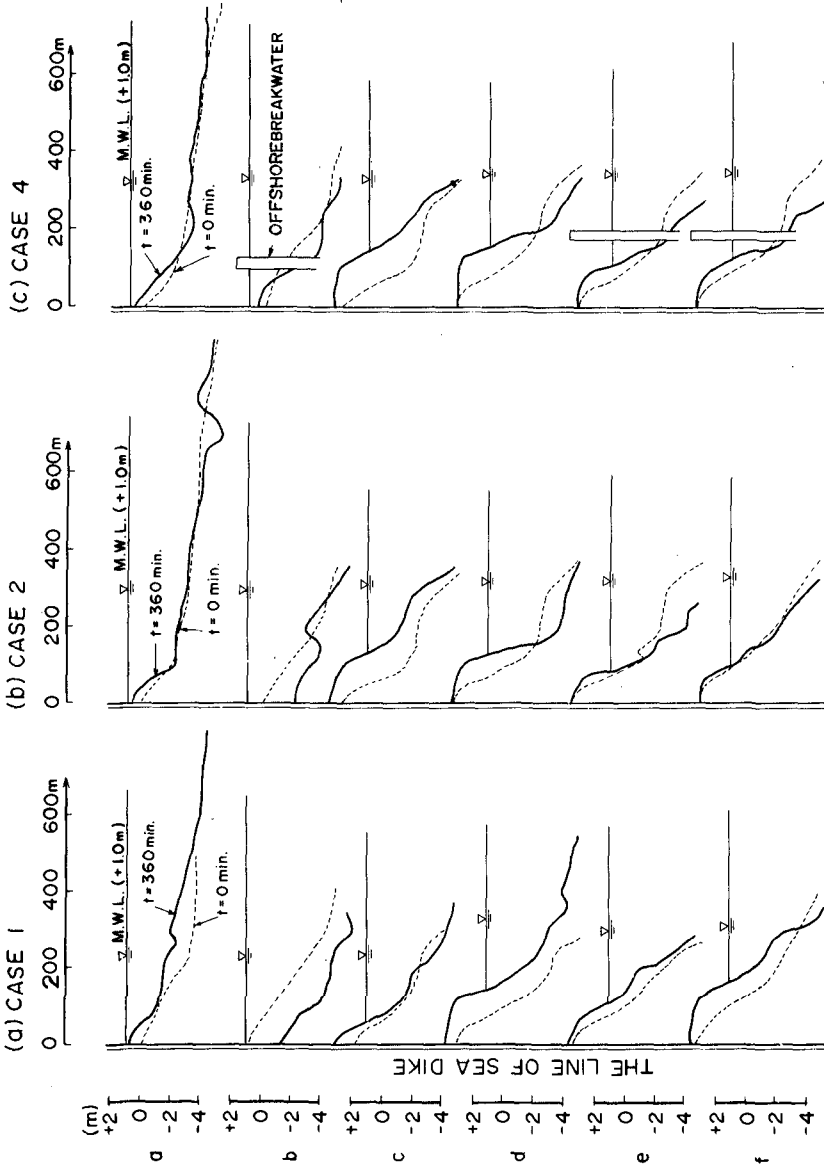

Figure 13. Changes of the beach profiles

The littoral sediment transport was measured in Cases 1 and 2 by using sand traps. A unit of the sand traps is a stainless steel box of 10 cm high and 30 cm wide, and has wings of 15 cm long on both sides, as shown in Figure 14. In Case 1, from minutes 120 to 130 of the run, the sand traps were set from the sea dike to the 7 m contour, in perpendicular to the shoreline on the line passing datum point No. 20 which lies on the proposed runway reclamation. In Case 2, from minutes 200 to 210 of the run, they were set seawards from the 7 meters contour on the same line as Case 1. These results are shown in Figure 15, where the volume of sand trapped in each trap is shown by dry weight. Most littoral transport is found to be concentrated landwards of the longshore bars as in the prototype. The peak values of trapped sand at the seaward end, in Cases 1 and 2, are considered to be caused by sand entering the trap from its offshore edge. On the other hand, the peak value at the landward end in Case 2 is thought to be due to sand travelling along the sea wall of the runway reclamation from the south.

From the results mentioned above, the total littoral transport rate in the case without the runway reclamation can be deduced to be the sum of the following two volumes:

11800 g/10 minutes minus the peak value of the seaward end (in Case 1)

and

2200 g/10 minutes minus the peak value of the landward end (in Case 2)

This gives 1200 g/minute. In the case with the runway reclamation, the transport is 2200 g/10 minutes from Case 2, that is, 220 g/minute.

The apparent specific gravity of sand in the sea bottom is supposed to be 1.6. 24 minutes in the model corresponds to one year in the prototype on the basis of the preliminary test. Considering, moreover, that the volume ratio of the prototype against the model is $200^2 \times 50$, the littoral sediment transport rate in the prototype would be calculated as follows:

(1) For the case without the runway reclamation

$$1200 \times \frac{1}{1.6} \times 24 \times 200^2 \times 50 \times 10^{-6} \doteq 36000 \text{ m}^3/\text{year}$$

(2) The littoral transport rate passing the offshore side of the runway reclamation

$$2200 \times \frac{1}{1.6} \times 24 \times 200^2 \times 50 \times 10^{-6} \doteq 6600 \text{ m}^3/\text{year}$$

On the other hand, the longshore wave energy which was calculated by using weather maps in period from 1971 to 1976 is shown in Table 4. The net longshore wave energy flux per year, according to Table 4, is approximately 1.9×10^5 ton·m/m northward. The relation between the littoral transport rate Q_i and the longshore wave energy flux E_i , on the basis of the diagram of Savage (1964)⁴, is given as follows:

$$Q_i = 0.21 E_i$$

Where Q_i is in unit of cubic meters and E_i ton·m/m. Substituting the value of 1.9×10^5 mentioned above for E_i in this equation, the littoral

Figure 14. Sketch of the sand traps

Direction of Deep-water wave	Longshore Energy Flux at the Breaking Line ($t \cdot m/m$)
NE	- 3,450
ENE	- 1,440
E	- 2,020
ESE	- 13,020
SE	+ 63,080
SSE	+ 867,300
S	+ 32,550
Total	+ 943,000

Table 4. Longshore wave energy flux calculated on the basis of waves estimated during 5 years from Jan. 1971 to Dec. 1975

Figure 15. Volume of sand trapped by the sand traps

transport rate is obtained to be $40000 \text{ m}^3/\text{year}$. This value is of the same order as that obtained in the model test. Therefore, the model test would also be considered to be similar to the prototype from the viewpoint of sand transport rate.

CONCLUSIONS

A movable bed model test has been conducted in order to estimate the changes of the bottom topography, mainly in the vicinity of the shoreline, which are caused by a reclamation of 600 m long injected into the sea for the extension of the runway of Tokushima Airport. The Matsushige coast, where the airport is located, is a sandy beach of nearly 4000 m long which is bounded by the breakwater of Imagiri Port to the north and by that of Awazu Port to the south. The model scale is 1/200 horizontal and 1/50 vertical, the sand with median diameter of 0.29 mm was used as movable material. The wave condition for the main test was selected so that the shoreline changes for the past five years from 1964 to 1969 would be reproduced and the quantity of the sand movement in the offshore zone of the model would be similar to that during the normal storm condition in the prototype.

From the main test using the above mentioned wave condition, the following points would be estimated:

(1) The volume of the net longshore sediment transport is about several ten thousands cubic meters per year on the basis of the volume trapped by sand traps, which agrees with the volume calculated from wave energy data

(2) The area where the beach disappears would gradually extend northward, if the coast remains in the present state without any countermeasures.

(3) The reclamation for the runway extension makes the length of the beach which will disappear less than in the case without reclamation.

(4) Double lines of offshore breakwaters are much more effective than a single line of them for restoring the eroded beach in the southern part of the coast.

(5) The area between the runway reclamation and the breakwater of Awazu Port will have a concave shoreline with slight erosion in the center. Offshore breakwaters are useful to prevent this change.

(6) The runway reclamation also decreases the littoral transport entering Awazu Port from the south, after passing the tip of its breakwater.

ACKNOWLEDGEMENTS

The authors express grateful thanks to the members of the Komatsujima Port Construction Office and the Kobe Investigation and Design Office of the 3rd Port and Harbour Construction Bureau, who conducted the field observation for this study, and Mr. Toshihiko Nagai of the same as the authors who engaged in this study.

APPENDIX

Surface Layer Movement and Completely Active Movement of Bottom Sand

Sato-Ijima-Tanaka (1963)³ have classified the distribution patterns by waves of radioactive glass sand injected in the offshore zone into the following four groups shown in Figure A-1:

(1) The first group This is the case that the point of the maximum count moves in the direction of the wave propagation and all equi-count lines also extend in the same direction.

(2) The second group This is the case that the point of the maximum count does not move, but all equi-count lines extend in the same direction of the wave propagation.

(3) The third group This is the case that the point of the maximum count does not move and only a part of equi-count lines extends in the direction of wave propagation. This group also contains the case that the count decreases markedly in total, despite the distribution of equi-count lines scarcely changes.

(4) The fourth group This is the case that the distribution of equi-count lines remains unchanged and the count also does not decrease significantly. The cases that all equi-count lines extend in the same direction as the tidal current or in the direction opposite to the wave propagation are also included in this group.

Figure A-1

Then, classifying the field data into these four groups, the results that they have been related with the wave characteristics are shown in Figure A-2⁵. This figure was obtained by Sato (1963)⁵, who plotted additional data in the similar figure by Sato-Ijima-Tanaka (1963)³. In the figure, wave height H and wave period T are those of the maximum significant wave at the injection point of glass sand during the period when the change of count-lines was monitored, and depth h the mean water

Figure A-2. Relation between the wave characteristics and the median diameter of sand for each distribution of radioactive glass sand (Sato-Ijima-Tanaka 1963 and Sato 1963)

Figure A-3. Calculation diagram of Eqs. (A-1) and (A-2)

depth at the injection point. H_0 and L_0 are the height and length of the deep water wave for H and T , d the median diameter of the glass sand which is the same as the bottom sand in the vicinity. In this figure, the transition from the second group to the third group is shown by the following equation:

$$\frac{H_0}{L_0} = 1.35 \left(\frac{d}{L_0}\right)^{1/3} \sinh \frac{2\pi h}{L} \cdot \left(\frac{H_0}{H}\right) \quad (A-1)$$

and the critical condition on which points enter into the first group is shown by the following equation:

$$\frac{H_0}{L_0} = 2.4 \left(\frac{d}{L_0}\right)^{1/3} \sinh \frac{2\pi h}{L} \cdot \left(\frac{H_0}{H}\right) \quad (A-2)$$

That is, Equation (A-1) corresponds to the state where all sand particles on the surface layer of the sea-bed move collectively in the direction of wave propagation and Equation (A-2) corresponds to such great movement of the bottom sand as to produce the change of water depth. The former is called the surface layer movement and the latter the completely active movement by Sato and Tanaka. Figure A-3 shows the calculation diagrams of those equations.

CHAPTER 112

MORPHOLOGIC EFFECTS OF WESTERLAND BEACH NOURISHMENT 1972

Dieter WENZEL ¹

Abstract

In 1972, a beach nourishment scheme was to delay the steady coast erosion near Westerland (Germany). Morphologic investigations state the development of the fill and its effects to adjacent beaches, and yield recommendations for another nourishment scheme in 1978.

The morphologic analyses are related to two different profile areas. They show that the effects of the nourishment were quite confined in space and time. Particularly the island base and the bar remained unaffected by the fill.

The analysis becomes more instructive and perhaps easier by the use of special means, such as the differential morphometric characteristic and the mean profile depth instead of mass computations or mass balances. The standard mean depth in the morphologic system of the investigation area is found to be NN-4,1 m.

1. Initial Situation

The west coast of the island of Sylt, Germany (fig. 1), is built up of sand and subject to an important erosion. The mean regression rate between 1793 and 1952 was 1,6 to 1,9 m per year. The urban area of the town of Westerland, adjacent immediately to the beach, had been protected by a vertical wall. This wall itself, built between 1907 and 1923, is threatened by the erosion of the shore and foreshore (fig. 2). A beach nourishment in 1972 provided a stock of about 750.000 m³ of sand, pumped on the beach in the form of a large groyne.

The typical beach profile in this central part of the coast consists in: beach - trough - bar - sea-bottom (fig. 3). It is likely to form a constant morphologic system produced by the specific hydrodynamic conditions. These are characterized by a normally

¹ Diplomingenieur, Civil Engineer, Department of Hydrology, Amt für Land- und Wasserwirtschaft Husum, D-2250 Husum, Federal Republic of Germany

Fig. 1. The situation of the investigation area

Fig. 2. Westerland sea-wall and its protection by tetrapods (14.01.76)

medium to high wave impact with variable incident angles, moderate current velocities of changing sense, and a mean tidal range of 1,85 m. The periods of calm sea surface normally do not exceed a total of 6 weeks per year, caused by seaward winds.

2. Investigations

The basic data for the morphologic investigations were collected by a lot of soundings and beach surveys. The soundings included an area till 1000 m offshore and down to a depth of NN-8 to -9 m.

These data were worked up to bathymetric charts and further on to differential bathymetric charts, profiles, maps of contour line shifting, mass calculations, and morphometric diagrams. For checking the reliability of the data obtained, an error estimate took into account especially the possible or existing systematic errors, so those influencing a whole survey or major parts of it in one sense.

It was found that the elevation error in the maps used has the following values:

	maximum	mean values
proportional error	5 %	2,5 %
constant error	0,35 m	0,01 m
+ temporary constant error	0,15 m	0,04 m

Respective error ranges are shown in the diagrams fig. 6 to 8.

The conclusion from this error estimate was, that overall mass balances are no good means to state shore and foreshore evolution. Moreover they suffer from being the result of records of an instantaneous, possibly singular shape and from neglecting the drifting sediments.

To render the statement of mass calculations persuasive, adequate marginal terms have to be chosen. For the present study, two different areas have been defined (fig. 3 and 4):

- the stock comparison area, limited by fixed boundaries or stationary lines, informing about the volume of the available sand masses and their distribution with regard to the coastal structures,
- the system comparison area, limited by defined contour lines (+1,5 m and -7,0 m), thus informing about the volume of sand contained within the morphologic system.

The length of shoreline computed is 1,5 km. The investigation period covers the years 1970 till 1978. Outstanding events during this period were:

- the beach nourishment in 1972
- a series of six heavy storms in November/December 1973, straining the shore with a wave energy superior to that of the whole winter 1971/72 (63100 versus 40700 kWh per 1 m shoreline)
- two heavy storm surges in January 1976, during which the water levels reached those of the catastrophic surges in 1962.

Fig. 3. Morphologic system and mass comparison areas

Fig. 4. Bathymetric chart July 1975 and plan of mass computation cells (strips)

3. Sounding and Morphologic Data Analysis

The characteristic phenomena before the filling action 1972 - decreasing beach width, increasing trough dimensions, bar diminution - were partially neutralized: the beach became larger in the immediate vicinity of the fill, and the trough became less wide and deep (fig. 4). But the holes just ahead of the beach continued to exist in their place, though somewhat less deep, and the bar remained unaffected by the fill.

At once after the fill, the situation started to develop towards the former condition, a fact which turns out more evident by the differential bathymetric charts (fig. 5). They show that in 1976 the sand stock in the beach is nearly consumed and the trough is even deeper (by 1 ... 1,5 m) than in 1972. The bar, however, did not change significantly.

The existence of seasonal effects (winter shape - summer shape) is here confirmed, too. They are accentuated by the occurrence of winter storms: The shape in March '76, after the January storm-surges, presents clearly a steeper seaward bar slope, a higher bar crest (by 0,5 m against August '76), a deeper trough (by 0,5 m against August '76), and a stronger erosion of the beach (up to 2 m deeper).

The mass computations within the stock comparison area (fig. 6) show a more pronounced erosion in the central part (0 ... 0,2N) of the investigation area before the fill. Towards the ends, at a distance of about 800 m from the filling center-line, the differences between the lines are rather small, meaning that a measurable deposition disappears. The line for February '74 runs near the former lines, meaning that the storm series of 1973 drifted the main part of the fill away.

The mass computations within the system comparison area (fig. 7) show little variation in time, apart from the stations 0 ... 0,2 N before the fill, where even the system had started to dissolve by losing of its specific volume.

But in principle there seems to be a substantial constancy of masses within the morphologic system. On the other hand it proves a small form variation capability, particularly when comparing it to the conditions at other sand coasts subject to heavy wave attack.

In order to identify the morphologic changes, which occurred nevertheless, in a simple and reliable way, the morphologic magnitude "mean profile depth h_m " is defined:

$$h_m = NN - 7 + d_m \quad [m]$$

$$\text{with } d_m = \frac{\text{mass of the profile strip } [m^3]}{\text{surface area of the profile strip } [m^2]} \quad [m]$$

NN = Normal Null, German Normal Chart Datum

The analysis of the mean depth diagram (fig. 8) gives a standard value of NN-4,1 m for the investigation area. In the central part,

Fig. 5. Differential bathymetric chart 1976-1972 (before the fill). Differences indicated in metre.

Fig. 6. Distribution of sand masses within the stock comparison area along the coast

Fig. 7. Distribution of sand masses within the system comparison area along the coast

Fig. 8. Mean profile depths of each profile strip within the system comparison area

subject to particular hydrodynamic stress, it increased up to NN-4,85 m before the fill, and afterwards it returned to its normal value again. Two potential danger areas may be indicated in 1975-78 by minima in stations 0,4 ... 0,2S and 0,2 ... 0,3N, and it is here (0,2N ... 0,7S) where the fill 1978 has been executed.

The mean depth informs about the development due to erosion or accretion of this one-bar system and thus indicates the "state of health" of a certain coast section.

The morphometric characteristic (according to RENGGER) represents the typical depth distribution by a generalized vertical section (fig. 9). It can be imagined as being obtained by shifting all the horizontal layers horizontally towards the island.

For easier analysis, the differences versus the mean values of the years 1970/71 have been drawn up (fig. 10). The application of this method to the shore and foreshore reveals that the effect of the beach nourishment, increasing the contour line areas, was confined to the zone above NN-5 m. Below NN-6 m, the 1973-line runs in the negative and even deeper than the 1972-line, meaning that the erosion of the deeper island base continued even during the filling action and afterwards. In these depths, accretion can be observed only in the immediate vicinity of the filling site.

The storm surges of November/December '73 caused a considerable erosion, most significantly between NN-3 m and NN-6 m. In the following years, a certain recovery took place in the deeper parts, but the tendency is obvious, that the slope of the overall profile is going to approach the former slope of 1970-72.

4. Conclusions

The simultaneous analysis of the morphologic data suggests the conclusion, that the morphologic effect of the beach nourishment extended only to the beach zone down to a depth of about NN-5 m. Particularly the bar of the central 1,5 km shoreline remained unaffected by the fill. Moreover the actual erosion tendency seems to point now to the southern part of the investigation area, affecting now a good length of the shoreline, where it already caused considerable losses of material.

The recommendation deducted from these analyses for the nourishment 1978 was to realize a longshore fill on a distance of 900 m, and in fact, this plan was adopted for execution.

Information about the development of a sand coast subject to erosion is necessary for planning and design of shore protection works. Reliable information can be obtained, rather than from overall mass balances, from the morphologic variations as found by the analysis of bathymetric charts and, more easily, from the interpretation of morphologic indicators, such as the mean profile depth.

CHAPTER 113

IMPORTANCE OF HANDLING LOSSES TO BEACH FILL DESIGN

R. D. Hobson^{*} and W. R. James^{**}

ABSTRACT

Beach nourishment models commonly employed by the U.S. Army Corps of Engineers compare textural properties of native beach and dissimilar borrow sediments to determine overflow and renourishment requirements for beach fill projects. It is assumed for these comparisons that the texture of borrow sediments is unchanged by dredging and handling operations but investigations have shown that significant handling losses do, in fact, occur.

This paper presents results from four field studies that document textural changes caused by dredging and sediment handling at Rockaway Beach, NY, and at New River Inlet, NC. Errors associated with calculating volumes of sediment dredged and lost using standard surveying and production methods are discussed and an alternate method is presented as a handling-loss model that compares bottom and dredged sediment texture to determine volumes lost.

The results of the studies presented are that handling operations do create significant changes in bottom sediment texture which, in turn, do affect beach fill model calculations by generally improving the predicted performance of these sediments as fill. The proposed handling-loss model predicts volumetric losses that greatly exceed losses generally anticipated during project construction. Discrepancies between loss estimates are discussed in terms of possible inadequacies of the model and of mechanisms that might consistently minimize losses using the standard methods for determining dredged sediment volumes.

INTRODUCTION

Beach nourishment is a commonly selected method of shore protection in the United States. Nourishment projects often receive substantial federal government support and they not only protect against loss and damage caused by storms and ongoing erosion, but also provide recreational benefits to an area while maintaining its natural aesthetics. Sand for beach fills is typically won offshore and may be pumped directly from the dredge to the beach when the borrow site is nearby. When the site is too far away for direct pumping, the sand is loaded into hoppers or barges, rehandled and pumped onto the beach from a location closer to the project.

* Coastal Engineering Research Center, Fort Belvoir, Virginia.

** U.S. Geological Survey, Reston, Virginia.

Studies of longshore transport, erosion rates, wave climate and storm history provide the kinds of data needed by the engineer to design a fill section that will withstand anticipated waves and water levels during storms as well as contain a sufficient volume of sand to meet expected erosion losses (U.S. Army Coastal Engineering Research Center, 1977). Renourishment needs are also considered in the design since most eroded beaches will continue to erode after nourishment and the fill section must also provide sufficient sand to meet these losses. Since beach fill design elements are determined using data from process-response studies of waves and currents interacting with native beach sediments, it is important to appreciate that the resulting fill volume requirements are for sediments similar to those found on the native beach. Dissimilarities between native beach and potential borrow sediments require adjustments to the designed volume which are commonly accomplished by applying beach fill models to calculate initial overflow and adjusted renourishment estimates (James, 1975). For these models, native beach sand serves as a standard for comparison with potential borrow sediments. The comparisons are between representative samples called composites (Hobson, 1977a) of the native beach and potential borrow sediments. Grain size distributions (gsd's) of these composites are expressed as phi sizes (Krumbein, 1938) and their phi means (M_ϕ) and phi sorting (S_ϕ) values commonly serve as input for the models.

HANDLING LOSS STUDIES

When applying the beach fill models, it is assumed that the volume and texture of sediment dredged from a borrow site is unchanged during project construction. However, sediment losses are commonly observed in the form of turbid water surrounding a dredge or as plumes extending seaward of a beach during nourishment. The term "handling loss" is used here to describe these project-related sediment losses. If significant, handling losses might modify the texture of borrow sediments enough to affect their performance as predicted by the beach fill models.

Handling losses are commonly caused by removal of sediment in suspension (elutriation) from the water-sediment slurry. These slurries commonly contain 10 to 25 percent solids and elutriation losses can occur during dredging on the bottom, during the overflow process used to fill hoppers with sediment, during recharge of sediment with water to allow hoppers to be pumped out, and during hydraulic placement of sediments on the beach. Documentation of this kind of loss has been minimal. Taney (1965) suggests losses in excess of 80 percent caused by prolonged overwashing of a dredge's hoppers and Mauriello (1968) reports that handling losses resulted in a fill sediment that was 0.2 mm coarser than the borrow sediment dredged. Neither of these studies was directly designed to examine handling losses and clearly there is a need for studies that both document these losses and assess their possible effects upon beach fill design.

Four handling loss examples are discussed below where suitable sedimentary data sets are available. Three of these sets were collected during field studies designed to investigate handling losses and these studies were conducted at New River, North Carolina, in the summers of 1976 and 1978, and at Rockaway Beach, New York, in 1977 (Figure 1). The fourth data set was also collected at Rockaway Beach but in 1975 during one phase of that project's construction, and by personnel from the New York Army Corps District office. For simplicity, these four examples are henceforth referred to as Rockaway (1975), Rockaway (1977), New River (1976) and New River (1978). Each example is briefly described below. Detailed descriptions of the Rockaway project are provided by Nersesian (1977) and Hobson (1977b), and the New River experiments by Hobson (1977b) and 1977c).

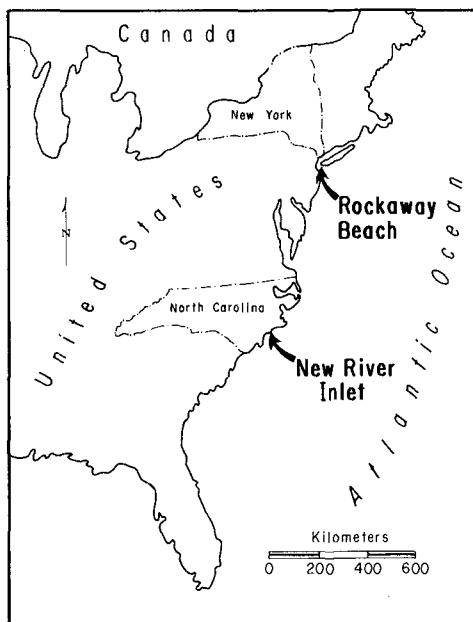

FIGURE 1. Location map - Rockaway Beach and New River Handling-loss studies.

Description and Sampling: Rockaway Beach is a barrier island with a morphology that has evolved over the past century in response to multiple episodes of artificial nourishment. The latest episode was accomplished in three phases during the summer months of 1975, 1976, and 1977. The beach was nourished along its 16 kilometer length with approximately 5,500,000 m³ of sand obtained from local offshore borrow sites. During the first phase (Rockaway 1975), borrow sediments were

dredged and loaded into scow barges offshore, transported 13 km to the leeward side of the barrier where they were recharged, and pumped hydraulically onto the beach. For phases two and three (Rockaway 1976, 1977), a suction dredging barge was used to load the sand, transport it to an offshore discharge point, recharge the load with water, and pump the slurry onto the beach. Sampling for Rockaway (1975) was conducted by the U.S. Army Corps of Engineers and consisted of coring bottom sediments at the borrow site using vibratory-type equipment, and collecting surface or grab samples from 26 of the scow barge loads and, of fill sediments at the 26 beach locations where the barged sediment loads were discharged. A three meter long, suction-assisted coring device was used to collect cores of bottom and barged sediments during the Rockaway (1977) study. Native beach sediments were sampled during pre-construction investigations of the area.

New River Inlet is periodically dredged to maintain a shallow access channel for small boats. A side-casting suction dredge and a split-hull barge have been employed by the Wilmington Corps of Engineers District office to accomplish this work. Studies were conducted by the Coastal Engineering Research Center (CERC) in 1976 and 1978 to evaluate sediment losses incurred during dredging. In 1976, the side-caster was used to fill the split-hull barge which then carried the dredged sediments to a nearshore dump site located downdrift of the inlet. By 1978, the split-hull barge had been equipped with suction drag heads and was able to perform all loading and dumping operations by itself. Sampling during both studies consisted of using divers to collect surface sediment samples from the bottom prior to a pass of the dredge, and using the suction corer to sample the entire thickness of the barged loads where sediments located near the bottom were subjected to less elutriation effects than upper layers. Three cores were taken from the hopper loads sampled and at least 10 surface samples were obtained to characterize each load. In addition, samples of sediments overwashed from the hoppers were collected as were samples of native beach sediments (e.g. 45 beach samples in 1976 and 22 in 1978). In both cases the beach was sampled at the downdrift dump area along profile lines that extended offshore from the storm berm to water depths of approximately 4.5 meters below MSL.

Discussion: Figures 2 and 3 are presented as typical plots of grain size distributions sampled during the Rockaway and New River studies, respectively. Table I is a summary of textural changes and beach fill model predictions for the four cases studied and it is evident from inspection of this table that in all cases, dredging and handling operations have coarsened dredged sediments (decrease in M_{ϕ} , Table I). The degree of coarsening varies but it is the kind of textural change anticipated where considerable overwashing is required to fill a scow or hopper. The smallest change in grain size occurred at Rockaway (1975) during the recharging and placement phase of handling where less overwashing was required to recharge the scow loads and where losses to the offshore were low during placement because the "fill" sampled included all sand placed on the beach within elevation limits of +3 to -5.5 m, sea level datum.

	TEXTURAL PARAMETERS				BEACH FILL MODEL PREDICTIONS	
	Native Sediments		Borrow Sediments		Overfill Factor	Renour. Factor
	M_ϕ	S_ϕ	M_ϕ	S_ϕ	R_A	R_J
ROCKAWAY 1975	1.69 0.72					
Native vs. Bottom			1.85	0.86	1.24	1.00
Native vs. Barged			1.31	0.66	1.00	0.64
Native vs. Placed			1.24	0.64	1.00	0.56
ROCKAWAY 1977	1.63 0.70					
Native vs. Bottom			2.23	1.02	1.20	0.58
Native vs. Barged			1.33	0.73	1.00	0.25
NEW RIVER 1976	2.39 0.80					
Native vs. Bottom			1.51	0.91	1.00	0.29
Native vs. Barged			1.04	1.02	1.00	0.13
NEW RIVER 1978	2.24 0.82					
Native vs. Bottom			1.20	1.25	1.01	0.14
Native vs. Barged			0.26	1.46	1.00	0.10

TABLE I Textural parameters describing native beach and handling-altered sediment gsd's, and beach fill model predictions for Rockaway Beach and New River handling loss studies. The symbols M_ϕ and S_ϕ are the phi mean and phi sorting values, respectively.

The observed coarsening should reflect selective removal, by washing, of finer sized sediments. The gsd's of elutriated sediments sampled during the New River experiments support this interpretation with mean sizes of 0.11 mm finer than bottom sediment means in 1976 and 0.21 mm finer in 1978. Losses of fine sediments should also improve the sorting of barged or placed sediments. Sorting does decrease with each handling episode for the Rockaway studies (Table I). However, at New River, sorting values were observed to increase with handling even though the mean grain sizes of barged sediments were significantly

coarser than for bottom sediments, and sediments overwashed were fairly fine grained. These curious changes in sorting at New River may reflect inadequate sampling of bottom sediments but they cannot be explained here using the data available from the experiments.

In all cases, the textural changes produced by handling do lower the overfill and renourishment estimates provided by the beach fill models (Table I) which suggests that handling improves a sediment's performance as fill. These changes are more striking for the Rockaway examples where borrow sediments were finer grained and more poorly sorted than native beach sediments than for the New River cases where borrow sediments were dredged from a high energy shoal complex and were significantly coarser than native beach sediments. At Rockaway, changes to the overfill ratios (R_A 's, Table I) of 0.20 (1977) and 0.24 (1975) indicate that losses of fines from the borrow material during construction will produce a fill sediment that will match the performance of native beach sand. Thus no overfill is predicted and project volumes are reduced by 17 and 20 percent, respectively. It is also predicted from the renourishment values (R_J 's) that the same winnowing losses will generally double the time span required between renourishment operations.

VOLUMETRIC CALCULATIONS

The experiments described provide some documentation of textural modifications to dredged sediments caused by handling operations. Sediments placed as fill contain a smaller fine-grained fraction than the same sediments contained prior to dredging, and thus initial fill volumes may be reduced and slower erosion rates may be expected. The effects of these potential changes upon project design and performance can be further evaluated by determining actual volumes lost during construction.

Handling loss volumes can be determined using estimates of the volumes of sediments dredged from the borrow site, volumes loaded into hoppers or rehandling sites, and volumes placed as fill on the beach. These volumetric estimates are typically calculated using data obtained by surveying, from plant production specifications, or from hopper load measurements. A general evaluation of these data sources reveals

potential problems with each and demonstrates the need for improved calculation procedures.

Surveying: Volumes of sediment placed on a beach or dredged from a borrow site are commonly calculated by multiplying differences in elevations surveyed along profile lines by some spacing factor between the profiles. Both land and hydrosurvey techniques are often used and errors in the volumes calculated are usually the result of inaccurately measured elevations or locations, and by inadequate profile spacing. Improvements in equipment are gradually reducing the measurement errors and are providing for quicker data collection as well. Nevertheless, considerations of time and costs often result in surveys with fewer profiles than needed for areas of irregular topography. For example, the self-loading suction barge used at Rockaway (1977) changed the fairly smooth bottom topography of the offshore borrow site into a surface irregularly dotted with cone-shaped depressions of varying diameter and depth (up to 6 meters deep). Obtaining an adequate estimate of the volume of sediment dredged in this case would have required that more profiles be surveyed than would have been possible during the time available to the crews assigned to the project.

Plant Production: Although slurry concentration and slurry flow meters are available for dredging plants, this equipment is seldom installed on American dredges. Determining production values therefore requires estimates of these factors which are usually provided as a slurry density constant for particular types of sediment (sand, silt, etc) and rating values for pump performance in clear water. No general factors are applied to account for density changes caused by variations in texture, bottom firmness, topography, and the like, nor for factors that affect the pump such as water depth or the degree of impeller wear. The result is that a competent leverman knows how to maintain a dredge's efficiency by watching his suction and engine performance gages but it is extremely difficult translating this kind of efficiency into actual volumes of sediment dredged, or lost, during a filling operation.

Hopper Loads: These kinds of data are fairly accurate with volumes determined from the number of containers filled (hoppers, scows, etc) or from the mass of sediment loaded into a container as metered by displacement-types of equipment. Although bulking and density changes can often be determined, these volume estimates still give no method for determining the total volume of solids lost overboard during the filling process. Clearly, alternate methods to surveying, plant production and load metering are desirable for calculating more accurate estimates of the volumes of sediment dredged and lost during handling.

HANDLING-LOSS MODEL

Comparing the properties of grain size distributions provides another method for estimating handling loss volumes. Losses are mostly from the finer grain sizes of a sediment and occur because the fines are carried away with the fluid phase of a dredged slurry to leave a coarser sediment in the hopper or on the beach. Only sizes small enough to be transported by fluids at the velocities present are removed. The result

should be that the smallest sizes are most affected and that losses should progressively decrease with increasing grain size until a critical size is reached that is too large to be transported. All grains larger than the critical size should therefore be retained and their relative proportion increased in the resulting gsd as compared to their proportion in the gsd of the pre-dredged sediments. These relationships lead to the following handling-loss model.

During dredging it is assumed that all sediments encountered on the bottom are picked up by the dredge head so that the volume dredged from the bottom (V_B) equals the sum of the volumes placed (V_P) and lost (V_L) during handling. A simple mass-balance equation provides the relation

$$V_B F_B(\phi) = V_P F_P(\phi) + V_L F_L(\phi) \quad (1)$$

where ϕ is a measure of grain size (Krumbein, 1938) and $F(\phi)$ is the proportion of material coarser than ϕ in each gsd. It is assumed that all losses are due to elutriation, that abrasion is negligible, and that losses are restricted to particle sizes finer than some critical size (ϕ^*). The result is that handling losses will effectively increase the proportion of sediments coarser than ϕ^* in the gsd and that for these coarse sizes $F_L(\phi)$ is zero value so that equation (1) leads to the relation

$$\frac{V_B}{V_P} = \frac{F_P(\phi)}{F_B(\phi)} = K, \quad (2)$$

where K is a constant reflecting the proportion of material lost. Therefore, inspection of the ratios of cumulative frequencies for all sizes coarser than ϕ^* should be fairly constant (Figure 4) and the percentage volume lost is given by

$$V_L = \left(1 - \frac{1}{K}\right) \times 100. \quad (3)$$

Evaluation of the Model: The textural data describing sediments collected during the handling-loss experiments were used to evaluate the model. The results of this evaluation are summarized as Table II. Figure 5 is presented as a typical plot of gsd ratios and is for the cumulative size distributions of barged and bottom sediments (Figure 3) collected at New River (1978). In general, the ratios of gsd's for each pair of composites plotted like those in Figure 5 and showed the kind of pattern predicted by the model (Figure 4) of fairly constant frequency ratios for an initial range of coarse sizes followed by a gradual decrease of the ratios to unity as grain size became finer. The only real variation to this pattern is that on some plots, the gsd ratios were quite variable (of both low and high value) for the very coarsest grain size fractions. These "irregularities" are interpreted to mainly reflect sampling errors as they usually occurred when cumulative weight percentages were less than five percent which is in that portion of a gsd where a very few grains constitute each size fraction and where grain number is easily affected by splitting and sieving

operations. Nevertheless, the presence of these fluctuations had little effect upon the calculated K-values (loss constants, Table II).

FIGURE 4 Relationship of K and ϕ^* for schematized plot of ratios of gsd's for bottom, $F_B(\phi)$ and pumped, $F_P(\phi)$, sediments as predicted by the proposed handling-loss model (for case of $K=1.3$ representing a 23 percent volume loss).

New River Inlet, NC (1978)

FIGURE 5 Observed ratios between gsd's for barged and bottom sediments, New River, 1978.

	ϕ^* Critical Size (mm)	K Constant of Loss	V_L Estimate of Loss	Increase in Mean (mm)
BOTTOM VS PLACED				
Rockaway 1975	0.39	2.10	52%	0.14
BOTTOM VS BARGED				
Rockaway 1975	0.33	1.71	42%	0.12
Rockaway 1977	0.55	2.96	66%	0.19
New River 1976	0.92	2.70	63%	0.47
New River 1978	0.46	2.33	58%	0.39
BARGED VS PLACED				
Rockaway 1975	0.46	1.23	19%	0.02
AVERAGED VALUES	0.52	2.17	50%	0.22

TABLE II Critical Size (ϕ^*), Loss Constants (K's) and Volume Loss estimates (V_L 's) predicted by the proposed handling-loss model for Rockaway Beach and New River studies (Mean grain size increases also shown).

The data presented in Table II suggest that handling losses for the cases studied: (a) tend to increase the average size of sediments handled by about 0.2 millimeters; (b) are from grain sizes finer than about half of a millimeter; (c) and average about 50 percent. The first suggestion simply reports those changes observed during the field studies. The second suggestion comes from estimates of the critical grain size (ϕ^*) determined from plotted gsd ratios and this suggestion is generally supported by inspection of the grain size distributions for three overwash samples collected during the studies. In these cases, 95 percent of the samples overwashed were finer than 0.64 mm (vs $\phi^* = 0.92$ mm) at New River (1976), finer than 0.70 mm (vs $\phi^* = 0.55$ mm) at Rockaway Beach (1977), and finer than 0.50 mm (vs $\phi^* = 0.46$ mm) at New River (1978). The third suggestion of fifty percent handling losses is

at least twice that expected and claimed during dredging operations at Rockaway (Nersesian, personal communication, 1977).

The discrepancy between handling loss volumes predicted by the proposed model versus losses estimated during construction may reflect inadequacies in the model; problems associated with sampling and analytical procedures, or possibly, greater losses do occur during project construction than have been generally recognized. A few different models have been examined which, using these same textural data, have not significantly narrowed the gap between predicted and estimated losses. New field studies are generally needed to collect adequate data for evaluating most other models.

The textural properties of nearshore zone sediments are typically quite variable over short distances and thus sampling procedures should be considered as possibly contributing to the textural differences found between bottom and dredge-modified sediments. Sampling procedures that might affect textural properties include the number and spacing of sample locations, the type of samples collected (e.g., surface vs. cored samples) to characterize sediment sources (bottom, barged, or placed), and the kind of equipment used to collect the samples. Evaluation of these procedures used in the studies reveals a need to investigate potential losses of fine sizes during core sampling operations and the desirability of increasing the bottom sampling density in future studies where suction, drag head plants are used to dredge over fairly large areas. Still it is tentatively concluded here that elements of sampling have not significantly affected the results of these dredge-loss studies since results from each study are similar in type and magnitude even though the sampling procedures varied from study to study.

Perhaps handling losses are greater than generally recognized. Potential errors in calculating sediment volumes using survey, production and hopper load data have been noted but no reasonable explanation is apparent for why these kinds of errors would consistently minimize losses. Other explanations are needed.

One possible explanation for the discrepancies in loss estimates is that handling operations not only cause sediment losses but that they also change the internal arrangement of dredged sediments in a way that creates a false impression of dredged volumes. For example, Turnbull and Mansur (1974) have shown that dredging tends to decrease the bulk density of sandy sediments in cases where the material is not well drained (as in hoppers below the water line?) whereas Poulos and Hed (1973), and Youd (1973), showed that the volume of solids in clean sands decreased with improvements in sorting and decreases in angularity, respectively. These relationships were applied using the Rockaway (1977) samples and the results are summarized in Table III.

Relative densities of the sediment sources at Rockaway (1977) were not measured in the field and thus estimates of their values are required for the following calculations. A relative density of 50 percent is assigned to the barged sand which is the average for hydraulically-

placed fills as measured by Paulos and Hed (1973), and a 78 percent value is calculated for the bottom sediments in-place that have been assigned a void ratio of 0.40. The percent of solids per unit volume of sediment determined using these relative densities is 64 percent for the barged sediment versus 71.4 percent for the sediment in-place. Volume differences like the 7.4 percent shown in this example would not be apparent during the construction phase of a beach fill but could become quite important at a later time when this uncompacted material was under attack by storm waves.

	Roundness (Powers, 1953)	Uniformity Index	Maximum Void Ratio (Youd, 1973)	Minimum Void Ratio (Youd, 1973)
Bottom Sand	0.37	3.00	0.62	0.34
Barged Sand	0.33	1.91	0.77	0.38

TABLE III Textural and Bulk properties of bottom and dredged (barged) sand collected at Rockaway Beach, NY, 1977.

Increased handling losses of 5 to 10 percent don't equalize volume losses estimated during construction with those predicted by the model. For Rockaway (1977) the predicted losses (model) are at least double those claimed during construction. Nevertheless, it is clear that many factors affect the volume of handling losses such as changes in textural and bulk properties and that interrelationships among these factors are not well understood even though they affect both the design and the economics of a beach fill project.

CONCLUSIONS

The following remarks summarize results, to date, of investigations of handling effects upon sediment properties and beach fill design. These investigations are part of an effort that will continue and that will hopefully explain those problems that remain unsolved.

1. Significant changes in sediment texture are caused by dredging and handling operations. For all cases studied, the winnowing (elutriation) of finer sizes produced a dredged sediment that was coarser (0.22 mm average increase) than bottom sediments. Sorting values decreased in some cases (Rockaway) and increased in others (New River).

2. Textural changes produced through handling can effect the estimates of overfill and renourishment elements of beach fill design. In all cases studied, the changes improved the predicted performance of sediments as beach fill.

3. Traditional methods of measuring beach fill volumes (surveys, plant production records, and hopper load measurements) often provide unreliable results and therefore, a need exists for improved or alternate methods.

4. A handling-loss model that compares textural differences between dredged and bottom sediments provides handling-loss estimates that are approximately double the losses estimated using the methods listed in item 3 above. These discrepancies are being evaluated by testing alternate handling-loss models, by evaluating different sampling procedures, and by considering mechanisms that explain handling losses of the magnitudes shown with the model.

5. Changes in the bulk properties of sediments caused by dredging can affect sediment volume calculations. These changes warrant further investigation as they may well affect the sediment's performance as beach fill.

ACKNOWLEDGEMENTS

CHAPTER 114

SOME FACTS AND FANCIES ABOUT BEACH EROSION

by

Richard Silvester

Associate Professor of Civil Engineering,

University of Western Australia,

Nedlands, 6009 W.A.

ABSTRACT

Coastal defense up to the present has employed seawalls, groynes and renourishment, all of which do not tackle the basic problem of lack in sediment supply from upcoast. The need is for sufficient sand to be continually available for the formation of the defensive offshore bar. If means are provided for this material to be returned directly on shore by subsequent swell, a stable situation ensues. Such normal re-deposition occurs within bays formed between headlands which have reached equilibrium shape or nearly so. Comparisons are made between various stabilization procedures. The influence of sand characteristics in renourishment is discussed.

Stabilization of coasts has been carried out over many decades. The remedies have taken three major forms, namely, seawalls, groynes, and in more recent times sand renourishment. Whilst shapes and orientation of these structures have been varied in order to optimise protection, engineers in the main have relied upon bigness for greater reliability. Investment in dredging to supply sediment "temporarily" to beaches is growing prodigiously. It is now time to sit back and re-assess the situation, so as to determine a change of outlook, be it only slight, that may effect greater long term economies.

AXIOMS OF BEACH PROCESSES

There are certain theorems respecting beach processes which, although proved separately, are not normally considered conjointly in the stabilization issue. These are:

- (a) On oceanic margins and even along coasts of enclosed seas there is a predominant or resultant wave direction which is usually oblique to the coastline.
- (b) The longshore component of wave energy both in the surf zone and offshore can transport a specific load of sediment across a given bed profile normal to the beach.
- (c) Flunctuations in river discharge of sediment, in wave incidence along the coast, in man's interception of littoral drift, and in storm

activity, cause continual variations in supply of material from upcoast on any section of shoreline.

(d) The transfer of sand from beach to offshore and back again in an oceanic margin during storm and swell sequences results in different beach and nearshore profiles than on shores of enclosed seas where swell is minimal.

(e) Waves reflected obliquely from walls, cliffs or submerged reefs create a short-crested wave system that generates strong vortices, resulting in increased macro-turbulence which magnifies sediment suspension in a situation of excessive mass transport.

(f) Groynes have no influence on bed erosion beyond their toes and cannot retain material collected between them during storms because of their promotion of rip currents.

(g) If waves arrive nearly normal to the coast the offshore slope must be very flat before the waves can effect longshore transport of sediment at the rate it is being supplied.

(h) An eroded shoreline will absorb a large proportion of sand re-nourishment supplied to it in order to construct the equilibrium profile appropriate to the wave energy normally present.

(i) Persistent swell arriving obliquely to alignments of headlands will form crenulate-shaped bays between the fixed points which have a limiting indentation and specific curved shape.

By combining the effects in these truisms one may be led to a solution of beach erosion which is economic in both investment and maintenance. It is the purpose of this paper to examine the real problems in littoral drift and suggest a comprehensive plan for management of the coast.

PAST MISTAKES

Remedial measures for beach recession have taken various forms, with periodic changes similar to those in womens' fashions. The reason for this copying sequence in engineering might be blamed on the control effected by some eminent or prominent person. The neophytes of the profession tend to emulate their peers, for purposes of promotion if nothing else. It is very difficult in a conservative atmosphere to introduce innovations. Engineering suffers as much from this as the medical profession where the caution is "Be not the first to adopt the new, nor the last to cast the old aside". This leads to the sequence: "When first discovered it is not proved. Twenty years later it is proved but not important. Thirty years more it is proved and important, but it is fifty years old - we have something better now!"

The phases in coastal engineering have been seawalls, groynes and the latest panacea is renourishment. It is well to see where these three concepts went astray, or to compare the disadvantages against the purported benefits.

Seawalls It was believed, even by eminent oceanographers and presumably by many engineers, that if the energy of incident waves could be thrown back to the sea all was well on the coastal front. Little was it realised that re-application of this energy to the seafloor, particularly if it involved oblique reflection, would expedite sediment removal and

suspension. (1) Not only does scour occur in front of a wall but also downcoast of it, where the diffracting reflected waves combined with the incident to continue the short-crested wave system. (See Figure 1) The rapid removal of material results in a shoal further downcoast because the incident waves cannot cope with the increased load removed and hence a shoal and even shoreline protuberance occurs. The sight of erosion between an accretion and the wall extremity has prompted the extension of walls downcoast and the displacement and expansion of the problem.

Even rubble-mound structures can reflect a large proportion of the wave energy, particularly that of the longer period components of the spectrum. Also submerged walls or reefs will reflect the lower sections of the wave motion and hence create water particle motions equivalent to short-crested waves at the surface. (2) This is a problem not fully realised with pipe outfalls experiencing angled waves, which fail due to scour, some little distance back from their extremities. The local phenomenon of vortex generation at sharp ends of walls or objects is another matter, but a very serious one for caisson type breakwaters.

Groynes Since man could observe the excessive turbulence and suspension of sediment in the surf zone, plus the current produced by oblique breaking of the waves, it was assumed that all important transport of material was occurring in this water strip at the beach margin. It was concluded, therefore, that an impediment placed across this pathway should retain sand on that section of coast. Thus groynes have been constructed out to the limit of normal breaking waves on the beach.

In recent years the importance of the offshore zone in transmitting sediment downcoast has been illustrated in the knowledge of mass transport and the influence of multiple wave trains in disturbing the bed. The added effect of swell waves angled to each other has not been examined thoroughly enough to date but the possible increase in transmission can be surmised. It has been propounded that the complete continental shelf can serve as a highway of this transport. (3)

Beyond the tip of a groyne the waves move sediment and hence any imbalance between material removed and that replenished from upcoast is unaffected by this structure. Many cases can be cited of continued deepening and steepening of the bed offshore from a field of groynes, which were constructed due to an erosive tendency, which will continue. (4). This offshore deepening permits subsequent waves, be they storm or swell in character, to approach at a more oblique angle and at a greater celerity, both adding to the longshore transporting capacity of the system.

But even the material blocked in transit by the groynes adjacent to the beach is in jeopardy during a storm. Waves will arrive from all seaward directions as the low pressure centre traverses the coast. Thus whilst they consume the adjacent beach to form a protective offshore bar the associated changeable longshore drift is deflected seawards by groynes to form strong rip currents. Material is thus carried seawards and when brought back to the beach by subsequent swell waves is deposited much further downcoast than if it had been just offshore. (See Figure 2)

Fig. 1 Interaction of incident and reflected waves at a seawall

Fig. 2 Groynes with erosion beyond toe and rip formation

Fig. 3 Crenulate shaped bay in stable and unstable condition

Fig. 4 Profile of stable beach profile plus fill

Groynes could thus be considered to enhance downcoast drift.

Because more than normal volumes of sand are removed between groynes the subsequent filling process during the swell season results in erosion downcoast of the groyne field.

There is one location where a structure running normal to the shoreline can be effective in accreting a beach. This is along the tangent section of a crenulate shaped bay, but this is unlikely to be in an erosive situation because the waterline is controlled by the downcoast headland. (See Figure 3) This tangential zone is little affected even when the bay is becoming more indented due to reduction or cessation of littoral drift upcoast. Instances can be cited where fluctuations in littoral drift have either buried groyne systems or inundated them as though they did not exist.

Renourishment This is the latest panacea of the erosion problem, with the more expensive alternative of dredging from the sea being promoted. Since the whole shelf can be considered the highway for transport any substantial holes dug in it can influence the sediment somewhere along the coast, not necessarily in the affected area. (5) But it is the benefit to the community as a whole from such artificial widening of a beach that should be of concern.

That there is a strong longshore drift resulting from oblique predominant waves must be accepted, otherwise there would be no erosion problem. This downcoast component will still exist after the refill and hence will transmit sooner or later (more likely the former) this expensive material in the same manner as the original coast. In fact, it will move it more rapidly, especially at first, because it is perched against the coast with a steeper than normal profile, almost the angle of repose of the sediment. (See Figure 4) Even just swell waves will spread this material both downcoast and over the eroded offshore region in an attempt to produce the original equilibrium profile appropriate to the wave climate for the area. Initial losses of 30 to 50% have been recorded (6)

Renourishment is a palliative which eases the problem but does not remedy the cause. This can be likened to the pill prescribed by the medical profession to get rid of the pain without attacking the root of the disease. Whilst the pain is gone there is less incentive to work on the real problem. Most engineering "doctors" applying this solution recognise the transitory nature of the benefit and recommend annual additions of the pain killer, possibly of 10 to 20% (6).

BASIC REQUIREMENTS

The essence of the beach erosion problem, or its solution, is to have sufficient sand on the beach to form an adequate offshore bar during any severe storm sequence. This natural defense mechanism cannot be bettered by man. Even if he were to place a fixed mound parallel to the coast to replicate this bar, it would serve as a reflecting wall during periods of swell and hence expedite transport of sand downcoast. Thus it is the swift construction of this feature in times of need that is so helpful to mankind, and its subsequent dismantling by the swell waves a few days later.

Whilst man cannot assist nature in this valued erosion limiting process he can assist by providing milder slopes to the offshore profile of the beach. Such a flatter bed requires less beach material to construct a bar of sufficient size to break incoming storm waves. It is a case of more material being maintained in the region, with a large proportion of it being submerged. This mode of storage inhibits the possibility of wind blowing it inland to form sand dunes.

The question is how to create this seaward accretion without it being subject to longshore wave energy and hence transport downcoast. Again nature has provided the answer because where the coast is so oriented that it is parallel to the crests of the persistent swell waves the offshore bed is mildly sloped, as can be gauged by the number of simultaneous breakers visible in the surf zone. (7) This is also understandable because a near-normal approach of waves makes it difficult for them to transmit material downcoast. Material is deposited until the depths are reduced to such a degree that the waves can disturb the bed sufficiently to balance the energy available with the load to be carried.

CRENULATE SHAPED BAYS

This necessary reshaping of the coast for it to receive the persistent swell (or predominant waves in the case of enclosed seas with little or no swell) normally has been carried out by nature over geologic time. When headlands or control points exist the sedimentary shoreline between has been sculptured into bays with specific curved outlines. Where the waves of greatest duration arrive obliquely to the headland alignment such bays assume a crenulate or zeta shape. (See Figure 3) These are the most abundant physiographic features on all coastlines of the world, whether they be on oceanic margins, in enclosed seas, or inland waterways where wave action is significant. (8)

Although these bays can be of any dimensions, hundreds of metres between headlands or even kilometres, they will be exact models of each other if the obliquity (β) of the persistent waves is the same. For a specific angle of approach to the headland alignment and a condition of no sand supply from upcoast or within the bay certain characteristics of the bay are now known. (9) (10). These are the ratio of maximum indentation (measured normal to the headland alignment) to the clear distance between the headlands, and the curvature of the logarithmic spiral which is applicable to the curved section of the bay. (See Figure 5) With knowledge of the limiting values of these parameters for specific wave obliquities (which angle is the same as that between the downcoast tangent section of the crenulate shape and the headland alignment) a tool is available to check the stability of any bayed coastline. (See Figure 3) If the values plotted do not fall on the equilibrium line further erosion can be expected if and when sand supply decreases or ceases in the future. Complete cessation is prevalent in modern times with the need for dredging deep channels across the shoreline to ports.

When a bay is nearing this final stable shape the incoming persistent swell will diffract and refract in the lee of the upcoast headland in such a way that it will break simultaneously around the whole

Fig. 5 Stability criteria for equilibrium shaped bay

Fig. 6 Comparison of renourishment schemes A: with groynes B: with no assistance and C: with headland control

periphery of the bay. This has been proven in model studies (11), as well as in this field (12). At this stage longshore drift cannot occur. Hence any offshore bar formed during a storm will be carried back to the beach by the swell and placed in its original position. Certainly there will be negligible loss of material between one bay and the next.

COMPARISON OF DEFENCE PROCEDURES

Consider a reasonably short section of straight coast requires stabilizing because of the investments already in jeopardy along the beach. The basic need as stated above is to maintain a reserve of sand in the area, which is readily available from year to year, to service the storm waves in constructing the defensive offshore bar. The alternative of building seawalls or revetments instead of providing this sand reserve is not worthy of discussion, because of the high maintenance cost, the high risks taken and the lack of aesthetic appeal.

Thus the solutions to be compared are plain renourishment, a field of groynes, or several headlands (offshore breakwaters). With sand placed on the beach in the affected area there will be a downcoast extremity to the widened beach. This will involve a more oblique approach of the waves in this region and therefore swifter removal than along the general shoreline. (See Figure 6). This in time will reorient the whole renourished beach to a more oblique line and hence downcoast removal is expedited. This will result in a hump of sand proceeding along the shoreline which could well silt up waterways and other marine facilities. Continual maintenance of this fill will be necessary.

The second alternative of groynes, even if provided concurrently with renourishment, will retain perhaps half the volume during the subsequent swell season. However, when the storm waves arrive they will take portion of the reserve to form a bar and the remainder will be carried further out to sea by rip currents. This latter material will be re-deposited on the beach beyond the field of groynes by the oblique swell. (See Figure 6) This means that the groyne field must now be partly refilled by littoral drift coming from upcoast. During this process the downcoast region will suffer erosion.

The third alternative of headland control implies structures which will be positioned further offshore than the tips of the groynes discussed above. Their spacing also should be great enough for the bays to be significant features on the coast. (See Figure 6) In this way a new equilibrium shape can be developed which involves milder offshore bed slopes. The reserve of sand, which may again be that available from renourishment, is not only stored on the beach but also under water. Less is taken from the beach during a storm and what is can be replaced directly back whence it came. No sand is exchanged between bays except the net littoral drift that existed in the first place. This drift will still pass through the bay system and hence give the same supply downcoast as before, but without the eroded load from the short section of beach being stabilized. The security obtained is that if all littoral drift ceases the bays in front of the important beach site will indent to a predictable limit and no further.

An ultimate aim by coastal engineers should be to reduce littoral drift along the whole coast to zero. If this could be accomplished the cost could in the long term be met by the savings in erosion, silting, by-passing and bar formation at river mouths and harbours. In this procedure new land could be won from the sea, which would be stable enough for maximum employment in recreation, housing or industry.

COMBINED RENOURISHMENT AND CONTROL

It is often recommended that groynes should accompany renourishment (6) (13). The author is not against such reclamation per se, but would recommend structures other than groynes for retaining this newly won but costly material in position. He has written on several occasions to local authorities, where renourishment has just been reported in the technical literature, suggesting that headlands be spaced along the resulting waterline. By such an economical expedient it would immediately be learned that about half the material would be kept as beach, probably one quarter would be stored offshore, and the remainder might possibly go downcoast. This would be a better balance sheet than 100% lost in a matter of three to five years. The cost of dumping rubble-mound rock or its equivalent at around mean tide level would be minimal compared to the overall investment in transitory reclamation.

It is instructive to discuss a method of headland control in combination with a renourishment scheme. Since dredging generally involves pipeline discharge onto the beach it is most inconvenient to concentrate deposition at certain points on the coast rather than spreading uniformly. (See Figure 7) In fact, this economical mode of operation has been utilised for filling beaches within a groyne field (14). If stone were deposited promptly at the tip of the sand spit the man-made tombols could intercept littoral drift from upcoast, whilst the downcoast beach would be sculptured into a logarithmic spiral, to connect with the adjacent downcoast headland. This spit construction could be aided by earthmoving equipment. The head and sides could be quickly protected if necessary by blocks placed there temporarily and later shifted to the main structure.

When it is realised that a reef at low-low-water is sufficient to maintain a shoreline in place, the design of headlands can be quite economical. Natural or fabricated armour units can be dumped on the beach face in the knowledge that they will progressively slump seawards as waves reflect obliquely from them. Sufficient material should be supplied initially to cater for this spreading action, to ensure that waves are broken even at the highest tide and storm surge. Random placement and shape can make the structure appear as a natural feature.

To reduce the use of stone, which continually becomes harder to obtain and more expensive to transport, sand sausages are an alternative worth considering (15). Membrane materials are now becoming available which can be welded or sewn into large diameter tubes which can be filled with sand, cement mortar or concrete. The advantage is that the bulk of the material is available at the site and only requires some technique of pumping into the sausage skin located in position offshore.

The massive infra-structure of roads, trucks and cranes is thus obviated, which is particularly beneficial at remote points of the coast.

Another economical construction method for headlands, or other coastal structure for that matter, is the large bag which again can be filled with sand, mortar or concrete (16). The size of this armour unit is limited only by the size and strength of the bag that can be handled underwater or in the surf. The stability of such structures has only been tested in prototype situations, where they have withstood waves from some of the fiercest hurricanes in the Gulf of Mexico. Comparative tests with fabricated concrete units should be carried out, but it can be rationalised that such bags filled in situ develop very close contact, unlike monoliths which have only point contacts. Particularly difficult is it for a wave to overturn or dislodge a flexible mass such as a bag filled with sand.

Tubes of 1m diameter have been used to form groynes and pseudo-seawalls (17), but if used on a lattice fashion as depicted in Figure 8B each sausage could be safe from displacement by the largest waves. The alternative larger sausage is not cylindrical in shape (15) but assumes a profile as illustrated in Figure 8A. Such structures need only be built to mean-low-water for them to break waves at all times. The construction procedure lends itself to this reef concept because it is not necessary to provide access some meters above high tide to transport armour units. Its width also can be planned to meet the hydraulic needs rather than those of construction equipment.

DUNES VERSUS EMBAYMENTS

The real comparison to be made is between sand dunes, as the currently believed stalwarts against the sea, and crenulate shaped bays, formed between headlands of natural or man-made origin.

Because dunes are built by wind blowing dry sand from the beach berm into vegetation closest to the beach, it is believed they are God's given gift for defense of the coastline. When a particularly prolonged storm arrives the beach berm disappears offshore together with the face of the first dune. Later, when swell waves return this bar material to the shore (swiftly at first and then more slowly) the berm is wider than usual, thus providing a greater width from which the wind can lift sand and deposit it against the damaged dune.

But it is not the most erodable beach that has the highest dunes available. A large proportion of the bar material here does not return because it is compensating for the offshore deepening that is continuing in this erosive situation. On the other hand, in a stable or accretory situation the constant supply of sand to the beach permits an extra high first dune to exist. Seldom is such a feature attached and hence the anomaly that where least needed Nature provides the largest safeguard and where most needed this back-up structure is not well developed.

The idea is often expressed that it costs nothing to let Nature, through its dunes, provide us with our factor of safety, or more appropriately our factor of ignorance. Like the equivalent reserve in the

Fig. 8 Sand filled membranes A: large version, B: multiple tube construction

Fig. 9 Relative erosion for steep and mild offshore slopes

bank it costs money, because some of the most valuable coastal real estate is not available for development by the community for residential, recreational or commercial purposes. The sparsely vegetated white sedimentary hills create their own peculiar problems of wind blown sand and inaccessibility to the water.

It should be kept in mind that the real defense of the coast is to have sufficient sand continually available for the offshore bar to be constructed by the storm waves. Dune storage involves loss to the inland by wind erosion. If the required volume of sand can be retained at the shoreline, partly as beach berm and the remainder offshore as a shoal then the acelian denudation is minimised, with all its secondary problems. (See Figure 9) The advantages of providing this storage in an equilibrium bay feature is that material removed from the beach to form the bar is returned by the swell directly to its original position. Hence the same berm is available for the next year or the next decade. Because the bulk of the material is stored offshore, in its flattened slope, less demand is made upon the beach for an adequate structure to be built for stopping further erosion. The berm therefore is narrower and hence reduces the problem of wind blown sand.

Besides the aesthetic value of breaking the coastline into beautifully curved beaches there are many other benefits (18). The wave energy around each bay periphery varies considerably, so providing bathing conditions for the toddler to the surf-board rider. On oceanic margins, where persistent swell is ever present, the calmer zones in the lee of the upcoast headland can serve as launching sites for small craft, including those of the surf-life savers. The predictable limit of bay indentation (See Figure 5) gives an encroachment or usability line that is dependable, hence permitting full utilisation of the coastal strip. This situation should be compared with the dune system where people are prevented from walking for fear of blow outs or despoilation of the massive hills of sand that have insufficient nutrients to support vegetation.

SAND FOR RENOURISHMENT

Some papers have concentrated on the characteristics of sand to be used for renourishment, whether it should be coarser or finer in order to minimise removal downcoast. To the author this consideration is very unimportant, the waves will resolve this matter. The fines will be removed offshore, leaving the coarsest proportions on the beach face and berm. (12) If only coarse material is used the beach face will become steeper so promoting greater wave reflection, and thus increasing the energy available to transport this larger size material.

As stressed before, the most important factor for retaining or losing reclaimed land is the approach angle of the most persistent waves, generally the swell, to the beachline. When this is normal or near normal the longshore energy component is negligible and hence littoral drift in the surf zone, plus longshore movement further seawards, is zero or very low. Whether the sand is coarse or fine makes little difference to the overall profile. If very fine the bulk of the material will migrate offshore to make a wide shoal.

Fig. 10 Advantages from bayed beaches.

Fig. 11 Mechanism of sand sorting nearshore

If more coarse the bulk will be stored above water as beach berm, but because of the narrow exposed area and the larger diameter these grains are not so subject to wind transport.

Hence it would appear that a mixture of fine and coarse sand can serve the purposes desired, of providing material on hand for the construction of the natural defensive bar. The offshore zone of fine material is a ready foundation whilst the coarser fraction can form the top of this mound. During the transitional period of being returned shoreward both the fine and coarse grains will be mixed, until the waves can sort them once again. This makes the timing of sediment sampling for comparisons extremely important.

CONCLUSIONS

1. There are certain axioms or facts that can be accepted without question which, when considered together, point to new methods of coast stabilization.
2. Many mistakes have been perpetrated in the past because novel approaches to old problems are not readily accepted in conservative quarters of the engineering profession.
3. The basic requirement of coast stabilization is to have available from year to year sufficient sand to form an offshore bar which dissipates incoming storm waves.
4. The return of bar material to its original location (instead of downcoast) can be achieved in crenulate shaped bays where the persistent swell arrives normal to all points of the periphery.
5. Reclamation on its own suffers swift degradation, groynes expedite the transmission of sand downcoast, whilst headlands provide stable bays that can be used to the full.
6. When renourishment is carried out insurance against swift removal can take the form of headland construction which still permits the passage of littoral drift to downcoast areas.
7. The sand storage alternatives of dunes or shoals within embayments, indicate the need to seriously consider the latter for their long-term economic advantages.
8. When a shoreline is reoriented to receive normally the persistent swell, or resultant wave vector, the characteristics of the sand in a renourishment scheme are of little consequence.

CHAPTER 115

DIFFRACTION CALCULATION OF SHORELINE PLANFORMS

by

Robert G. Dean⁽¹⁾

ABSTRACT

A method is presented, and illustrated with examples, for calculating planforms for a class of "pocket" beaches. This type of pocket beach is formed of mobile sediment due to waves diffracting through an opening in erosion resistant material, for example behind a break in a revetment or behind closely spaced offshore breakwaters. The opening is considered as a series of sources with circular wavelets radiating landward from each element. The height and phasing of each wavelet is varied depending on whether the depth at the element limits the wave height and on the wave direction relative to the opening, respectively. Based on reasonable, but not complete, considerations of sediment transport, the equilibrium bathymetry is considered to exist when the wave front is everywhere tangent to the local bottom contours. A differential equation is developed for the local orientation of the contours; this equation is solved numerically starting from a reference transect and extending the contour until it intersects the line defining the opening.

Examples are presented illustrating the method for the following cases: (1) normally incident waves diffracting through a single relatively narrow opening, (2) obliquely incident waves diffracting through a single relatively narrow opening and (3) spiral bays which are contained by two relatively widely spaced headlands. In addition, a procedure is suggested for applying the results to the case of normally and obliquely incident waves diffracting through the openings formed by a series of offshore breakwaters.

INTRODUCTION

Wave diffraction is known to play an important role in the determination of the equilibrium planforms of pocket beaches particularly when the waves propagate through a restricted opening. An ability to predict the planforms for this type of beach would allow improved design for recreation and beach erosion protection and would also assist in the interpretation of the "effective" wave climates which form existing pocket beaches.

REVIEW OF PREVIOUS WORK

A number of studies have been concerned with the prediction of beach planforms under conditions where diffraction effects are significant. Yasso (1965) studied four beaches for which there is an updrift

¹Professor, Dept. of Civil Engineering and College of Marine Studies, University of Delaware, Newark, DE 19711.

headland and very little sand supply. These features were termed "headland bay beaches" by Yasso and it was demonstrated that the planforms could be fit very well by a logarithmic spiral equation of the form

$$r = e^{\theta} \cot \alpha \quad (1)$$

in which r is the radius from the log spiral center, θ is the horizontal angle from the origin, and α is a characteristic of the particular logarithmic spiral and represents the angle between a radius vector and tangent to the curve at that point.

Silvester and his co-workers (1970), (1972) have conducted studies of spiral bays lending further credence to the empirical fit provided by the logarithmic spiral. Based on an examination of planforms in nature and those evolved through laboratory studies, the conclusion has been reached that the planforms consist of three segments: (1) a circular arc segment in the lee of the updrift headland, (2) a log-spiral segment, and (3) a straight segment extending to the downdrift headland or other littoral control. It was also concluded that both refraction and diffraction effects significantly influence the beach planform. Silvester and Ho (1972) have utilized the spiral bay concept in which artificial headlands were constructed of gabions and rubble in an attempt to stabilize a landfill.

LeBlond (1972) has developed a numerical model to simulate the evolution of a straight shoreline to a spiral bay. Numerical stability problems occurred and the model was not successful in predicting the equilibrium beach planform characteristics. O'Rourke and LeBlond (1972) utilized the equations of motion including the radiation stress terms to investigate the water circulation patterns in a semi-circular bay. No attempt was made in the latter study to infer the associated beach planform.

Rea and Komar (1975) have developed a numerical model to simulate the formation of a crenulate bay. Diffraction effects were parameterized with the wave crests in the "shadow zone" described as circular arcs with the relative wave height decreasing from unity outside the shadow zone to progressively reduced values further in the lee of the headland. The unique feature of this model is that shoreline elements of two different orientations were used. In proximity to the updrift headland, the displacements of the elements were parallel to the axis of the headland and approximately perpendicular to the local wave crest. Outside of the shadow zone, the elements were perpendicular to those just described so that again the shoreline displacement was generally perpendicular to the local wave front. Good qualitative agreement was found with the general form of logarithmic spiral beaches.

Font, Sanabria and Silva (1976) have included the effect of the longitudinal gradients of breaking wave heights and the associated currents. The total longshore current consists of that due to the obliquity of the waves and that due to the gradient of the wave setup. The condition adopted for the equilibrium beach planform is zero total current. This is in contrast to the observations of Silvester (1970) that the waves break with crests parallel to the shoreline for

the equilibrium planform.

Walton (1977) has analyzed beach planforms of the spiral bay type and the associated waves and has concluded that the planform is everywhere perpendicular to the local wave energy vector. A family of possible beach planforms is determined and the planform selected which provides a best fit to the beach of interest. The method does not allow for diffraction and has the disadvantage of predicting that in the "gap" between two headlands, a wave system characterized by a single height and direction would result in a straight beach planform perpendicular to the incoming waves.

Dean and Maurmeyer (1977) have presented an approach to calculating the beach planforms resulting from "narrow" and "wide" openings between littoral controls. The method was compared with two measured planforms and demonstrated reasonably good agreement. One limitation of the method was that for the "narrow" gaps, it was necessary that the waves approach perpendicular to a line connecting the two headlands. The present paper presents an extension of that just described, including: (1) waves can approach the opening from any direction, and (2) an improved calculation procedure is utilized.

METHODOLOGY

General

The approximate method to be presented considers waves incident on an opening between two control points or headlands with a connecting sill of arbitrary depth, see Figure 1. The effects of diffraction are accounted for by using a simple representation of a series of wave sources distributed along the sill. The equilibrium beach and contour planforms are defined as coinciding with lines of constant wave phase; the effects of wave refraction are accounted for directly by the method in an approximate manner. The effect of currents due to gradients of breaking wave heights are not included. Although other authors, for example Font, Sanabria and Silva (1974) and LeBlond (1972) have emphasized the importance of these currents, other investigators, for example Silvester (1970), have noted that the equilibrium planform occurs when the wave breaks at normal incidence to the beach. My observations of beach planforms in apparent equilibrium tend to verify the latter assessment. Future studies will attempt to address the relative importance of these currents.

Headlands and Connecting Sill

The two headlands are considered to be separated by a distance, b , and to be connected by a non-erodible sill. For computational purposes, the sill is subdivided into N segments, each of which will be considered as a wavelet source radiating outward with a circular crest.

Figure 1. Definition Sketch Showing Method of Extending Contours From Reference Profile.

Incident Wave Representation

The incident wave, $\eta(x,t)$, is represented as the sum of M incident waves of height, H_{I_m} , angular frequency, $\sigma_m (= 2\pi/\text{wave period})$, wave number, $k_m (= 2\pi/\text{wavelength})$, and phase, ϵ_m , propagating in a direction, β_m , with respect to a line joining the two headlands forming the pocket beach, see Figure 1.

Reference Profile

The computations are initiated and extended from specified depths along a reference transect as shown in Figure 1. The depths, $h(x)$, along this reference transect could be based on measurements or could be based on an idealized form

$$h(x) = A(x_{\max} - x)^{2/3} \quad (2)$$

as found by Dean (1977) in an analysis of 502 beach profiles from the Atlantic Coast and the Gulf of Mexico. In Eq. (2), the parameter, A, depends on sediment properties, primarily the fall velocity.

Wave Propagation Into Bay

The wave height, H_s , radiating out from the sill elements is considered to be equal to the incident wave height if no breaking at the sill occurs or to be limited by breaking in accordance with the usual assumptions for spilling breakers.

$$\left. \begin{aligned} H_{S_m} &= \kappa h_s, H_{I_m} > \kappa h_s \\ H_{S_m} &= H_{I_m}, H_{I_m} \leq \kappa h_s \end{aligned} \right\} \quad (3)$$

As noted, the wave height and phase at any location in the bay are determined from the linear sum of all contributions from the sill elements. The resulting water surface displacement in the bay can be expressed as

$$\eta(x,y,t) = [\eta(x,y)]_{\max} \cos[\sigma t - \epsilon(x,y)] \quad (4)$$

in which $\epsilon(x,y)$ is the phase angle associated with the maximum water surface displacements as defined by

$$\tan \epsilon = \frac{S_2}{S_1} \quad (5)$$

where

$$S_1 = \sum_{m=1}^M \sum_{n=1}^N \frac{H_{n,m}}{2} \cos \mu_{n,m} \quad (6)$$

$$S_2 = \sum_{m=1}^M \sum_{n=1}^N \frac{H_{n,m}}{2} \sin \mu_{n,m} \quad (7)$$

and

$$\mu_{n,m} = k_{s_{n,m}} x_{n,m} \cos \beta_m + k_{s_{n,m}} y_{n,m} \sin \beta_m + \sigma_m r_n / \bar{C}_m \quad (8)$$

In these equations, the outer and inner summations are carried out over the number of incident wave components, M, and sill elements, N, respectively. The subscript s refers to conditions at the sill, \bar{C}_m is the average propagational speed of the mth wave component from source element to contour point of interest, a distance r_n , where

$$r_n \equiv \sqrt{(x - x_{s_n})^2 + (y - y_{s_n})^2} \quad (9)$$

The average propagational speed for a shallow water wave directed normally along a profile as given by Eq. (2) can be shown to be

$$\bar{c} = \frac{(\Delta x)_* \sqrt{gA^3}}{1.5[h_* - h']} \quad (10)$$

where h_* and h' are the depths just bayward of the sill and at the water depth of interest, respectively, and Δx_* is the normal distance along that contour separating the two end depths, h_* and h' . It is assumed that the propagational speed from the sill element to the location of interest is the same as if the wave were propagating normally along a profile given by Eq. (2).

Although not necessary for computation of the equilibrium planform contours, it is noted that the resultant wave height, $H(x,y)$, at any location is

$$H(x,y) = 2 \sqrt{S_1^2 + S_2^2} \quad (11)$$

Since the consideration for the locus of an equilibrium contour is that the contour be parallel to the wave crest, this is equivalent to establishing the locus of isolines of constant $\epsilon(x,y)$ (or $\tan \epsilon(x,y)$). Expressed analytically, using Eqs. (5), (6), and (7),

$$d(\tan \epsilon) = \frac{\partial(\tan \epsilon)}{\partial x} dx + \frac{\partial(\tan \epsilon)}{\partial y} dy = 0 \quad (12)$$

which can be simplified to the differential equation for the locus of a line of constant $\epsilon(x,y)$

$$\frac{dy}{dx} = - \frac{S_1 \frac{\partial S_2}{\partial x} - S_2 \frac{\partial S_1}{\partial x}}{S_1 \frac{\partial S_2}{\partial y} - S_2 \frac{\partial S_1}{\partial y}} \quad (13)$$

Contour Determination

The phase $\epsilon(x,y)$ to be held fixed along a given contour is first determined at the contour of interest on the reference profile through direct application of Eq. (5). The contour is next extended from the reference profile by a selected increment Δs in accordance with the direction established by Eq. (13), see Figure 2. The incremental Δx and Δy are

$$\left. \begin{aligned} \Delta x &= \Delta s \cos \delta \\ \Delta y &= \Delta s \sin \delta \end{aligned} \right\} \quad (14)$$

where

$$\delta = \tan^{-1} \left(\frac{dy}{dx} \right) \quad (15)$$

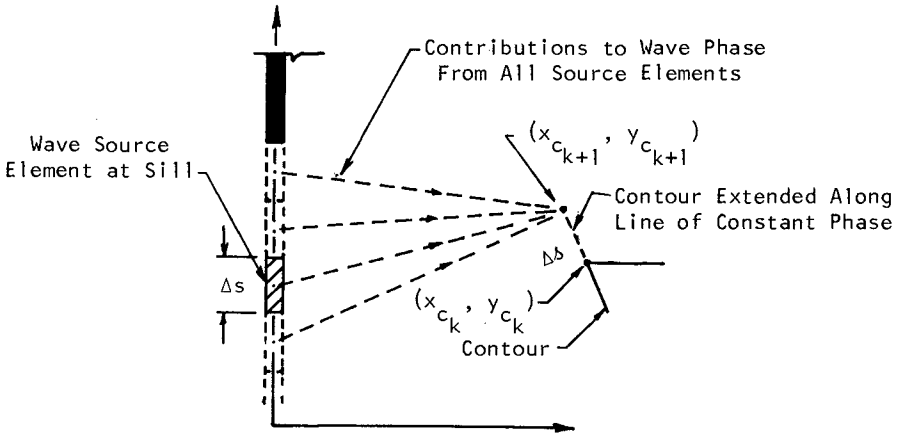

Figure 2. Step-Wise Extension of Contour Along Line of Constant Wave Phase.

The values of the (k+1) coordinates are now

$$\begin{aligned} x_{k+1} &= x_k + \Delta x \\ y_{k+1} &= y_k + \Delta y \end{aligned} \tag{16}$$

With estimates of the location of the extended contour now available, improved values of (x_{k+1}, y_{k+1}) are determined by applying a Newton-Raphson procedure repeatedly to establish the "target" value of $\epsilon(x,y)$. This involves modifying (x_{k+1}, y_{k+1}) along a direction which is perpendicular to the local value of (dy/dx) as determined from Eq. (13). In the results to be presented, this correction procedure was applied eight times for each point. It was usually possible to achieve the "target" value of $\epsilon(x,y)$ within 0.5° . In this manner the contour is progressively extended until it intersects the line connecting the two headlands. Each successive contour of interest is then calculated in the manner described. This completes the calculation of the embayment planform.

APPLICATIONS

In this section the method will be applied to several idealized cases of interest.

Normal Wave Incidence

A number of cases of varying relative gap width have been computed for normally incident waves. For an incident wave of a single period, it was found that the contours were somewhat irregular; the irregularities were reduced when the incident wave was represented by two components of slightly different periods. Figure 3a presents the planform associated with an incident wave of a single period of 8 seconds.

a) Planform for a Single Incident Wave, $T = 8$ sec. b) Planform for An Incident Wave System Comprising Two Components. Reference Wave Period is 8.0 sec.

Figure 3. Calculated Pocket Beach Planforms. Distance Between Headlands is 120 ft.

The contours contain slight irregularities characteristic of diffracted wave fields. Figure 3b presents the planform for the same case except that the incident wave system comprises two individual waves of equal height but of different periods: 8.0 and 8.8 seconds. For all examples presented hereafter, the incident wave system will consist of two components of the same height and two periods equal to 1.0 and 1.1 times the "reference" period.

The effect of wave period, relative gap opening, and sill discretization were examined. It was found that for the longer

periods, the planforms were smoother and less elliptical (i.e. more circular) in shape. Figure 4 presents the calculated planform for the same case as Figure 3b, except the reference period is 24 seconds, and the differences noted above are evident.

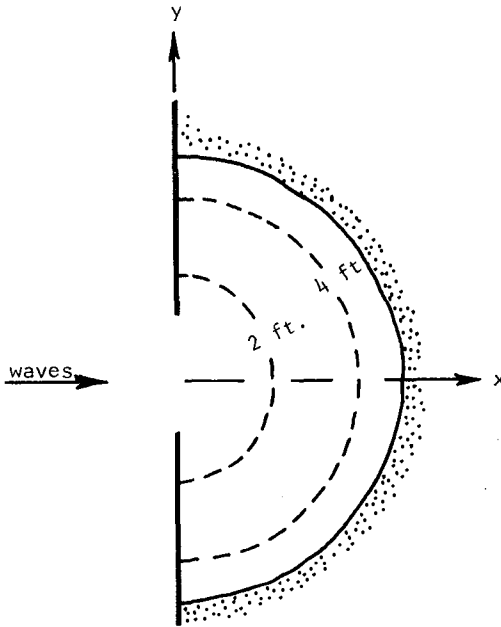

Figure 4. Calculated Planform for a Reference Wave Period of 24 Seconds. Distance Between Headlands is 120 ft.

The ratio of the major-to-minor semi-axis, a_2/a_1 , was evaluated as a function of ratio of half gap width to minor semi-axes, $b/2a_1$, for three reference wave periods. Based on simple geometric considerations, an approximate relationship for these variables is

$$\frac{a_2}{a_1} = 1 + \frac{b}{2a_1} \tag{17}$$

Figure 5 presents the calculated planform results where it is seen that Eq. (17) represents an upper limit. For any given relative gap width, the ratio of major to minor semi-axis (a_2/a_1) is larger for the shorter periods. The irregularities in the results are believed to be associated with the previously described characteristics of diffraction patterns.

The effect of finer discretization of the sill width was found to reduce slightly the irregularities in the calculated planforms.

Figure 5. Variation in Calculated Ratios of Major to Minor Semi-Axes for Cases of Normal Wave Incidence and Various Wave Periods.

Oblique Wave Incidence

Figure 6 presents the calculated planforms for waves propagating at a 60° angle with respect to the x-axis and for two gap openings. For the relatively narrow gap opening ($b/2a_1 = 0.11$), it is seen that there is little asymmetry in the two major semi-axes, the ratio of the down-wave to up-wave semi-axes being 0.88. For the wider gap opening ($b/2a_1 = 0.29$), the ratio of the major down-wave to up-wave semi-axes is reduced to 0.71. It is also of interest that in the vicinity of the opening, the 4 ft. contour is oriented approximately normal to the incident wave direction for the wider gap.

Spiral Bays

The method was applied to the calculation of two spiral bay planforms for incident wave angles of 30° and 60° respectively, see Figures 7 and 8. The planforms are in qualitative agreement with the characteristics of spiral bays as produced in laboratory experiments and as found in nature.

- a) Planform for Relatively Narrow Opening, $b/2a_1 = 0.11$. b) Planform for Relatively Wide Opening, $b/2a_1 = 0.29$.

Figure 6. Calculated Beach Planforms for Oblique Wave Incidence. Reference Wave Period is 8.0 sec. The Minor Semi-Axis = 235 ft. in Both Cases.

Figure 7. Calculated Spiral Bay Type Planform for 30° Wave Obliquity. Reference Period = 16 sec. Distance Between Headlands = 840 ft.

Figure 8. Calculated Spiral Bay Type Planform for 60° Wave Obliquity. Reference Wave Period = 16 sec. Distance Between Headlands = 380 ft.

Application to Planforms Associated With Offshore Breakwaters

The planforms computed as described herein can be extended in a very approximate graphical manner to the case of offshore breakwaters. The procedure is first applied to planform computation for a single opening, the wave conditions of interest and with the reference transect representing the proper offshore distance of the breakwater. These planform results are then transferred to an overlay with the offshore breakwaters shown. If the spacing of the breakwater gap centerlines is greater than the major axis of the planform, then a tombolo is indicated, see Figure 9. If the spacing of the breakwater gap centerlines is less than the major axis of the planform, then the breakwater is not connected to the shoreline, see Figure 10. In order for this approach to be approximately valid, the reference transect must be correct and there must be adequate sand in the system to form an equilibrium planform in the proper geometric relationship to the profile along the reference transect.

SUMMARY AND CONCLUSIONSSummary

A method has been presented and illustrated with examples for calculating the equilibrium planform characteristics of pocket beaches contained by erosion resistant features, herein called headlands. In accordance with the observations of some investigators, the method considers the planform contours to coincide with lines of equal wave phase. The opening between the headlands is represented as a series of sources from which circular wavelets radiate landward. The water surface displacement at any location in the bay is considered as the linear sum of the contributions from all sill elements. Starting from the known contours on a reference transect, the contour is extended in accordance with a differential equation defining the locus of that contour. Examples presented include planforms for relatively narrow openings with normally and obliquely incident waves. In addition planforms are calculated for spiral bays which are associated with reasonably wide openings.

Conclusions

There are irregularities associated with the calculated planforms of lines of equal wave phase. These are found to be reduced somewhat for an incident wave system comprising two waves of differing periods. It appears that planforms in nature may be smoothed by a range of effective wave periods and directions. The general characteristics of the calculated planforms are reasonably representative of those found in nature. However, a full evaluation of the method will require additional laboratory and field data.

CHAPTER 116

CONCENTRATION OF SUSPENDED CLAY IN PERIODIC FLOW

BY

- A. Watanabe - Associate Professor, University of Tokyo, Japan, formerly Associate Professor, Asian Institute of Technology, Thailand
- P. Thimakorn - Associate Research Professor, Asian Institute of Technology, Thailand

SYNOPSIS

A diffusion model of clay-water flow is formulated to determine the time dependent concentration distribution of suspended clay in a two dimensional periodic flow. Taking into account the entrainment rate of the clay particle from the bed, the integrated diffusion equation to yield a solution of the time-variation of the clay concentration in the vicinity of the channel bed is derived. In addition the original diffusion equation is solved by means of the finite element method. An experiment was conducted in a recirculating two dimensional channel where sinusoidal current variation was generated upon the clay-water mixture. Results obtained from the experiment are compared with those derived from the model.

INTRODUCTION

Transport of fine cohesive clay over a mud bed always appears in the form of full suspension. This phenomena is mostly found in the estuaries of large rivers which flow through flat alluvial flood plain into the sea. Under the influence of tide from the sea the flow in the estuary becomes periodic. Estimation of the sediment transport in the estuarine environment of this nature is practically dependent on four predominant factors, namely, tide, velocity, cross sectional area and concentration of suspended solids in the flow. Though factors influencing the suspended clay transport in an estuary, such as effect of salinity on flocculation, mixing of salt and fresh water (well mixed, partially mixed or stratified flow) and others are important, it is however useful to consider at the beginning the dynamic of the transport process only so that the phenomena can be understood. This dynamic characteristic of the clay-water flow is recognized by the two factors, the velocity and the concentration.

This phenomena was noted by Postma [1] in which the periodicity of the suspended clay in the periodic flow field in the Wadden Zee in Holland was shown. Later on Krone [2] found that in a steady flow the concentration of suspended clay when expressed in the form of percent of deposition attains

an inversely linear relationship with the bed shear stress. Similarly Metha and Partheniades [3] showed that the equilibrium concentration of clay-water mixture under a steady flow has a logarithmic relationship with the relative bottom shear stress. Recently Thimakorn and Gupta [4] correlated the two periodic parameters by means of cross correlations of the velocity and concentration data collected from field measurements in an estuary in Thailand. In this paper a diffusion model of a two dimensional clay-water flow is formulated to find out the response of the clay concentration under a periodic flow condition of simple sinusoidal type. The time variation concentration obtained from the experiment is compared with the diffusion model results.

THE MODEL

The definition sketch of the instantaneous suspended concentration profile, $C(y,t)$ within a two-dimensional time dependent flow, $u(t)$, is shown in Fig. 1. From the figure the governing equation of the vertical diffusion is:

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial y}(w_o C) + \frac{\partial}{\partial y}(K_v \frac{\partial C}{\partial y}) \quad (1)$$

where C is the concentration at any depth y , w is the terminal fall velocity of clay and K_v is the vertical diffusion coefficient.

Two boundary conditions are valid. One at the free surface where there is no net flux of the sediment across it is:

$$\text{at } y = h; \quad w_o C + K_v \frac{\partial C}{\partial y} = 0 \quad (2)$$

And at a reference level, y_o , near the bed the vertical diffusion is replaced by the variation of the entrainment rate, $q(t)$:

$$\text{at } y = y_o; \quad K_v \frac{\partial C}{\partial y} = -q(t) \quad (3)$$

Integration of Eq. (1) from $y = y_o$ to $y = h$ thus yields:

$$\frac{d}{dt} \int_{y_o}^h C dy = q - w_o C_b \quad (4)$$

which becomes:

$$(h - y_o) \frac{d\bar{C}}{dt} = q - w_o C_b \quad (5)$$

where \bar{C} is the vertical average of concentration and C_b is the concentration near the bottom ($y = y_o$).

Under steady flow, after some time the concentration reaches its equilibrium, and the entrainment rate, q , is balanced by the settling rate of the particles, or Eq. (5) becomes:

$$q = w_o (C_b)_{eq} = \text{constant} \quad (6)$$

where $(C_b)_{eq}$ is the nearbed concentration at equilibrium.

Assume that the entrainment rate thus evaluated can be applied to the time dependent flow at any instant time, t , which is analogous to the gradually varied flow (quasi steady) such as tidal current.

Introducing:

$$\beta = \frac{\bar{C}}{C_b} \quad (7)$$

Fig. 1 Definition Sketch of Concentration Field Time Dependent Concentration.

Fig. 2 The Circulating Channel.

and assuming further that it is nearly constant, Eq. (5) is transformed into:

$$\frac{dc_b(t)}{dt} = \gamma [(C_b)_{eq}(t) - C_b(t)] \tag{8}$$

which expresses the time variation of the bottom concentration in the form of the integrated diffusion equation of the original equation, Eq. (1).

The parameter γ is derived from:

$$\gamma = \frac{w_o}{\beta(h-y_o)} \tag{9}$$

In a steady flow condition, the general solution of Eq.(8) becomes:

$$C_b(t) = (C_b)_{eq} + [C_b(0)-(C_b)_{eq}] \exp(-\gamma t) \tag{10}$$

which is then:

$$\ln \frac{C_b(t)-(C_b)_{eq}}{C_b(0)-(C_b)_{eq}} = -\gamma t \tag{11}$$

This equation is used to determine the value of γ from the asymptotic variation of the concentration measured at time intervals before it reaches equilibrium.

To determine the time dependent bottom concentration, Eq. (8) is solved numerically by means of the Runge-Kutta method. In order to obtain the numerical result, values of β , γ , w_o and q are needed, which can be obtained from the steady flow experiments.

The result obtained from the integrated diffusion equation, Eq. (8), gives only the time variation of the bottom concentration in a periodic flow. In order to determine the vertical distribution of concentration at any time, Eq. (1) must be solved.

Here we shall apply the finite element analysis to Eq. (1).

First an approximate expression for $C(y,t)$ is introduced as:

$$C(y,t) = \sum_{i=1}^I N_i(y) C_i(t) \tag{12}$$

in which N_i , is the interpolation function and C_i the nodal concentration. By means of the Galerkin's method, the original diffusion equation, Eq. (1), with the two boundary conditions, Eqs (2) and (3) is expressed as:

$$\int_{L_e} N_i \left[\frac{\partial C}{\partial t} - \frac{\partial}{\partial y} (w_o C) - \frac{\partial}{\partial y} \left(K_y \frac{\partial C}{\partial y} \right) \right] dy = 0 \tag{13}$$

governing the behavior of a line element, L_e .

Integrated by parts Eq. (13) becomes:

$$T_{ij} C_j + (W_{ij} + K_{ij}) C_j + F_i = 0 \tag{14}$$

which is the finite element expression to give the behavior of C_i in one element only, where $C_j = dC_j/dt$,

$$T_{ij} = \int_{L_e} N_i N_j dy, \quad W_{ij} = \int_{L_e} w_o \frac{dN_i}{dy} N_j dy$$

$$K_{ij} = \int_{L_e} K_y \frac{dN_i}{dy} \frac{dN_j}{dy} dy, \quad F_i = \begin{bmatrix} f_i \\ 0 \\ 0 \\ -f_r \end{bmatrix}$$

$$\text{and } f_i = (w_0 C + K \frac{\partial C}{\partial y}), \quad y = y_i$$

After some manipulations and assembly procedure, the final equation for solution takes the form of:

$$P_{ij} \dot{C}_j + Q_{ij} C_j + R_i = 0 \quad (15)$$

where the explicit forms of P_{ij} , Q_{ij} and R_i are omitted since they are readily obtained.

Note that the influence matrix P_{ij} is constant in time and symmetric, while the other two matrices Q_{ij} and R_i are time dependent and in particular Q_{ij} is unsymmetric. Time derivatives in Eq. (15) are expressed in the finite difference form as:

$$\begin{aligned} & [P_{ij} + \frac{\Delta t}{2} Q_{ij}^{(n+1)}] C_j^{(n+1)} \\ & = [P_{ij} - \frac{\Delta t}{2} Q_{ij}^{(n)}] C_j^{(n)} - \frac{\Delta t}{2} [R_i^{(n)} + R_i^{(n+1)}] \end{aligned} \quad (16)$$

In order to solve this equation it is assumed that the diffusion coefficient K_y is given by the modified Rouse's formula

$$\begin{aligned} K_y &= u^* K_y (1 - \frac{y}{h}) & \text{for } y \leq \frac{h}{2} \\ &= \frac{1}{2} u^* K_h & \text{for } y > \frac{h}{2} \end{aligned} \quad (17)$$

and the vertical velocity profile is logarithmic:

$$u = u^* (3.0 + 5.75 \log \frac{u^* h}{v}) \quad (18)$$

THE EXPERIMENT

The objectives in conducting the experiments are three-faced; namely: 1) to demonstrate the physical behavior of the clay-water mixture under periodic flow; 2) to determine numerical values, β , γ , w_0 and q to be used in solving Eq. (8); and 3) to compare the time dependent concentration with that of the model result. A two-dimensional recirculating channel, Fig. 2, having the width of 15 cm and the depth of 40 cm is used in the experiment. Clay-water mixture is moved by a rotating paddle wheel which can generate both steady flow velocity and sinusoidal velocity by means of a sine-current regulator derived from a rotating linear potentiometer. Flow velocity is measured by an impulse generating 1 cm diameter propeller current meter. Samples of water are collected to find the concentration from a series of five 2 mm diameter syphons. A long scale galvanometer reads the current from the photo transistor receiving the light through the measuring sample cell from the light emitting diode (LED). The following is the steps of the test:

1) Steady Flow: By means of generating different velocities, maintaining the steady flow condition of each velocity, and taking samples at different time intervals it was found that;

- The concentration reaches the equilibrium state within one hour, no matter whether the initial concentration is higher or lower than the equilibrium value, (Fig. 3);

Fig. 3 Bottom Concentration in a Steady Flow.

Fig. 4 Equilibrium Concentration in a Steady Flow.

- A linear relationship between the bottom concentration at equilibrium condition and the flow velocity exists as, (Fig. 4):

$$(C_b)_{eq} = 370 + 2u \text{ (mg/liter) (u:cm/sec)} \quad (19)$$

The bias value of 370 mg/liter can be considered as the base concentration corresponding to very fine particles of almost zero fall velocity; and

- The time variations of the bottom concentration in a transient period before the equilibrium is plotted as shown in Fig. 5. It shows a good agreement with Eq. (11). The value of γ obtained from this plot is 0.06 min^{-1} or 0.001 sec^{-1} .
- 2) Periodic Flow: The results obtained from tests with periodic flow conditions are:-
 - The velocity profiles illustrate similar logarithmic profile and that the sinusoidal velocity curve is obtained as $u(t) = |u_{\max} \sin \frac{2\pi t}{T}|$, (Fig. 6);
 - Change of the concentration is relatively small for a short period of a cycle when compared to a larger change found in a longer time period, Fig. 7. This is because the effect of time response in the transport process which is represented by the coefficient γ in Eq. (8);
 - Time lag between the maximum concentration and the maximum velocity is larger in a short period flow than that in a long period flow, Fig. 8. Again this phenomenon is demonstrated by the time response factor γ ;
 - Vertical distribution of the concentration is almost uniform except near the bed and it shows that the difference between the concentrations for different phase angles increases as the period, T , increases. The parameter $\beta = C/C_b$ is about 0.95 for all conditions, Fig. 9; and
 - By means of plotting the time variation of the bottom concentration, for comparison between the flow having 2 hour, 6 hour and 12 hour periods, taking the phase angle equal to zero at zero velocity and 90° at maximum velocity, Fig. 10, it is shown that the larger relative concentration variation is found in the 12 hour period compared to those of the 6 hour and 2 hour periods. On the other hand the time lag is larger in the 2 hour periods than those found for the 6 hour and 12 hour periods.

MODEL ASSESSMENT

In order to determine the validity of the model, an exercise is carried out to find the concentration variation in two ways; namely the solution of the integrated diffusion equation, Eq (8), which gives the time variation of the bottom concentration, $C_b(t)$, and the solution of the original diffusion equation by means of the finite element method, Eq.(16), which determines the depth-time dependent concentration variation, $C(y,t)$. The two consecutive solutions are as follows:

1) Time Variation of Bottom Concentration: From the experimental data, the values of the necessary parameters, namely β and γ are first obtained as

Fig. 5 Concentration Variation in a Transient Period in Steady Flow.

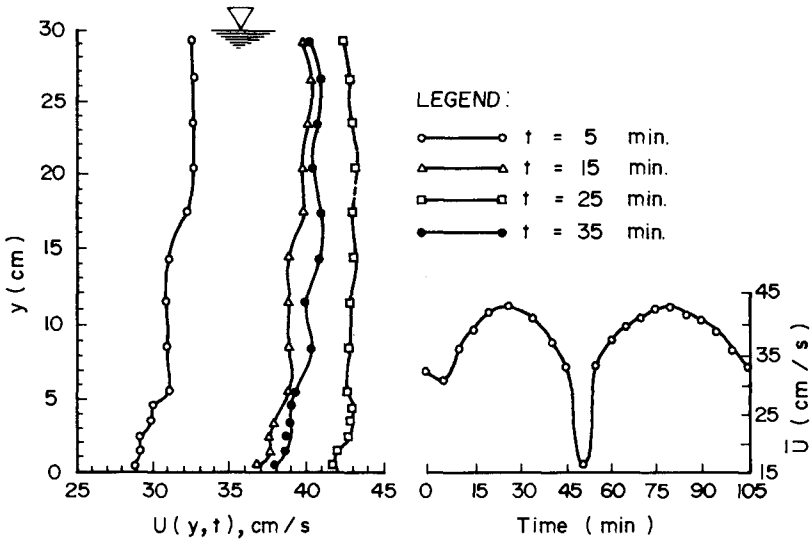

Fig. 6 Velocity Profiles and the Sine-Velocity Variation

Fig. 7 Concentration Variation at Different Periods.

Fig. 8 Effect of Time Period on Lag Time of Peak Values.

Fig. 9 Vertical Distributions of Concentration for Periodic Currents.

mentioned in the former section. In addition the fall velocity, w_o , is obtained from Eq. (9), which is about 0.024 cm/s. Introducing the empirical formula which shows the relationship between the velocity, u , and the equilibrium concentration, $(C_b)_{eq}$, as shown in Eq. (19) and with the sinusoidal velocity variation, the final form of Eq. (8) becomes:

$$\beta(h - y_o) \frac{dC_b}{dt} = A + \alpha |u_{\max} \sin \sigma t| - w_o C_b \quad (20)$$

where A and α are the constants relating to the linear relation between the entrainment rate, q , and velocity, u , as:

$$q = A + \alpha u \quad (21)$$

Although the solution of this equation is an initial value problem, the effect of the initial concentration disappears rather rapidly so that any arbitrary initial value can be chosen. Solution to Eq. (20) for 2 hour, 6 hour and 12 hour tidal periods with assumed initial concentration is shown in Fig. 11. The plotted results show similar tendencies in both magnitude and phase lag as those obtained from the experiment (Fig. 10).

2) Solution of the Original Diffusion Equation: The final form of the diffusion equation, Eq. (16) is solved for $C(y,t)$. The value of the base concentration is taken as zero for the simplicity in this model. Two solutions are shown in Fig. 12 for the near bed ($y = 0.5$ cm) and mid-depth ($y = 10$ cm) concentrations for the case of 2 hour, 6 hour and 12 hour tidal periods. Again similar tendencies of both magnitude and time variation are observed with the experimental results. In addition the concentration profiles given in Fig. 13 show a slight difference from the experimentally obtained profiles, particularly the concentration gradient near the bed. However, the trend of the calculated profiles is similar to the experimental ones.

CONCLUSIONS

The one-dimensional diffusion model, or its integrated form, proposed in this paper was found to give reasonable estimation of the concentration variation of suspended clay particles in a periodic flow, which is needed for estimating the sediment transport in tidal estuaries. The parameter, γ , the ratio of the fall velocity to the water depth plays a significant role as the time response factor in the transportation process of clay together with the rate of entrainment from the bed. Further investigation is necessary in particular, to establish the universal relationship between the entrainment rate, sediment properties and flow conditions, and to evaluate the diffusion coefficient properly.

CHAPTER 117

SUSPENSION AND TRANSPORTATION OF FLUID MUD

BY SOLITARY-LIKE WAVES

John T. Wells, James M. Coleman, and Wm. J. Wiseman, Jr.

Coastal Studies Institute, Louisiana State University

Baton Rouge, Louisiana 70803

ABSTRACT

The suspension and transportation of fluid muds in the near-shore zone by shallow-water, solitary-like waves has been investigated along the coast of Surinam, South America. Accumulations of fluid mud which front the coast at a spacing of 30-60 km affect incoming swell by changing the wave profile from sinusoidal to solitary-like and by preventing wave breaking except for occasional spilling. Simultaneous time-series measurements of wave height and period, fluid-mud density, and tide elevation, along with results of suspended-sediment measurements, indicate that in cases when the bulk density is less than 1.20 g/cm^3 and where water depths are less than 5 m fluid mud is suspended from the bottom in two frequency modes: wave-by-wave suspension (~10 sec) and tide-related suspension (~12.4 hr). Surface-water suspensate concentrations exceed $3.4 \times 10^3 \text{ mg/l}$ as up to 0.5 m of fluid mud is periodically removed from the bottom.

High concentrations of suspended fluid mud, together with solitary-like waves from the northeast throughout the year, can lead to extraordinarily high sediment transport volumes. Calculations based on solitary wave theory and on data obtained from this study indicate that $15\text{-}65 \times 10^6 \text{ m}^3$ of mud can move along shore each year without involving breaking waves, the concept of radiation stress and a nearshore circulation cell, or bed-load transport. These values are 10 to 100 times greater than typical transport rates along sandy coasts.

INTRODUCTION

As a generalization, research on fluid muds prior to the 1970s was restricted almost entirely to the laboratory, and even today field data are scarce. In this study we report results of field measurements conducted along the open, unprotected coast of northeastern South America, where incoming waves are affected by mud shoals composed partly of thixotropic, gel-like fluid muds. Our primary objectives were to examine the interaction between incoming waves and fluid mud and to assess the role of waves in the suspension and transportation of fluid mud.

The lack of field data can be explained partly by the difficulties encountered in obtaining direct measurements of near-bottom processes such as suspension and deposition. Several innovative techniques for studying fine-grained sediment dynamics, including acoustic systems (Kirby and Parker, 1974; Orr and Hess, 1978), a sea-floor flume (Young and Southard, 1978), and nuclear densimeters (Parker et al., 1975), have been utilized in recent years with varying degrees of success. As part of the present study an instrument was developed that could be used as a combination wave gage and sediment-density sensing device. By assuming that variations in mud density must be related to suspension, deposition, and near-bottom transport processes, we have been able to examine the details of fluid-mud dynamics in both intertidal and subaqueous hydrologic settings. Based on actual field measurements and reasonable assumptions, an explanation for transport by waves of suspended fluid mud is presented.

FIELD AREA AND METHODS

During field seasons in 1975 and 1977 data were collected at ten sites off the coast of Surinam, South America, on a section located midway along the 1,600 km of muddy coast that extends from the Amazon River in Brazil to the Orinoco River in Venezuela (Fig. 1). Climatic conditions and coastal processes in the study section are generally representative of those in northeastern South America. The warm tropical climate is controlled by the northeast trade wind system and periods of high and low wind speeds, each several months in duration, alternate throughout the year. During the months of data acquisition, August through October, conditions are typically dry and winds are low to moderate (~10-15 km/hr).

Formed during the Holocene by Amazon-derived muds, the coastline of the Guianas is both interesting and somewhat unique. Linear mud shoals, tens of kilometers long, front the coast at a 30-60-km interval and form a buffer to wave attack, thus controlling the distribution of nearshore wave energy. A spectacular alongshore cycle of erosion and accretion results; in interbank areas, plunging breakers may impinge directly upon stands of mangroves at high tide, whereas in shoal, fluid-mud regions waves are virtually absent at the shoreline and coastal progradation proceeds rapidly. As a result of alongshore mudbank migration, this erosion/accretion system moves to the northwest at an average rate of 1.5 km/yr, suggesting that any given segment of coast has undergone many cycles of erosion and accretion during the last 5,000 yr (Augustinus, 1978).

Simultaneous measurements of wave height and period, fluid mud density variations, suspended-sediment concentration, and tide

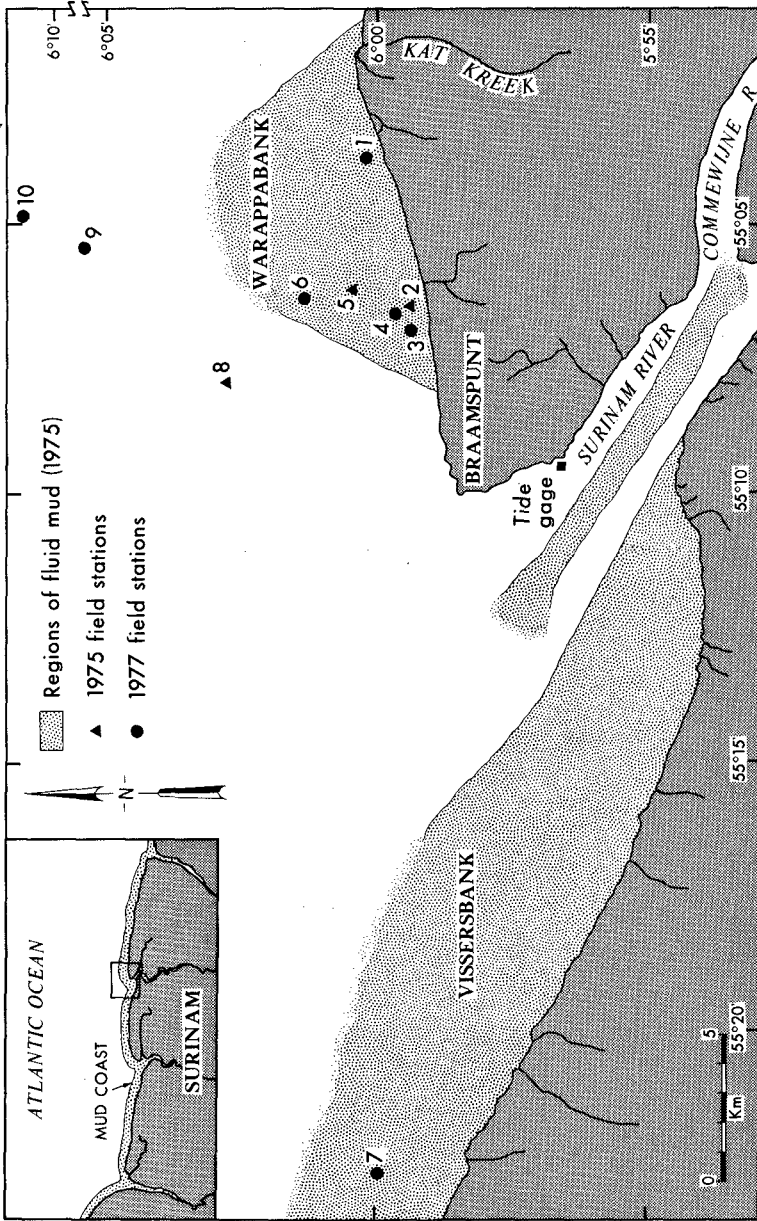

Figure 1. Index map of station locations.

elevation were made at field sites located over Warappabank and Vissersbank, regions where fluid mud up to 1.5 m thick blankets the bottom (stations 1-7, Fig. 1). Wave data were also taken farther offshore where substantial quantities (<0.1 m) of fluid mud are lacking (stations 8-10, Fig. 1). A moderate tide range (~3.2 m at spring tide), combined with a gentle offshore slope, leads to the exposure of a wide expanse of fluid mud at low tide (Fig. 2). Several of our field sites were located in these intertidal regions where water depths never exceeded 2 m (stations 1-3, Fig. 1). At other field sites water depths ranged from 1 to 10 m depending on the location and the stage of the tide.

Fluid mud is defined as a fine-grained sediment-water mixture in which the sediment concentration is greater than 1.0×10^4 mg/l (Krone, 1962). Where fluid mud is present the bottom is taken to be the upper surface of the fluid-mud layer, even though survey instruments may penetrate through this layer to more consolidated sediments (Odd and Owen, 1972). Properties of coastal fluid muds in the study area are given in Table 1.

Two Statham Model PA-506 Amplibrigde pressure transducers, fastened securely to an adjustable sleeve on pipe that was driven into the bottom, formed the sensing unit of the wave/fluid mud pressure (density) sensing device (Fig. 3). Pressure under a wave, less atmospheric pressure, is given by

$$P = \rho g (\eta K_z - z) \quad (1)$$

Figure 2. Prograding mudflat photographed at low tide, eastern Surinam coast.

Figure 3. Schematic of field setup for wave/fluid mud pressure-sensing device, showing typical arrangement of pressure transducers relative to fluid-mud layer.

where, in the linearized case,

$$\eta = \frac{H}{2} \cos\left(\frac{2\pi x}{L} - \frac{2\pi t}{T}\right) \quad (2)$$

and the pressure response factor, K_z , is given by

$$K_z = \left(\frac{\cosh [2\pi(z+h)/L]}{\cosh (2\pi h/L)}\right). \quad (3)$$

In equations (1) - (3), ρ = density of seawater, g = acceleration resulting from gravity, z = distance below still-water level, h = water depth, L = wave length, H = wave height, t = time, T = wave period, and x = horizontal distance. For shallow-water waves such as the tide, $h/L \ll 0.05$, $K_z \rightarrow 1$, and equation (1) reduces to

$$P = \rho g(\eta - z) = \rho g z' \quad (4)$$

where z' can be considered a depth below the time-varying surface. If pressure is measured simultaneously at two depths below the surface, z_A' and z_B' , then

$$P_B - P_A = \rho g (z_B' - z_A') \quad (5)$$

Table 1

and, provided that $z_B' - z_A'$ is constant with time, any variation in $P_B - P_A$ is directly proportional to a density variation.

For higher frequency gravity waves, say $T = 1-15$ sec, K_z becomes significant and density can be obtained from equation (5) only if K_z is known at depths z_A' and z_B' . From linear theory, K_z between pressure sensors ranges from 0.01 to 0.07 for wave frequencies encountered in this study. However, observational data indicate that values of K_z are not in perfect agreement with linear theory (Hom-ma et al., 1967; Tubman and Suhayda, 1977), and a correction factor m is usually applied to equation (1). In this study m ranges from 1.0 to 1.05. The determination of density variation from pressure variation is further complicated by the fact that attenuation rate is altered when one transducer is placed in a denser medium than the other, as depicted in Figure 3. Although these problems have been largely overcome by running field tests to determine differential attenuation in clear water and in fluid muds over a range of frequencies, an empirically determined differential density scale has been assigned in cases where $K_z < 1$.

Applying the above concepts in the field, $P_B - P_A$ is nulled out of each transducer electronically by a potentiometer located on the instrument panel (Fig. 4). Once this step is completed, any deviation from the zero null position is directly proportional to a density change. By using 10 or 20 sec time constant filters, high frequency noise is removed from the signal and, if desired, resolution of the signal can be increased up to 0.004 g/cm³.

In order to obtain useful time-series data, waves were recorded in real time from transducer A simultaneously with the filtered pressure differential between transducers A and B. All data were recorded as analog signals on strip chart recorder. The final step, conversion of differential pressure into absolute density units, required that sediment samples be taken between instrument sensors for initial calibration.

SHALLOW-WATER WAVES

Examination of approximately one hundred and fifty 20-min wave records, taken over all stages of the tide, indicates that waves undergo a severe shoaling transformation when propagating over a fluid-mud bottom. In addition to the rapid height attenua-

Figure 4. Wave/fluid mud pressure-sensing device (recorder not shown).

tion, described qualitatively in previous reports as a major factor in natural sea defenses (Delft Hydraulics Laboratory, 1962; NEDECO, 1968; Augustinus, 1978), waves are deformed from sinusoidal into solitary-like profiles, similar to that which can be observed in gentle swell just prior to breaking. Long, flat troughs separate sharp, isolated crests and, on days when local winds and associated sea chop are low, waves with periods of 15 sec can be recorded.

Information obtained from spectral analysis shows spectral peaks in the frequency range 0.07-0.25 Hz ($T = 15 - 4$ sec) and H_{rms} of 0.2-1.2 m for waves in water 1-5 m deep. Typical analog wave records and pressure spectra are given in Figure 5 for the consolidated interbank area (station 8), the soft mudbank area (station 5), and for solitary waves given by theory. Note the similarity in profile for waves recorded over a fluid-mud bottom and waves given by solitary wave theory. Wave spectra for solitary-like waves show a wide distribution of variance density with peaks often occurring at harmonic frequencies. Multiple peaks for true solitary waves occur exactly at harmonic frequencies. In interbank areas or farther offshore the spectra display a single well-defined peak in variance density.

In general the boundaries of a mudbank can be delineated simply by the appearance of surface waves (Moni, 1971; Nair, 1976). Height attenuation in the areas between mudbanks is substantially

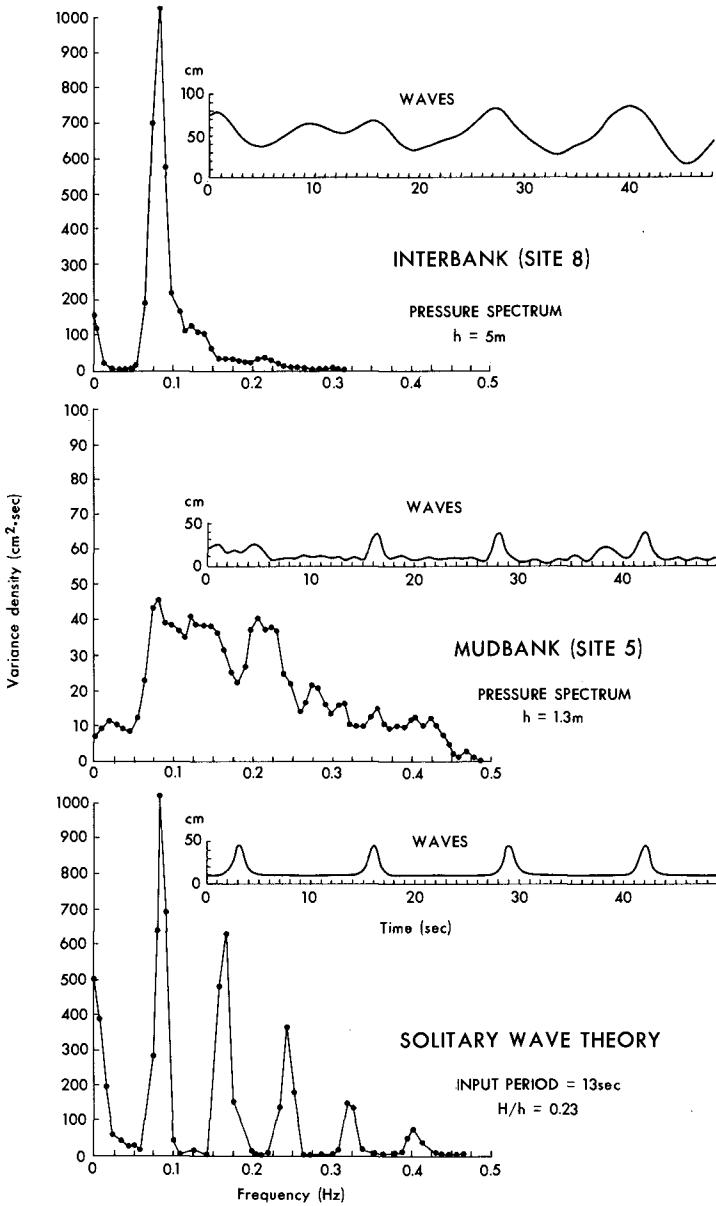

Figure 5. Typical wave records and pressure spectra from inter-bank area (consolidated bottom, site 8), mudbank area (fluid mud, site 5), and from solitary wave theory.

less and, for a given water depth, wave height may vary by as much as 100% from mudbank to interbank areas. The above generalizations become more complicated in the direction of propagation as waves encounter variations in thickness and density of fluid mud. Analysis currently underway suggests that wave height, period, and form are extremely sensitive to spatial and temporal variations in bottom consistency.

Three features of the solitary-like waves are important with respect to sediment transport. First, they maintain a nearly constant wave height to water depth ratio, $H_{rms}/h = 0.23$, a value that is considerably less than the 0.78 given as the limit of solitary wave theory. In a true solitary wave the volume of water transported is a function of H/h and higher ratios lead to greater transport rates. Second, although spilling breakers have been noted near the shoreline, solitary-like waves over a fluid mud bottom seldom break; rather, they decrease in height until they disappear at the shoreline, indicating that breaking waves and the conventional momentum flux approach to sediment transport problems may not be applicable. Third, waves become noticeably more like true solitary waves in appearance as sediment concentration in water increases. The most solitary-like waves have been observed from mid-tide to mid-tide during the lower half of the tidal cycle.

SEDIMENT SUSPENSION

In the broadest sense, shallow-water waves propagating over a soft muddy bottom maintain a large volume of sediment in suspension. Wells and Coleman (1977) have shown that suspensate concentrations in regions of fluid-mud bottom are orders of magnitude higher than in interbank areas and may attain surface-water values of several thousand milligrams per liter. Some spatial (depth) and temporal (stage of tide) variability also has been observed. Data from that study, combined with data obtained since publication of those results, are given in Table 2. Generally, inshore waters are more turbid than offshore and near-bottom are more turbid than surface waters.

Much of our information concerning suspension processes has been obtained by monitoring density variations in the upper 0.5 m of fluid mud. In general, variations in mud density can result from suspension or deposition, gain or loss of pore waters, and from advection of sediment past instrument sensors. By obtaining measurements over a range of fluid-mud densities (1.03 - 1.24 g/cm³) with sensors at several depths relative to the surface of the fluid-mud layer, we have been able to examine details of near-bottom processes in a variety of situations, from which generalizations have been made concerning sediment suspension.

Suspension of sediment by solitary-like waves takes place in two predominant frequency modes: tide-related suspension (~12.4 hr) and wave-by-wave suspension (~10 sec). In mud with a bulk density less than 1.20 g/cm³ and with water depths less than 5 m, an exchange process between the fluid mud and overlying water operates at the tidal frequency. Data from several field sites (stations 2, 3, and 5) indicate that on a falling tide, near mid-tide level, 10-50 cm of fluid mud is dispersed into water. This

Table 2
Maximum and Minimum Surface Suspended-sediment Concentration,
Coast of Surinam

Field Site	Range in Water Depth (m)	Concentration (10^2 mg/l)	
		Maximum	Minimum
1	0.0- 2.0	3.33	0.21

10	9.0-11.5	No	data taken

*Sampled from surface of fluid mud exposed at low tide.

NOTE: A total of 183 samples was collected. A least squares best fit to all data indicates that concentration varies with height (m) above the bottom, y , as $c = 5.31 e^{-1.80 y}$, where c is in milligrams per cubic meter. Coefficient of determination, r^2 , is 0.38 ($P < 0.001$).

dispersion is concurrent with the time that waves initially change to the pronounced solitary-like wave profile. Suspended-sediment concentrations increase rapidly and coastal waters become noticeably more turbid. Maximum concentrations of suspended sediment occur at or near low water. On a rising tide concentrations decrease and fluid mud is, presumably, redeposited during the period between mid-tide and high water.

In muds where bulk density exceeds 1.20 g/cm^3 , such as inter-bank areas or the more consolidated eastern edges of mudbanks, less than 1 cm of the bottom is suspended by incoming waves (this value assumes that mass of sediment dispersed into the water reflects the volume of known density removed from the bottom).

Figure 6 shows results of a 3-hr experiment beginning at low tide on an intertidal flat composed of fluid mud with initial density of 1.16 g/cm^3 . Five time-series sections, each approximately 20 min, show that bulk density decreased from approximately 1.16 to 1.05 g/cm^3 as water level rose and incoming waves suspended the fluid mud. Figure 7 shows diagrammatically the suspension process. At the termination of this experiment nearly 50 cm of fluid mud had been suspended. The considerable variation in bulk density of fluid mud prior to the first impingement of waves (Fig. 6, sections A and B) was the result of interstitial pressure waves from offshore which, in low density muds, generally precede

Figure 6. Time series of bulk density variations in upper 0.5 m of fluid mud, beginning at low tide, 8 October 1975. Numbers above each time-series section are surface suspended-sediment concentrations.

Figure 7. Suspension of Fluid mud by solitary-like waves.

the arrival of surface waves.

The relatively stable wave height to water depth ratio, $H_{rms}/h = 0.23$, may be partly a result of adjustment of the bottom to the amplitude of incoming waves. On days when stronger winds from the northeast produced local waves that were larger than the solitary-like swell waves, suspended-sediment concentrations increased rapidly. Thus, at a given stage of the tide, higher waves suspended more sediment. An example of this process is given in Figure 8. Following a wind shift from southeast to northeast (1200 hr), waves increased in height rapidly and suspended sediment concentration increased by an order of magnitude as fluid mud was suspended at field site #6. The suspension of mud from the bottom was manifested as an overall decrease in bulk density between 1200 and 1400 hr. Field site #9, farther offshore over a relatively consolidated bottom, was unaffected.

Wave-by-wave suspension, often superimposed on the longer term processes described above, is shown in four sections of time series data in Figure 9. As each wave crest passed instrument sensors differential density rose rapidly, then fell gradually; the process repeated when the following wave arrived. The initial explanation of these density variations (Wells, 1977) hypothesized that a cloud of sediment was instantly suspended, followed by rapid settling of this densely flocculated sediment. Based on previous laboratory and field results (Partheniades, 1971; Krone, 1972), it is difficult to explain such rapid settling, which in this case would require that the center of mass settle at 10 cm/sec. In light of the apparent nonlinear properties of waves, a more plausible explanation may be the advection of this sediment cloud past the sensors. Theoretical bottom particle velocities under solitary waves exceed 100 cm/sec for the range of wave heights observed in this study. The persistence of high-frequency

Figure 8. Surface suspended-sediment concentration and fluid-mud density variations, 20 August 1977.

suspension and transport by waves results in temporary or even permanent removal of fluid mud from the bottom. During 3.5 hr of observation (Fig. 9) average density in the upper 0.25 m of fluid mud decreased by 0.04 g/cm^3 , an amount that could be achieved only by the removal of 10 cm of fluid mud from the bottom. The possible fate of this suspended fluid mud will be discussed in the next section.

MUD TRANSPORT

Recent estimates of sediment transport along the mud coast of northeastern South America indicate that approximately 20-40% of the total sediment load from the Amazon River makes its way northward along the coastlines of French Guiana, Surinam, and Guyana (Eisma and van der Marcel, 1971), resulting in one of the highest littoral transport rates in the world. Approximately $150 \times 10^6 \text{ m}^3/\text{yr}$ of "through transport" takes place in the form of suspended sediment, and another $100 \times 10^6 \text{ m}^3/\text{yr}$ moves as a result of the propagation of coastal mudbanks to the northwest (summarized from Delft Hydraulics Laboratory, 1962; Gibbs, 1967; Allersma, 1968; NEDECO, 1968; and Eisma and van der Marcel, 1971). Previous investigators have generally attributed these exceedingly high longshore transport rates to suspension of mud by wave orbital

Figure 9. Variations in near-bottom fluid-mud density. Recorded during the passage of waves from HW + 4.5 hr to LW + 2 hr, 26 September 1975. The attenuation of high-frequency signals (less than 100 sec) resulting from a 20-sec time-constant filter requires that a separate scale be used for wave-by-wave variations.

scour, followed by transport to the northwest by the Guiana Current.

The finding in this study that suspensate concentrations are highest in fluid-mud regions where solitary-like waves occur, combined with the fact that 93% of sea and swell arrive at the coastline between N30°E and east (NEDECO, 1968), suggests that a tremendous potential exists for sediment transport by waves acting alone. In theory a solitary wave is a wave of translation whereby water particles move only in the direction of wave travel. Laboratory studies on solitary waves have shown that if wave profile is similar to that given by theory, then particle trajectories are unidirectional and each wave clearly produces a mass transport (Daily and Stephen, 1953). Numerous observations in this and other field studies (for instance, Inman et al., 1963) have provided qualitative verification that particle velocity is greater in the onshore than in the offshore direction for solitary-like waves. In the following paragraphs a simple model for explaining sediment transport, based on results of this study and above-mentioned rationale, is examined.

Consider mass transport of suspended sediment, as applied to surf zone problems, to be given by

$$T_M = \iint_A c V \sin \alpha \, dA \quad (6)$$

where $dA = dx dy$, c = suspended-sediment concentration, V = current velocity, and α = angle of wave approach.

Cross-sectional area through which transport takes place (Fig. 10a, b) varies with water elevation, h , and is given by

$$A_i = \int_0^{x_i} h \, dx \quad (7)$$

where horizontal distance, x_i , is determined by h and offshore slope is given by β . As a simplification, regional variations in water depth that result from fluid-mud suspension and deposition processes (as discussed in the last section) are ignored.

The most justifiable estimate for suspended-sediment concentration is given by the least squares best fit to all suspended-sediment data

$$c = 5.31 e^{-1.80 y} \quad (8)$$

where c is concentration in kilograms per cubic meter and applies to any location offshore, y is height above the bottom in meters, and $0 \leq y \leq h = 5$ m.

Assuming pure solitary waves, total volume of a wave per unit crest length above still water level can be obtained as

$$Q = 2 \int_0^{\infty} \eta \, dx \quad (9)$$

where

$$\eta = H \operatorname{sech}^2 \left[\sqrt{\frac{3}{4}} \frac{H}{h^3} (x - Ct) \right] \quad (10)$$

and H = wave height, C = wave speed, and t = time. Substituting equation (10) into equation (9) and integrating, Munk (1949) gives

$$Q = 4h^2 \sqrt{\frac{1}{3}} \frac{H}{h} \quad (11)$$

which, averaged over one wave period from the surface to the bottom, gives

$$\bar{v} = \frac{Q}{hT} = \frac{4h(1/3 H/h)^{1/2}}{T} \quad (12)$$

as volume transport rate. Investigation of analytical solutions indicates that there is little velocity shear in the vertical, thus a uniform surface to bottom transport rate is reasonable.

Mass transport, averaged over a wave period, now becomes

$$T_M = \sin \alpha \int_X \bar{v} \int_0^{h(x,t)} c \, dy \, dx \quad (13)$$

Average mass transport over a tidal cycle

$$\langle T_M \rangle = \frac{1}{T} \int_0^T \sin \alpha \int_X \bar{v} \int_0^{h(x,t)} c \, dy \, dx \, dt \quad (14)$$

can now be approximated through numerical integration by taking a 2-min time step, an average tide range of 2.5 m, and a water elevation (depth in meters) to be given as

$$h = 3.75 + 1.25 \cos \omega \quad (15)$$

where $\omega = 2\pi t/T$.

Finally, if bulk density of the transported mass, including pore space of static grains, is known or assumed, then volume transport is found by dividing by sediment concentration at that density

$$T_v = \frac{T_M}{\rho_c} \quad (16)$$

This allows mass transport values to be converted into units of volume transport that are useful in assessing coastal accretion or erosion.

Volume transport in cubic meters per year is plotted as a function of wave period for angles of wave approach from 6° to 12° ,

taking $H/h = 0.23$, $\rho_c = 375 \text{ kg/m}^3$ ($\rho = 1.25 \text{ g/cm}^3$), and $\beta = 0.001$ (Fig. 11). Only transport during one-half of the tidal cycle, that half extending from mid-tide through low water to the following mid-tide, has been considered since this is the time that the most solitary-like waves are observed.

The range in transport spans roughly from 15 to $65 \times 10^6 \text{ m}^3/\text{yr}$. Higher angles of wave approach lead to higher transport rates, as do shorter wave periods (more pulses of water per unit of time). Values for H/h , ρ_c , and β have been determined from field data and any realistic variations in these parameters will produce small changes in transport values.

Longshore transport rate is most sensitive to horizontal and vertical variations in suspended sediment. Unfortunately, processes controlling the distribution of suspended sediments are more complex and varied than presented here. Thirty-eight percent of the variability in suspended-sediment concentration ($P < 0.001$) can be explained by water depth, leaving 62% to be explained by such factors as local wind-generated waves and density and thickness of the fluid-mud layer. However, inasmuch as most studies of this nature (Galvin, 1973; Komar, 1976) take an average concentration for the entire surf and breaker zone, equation (8) provides an equally good or better estimate.

Values reported in Figure 11 at first appear considerably lower than littoral transport estimates for the coast of northeastern South America, leading one to believe that, even if waves are indeed solitary, only one-quarter or less of the transport can be explained by this mechanism. However, close examination indicates that the total estimated sediment transport rate, cited by previous investigators as $250 \times 10^6 \text{ m}^3/\text{yr}$, has been determined for a 30-km-wide band extending offshore. If one-sixth of this volume moves alongshore in a band that is only 5 km wide, the width of the hypothetical mudbank in Figure 10a, then the rate becomes $42 \times 10^6 \text{ m}^3/\text{yr}$ and a remarkable similarity can be seen.

Several simplifications that require qualitative evaluation have been introduced into these transport calculations. First, the shoreward component of net drift assumes a return flow to satisfy continuity considerations. If return flow is taken perpendicular to the coastline in the area between mudbanks (Fig. 10a), then longshore transport may be unaffected. This is a logical pattern of onshore/offshore transport since solitary-like waves, which break only by spilling, produce a greater setup over mudbanks than do plunging breakers in areas between mudbanks. In support of this concept, Sonu (1972) has shown that, on the west coast of Florida, wave-induced currents move shoreward over shoals where waves break by spilling and a return flow occurs in troughs where waves break by plunging.

Second, the transport model considers only that transport which occurs in regions of fluid mud, yet assumes that these rates reflect transport in interbank areas as well. This results in an overestimation, even though some transport may take place in interbank areas as a result of an oblique wave approach or by longshore currents produced by breaking waves through the concept

Figure 10a. Plan view of idealized mudbank used in transport calculations. Dashed lines represent longshore component of wave drift.

Figure 10b. Cross section along line A-A' (Fig. 10a). Maximum area coincides with high tide when $h = 5$ m and $x = 5$ km.

of radiation stress, as normally applied to sandy coasts (Komar, 1976, p. 190). Moreover, all waves over mudbanks are not solitary and probably do not have particle velocities of true solitary waves. Thus, the longshore volume transport rate given in Figure 11 should be considered as an upper bound for that which can be explained by solitary-like waves.

Third, large-scale circulation patterns along this coast are unknown and have been neglected. Such circulation patterns may

Figure 11. Longshore volume transport as a function of wave period.

provide avenues for moving sediment both onshore and offshore.

Despite the simplifications and unknown processes, the basic conjecture remains that if waves in high suspended-sediment regions have hydromechanical properties of true solitary waves, then sediment transport by waves alone needs to be considered as an explanation for high volume transport rates. The fact that the littoral zone has been taken in this study to extend 5 km offshore, rather than a few meters or a few hundreds of meters, is responsible for longshore sediment transport rates that are orders of magnitude higher than those reported for sandy environments. These estimates, taken across the entire zone in which waves appear to be solitary, may be more realistic than estimates along sandy coasts where only that volume moved by waves in the swash zone is considered.

Finally, we believe the idea presented in this paper, namely

that solitary waves can suspend and transport large volumes of fine-grained sediment without utilizing breaking waves, the concept of radiation stress and a nearshore circulation cell or sediment moving as bed load should be vigorously checked along the world's muddy coastlines. A logical next step would be to take field measurements for determination and verification of orbital speeds under solitary-like waves.

ACKNOWLEDGMENTS

This research was performed under a contract between the Geography Programs, Office of Naval Research, Arlington, Virginia 22217, and the Coastal Studies Institute, Louisiana State University, Baton Rouge. Cooperation and field support were provided by Drs. R. A. Cambridge, E. H. Dahlberg, and Th. E. Wong, Government Service for Mining and Geology, Ministry of Development, and Mr. A. M. Suttmuller and his staff, Hydraulic Research Division, Ministry of Public Works and Traffic, Paramaribo, Surinam. Technical assistance in the field was provided by Mr. R. G. Fredericks, and Mrs. A. F. Dunn prepared the illustrations. Drs. S. P. Murray and E. H. Owens reviewed the manuscript and offered helpful suggestions.

CHAPTER 118

HYDRODYNAMICS AND SEDIMENT TRANSPORT IN A SALT MARSH TIDAL CHANNEL

Larry G. Ward
Coastal Research Division
Department of Geology
University of South Carolina
Columbia, South Carolina 29208

ABSTRACT

Processes and sediment transport were investigated in a salt marsh drainage system at Kiawah Island, South Carolina. A general survey of the tidal current was done in the major tidal channel (Bass Creek) for a 10 tidal cycle period in August, 1977. Detailed determinations of current velocity, discharge, and suspended load were conducted during 15 tidal cycles in March, 1977 and again during 8 tidal cycles in July-August, 1977. For each of these periods, mass budget for the total suspended load were computed.

The tidal currents have a pronounced time velocity asymmetry with the maximum current velocity occurring nearer high slack water and the peak ebb velocity being 20 - 30% stronger than the flood. Suspended load transport is significantly affected by the time velocity asymmetry. Peak current occurring nearer high slack water causes a net displacement of suspended material in an ebb or seaward direction under normal conditions. This process is enhanced by the stronger ebb currents. Mass budgets reflect the ebb dominance of the system showing a net export of combustible (organic) material during the March sampling period and a net export of both noncombustible (inorganic) and combustible material during the July-August period. Also important to suspended load transport in marsh systems are stressed meteorological conditions. High winds or heavy rains increase suspended load concentration and can cause significant import or export of fine-grained material.

INTRODUCTION

The physical and sedimentological processes occurring in a salt marsh tidal channel system were studied at Kiawah Island, South Carolina (Fig. 1). The purpose of the investigation was to monitor hydrodynamic processes and determine their effect on suspended material transport. Therefore, the tides, currents, and suspended load were monitored within the tidal channel system, and mass budgets for the total suspended load computed.

Physical Setting

Study area. - The investigation was conducted in a small marsh system (5 km²) on the northeastern end of Kiawah Island (Fig. 2). The marsh is enclosed on three sides by Holocene beach ridges (Hayes,

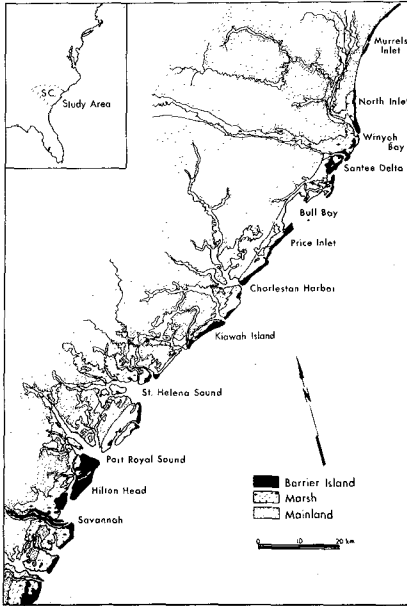

Figure 1. Location map of Kiawah Island, South Carolina.

1975) which isolates it from any other major drainage system. One main tidal channel, Bass Creek, and its small tributaries, form the entire drainage network. The Bass Creek marsh system was chosen because it is unpolluted, essentially undisturbed by man, has no fresh water influx and has a simplified drainage system.

The primary marsh vegetation is Spartina alterniflora with Salicornia ambigua and Borrchia frutescens found at higher elevations. The marsh is composed of silt and clay-sized sediments (kaolinite and illite) except adjacent to abandoned beach ridges which have a high quartz sand content. Underlying the marsh sediments are fine-grained cohesive tidal flat sediments that have abundant oyster shell (Crassostrea virginica) deposits. The tidal channels normally have beds composed of fine sands, and the banks are composed of silts and clays. The channels are relatively unstable, showing numerous abandoned channels (cutoffs, oxbows, etc.). Channel migrations of up to 75 m in 24 years have occurred at locations where the channels have eroded into abandoned beach ridges (Ward and Domeracki, 1978).

Climate. - Kiawah Island has a marine subtropical climate modified by the Atlantic Ocean (Kjerfve, 1975). The monthly average temperatures for the period from 1935-1974 range from 10.2°C in January to 27.5°C in July with a mean of 18.9°C (Fig. 3). The average precipitation ranges from 6 cm in November to 18 cm in July, totaling 124 cm per year (data obtained from the National Weather Service).

Kiawah's climate is greatly influenced by frontal systems moving across the United States in an eastward direction (Kjerfve, 1975). During the winter months, when polar air masses traverse portions of the southeast, cold fronts produce west and northwest winds of considerable velocity. During the summer months, the Bermuda High creates anti-cyclonic circulation off the South Carolina coast causing southerly winds. The dominant winds are associated with the passage of low pressure systems or northeast storms.

The weather conditions that most affect marsh and tidal channel processes (observed in this study) are the occurrence of frequent afternoon and evening thundershowers. During the late spring and summer, severe thundershowers occur on a regular basis. During a single storm, several inches of rainfall and winds of over 50 km/hr may occur.

Tides. - The tides at Bass Creek are semi-diurnal with a strong diurnal component. The mean tidal range for 28 weeks of tidal data measured within Bass Creek is 1.75 meters. Two week averages vary from 1.54 to 1.92 meters. Individual tidal cycles have ranges from a maximum of 2.40 meters during spring tides to 0.84 meters during neap tides.

CHARLESTON HARBOR 1935 - 1974

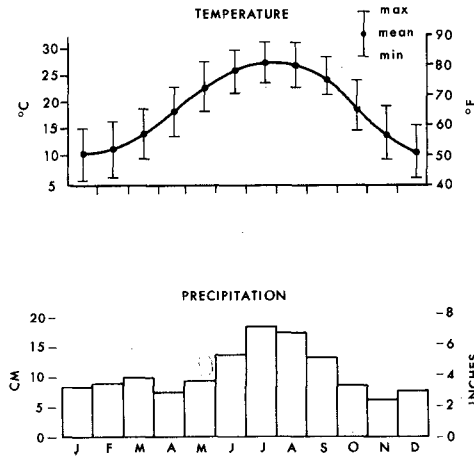

Figure 3. Average monthly temperatures and precipitation for Charleston Harbor, South Carolina, from 1935-1974.

Figure 4. Seasonal fluctuations in water levels for Bass Creek and Charleston Harbor. Mean water levels for Bass Creek were determined by averaging hourly readings during two week periods. MSL is the mean water level at Bass Creek for 1976-1977. The curve for Charleston Harbor is from Hicks and Crosby (1974).

The mean water level, determined for 14 two-week periods by averaging $\frac{1}{2}$ hour water level readings, shows a yearly variation of 22 cm (Fig. 4). The highest mean water level occurs during the late summer and early fall; while the minimum values occur during mid-winter. Similar trends have been reported by Humphries (1977) and Kjerfve, *et al.* (in press) for tidal creeks at North Inlet and by Hicks and Crosby (1974) for Charleston Harbor, South Carolina. The fluctuations in mean water level have been attributed to steric sea level changes (Patullo, *et al.*, 1955).

During periods when the mean water level is at a maximum, the height and consequently the duration to which the marsh surface is flooded increases (as illustrated by the two-week averages for mean high water levels in Figure 4). Kjerfve, *et al.* (in press) found that due to higher autumn water levels at North Inlet, South Carolina, the marsh surface is inundated 42% of the time in October compared to 27% of the time in January. The length of time the marsh surface is covered is important to both depositional processes and nutrient exchanges. The marsh vegetation acts as a baffle, increasing sedimentation rates while it is covered with water. In addition, the marsh surface is the primary source of decaying vegetation. Increased flooding facilitates the removal of this material into the estuarine system where it can be utilized by the aquatic food chain.

Previous Studies

Physical and sedimentological processes in salt marsh tidal channels have been studied by a number of investigators trying to determine the flux of suspended material and dissolved substances. An excellent review of many of these articles is given by Frey and Basan (1978). Probably the most precise study was conducted by Boon (1973) in a marsh tidal creek in Virginia. The results of his work indicate that small low order tidal channels act as conduits, transporting both inorganic and organic particulate matter in a seaward (ebb) direction. His conclusions were based on sediment flux measurements done at a single channel cross section. Settlemyre and Gardner (1975) computed mass budgets for a larger tidal channel in an enclosed marsh in Charleston Harbor, South Carolina. Their results, contrary to Boon's, show an influx of inorganic particulate matter and an export of organic particulate matter. Hackney (1977), working in a marsh tidal channel in Mississippi, found an import of both organic and inorganic material during the summer and an export of both during the winter. Odum and de la Cruz (1967) computed mass budgets for organic detritus and found that it was exported from a Georgia salt marsh during all seasons.

A number of studies pertinent to understanding the processes in salt marsh tidal channels have been conducted on tidal flats. Some of

the earlier investigations were done in the Dutch and German North Sea by Van Straaten and Kuenen (1957), Van Straaten (1961), Postma (1967) and Groen (1967). The results of these investigations indicate a landward increase in the fine-grained suspended material concentrations in tidal channels due to a "settling lag" and "scouring lag" effect. Coupled with this is a tidal current asymmetry, with the peak flood and ebb velocities occurring nearer low slack water. The effect of this asymmetry is that suspended material can be transported for a longer period on flood than ebb tides. Therefore, over a number of tidal cycles, there is a net landward displacement of the suspended load. They argued that, under normal conditions, this would cause a build-up of fine-grained material toward land with the North Sea being the source. Pestrong (1972a, 1972b) studied tidal flats and salt marshes in the San Francisco Bay area. His work suggests that tidal flats are overgrown by salt marshes by eroding sediment from the head of the marsh and flushing it seaward by ebb flow. Thus, the growth of the marsh onto the tidal flat is partially cannibalistic. Anderson (1972) has shown the importance of wave activity on the tidal flats in New Hampshire. At this location, it was illustrated that even small amplitude waves resuspend significant amounts of fine-grained sediment.

PROCESSES AND SEDIMENT TRANSPORT

Tidal Currents

Methods. - The current was monitored for a 10 tidal cycle period in August, 1977 at three locations within Bass Creek ranging from the mouth to a position 4 km in the flood direction (Fig. 2). At each location, a General Oceanics current meter was moored near the bottom (less than 1 meter) at mid-channel. Velocity and direction readings were taken at approximately 4 minute intervals for the 10 tidal cycle period.

Results. - The current velocity at all three locations has a pronounced time asymmetry (Fig. 5). Maximum current velocity normally occurs 1 to 3 hours before and 1 to 2 hours after high slack water. The current velocity at the two stations in Bass Creek away from the mouth also has a velocity asymmetry with the ebb current being much stronger than the flood. The average ratios of the maximum flood velocity (F max) to maximum ebb velocity (E max) at the two stations located 2 km and 4 km away from the mouth are 0.64 and 0.68 respectively for the 10 tidal cycles monitored. The station located in the mouth of Bass Creek shows no velocity asymmetry, having an average F max/E max ratio of 0.98.

In addition to the time velocity asymmetry of the currents, there is an asymmetry or difference in the duration of the flood and ebb flow. Inspection of Figure 5 shows that the flood currents normally occur for over $6\frac{1}{2}$ hours, while the ebb currents flow for less than 6 hours. This

difference in duration is further verified in the 28 weeks of tide data analyzed in Bass Creek. The average duration of the flood component of the tide is 6.54 hours; while the average duration of the ebb is 5.69 hours. It should be pointed out that only half-hour readings were taken from the tidal records and used to compute these averages. Therefore, there may be some error. To determine the reliability of these figures, a number of tidal cycles were measured directly to obtain accurate flood and ebb durations. The results indicate that there is a large amount of variability in the duration of individual cycles, but the averages compare well to the 2-week averages (within 0.1 - 0.2 hours). Similar duration asymmetries in tidal inlets and marsh channels have been reported by Boon (1973), FitzGerald, et al., (1976), and Nummedal and Humphries (1978), and were attributed to distortion of the tidal wave and the formation of overtides. Nummedal further pointed out that if the flood and ebb discharges are similar, then because of the shorter duration, the ebb velocities would have to be higher than the flood to transport the same volume of water in a shorter period. This process contributes to the velocity asymmetry of the current.

Suspended Load Transport and Mass Budgets

Method. - The current, discharge, and suspended load were monitored during 23 tidal cycles in Bass Creek at a location that transmitted the entire tidal prism to an isolated area of the marsh (Fig. 2). The first sampling session was conducted in March, 1977, during which 15 out of 18 consecutive cycles were monitored. The other 8 tidal cycles were monitored during July-August, 1977. These two periods were chosen because March is representative of winter conditions in the southeastern United States, having minimum temperatures and precipitation (Fig. 3); while July-August represents summer conditions having maximum temperatures and precipitation.

Prior to these sampling sessions, preliminary surveys were done to assess the accuracy at which the mean current, discharge, and suspended load could be determined. This information was then used to determine the experimental error involved in computing the instantaneous and total flux of suspended material over a flood or ebb portion of a tidal cycle. It was found that the mean current could be estimated within $\pm 4.2\%$ to $\pm 8.5\%$ and the suspended load within $\pm 6.3\%$, if measurements were made at $1/5$, $1/2$, and $4/5$ the distance across the channel and at 0.2 and 0.8 the relative depth at each location (Figs. 6 and 7). The error involved in computing the instantaneous flux is the combined error for the current and suspended load or approximately ± 7.6 to $\pm 10.6\%$ (Ward, 1978). The error for determining the total flux of suspended material over a flood or ebb portion of a tidal cycle is slightly less (Boon, 1973). Therefore, any net or residual flux of material

INSTRUMENT ARRAY

Figure 6. Schematic of the instrument array. The channel was approximately 50 meters wide, and the instrument frames were located $1/5$, $1/2$ and $4/5$ the distance across the channel. The current meters and intakes for the water pumping system were able to rotate freely and were always aligned into the current. The current velocity, temperature, and salinity readings were taken inside a tent located on the platform. The water samples were taken at the out-flow valves of the pumping system also located on the platform.

INSTRUMENT FRAME

Figure 7. Schematic of the instrument frame. The base was augered into the channel and a float attached to the top. A hinge allowed the frame to raise and lower with changes in tidal height, keeping instruments at 0.2 and 0.8 of the total depth at all stages of the tide.

greater than $\pm 10\%$ for the mass budget is considered to be significant and not the result of sampling errors.

Results. - The suspended load concentrations during the March sampling session are normally between 10 - 20 mg/l except during periods of high wind or heavy rain when concentration exceed 50 mg/l. During the July-August sampling session, the total suspended loads range from 20 - 200 mg/l, but are normally between 50 - 100 mg/l. The organic fractions range from 0 to 70% but have a mode at about 20%.

Time series data of the suspended load and current for the first two tidal cycles monitored during the July-August session illustrates the relationship between highest sediment transport and maximum current velocity (Fig. 8). During the first tidal cycle, highest suspended load concentrations during flood tide occur simultaneously with the strongest current. The suspended load concentration is over 160 mg/l, but drops to about 30 mg/l as high slack water approaches, and the coarser material settles out. After the ebb current reaches a maximum, the suspended load increases to 160 mg/l again.

Mass budgets of the suspended load for the tidal cycles monitored in March are shown in Figure 9. The first 6 cycles (TC1-6) are during spring tides, 7-10 during mean, and 13-18 during neap tides. In general, the spring tides are much more dynamic than neap tides in respect to sediment transport. Fluxes for the total suspended load are normally greater than 5×10^6 grams for any half cycles during the spring tides, while neap tide fluxes are normally closer to 1.0×10^6 grams. These higher transport rates result from greater discharges and stronger currents that occur during spring tides.

The flux of material for tidal cycles 1-6 was summed in order to determine the net movement of material for that period. The net mass budget for the 6 cycle periods shows an export of 2.3×10^6 grams or about 5% of the total suspended load flux. Results of the error analysis indicate that fluxes this low are not reliable, as they may be accounted for by experimental error. Therefore, the budget is considered to be in balance. Inspection of the components of the total suspended load indicates there is also a balance of the non-combustibles (inorganic) fraction, but an export or ebb-directed net flux of 1.5×10^6 grams of combustibles (organics) fraction. The net export of combustibles accounts for a residual transport of approximately 16% which is considered reliable.

The effects of the meteorological conditions on suspended load transport become evident when individual tidal cycles are inspected. During cycles 1-4, when there were only light winds and no rainfall, the mass budgets reflect the movement of material due to the large tidal prisms associated with spring tides. As the tidal range and tidal

Figure 8. Time series profiles of the mean suspended load and current velocity in Bass Creek during the July, 1977 session. Note that the maximum suspended load concentrations occur with peak current velocity. Also note the time velocity asymmetry of the current.

Figure 9. Mass budgets for the suspended load in Bass Creek during March, 1977. Tidal cycles 1-6 were during spring tides while 13-18 were during neap tides. Hatched columns represent the flood fluxes; open columns represent ebb fluxes.

Figure 10. Wind velocity and directions for Charleston Harbor, South Carolina. The times that correspond to the tidal cycles monitored are labelled TC1-18. Note the strong gusting winds from the north-east during TC-9.

prism decrease, sediment transport reduces. During tidal cycle 5, winds gusting to 40 km/hr from the northeast and east (Fig. 10) caused a slight set-up in the tidal height and an increase in wave activity within the tidal channels. The wave activity eroded material from the channel margin, increasing the total suspended load and the mass budgets. During the following tidal cycle, the winds remained strong, but began blowing from the south. The marsh system is orientated such that winds from the northeast are most effective in increasing the wave activity and causing a set-up in the tides. Winds from other directions seem to have only a minor effect on marsh processes; therefore, the sediment flux for tidal cycle 6 is markedly reduced.

The relationship between meteorological conditions and sedimentary processes is again demonstrated during tidal cycle 9. During the ebb portion of tidal cycle 8, the wind began to blow consistently from the northeast at about 25 km/h. During the flood portion of tidal cycle 9, the winds remained from the northeast, but increased in velocity reaching nearly 50 km/h. This caused a water level nearly 40 cm higher than would normally be expected and a flood duration of over 7 hours. These increases resulted in the water elevation being abnormally higher than the ocean level which produced an abnormally steep hydraulic slope. When the tide turned, the increase in the hydraulic slope created currents of over 75 cm/sec which were greater than those measured during maximum spring tides. Due to the set-up, wave activity, and high ebb currents resulting from the northeast winds, much more material was transported than in any of the previous cycles. Over 10.6×10^6 grams and 16.9×10^6 grams were transported on the flood and ebb respectively.

Mass budgets for the summer show similar trends as the March budgets except for the quantity of material being transported (Fig. 11). During the winter sampling period, the maximum amount of material transported over any $\frac{1}{2}$ tidal cycle past the channel cross-section is 20×10^6 grams. During the summer sampling period, the maximum value reaches 87×10^6 grams. This dramatic increase may be attributed to three factors. Steric sea level is at a maximum which would conceivably increase the tidal prisms (Fig. 4). Second, the warmer water temperatures may reduce the cohesiveness of the fine-grained material, making it more erodable. Finally, there is an increase in biologic activity during the summer. Observations in the field show that the activity of the fiddler crab (*Uca pugnax*) and other organisms is greatly increased. This, in addition to the increase in the floral growth, increases the turbidity and suspended load and, consequently, the mass budgets. In all probability, it is a combination of these factors.

The net flux of material for the five tidal cycles monitored during the spring tides (TCL-5; Fig. 11) indicate that there is an export of both the combustible and noncombustible fractions of the suspended load. A residual of approximately 40.7×10^6 grams (35%) of noncombustible and 2.9×10^6 grams (10%) of combustible material was exported.

Figure 11. Mass budgets for the suspended load in Bass Creek during July-August, 1977. Tidal cycles 1-5 were during spring tides while 6-8 were during neap tides. Hatched columns represent flood fluxes; open columns represent ebb fluxes.

Figure 12. Representative current profiles from tidal channels and tidal flats in the Wadden Sea (Postma, 1967) and the marsh channel at Bass Creek, South Carolina. Note the shifting of peak current velocity from being asymmetric toward low slack water in the Wadden Sea to high slack water in Bass Creek.

Discussion

The time velocity asymmetry strongly affects the movement of sediment within tidal channels and ultimately controls the flux of particulate matter under normal meteorological conditions. As illustrated in Figure 8, the strongest current occurs 1-2 hours before and 2-3 hours after high slack water, and the maximum ebb current velocity can be between 50 to 100% stronger than the flood. The net effect of the time asymmetry is that a parcel of water can be transported at maximum velocity only 1-2 hours during the flood. Conversely, the same parcel of water can be transported up to 3-4 hours on the ebb tide. Consequently, even without the maximum currents being unequal, the water parcel undergoes a net seaward or ebb-directed displacement. This effect is further enhanced by the stronger ebb currents. The suspended load reaches a peak simultaneously with the current and therefore would be displaced in a similar manner as a water parcel. Thus, the time velocity asymmetry causes a net movement of material seaward. This same relationship, but, in reverse, is used along with "settling and scouring lag" to explain a net landward transport of suspended material in the Wadden Sea (Van Straaten and Kuenen, 1957; Postma, 1967; Groen, 1967). Data published by Postma (1967) shown in Figure 12 illustrates the time velocity asymmetry measured in the Wadden Sea. The maximum current velocity occurs near low slack water causing a net displacement of water and suspended material landward. If the period of maximum current is shifted toward high slack water as in the southeastern United States, then there is a seaward flux of material.

CONCLUSIONS

This study of the physical and sedimentological processes in the Bass Creek salt marsh tidal channel system illustrates the complex relationship between the tidal regime and, consequently the tidal currents, the meteorological conditions, the biologic activity, and the transport and deposition of sediment. The major findings of this study based on the two extended sampling periods and the general monitoring of the tides and currents at Bass Creek, S. C. are:

1. Sediment transport varies nearly an order of magnitude from the high transport period of the summer to the low transport period of the winter. This variation is primarily attributed to steric sea level fluctuation and changes in biologic activity.
2. Sediment transport varies a great deal from tidal cycle to tidal cycle under normal conditions due to changes in tidal prisms or discharge.
3. There is a net export of combustible (organic) suspended material during both the summer and winter in the marsh tidal channel.

4. There is an export of noncombustible (inorganic) suspended material during the summer and a balance during the winter.
5. The net export of material under normal conditions can be attributed to the time velocity asymmetry of the currents.
6. Stressed meteorological events (such as heavy rains or strong winds) increase sediment transport in marshes dramatically.

ACKNOWLEDGEMENTS

Financial support for this study was given by the South Carolina Wildlife and Marine Resources Department and by a National Science Foundation Doctoral Dissertation grant. Exceptional field and laboratory assistance was given by John Barwis, Daniel Domeracki, Michael Waddell, Chris Ruby, Stephanie Ward, Mary Ann Capria, and Ian Fischer. The drafting was done by Nannette Muzzy, and the final text typed by Priscilla Ridgell. I would also like to acknowledge Frank Stapor for the use of the General Oceanic current meters and the Kiawah Island Company for access to their property.

CHAPTER 119

TWO-DIMENSIONAL STABILITY ANALYSIS OF TIDAL BASINS AND TIDAL FLATS OF LARGER EXTENT

by
Eberhard Renger ^{*)}.

Abstract

Stability studies of natural tidal basin system demand a regime-oriented analysis and a characteristic quantification of the morphological values. Hence it was necessary to create relative form parameterization dependent on the location by means of a two-dimensional system of natural coordinates (z = elevation, s = gully length coordinate).

The underlying logic for the determination of the equilibrium of the tidal basins and tidal flats is as follows:

When the continuity equation for non-steady flow at any cross-section (s_i, z_i) of a tidal basin, within the mean tidal range is applied, a dimensionless relationship between horizontal and vertical cross-sections (A and F) and tide-generated mean velocities of current (\bar{u}) and tidal rise and fall ($\pm v$) can be derived with an accuracy of more than 90 %:

$$\frac{u}{v} \approx \frac{A}{F}$$

The analysis of the term on the right-hand side of this equation showed a characteristic vertical distribution of the relationship for all investigated tidal basins of the German Bight and look rather similar. The reference values of the corresponding relationships depend on the area of the tidal basin (E) at MHW and the mean tidal range (H).

The influence of the horizontal extent has been elaborated by varying the line of intersection systematically along the gully-length-coordinate (s). In addition it was possible to point out the differences between the characteristics of stable and (well-known) non-stable conditions by means of a two-dimensional analysis of the dammed-off tidal river EIDER/German Bight.

The relations derived may prove to be useful in the planning of future constructions and even in understanding and influencing the disadvantageous changes in running systems.

University, Hannover

Introduction

Stability conditions of tidal basins and tidal flats have been mainly observed from natural systems of minimum morphological change. Some well-known basic relationships between morphological and hydrological components have been empirically derived by making wider comparisons of similar systems. As a fundamental result several investigations have pointed out the most important equilibrium relationships between the cross-sectional area of a tidal basin inlet and the associated tidal prism or the area of the tidal basin (see Ref.).

However, the entrance is only one particular part of a tidal basin or estuary. Cross-sections and tidal prisms show a characteristic variation during tidal rise and fall (z) and along the gully axis (s). As a consequence, and in addition to earlier stability investigations, the local distribution and the relationship between horizontal (s) and vertical (z) components of the system have to be taken into account.

The present paper concerns a two-dimensional analysis which has been elaborated in order to obtain basic informations about the forecasting-modelling of morphological change, i.e. the proof of stability and the calculation of sand balances.

Because of the complicated interactions within these "tidal basins with movable bed" attention is focussed on the following three aspects which in author's view are the most instructive with the knowledge that is available to us at the moment:

1. The method of analysis
2. The comparison of the derived form parameters due to stability conditions
3. The proof of instability and time-dependent change of the representative form parameters by means of the regime of the EIDER, a tidal river in the inner German Bight.

It is hoped that the relations derived may prove to be useful in the planning of future constructions and even in understanding and influencing the disadvantageous changes in running systems.

Basic assumptions and analysis

In contrast to the results of former investigations carried out by various authors, this investigation had to elaborate a two-dimensional approach to quantifying the tidal-hydrodynamic and morphological characteristics of the system as a whole. Therefore natural coordinates were assumed within the area of the tidal basin both vertically (z = elevation) and horizontally (s = gully length coordinate).

The horizontal and vertical cross-sections (A and F) were measured and calculated from the maps at a scale of 1 : 10 000. They were mainly analyzed within the mean tidal range for the 6 different tidal basins at the seaward boundary at the bar with the help of computers (Fig.3). It must emphatically be pointed out that a comparison of tidal basins as a whole can only be successful if they are taken as a physiographic unit within the seaward boundary at the bar! RENGER, (5,7)

The physical behaviour of the tidal wave within the basin may be easily described by the continuity equation for non-steady flow.

$$u = \frac{\tilde{A}}{\tilde{F}} \cdot \frac{dh}{dt} \quad (1)$$

On the right-hand side of Fig. 1 there is a schematical cross-section over a plan view.

In this elementary tidal basin (section)

- the inflow volume ($Q \cdot dt$) equals the increase of the tidal volume ($\tilde{A} \cdot dh$) and
- the flow (Q) equals the term ($\tilde{F} \cdot u$).
- The mean velocity of tidal rise and fall (dh/dt) is substituted by (v) - as seen on the left hand side of Fig. 1.

When these basic equations are combined the mean current velocity (u) in the cross-section (\tilde{F}) is derived within a good accuracy as

$$u = \frac{\tilde{A}}{\tilde{F}} \cdot v \quad (2)$$

When this equation is transformed into a dimensionless expression, the hydrodynamical components are separated from the morphological ones (Fig. 2)

$$\frac{u}{v} = \frac{\tilde{A}}{\tilde{F}} = \frac{A}{F} \quad (3)$$

\swarrow morphological
 \downarrow hydrological

As the values depend exactly on three variables of space and time $f(z,s,t)$ a restriction on two variables of space is very useful in this first approach. Thus the term on the right-hand side of this equation was preferred for analysis. In addition the morphological system shows an integrating character from the morphogenetic point of view because of its much greater inertia of change.

One-dimensional comparison of tidal basins as a unit (E_{σ})

The vertical distribution of the corresponding relationships (A/F) are shown in Fig. 4.

As a first result it can be pointed out that

- the curves show a characteristic distribution in the vertical and look rather similar,
- the (A/F) varies from about 2,500 at MLW up to 7,000 and more at MHW, and that
- there is an optimum near MHW, which has to be pointed out for future analysis.

In order to make the systems comparable the distribution functions were made uniform in both variables. Therefore the vertical component (z) was shifted to MLW (z') and related to the mean tidal range (H), with ($\zeta = z'/H$). (4)

The abscissa (A/F = \mathcal{J}) was related to the optimum value of (\mathcal{J}), with $\mathcal{J}^* = [(A/F)/(A/F)_R]$. (5)

This dimensionless relationship

$$\mathcal{J}^* = f(\zeta) \quad (6)$$

is used as a basic relationship for every further comparison (see Fig. 5).

The following 4 parameters are of main interest for the stability analysis:

- the vertical distribution curve ($\mathcal{J}^*(\zeta)$)
- the range of the (\mathcal{J}_R)
- the range of the corresponding (A_R) (meaning a "measuring area" for modelling purposes)
- the mean tidal range (H)

As a first result of this investigation about morphological similarity it was possible to work out some significant attributes:

- The vertical distribution-curve ($\mathcal{J}^*(\zeta)$) shows a rather uniform characteristic.
- The (\mathcal{J}_R) (at the optimum) was found to have an average value of about 5,200 for the inner German Bight with a mean tidal range of about 3 m (cf. table on Fig. 5 and upper graph of Fig. 10).
- One investigated tidal basin of an area with a smaller mean tidal range of about 2,2 m (Borndiep, The Netherlands) showed a greater \mathcal{J}_R -value.
- The A_R -value was found nearly to be almost equal with the area of the tidal basin (E) at MHW-level.

Fig. 5

0878 Re 05

Fig. 6

Two-dimensional comparison of tidal basins within the physiographical unit (E_0)

In order to ascertain the horizontal variation of the relationships within the tidal basins, the sections were iteratively varied along the gully axis (see Fig. 6); in other words:

the $A(z)$ becomes an increasing variable due to the gully-length coordinate (s) (Ref. 7). Precisely the procedure of analysis was carried out at every section as explained before.

The vertical variation ($\mathcal{Y}^*(\mathcal{Y})$) due to the gully length (s) of three investigates tidal basins of very different size and type is shown in the next three graphs (Figs. 7,8,9).

Fig.	Tidal basin	Area at MHW (E_0)	Mean tidal range (H)
7	Süderhever, 1966	142 km ²	3,0 m
8	Born-diep (NL)1967	320 km ²	2,2 m
9	Jade-Estuary 1960/70	446 km ²	3,3 m

One most important result is that in every example the set of curves look rather similar and the curves always coincide very well.

The horizontal variation of the morphological characteristics only shows differences in the \mathcal{Y}_x -value. The dimensionless reference parameter seems to depend mainly on the mean tidal range (Fig. 10). On the one hand it is dependent on the order of the tidal range in general and on the other hand it seems to increase due to the decreasing tidal range along the gully length coordinate from land to sea.

The proof of instability

Referring to the last graphs on Fig. 10 we find some irregularities and deviations which may be of different origins, such as:

- methodical errors or mistakes
- influence of simplification (2 variables of space)
- individual attributes of the system that are not covered by the approach
- or even a certain degree of instability.

SÜDERHEVER 1966

Fig. 7

BORNDIEP, 1967

Fig. 8

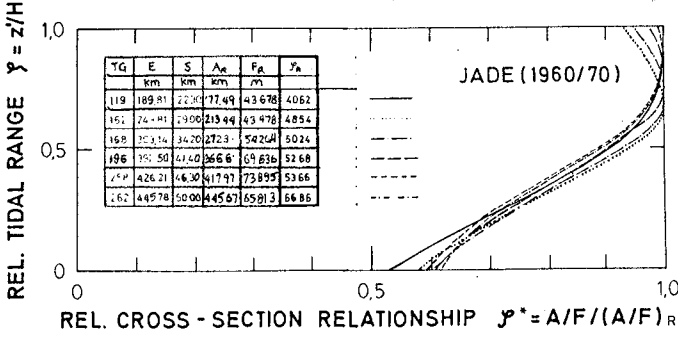

Fig. 9

0878 Re 08

Fig. 10

0878 Re 10

However, this is an open question at the present, and the deviations must be analyzed systematically by future investigations.

For these reasons we have to appreciate all the more the measurements of a tidal regime in the nature of which the non stability is well-known from its time-dependent change in the past towards an equilibrium state. The change of the characteristic form parameters are to be proved by the tidal river EIDER in the inner German Bight, which was dammed off at km 78 in 1936 (note the black part on Fig. 11.)

To get some idea about the change of the regime during the following 30 years the very heavy accumulation of about 50 Mio m³ of silt has been observed outside the barrage over an area of about 25 km² and 30 km length.

In the lower part of the graph 3 time-stages of the investigated change of the regime are shown schematically (1935, 1936 and 1967). As an example the three time-stages are pointed out for the selected profiles nos. 78 and 115 at km 10 and km 20 in front of the barrage which are to be discussed subsequently in the next two graphs (Figs. 12 and 13).

The related (A/F)-distribution $\mathcal{Y}^*(\zeta)$ is nearly the same just before and just after the damming off in 1935 and 1936 as can be shown on both profiles. But in contrast, the $\mathcal{Y}^*(\zeta)$ -curve of the situation 31 years later in 1967 after the heavy accumulation mentioned above is not quite similar.

The corresponding \mathcal{Y}_R -distribution due to the length-coordinate (s) is given in the next graph (Fig. 14). It is surprising to find that the \mathcal{Y}_R -values of the non-influenced tidal river EIDER as a constant almost exactly the same as the average value of about 5,200 that was analyzed from tidal basins, although the $\mathcal{Y}^*(\zeta)$ -curve was very different.

At the second time-stage just after the damming-off the reference values were found to be drastically diminished, as can be seen from the dotted line near the abscissa. Within the next 31 years the values had increased slowly towards the original level of 5,200 due to the accumulation of silt that had taken place.

At the moment we are not quite sure about the degree of non-stability (instability) because the type of the tidal basin has changed too much. But for other reasons a certain accumulation in consequence of the damming-off is still to be expected.

Fig. 11

Fig. 12

Fig. 13

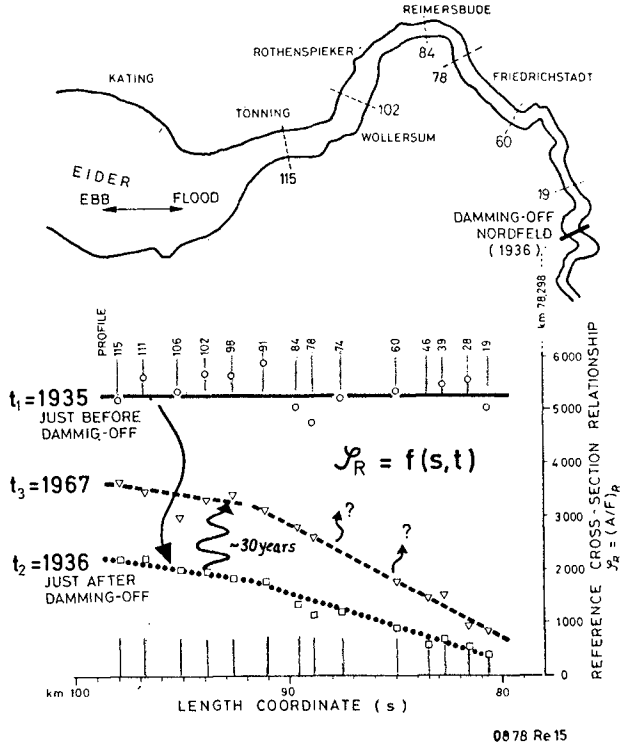

Fig. 14

Fig. 15

Conclusions

Morphological change of tidal regimes is, to be precise, dependent on four variables:

- 3 variables of space and
- 1 variable of time

In addition complicated boundary conditions of the regime have to be covered. As a consequence a certain simplification due to the approach and a certain selection of parameters as well as a drastic data reduction is necessary and even possible.

In order to apply the method, morphological data (maps) in particular, as well as mean tidal conditions, must be known. The extensive quantity of data can only be handled with the help of computers, as has been pointed out in earlier publications.

Because of open boundary conditions in tidal flats, stability criteria must be specified by further systematic investigations, and with reference to the boundary conditions. The universal application of these investigations to other tidal basin systems may result in similar equilibrium characteristics.

At the moment there are only a few results, and these have only exemplary significance. But these first results promise to be a good tool in stability analysis and forecasting modelling of tidal flats and tidal basins due to man-made influences on the regime.

Acknowledgements

This study is part of the Research Project "Morphological Analysis of Tidal Basins" which is carried out in the Special Research Center 79 of the Technical University of Hannover. The research upon which this paper is based was supported by the Deutsche Forschungsgemeinschaft which is gratefully acknowledged by the author.

Morphological data was provided by various coastal administrations of Germany, The Netherlands, Denmark and Great Britain. Special thanks are due to my colleagues Dipl.-Ing. H. Messal and R. Dieckmann who were always available for help and discussion.

CHAPTER 120

TIDAL SEDIMENTATION IN GROS-CACOUNA HARBOR

by

Georges Drapeau¹ and Guy Fortin²

ABSTRACT

The harbor of Gros-Cacouna on the South shore of the St. Lawrence Estuary has been silting at the rate of 31 cm/yr. since it was dredged at the depth of 14 meters in 1968. Measurements of temperature, salinity, turbidity, current speed and direction were carried out as well as bottom sampling and reflection seismic profiling. A model of suspended sediment transport combines the tidal volumes and the current profiles at the harbor entrance.

During a period of high turbidity (Spring) in the St. Lawrence Estuary, 54.2 tons of suspended sediments entered the harbor during the flood phase, while 41.1 tons were carried out during the ebb phase of a semi-diurnal tide, leaving 13.1 tons of sediments in the harbor. The transfer coefficient is 0.24 indicating that one quarter of the suspended sediment load settles in the harbor during one tidal cycle. In September, the turbidity is low in the Estuary and the suspended sediment budget in the harbor is 4 times smaller but the ratio of deposited sediments versus the total quantity of sediments transported in suspension is the same.

INTRODUCTION

The harbor of Gros-Cacouna is located on the south shore of the St. Lawrence Estuary at latitude 47°55'42" North and longitude 69°31'12" West, 230 kilometers downstream Quebec city (Fig. 1).

The St. Lawrence Estuary is 20 km wide and 70 meters deep off Gros-Cacouna. Water temperature varies between 10°C and freezing.

 2. Section d'Océanographie, Université du Québec à Rimouski.

FIGURE 1 The location of Gros-Cacouna harbor on south shore of St. Lawrence River system is shown by an arrow.

FIGURE 2 Location of Gros-Cacouna harbor at the southern end of Gros-Cacouna Island and rose of offshore tidal currents (H: high tide, L: low tide, H+1: one hour after high tide, etc). (Canadian Hydrographic Service, 1939).

The harbor is often surrounded by drifting ice in winter. Salinity varies seasonally and also with depth and ranges between 20 ‰ and 29 ‰. The limited fetch across the Estuary and the presence of islands along the southern coast prevent the formation of large waves. During the windiest month (January), 4 meter waves are expectable 5% of the time and only if the Estuary is not ice covered.

Tide is mixed, dominantly semi-diurnal, and ranges from 3.7 m (neap) to 5.7 m (spring). The difference between day and night tide reaches one meter at some phases of the lunar month.

Tidal currents in the St. Lawrence Estuary are strong and reverse with the semi-diurnal tide. Off Gros-Cacouna the surface currents reach 130 cm/sec during the ebbing tide and 100 cm/sec during the flood (fig. 2). The circulation is typically estuarine; the water column is stratified and the two layers are flowing in opposite directions most of the time, as observed outside the harbor during this survey as well as some 3 km offshore by d'Anglejan and Ingrassia (1976).

The rubble-mound jetties of Gros-Cacouna harbor were built in 1966. They enclose an area of $5.3 \times 10^5 \text{ m}^2$. A $2 \times 10^5 \text{ m}^2$ basin was dredged at a depth of 14 meters in 1968 (fig. 3). As the harbor was not yet complemented with wharves in 1976, it was an ideal hydraulic model where experiments could be carried out at the 1:1 scale.

Previous studies (E.R.S.L., 1973) indicated that the suspended sediment concentration was relatively high (10 to 19 mg/l) in the harbor and that siltation was progressing rapidly in the basin dredged in 1968. By contrast, essentially no sediment transport is taking place in the intertidal zone in this area. A small wharf at Cacouna Village did not retain sediments on either side since it was built 30 years ago.

FIELD INVESTIGATIONS AND METHODS

The suspended sediment load varies considerably in the St. Lawrence Estuary and is related to the fresh water run off of the St. Lawrence drainage Basin although that run off is regulated to 1.7:1 (Neu, 1976). Two cruises were organized to survey the harbor during periods of high turbidity (31 May - 4 June 1976) and low turbidity (30 August - 3 September 1976).

Precise measurements of temperature, salinity, turbidity, current speed and direction were carried out at the entrance and both inside and outside the harbor. Bottom samples were taken as well as continuous reflection seismic profiles to gain a thorough understanding of the harbor sedimentation dynamics. The precision of measurements was $\pm 0.02^\circ\text{C}$ for temperature, $\pm 0.02 \text{ mmhos/cm}$ for conductivity and $\pm 25 \text{ cm}$ for depth. Shipborne current measurements permitted to obtain continuous profiles of current speed and direction versus depth.

FIGURE 3 Bathymetry of Gros-Cacouna harbor (depth contours in meters).
The depth contours at two-meter intervals outline the basin dredged at a depth of 14 meters.

The concentration of suspended sediment particles was determined with a turbidimeter during the May-June cruise. Calibration of the instrument specifically for that cruise showed that the transmissivity for a 10 cm beam was linear within a range from 10 mg/l to 100 mg/l. During the August-September survey the suspended sediment concentration was too low to use a turbidimeter and the concentration of suspended sediments was determined by filtration of 250 ml water samples on 0.45 micron filters.

TIDAL CIRCULATION IN THE HARBOR ENTRANCE

The variation of current speeds and directions as a function of depth and time is shown in the upper portion of figure 4 for the day-time tide of September 1st, 1976. At high tide (09:00 hrs) water is flowing out of the harbor through the upper half of the entrance and inward at the bottom. The flow pattern evolves through the tidal cycle and at low tide (15:00 hrs) it has reversed and water flows inward through the upper half and flows out at the bottom of the entrance. This two-layer flow across the harbor entrance reflects the main features of the tide-induced circulation in the Estuary. The circulation of water masses across the harbor entrance more than compensates for changes of water levels due to the propagation of the tide in the harbor.

SEDIMENTATION RATE IN GROS-CACOUNA HARBOR

Continuous reflection seismic profiles were surveyed at the completion of the dredging of the harbor basin in 1968 and were repeated along the same base lines in 1971 and 1972 and during this survey, in 1976. Bottom samples were taken to determine the nature of the sediments deposited on the bottom of the basin since 1968. These data were used to determine the rate of sedimentation in the harbor. The results appear on table 1.

TABLE 1

SEDIMENTATION IN GROS-CACOUNA HARBOR ($2 \times 10^5 \text{ m}^2$ basin dredged in 1968)

	Volume ($\times 10^3 \text{ m}^3$)	Weight ($\times 10^3$ tons)	Sedimentation rate (cm/yr)
1968-72:	314.7	535	39
1972-76:	248.8	423	31
1968-76:	563.5	958	35

FIGURE 4 Top: Current speed profiles (cm/sec) as a function of time (ebb and flood) at the harbor entrance. Inflowing currents are positive and are outlined by inclined lines. Middle: Suspended sediment concentration (mg/l); inflow is positive. Bottom: Suspended sediment transport in hundreds of kilograms (+:inflow) corresponding to current velocities and suspended sediment concentrations shown above.

The texture of these sediments ranges from sand to clay-size particles. On the basis of textural analyses of the sediments deposited in the basin, the total suspended load is estimated to be in the order of 268×10^3 tons (Fortin et Drapeau, 1979).

TRANSPORT MODEL FOR SUSPENDED SEDIMENTS

The tide being the dominant phenomenon, the objective of the model is to determine the net quantity of sediments that remain inside the harbor at the end of a tidal cycle. The problem is simplified by the fact that no rivers flow in the harbor, the jetties are impermeable and the harbor has only one entrance.

Firstly the flow pattern at the entrance is determined and secondly the measurements of suspended sediment concentration are used to calculate the transport of sediments based on the flow pattern.

Flow at the harbor entrance

The proposed model is empirical and integrates two types of data: 1) tidal volumes of the harbor, that is the net quantity of water flowing through the harbor entrance calculated on the basis of changes of water level during given time intervals, and 2) current velocity profiles measured at the harbor entrance for the same time intervals.

The net volume of water (W_i) either entering or flowing out of the harbor during a specific time interval (ΔT_i) is the product of the change of height (ΔH_i) of the water level during that time interval by the area of the water surface of the harbor (A_i):

$$W_i = \Delta H_i A_i \quad (1)$$

To be significant in terms of sediment transport, it is essential at the end of the tidal cycle analysed that exactly the same volume of water flows in and out the harbor that is:

$$\sum W_i = 0 \quad (2)$$

Current speed and direction profiles were monitored at the harbor entrance with a shipborne current meter and recorded at 8 to 10 depths depending on the height of the tide. These current measurements are transformed into a matrix of current vectors $[V_{i,d}]$ perpendicular to the entrance of the harbor. The vectors are positive (+) for inflow.

FIGURE 5

The cross-sectional area of the harbor entrance is divided into a given number (d) of horizontal layers corresponding to each current measurement. L_d is the cross-sectional area of each horizontal layer (see fig. 5).

During a given time interval ΔT_i , the volume of water ($Q_{i,d}$) flowing through one layer is:

$$Q_{i,d} = V_{i,d} L_d \Delta T_i \quad (3)$$

and the net flow of water through the entrance during the interval ΔT_i is:

$$Q_i = \left(\sum V_{i,d} L_d \right) \Delta T_i \quad (4)$$

In theory Q_i and W_i are equal. In practice hundreds of current measurements would be necessary to make Q_i consistently equal to W_i . This difficulty is overcome by calibrating the current vectors ($V_{i,d}$). A correction factor (C_i) is determined for each series (i) of measurements:

$$C_i = \frac{W_i}{Q_i} \quad (5)$$

This correction factor is used to generate a calibrated matrix of current vectors $[V_{i,d}^*]$

$$V_{i,d}^* = C_i V_{i,d} \quad (6)$$

These corrected current vectors are introduced in equations (3) and (4)

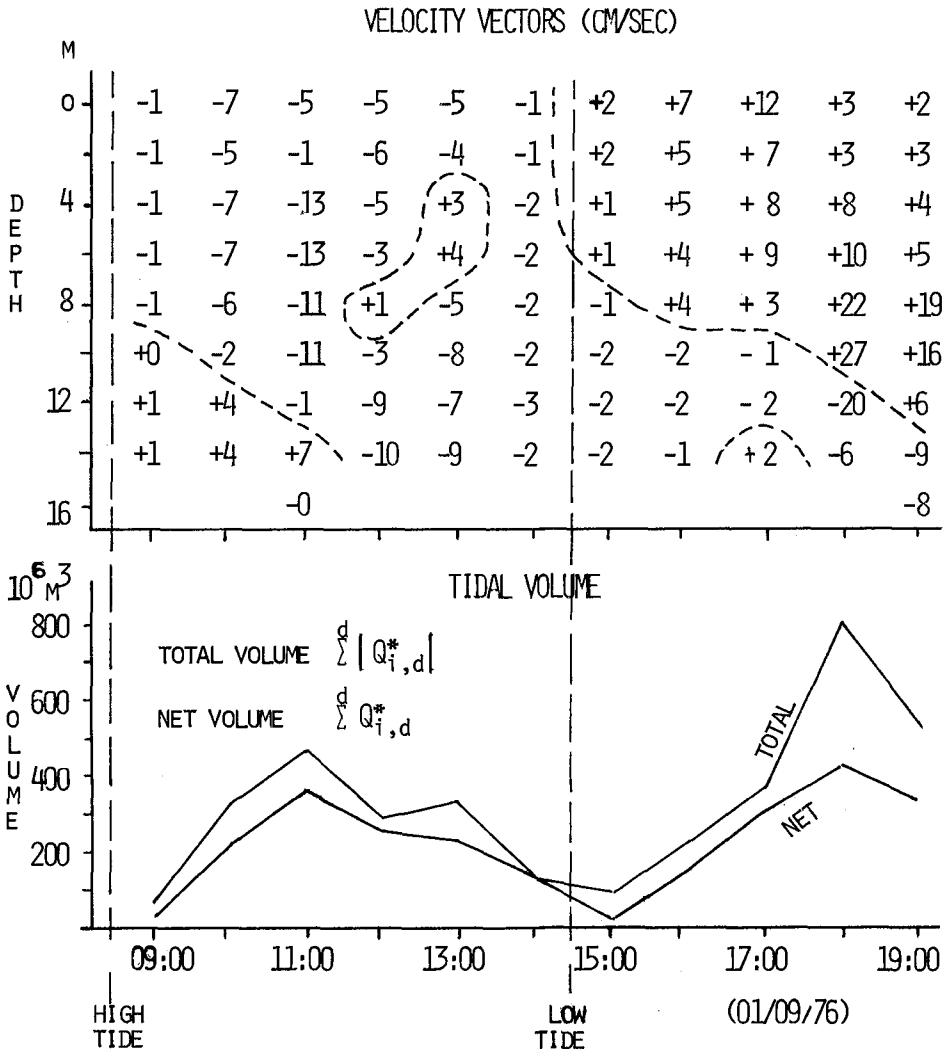

FIGURE 6 Top: Current vectors perpendicular to the cross-sectional area of the harbor entrance and calibrated according to the tidal volume of the harbor. Bottom: Diagram showing the net and the total volume of water flowing through the entrance of the harbor at different phases of the tide.

$$Q_{i,d}^* = V_{i,d}^* L_d \Delta T_i \quad (7)$$

$$Q_i^* = \left(\sum^d V_{i,d}^* L_d \right) \Delta T_i \quad (8)$$

These calibrated data fulfill the requirement that at the end of a tidal cycle, that is when the water level reaches the same height as at the beginning of the tidal cycle:

$$\sum Q_i^* = 0 \quad (9)$$

As already mentioned, the validity of the model is based on equation (9). The model has to be in accordance with the fact that tide in the harbor is a purely harmonic phenomenon.

The matrix of calibrated current vectors $[V_{i,d}^*]$ for September is tabulated on figure 6. It schematizes the circulation at the entrance of the harbor. The flow pattern has the same characteristics as those shown on the upper portion of fig. 4, except that the individual velocities are calibrated to fulfill the requirements of equation (9). The matrix outlines the two-layer circulation and its evolution with the progression of the tide. Only at station 33 is the whole water column flowing in the same direction. During all other time intervals the flow is bi-directional, that is, more water than necessary to compensate for the tide flows through the entrance of the harbor. The difference between the total flow ($\sum |Q_{i,d}^*|$) and the net flow ($\sum Q_i^*$) is outlined on the lower half of figure 6. Summation of these data indicates that 1.57 time the water necessary to compensate for the tidal volume of the harbor did flow through the entrance during that tidal cycle.

Transport of suspended sediments

Calculations for the transport of suspended sediments are based on the calibrated flow matrix $[Q_{i,d}^*]$ and the suspended sediment concentration measurements $(F_{i,d})$. The quantity of sediments $(S_{i,d})$ transported through one layer during a given time interval (ΔT_i) :

$$S_{i,d} = Q_{i,d}^* F_{i,d} \quad (10)$$

The net suspended sediment transport through the entrance during a given time interval is:

$$S_i = \sum^d Q_{i,d}^* F_{i,d} \quad (11)$$

The net suspended sediment transport during one tidal cycle is:

$$S = \sum S_i \quad (12)$$

18:26-19:37	322.1	3,324		

The results of these calculations for each time interval (S_i) and for the net transport during a tidal cycle (S) are shown on Table 2 for the June survey and on Table 3 for the September survey.

TRANSFER COEFFICIENT

Table 2 shows that during the tide studied in June, 54.2 tons of suspended sediments were transported inside the harbor during the flood of the tide while 41.1 tons were carried out during the ebb; leaving 13.1 tons in the harbor. This survey coincided with a period of high turbidity in the Estuary. The second survey (September) was carried out during a period of low turbidity and the suspended sediment transport rates were lower, as shown on Table 3. The net transport for a comparable tidal cycle was only 13.8 tons, that is 4 times less than in June. The proportion of sediments that remained in the harbor at the end of a tidal cycle is the same in both cases however. The term "transfer coefficient" is used to describe that characteristic.

Transfer coefficient:

June:	13138/54198 = 0.24
September :	3466/13812 = 0.25

The transfer coefficient bears some analogy with the "equilibrium concentration" defined by Mehta and Partheniades (1974) to discuss the depositional properties of estuarine sediments. The equilibrium concentration is a parameter defined experimentally while the transfer coefficient is empirical and would need further investigation.

COMPARISON OF SUSPENDED LOAD TRANSPORT WITH MEASURED SILTATION

The total accumulation of sediments in the harbor basin is in the order 95.8×10^4 tons over a period of 8 years, that is an average sedimentation of 164 tons per tidal cycle. A large proportion of these sediments is too coarse to be transported in suspension and the average transport in suspension is estimated to be 45.8 tons per tidal cycle (Fortin and Drapeau, 1979). That quantity of sediments is much higher than what was measured during June (13.1 tons) and September (3.5 tons) surveys.

The suspended sediment concentration most reach higher values in Gros-Cacouna area than those observed in June 1976 (24-48 mg/l). Although the turbidity maximum of the St. Lawrence Estuary is further upstream, the suspended sediment longitudinal gradient is 1.5 mg/l per kilometer in April-May in Gros-Cacouna area (Poulet and Chanut, 1979). High concentrations of suspended sediments are then susceptible to reach Gros-

Cacouna harbor and produce high siltation rates during these periods of high turbidity.

Differences in ranges of successive tides (1 meter at neap tides) can lengthen the residence of water masses in the harbor and favor the deposition of suspended sediments. The importance of this phenomenon is difficult to evaluate however at the present stage of the investigations.

SUSPENDED SEDIMENT TRANSPORT MECHANISMS

Distribution of suspended sediments

Figure 4 shows simultaneously the currents, the suspended sediment concentration and the transport of sediments across the entrance of the harbor during a tidal cycle. The suspended sediments are concentrated in streams in the upper half of the water column. This phenomenon has also been observed outside the harbor (Fortin, 1978). D'Anglejan and Ingram (1976) have sampled mid-depth concentration maxima once each semi-diurnal tidal cycle at seven stations surveyed in the Middle St. Lawrence Estuary. They relate these maxima to both the turning time of tidal currents from ebb to flood and the intensity of cross-channel flow.

Floculation

Floculation of fine sediment particles is playing an important role in Gros-Cacouna harbor. On the basis of a settling velocity of 0.5 mm/sec determined by Migniot (1977) for the muds of many estuaries, the flocculated suspended sediments could fall a distance of 7 meters (centrum of harbor depth) in 4 hours. If macro-flocs are formed, the settling velocity could be higher. Such mechanisms must be particularly efficient in Gros-Cacouna harbor considering the high rate of sedimentation.

Tidal volume

The concept of tidal basins as used by Renger and Partenscky (1974) and Renger (1978) is useful to evaluate the importance of tidal movements in the nearshore zone. The nearshore zone can be divided according to natural tidal basins or into more arbitrary cells. As shown on figure 7 a cell of width A , the size of the harbor, is delineated perpendicularly to the coast. The change of tidal volume of that cell is calculated for different heights of the tide. If the cross-sectional area A is considered, less water is flowing through that cross-section because of the presence of the harbor that prevents the free movement of water.

FIGURE 7

The diagram on figure 7 shows the volume of water flowing in the harbor as well as the total volume of water that would otherwise flow through the cross-sectional area A. Less than half the initial volume of water is now flowing over the harbor area. It disrupts the hydraulic equilibrium that used to prevail. Although water is flowing faster at the very entrance of the harbor, the water mass is more tranquil and sedimentation is favored.

CHAPTER 121

Factors Governing The Distribution of Dredge - Resuspended Sediments

ABSTRACT

Field observations are analyzed to determine the primary factors governing the distribution of sediments suspended by clam-shell bucket dredge operations. These data show the plumes produced under typical estuarine conditions to be relatively small scale features having maximum longstream dimensions of approximately 700 m. Plumes can be considered to consist of three contiguous zones: an initial mixing zone, a secondary zone and a final mixing zone. The initial mixing zone immediately adjacent to the dredge has dimensions governed by bucket induced mixing and suspended material concentrations determined by dredge efficiency. Observations indicate that dimensions can be reasonably estimated using wake theory and that efficiencies result in the introduction of 2-4% of the sediment mass contained in each bucket load. Resultant concentrations range between 200 and 400 mg/ℓ. Progressing downstream into the secondary mixing zone concentrations decay rapidly due primarily to gravitational settling. The observed decay rates indicate an average settling velocity of 4.7cm/sec well in excess of values based on the grain size characteristics of the dredged sediment. The behavior suggests significant particle agglomeration within this area. At the downstream limit of this zone distributions become essentially exponential in character and remain so through the final mixing zone. In this area concentrations progressively approach the upstream background levels and variations are governed primarily by diffusion. In each of these zones the observed distributions appear amenable to relatively straightforward modeling.

Introduction

In many coastal areas of the United States routine channel dredging represents the most common marine engineering operation. Much of the sediment removed during these projects is contaminated by a variety of organic and inorganic compounds, and as a result dredge-induced suspensions have the potential to perturb water quality and impact local biota. During the past few years a variety of investigations have been conducted to assess both the short and long term character of these impacts (see the review by Morton, 1976). In addition some investigations have examined dredge efficiency (Yagi, et. al., 1977) and developed schemes intended to reduce and/or predict project related turbidity (Huston and Huston, 1976; Barnard, 1978). The majority of these studies however, provided little quantitative information concerning the distribution and dispersion of materials suspended by the dredge. This paucity of data has tended to limit the development of predictive schemes applicable within coastal and estuarine waters.

During the summer and early fall of 1977 several detailed surveys of dredge-induced suspended material plumes were conducted within the lower Thames River estuary near New London, Connecticut (Bohlen, et. al., 1978). Suspended material distributions were sampled and both concentration levels and composition were analyzed. These data provide a reasonably comprehensive view of the longstream character of the dredge-induced plume and permit evaluations of both dredge efficiency and some of the primary factors governing the distribution and dispersion of the suspended sediments. This paper presents the results of these evaluations.

Study Area and Project Characteristics

Long Island Sound (Fig. 1) represents one of the major embayments along the eastern coast of the United States. Extending a distance of approximately 120 Km to the east of New York City, the Sound has a varied coastline providing several major port areas and numerous smaller, recreational anchorages. Regional hydrography dominated by the interactions between freshwaters supplied by three river systems entering along the northern margin and the local tidal currents favors nearshore deposition of fine grained sediments and requires regular dredging to maintain port and harbor viability. These dredging operations typically employ one of three methods; hydraulic, dragline or clamshell bucket. Hydraulic and dragline techniques have typically been restricted to relatively small volume projects. Major projects involving the removal of more than 100,000 m³ of material generally have employed clamshell buckets and hopper barges to transport spoils for disposal at selected offshore sites.

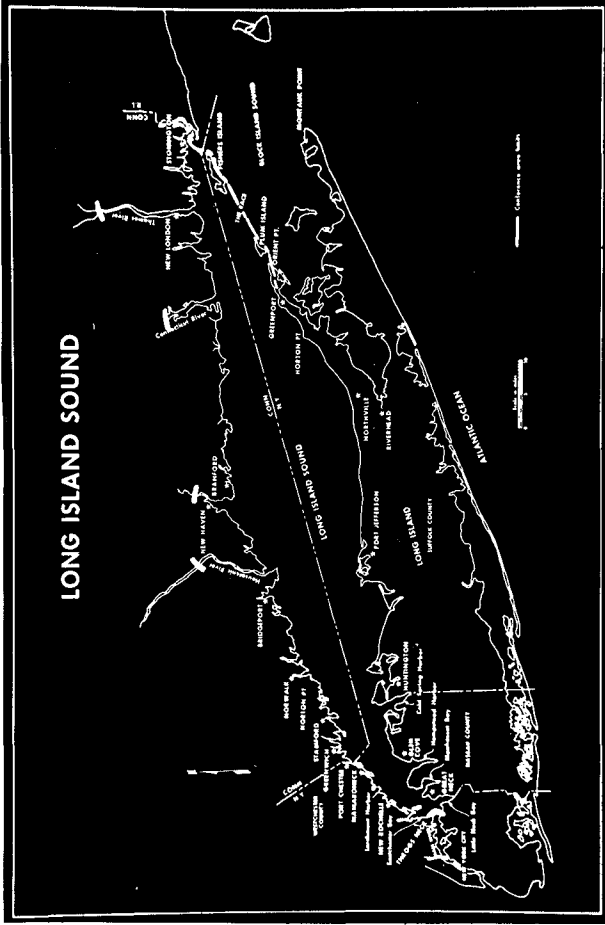

Fig. 1. Long Island Sound. Note the location of the Thames River entering near the eastern limit in the vicinity of New London, Connecticut.

Since 1974 the lower Thames River (Fig. 2) has been the site of a major dredging project intended to increase the depth of the main navigational channel to approximately 10 - 12 m. This stream is a typical small estuary having an annual average streamflow of approximately $75 \text{ m}^3/\text{sec}$ and tidal range of 0.78 m at New London. The combination produces a density field displaying persistent vertical stratification and an evident seasonal variability. Wind stress effects are generally negligible.

In July of 1977 dredging of the northern reach of the project area (outlined in Fig. 2) was initiated. Local sediments consisting primarily of fine-grained sands and silts (Fig. 3a) were removed using a floating barge-mounted crane equipped with a 10 m^3 open clamshell bucket (Fig 3b). Spoils were placed in a 1500 m^3 hopper barge typically moored alongside the operating dredge. This operation served to introduce sediments into the water column due primarily to bottom impact and washover from the open bucket during the subsequent ascent phase (Fig. 4a). The volumes of material supplied by overflow from the barge were negligible.

Survey Methods and Procedures.

In August and September, 1977 the suspended material plume extending downstream of the operating dredge was surveyed in detail (see Fig 2 for dredge locations). Hydrographic conditions during both survey periods were essentially identical although a slight increase in streamflow in September caused a decrease in near surface salinity and increased the degree of vertical stratification characteristic of the local density field (Fig. 4b).

The field methods and analytical procedures used in these surveys have been described in detail in an earlier paper (Bohlen, et. al., 1978). Very briefly, optical techniques were used to define the limits of the plume and to establish a network of stations along the defined centerline. At each station the suspended material field was sampled directly using 5ℓ van Dorn bottles. These samples were returned to the laboratory and vacuum filtered using dried and pre-weighed Nuclepore filters (0.40μ pore-size-57mm dia.). After careful washing, the filters were dried and re-weighed to determine the by-weight concentration of total suspended solids. Both surveys were conducted during the ebb tidal cycle.

Results and Conclusions.

The suspended material distributions along the centerline of the plume downstream of the operating dredge for each survey period are

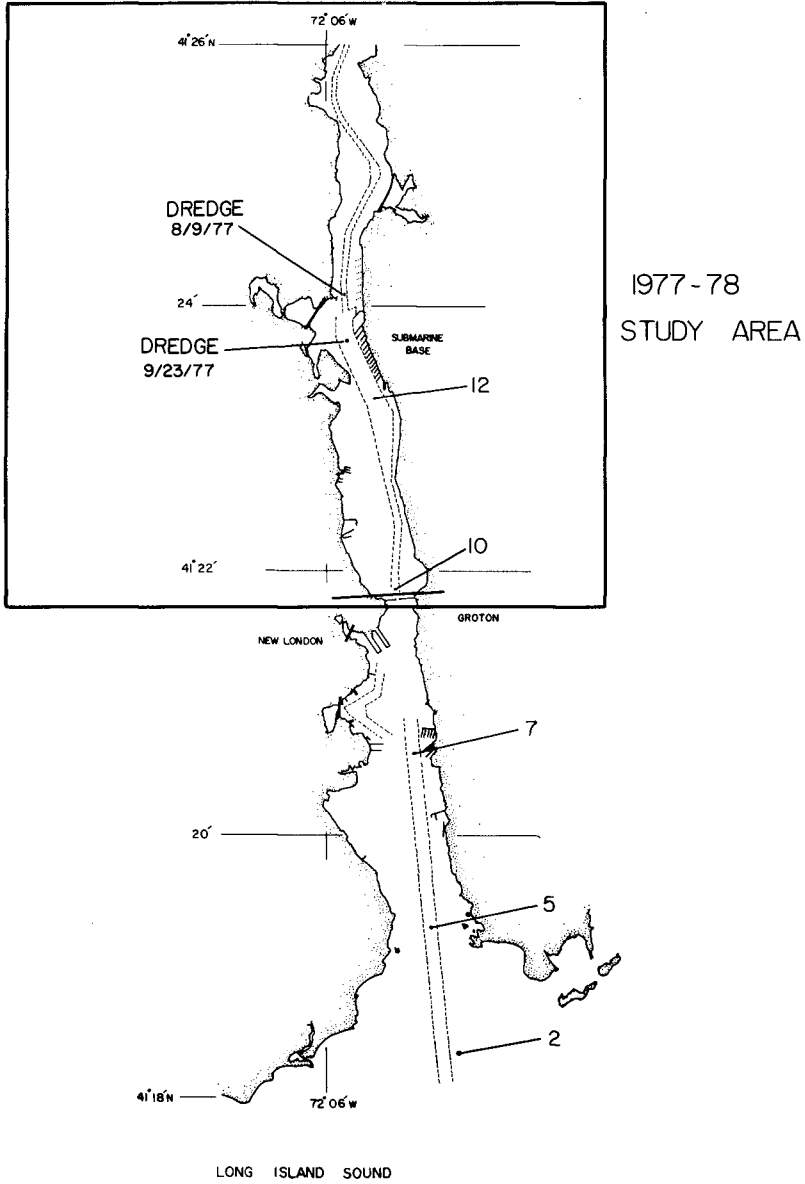

Fig. 2. Lower Thames River Estuary showing dredge locations during August and September, 1977 surveys. From (Bohlen et. al., 1978).

Fig. 3a (lower) Grain size characteristics of sediments being dredged in Thames River.

shown in Figs. 5 and 6. Qualitatively, these distributions are quite similar. As expected maxima occur in the area adjacent to the dredge with concentrations averaging between 200 and 400 mg/l. These values exceed the ambient or background levels measured at an upstream station clear of dredge influence by factors ranging from 4 to 10. Proceeding downstream concentrations decay rapidly and in both cases return to background within approximately 700 m.

The observed suspended material distributions are similar in character to those displayed by a variety of dispersing materials and/or particles (see Sayre and Chang, 1968 e.g.). As such they can reasonably be considered to consist of three principal areas or zones.

a. An initial mixing zone - immediately adjacent to the dredge where bucket induced suspensions and mixing combine to produce the initial suspended material concentrations.

b. A secondary zone - analogous to the convection dominated region in classical dispersion theory (Fischer, 1967). Material concentrations in this area are expected to vary primarily in response to advection and gravitational settling. And,

c. A final zone - extending downstream from the limit of the secondary zone to the point where material concentrations again approach background levels. The field observations provide some useful insights into the factors governing the suspended material distributions in each of these zones.

1. The initial mixing zone. - This area is clearly bucket dominated. During each dredging sequence, bottom impact and washover serve to introduce sediments which are subsequently mixed through the water column by the mechanical agitation produced by the vertical ascent and descent of the bucket. The resultant vertical column of materials, representing the initial source or concentration immediately proceeds to move downstream at a rate governed by the local mean velocity. Following approximately 1 min. another column of materials is introduced by the next pass of the bucket. This delay results in an intermittent source favoring a high degree of spatial variability in the vicinity of the dredge (see Fig. 7). The displacement in peak concentrations observed during the September, 1977 survey (Fig. 6) is evidence of this spatial inhomogeneity.

Fig. 5. Suspended material concentrations along the centerline of the plume downstream of the operating dredge. August 9, 1977. (from Bohlen, et. al., 1978).

Fig. 6. Suspended material concentrations along the centerline of the plume downstream of the operating dredge, September 23, 1977. (from Bohlen et. al., 1978).

The initial dimensions of the vertical source columns are a function of the water depth and the horizontal area influenced by bucket induced mixing. The observations indicate that this latter area is several times larger than the cross-section of the bucket and has dimensions that appear to be simply proportional to the wake of the closed bucket. Examination of a typical dredging sequence (Fig. 7) shows the ascending bucket producing a very nearly circular wake having a diameter of approximately 16 m. The resultant mixing area of 201m² is substantially larger than the 12 m² cross-section of the bucket.

Given the above characteristics it appears possible to develop reasonable estimates of the horizontal mixing area using classical wake theory (Schlichting, 1968). If a simple equivalence is assumed between drag on the bucket and fluid momentum it can be shown that,

$$b \sim (\beta C_D A_f d)^{1/3} \quad (1)$$

where

b = half width of the wake

$\beta = \lambda/b = \text{Const}$ with λ defined as the characteristic mixing length within the wake

C_D = drag coefficient of the bucket

A_f = frontal area of the bucket

d = water depth

Observations of the residual wake (Fig.7) indicate characteristic eddy scales or mixing lengths within the wake of approximately 1 m yielding β values between 0.1 and 0.2. These values in combination with the observed wake dimensions, a bucket frontal area of 12 m², and water depths averaging 10 m suggest drag coefficients ranging between 20 and 40. At present the accuracy and general applicability of these numbers cannot be specified because of generally insufficient data. As a result, although the wake method appears internally consistent in terms of the limited observations provided in this study, its utility as a general means to predict the horizontal area of bucket induced mixing must remain speculative.

The mass of sediment suspended within the initial mixing zone is a function of the efficiency of the dredging process. Given the observed dimensions and suspended material concentrations ranging between 200 and 400 mg/ λ , an assumed specific gravity of 1.5 and negligible porosity indicates that approximately 2 to 4% of the mass of each bucket load is introduced into the water column. These numbers are similar to those observed in previous studies (Bohlen and Tramontano, 1977; Gordon, 1973) and appear to be representative of the general class of

Fig. 7. A typical dredging sequence - beginning ascent upper left - residual wake - lower right. Thames River 1977 - 1978.

clam-shell bucket operations conducted in relatively cohesive, fine-grained sediments. If future work proves the value of the above wake method as a means of predicting mixing volumes, these values should permit reasonable estimates of the initial concentration levels adjacent to the dredge.

2. The Secondary Zone - Proceeding downstream from the initial mixing zone the cloud of suspended materials begins to disperse due to the combined effects of advection, turbulent diffusion, and gravitational settling. Concentrations decrease rapidly with values during the August survey falling by more than a factor of 10 within the first 100 m (Fig. 5). Such rapid rates of decay suggest that gravitational settling dominates the concentration variations in this area since the observed width of the plume is insufficient to provide the required dilutions. An estimate of the settling velocities required to affect the observed reductions can be developed using the methods described by Sumer (1977). He showed that the settling length L required to produce a given percent removal of materials suspended in typical channel flows could be evaluated using

$$L = \frac{-6 (\bar{U}) d}{k \lambda} \ln (1-r) \quad (2)$$

where \bar{U} = the average cross-sectional velocity

u_* = the shear velocity = $\bar{U} \sqrt{f/8}$

f = Darcy - Weisbach friction factor, assumed = 0.02

d = water depth

k = von Karman's constant = 0.42

λ = mean rate at which particles settle out of suspension

r = percentage of sediments removed

Solving for the case of the August survey where $\bar{U} = 30\text{cm/sec}$ and $r = 0.9$ at $L = 100\text{ m}$ yields a $\lambda = 40$ corresponding to an average assemblage settling velocity of 4.78cm/sec . This value is equivalent to the settling velocity of an individual quartz sphere having a mean diameter of 0.35 mm and is substantially higher than values computed using the average grain size characteristics of the dredged materials (Fig. 3a) in combination with standard graphical techniques (Vanoni, 1975). The cause of these differences is not immediately apparent. Some bias is undoubtedly introduced due to the neglect of diffusion. Given the spatial scales however, the magnitude of this error should be small. More likely, the differences result from the character of the settling process in this area. Within these high concentration zones particle-by-particle settling can be limited by processes tending to favor agglomeration of particles and the formation

of particle assemblages having settling velocities substantially higher than the individual member particles. Additional work remains before the details of these processes can be quantitatively specified. For the moment the field data are best taken as an indication of the effectiveness of these processes and the possible hazards inherent in the application of single particle settling velocities within models of suspended material plumes.

As rapid gravitational settling acts to remove the coarser grained materials from the water column, the initial distribution of suspended sediment concurrently spreads laterally under the effects of local turbulent mixing. The former process tends to reduce the average grain size of the materials in suspension while the latter reduces the influence of convective processes as the spatial scales of the plume approach those characterizing the local turbulence field. In time this combination produces conditions in which the distribution of suspended material behaves in a manner similar to that displayed by a neutrally buoyant dispersant. By definition, this occurs at the downstream limit of the secondary mixing zone. An estimate of the distance required for this transition to occur can be developed if the assumption is made that subsequent downstream distributions will be diffusion dominated. Applying a simple Fickian construct, the resultant distributions will have centerline concentrations varying exponentially with a form:

$$C(x) \approx C_0 e^{-\frac{\bar{U}_x}{2k}} \quad (3)$$

where x = longstream dimension

C_0 = an initial suspended material concentration

k = a dispersion coefficient $\sim u_* d$

Using the August survey data to test the "goodness of fit" of this expression (Fig. 8) indicates that slightly more than 100 m is required before the exponential reasonably conforms to the observed distribution. This is one indication of the downstream extent of the secondary mixing zone.

Another measure of the extent of the secondary mixing zone can be developed by considering the lateral spreading characteristics of the plume as it progresses downstream. The typical time t required for this cross-sectional mixing can be estimated using:

$$t = \frac{\ell^2}{K_z} \quad (4)$$

where ℓ = characteristic cross-stream length scale

K_z = lateral diffusion coefficient = $0.2 u_* d$

Fig. 8. Tests of the suitability of an exponential distribution function

- ——— □ Vertical average suspended material concentration
- - - - Exponentials beginning at various longstream locations
- ... → Inferred downstream limit of secondary mixing zone.

Fischer (1973) showed that this expression provides a useful means for evaluating the extent of the convection dominated zone. Since downstream of this zone the distributions of a neutrally buoyant dispersant can be predicted using one dimensional diffusion equations with solutions similar in form to (3), use of (4) should provide estimates similar to those given by the above curve fitting routine with the added advantage that these predictions require a minimum of data.

Evaluation of (4) for the Thames River study area using the August survey data indicates that

$$t \cong 300 \text{ sec}$$

Applying Fischer's (1973) criteria the concurrent convective time scales can be expected to range between 150 and 300 sec. At the observed average velocities these convective times imply that materials suspended by the dredge will have moved downstream distances of 50 to 100 m before the distributions become primarily diffusion dominated. The similarity between these values and those provided by the above curve fitting suggests that this method may provide the best means of predicting the longstream extent of the secondary mixing zone and encourages further investigation.

3, The final Mixing Zone - Downstream of the secondary zone, concentrations continue to progressively decay but at rates significantly lower than those observed nearer the dredge. The distributions in this, the final mixing zone are diffusion dominated although gravitational settling continues to act. The vertical average suspended material concentrations are essentially exponential in character (Fig. 8). Dispersion coefficients for this area were estimated using the guidelines provided by Fischer (1973). Constants of proportionality of 5-25 for the longitudinal coefficient and 0.15 to 0.25 for the lateral coefficient provided reasonable agreement with the field data. Despite this agreement however, additional work is required in this area with particular emphasis on the character and magnitude of dispersion and time and space variant interactions produced due to gravitational settling.

Summary

The field observations show that the suspended material plume induced by an operating, clam-shell bucket dredge is essentially a small scale feature. Under typical estuarine conditions the observed plumes had average longstream dimensions of approximately 700 m. The resultant distributions can be divided into three primary zones:

- An initial mixing zone - immediately adjacent to the dredge, where bucket operations tend to suspend and mix materials over a well defined vertical column.

- A secondary zone - extending downstream a distance of approximately 100 m in which material distributions vary primarily in response to gravitational settling.

-final mixing zone - where concentrations continue to decrease progressively approaching pre-project or background levels with variations governed primarily by turbulent diffusion.

Each of these areas appears amenable to reasonably straightforward modeling schemes sufficient to permit quantitative prediction of the suspended material distributions.

A variety of work however, remains to be done. In particular additional information on the adequacy of the wake method as a means of estimating mixing area is required. In addition more detailed observations of dredge efficiency should be obtained so that the functional relationships between sediment type, bucket size, character and operational techniques and the mass of sediment introduced into the water column can be established. Finally a comprehensive in situ investigation of sediment settling velocities is required. Each of the above studies would provide information essential within future efforts to quantify suspended sediment dispersion in the vicinity of coastal dredging operations.

CHAPTER 122

MOVABLE BED MODEL TESTS ON DUNE EROSION

by

P. Vellinga*

1 Introduction

The primary sea defence system of the Netherlands consists for a large part of sandy beaches and dunes. The row of dunes, however, is rather narrow in some places, due to long-term erosion, and reinforcement has become necessary (Figure 1 and 2). In this connection a special governmental committee requested the co-operation of the Delft Hydraulics Laboratory to develop a design criterion for a dune sea defence system that could withstand a storm surge with a frequency of occurrence of once in 10,000 years (Figure 3). For that purpose all available field observations on dune erosion were analysed and a provisional, empirical, guide-line was developed in 1972 [1], but because of the limited amount of field data and the complexity of a theoretical approach it was decided to check the validity of this guide-line by means of a model investigation.

As no adequate scaling relationships are available for movable bed models with waves, the tests were set up in the form of a scale series. A large number of two-dimensional tests with various geometric scales using two types of sand ($D_{50} = 225 \mu\text{m}$ and $D_{50} = 150 \mu\text{m}$) was carried out in 1975. Simple relations were assumed for the model distortion n_l/n_d (length scale over depth scale) and for the morphological time scale n_t , namely:

$$n_l/n_d = n_d^\alpha; n_t = n_d^\beta,$$

in which α and β are constants, while n represents prototype value over model value. The values of α and β were determined by a correlation analysis and the following relations were found for $n_D = 1$: $n_l/n_d = n_d^{0,28}$; $n_t = 1$. Consequently the scale of the dune erosion quantity per unit length of coast is

$$n_A = n_l n_d = (n_d)^{2,28}.$$

On the assumption that these relations are also valid outside the scale range used, a prototype value for the dune erosion was found [1]. The model tests, however, produced a number of scale effects especially as prototype sands were used leading to profiles that were steeper than in the field. Although these scale effects have been implied by the scaling relations, the prototype result was very sensitive to minor changes in the empirically determined distortion relation. Therefore additional tests were carried out with finer sands to reduce the distortion of the model and consequently to increase the reliability of the prototype result. It is the results of these tests which are described in this paper.

* Project Engineer, Harbours and Coasts Branch, Delft Hydraulics Laboratory, Laboratory De Voorst, The Netherlands.

2 Scaling relations

The problems of scale effects in beach process modelling are not new, and especially geometric similarity in beach profile development has been given much attention. Kemp [2] suggested a distortion relation of the form $n_1/n_d = (n_d)^\alpha$ with $0.45 < \alpha < 0.65$, while Noda [3] found from his experiments with various materials: $n_1/n_d = (n_d)^{0.32} (n_\gamma)^{-0.386}$ in combination with $n_p(n_\gamma)^{1.85} = (n_d)^{0.55}$; (γ is the specific weight of sediment and D is the sediment size D_{50}). Saville [4], Saville and Watts [5], Kohler and Galvin [6] and Dean [7] stress the importance of the dimensionless fall velocity parameter H/Tw for the description of beach profile development, while theoretical and practical considerations lead Dalrymple and Thompson [8] to recommend $n(H/Tw) = 1$ as most promising scaling relation for the modelling of beach processes.

(H = wave height, T = wave period, w = fall velocity of sediment particles).

From the earlier tests on dune erosion with two types of sand Van de Graaff found indeed that the results from different sands compared very well using the H/Tw concept. Therefore the present tests have been carried out with the finer sands, assuming that equal H/Tw values imply geometrically similar profile development.

In fact, the condition $n(H/Tw) = 1$ could not be entirely satisfied for the design storm surge in view of the grainsize of the available fine sand and the possible model scales. Consequently a distortion of the model could not be prevented, the value of which can in the first instance be deduced from the requirement of kinematical similarity $n_1/n_d = n_u/n_w$ [9] (u = horizontal orbital velocity). Since the waves are reproduced according to Froude's Law, this relation can be written as $n_1/n_d = (n_d/n_w^2)^{0.5}$. In case $n_w = 1$ the relation $n_1/n_d = n_d^{0.5}$ follows, which agrees again with Kemp [2]. However, from the previous series it was found that $n_1/n_d = n_d^{0.28}$ is more realistic. Thus for different types of sand the relation $n_1/n_d = (n_d/n_w^2)^\alpha$ with $\alpha = 0.28$ would follow. The empirical exponent α incorporates any scale effect in sediment entrainment, wave breaking, wave run-up, etc.

3 Model tests

To check the suggested scaling relations for the finer sands a total of 24 tests was made, covering four types of sand and three different depth scales. The tests were carried out in the wind-wave flume of the Laboratory De Voorst (see Figures 4 and 5). Hydraulic prototype conditions as shown in Figure 6 were reproduced in all tests. The Pierson Moscovitch spectrum was used for the description of the wave field. The water level was kept constant at the maximum storm surge level because the time-scale of the morphological process is not fully understood. For each depth scale and each type of sand two tests were run with different initial profile steepness (see Table 1).

4 Test Results

During the tests the erosion profile was recorded at various times, and the results are shown in Figures 7 to 30, for the part of the profile that shows major changes and for the length of time with heaviest erosion. As can be seen from these plots, the profile-changes at a water depth greater than $\frac{1}{2} H_{0s}$ are relatively small; bars and troughs are formed at a later stage. An important phenomenon to be noticed from these recordings is that for tests with equal sand and depth scale, the form of the eroded coastal profile is independent of the initial profile. The erosion quantity above storm

Fig. 30

surge level has been computed from these recordings, and the cumulative result is shown in Table 1. As from the first recording it was found that the initial profile was not in all cases reproduced as desired, a corrected steepness factor has been introduced (see Table 1). Other phenomena have also been recorded, like wave height, grainsize, ripples and water temperature.

From the wave height recordings it appears that close to the wave generator the significant wave height shows some scatter but is generally reasonably in accordance with scale; further down the flume, however, the wave height decreases considerably and is no longer exactly to scale (see Tables 1 and 2).

The bottom sediment, sampled at $t = 40$ hrs, was found to be the coarsest just seaward of the still water line.

The ripples were measured at $t = 6$ hrs (see Table 3); but a clear variation pattern could not be determined.

The water temperature was $12 \pm 3^\circ$ C for all tests.

5 Conversion of model results to prototype

The scaling relations established in the earlier scale series, combined with the dimensionless fall velocity parameter, are:

$$n_t = 1 \text{ and } n_1/n_d = (n_d/n_w^2)^{0.28}.$$

A reasonable agreement among the erosion quantities was found when all test results were converted to prototype with these scaling relations. A closer look, however, revealed that the erosion quantities, as well as the profile forms, from the tests with finer sands showed a clear dependency with the depth scale. This indicated that the α -value for the finer sands may not equal 0.28. Therefore a correlation analysis to find the optimal combination of time scale and distortion relationship, as described in [1], was carried out for each individual type of sand.

6 Correlation analysis of test results

The erosion quantities above storm surge level were taken as a basis to determine the "best" value of the empirical exponents in the relations $n_1/n_d = (n_d)^\alpha$ and $n_t = n_d^\beta$. For a certain β -value each α -value gives a correlation coefficient for the conformity of the erosion quantities of the tests with the different depth scale factors. The analysis was carried out for discrete model time-steps that, taking the time scale into account, fell within the relevant time period for dune erosion in the field (2 to 10 hours).

Each time step provided a "best" α -value and a corresponding maximum correlation coefficient. To find the "best" combination the average of the maximum correlation coefficients for the relevant time period has been plotted as a function of the value of β . In Figures 31 to 34 this graph is shown for the present tests, while in Figures 35 and 36 the results are shown for the combination of the present tests and the previous ones with coarser sands. The "best" combination of α and β can be seen to vary with the type of sand. An important trend to be noticed is that for the finer sands the best morphological time scale approaches the hydrodynamical time scale. Regarding the coarser sands, it was found that the differences in correlation coefficient are hardly significant when the hydrodynamical time scale is compared with the formerly found time scale $n_t = 1$. Therefore the time scale with more physical background $n_t = (n_d)^{0.5}$ was chosen for further elaboration of all tests results.

Fig. 31

Fig. 32

Fig. 33

Fig. 34

Fig. 35

Fig. 36

Fig. 31 ... 36 Results of correlation analysis

The "best" α -values found for this time scale are shown in the mentioned graphs. It appears that α increases with decreasing particle diameter and that the "theoretical" value of 0.5 is approached for the finer sands. This seems logical, because the suspended transport with finer sands is more predominant than with coarser sands and thus the theoretical distortion relation based on kinematical similarity for a suspended particle should be more valid.

7 Discussion of the results

From the fact that the α -value was found to be a function of the absolute fall velocity of the sand particles it may be concluded that the dimensionless fall velocity parameter does not apply for the comparison of the test results. The higher α -values, however, may have purely physical reasons and perhaps the substitution of the significant deep water wave height H_{0s} and the spectrum top period \hat{T} and the fall velocity in stagnant water w in the H/Tw parameter is too simple. A better parameter may be something like H_*/Tw or H/Tw_* in which H_* is some function of H in the breaker zone and w_* is an adjusted fall velocity under breaking waves. However, the limited number of tests prohibited the determination of such adjusted parameters for the conversion of the model results to prototype values.

Another cause of the varying α -values may be the fact that the wave height recorded just outside the breaker zone was not exactly to scale due to wave height attenuation along the flume. This attenuation has been greater for tests with greater depth scale factors and finer sands, and so this phenomenon may have led to an overestimation of the α -value. Therefore, renewed analysis based on a H_{br}/Tw parameter in which H_{br} is determined from the actual wave recordings may well be more successful. Especially because this will lead to lower values of α for the finer sands there is a chance that a unique value for α will be found covering all types of sand. To carry out this analysis a large number of corrections has to be carried out because the scales of wave height, wave period and initial profile do not correspond. Consequently any prototype result found after such a correction would have a limited reliability.

For practical reasons, therefore, a simple approach has been made. Given a prototype situation that is to be reproduced to scale. It is assumed that the best tests to be performed are those with a H/Tw value equal to that in prototype. Unfortunately such tests could not be performed in the available model facility due to wave height and grain size limitations. Therefore a series of tests were carried out with various types of sand on various depth scales covering a range of smaller H/Tw values. Subsequently the results of these tests were extrapolated, for each type of sand separately, to imaginary tests having the required H/Tw value. The results obtained that way were converted to prototype by means of linear scaling ($n_1 = n_d$) as follows from the H/Tw concept.

The elaboration of the test results as indicated above can be summarized by means of the scaling relation $n_1/n_d = (n_d/n_w^2)^\alpha$ in which α is dependent on the type of sand and has values as already found from the correlation analysis.

8 Conversion to prototype with renewed scaling relations

The result of the conversion to prototype with the tentative scaling relations is rather good. Only the results from the tests with the second

finest sand ($D_{50} = 130 \mu\text{m}$) fall a little apart. The reliability of the α -value applied for this type of sand is relatively low due to the small number of tests. Therefore a correction based on the extrapolation of the α -values for the coarser sands with reference to the finest sand seems acceptable.

The ultimate α -values to be applied now are shown below, together with the corresponding grain sizes and fall velocities (from the Shore Protection Manual for 10°C [6]):

D_{50}	μm	225	150	130	95
fall velocity	m/s	0.0250	0.0130	0.0100	0.0060
α -value	-	0.28	0.34	0.40	0.64

The prototype results show greater conformity now; the erosion quantities are shown in Figure 37. On the horizontal axis the value 1 refers to model tests with an initial profile related to the prototype reference profile with the scaling relation $n_1/n_d = (n_d/n_w^2)^\alpha$. And thus the corresponding erosion refers to the average profile along the Dutch coast. Automatically the tests with initial profiles a factor S steeper than required correspond to prototype profiles a factor S steeper than the reference profile.

Also the erosion profiles have been converted to prototype, as shown in Figure 38. The water line has been chosen as a reference. Above this line the conformity is rather poor, but below it the erosion profiles agree very well. It should be borne in mind that comparison is only valid for the part of the profile that has really changed, thus to a depth of about $\frac{1}{2} H_{0s}$ (see Figures 7 to 30).

9 Evaluation

The conformity among the erosion quantities and the erosion profiles for prototype conditions gives support to the applied scaling relations. Regarding the actual prototype erosion quantities to be expected, it should be stated that a correction for the actual wave height in the model as suggested before will lead to lower α -values and consequently to smaller prototype erosion quantities.

The consequences for the prototype erosion caused by the uncertainty in the derived α exponent is shown in Figure 39. In this graph the prototype erosion quantity for the reference profile, derived from the tests with depth scale factor $n_d = 26$, is shown as a function of the α -value. The difference in prototype erosion for α -values between of 0.5 and 0.3 is only 20% for the finest sand.

From the model tests with prototype sand the corresponding difference is found to be 400%, and so it must be concluded that the reliability of the model tests has been greatly increased by the additional tests with very fine sands.

10 Reproduction of storm surge 1953

To verify the H/Tw parameter in a different manner, a final test was carried out. The 1953 storm surge, of which some prototype observations were available, was reproduced in the model. For this test α -values were not of any

Fig. 37 prototype erosion quantity, model result compared with empirical guide-line

Fig. 38 prototype erosion profile

Fig. 39 prototype erosion as a function of α

importance because the H/Tw -value of the field conditions could be obtained in the model and consequently a profile distortion was not necessary. The field conditions showing a maximum storm surge level of 3.9 m above M.S.L., a wave height $H_{0s} = 5.0$ m, and a beach sand with $w = 0.025$ m/s have been reproduced with depth scale factor $n_d = 17$, thus $n_d = n_l = n_T^2 = n_w^2 = n_u^2 = 17$. Unfortunately the varying wave and water level conditions were reproduced on the formerly established time scale $n_t = 1$, because the time scale $n_t = n_d^{0.5}$ was not yet recognized at this stage of the model investigations. The final erosion quantity found from this test, and also the deliberately corrected quantity for $n_t = (n_d)^{0.5}$, fell within the range of quantities measured in the field, with the corrected value fitting best. Also the erosion profile agreed rather well with the field measurements, and therefore it must be concluded that this test supports the validity of the dimensionless fall velocity parameter H/Tw for small-scale modelling of beach processes.

11 Conclusions

- Results of model tests on dune erosion with very fine sand support the validity of the dimensionless fall velocity parameter H/Tw for small-scale modelling of beach processes.
- If the requirement $n(H/Tw) = 1$ cannot be satisfied in the model, a profile distortion based on kinematical similarity $n_l/n_d = n_u/n_w = (n_d/n_w^2)^\alpha$ with $\alpha = 0.5$, gives good results for the finer sands. For coarser sands ($D_{50} = 130 - 225 \mu\text{m}$) values of α ranging from 0.5 to 0.3 are found.
- A morphological time-scale equal to the hydrodynamical time scale $n_t = n_d^{0.5}$ is most plausible in view of the scaling of the fall velocity. This is supported by the model results of tests with very fine sand ($D_{50} \approx 100 \mu\text{m}$) and irregular waves.
- For the gentle beach profiles along the Dutch coast the model results support the earlier-developed and presently-used "provisional guide-line for dune erosion". For the steeper profiles, the model results fall below this guide-line.

CHAPTER 123

USING FENCES TO CREATE AND STABILISE SAND DUNES

Brian B. Willetts¹ and Christopher J. Phillips²

Introduction

Coastal sand dunes act as a barrier to wind and sea, as a reservoir of sand available to supply areas of eroding coast, and as a trap for mobile sand which would otherwise be blown inland and become a nuisance. Breaches of the dune system and areas bare of vegetation should be avoided or repaired in order to protect the stability of the dunes and so enable these useful functions to be sustained.

The agents of initial damage to the dunes are water, which undermines them, and animals (including man) which damage the protective vegetation by grazing or trampling. Of these, man has recently assumed predominant local importance because of the popularity of sea-side holidays and of the land-falls of certain marine engineering works such as oil and gas pipelines and sewage outfalls. The need is therefore increasing for active dune management programmes to ensure that under these accentuated pressures, the coast retain an equilibrium comparable with that delicately balanced equilibrium which obtains naturally at a particular location.

Such management programmes are already established in many countries. They tend, however, to be empirical and based on local experience (often of a very small number of people) because the difficulties of generalisation render transfer of information and technique meagre. Accounts of management techniques can be found in the literature (e.g. ref 1) but in most of such papers great emphasis is placed on vegetative restoration. Whilst this is the best way of re-introducing a lasting stability, it is often not a practical way of beginning the restoration of a deteriorating situation. The sand movement or the season may be such that planting alone is unlikely to be successful. It is the authors' opinion that, of the techniques at present available, the placement of porous fences provides the most effective means in relation to cost of creating and stabilising sand dunes (and should normally be supplemented by plantings).

The object of this paper is to present a simple numerical model of dune formation at a fence. The model is based on what is known of the physics of air and grain movements near the fence, and the purpose of approaching the problem at such a basic level is to seek sufficient understanding to enable information and prediction methods to be transferred from person to person and applied at different sites. This requires that the processes which take place at the fence be better understood than at present.

1. *Senior lecturer in engineering, University of Aberdeen, Scotland*
2. *Reservoir engineer, B.P. Petroleum Development Ltd., Aberdeen*

Previous work on sand movement and stabilisation has been reviewed at some length by the authors and a shortened bibliography provided (ref 2). The principal deduction of practical significance about sand fences which can be drawn from a study of the literature is that for best results a fence of approximately 40% porosity should be placed with its plane normal to the flow. Some uncorroborated recommendations can be found about multiple fence placings. Since natural winds vary in direction at a given site and since artificial deposits of greater height than a single fence are normally required, it is clear that this deduction from the literature is not an adequate background to practical dune management, but that more information is needed. We do not provide all this additional information and some remaining obscurities will be discussed at the end of the paper.

Uniform sand flow

As wind increases over a dry sand surface, a threshold is reached at which individual grains are dislodged by the wind and jerk forward or perform feeble saltations. At wind speeds only slightly greater than the threshold value, the population of saltating grains becomes dense enough to extract a substantial amount of momentum from the air layer adjacent to the sand surface, so screening the surface from wind strong enough to dislodge grains and changing the mechanism of dislodgement to one of intergranular collision. This mechanism is more effective than direct "plucking" by the wind, and if the wind speed is slightly reduced, the threshold at which grain motion stops is significantly lower than that at which it began in the rising wind.

A plot of point velocity against the logarithm of the distance of that point from the ground illustrates this point clearly. Fig 1 is an idealised form of such a diagram. The velocity profile corresponding to each mean "wind strength" can be characterised by the shear velocity, V_* , defined by

$$V_* = \sqrt{\frac{\tau_0}{\rho}} \quad (1)$$

where τ_0 is the surface shear stress and ρ is the fluid density.

The velocity at height z in the flow may be expressed as:

$$V_z = 5.75 V_* \log_{10} \frac{z}{k'} + V_t \quad (2)$$

As illustrated in fig 1, k' and V_t are the coordinates of the focus of velocity profiles which converge very nearly at a point, V_t being the threshold velocity. As the wind strengthens above the threshold, the velocity at any fixed height which is less than k' does not increase, and so the direct action of the wind remains insufficient to mobilise sand. It is also interesting to note that the effective origin of the logarithmic velocity profiles rises with wind strength, as the population of saltating grains becomes more dense.

Fig 1 Velocity distributions of wind blowing over moving sand at three strengths, the lowest one corresponding to the threshold of motion.

Fig 2 Shear velocity distribution with distance from the fence (of height h) for five fence porosities. (v_{*ref} is a value of shear velocity beyond the influence of the fence).

Of several formulae for calculating the uniform rate of sand transport, the best known is the early one of Bagnold (ref 3), viz:

$$q = C \left(\frac{d}{D} \right)^{0.5} \frac{\rho}{g} v_*^3 \quad (3)$$

in which d is the grain diameter,

D is the diameter of a "reference grain",

ρ is air density,

C is a coefficient which takes account of population grading and which is determined by experiment.

The range of values quoted for C is 1.5 - 2.8 so that big differences in predicted transport rate occur for different grain populations each having the same mean grain size. Consequently it is only with reluctance that one would choose a value of C by rule-of-thumb, and usually an experiment is needed to re-cast equation (3) in a form suitable for prediction. The sand used in all experiments reported here was a local dune sand having $d_{50} = 0.25$ mm and in measurements of uniform transport rate proved to obey the relationship

$$q = 4.02 \times 10^{-6} v_*^3 \quad (4)$$

This formula has been used throughout the reported work.

Non-uniformity and unsteadiness

Any change of condition, either spatial or temporal, whether of the sand or of the driving wind, initiates adjustments of the saltating cloud and the near-surface wind structure. Because the momentum exchanges inherent in these adjustments cannot, by the nature of the mechanisms involved, be made instantaneously, the influence of conditions before the change persist somewhat after it has taken place.

The introduction of a porous fence into a steady air-stream produces a local distortion of the near-surface flow which leads to deposition of sand. We have measured shear stress changes in the vicinity of a fence by means of Preston-tubes (surface Pitot-tubes) and have used the shear velocity pattern derived from these stress measurements to indicate the magnitude of the flow distortion. Calculations of sand deposition have been based on the graphs of shear velocity distribution (fig 2).

Unfortunately, because the velocity profile is distorted near the fence (particularly close to the ground), shear velocity alone no longer characterises the flow field at a particular location. As fig 3 shows, the velocity gradient at ground level (and hence shear stress and shear velocity) is not consistently related to the velocity at an arbitrarily chosen distance from the surface.

Fig 3 Distortion of velocity profile near the fence.

Fig 4 Control sector used in calculation method 1.

Fig 5 Scheme of calculation - method 2
 Removal rate of material at P calculated from local shear velocity and saltation a.
 Deposition rate at P calculated from shear velocity at Q and saltation b.

Since saltating grains experience the influence of the wind at considerable distances from the ground, it would be more rigorous to describe each velocity profile fully and to use the full description in calculating the behaviour of grains in the flow field. However, as a first approximation, shear velocity has been used as independent variable in this numerical work. The complications of a full description of the time-averaged flow field are such that use of the simplistic description has great advantages and, should it provide acceptable accuracy in calculation of deposits, could well be retained despite its crudity.

Calculation methods

Two methods have been used for calculating the deposition at a fence, both are more fully reported elsewhere (ref 4). Briefly the two schemes of calculation are as follows. Both are two dimensional and it is convenient to consider unit horizontal depth of field parallel to the fence.

Method 1 (Fig 4)

For the extent of the influence of the fence, space is divided into sectors Δx in the wind direction (normal to the fence). For the sector between locations x_i and x_{i+1} it is argued that the mean rise of surface level in time Δt is equal to the difference between the weight of sand entering the sector and leaving it in that time divided by the superficial area and the bulk density of the deposit. The rate at which material enters and leaves the sector is calculated by means of equation (4) from the local values of shear velocity at x_i and x_{i+1} respectively. Shear velocity values are obtained from fig 2. The calculation proceeds in the direction of increasing x for the extent of the fence's influence for each time increment. After each pass the fence height is adjusted to the extent it has been buried by the accumulating sand.

Method 2 (Fig 5)

Again, the ground is divided into stream-wise sectors of length Δx . In this method, however, the book-keeping is done in terms of erosion rates per unit area rather in terms of transport rates per unit width. For each sector, the change of surface level in Δt is made equal to the difference between the deposit rate of grains landing on it and the erosion rate of grains removed from it divided by the bulk density of the deposit. It is assumed that the erosion rate at a particular position can be calculated from the local value of boundary shear stress and that the deposition rate should be calculated from the value of shear stress at one saltation length upstream. In both cases the rates by area are obtained by dividing the transport rate per unit width by a saltation length. The appropriate saltation length is that of the saltation relative to which the unit of area is central.

Experimental evidence

Most of the evidence which is useful for direct checks on the calculation method derives from wind-tunnel experiments. Field checks require that changes of wind strength and direction are monitored continuously and there is little data available from experiments in which this has been done.

Wind tunnel measurements using 5 cm and 7.5 cm high fences of various porosities between 32% and 51% corroborate calculations by either method in respect of the size and shape of the deposit. However, the position of the deposit calculated from the shear stress profile by either method is misplaced upstream by a significant amount (the crest of the deposit is predicted to be upstream of the fence, whereas it is observed to be downstream of the fence both in the wind-tunnel and in the field). This error of position is approximately proportional to fence height and is corrected by introducing a numerical routine to represent; the jetting of flow between fence members. The routine raises the shear stress on the sand by a factor equal to the reciprocal of the porosity and operates with that enhanced shear stress on the net bed width. As fig 6 shows, the resulting prediction accords reasonably well with observation at miniature fences. (The figure shows an arbitrarily chosen porosity and flow condition, but comparisons are successful to approximately the same extent for other wind strengths, porosities and experiment durations).

Near its leading edge the deposit is considerably deeper in the numerical prediction than it is observed to be when measured in the wind-tunnel. A heavier deposit is predicted as soon as the boundary shear stress begins to fall than actually occurs. There are two obvious omissions from the calculation method which might be held responsible for this error of detail. The first is neglect of the velocity profile distortion in favour of dependence on boundary shear stress alone, the second is omission of the enhancement of boundary shear stress to be expected on the convex surface formed by the developing dune. Rough and ready checks have been run on both these influences. The incorporation in the calculation of pitot-static measurements of velocity made upstream of the fence at a distance above the bed equal to approximately three-quarters the maximum saltation height effects a small improvement in the prediction of the upstream portion of the deposit as compared with Preston tube measurements of shear stress at bed-level. Also, the introduction of empirical hill-effect shear stress enhancement reduces the thickness of this early deposit without substantially

Fig.6 Comparison of measured dune profile with profile calculated for corresponding conditions and elapsed time, incorporating jetting.

changing the faithful down-wind modelling. However, the influence on transport rate of changes of surface gradient is not confined to that associated with changed shear stress; the angle and velocity at which moving grains attack the bed is also changed, and this has a significant effect on transport rate. The transport rate perturbation due to the hill effect is incapable of resolution at present, and its effect is confined to the zone upstream of the fence until the fence becomes submerged in sand. For these reasons the effect has been omitted from calculations so far, and the discrepancy at the leading edge of the deposit tolerated.

Scope for practical use of calculations

The calculation methods which have been reported have been applied only to the simplest possible circumstance, namely a fence on an initially flat sand surface with wind normal to the fence plane. Obviously practical applications would involve much more complicated geometry, and one is bound to ask whether the calculation method could be extended and modified successfully enough to become useful in real situations. The answer involves a closer look at the coastal dune system and particularly at the symptoms which show when major damage is impending (for the stable dunes require no predictive calculation).

Mature coastal dune areas consist of non-cohesive soil in undulating features usually covered almost completely in marram grass with smaller colonies of other plants tolerant of sand and salt. Such a system will survive quite high rates of deposition of incoming sand and is retentive of deposited sand because of the protection from wind given to the surface by vegetation. It is therefore quite stable, and before sand blowing can impair the stability of the dunes, there is usually preceding mechanical damage to vegetation, the removal of which exposes the bare sand to the wind. The agents of such damage may be waves, fresh-water streams, engineering works, grazing animals, vehicle or pedestrian access, and they often result in two particular types of erosion feature. The first, resulting from water attack, consists of exposure of a near-vertical sand face of considerable length, such as can often be seen when waves have reached the fore-dune. Wind processes are often important in the subsequent development of a feature initiated in this way but the present calculation method is not useful in this case. It fails because gravity, drying processes and secondary air flows dominate the situation. The second type of feature is even more important and is often called a "blow-out". It consists of a U-shaped trough often intersecting a dune ridge and growing in size by means of two processes. Sand is blown along the trough and out of it down-wind, thus increasing the depth of the feature and the steepness of its sides. At some point the vegetation securing these sides at more than the natural angle of repose is torn away, and sand and grass tussocks fall into the base of the blow-out. Wet or calm weather at this stage may enable the grass to re-establish itself and stabilise the

feature in the new geometry, but often the fallen debris is itself blown out of the trough so that the blow-out becomes both wider and deeper. Such blow-out development is a response to winds which blow along the axis of the feature (its base is protected from transverse winds) and it is reasonable to model the sand transport two-dimensionally as is done in the present calculation method rather than three dimensionally.

A common method of reversing the blow-out process is to place sand fences across the base of the blow-out to accumulate sand which is blown along its axis and so to reduce its depth. As this procedure improves the geometry of the feature, marram plantings are made to stabilise the new surfaces. The accumulation of sand at the fence in this case conforms closely to the assumptions of the reported numerical model; the sand is bare, the winds which propel the sand are virtually normal to the fence plane and initial longitudinal curvature of the sand surface is small. A useful indication of the growth of the sand deposit can be expected from calculation methods such as those described.

Caution is needed, however, in interpreting the results of such calculations. One difficulty, which is unavoidable, is that the rate of accumulation of sand depends on quite detailed features of the weather pattern (because the sand transport rate depends on dryness as well as wind strength and direction). It is common to base design predictions on an extreme event chosen statistically but not on the more difficult statistics of pattern occurrence. A second problem of interpretation concerns the imperfections of the present calculation methods, and is capable of reduction by improvement of those methods. There are several possible improvements, the important ones involving the effects of the dune shape on the boundary shear stress, and the influence of grain size distribution and characteristic grain shape on the uniform sand transport rate. Both of these matters merit further research.

It is also evident that the method of calculation of topographical changes from shear stress patterns can be applied to problems other than sand fence ones. Provided, in some other class of problem, it is possible to predict or measure the shear stress pattern, then consequent changes of topography will be calculable. The success of such calculations will be linked to the steepness of gradient of the shear stress change, but should be comparable with that of the fence calculations.

Conclusions

The deposition of sand at porous fences can be predicted with some success using uniform transport rate equations for the non-uniform conditions near the fence. It is necessary to incorporate the effect on sand of the locally high velocities of air between fence members.

The calculation is dependent on empirical descriptions of the flow field near the fence expressed, for the purpose of substitution in sand transport formulae, in terms of boundary shear stress. The pattern of boundary shear stress for a given porosity is scaled by fence height and therefore can be evaluated for any particular fence in terms of a dimensionless plot of data for a reference fence of the same porosity.

Scope for useful application of the calculation method is limited by ignorance of the mechanisms by which dune systems deteriorate, a topic which merits further work.

BEACH GROUND-WATER OSCILLATIONS

Andrzej LEWANDOWSKI *

Ryszard B. ZEIDLER **

ABSTRACT

Oscillations of ground-water table were measured in perforated piezometers distributed across the Baltic beach at the coastal research station of Lubiatowo. From spectral and correlation analysis it appears that the most pronounced wind-wave oscillations having a period of about 6 seconds have not been detected in the beach, while longwave oscillations, dominant in the beach spectrum, correlate well with nearshore long waves. Among the longwave oscillations, it is only those having periods about or slightly longer than 100 seconds that obey the Boussinesq law. However, some longer waves may also be generated by the interaction of shorter waves. Oscillations with periods from 50 to 100 s are very coherent throughout the beach. In the absence of stochastic noise and variety of inputs, low values of coherence for other periods indicate presence of nonlinear effects. More light should be shed on the origin of this nonlinearity and theoretical tools should be tried to complement the Boussinesq model.

INTRODUCTION

During the past decade, extensive measurements of hydro- and lithodynamical factors were continued in the Polish Academy of Sciences' coastal research station at Lubiatowo, stretching along a rectilinear coastline section some 100 km northwesterly of Gdańsk.

A set of nine measuring posts (Fig. 1), reaching a depth of 6 m at a distance of 700 m from shore line, permits investigations of waves, currents, turbulent diffusion, sediment transport etc.

Fig.1 - Coastal Research Station at Lubiatowo

The data collected in two international expeditions of 1974 and 1976, together with relevant scientific results, can be found in References 1 and 2.

About five years ago the motion of ground water was added to the phenomena studied at Lubiatowo. Oscillations of ground-water table (GWT) were measured in the network of

piezometers shown in Fig.2 .

Measurements in piezometers No 01, 02, 015, 035, 055, 061, 071, 081 were carried out in 1974
 Measurements in piezometers No 1, 2, 3, 4, 5, 6, 7 were carried out in 1978

Fig.2 - Layout of Piezometers at Lubiatowo

All piezometers were made of 4-inch steel pipes, with filters as perforated sections lined with a filter gauze. The diameter of the gravel layer around the filter sections was 8 inches. The instrumentation for measurements of oscillations consisted of three resistance wave probes, electronic system HAG-1 (designed at the Institute) and recorder. Calibration of the piezometers in a wave flume has indicated that free surface oscillations having periods of 1 second and longer are undistorted.

Changes in the sea water level, both slow and fast, bring about oscillations of ground water in the beach, which can be felt far away from shore line, e.g. in case of strong storm surges. Recognition of long oscillations has economic bearings because of floods, agriculture of hindlands, water sources etc. Shortwave oscillations are also important, as they determine the dynamics and stability of coastline, penetration of water

and beach consolidation etc. Studies of these oscillations can elucidate hydro- and lithodynamical processes about civil engineering structures, e.g. distribution of pressures, dynamics of dikes and so forth.

A general description of the dynamics of beach ground water, using hydrochemical and hydrophysical indicators, has been given in the doctor's thesis of the junior author. This paper presents only the results concerning the ground-water oscillations. The measurements carried out under the thesis program have been revised and supplemented by this year's findings. The available experimental material is limited to longshore homogeneity, stationary conditions at the land boundary far off shore, and lack of atmospheric precipitation.

BASIC CHARACTERISTICS

Even a cursory glance at the records of ground-water oscillations exposes the effect of sea level oscillations on GWT. Under conditions of heavy storms (wave height H about 2 m some 350 m from shore line) this effect is pronounced as far as 50 m landwards (piezometers 051 - 055). Haphazard measurements in piezometer 061 have not detected shortwave GWT oscillations. The effect of lower sea waves ($H = 1$ m) can be distinguished by 30 m from shore line.

Since GWT oscillations are random, the theory of random processes has been harnessed in their analysis. Nevertheless, the stochastic findings have been combined with theoretical considerations for non-random ground-water filtration. - Fig.3 shows spectra of waves measured at stations D2 and D5 (150 and 350 m off shore) and GWT oscillations in piezometer P.01, located about 2 m from shore line. Note different ordinate scales. It can be seen that the frequency band of maximum energy (sea versus beach) do not overlap. In general, the spectral peak of wind waves and swell at Lubiatowo occurs at the linear frequency f about $0.16s^{-1}$, which corresponds to

Fig.3 - Spectra of Sea Surface and GWT Oscillations

a period T of 6 s. These oscillations do not penetrate too far into land: the spectrum of P.01 does not contain significant 6-second components. On the other hand, because of technical shortcomings, the initial measurements of 1974 did not point to the presence of long sea waves, corresponding to those detected in the beach. It was only in this year's measurements, including recordings of sea surface displacements over hours, that it was possible not only to expose the longwave oscillations of water level in the nearshore zone but also to look at their correlation with the GWT oscillations.

The correlation and spectral analysis of GWT oscillations provides basic characteristics of the behavior of ground water in the beach. Fig.4 presents spectral densities measured in piezometers 01, 02 and 015. One can note characteristic confinement and displacement of the spectral band with distance, increasing from shore. The further landwards the given spectrum, the narrower its band and the more it is shifted towards lower frequencies. As they travel across the beach, shortwave oscillations become gradually filtered out, by the mechanism of damping. - Similar conclusions can be drawn from

Fig.4 - GWT Oscillation Spectra

review of autocorrelation functions. The typical form of the latter (sinusoid(s) plus exponential attenuation) suggests the existence of a narrow-band random process with one (or two) sinusoidal signals. Principal parameters of these signals, determined from the spectral density peaks and clear-cut sinusoids in the autocorrelation functions, are given in Table 1.

The spectral density functions shown in Figures 5 and 6, normalized with regard to variances, expose some common features of the measured random functions. It appears that $S(\omega) \sim S(f)$ are decreasing power functions with an exponent about 3, which also falls with distance from shore line (3.1 at P.02 versus 2.7 at P.01). Attention should be called to the maxima of $S(f)$ (for f about 0.01 s^{-1}), especially in Fig. 5 for P.01. They might indicate the inflow of energy from outside (from the sea), conveyed by oscillations having periods $T = \frac{1}{f}$ about 100 seconds. The band of maxima in Fig.6, for P.02, is more smeared, which seems to point to the generation of longer GWT oscillations in the beach, which in turn could receive energy from shorter waves. This observation is

supported by the results for some autocorrelation functions, with the periods of sinusoidal signals growing longer, or even doubling, over a short distance between piezometers. Some secondary long waves, superimposed on primary oscillations close to the shore line and becoming uncreasingly distinct at greater distances, are shown in Table 1 for piezometer P.02.

Thus, tentative analysis of GWT oscillations (their simple stochastic characteristics) indicates that the waves having periods about 100 seconds are somehow critical: they travel across the beach without strong attenuation, so characteristic for shorter periods. On the other hand, longer waves can come from secondary sources (can be generated by interaction mechanisms). Deeper insight into the physical structure of GWT oscillations can be provided by a bit more sophisticated considerations presented below.

UNSTEADY FILTRATION AND SUPPLEMENTARY STOCHASTIC CHARACTERISTICS

Two-dimensional unsteady filtration of free-surface ground water in soil having inhomogeneous hydraulic properties is described by the Boussinesq equation

$$\frac{\partial \zeta}{\partial t} = \frac{\partial}{\partial x} \left[\frac{k}{\mu} (\zeta - h_s) \frac{\partial \zeta}{\partial x} \right] + \frac{\partial}{\partial y} \left[\frac{k}{\mu} (\zeta - h_s) \frac{\partial \zeta}{\partial y} \right] + \frac{w}{\mu} \quad \dots 1$$

in which

- $\zeta = \zeta(x, y, t)$ = elevation of ground-water table
- $h_s = h_s(x, y, t)$ = ordinate of floor of aquiferous stratum
- $k = k(x, y)$ = coefficient of permeability
- $\mu = \mu(x, y)$ = coefficient of yield
- $w = w(x, y, t)$ = source function

Equation (1) can be substituted by an explicit finite difference scheme with time as a parameter. The equivalent

equation was solved in ALGOL on an ODRA 1204 computer. For 160 by 220 m section of the Lubiatowo beach the boundary conditions were taken as constant water level far away from the sea, a sinusoidal variation of sea level at shore line and impermeability along the two remaining sides of the rectangle. The source function was taken as inhomogenous atmospheric precipitation measured in situ. All the boundary conditions have resulted from two-year investigations, the data of which was used for verification of the computations. The verification (comparison of computations with yearlong field measurements) has shown that the Boussinesq equation describes well the behavior of long waves having periods of several hours, or even longer. Moreover, it turned out that the filtration processes in the Lubiatowo beach are almost unidirectional, i.e. do not vary considerably along the beach over distances of hundreds of meters. Thus, they can be described fairly by the Boussinesq one-dimensional equation with constant coefficients:

$$\frac{\partial \zeta}{\partial t} = \frac{k}{\mu} h_s \frac{\partial^2 \zeta}{\partial x^2} \quad \dots 2$$

For the boundary conditions

$$\begin{array}{lll} \zeta = \zeta_0 \sin \omega t & \text{at} & x = 0 \\ \zeta = 0 & \text{at} & x \rightarrow \infty \\ \zeta = 0 & \text{at} & t = 0 \end{array}$$

a solution of Eq.2 for sufficiently long t assumes the form

$$\zeta = \zeta_0 \exp(-bx) \sin(\omega t - bx) \quad \dots 3$$

in which

$$b = \left(\frac{\omega \cdot \mu}{2k \cdot h_s} \right)^{1/2}$$

The Fourier transform of Eq.2 in the time domain is

$$\frac{k \cdot h_s}{\mu} \cdot \frac{\partial^2 S(f, x)}{\partial x^2} - j f S(f, x) = 0 \quad \dots 4$$

From its solution with respective boundary conditions (or through the Fourier transformation of the response function included in Eq.3) one obtains the following spectral density of GWT oscillations

$$S(f, x) = S_0(f) \exp\left(-\sqrt{\frac{f}{k \cdot h_s}} x\right) \quad \dots 5$$

in which $S_0(f)$ determines the spectrum of sea surface oscillations at the input to the area of ground-water motion ($x = 0$).

From solution (5) it follows that the spectrum of GWT oscillations should curve down to the abscissae axis: in the bilogarithmic system of Figures 5 and 6, because of the exponential factor in Eq.5, the straight lines $S(f)$ should become curvilinear with increasing f . Similarly, for higher x the curves $S(f)$ must be steeper.

Although the second tendency is fairly distinct (compare slopes of the curves for piezometers P.01 and P.02), the former trend is difficult to expose. From this fact it can be inferred that the Boussinesq equation is inadequate for the description of shortwave oscillations in the beach. At least three additional factors point to inadequacy. Firstly, the shortwave oscillations ($f \sim 0.01 \text{ s}^{-1}$) measured at Lubiatowo are attenuated much more strongly than it is given by the attenuation factor b in formula (5).

Secondly, the experimental data shows that the frequency modulation predicted by the Boussinesq $\sin(\omega t - bx)$ is unrealistic. The factor b computed for the known beach characteristics is much greater than that encountered in the

piezometers. Finally, the Boussinesq model does not shed light on the origin of very long oscillations (having however periods shorter than the diurnal oscillations mentioned with reference to Eq.1) ; these oscillations seem to be generated by interactions of shorter waves.

Further information about the ground-water motion is borne by such statistical characteristics as coherence and transfer functions. The coherence functions γ_{xy} computed for two different piezometers indicate that it is only GWT oscillations with periods about 100 seconds that come from the same source (read: from the sea, as sea surface oscillations) . This is illustrated by examples given in Fig.7.

Fig.7 - Coherence Functions

The filtered data was obtained by the well-known filtering technique with a cosine kernel. - It can be seen that high values of coherence occur only in a narrow frequency band. Oscillations with other frequencies have coherences between 0 and 1.

For the ideal case of a linear constant-parameter dynamic system with single, strictly defined, input and output (a "deterministic" system), the coherence function is equal

to one. If γ_{xy} lies between 0 and 1, at least one of the three following cases is possible:

- a) results of measurements are subject to errors due to external noise
- b) the system which couples the input and output signals, $x(t)$ and $y(t)$ is nonlinear
- c) the output signal $y(t)$ is a resultant of a few input signals, instead of a single $x(t)$.

Analysis of the physical processes and experimental techniques inherent in this study of GWT oscillations makes it possible to exclude the cases (a) and (c), as irrelevant under the Lubiatowo conditions. Thus, the only acceptable explanation of the low coherence of most GWT oscillations is confined to nonlinear effects. The values of γ_{xy} measured in various situations indicate that the nonlinear effects are strong both in the band of "short" waves having periods T below 50s, in which GWT oscillations cannot be treated analytically by the Boussinesq equation, and in long waves, with T above 100 s, which might obey the Boussinesq approach but are subject to interaction effects.

The finding that the period T about 100s is somehow critical is also supported by the measured values of the amplification factor.

$$|H(f)| = H(f) \cdot \exp[i\theta(f)] \quad \dots 6$$

From the examples presented in Fig.8, with $|H(f)|$ computed for original GWT level series prior to and after filtering, it can be seen that attenuation of waves is smallest (high $H(f)$) for $f \approx 0.01s^{-1}$.

Analysis of the phase angle $\theta(f)$ shows that the waves passing across the beach (piezometers P.01 ... P.02 etc.) travel toward the dunes, and not along the shore (as should be in case of the edge wave type interaction waves). The phase velocities of these waves vary from 50 to 100 cm per s,

in good agreement with the values of ω/b for waves with periods longer than 100 seconds, another indication of the critical character of these oscillations.

Fig.8 - Amplification Factor

ACKNOWLEDGEMENTS

This study was financially supported by the Polish Academy of Sciences under MR I.15.3.1 program. Dr. T. Piwecki of the Gdańsk Technical University is gratefully acknowledged for his computer routine, which permitted analysis of unsteady filtration.

COASTAL STRUCTURES AND RELATED PROBLEMS

Light House, Weser Estuary

COASTAL STRUCTURES' EFFECTS ON SHORELINES

by Ronald M. Noble*

ABSTRACT

Coastal structures have caused significant impacts to adjacent shorelines, especially when these shorelines are composed of sand. Many times, these shoreline impacts have not been expected due to improper planning prior to the design and construction of these structures. Consequently, excessive erosion and/or deposition of sediment as a result of these structures has necessitated costly, and in some cases, continuous maintenance operations.

This paper reviews the expected shoreline effects for an offshore pier-trestle and breakwater system for an LNG marine terminal. Coastal structures originally proposed for the LNG marine terminal consisted of a 4,600-foot-long pile supported "T" head pier/trestle system and a 1,000-foot-long detached rubble-mound breakwater. This investigation involved field and historical aerial photographic examination of 30 structures in the Southern California Bight and a literature review of similar structures in other environments. Also, a review of theoretical and physical model studies applicable to structures within the coastal marine environment was conducted.

The results of this investigation of existing structures, in conjunction with theory and model studies, indicate that within the study region, pile-supported piers have no appreciable impact of the adjacent shoreline. This investigation also indicates that detached breakwaters produce only minimal impact when the offshore distance of the structure is greater than six times the breakwater length. Of course, consideration was also given to the structure's position relative to the littoral zone, to the depth of water at the shoreward face of the structure, and to the wave climate approaching the structure.

This study included a review of such factors as the local topography, nearshore bathymetry, beach processes, shoreline configuration, beach materials, range of water levels, and local wave climate. The controlling parameters identified in this study are discussed, and the final recommendations presented. This paper illustrates the importance of proper advance shoreline planning before the final design and construction of shoreline facilities.

INTRODUCTION

The construction of, or the nonconstruction of, coastal structures have resulted in significant impacts along our shorelines. It works both ways; structures built for inlet stabilization or for providing protection such as jetties and breakwaters, and for shoreline stabilization such as groins, bulkheads, revetments, etc. which have not properly considered the existing wave climate and shore processes taking place have resulted in costly maintenance operations; whereas, shoreline developments at other locations have not considered the potential erosion of shorelines from coastal processes and therefore, have not provided adequate coastal structures in the form of shoreline protection or the proper setback and floor elevation for development.

This paper discusses the assessment of the potential impact of a proposed marine terminal on the longshore movement of sand. This study was a preliminary assessment performed in a short time frame in order to ascertain whether the proposed marine terminal posed a significant impact to the adjacent shoreline and if more detailed studies were required.

Included in this study was a review of the site baseline conditions, the effects existing similar structures have had on adjacent shorelines, and theoretical and model studies pertaining to the effects of coastal structures on the littoral environment.

COASTAL STRUCTURES

A liquefied natural gas (LNG) facility has been proposed for construction at Point Conception, California (Figure 1) by Western LNG Terminal Associates. The original¹ proposed coastal structures for the LNG marine terminal consisted of a 4,600-foot-long pile supported "T" head pier/trestle system for LNG carrier offloading and a 1,000-foot-long detached rubble-mound breakwater for support boat and barge mooring.

The 4,600-foot main trestle and the 1/2-mile "T" head pier were to be supported by 60-inch-diameter piles placed four to a bent across the 50-foot pier/trestle width with bents placed approximately 130 feet on centers. The water depth at the pier head would be to approximately -60 feet mean lower low water (MLLW). The proposed rubble-mound breakwater would be located adjacent to the main trestle

¹The design specifications for the proposed coastal structures have been subsequently modified.

FIGURE 1
SITE MAP

on the trestle's east side and extend 1,000 feet from the trestle aligned approximately parallel to the shoreline along the -20-foot MLLW water depth contour.

The potential effect these proposed structures could have on the adjacent shoreline was assessed by considering the following:

- o Limited site field investigation
- o Review of existing similar structures
- o Review of literature on theoretical and model studies

In review of the above, a good understanding of the shore processes taking place in the site area is required, especially concerning wave climate, sediment transport volumes and sediment transport directions of movement.

EXISTING CONDITIONS

Longshore sediment transport is dependent on such physical conditions as wave climate, beach profile, shoreline configuration, sediment budget, currents, offshore bathymetry, and existing shoreline structures. Waves are the primary driving force controlling the longshore movement of sediment. Therefore, these physical conditions were investigated for the site area.

The proposed site is located at the west end of the Santa Barbara Channel in Santa Barbara County (see Figure 1). This location is approximately 2 miles east of Governement Point within what is known as the Southern California Bight. Due to the abrupt change in orientation of the coastline in the Point Conception area, the coastline within the Southern California Bight is sheltered from wave approach out of the northwest. Additionally, eight offshore islands within this region intercept a portion of the incoming open ocean wave energy from the west, southwest, and south. Consequently, this portion of the coastline may be thought of as a "semiprotected" open ocean coast.

The proposed LNG terminal site is exposed to wave activity from directions southeasterly clockwise through westerly. It is directly exposed to deepwater ocean wave conditions from directions southerly clockwise through westerly directions. Deepwater waves approaching from directions northwesterly through northerly will be refracted toward the east up the Santa Barbara Channel. Due to significant refraction effects and the natural protection

provided to the site by Government Point, these waves do not significantly affect the site. Deepwater ocean waves approaching the site from directions southeasterly clockwise through southerly directions will undergo the effects of diffraction and refraction around the Santa Barbara Islands before reaching the site area. Waves generated within the Santa Barbara Channel can also reach the site from these directions. Several wave hindcast and refraction studies performed in the vicinity of Point Conception were used to verify these findings.

Stations 5 and 6 from National Marine Consultants (1960) deepwater hindcast wave statistics are located in the Point Conception area as shown on Figure 1. There also presently exists wave gages both offshore and in the site area.

The coastline in the vicinity of the proposed site trends in a westward direction and turns northward upcoast from Point Arguello. Sedimentological studies conducted in this area have established the direction of net longshore sediment movement as west to east or downcoast and have also verified the fact that some sediment does move southward around the rocky promontories of Point Arguello and Point Conception. Additionally, investigations by Bowen and Inman (1966) and the U.S. Army Corps of Engineers (1965) have attempted to quantify the sediment transport rate along this portion of California coast. At present, estimates range between 50,000 and 100,000 cubic yards annually. Field and literature investigations suggest that most of this volume of sediment moves downcoast inside of the surf zone. Field studies conducted during the present investigation indicate that the effective boundary of the littoral zone at the site may be approximated by the -20-foot MLLW contour. Seasonal onshore/offshore migration of sand deposits and the redistribution of deposits during a storm event may move the position of the boundary seaward.

SHORELINE PIERS

To effectively assess the potential impact of the proposed pier on the longshore movement of sediment in the site area, case histories of existing piers were investigated and a review of the theory and model studies applicable to pile-supported structures was performed. In all, 20 piers were involved in this study, all situated within the Southern California Bight. The pier locations investigated are shown on Figure 2. The wave climate south of Point Conception, as previously mentioned, is strongly

FIGURE 2
**OFFSHORE STRUCTURES
 INVESTIGATED WITHIN SOUTHERN
 CALIFORNIA BIGHT**

influenced by the change in orientation of the coastline and the presence of the offshore islands. Similarities between each of the pier environments are afforded by this regional physiography.

Factors reviewed for each pier structure are shown in Table I and were as follows:

o Environment

- Location of structure
- Wave exposure
- Physiographic setting
- Configuration of pier
- Net longshore transport

o Structural Characteristics

- Pile diameter
- Number piles per bent and pile spacing
- Bent spacing
- Length of structure
- Width of structure

o Effects on Adjacent Shoreline

The piers in this study were all pile-supported structures with evenly spaced pile bents. The foot of each pier was located shoreward of the mean high water level, and the pile-supported structures extended seaward through the nearshore zone. Pile diameters were uniform over the length of each pier as were the bent spacings, and with few exceptions, the number of piles per bent was consistent over the length of the piers.

Although similarities existed between the various piers, the observed ranges in dimensions and configurations were large. The piers ranged in length from 625 to 2,500 feet and in width from 15 to 300 feet. Designs varied from straight "finger-type" piers to complex "U-shaped" or "Dog Leg" piers. Pile diameters ranged from 12 to 30 inches and exhibited a transverse, on center spacing of 4 to 28 feet. The 20 piers also exhibited a minimum bent spacing of 15 feet and a maximum of 60 feet.

Field inspections and historical aerial photographs provided the necessary information for evaluation of the impact on littoral sand transport for each of the structures. Field observations and review of the aerial photographs indicated that these piers have had a negligible effect on the adjacent shoreline. In two cases, where

³Characteristic pertaining to the inshore portion of pier.

substantial accretion effects were observed, it was apparent that the presence of structures other than the pile-supported piers had been the cause.

The results of these "similar structure" observations for piers are supported by the result of two previously conducted studies, one by J.W. Johnson in 1973 and another by C.H. Evert and A.E. DeWall in 1975. Johnson inspected approximately 34 piers along the California coast and found no discernible effects on the adjacent shorelines as a result of pier installation. Everts and DeWall, in a beach survey conducted in North Carolina, likewise found that out of five fishing piers inspected, none had a significant effect on accretion or erosion along adjacent shorelines.

Theoretical/analytical studies have been conducted to determine the effects of pile-supported structures on the transmission of wave energy. Most of the studies have attempted to identify the factors which control or greatly influence the transmission losses as waves pass through pile structures. The purpose of these particular studies has been to evaluate the use of closely spaced piles as a breakwater (Wiegel, 1961; Macknight and Thomas, 1973) and to predict wave transmission losses through pile arrays (Costello, 1952, van Weele and Herbich, 1972). In these studies single rows and multiple rows of piles were considered. Both longitudinal and transverse pile spacings were varied along with diameter and total number of piles. Considerations were given to incident wave height and steepness and diffraction effects as the wave passed through the pile arrays. Results of these studies indicate that within a range of incident wave steepness, when pile spacing is greater than four times pile diameter, reflection and eddy losses are of minor importance and the ratio of transmitted wave height to incident wave height should approach unity. This holds true for both transverse and longitudinal pile spacings.

Predominant swell conditions within the Southern California Bight fall well within the wave steepness boundaries established in these investigations. In the case of the surveyed piers, both the longitudinal and the transverse pile spacing were beyond the "four-diameter" range. It would be expected from theory that transmissibility should be very close to unity for all of the structures examined; consequently, as wave energy losses are negligible, there should be a minimal impact on the littoral environment.

OFFSHORE STRUCTURES

To effectively assess the potential impact of the proposed breakwater on the longshore movement of sediment in the site area, case histories of nine existing offshore structures were investigated and a review of the theory applicable to these structures was performed. The structures examined included three detached breakwaters and six artificial islands, all located within the Southern California Bight. The offshore structure locations investigated are shown on Figure 2.

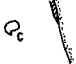

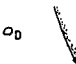

Factors reviewed for each offshore structure are shown in Table II and were as follows:

- o Environment
 - Location of structure
 - Wave exposure
 - Physiographic setting
 - Configuration of structure and adjacent shoreline
 - Net longshore transport
- o Structural Characteristics
 - Structure type
 - Depth at shoreward face of structure
 - Offshore distance to structure
 - Length of structure
 - Ratio: $\frac{\text{distance offshore}}{\text{length of structure}}$
- o Effect on Adjacent Shoreline

Like the piers, the detached structures may be defined by a set of measurable parameters. For the breakwaters, these parameters included the longshore length, the distance from the shoreline, and the depth of water at the shoreward face of the breakwater. Similarly, the measurable parameters for the artificial islands included the distance from shore (measured parallel to the predominant wave approach direction), the structural length (measured perpendicular to the predominant wave approach direction), and the depth of water at the shoreward face of the structure.

The detached breakwaters ranged in length from 600 to 2,800 feet, in distance from the shoreline from 600 to 1,850 feet, and in water depth at the shoreward face from 6

³Distance to shore parallel to predominant wave approach direction.

to 25 feet. The artificial islands ranged in length from 380 to 1,172 feet, in distance from the shoreline from 1,547 to 8,400 feet, and in water depth at the shoreward face from 26 to 44 feet.

Comparison of historical aerial photographs provided most of the information needed to assess the impact of the breakwater and artificial island structures on the littoral environment. These photographs indicated appreciable sediment buildup in the lee of each breakwater. Aerial photography of the artificial islands, before and after construction, showed that some of these structures also may have produced accretionary effects along the adjacent shorelines.

Previous case studies and field investigations have been conducted to evaluate the impact of offshore structures on the littoral zones. Most of these studies have acknowledged one or more of the following parameters as being important in performing this evaluation:

- o The length of the structure relative to its offshore distance
- o The incident wave length relative to the offshore distance of the structure
- o The depth of water at the shoreward face of the structure
- o The incident sector of wave approach at the structure and the resultant wave shadow in the lee of the structure
- o The position of the structure relative to this active littoral zone

Inman and Frautschy (1965) observed that along the southern California coast, pronounced accretion occurs if a detached breakwater is located offshore a distance of less than three to six times the length of the breakwater. Dames & Moore (1974) investigated the effects of artificial islands along the southern California coast on the inshore littoral processes. Through aerial photographic analysis they attempted to document what, if any, effects had occurred on the adjacent shoreline since the time of island construction. This study generally confirms the basic guideline put forth by Inman and Frautschy.

Theoretical and model studies conducted by Harms and others (1973) along with the investigations by Savage de

Saint Marc and Vincent (1968) indicate that a region of reduced wave energy will develop in the lee of an offshore structure. Further, the study by Savage de Saint Marc and Vincent indicates that the effect of an offshore structure on a given shore is dependent mainly on the length of the structure relative to its distance from the shoreline.

The detached structure case studies established distance to shore/length of structure relationship as being the controlling parameter in evaluating the impact of an offshore structure on the adjacent shoreline. Model study investigations supported this finding.

RESULTS

The proposed LNG terminal pier, like all of the piers investigated, is a pile-supported structure. Although the proposed pile diameter is larger than the pile diameters measured for existing piers, the pile density (pile area/total pier area) for the proposed structure is at the low end of pile densities for the surveyed piers. The longitudinal spacing is 20D (20 pile diameters) and the transverse spacing is 4D (4 pile diameters).

Potential impacts associated with the proposed pier are a function of pile density, pile spacing, and incident wave steepness. Pile densities for the piers investigated along the southern California coast produced no discernible impacts on the net longshore movement of sediment. These piers exist in an environment similar to that found at the proposed site, both in terms of wave exposure and longshore sediment transport rates. Because the pile density of the proposed LNG pier is lower than 90 percent of all the piers investigated, it is expected that this pier would have a negligible impact on the longshore movement of sand. Consideration of incident wave steepness and pile spacing from theoretical and model studies also supports the conclusion that the proposed pier would not significantly affect the longshore transport of sand.

Potential impacts associated with the proposed breakwater were found both in the similar structure/similar environment and the model studies to be primarily a function of the distance to shore/length of structure ratio. Of course, consideration was also given to the structure's position relative to the littoral zone and the wave climate approaching the structure. The proposed breakwater's distance to shore/length of structure ratio was approximately two, and its location was in the proximity of the effective littoral boundary. This could cause a substantial reduction in wave energy reaching the littoral zone

in the lee of the breakwater and, therefore, diminish the sediment transporting capacity of waves and currents in this area with a resultant deposition of sediment.

According to the findings of both the case studies and the model studies, at the proposed site, the distance offshore at which the breakwater would be expected to have no discernible impact on the adjacent shoreline would be 6,000 feet (6:1 ratio).

It was felt that the shoreline impact associated with the proposed breakwater would be significantly reduced, for a particular distance offshore, if the structure's length was shortened. In this manner, the ratio of 6:1 offshore distance/length of structure, established in both the similar structure/similar environment investigations and supported by the findings of model studies, could be maintained. However, it would still be important to verify if there would be any wave energy reduction in the effective littoral zone due to wave shadow effects caused by the breakwater.

Rosslyn Bay Breakwater, Queensland, Australia

by

D.N. Foster⁽¹⁾, B.L. McGrath⁽²⁾, W. Bremner⁽³⁾

Introduction

The Queensland Harbours and Marine Department is charged with the responsibility of providing small craft facilities throughout the State. In 1964, the Department engaged a firm of consulting engineers, Blain, Bremner and Williams Pty. Ltd. to prepare a preliminary report on possible boat harbour sites between Yeppoon and Port Alma on the Central Queensland Coast.

Five sites were evaluated according to the following criteria:-

- (i) Degree of protection afforded
- (ii) Tidal access
- (iii) Degree of maintenance dredging anticipated
- (iv) Capital cost necessary to establish the harbour and the ability to construct the harbour in stages
- (v) Availability of foreshore area for development
- (vi) Accessibility by road transport and to established amenities
- (vii) Availability of suitable quarry material

The recommendation that the most suitable site would be at Rosslyn Bay (Figures 1 & 2) was accepted and approval to commence construction was obtained. A 105m rubble mound rock breakwater was constructed in 1968. The breakwater was extended to 210m in 1970 and was further extended to 300m in 1972.

In 1976 tropical cyclone 'David' extensively damaged the breakwater and harbour facilities. Subsequently the breakwater has been re-designed following model studies and reconstruction was completed in May 1978.

This paper discusses damage to the breakwater from wave and surge action, model studies and repair of the breakwater.

Original Design

The area on the Central Queensland Coast between Port Alma and

FIGURE 1: LOCALITY SKETCH
AND PATH OF CYCLONE DAVID.

FIGURE 2: OFFSHORE TOPOGRAPHY AND LOCATION OF WAVE RIDER BUOY

Yeppoon, although sheltered from deep ocean swell by the Great Barrier Reef, has no natural boat havens (except for tidal estuaries) and is subject to cyclonic storms. The fetch length from the Great Barrier Reef to the coast is approximately 80 km. As any structure is subjected to large wave forces, construction of small craft harbours in the region is relatively costly. Tidal estuaries in the area (indeed on the whole of the eastern coast of Queensland) are generally avoided for boat harbour development because of the high frequency of major floods with accompanying high water levels and flow velocities, debris and siltation problems. However, they are used by small craft as shelter during cyclones.

Due to the limitation of available funds, economic considerations were a major factor in fixing the design of the harbour.

Double Head (Figure 2) provides a degree of natural shelter against the prevailing south-easterly winds. To provide protection against north-easterly weather and south-easterly waves diffracted around Double Head, a breakwater was constructed running parallel to the natural contours in a north-westerly direction. In order to reduce costs, the breakwater was designed to the minimum standards necessary to provide shelter against the majority of anticipated weather conditions. To construct a breakwater designed to provide protection during severe cyclonic conditions proved too costly for the available funds. This factor, together with the availability close by, of effective cyclone shelter to small craft in mangrove lined estuaries led to the decision to accept a higher than normal degree of risk of severe storm damage to the breakwater.

The following design criteria were adopted for the breakwater design:

High tidal level	4.27m above L.W.D.
Storm surge	1.22m
Wave height	2.13m
Crest level	7.32m above L.W.D.

A typical section through the breakwater and armour specification is shown in Figure 3. The seaward face was armoured with a nominal 3 ton rock. The crest was armoured with nominal $\frac{1}{2}$ ton rock blinded with fine material to provide an access road and was not designed to resist overtopping.

As there were no wave records for the area, the design storm surge and wave heights were estimated by hindcasting using available wind records. In Jan. 1967 the Consulting Engineer estimated from the available cyclone records that damage to the breakwater may occur once in every 10 years and such damage was likely to be severe. As it happened, the breakwater was severely damaged by overtopping some 8 years after construction of its first section.

FIGURE 3: TYPICAL CROSS SECTION OF BREAKWATER

Cyclone "David"

Cyclone "David" originated in the Coral Sea on 15.1.76, moving first in a south-south-westerly direction and then west to cross the coast approximately 50 km north of the harbour at a speed of 28 km/hr. The path of the cyclone is shown in Figure 1. Central pressure as it crossed the coast was 961 mb and the radius to maximum wind was estimated by the Bureau of Meteorology to be 35 km using radar interpretation methods.

Associated with the cyclone, there was an intense high pressure system (central pressure 1010 to 1024 mb) located in the Tasman Sea some 1500 km to the south-south-east. The consequential steep pressure gradient resulted in a general strengthening of the south-east winds which had persisted since 15th January. This climatic situation is assessed as having had a significant influence on the abnormally long duration of the storm surge which accompanied the cyclone.

Deep water wave conditions during the cyclone were recorded at 12 hr. intervals on wave rider buoys at Double Island Point, 390 km to the south, Mackay 270 km to the north and Yeppoon immediately offshore of the harbour. Recorded wave conditions are given in Table 1.

Water levels during the cyclone were recorded on a network of tide gauges along the Queensland coastline. Storm tide levels at Rosslyn Bay and Gladstone are given in Table 2. Unfortunately the tide gauge at Rosslyn Bay was inoperative over part of the storm but a close estimate of water levels can be obtained from the Gladstone records.

A feature of the storm was the long duration of the surge which reached a maximum of 1.1m during the p.m. tide on 19.1.76. The peak water level of 5.3m occurred during the a.m. tide on 19.1.76.

Wave and storm tide conditions during the cyclone are summarised in Figure 4. Wave conditions at the breakwater are complicated by partial protection provided by two offshore islands approximately 15 km to the east and north-east of the harbour and refraction over a rather complex bed topography (see Figure 2).

From energy considerations wave heights at the breakwater have been estimated to be between 0.8 and 0.9 of the deepwater conditions. In-shore visual observations by two independent observers, one by Bremner and one by COPE,* during the peak of the storm estimated wave heights of 2.5 and 3.3m against a measured deep water significant height of 3.8m.

Wave conditions following the cyclone and prior to a detailed survey of

FIGURE 4: WAVE AND STORM TIDE CONDITIONS

the damage were mild with significant wave heights of less than 2m and zero crossing period of between 4.0 and 5.0 seconds.

Breakwater Damage

Inspection of Figure 4 shows that the breakwater was subjected to wave and surge conditions approaching or exceeding the design conditions from 17th to 20th January. Overtopping of the breakwater occurred at high tide with very heavy overtopping being observed during 19th and 20th. The observed history of damage is given in Table 3.

Table 3: History of Damage

Day Jan. 1976	Time (hours)	Damage
16th	2230	No observable damage
17th	0900	No observable damage
17th	2100	No observable damage
18th	0950	Slight damage
18th	1630	Slight damage
19th	1130	Heavy overtopping - slight damage
19th	2400	Heavy overtopping - minor damage
20th	Early hours	Major failure

Major damage to the breakwater occurred at or soon after the evening high tide on 19th. At this time the breakwater failed catastrophically with the crest being destroyed and lowered within a few hours by some 4m over most of its length. The majority of the rock was displaced landwards coming to rest immediately on the harbour side. There was little damage to the seaward face.

A survey of damage to the breakwater was undertaken 20 days following the failure as shown in Figure 5.

Some comments on the damage are worthy of note. The damage resulted from wave overtopping, the majority of the rock being displaced landwards. When damage occurred it was catastrophic, taking place over a few hours. Despite high combinations of wave and storm tide levels and heavy overtopping little damage was noted prior to final collapse. It is difficult to believe that the class C or B material at the crest (Figure 3) would withstand any significant overtopping as was observed to be the case (see section on model simulation of failure). It is possible that as a result of compaction under road traffic the crest acted as an impervious scour blanket giving protection until incipient failure occurred, after which total failure followed quickly. Damage was very uniform over the entire length of the breakwater except at one section where a wharf abutment on the harbour side acted as a buttress. At this location damage was slight. Little damage occurred to the seaward face for deep water wave heights of up to

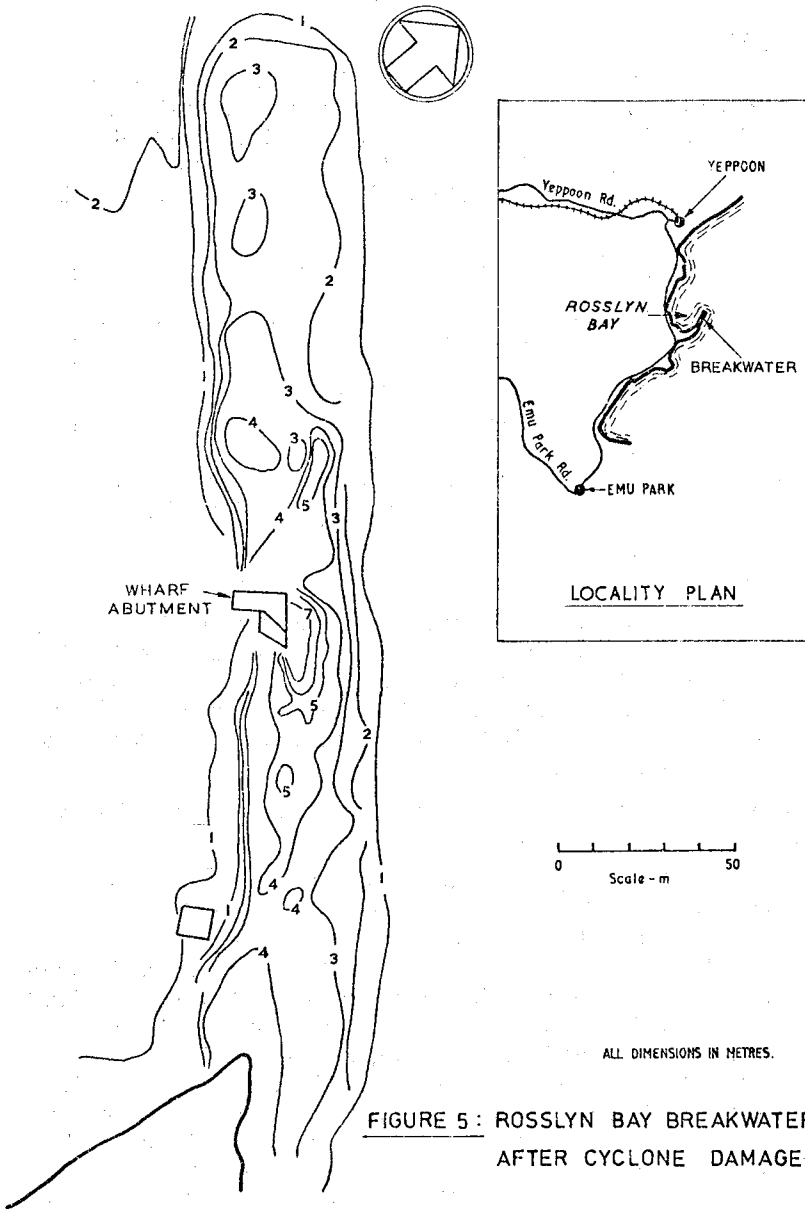

FIGURE 5 : ROSSLYN BAY BREAKWATER AFTER CYCLONE DAMAGE .

3.8m and estimated wave heights at the structure of between 3.0 and 3.4m. Equivalent damage coefficients in Hudson's equation are approximately 2.7 to 3.9 and wave conditions varied between breaking at low tide and non-breaking at high tide.

After failure the structure continued to give substantial protection by acting as a partially submerged breakwater, significantly reducing damage to the harbour infrastructure during the storm and enabling the harbour to be used for its design function under the more common weather conditions that followed. The action of prudent yachtsmen in removing their vessels from the harbour to nearby natural shelter at the onset of the cyclone resulted in the damage to moored vessels being not too severe.

Model Simulation of Failure

As part of the model studies to investigate methods of repairing the breakwater, tests were undertaken to simulate the failure. The test layout for the model is shown in Figure 6. The studies were carried out in a monochromatic wave flume using Froudian scaling. The model scale was 1:27.6. Test conditions reproduced were, offshore significant wave height (approximately H_{10} at the structure), peak spectral period and storm tide assuming a linear variation between high and low water. Typical test results are shown in Figure 7.

The test began at 2230 hours on 16th (low tide) and was continued until 0700 hours on 20th (low tide). Initial damage to the breakwater occurred at 0900 hours on 17th when the crest was destroyed in a landward direction.

Damage continued during each period of high tide when the crest was overtopped. The main damage was the result of overtopping and only a small proportion of the armour was displaced seaward.

At the completion of the test series the structure was subjected to continuous wave attack under stationary conditions corresponding to a wave height of 3.8m, wave period of 1.8s and a storm tide level of 5.1m. Little additional damage occurred indicating that near equilibrium conditions had been reached.

Repeating the test gave almost identical results both as to incidence of damage and the final profile.

The mechanics of damage in the model and prototype were the same with the majority of damage resulting from rock being displaced from the crest and settling on the immediate harbour side. No significant damage occurred to the seaward face. However, the model differed from the prototype in that initial failure happened much earlier. As soon as the structure was significantly overtopped class C and B material was removed and the crest destroyed. (See comment on prototype damage). Damage in the model continued over five high tide

FIGURE 7: MODEL SIMULATION OF FAILURE

periods whilst the prototype damage occurred predominantly under one tide. The rate of damage (Froudeian scaling) was somewhat slower than the prototype. This was somewhat surprising (especially as the H_{10} height was used in the tests) as comparison between random and monochromatic wave tests on non-overtopped structures tend to indicate a faster rate of damage under monochromatic waves. It is possible that the higher waves in the spectra and wave period play a more significant role in the stability of overtopped structures.

The final profile reached in the model showed close agreement with the prototype. However, it is not known whether further damage to the prototype would have occurred if the storm had continued, whilst the final model profile was in equilibrium with the wave and surge conditions.

Modified Design

A section through the modified design is shown in Figure 8. The repair made as much use of the failed breakwater as possible. The design wave height was increased to 4.6m and the maximum storm tide level to 8.5m. The seaward face was flattened to 1 on 4 and the landward face to 1 on 2. Armour mass was increased to 5 tonne nominal and was carried over the crest and down the landward face to allow for overtopping.

Model tests indicated that the proposed design would be satisfactory although some damage could be expected, particularly at the crest under critical combination of wave period and storm tide conditions. A typical set of test results is shown in Figure 9. The tests were undertaken in a monochromatic wave flume using the design offshore significant wave height. Storm tide levels were increased in steps of 1m from RL 3m up to the maximum design value of 8.5m and then decreased in a similar manner. At each water level the structure was subjected to waves for an equivalent prototype duration of 82 minutes. The test was repeated over a range of wave periods of between 9 and 16 seconds. Rock displaced was counted as damage and expressed in terms of a percentage of the total number of armour rock. It will be noted that the rate of damage (particularly to the crest) is dependent upon both wave period and storm tide level. Maximum damage to the seaward face occurred for a wave period of 12 seconds and to the crest for a wave period of 14 seconds. At very high surge levels the crest is submerged and wave forces are reduced by a water cushion between the wave and the armour and damage is reduced. For the same reason it may be that a steeper landward face may have been more stable than the 1 in 2 slope used. However, this was not investigated in detail. Test results shown in Figure 9 are for random placed stone. By careful placement of the crest rock a substantial increase in stability could be obtained.

FIGURE 8: REPAIRED SECTION AS MODELLED

FIGURE 9 : DAMAGE AS A FUNCTION OF SURGE LEVEL FOR WAVE PERIODS FROM 9 - 16 SECONDS

Breakwater as Constructed

After the quarry was opened up the yield of 5 tonne rock was less than anticipated. For this reason the crest was actually armoured with 3.2 tonne modified cubes and the front and back slopes with a random mixture of 5 tonne rock and 3.2 tonne modified cubes on an approximately fifty-fifty basis. Repairs to the breakwater have been completed but as yet the structure has not been subjected to significant storm action.

Sampaio Ferraz Jardim Sayão (3)

I - INTRODUCTION

The elimination of land transportation costs for raw materials and/or industrialized products has encouraged integration of industrial and port activities and, at many ports, facilities are being built for the installation of industrial complexes adjacent to the port areas.

This general trend has been clearly observed along the coast of the State of Espírito Santo, Brazil, north of Rio de Janeiro. Several new port terminals, associated with industrial plants, are under construction or were designed recently.

In fact, the State's port development began with its Commercial Port in Vitória, located at the mouth of the Santa Maria river. The following terminals connected with industries were built at a later date:

a) Tubarão Maritime Terminal, which was brought into operation in 1966, sited at the outer end of Espírito Santo Bay, 9 Km away from Vitória, for iron ore exports. This terminal belongs to the state-owned Companhia Vale do Rio Doce - CVRD. Iron ore exports reached more than 50 million ton per year during the last three years.

b) Ubu Maritime Terminal, inaugurated in 1977 and sited in the south of the State, was designed for exporting pelletized iron ore produced by a plant sited in the port area. This plant receives its raw material (ore fines) through a pipeline approximately 400 Km long. These facilities belong to privately-owned SAMARCO Mineração S.A., and will have a total export capacity of 7 million tons of pellets per year when it reaches its final expansion phase.

c) Barra do Riacho Port, which should start operation in 1978, built by PORTOCEL (owned jointly by PORTOBRÁS, Aracruz Celulose and CVRD) is intended to export wood chips and pulp produced at industrial facilities adjacent to the port.

In addition to these terminals, there are plans to build other ports which will handle goods to be produced by industries now moving into Espírito Santo.

-
- 1) Director of Amazônia Mineração S.A.; Professor of Hydraulics, Faculty of Engineering, Federal University of Espírito Santo, Rio de Janeiro, Brazil.
 - 2) Head of Port Department of Amazônia Mineração S.A.; Assistant Professor of Ports and Inland Waterways, Faculty of Engineering, Federal University of Rio de Janeiro, Brazil.
 - 3) Assistant Professor, Coastal Engineering Area, Federal University of Rio de Janeiro, (COPPE/UFRJ), Rio de Janeiro, Brazil.

The main already designed is Praia Mole Port, to be built just north of Tubarão in order to attend the steel mill of Companhia Siderúrgica de Tubarão - CST - being built in that area.

This terminal is planned mainly for export of steel products and for import of coal for steel production.

Several studies and surveys have been made for designing and constructing the above mentioned ports. These studies and surveys provide a rather reasonable sample of coastal conditions in Espírito Santo. This paper aims at analysing and consolidating the most pertinent Coastal Engineering data already collected, so as to serve as a possible guideline for future designers engaged in coastal studies in this area.

II - DESCRIPTION OF THE COAST AND ITS MAIN PORTS

The coast of the State of Espírito Santo, approximately 205 miles long (Fig. 1), may be divided into four well-defined areas:

a) For the first 84 miles, from the Lençóis Cape, at the extreme north, to the Doce River Mouth, the coast is almost entirely flat, low and sandy, covered with low vegetation, and uniformly shaped. The main feature in this area is the São Mateus river mouth, conspicuous for its long sand dunes.

b) For the next 46 miles, from the mouth of the Doce River to the Espírito Santo Bay, the coastal line rises against the background of the Aimorés mountains. The coast is again sandy, often interrupted by reddish cliffs and protected by occasional reefs that extend sometimes up to one mile into the sea.

c) The Espírito Santo Bay, approximately 2.5 miles long, is located between the Tubarão and Santa Luzia headlands. Here the Santa Maria River drains into the sea, its two main arms forming the Island of Espírito Santo, where the capital of the State is sited, with 300,000 inhabitants and forming the main commercial port of the area.

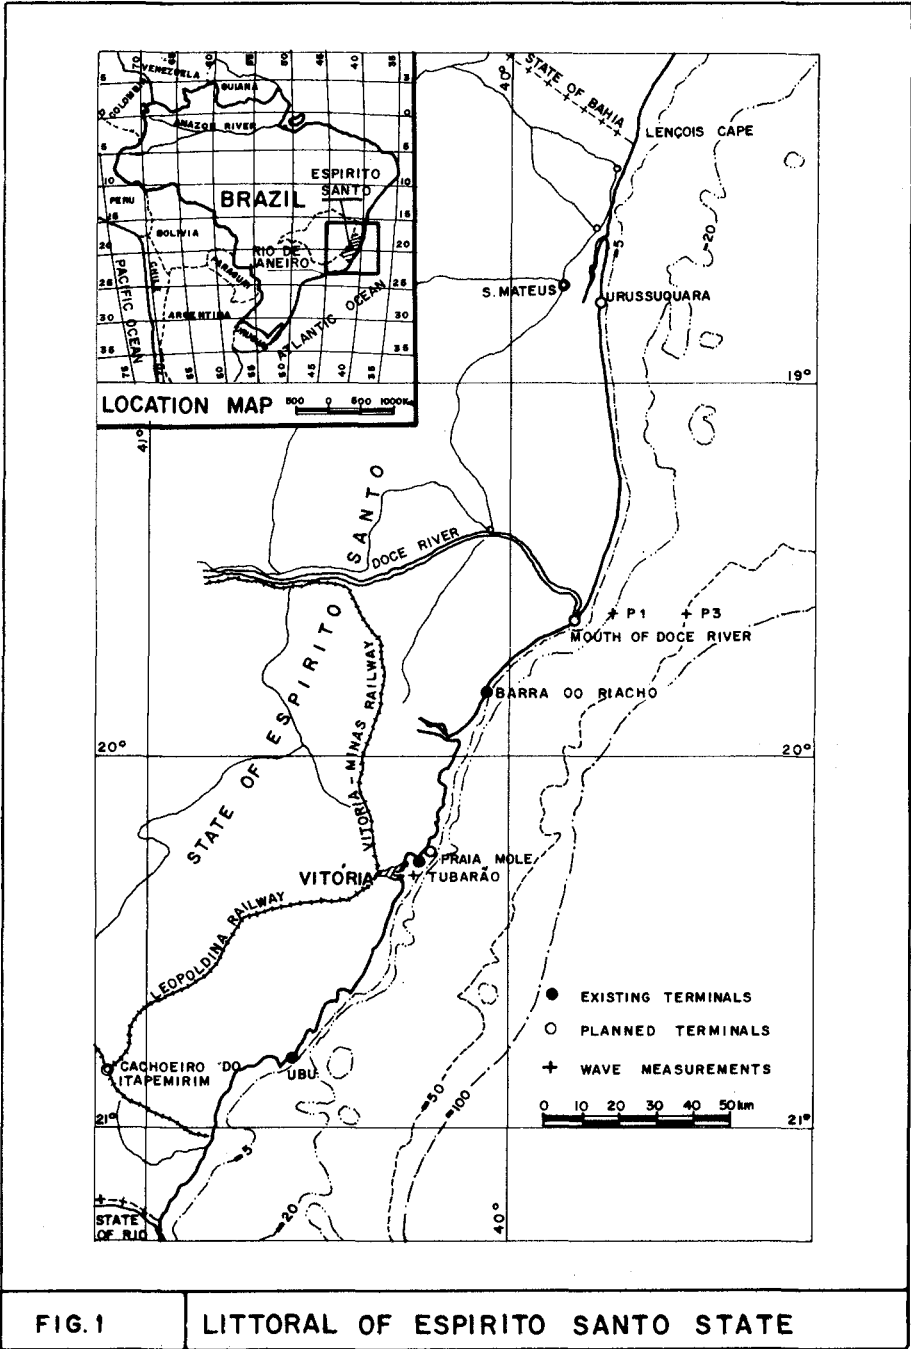

d) For the last 72 miles, from the Espírito Santo Bay to the Itabapoana River bar, the coastal aspect and shape are quite varied. The coastal plain becomes increasingly narrower in this area, as the Aimorés mountains reach closer and closer to the sea.

In these four areas some of the main specialized cargo terminals in Brazil are sited. Others are in design stage and should be built in the near future. A description of these ports is found below:

2.1 Existing Ports

2.1.1 Ubu Maritime Terminal

This maritime terminal, sited at the Ubu headland (Fig.2), was built for the export of 5 million tons of pelletized iron ore per year. The ore is mined in the State of Minas Gerais and is transferred through a pipeline, in the form of slurry, down to the port facilities, where it is pelletized and stockpiled for shipment. The harbor will take in ships up to 250,000 DWT after expansion (Ref. 1).

The marine terminal is formed by an "L" - shaped stone breakwater, 1,250 m long, and a 313 m long reinforced concrete pier. Ships reach the pier through a dredged channel, 18 m deep, which becomes wider near the pier so as to form a turning basin.

2.1.2 Tubarão Maritime Terminal

The Tubarão Maritime Terminal sited north of the city of Vitória, is designed for a yearly throughput of 60 million tons of iron ore. An additional ore handling berth was built between 1972 and 1973 to handle 270,000 DWT vessels (Pier nº 2), with a 2-mile approach channel dredged to a depth of - 23 m (Ref. 2). Fig. 3 shows the terminal's layout after expansion, including the originally built Pier nº 1, which can handle ships up to 100,000 DWT, as well as the protecting rubble mound breakwater.

2.1.3 Barra do Riacho

A specialized port complex at Barra do Riacho is under construction for the export of cellulose produced by local existing and future plants.

In their initial stage, the facilities will comprise a 200 m long berth capable of handling bleached pulp vessels of up to 35,600 DWT. This has involved the construction of protecting wharves and a docking pier, as well as dredging the approach channel and turning basin, as shown in Fig. 4.

In addition to the cellulose, the port complex will handle the raw materials required by the local plants, in the form of liquid or solid bulks. The largest vessels expected to call at this part of the port will be 30,000 DWT oil tankers.

2.2 Port Projects

In addition to these ports already in operation, the coast of the State of Espírito Santo is being considered for future facilities, for which hydrographic data have been gathered along the coast from north of the Doce River mouth to Espírito Santo Bay. (Refs. 3,4 and 5).

2.2.1 Praia Mole

A basic layout for the port facilities being planned for Praia Mole has been arrived at, the harbor being artificially protected by a 7 km long rubble mound breakwater, at an estimated dredging volume of 20 million cubic meters (Fig. 5).

The approach channel to the Praia Mole port will be dredged to a - 19 m depth, which will permit handling vessels up to 120,000 DWT. In addition to the general cargo and coal handling berths, which will service the steel plant, other specialized terminals are being contemplated within the basin of the port.

III - ANALYSIS OF EXISTING DATA

This section presents the main conclusions of the studies performed along the coast of Espírito Santo.

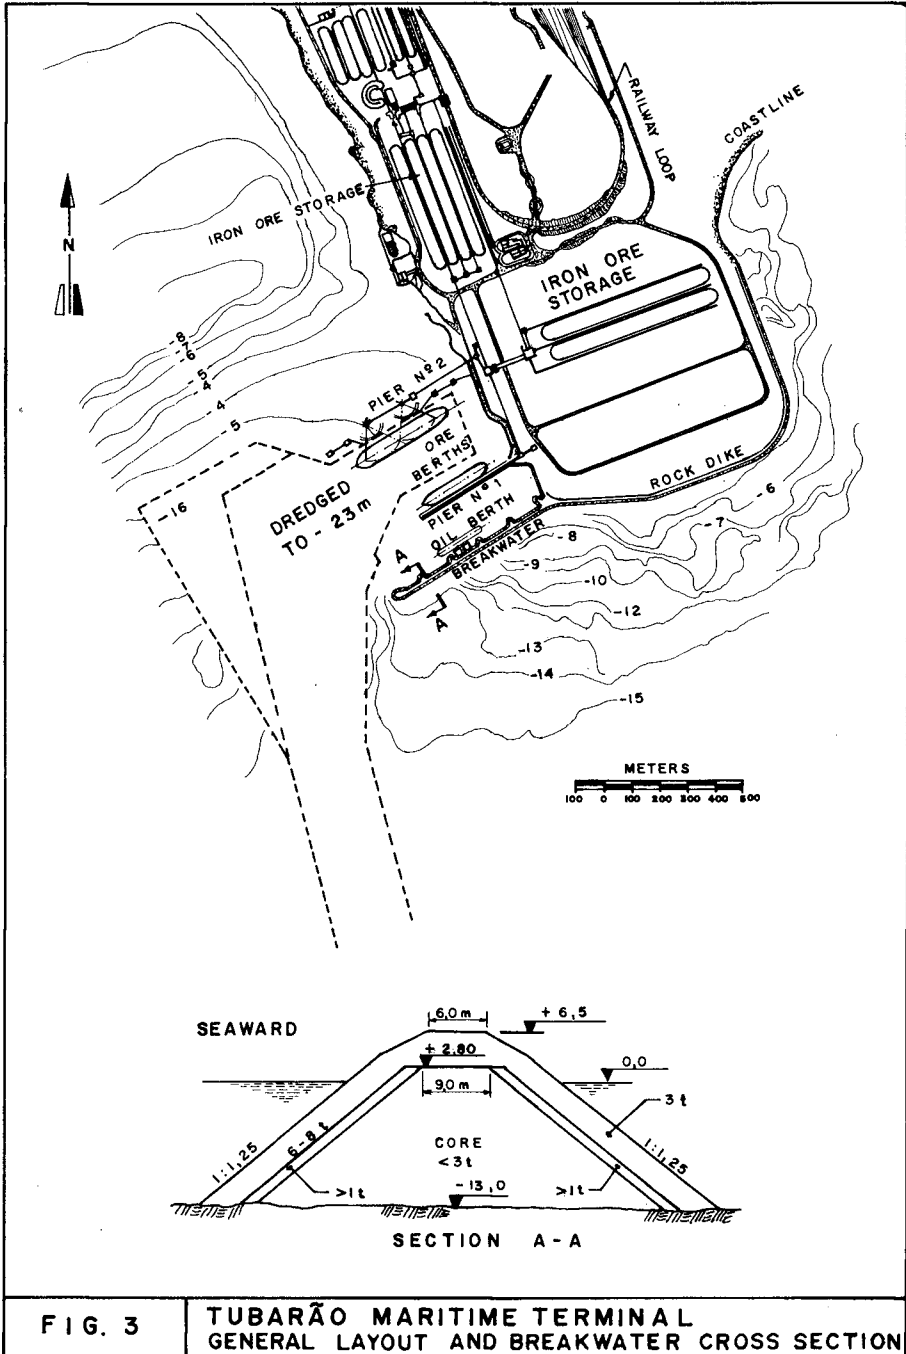

FIG. 3

TUBARÃO MARITIME TERMINAL
GENERAL LAYOUT AND BREAKWATER CROSS SECTION

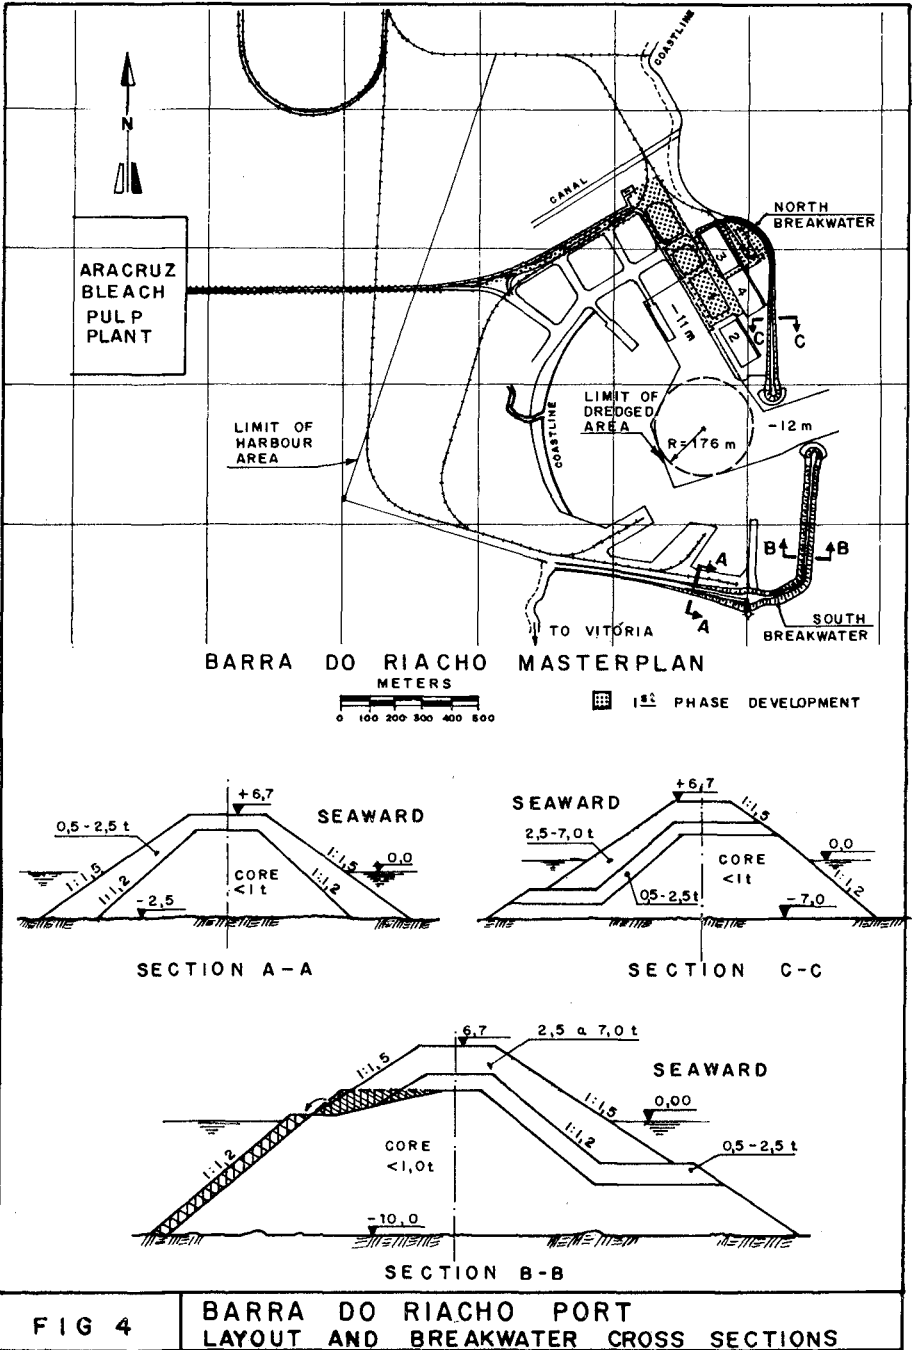

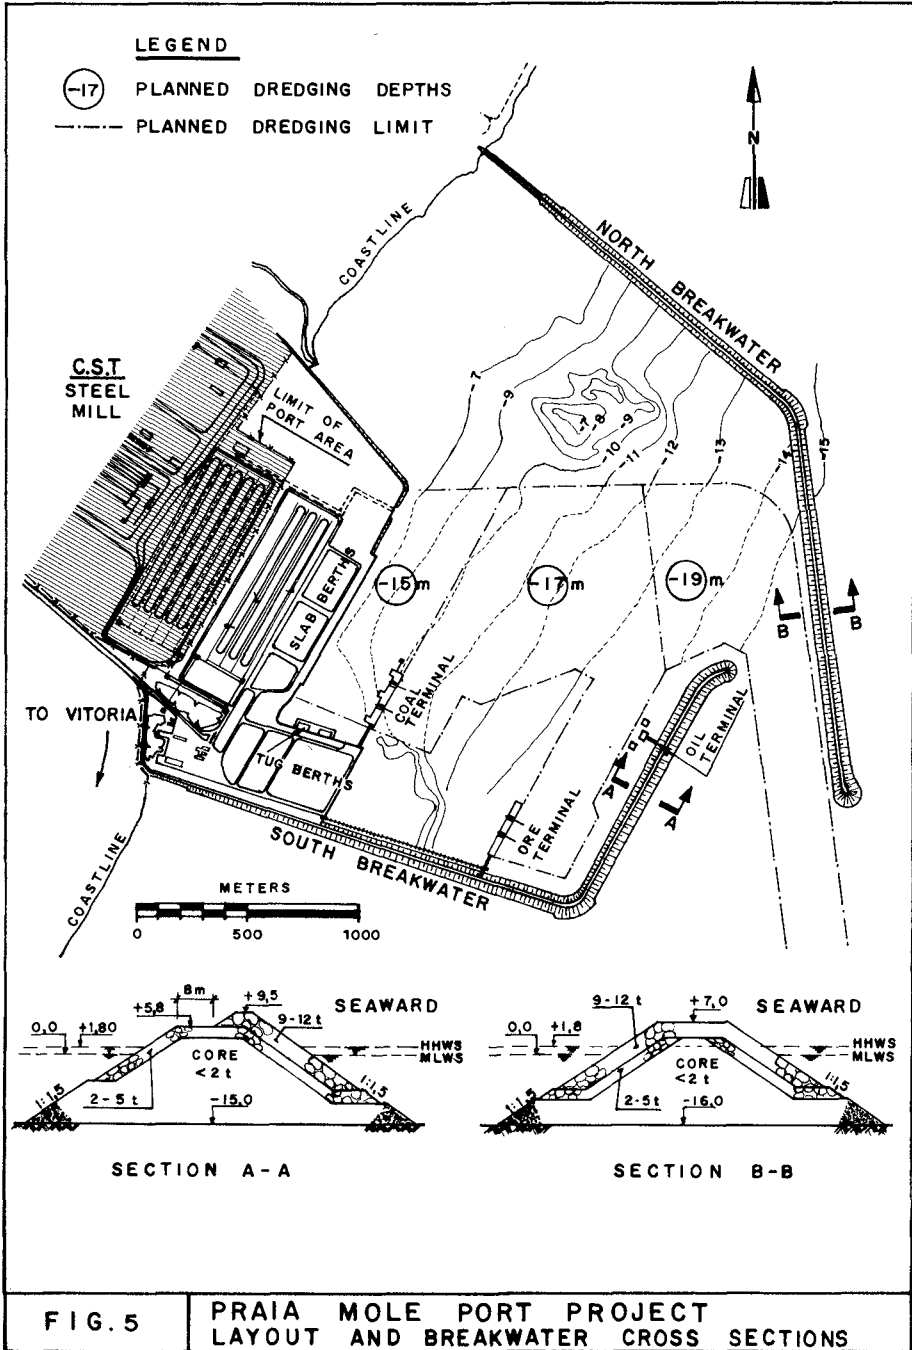

FIG 4

BARRA DO RIACHO PORT LAYOUT AND BREAKWATER CROSS SECTIONS

3.1 Wind Conditions

In general, the Brazilian east coast is considered to be a meteorologically very calm area, unaffected by violent tropical storms.

For the Barra do Riacho (PORTOCEL) project, the Danish Hydraulic Institute (DHI) performed anemographic measurements throughout the year of 1974 (Ref. 6). Such measurements are representative of the entire region, from Vitória to Doce River, and are presented in the wind rose of Fig. 6. Measurements made at Barra do Riacho have shown a maximum wind speed of 22 m/s, but only 0.3% of all measurements were in excess of 15 m/s.

The predominant wind directions are from NE-E and from S-SW, with the northeasterly winds dominating in strength. During more than 2.5% of the year, these winds exceed 10 m/s.

Daily maximum wind speeds at Barra do Riacho for the year of 1974 have been compared with measurements made at Vitória for the years 1971-73 (Ref.6). There was good agreement between data, which are shown in Fig. 6.

3.2 Wave Climate

The currently available information on wave conditions along the Espírito Santo coast stems from the wave observation sources listed below (items a and b) as well as from wave measurements mentioned in items c, d and e:

a) Ocean Wave Statistics, compiled from visual observations on ships by the National Physical Laboratory, London, covering a 9 year period. The Marsden Square areas that are of particular interest to this study are MS37 and MS40, set apart from each other by the 20° parallel, crossing slightly south of Barra de Santa Cruz. The Ubu, Tubarão and Praia Mole harbors belong to MS40, whereas Barra do Riacho and other planned harbors to be sited near mouth of Rio Doce River belong to MS37. Fig. 7 shows the deep-water roses for MS37 and MS40.

b) Atlas of Sea and Swell Charts-South Atlantic, compiled by the U.S. Navy Hydrographic Office also from visual observation in deep waters.

c) Measurements off Barra do Riacho, performed by DHI with the help of two wave recorders for a period of 15 months in 1973/74.

d) Wave measurements performed at Petrobrás Oil Rigs P1 and P2, for a period of 8 months, during 1972/73.

e) Wave measurements made at the Tubarão Iron Ore Terminal for a period of 9 months, during 1971/72.

Table 1 below summarizes the data obtained from the various wave measurement campaigns up to 1974.

Due to the short duration of the measurement work performed by the Petrobrás P1 and P3 Oil Rigs and Tubarão Terminal, these data were not used for engineering purpose.

WAVE CONDITIONS OBSERVED AT VARIOUS LOCATIONS
ON THE COAST OF THE ESPÍRITO SANTO STATE

LOCATION	Maritime Terminal of Tubarão (CVRD)	Petrobrás Oil Rigs P1 and P3	Barra do Riacho Port
OBSERVATION SITE	Seaward of Tubarão's breakwater	Off Doce River mouth	South of Riacho River mouth, off the Southern reef.
WATER DEPTH OF INSTRUMENT	9.0 m	P1: 22.0 m P3: 53.0 m	16.0 m
PERIOD OF MEASUREMENTS	June 1971 to April 1972	October 1972 to May 1973	September 1973 to December 1974
TYPE OF WAVE RECORDER	Pressure wave recorder (Hydro Products O.E.C. type WR 421)	Ultrasonic recorder (Neyrpic)	Waverider System (Datawell) and Pressure Wave recorder (OSPOS)
RECORDING PROGRAM	15 min. of continuous records, at 12 hours intervals	15 min. of continuous records, at 12 hours intervals	20 min. of continuous records each 3 hours (Datawell) and 15 min. each 3 hours (OSPOS)
AVERAGE WAVE PERIOD (\bar{T}_Z)	10 sec.	Between 7 and 8 sec.	8 sec.
HIGHEST OBSERVED SIGNIFICANT WAVE HEIGHT ($H_{S\max.}$)	4.25 m	2.7 m	2.2 m
MONTHS OF HIGHEST OBSERVED WAVES	June and September	March and May	June, July and September
MONTHS OF LOWEST OBSERVED WAVES	January and March	October and February	February, March and April
HIGHEST WAVE DIRECTIONS	S and SE	NE and S	S-SE
MOST FREQUENT WAVE DIRECTIONS	S and SE	E-NE and E	E and NE

The data obtained from wave recorders at Barra do Riacho are of good quality, and they supersede the ones originating from visual observations, which can be used only for comparison or on a preliminary basis.

DHI conclusions based on comparisons with the measured wave data are that wave heights calculated on the basis of deep water (observed) data will result in considerably higher waves, but with a direction distribution very similar to that obtained off Barra do Riacho during 1973/74.

Wave measurements made off Barra do Riacho by DHI in 1974 are shown in Fig. 6. Waves have been recorded by a Datawell Waverider together with an Ospos recorder. The Waverider was programmed to record a 20-minute time series every three hours, whereas the Ospos records were for 15 minutes every three hours. Observations of wave directions were performed by the local operator.

During the time interval covered by the observations the highest significant wave height was $H_s = 2.2$ m, corresponding to a maximum wave height of $H_{max} = 3.4$ m., at a depth of water of 16 m. The highest waves were measured in June, early July and September. Waves did not exceed $H_s = 1.5$ m from January through May, as well as during the greater part of July and October. The season with lowest waves was February to April. Mean wave periods between 5s and 15s were measured. The average mean period is 8s.

Along the Espírito Santo coast, from the Ubu Terminal up to the mouth of the Doce River the highest waves occur from S-SE, but most frequently wave directions are between E and NE. For the highest waves, the wave period varies between 8 and 12 s.

3.3 Water Levels and Currents

The water level variation caused by tide and storm surges has been reproduced by the Ospos wave recorder during the measurements performed by DHI. The discrete values of the water level obtained at Barra do Riacho were compared with the water level at the tide recorder at Vitória/Tubarão. The result was that the water level measured by the Ospos recorder at Barra do Riacho follows the tidal prediction for Vitória and Tubarão closely. From the predictions, the maximum yearly tidal range is found to be 1.8 m. In addition to the astronomical tide, the water level may be affected by rises resulting from storm surges.

On the grounds of DHI float tracking at Barra do Riacho (Ref. 6), it is estimated that a current velocity of 0.25 m/s will on the average be exceeded with a total duration of 75 days per year, and that a velocity of 0.6 m/s will be exceeded 24 hours per year.

3.4 Soil Characteristics

In the area between Tubarão and Barra do Riacho, the subsoil material is of a complex nature. In general, there occurs a predominantly sandy surface layer of average compactness. Underlying it, there is a stiff clayey layer of varying thickness, below which the soil again becomes sandy, though more compact than at the surface.

Sandstone reefs (limonitic "cangas") are commonly found in most of the Espírito Santo coastline. Reefs or "cangas" outcrop in certain areas, which makes dredging work difficult and reduces equipment productivity - a problem which occurred with major or lesser intensity while dredging at Tubarão, Ubu and Barra do Riacho was in process.

The analysis of bottom sediment samples indicates that the median diameter (D_{50}) of sandy material is of the order of 0.2 to 0.3 mm at Praia Molé, and it ranges between 0.4 and 0.6 mm at Barra do Riacho. Along the beach stretch south of the mouth of the Doce River (Fig. 8), the median diameter of sand varies from 0.15 to 0.6 mm when in water depths up to 10 m and from 0.15 to 0.9 mm at depths between 10 and 15 m.

3.5 Coastal Processes

The beach slopes which form the eastward boundary of the Espírito Santo coastal plain vary accordingly with the size of the sand material.

Both north and south of the Doce River mouth, these slopes are between 9° and 12°, but they may exceptionally be as steep as 15°. North of the Doce River, where finer sand is found, beach slopes may be as flat as 5°.

The large area of alluvial material which extends from Barra do Riacho, in the south, to Conceição da Barra, in the north, makes up a huge delta deposit formed by sediments brought down to the sea over geological times by the rivers in the area, particularly the Doce River (Ref. 7). Waves, tidal currents and wind action have shaped the seaward side of this delta to bring about the coastline configuration as it is today.

The Doce River delta formation process may be summarized as follows:

- The finer materials (silt and clay) are carried in suspension in the directions determined by currents. Waves stir up all sediments which may have been deposited in the sedimentary platform, where depths are small. Thus, the part of the delta formed by silt and clay has a tendency to migrate northwards along the coast, causing depths to decrease in this area as the submerged slopes gradually become less steep. This trend is confirmed by the shape of the alluvial fan of the river which expands little towards the south (see Fig. 8), while it becomes longer and wider towards the north, as indicated by bathymetric readings in the area. The result is an evident spread of the deltaic front towards the north.

- Coarser material (sand) is moved mainly by waves, being carried and deposited at each point in accordance with the local wave regime. Any sandy material not retained at the mouth, but flushed out to sea beyond the river bar, tends to be caught in areas relatively close to the mouth; there occurs a natural sorting of diameters, the less coarse material advancing further than the others.

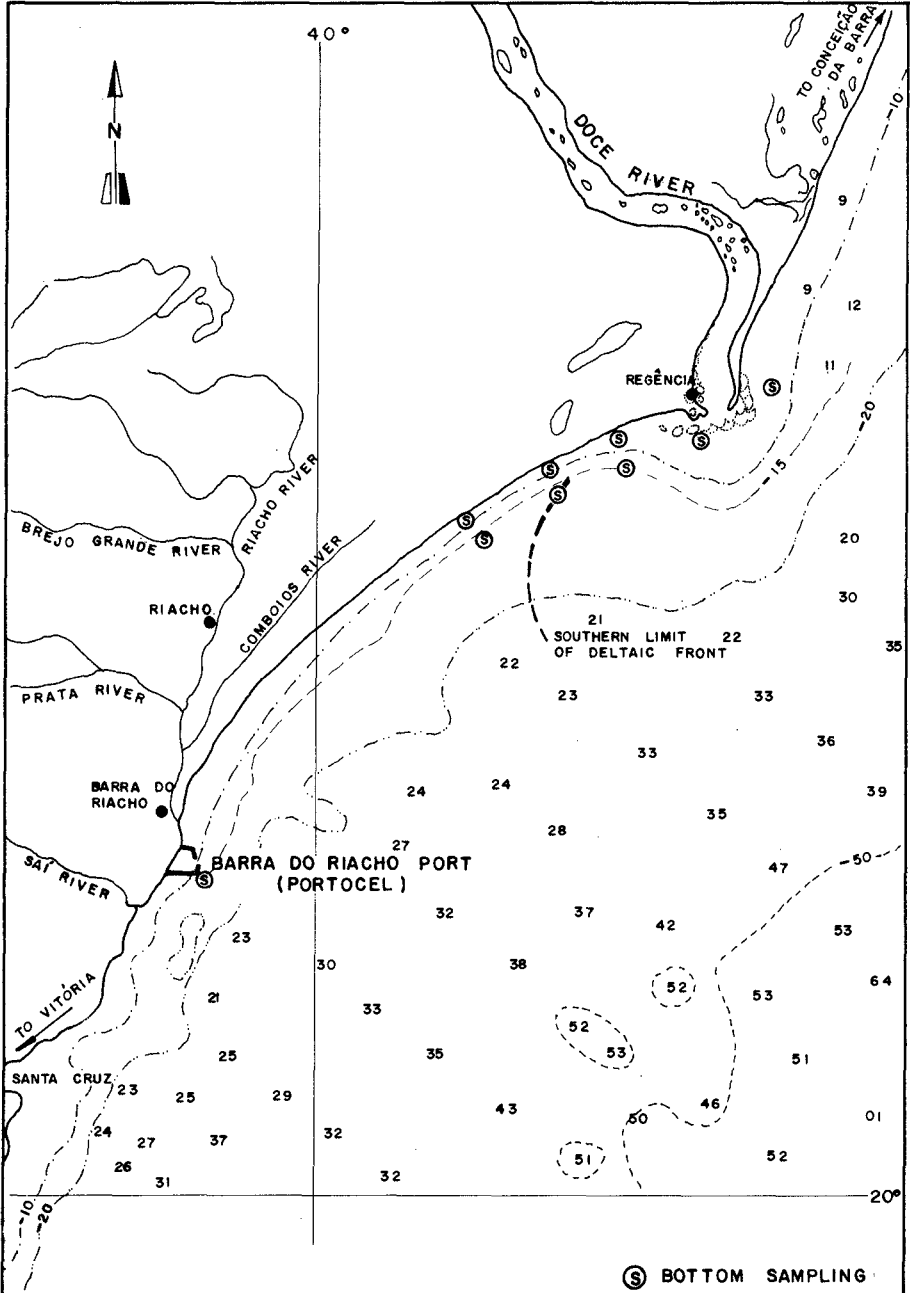

FIG. 8 MOUTH OF DOCE RIVER

The sand accumulates initially in the shallower zones of the alluvial fan itself. Waves are the determining factor for sand movement, due to the small depths and the gentle slope of the sedimentary platform which results in a wide surf zone.

The Doce River mouth constitutes an inflection point in the Espírito Santo coastline. South of it, the coastline heads SW, which gives it a smaller inclination with regard to the highest waves from SE and more protection against waves from NE. This coastal configuration has significant implications for sand movement along the coast.

Between Tubarão and Barra do Riacho the coastline is formed by a succession of pocket beaches between reef headlands. From Barra do Riacho to the south of the Doce River mouth, sand is moved either north or south, depending on the wave climate, but the net direction of the littoral drift is southward.

In the case of sand movement towards the north, sand is carried along the coast in this direction as long as waves from S and SE prevail; however, they will always tend to show an annual net movement towards the south, since this is the direction of the resulting littoral drift.

South of the Doce River mouth, the southward component of the littoral drift decrease as one moves down along the coast. It is estimated that, midway between Regência and Barra do Riacho (Ref. 5), the maximum annual littoral drift is about 500,000 m³/year while the net annual littoral drift is 150,000 m³/year, both southwards according to C.E.R.C.'s formula (Ref. 8) and Ocean Wave Statistics' deep water data. As one moves further south along the coast, the southward littoral drift decreases as the northward one increases; in the vicinity of Barra do Riacho, they practically cancel each other.

It has been gathered from examination of hydrographic charts, deep water wave data and aerial photographs, that the dominant direction of littoral drift north of the Doce River is northward. Typical signs of this are the shapes of bars, of beach stretches where natural sandstone spurs occur, and of tombolos formed in the lee side of the reefs.

A more accurate description or quantification of the littoral drift north of the Doce River can only be made after detailed knowledge of wave characteristics in the area has been obtained through wave measurement records and observation of directions for at least one whole year.

3.6 Breakwater Survey

Table 2 shows conditions for rubble mound breakwater designs for the artificial harbors along the Espírito Santo coast (Ubu, Tubarão and Barra do Riacho) and for the Praia Mole Harbor Project.

In June, 1978, CVRD performed a survey of the breakwater at the Tubarão Maritime Terminal, comprising the four cross-sections shown in Figs. 9 and 10.

TABLE 2
DESIGN CONDITIONS FOR RUBBLE MOUND BREAKWATERS

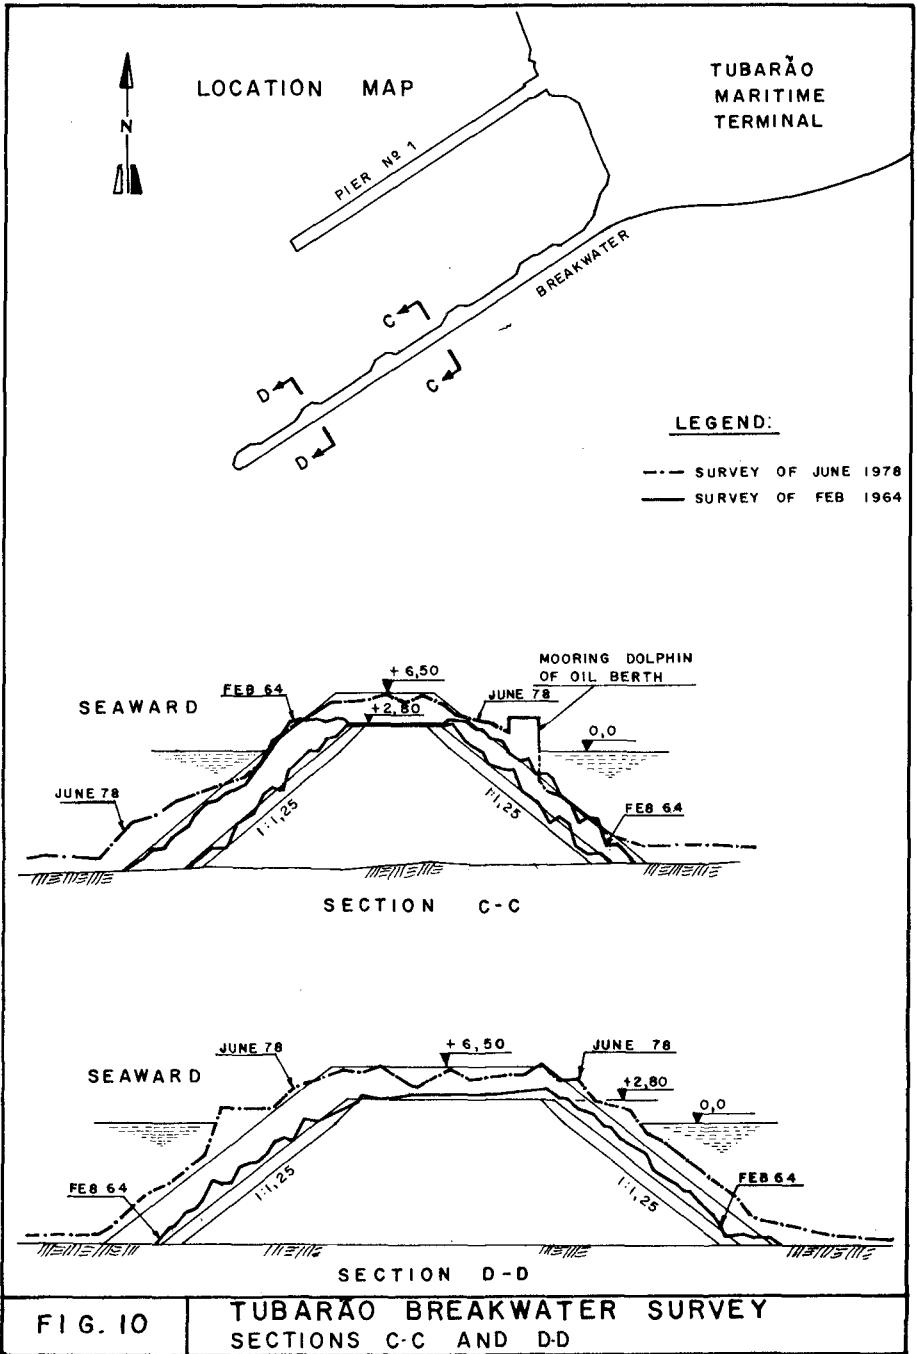

FIG. 10 TUBARÃO BREAKWATER SURVEY SECTIONS C-C AND D-D

The Tubarão breakwater extends in a straight line in the NE-SW direction, and provides protection for iron ore piers 1 and 2, in addition to the oil berth located at its lee side. It is directly exposed to wave action from the SE direction.

The survey shows an irregular cross-section. A certain amount of settlement of the breakwater crest was observed, probable due to loss of core material. The slope towards the sea is more regular from the shore end to the oil berth; from then on, it shows a decline of 1:1 at certain points above sea level which means that the armour stones were displaced by wave action and/or as a result of soil settlement. Below sea level the seaward slope has shown a flattening trend with time. No maintenance work has been done on the breakwater since it was built in 1963/64.

IV - CONCLUSIONS AND RECOMMENDATIONS

The port designs developed for the Espírito Santo coast have been based on different criteria. Due to the fact that wave climate measurements were made only for the harbor at Barra do Riacho, the various breakwaters were calculated with different design wave heights.

4.1 A comprehensive knowledge of wave characteristics is the basic requirement for Coastal Engineering designs. For the Espírito Santo coast, such characteristics will have to be determined by installing wave recorders at least at three points along the coastline: one north of the Doce River mouth, a second, south of the Doce River mouth, between Tubarão and Barra do Riacho (an OSPOS recorder is already being operated by INPH/PORTOBRÁS at Barra do Riacho); and a third, south of the Espírito Santo Bay, possibly near the Ubu Maritime Terminal. From the analysis of the data thus obtained, the distribution, of wave periods, wave heights at given depths, wave directions, as well as wave frequency and direction spectra can be obtained for each of these areas.

4.2 Additional studies are required to provide a better insight of coastal processes. In order to determine current direction and speed, it will be necessary to operate current meters for at least one year at certain points along the coast, preferably at those points where wave recording is carried out. To help quantify the littoral drift, the velocity of longshore currents may be measured and bottom sampling may be carried out at certain sites, from the shore to a depth of about 20 m, together with the analysis of such samples for determining mechanical and mineralogical characteristics. It is important to perform a mineralogical analysis of the materials carried by the Doce river, and to compare them with the heavy minerals found along the shoreline.

4.3 Systematic yearly surveys are also recommended for the cross-sections of the various breakwaters recently built on the Espírito Santo Coast, in order to evaluate the damage experienced in time.

V - ACKNOWLEDGEMENTS

The authors wish to thank the supporting material kindly provided by various companies, in particular CVRD for information on the Tubarão breakwater. The authors are also indebted to Prof. Victor Freire Motta of COPPE/UFRJ for helpful discussions and review of manuscript.

CHAPTER 128

PROBLEMS OF DESIGN AND CONSTRUCTION OF AN OFFSHORE SEAWATER INTAKE

by

D.W. STANDISH-WHITE^{*}

and

J.A. ZWAMBORN^{**}

ABSTRACT

A seawater intake had to be constructed for a diamond mine on the coast of Namibia just north of Oranjemund. The solution adopted consisted of a piled jetty with a dolos island on its seaward end protecting the pump chamber which was built of closely spaced concrete piles.

The paper briefly describes the various problems encountered during the construction of the intake, including :

- limited penetration of the piles leading to the failure of the first jetty,
- serious slump of the initial dolos island,
- breakages of dolosse due to excessive movements during storms,
- considerable wear of the vertical spindle pumps due to sand and surging.

Also described are the engineering solutions which had to be found at very short notice for immediate application.

INTRODUCTION

An assured supply of 2 200 m³ per hour (37 m³/min = 10⁴ U.S. gall/min) of sea water was required for a diamond recovery plant to be commissioned early in 1977 on the southern coast of Namibia (South-West Africa). This coastline consists of a particularly featureless beach of deep sand underlain by variable coarse boulder gravel beds covering saw-tooth profile schistose bed rock. Often pounded by high surf caused by heavy swells, a strong littoral drift transports large amounts of sea-bed material

** National Research Institute for Oceanology, CSIR, Stellenbosch, South Africa

northwards along the coast, depending on the prevailing weather conditions.

Various alternative solutions were considered for this sea water intake, including a submarine tunnel, an on-shore stilling basin, in-shore beach filtration ponds, radial interception caisson wells and finally a piled jetty with a vertical pump well formed of closely spaced piles at its seaward end situated in the centre of an artificial dolos island. All but the last alternative had already been tried before with varying degrees of success along the 200 km of arid coastline reserved exclusively for diamond mining.

Having no time to conduct extensive model studies but armed with offshore seabed profiles and various other regional marine data and experience, it was decided, because of the evident impracticability of the other solutions in this locality, and on the advice of the Specialist Marine Contractors, to opt for the offshore island approach.

ORIGINAL JETTY DESIGN

The design adopted was for a light precast concrete jetty carried on slim precast concrete piles, each with a stub rail toe to penetrate the heavy seabed gravels (see Fig. 1.a). This type of construction had been used successfully by the contractors in other situations along the same coast. Construction commenced late in 1974, but it soon became apparent that adequate penetration of the piles to the bedrock through the overlying layer of boulders and gravels was not being achieved and various means of grout stabilization of the toes were attempted in 1975. After 180m had been completed this jetty failed in a storm, partly through excessive pile settlements from the scouring action around some of the pile toes and partly because the whole structure was set too low, and this jetty was abandoned.

FINAL JETTY DESIGN

After full scale tests on shore, a redesigned special pile which would penetrate down to the bedrock and then allowed for subsequent axial drilling, rock anchoring and grouting was developed. The modified pile toe adopted consisted of a long, thick-walled steel tube with a specially hardened cutting edge (see Fig. 1.b). A new similar jetty 321 metres long (but 1.5m higher) was successfully constructed on this basis adjacent to the old one between September 1975 and February 1976 (see Figs. 2 and 3).

The old jetty was partially demolished to avoid any possible future interference with the stability of the new one due to its further collapse. Both the embedded and attached steelwork of the new structure were cathodically protected against corrosion using a constant impressed current and sacrificial anodes.

DAMAGE TO ORIGINAL DOLOS MOUND

The Contractor designed and constructed the first terminal island mainly of 6 ton dolosse below MSL, capped with 10 ton units above MSL, on a

FIG. 1 SPECIAL PILE TOES

FIG. 2 NEW AND OLD JETTIES WITH DIAMOND RECOVERY PLANT IN THE BACKGROUND

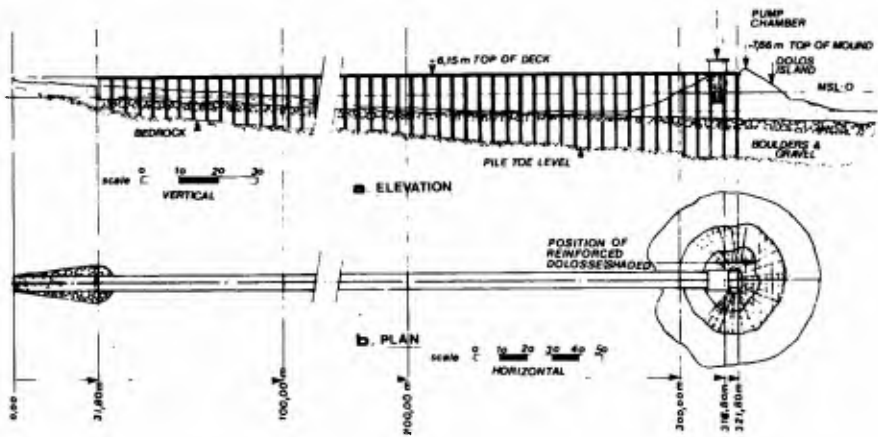

FIG. 3 FINAL JETTY LAY-OUT

FIG. 4 CLOSE-UP OF DAMAGED DOLOS MOUND

foundation of a carefully placed gravel mat. A total of 1100 6 ton and 120 10 ton dolosse were placed between April and June of 1976 but the mound settled considerably more than expected. At this stage, the National Research Institute for Oceanology was called in for advice and during an inspection in September 1976 it was noted that several 6 and 10 ton Dolosse had broken and the mound had slumped by about 3 to 4 m, exposing the pump chamber (see Fig. 4).

The apparent reasons for the damage to the dolos mound were :-

1. The dolos mass was too small, resulting in their removal from the mound.
2. Sea-bed changes of up to 4 to 5m have been recorded in the jetty area, and underscour of the mound itself could well have occurred, also resulting in larger waves.
3. Dolos breakage of up to 5 per cent occurred during placing and further breakages may have occurred due to excessive movements during heavy seas.
4. Possibly insufficient tensile strength of the original dolos concrete for the wave loads imposed.

REQUIRED DOLOS MASS

The structure was originally designed for a wave height of 6m, but a further study using more extensive wave data revealed that a 7,1m deep-sea wave could occur once in 25 years, which would increase (due to shoaling) to 7,7m at the seaward toe of the structure. The original foundation of the dolos mound was set at about -5m to mean sea level, but the water depth immediately seaward of the structure could well increase up to about 10m due to scour, and thus a 7,7m wave could reach the structure. A 7,7m wave height was therefore adopted for the re-design of the dolos mound.

Using a simple formula for a breakwater trunk¹, the following desirable dolos unit mass was deduced :-

$$W = (0,3H)^3 = (0,3 \times 7,7)^3 = 12,3t$$

Considering that the mound is effectively a 'double breakwater head', this mass should be further increased by 50 per cent to 18,5t as compared with the original 6 to 10t dolos design.²

Because no tower crane was readily available to handle such heavy units it was decided to try to increase the concrete density to 2,7t/m³ in an attempt to increase dolos stability. From all known stability formulae, the required block mass is inversely proportional to the relative density

to the third power³ and an 11,3t dolos should theoretically be as stable as an 18,5t dolos, if cast in the same moulds as the earlier 10t units, but with a nett density of 2,7t/m³. Moreover, the available tower crane could still handle these units. A re-design, using 11,3t dolosse of higher density to protect the pump well and an 8m wide toe protection of 6t normal density dolosse was therefore adopted as the best expedient in all the circumstances of the problem (see Fig. 5).

HYDRAULIC MODEL TESTS

Due to the exposed position of the structure - right in the breaker zone during heavy seas (see Fig. 6) - and because of its dissimilarity to usual breakwater structures, it was considered necessary to carry out confirmatory hydraulic model tests. Due to severe lack of time, only two simple tests using a 'half model' in a wave flume could be done, one test using normal density dolosse (2,31t/m³ in the model representing 2,37t/m³ prototype), and a second test with higher density dolosse (2,57t/m³ representing 2,63t/m³ prototype). The tests were done in a 1,5m wide and 0,7m deep regular wave flume with the model built on the available 1:20 slope (prototype slope was about 1:30). A water depth of -7,5m below mean sea level at the centre of the mound was used. The entire mound (half model) was built of 530 82 and 92 gr dolosse, representing 10,3 and 11,5t full scale units. Model wave heights were increased in small intervals up to the equivalent of 7 m high waves with a period of 11,5s. A model view is shown in Fig. 7.

With the *normal density* dolosse, the model showed the first damage for 5m high waves. The damage, particularly on the side of the mound, increased rapidly with the 7m waves causing a 2m slump thus exposing the pump sump to the direct wave forces. A marked improvement was obtained using the *high density* dolosse. With the 5m waves, very few dolosse were displaced (< 1%) while a total of only 17 model dolosse were displaced with the 7 m waves (about 4%).

HIGH DENSITY DOLOSSE

The tests thus confirmed the significantly greater stability for the higher density dolosse and a high density concrete mix was designed to produce the required 11,3t dolosse using the original 10t dolos moulds. Cost and time considerations ruled out importing a very suitable magnetite ore from inland with a relative density of 4,8t/m³ and any other densifying possibilities such as the use of cast steel Scrubber-Mill Balls. Some higher density aggregate was eventually obtained from the mine itself, being the lighter fraction (S.G. 2,89t/m³) from the heavy media separators of the diamond recovery process. A 2,7t/m³ concrete mix was achieved in the laboratory using this heavier aggregate, with a compressive strength of 40 MPa.

FIG. 5 RE-DESIGN OF DOLOS MOUND

FIG. 6 HEAVY SURF POUNDING THE STRUCTURE

FIG. 7 FLUME TEST ON 'HALF MODEL'
7 M BREAKING WAVES

Unfortunately it was later established that, because of high density aggregate supply problems from the mine, the concrete density actually obtained was only $2,55\text{t/m}^3$ and not the $2,7\text{t/m}^3$ required, thus making the dolosse still too light (maximum mass $10,7\text{t}$) for the accepted design wave height.

The physical dimensions of the dolosse were as follows : dolos height 3,00 m, waist to height ratio 0,313, circular fillets 0,033 of the dolos height and a volume of $4,2\text{m}^3$.

STORM DAMAGE DURING CONSTRUCTION OF THE REDESIGNED DOLOS MOUND

Placing the new heavier dolosse to the revised profiles began in the late summer (February 1977) and during the subsequent two months, half of the required additional 518 "ten ton" and 1 150 "six ton" dolosse had been placed. At this juncture the Contractor was on schedule to complete the mound before the winter storms, but the availability of the placing crane became less and less as the plant engineers used it while battling to keep the pumps operating at a rate sufficient to supply adequate water to the plant.

Early in May 1977 and before the island was complete, a heavy swell arose, coinciding with a near equinoxial high tide (2m variation). By then, 350 ten-ton capping units and 617 six-ton toe protection units had been placed.

Breakers of between 5 to 6m, corresponding to 4 to 5m incident waves with a projected occurrence of 7 and 1 day per year respectively, occurred continuously for three days. Over 100 dolosse were lost from the mound which represented about 10 per cent damage. The damage was especially heavy on the seaward side, where the mound slumped some 3m. The dolos breakages varied from a single fluke broken off to breaks through the shank. It was also obvious from the wear on the dolosse that the units had been thrown around during the storm.

The main reasons for the damage to the structure are as follows :

1. For an incident wave height of 5m, the model tests showed considerable damage for the $2,37\text{ t/m}^3$ but only 1% damage for the $2,63\text{ t/m}^3$ dolosse. For the $2,55\text{ t/m}^3$ dolosse, which were used on the island, several per cent damage, were therefore, to be expected.
2. It had been reported by the supervising staff that 5 per cent of the dolosse broke during placing which was probably caused by generally heavy surf conditions (see Fig. 6). This represents about 17 of the ten ton and 30 of the six ton units placed since February 1977. The broken dolosse were thrown around during the storm causing other units to break.
3. Because the crest of the mound was still several metres below its

final design height, the top layer of dolosse was relatively loose and exposed to the full overtopping breaker force, causing excessive dolos movement resulting in breakages.

4. The timing of the storm was also particularly destructive, because a freshly-built dolos structure usually requires an initial shakedown period for minor settlement caused by average waves.

FINAL COMPLETION OF THE DOLOS MOUND

Although attempts to produce high density dolosse have not been abandoned, the need to complete the dolos island, which forms the protection of the pump chamber, dictated an urgent 'engineering' solution. Accepting that the 10,7 ton dolosse were too light for the 7,1 m incident design wave height, it was decided to 'reinforce' them using sections of old 20 kg/m railway lines readily available on the mine. This rail reinforcement was tack-welded in a dolos shape to provide core reinforcement. Experience has since shown that this reinforcement holds the dolosse together well, even if the concrete cracks. Thus, although the steel may eventually corrode, it meanwhile contributes to the mound's stability by keeping the dolosse intact for a much longer period. A small beneficial increase in total mass also results from the steel inclusion but these 'reinforced' dolosse were made of normal density concrete (S.G. 2,4) and the mass of these units was therefore only about 10,0t.

It finally took a total of 2 414 six ton and 853 ten ton dolosse to complete the dolos mound in accordance with the profile shown in Fig. 8 (August 1977).

Settlement of approximately 1 metre has since occurred during its first winter season, but no heavy storms have been experienced so far. Considerable stability does now seem to have been achieved, together with calm pumping conditions. A close watch will be kept of the island's future performance and its behaviour will be correlated with wave heights recorded seaward of the jetty with a waverider buoy.

PUMP PROBLEMS

During the early commissioning of the large (175 kw) vertical spindle centrifugal pumps (Early 1977), it became apparent that surging and turbulence in the pump chamber was far greater than had been expected. A concrete baffle platform was then cast and lowered down the chamber and set at mean sea level, and the pumps were encased in stainless steel sleeves (see Figs. 9 and 10). These measures were highly successful in both supporting the pumps and in damping out the surges in the chamber. Completion of the final mound has also had a beneficial effect on surging and sand build-up in the sump.

The pump installation has necessarily been fully operational since July 1977, but was plagued with high wear rates due to the high

FIG. 9 PUMPHOUSE

SECTION AT MEAN SEA LEVEL

FIG. 10 PLAN OF BAFFLE SLAB IN PUMPING CHAMBER

percentage of sand suspended in the seawater inside the chamber. Each of the four pumps had an average initial life of only 30 days before lifting for replacement of the wearing components. A number of mechanical solutions were tried but no suitable vertical spindle pumps of this size and duty are on the market at present.

Very reluctantly, recourse had to be made to installing a pair of horizontal spindle, rubber-lined dredge pumps mounted on a platform underslung below the jetty in the immediate lee of the mound (see Fig. 8). This system has proved embarrassingly effective and reliable up to date. Two standby submersible pumps are installed in two of the draft tubes and an experimental vertical spindle pump with continuously grease-fed bearings is being operated in the third tube with good results over the past six months.

CONCLUSION

This paper is presented not as a technical success story but as an opportunity for fellow coastal engineers to assess and consider the many problems that presented themselves and perhaps to avoid them on a similar structure in the future.

Figs. 11 and 12 show the structure about one year after completion.

CHAPTER 129

WAVE TRANSMISSION THROUGH TRAPEZOIDAL BREAKWATERS

by

Ole Secher Madsen⁽¹⁾, M.ASCE, Paisal Shusang⁽²⁾, and Sue Ann Hanson⁽³⁾

INTRODUCTION

In a previous paper Madsen and White (1977) developed an approximate method for the determination of reflection and transmission characteristics of multi-layered, porous rubble-mound breakwaters of trapezoidal cross-section. This approximate method was based on the assumption that the energy dissipation associated with the wave-structure interaction could be considered as two separate mechanisms: (1) an external, frictional dissipation on the seaward slope; (2) an internal dissipation within the porous structure. The external dissipation on the seaward slope was evaluated from the semi-theoretical analysis of energy dissipation on rough, impermeable slopes developed by Madsen and White (1975). The remaining wave energy was represented by an equivalent wave incident on a hydraulically equivalent porous breakwater of rectangular cross-section. The partitioning of the remaining wave energy among reflected, transmitted and internally dissipated energy was evaluated as described by Madsen (1974), leading to a determination of the reflection and transmission coefficients of the structure.

The advantage of this previous approximate method was its ease of use. Input data requirements were limited to quantities which would either be known (water depth, wave characteristics, breakwater geometry, and stone sizes) or could be estimated (porosity) by the design engineer. This feature was achieved by the employment of empirical relationships for the parameterization of the external and internal energy dissipation mechanisms. General solutions were presented in graphical form so that calculations could proceed using no more sophisticated equipment than a hand calculator (or a slide rule). This simple method gave estimates of transmission coefficients in excellent agreement with laboratory measurements whereas its ability to predict reflection coefficients left a lot to be desired.

Accepting the assumptions of the validity of linear long wave

 - (3) Graduate Student, Dept. of Civil Engineering, U. of California, Berkeley (formerly Undergrad. Assist. R.M. Parsons Lab., MIT).

theory, nonbreaking incident waves and the validity of the empirical relationships for the dissipative mechanisms the major assumption made in the previous approximate analysis is the separate treatment of external and internal dissipation. The present paper presents a more rigorous analysis of the wave-structure interaction in that external and internal dissipation are treated together rather than separately. Results obtained from this more elaborate analysis are compared and with results obtained from the previous simple procedure and with laboratory measurements of reflection and transmission characteristics of homogeneous, porous breakwaters of trapezoidal cross-section.

ANALYSIS

Governing Equations

Figure 1: Definition Sketch

The analysis considers a homogeneous, trapezoidal breakwater subject to normally incident waves. The incident waves are assumed to be non-breaking and adequately described by linear long wave theory. Five different computational regions are identified in Figure 1. In regions I and V which are of constant depth, h_o , the general solutions for the wave motion is well known and consists of an incident and a reflected wave (Region I) and a transmitted wave (Region V). In Region III the general solution, after linearization of the flow resistance in the porous material, is given by Madsen (1974). Thus, we need only be concerned about the governing equations and the general solution for Regions II and IV, i.e., the slope regions.

For these regions the continuity equation reads

$$\frac{\partial \eta}{\partial t} + \frac{\partial (h_1 U_1)}{\partial x} + \frac{\partial (h_2 U_2)}{\partial x} = 0 \tag{1}$$

where h_1 , h_2 and U_1 , U_2 refer to the depths and discharge velocities in the water and porous wedges, respectively; and η is the free surface elevation.

The linearized momentum equation for the fluid wedge reads

$$\frac{\partial U_1}{\partial t} + g \frac{\partial \eta}{\partial x} + \frac{\tau_b}{\rho h_1} = 0 \quad (2)$$

in which g is gravity, ρ is fluid density, and τ_b , the bottom shear stress, is expressed in its nonlinear and linearized form as

$$\tau_b = \frac{1}{2} \rho f_w |U_1| U_1 = \rho f_s h_1 \omega U_1 \quad (3)$$

where f_w may be taken from the empirical expression developed by Madsen and White (1975), f_s is a linearized friction factor, and ω is the radian frequency of the incident waves. Substitution of (3) into (2) yields the linear momentum equation for the fluid wedge

$$\frac{\partial U_1}{\partial t} + g \frac{\partial \eta}{\partial x} + f_s \omega U_1 = 0 \quad (4)$$

The linearized momentum equation for the porous wedge is given by

$$\frac{1}{n} \frac{\partial U_2}{\partial t} + g \frac{\partial \eta}{\partial x} + f \frac{\omega}{n} U_2 = 0 \quad (5)$$

in which n is porosity and the flow resistance has been linearized by taking

$$\delta F = \rho(\alpha + \beta |U_2|) U_2 = \rho f \frac{\omega}{n} U_2 \quad (6)$$

Since the governing equations, (1), (4) and (5) are linear it is expedient to use complex variables. Thus, for a periodic motion of radian frequency ω we express the variables as the real part of the complex expressions given by

$$(\eta, U_1, U_2) = (\zeta(x), u_1(x), u_2(x)) e^{i\omega t} \quad (7)$$

with $i = \sqrt{-1}$.

Substituting (7) into (4) yields

$$u_1 = \frac{ig}{\omega} \frac{1}{1-if_s} \frac{d\zeta}{dx} \quad (8)$$

whereas (5) reduces to

$$u_2 = \frac{ig}{\omega} \frac{n}{1-if} \frac{d\zeta}{dx} \quad (9)$$

which expresses the fluid velocities in terms of the slope of the free surface.

With (7), (8) and (9), equation (1) may be written

$$\frac{\omega^2}{gh_0} (1-if_s)\zeta + \frac{d}{dx} \left[\frac{h_1}{h_0} \frac{d\zeta}{dx} \right] + \frac{n(1-if_s)}{1-if} \frac{d}{dx} \left[\frac{h_2}{h_0} \frac{d\zeta}{dx} \right] = 0 \quad (10)$$

Realizing that $h_1 + h_2 = h_0$ and therefore $h_1/h_0 = x/\ell_s$ and $h_2/h_0 = 1 - x/\ell_s$ for $0 < x \leq \ell_s$, and introducing the notation

$$\gamma = \frac{n(1-if_s)}{1-if} \quad (11)$$

we may write (10) in the form

$$\frac{\omega^2}{gh_0} (1-if_s)\zeta + \frac{d}{dx} \left[\left\{ \gamma + (1-\gamma) \frac{x}{\ell_s} \right\} \frac{d\zeta}{dx} \right] = 0 \quad (12)$$

Here $\omega^2/(gh_0) = k_0^2$ is the long wave dispersion relationship for waves in constant depth, h_0 . Introducing this notation and changing variable to

$$Z = \gamma + (1-\gamma) \frac{x}{\ell_s} \quad (13)$$

we finally obtain the simple governing equation for the surface wave amplitude

$$\frac{d}{dZ} \left[Z \frac{d\zeta}{dZ} \right] + \frac{(k_0 \ell_s)^2 (1-if_s)}{(1-\gamma)^2} \zeta = 0 \quad (14)$$

This equation reduces, as it should, to that of Madsen and White (1975) for the porosity $n \rightarrow 0$ or for the internal friction factor $f \rightarrow \infty$, both of which are limits resulting in an effectively impermeable slope.

General Solution

Equation (14) is of the Bessel type (Hildebrand, 1965) and its general solution may be expressed as

$$\zeta = A J_0(\text{Arg}) + B Y_0(\text{Arg}) \quad (15)$$

where Arg in the original variables is given by

$$\text{Arg} = \frac{2k_o \ell_s}{1-\gamma} \sqrt{1-if_s} \sqrt{\gamma + (1-\gamma)x/\ell_s} \quad (16)$$

From the property of Bessel Functions we further obtain the derivative

$$\frac{d\zeta}{dx} = - \frac{k_o \sqrt{1-if_s}}{\sqrt{\gamma + (1-\gamma)x/\ell_s}} [A J_1(\text{Arg}) + B Y_1(\text{Arg})] \quad (17)$$

where Arg again is given by (16).

The fluid velocities are obtained from (8) and (9) as

$$u_1 = -i \sqrt{\frac{g}{h_o}} \frac{1}{\sqrt{1-if_s}} \frac{1}{\sqrt{\gamma + (1-\gamma)x/\ell_s}} [A J_1(\text{Arg}) + B Y_1(\text{Arg})] \quad (18)$$

for the water wedge, and

$$u_2 = -i \sqrt{\frac{g}{h_o}} \frac{n \sqrt{1-if_s}}{1-if_s} \frac{1}{\sqrt{\gamma + (1-\gamma)x/\ell_s}} [A J_1(\text{Arg}) + B Y_1(\text{Arg})] \quad (19)$$

for the porous wedge.

From the general solutions presented above the solutions for the seaward and landward slopes are obtained by taking $x=x_1$ and $x=x_t$, respectively, and the appropriate ℓ_s , f_s , and n values (see Figure 1).

For Region III which is entirely porous the governing equations consist of the momentum equation which in its linearized form is identical to (5) and the continuity equation which reads

$$n \frac{\partial \eta}{\partial t} + h_o \frac{\partial U}{\partial x} = 0 \quad (20)$$

As previously mentioned the general solution to equations (5) and (20) was given by Madsen (1974) and in complex form it may be expressed as

$$\zeta_{III} = A_{pi} e^{ikx_i} + B_{pr} e^{-ik(x_i + \ell_p)} \quad (21)$$

where

$$k = \frac{\omega}{\sqrt{gh_o}} \sqrt{1-if_p} = k_o \sqrt{1-if_p} \quad (22)$$

and

$$u_{III} = -\sqrt{\frac{g}{h_0}} \frac{n_p}{\sqrt{1-if_p}} [A_{pi} e^{ikx_i} - a_{pr} e^{-ik(x_i + \ell_p)}] \quad (23)$$

Outside the structure the general solution is in Region I

$$\zeta_I = a_i e^{ik_0 x_i} + a_r e^{-ik_0 x_i} \quad (24)$$

$$u_I = -\sqrt{\frac{g}{h_0}} [a_i e^{ik_0 x_i} - a_r e^{-ik_0 x_i}] \quad (25)$$

where a_i is the incident wave amplitude and a_r is the complex amplitude of the reflected wave.

For Region V the motion consists of only the transmitted wave of complex amplitude a_t , i.e.,

$$\zeta_V = a_t e^{-ik_0 x_t} \quad (26)$$

$$u_V = \sqrt{\frac{g}{h_0}} a_t e^{-ik_0 x_t} \quad (27)$$

Matching Conditions

Assume for the moment that all linearized friction factors, porosities and incident wave characteristics are specified. The general solutions developed in the preceding section then contain 8 unknown constants of which the magnitudes of a_r , the reflected wave amplitude, and a_t , the transmitted wave amplitude, of course, are of primary interest in the present context. To determine the constants the general solutions for the surface elevation, ζ , and the horizontal discharge velocity, u , are matched at their common boundaries, i.e., at $x_i = \ell_{si}$, $0, -\ell$ ($x_t = 0$); and at $x_t = 0$ ($x_i = -\ell$) and ℓ_{st} . This yields 8 equations from which the 8 unknowns may be determined.

It is of special interest to note that the solution for the velocity in the water wedge, i.e., u_1 , is matched to the solution outside the structure at $x_i = \ell_{si}$ and $x_t = \ell_{st}$, whereas the velocity in the porous wedge, i.e., u_2 , is matched to the solution inside the structure, u , at x_i and $x_t = 0$. It is also noted that the value of the argument^p of the Bessel^t Functions in the general slope solution remain finite at $x = 0$ and $x = \ell_s$ since

$$\text{Arg} \quad \begin{array}{ll} 1 & \text{for } x = l_s \\ \sqrt{\gamma} & \text{for } x = 0 \end{array} \quad (28)$$

Evaluation of Linearized Friction Factors

Once the solution for given values of the linearized friction factors has been obtained Lorentz principle is invoked in order to obtain a new estimate for the friction factors. For the external dissipation Lorentz' principle takes the form of the integral

$$\frac{1}{T} \int_0^T dt \int_0^{l_s} \tau_b U_1 dx \quad (29)$$

being independent of whether τ_b is expressed by its nonlinear or linear form given by (3). Since f_w in (3) is taken from Madsen and White (1975) this leads to an equation for f_s . The integration is carried out on a high speed computer.

For the internal dissipation Lorentz' principle is expressed by the invariance of the integral

$$\frac{1}{T} \int_0^T dt \int_{\Psi} (\delta F) U_2 \delta \Psi \quad (30)$$

with frictional law used to express δF (equation 6). The integral in (30) is evaluated numerically over the appropriate volume, Ψ , by high speed computer. Since the nonlinear friction law in (6) contains two parameters, α and β , these must be specified before (3) yields a determination of the linearized friction factor f . The empirical expressions

$$\begin{aligned} \alpha &= \alpha_0 \frac{(1-n)^3}{n^2} \frac{v}{d^2} \\ \beta &= \beta_0 \frac{(1-n)}{n} \frac{1}{d} \end{aligned} \quad (31)$$

in which d is the stone diameter, v is the kinematic viscosity of the fluid. The constants α_0 and β_0 vary with the characteristics of the stones with a range of $800 < \alpha < 1500$ and $1.8 < \beta_0 < 3.6$. Since the stones used in the present experiments were highly angular (crushed quarry stones) values of $\alpha_0 = 1500$ and $\beta_0 = 3.6$ were used in (31).

With updated values for all friction factors the governing equations are again solved and renewed application of Lorentz' principle yield new values for the friction factors. From experience a final solution is obtained after 3 to 5 iterations.

COMPARISON WITH EXPERIMENTS

A set of 54 experiments on the reflection and transmission characteristics of homogeneous trapezoidal breakwaters were carried out in a 24 m long wave flume in the R.M. Parsons Lab. at MIT. The water depth was 30 cm and three wave periods (1.6, 1.8 and 2.0 sec.) were used. For each period 6 different values for the incident wave height were run on the structure having front slopes of 1 on 2.5, 2.0 and 1.5 with the rear slope remaining constant at 1 on 1.5. The stone material was crushed quarry stones with an equivalent diameter of $d = 1.5$ cm. Porosity was found to be 0.4.

The experiments were run continuously and incident reflected and transmitted wave amplitudes were determined by the accurate procedure developed and described by Madsen and White (1975). The structure was located approximately 12 m from the wave generator and reflection from the end of the wave flume was minimized by a 1 on 6 sloping absorber beach covered by horsehair.

Experimental results for reflection and transmission coefficients are shown in Figures 2a, b, c for a wave period of 2.0 sec. and front slopes of 1 on 1.5, 2 and 2.5, respectively. The experimental results are compared with predictions by the "new" method described in this paper (indicated by subscript N) as well as with predictions of the "old" method (indicated by subscript O) developed by Madsen and White (1977). From Figures 2a,b,c it is evident that the "new" as well as the "old" methods are quite successful in their prediction of transmission coefficients. It is, however, painfully obvious that both methods are quite weak in their ability to yield accurate predictions of the reflection coefficient. In fact, the "old" method yields high estimates of reflection coefficients whereas the "new" method yields low values. The discrepancy between the predicted and observed reflection coefficients is seen to increase with decreasing front slope.

A possible explanation for this discrepancy could be associated with an artificial discontinuity introduced in the analysis. Referring back to equation (1) it is seen that the storage term in the continuity equation is taken to be $\partial\eta/\partial t$ for the slope regions, i.e., storage is in the form of pure water on the slopes even in the areas where the water wedge pinches out. At the same time immediately inside the structure the storage term in the continuity equation, equation (20), indicates that storage takes place within the porous medium. This discontinuity was removed artificially by evaluating the slope solution at a value of $x = H/\tan\delta$, where δ is the slope, rather than at $x = 0$. It was found that this change had a relatively minor effect on the predicted transmission coefficients whereas the effect on predicted reflection coefficients was substantial. There was, however, no clear trend in the results obtained in this manner. Sometimes the reflection coefficient prediction improved, sometimes it got worse.

It is worthwhile to note that the experimental results for the

Figure 2: Comparison of Predicted and Observed Reflection (R) and Transmission Coefficients of Porous Trapezoidal Breakwaters. ——— Predictions by present method. - - - - - Predictions by previous method. Wave Period 2.0 sec., Water Depth 30.5 cm. Front slope 1 on 1.5(a), 1 on 2.0(b), 1 on 2.5(c).

Figure 2(c): For legend see previous page.

reflection coefficients, which are believed to be quite accurately determined, on the gentler slope show a trend of decreasing reflection coefficient with increasing wave steepness (Figure 2). This feature, which cannot be reproduced by the "old" method appears to be represented by the results obtained from the present theory.

As a final test of the procedure developed in this paper predicted values of reflection and transmission coefficients are compared with the experimental results obtained by Sollitt and Cross (1972) for a multi-layered trapezoidal breakwater. To apply the present methodology the multi-layered breakwater is modeled as a homogeneous breakwater of the same geometry. The uniform stone size of the homogeneous breakwater is chosen so that the two breakwaters are hydraulically equivalent in the sense defined by Madsen and White (1977). The results are shown in Figure 3 (from Madsen and White, 1977) as dashed and dotted lines. Again the predicted transmission coefficients are in close agreement with measurements, whereas predicted reflection coefficients, although better than predictions afforded by the "old" method, still leave somewhat to be desired.

CONCLUSIONS

The present investigation was undertaken to improve on a previous simplified model for the determination of reflection and transmission characteristics of porous breakwaters of trapezoidal cross-section. The improvement consisted of a more rigorous analysis of the wave-structure interaction on the seaward and landward slopes of the breakwater thereby removing the somewhat artificial treatment in the previous model of external and internal dissipation as separate mechanisms.

The resulting theory retains the practicality of the previous theory in that only parameters which may be expected to be approximately known are needed to carry out the computations. However, the new theory is more elaborate and does require calculations to be carried out on a high speed computer.

From a comparison with experimental data it appears that the new as well as the old method are quite successful in their determination of transmission coefficients. Neither the new nor the old method is very successful in their prediction of reflection coefficients. For relatively gentle seaward slopes (1 on 2.0 to 2.5) the new method underpredicts whereas the old method overpredicts the reflection coefficient. For relatively steep seaward slopes both methods give reflection coefficients in reasonable agreement with observations. Slight changes in the assumed geometry of the breakwater have an insignificant effect on predictions of transmission coefficients by both the new and the old method. Whereas the old method is quite insensitive to breakwater geometry also for prediction of reflection coefficients, the new method is in this aspect very sensitive which suggests that a major renewed effort is needed if one wishes to obtain better predictions of reflection coefficients.

PERFORMANCE CHARACTERISTICS OF SUBMERGED BREAKWATERS

J. Dattatri¹, H. Raman², and N. Jothi Shankar³

INTRODUCTION

Submerged breakwater is a barrier with its crest at or slightly below the still water level. In situations where complete protection from waves is not required, submerged breakwaters offer a potentially economic solution. Submerged breakwaters have been effectively used to protect harbour entrances, to reduce siltation in entrance channels, against beach erosion, and for creation of artificial fishing grounds. However quantitative information available about the hydraulic behaviour of these submerged breakwaters is rather limited. Theoretical analysis of the problem has not proved satisfactory primarily because of the difficulties in quantifying the energy losses that always accompany these wave - structure interactions. Recourse has to be taken to laboratory studies to provide the necessary information regarding the performance characteristics of submerged breakwaters.

A comprehensive laboratory investigation to evaluate the performance characteristics of the submerged breakwaters of various types and shapes, permeable and impermeable was undertaken. The results of these investigations are presented in this paper.

EXPERIMENTAL FACILITIES AND PROCEDURES

The experiments were conducted in a wave flume (25m x 0.9m x 0.9m) provided with a plunger type regular wave generator. The water surface time histories were recorded using a parallel - wire resistance probe in conjunction with a Kempf and Remmers three channel strip chart recorder.

The submerged breakwaters investigated were:

- 1) Horizontal fixed plate type,
- 2) Thin vertical wall type, Impermeable,
- 3) Triangular type, Impermeable,
- 4) Rectangular type, Permeable and Impermeable,
- 5) Trapezoidal type: Sea face sloping and beach face sloping, Permeable and Impermeable,
- 6) Trapezoidal type: Sea face sloping and beach face vertical, Impermeable.

The impermeable breakwater models were fabricated using mild steel and aluminium plates of 6mm thickness. For the sloping faces, a slope of 2 horizontal to 1 vertical was used. The details of all the breakwater models investigated is given in Fig.1. To study the influence of permeability, the breakwaters of the rectangular type (50 cm crest width) and the trapezoidal type (both faces sloping) were used. These breakwaters were formed using crushed stone aggregates, and the required cross-sections were maintained by confining the aggregates in wire mesh cages. Two types of aggregates, Type A and Type B were used. Type A aggregate had a median size of 16.5mm and a porosity of 0.41, while the Type B aggregate had a median size of 43.4 mm and a porosity of 0.42.

The water depth, d , was maintained constant at 50cm. The depth of crest submergence, d_s , of the breakwater was altered to any desired value by keeping the water depth constant but varying the crest level of the breakwater.

FIG-1 SUBMERGED BREAKWATERS INVESTIGATED : TEST CONDITIONS AND DIMENSIONS

Experiments were conducted covering a wide range of experimental conditions consistent with the available facility. The relative water depth, d/L was varied from 0.123 to 0.331, the incident wave steepness, H_1/L was varied from 0.007 to 0.083, while the relative depth of crest submergence d_s/d was varied from 0.0 to 0.4.

The incident wave characteristics, H_1 and L were measured in steady state runs without the breakwater in position. The transmitted wave was generally found to be irregular though periodic. To provide a basis for comparison of test results as free as possible from subjectivity, the equivalent wave height concept of Dick and Brebner (2) was used to evaluate the transmitted wave height, H_t . The reflected wave which results when the incident wave interacts with the structure, gives rise to a partial standing wave in front of the structure. The reflected wave height, H_r was evaluated by resolving the wave envelope of this partial standing wave. An equivalent wave height, H_l corresponding to the energy lost in the wave - structure interaction process was evaluated from energy balance considerations. The experimental data was processed using a IBM 370/155 digital computer facility.

PRESENTATION AND INTERPRETATION OF EXPERIMENTAL DATA

The data obtained from the experiments was analyzed using the method of dimensional analysis. The pertinent parameters influencing the phenomenon were obtained from dimensional considerations. The influence of the various parameters on the Transmission coefficient, $K_T (= H_t/H_1)$, the Reflection coefficient, $K_R (= H_r/H_1)$ and the loss coefficient, $K_L (= H_l/H_1)$ were analyzed. Restriction of space does not permit the presentation of all the results here. The important results regarding the study concerning the transmission coefficient only are presented here.

The complete details can be found in Reference 1.

The following dimensionless parameters can be considered to be important in the study of the transmission coefficient,

$$K_T = H_t/H_i = f(H_i/L, d/L, B/L, d_g/d, S, s, p)$$

in which H_t is the transmitted wave height, H_i is the incident wave height, L is the incident wave length, d is the depth of water, B is the crest width of the submerged breakwater, d_g is the depth of crest submergence below SWL, S is a parameter characterizing the shape of the breakwater, s is the slope of the breakwater faces, and p is the porosity of the breakwater. The dimensionless parameters H_i/L , d/L , B/L , and d_g/d represent the incident wave steepness, the relative depth of water, the relative crest width, and the relative depth of crest submergence respectively.

The shape has been represented by a variable, S only for mathematical definition. S will represent whether the breakwater is triangular, rectangular or trapezoidal. In the analysis that follows, the shape is not represented by assigning any specific value to S , but instead the shape will be specified. Similarly the slope, s was not varied but the distinction will be between a vertical face and a sloping face.

Influence of incident wave steepness, H_i/L on K_T

The incident wave steepness has an important influence on the wave breaking phenomenon. Waves near the critical steepness may be induced to break by the submerged breakwater, and since wave breaking process is always accompanied by energy losses, steeper waves are likely to be attenuated more than the flatter waves. Hence it can be logically concluded that the wave steepness is likely to be a significant parameter. In fig. 2. the transmission

FIG. 2 EFFECT OF WAVE STEEPNESS ON WAVE ACTION OVER A RECTANGULAR IMPERMEABLE SUBMERGED BREAKWATER

coefficient, K_T is plotted against the relative depth of crest submergence, d_s/d , with the incident wave steepness, H_i/L as the third parameter. The curves for the higher steepness values appear to merge into one, indicating that in the range of higher wave steepnesses the influence of H_i/L on K_T is not significant. Similar tendencies were observed for data corresponding to other breakwaters also. Goda et al (3) and Johnson et al (4) have also arrived at similar conclusions.

Another important trend in Fig.2 is the influence of d_s/d on K_T . As d_s/d approaches zero, i.e., the crest of the breakwater approaches the SWL, there is a general decrease in K_T . For large values of d_s/d ($= 0.40$), the transmission is very high of the order of 75% to 95%. As such d_s/d values greater than 0.40, are not likely to be of any practical significance from the point of view of wave damping. In view of this, the maximum value of d_s/d used in the present investigation was restricted to 0.40.

Influence of relative water depth, d/L on K_T

The data to study the influence of the relative water depth, d/L on K_T is presented in Fig.3. To reduce the influence of other parameters, the incident wave steepness is maintained constant at 0.03. The data show very similar tendencies and in general it can be seen that the relative water depth does not have significant influence on K_T . In the range $d_s/d = 0.0$ to 0.2, the relative water depth did not have any influence, but in the range $d_s/d = 0.2$ to 0.4, larger values of d/L show a tendency towards slightly greater transmission. This is to be expected because larger values of d/L correspond to relatively deeper water waves, wherein more energy is concentrated near the surface. When d_s/d is also large, this energy concentrated near the surface is easily transmitted across the structure.

FIG. 3 EFFECT OF RELATIVE WATER DEPTH ON WAVE ACTION OVER A RECTANGULAR IMPERMEABLE SUBMERGED BREAKWATER.

Influence of relative crest width, B/L , and relative depth of crest submergence, d_s/d , on K_T .

In the case of impermeable submerged breakwaters, the energy transmission to the shoreward side must take place only above the crest of the breakwaters. The amount of energy transmitted across will naturally be more, if the depth of crest submergence is more. So it is logical to conclude that the relative depth of crest submergence, d_s/d is likely to be the most important parameter influencing the performance characteristics of the submerged breakwaters. This conclusion is in general also applicable to the permeable breakwaters also, since the energy transmitted through the structure is likely to be a small percentage of the energy transmitted over the crest.

The relative crest width, B/L influences the wave transformation over the breakwater. In the case of breakwaters with very small crest widths, it was observed that the incident wave steepens and reaches a condition when it is about to break. But before the wave can break, it enters the relatively deeper waters in the lee of the breakwater, which prevents the wave from breaking. In the case of breakwaters with sufficient crest width, the wave breaks resulting in a greater dissipation of energy and consequently lesser transmission. An increase in the crest width over the minimum necessary to trigger breaking, is unlikely to have any significant influence on the transmission characteristics.

The experimental data is in general agreement with these logical conclusions as can be clearly seen in Fig.4. The data for the rectangular impermeable breakwaters is plotted in Fig.4. in terms of K_T and B/L with d_s/d as the third parameter. The scatter of data is slightly large for small values of B/L . The data corresponding to the

FIG. 4 TRANSMISSION COEFFICIENT VS RELATIVE CREST WIDTH:
RECTANGULAR IMPERMEABLE SUBMERGED BREAKWATER.

three crest widths (25, 50, and 100cm) overlap in this range and the scatter may be partly due to this. K_T decreases as B/L increases, until K_T reaches a minimum value. This occurs for B/L values between 0.2 and 0.3. The position of the minimum shifts gradually from 0.2 to 0.3, as d_s/d increases from 0.0 to 0.4. After the minimum is reached, K_T tends to increase slightly with further increase in B/L , before it becomes asymptotic. Increase of crest widths beyond $B/L = 0.3$, does not significantly add to the damping characteristics of these breakwaters. Fig.4 clearly points to the existence of an optimum crest width of the breakwater ($B/L = 0.2$ to 0.3). The K_T Vs B/L curves show some sort of a sinusoidal variation which cannot be satisfactorily explained.

The data in Fig.4 group themselves remarkably well for the different values of d_s/d , and the trend lines for constant values of d_s/d , show consistent tendencies. As is to be expected, larger values of crest submergence show greater transmission.

Influence of shape and slope

The transmission characteristics of the impermeable breakwaters of different shapes, but with finite crest width (50 cm) are shown in Fig.5. The transmission curves for the three shapes have very similar characteristics. In the case of the rectangular breakwaters, the reflections will be high, while for the trapezoidal breakwater, the reflection would be low but the losses are likely to be higher due to wave breaking. Thus in both cases, the transmission would be the same. Providing a slope on the beach face of the breakwater has not influenced the transmission characteristics in comparison with the trapezoidal breakwater with beach face vertical. Kabelac (5) has concluded that the magnitude of the wave attenuation depends not only

on the slope of the sea face of the breakwater, but also on its cross-sectional area. The cross-sectional areas of the three breakwaters whose results are presented in Fig.5, are 2500, 5000 and 7500 cm². But the transmission characteristics of all these three types are very nearly the same although the cross-sectional areas have a three fold variation.

It can be concluded that for the various shapes of the breakwaters tested in the present investigations, the transmission characteristics do not depend on the shape. Breakwaters with vertical faces on the sea side induce large reflections, creating partial standing waves. These create problems of scour and consequent undermining at the base of the breakwaters. Further, large reflections result in greater wave forces on the structure due to the formation of the standing wave. These considerations necessarily preclude the rectangular type of submerged breakwaters for practical use.

Submerged breakwaters with their sea faces sloping have the possible advantage that they allow for the free passage of sediment on its face compared to a vertical face. If the beach face of the breakwater is also sloping, the sediment trapping efficiency will be less. So the ideal one appears to be a breakwater with sea face sloping and beach face vertical. The prototype experience as reported by Kabelac (5) confirms the sediment trapping efficiency of these types of breakwaters, in addition to their efficient wave damping characteristics.

Influence of porosity

The experimental data to study the effect of porosity is presented in Fig.6. The data corresponding to the horizontal plate type is also included. This type can be considered as a rectangular breakwater with a porosity,

FIG. 6 EFFECT OF POROSITY ON THE TRANSMISSION COEFFICIENT: RECTANGULAR SUBMERGED BREAKWATER

$p = 1.0$, in comparison with the rectangular impermeable type which has a porosity, $p = 0.0$. In Fig.6, K_T is plotted against H_1/d (and H_1/L) with porosity, p as the third variable. The relative water depth, d/L was maintained constant. All the curves are nearly horizontal, which incidentally confirms the earlier conclusion that the wave steepness has no significant influence on K_T . Regarding the influence of porosity, a regular and a systematic trend is seen for the data corresponding to $d_s/d = 0.0$. The impermeable breakwater has the minimum transmission, and as the porosity increases, the transmission also increases. For $d_s/d = 0.10$, the impermeable breakwater has the minimum transmission for most of the range, but the data for other porosities cannot be distinguished from each other. For $d_s/d = 0.20$, the curves for the permeable and impermeable cases appear to merge. This is because for large depths of crest submergence, the energy transmitted through the breakwater will be a very small percentage of the energy transmitted on the top, and hence the porosity is unlikely to have any significant influence on K_T .

In general we find the behaviour of the permeable breakwaters to be very similar to the behaviour of the impermeable breakwaters. This is in contrast to the conclusion of Dick and Brebner (2) that permeable breakwaters behave differently from impermeable types. However it should be noted that the permeable breakwaters used by Dick and Brebner were of the nested tube type, while in the present case they were of crushed stones.

PERFORMANCE CHARACTERISTICS OF SUBMERGED BREAKWATERS

The investigations regarding the influence of the various parameters on the transmission coefficient, K_T as detailed above, indicate that the two parameters,

relative depth of crest submergence, d_s/d , and the relative crest width, B/L to be the most significant. The performance characteristics for each of the type of breakwater tested can be represented as K_T Vs B/L plots with d_s/d as the third parameter. Such a plot for the rectangular impermeable submerged breakwaters was presented in Fig.5. In Figs. 7 and 8, the performance characteristics of some of the other submerged breakwaters tested have been presented. An important feature of these plots is the considerable similarities and consistent tendencies.

TRANSMITTED WAVE CHARACTERISTICS

The waves formed shoreward of the submerged breakwaters were quite complex and showed the presence of several smaller waves. However periodicity was maintained and this period corresponds to the incident wave period. This indicates the generation of a system of harmonics with a fundamental frequency equal to that of the incident wave. To examine this aspect, some of the transmitted wave records were subjected to a spectral analysis and the results confirmed this. The generation of higher harmonics was found to be more pronounced when the crest of the breakwater is close to the still water level. However, in a majority of these cases, the energy contents of the higher harmonics were considerably less than that corresponding to the fundamental. Thus it can be concluded that the transmitted wave has the same fundamental frequency as the incident wave but part of the energy is shifted to the higher frequencies.

CONCLUSIONS

The results of the present investigations indicate that submerged breakwaters can effect substantial wave attenuation and can be successfully used in places where only partial protection from waves is required. The important parameters that influence the performance are the

FIG. 7 PERFORMANCE CHARACTERISTICS OF TRAPEZOIDAL IMPERMEABLE SUBMERGED BREAKWATER.

FIG. 8 PERFORMANCE CHARACTERISTICS OF PERMEABLE SUBMERGED BREAKWATERS.

crest width and the depth of crest submergence. Permeability does not have significant influence, particularly for large depths of crest submergence. The shape of the breakwater has significant influence on the reflection characteristics only. The ideal shape appears to be one with the sea face sloping and the beach face vertical. The transmitted wave has the same period as the incident wave, but for cases with the crest of the breakwater near the still water level, higher harmonics are generated.

The performance characteristics of the submerged breakwaters can be represented in the form of design charts with the relative crest width and the relative depth of crest submergence as the significant parameters. These curves show remarkable similarity for the different types studied.

COMBINATION EFFECT OF PNEUMATIC BREAKWATER AND OTHER TYPE BREAKWATER ON WAVE DAMPING

by

Yuichi Iwagaki,^{*} Toshiyuki Asano,^{**} Tsutomu Honda^{***}

ABSTRACT

This paper deals experimentally with combinations of the pneumatic breakwater and other type breakwaters in order to increase the effectiveness of wave damping.

Firstly, a submerged breakwater is picked up, and the wave damping effect of this combined type breakwater is examined. Results obtained in this experiment show that some improvements on the wave damping are found for low frequency waves that cannot be damped by the pneumatic breakwater only. The reason of appearance of the combination effect is explained that a part of energy of the transmitted waves over the submerged breakwater transfers to shorter period waves.

Secondly, a floating breakwater is combined with the pneumatic breakwater. Experiments show that the transmission factor for high frequency waves becomes smaller than that of the pneumatic breakwater only, while there is not so much wave damping effect for low frequency waves even when the floating breakwater is combined. In addition, a guide plate is set below the bottom of the floating breakwater in order to increase the horizontal flow velocity for a given air discharge. It is found that the velocity of horizontal surface flow by using the guide plate increases as much as about 1.3 times that in the case of the pneumatic breakwater only. As a result, a little improvement on the wave damping due to the guide plate is also found.

INTRODUCTION

The pneumatic breakwater is one of mobile breakwaters, so it has several specific characters of the mobile breakwater such as mobility, temporality, cheapness, etc. Besides these, it is pointed out as a special merit of the pneumatic breakwater from environmental point of view not to interrupt the exchange of water in harbors and facilities of air discharge are placed on the sea bottom.

However, existing studies on the pneumatic breakwater have clarified its defect that the effectiveness of wave damping suddenly disappears when the wave period becomes longer than a certain period. This property prevents it from practical use.

The horizontal flow velocity, which is strongly related to the wave damping, generated by the air bubble curtain, is proportional to $1/3$ power of the air discharge, so it is not expected to increase the horizontal flow velocity by increasing the air discharge.

In the present paper, in order to increase the damping effect, an attempt that other type breakwaters are combined with the pneumatic breakwater is carried out. The submerged breakwater and the floating breakwater are picked up as combined breakwaters.

DAMPING CHARACTERISTICS OF PNEUMATIC BREAKWATER ONLY¹⁾Experimental apparatus and procedure

A wave tank used for the test was 27m long, 0.5m wide and 0.7m deep. The power of a compressor used was 5.5kW, and the maximum pressure was 7kg/cm². A pressure regulator was installed for reducing the pressure and keeping it constant. A pipe for discharging air set on the bottom was 47.5cm long and 1 inch in diameter. Nozzle holes of the pipe were 1mm in diameter and opened 6mm interval.

Experimental results

At first, characteristics of wave damping for monochromatic waves were examined. The result is shown in Fig.1. The transmission factor HT/HI (HT : transmitted wave height and HI : incident wave height) suddenly decreases with increase in the frequency of incident waves. A critical frequency, which is defined as the frequency of which waves are damped almost completely, shifts to lower frequency as the air discharge increases.

Secondly, experiments for random waves were carried out. The energy spectra of incident waves and transmitted waves are shown in Fig.2 as an example. As the air discharge increases, the power of the spectrum of transmitted waves decreases. This figure also shows that the powers of them increase reversely for the waves around 2Hz. This reason is considered that the air bubble curtain flow generates some disturbance of which frequency is around 2Hz on the water surface. The value of transmission factor for random waves shows close agreement with that for monochromatic waves, so it is concluded that the pneumatic breakwater has same characteristics for both waves.

COMBINATION WITH SUBMERGED BREAKWATER²⁾Experimental apparatus and procedure

A schematic view of experimental apparatuses is shown in Fig.3. The wave tank is the same as described previously. In the experiment, the following four models were provided as submerged breakwaters.

- 1) impermeable type and smooth surface
- 2) impermeable type and with roughness on the upper surface
- 3) permeable type and made of stellersheet
- 4) permeable type and made of ripraps

The impermeable type submerged breakwaters were made of vinyl chloride and anchors were put in it not to be swayed by the wave motion. The roughness were made of glass sticks of 10mm in diameter and placed on the upper surface at 30mm interval. The void ratio of stellersheet and ripraps, which were used as the materials of the permeable type submerged breakwater, were 98% and 45% respectively. The diameter of ripraps was about 30 ~ 60mm. The height of the submerged breakwater, Sh , was changed 30cm, 35cm, 40cm and 45cm for the impermeable type, 30cm, 35cm and 40cm for the permeable type. Only for the impermeable and 30cm high model, the width Sw was changed 20cm, 40cm and 60cm, and for others

Fig.1 Relation between transmission factor of pneumatic breakwater and frequency of incident waves

Fig.2 Damping effect of pneumatic breakwater for random waves

always $S_w=20\text{cm}$.

Experiments on the damping characteristics of the submerged breakwaters were carried out for monochromatic waves of $4\text{cm} \sim 6\text{cm}$ in height and $0.4\text{Hz} \sim 1.6\text{Hz}$ in frequency. The submerged breakwater was placed at the location where its front face was as far as 13m from the wave generator. Three wave gauges of electric resistance type were installed as shown in Fig.3. The first gauge was for incident waves, and other two were for transmitted waves. The reason why two gauges were installed was to examine the change of the transmission factor with measuring points.

Experiments of the submerged breakwater combined with the pneumatic breakwater were carried out for incident waves having the same characteristics as those used in the previous experiment. The air discharge was kept always constant 300 l/min , and this discharge corresponds to 7.09 l/sec.m under the condition of 0°C temperature and the atmospheric pressure.

Changing the distance between the air nozzle pipe and the submerged breakwater to $0\text{cm}, 45\text{cm}, 90\text{cm}, 135\text{cm}$ and 180cm onshore and offshore sides respectively, the most advantageous arrangement was investigated. The experiment on the wave damping was carried out under this arrangement.

Damping effect of submerged breakwater

The purpose of this study is to examine the combination effect, so the damping effect of the submerged breakwater is not concerned with this purpose directly. But the combination effect cannot be discussed unless the damping effect of an individual breakwater is clarified. The experimental results on the transmission factor of several kinds of submerged breakwaters are shown in Fig.4. The variation of the transmission factor H_T/H_I with the height of submerged breakwaters S_h , and with the kind of materials are presented herein. The transmission factor decreases with increase of the height for the same type submerged breakwater, and becomes smaller in the order of the impermeable type of smooth surface, the impermeable type of rough surface, the permeable type made of ripraps and the permeable type made of stellersheet.

However, the most effective submerged breakwater on the wave damping is not always the most effective one for the combination type breakwater. It is assumed that the combination effect is caused by the energy transfer to shorter period waves which can be damped by the pneumatic breakwater. If this assumption is right, a submerged breakwater which can transfer more part of energy of transmitted waves to shorter period waves is the most effective as the combination type breakwater. From this point of view, it becomes important to investigate the characteristics of transmitted waves over the submerged breakwater.

Fig.5 shows the comparison of the transmitted wave amplitude spectrum over the submerged breakwater with the incident wave amplitude spectrum. In this case, the wave frequency is 0.4Hz , and the submerged breakwater is impermeable, 40cm high and 20cm wide. It is found that the wave height at the fundamental peak frequency f_p , which corresponds to that of the incident monochromatic waves, decreases about 2cm , while the wave heights at the double and tripple frequencies of f_p increase conversely.

Fig.6 shows the amplitude spectra of incident and transmitted waves

Fig.3 Experimental apparatus when submerged breakwater is combined with pneumatic breakwater

Fig.4 Relation between transmission factors of impermeable and permeable submerged breakwaters and frequency of incident waves

Fig.5 Comparison of amplitude spectra of transmitted waves over submerged breakwater and incident waves

Fig.6 Comparison of amplitude spectra of transmitted waves through pneumatic breakwater and incident waves of finite amplitude with frequency of 0.77Hz

Fig.7 Variation of transmission factor with location of air nozzle pipe

through the pneumatic breakwater when incident waves are of finite amplitude and the frequency of 0.77Hz. It is found that the second harmonic component waves are not damped at all. That means that the pneumatic breakwater is not capable of damping bound waves of the second and third harmonics, even if their frequencies are in the region where the pneumatic breakwater is effective to wave damping. Therefore, it becomes important to clarify whether waves of the second and the third harmonics generated by passing over the submerged breakwater are free waves or bound waves.

A phase lag of component waves $\Delta\theta$ is obtained experimentally by calculating the phase spectrum from water surface variations measured at two points simultaneously. While a theoretical phase lag is calculated from the distance between recording points l and the wave length of component waves Lc , as follows

$$\Delta\theta = 2\pi l / Lc \quad (1)$$

The comparison of the experimental phase lag with the theoretical one is shown in Table 1. Frequencies of waves used in this consideration are 0.586Hz and 0.781Hz. For free waves, the wave length Lc is calculated by the small amplitude wave theory, while for bound waves of the second harmonics Lc is assumed to be half of the wave length of fundamental component waves. The submerged breakwater used here is impermeable, smooth, 35cm and 40cm high and 20cm wide. The results of Cases 5, 7 and 8 show that experimental values of the phase lag of the second harmonic component waves agree well with theoretical results of free waves. Therefore, it is reasonable to conclude that these waves generated by passing over the submerged breakwater are free waves.

Advantageous arrangement of pneumatic breakwater and submerged breakwater

Fig. 7 shows the variation of the transmission factor with a location of the air nozzle pipe. The abscissa is the ratio of the distance between the air nozzle pipe and the submerged breakwater to the water depth, x/h , and the positive sign denotes the case when the air nozzle pipe is located onshore side. The submerged breakwater is in the section between $x/h = -0$, and $x/h = +0$. This figure shows the locations where the damping effect is remarkable are at $x/h \geq 2$ in the case when $f = 0.6\text{Hz}$, and at $x/h = -0$ and $x/h \geq 2$ in the case when $f = 1.2\text{Hz}$. From the results of two cases, the most advantageous arrangement is where the air nozzle pipe is located onshore side of the submerged breakwater apart more than twice the water depth. Accordingly, the location of the air nozzle pipe is determined to be at $x/h = 2$ in the following experiment.

Damping effect of pneumatic and submerged breakwater

The wave damping effect of the combination type breakwater is examined by changing the size and material of the submerged breakwater. The results are shown in Fig. 8. The transmission factor of the combination type breakwater decreases compared with those of the pneumatic breakwater only and of the submerged breakwater only. That is, for low frequency waves which cannot be damped by the pneumatic breakwater only, it decreases to some extent. But from the results in Fig. 8, it is impossible to decide whether the combination effect exists or not. Therefore, the

- (2) Impermeable type and rough upper surface
- (3) Permeable type and made of stellarsheet
- (4) Permeable type and made of riprap

following equation is proposed as a quantitative expression of the combination effect:

$$ES = \left(\frac{HT}{HI}\right)_S \left(\frac{HT}{HI}\right)_P - \left(\frac{HT}{HI}\right)_{S+P} \quad (2)$$

in which $(HT/HI)_S$ and $(HT/HI)_P$ denote the transmission factors of submerged and pneumatic breakwaters only respectively. If the phenomenon is represented as a linear problem, the transmission factor of the combination type breakwater $(HT/HI)_{S+P}$ can be estimated as the product of each one. Consequently, the value of ES , which is the difference between the above mentioned product and the value of $(HT/HI)_{S+P}$, denotes the combination effect.

Fig.9 shows the transmission factors and the combination effects calculated by Eq.(2) for several kinds of combination type breakwaters. It is found from Figs.9 (a) and (b) that both the damping effect and the combination effect become remarkable as the height of the submerged breakwater increases. With regard to the width of the submerged breakwater, there is not so much difference of the damping effect as shown in Fig.9 (c). But in the case when $S_w=60\text{cm}$ the curve of combination effect has a clear peak at the frequency of 0.6Hz. This phenomenon may be concerned with the effect of the width of the submerged breakwater on wave energy transfer to higher frequency waves. Fig.9 (d) shows the comparison between the effects by the materials constructing the submerged breakwaters.

It is concluded that the permeable type breakwater, especially made of stellersheet, is more effective on the damping effect than the impermeable type breakwater, but with regard to the combination effect, the impermeable type is more predominant than that of the permeable type.

In each case, it is found that existance of the combination effect is limited in the region of the frequency from 0.5Hz to 1.4Hz. The reason why the combination effect does not appear in the region $f < 0.5\text{Hz}$ is that the double frequency 1.0Hz of incident waves is a critical frequency for wave damping of the pneumatic breakwater. On the other hand, when $f > 1.4\text{Hz}$, the combination effect also becomes negative because higher frequency waves are damped sufficiently by the pneumatic breakwater only.

COMBINATION WITH FLOATING BREAKWATER³⁾

Experimental apparatus and procedure

A schematic view of the experimental apparatus is shown in Fig.10. Floating bodies used as floating breakwaters were made of Lucite board, and 30 ~ 90cm long, 48cm wide and 10cm high. The floating body was supported by anchor ropes which were $\sqrt{3}$ times as long as the water depth. A guide plate was set below the bottom of the floating breakwater as shown in Fig.11 to guide the horizontal surface flow in the opposite direction to wave propagation. The figure shows two ways of setting the guide plate. In the following, the guide plate shown in Fig.11(a) is named a vertical guide plate, and the other plate shown in Fig.11 (b) is named an inclined guide plate. The vertical guide plate was placed at the position dividing the length of the floating body into the ratio of 7:3, and the length of the vertical plate was 9cm. The angle of inclination

Fig.10 Experimental apparatus when floating breakwater is combined with pneumatic breakwater

Fig.11 Setting ways of guide plate

of the inclined guide plate to the bottom of the floating body was kept constant 12° .

The water depth was 45cm, and the air discharge was 400 l/min throughout the experiments. This discharge corresponds to 15.15 l/sec.m under the condition of 0°C and the atmospheric pressure. Measurement of the horizontal flow velocity was carried out by a propeller type current meter of 18mm in diameter.

The draught depth of the floating body and the tension of anchor ropes are considered to affect significantly the transmission factor of the floating breakwater. Therefore, the draught depth was kept constant 2.5cm for the floating bodies which were 30cm, 45cm and 60cm long, and 2.0cm for ones which were 75cm and 90cm long. The tension was not measured, but the experiment was made to keep the tension nearly constant.

Characteristics of horizontal surface flow velocity

Experiments were carried out in the following four cases:

Case-1 The pneumatic breakwater was used only.

Case-2 The floating breakwater without a guide plate was combined with the pneumatic breakwater.

Case-3 The floating breakwater with a vertical guide plate was combined.

Case-4 The floating breakwater with an inclined guide plate was combined.

Some examples of the velocity profile of the horizontal surface flow are presented in Fig.12. In this case, the velocity was measured at the section horizontally from the air nozzle pipe the same distance as the water depth. The length of the floating breakwater was 45cm. It is found that the velocity of the horizontal surface flow in the case of combination with the floating breakwater, especially with the vertical guide plate, increases as much as about 1.3 times that in the case of the pneumatic breakwater only. Regarding the thickness of the horizontal surface flow, the results in Case-2 and Case-4 show a little decrease of the velocity compared with Case-1 of the pneumatic breakwater only.

Damping effect of pneumatic and floating breakwater

At first, in the case of combination with the floating breakwater without a guide plate, the damping effect was examined. Fig.13 shows transmission factors in cases of the pneumatic breakwater only, the floating breakwater only and the combination of both breakwaters. Both the pneumatic and floating breakwaters have similar characteristics to be effective for the waves of higher frequency than a certain frequency. This characteristics remains same when both breakwaters are combined, but for the waves of higher frequency than a certain frequency the transmission factor becomes smaller than that in the case of simple use.

Change of the transmission factor with the length of the floating body is shown in Fig.14. The transmission factor of the floating breakwater only decreases a little as its length becomes longer. While, this tendency is not clear when the floating breakwater is combined with the pneumatic breakwater. This phenomenon is explained from the observation as follows. Incident waves increase in their height due to the horizontal

Fig.12 Velocity profiles of horizontal surface flow

Fig.13 Transmission factors of pneumatic breakwater only, floating breakwater only and combined breakwater

(a)

(b)

Fig.14 Effect of length of floating body on transmission factor

- (a) Floating body only
- (b) Combination type breakwater

surface flow in the opposite direction, and wave energy is dissipated when waves clash in front of the floating breakwater. This result is rather convenient in practical use of the combination type breakwater, because it is not necessary to lengthen the floating breakwater.

Fig.15 shows the comparison of the transmission factors between the combination type breakwaters without the guide plate and with the guide plate, and between with the vertical guide plate and with the inclined guide plate. It is shown clearly that the transmission factor decreases when the guide plate is placed, but there is not so much difference between using the vertical guide plate and the inclined one.

The variation of the transmission factor with the method of supporting is examined by changing the anchor support into the fixed support. The length of the floating body used was changed 30cm, 60cm and 90cm. Fig.16 (a) is the case of the floating breakwater only and (b) is the case of the combination type breakwater. A considerable improvement on the wave damping effect is achieved by changing the anchor support into the fixed support. It is also shown that the waves of higher frequency than 1.2Hz are damped almost completely when the fixed support floating breakwater is combined.

In the field, it is difficult to fix the floating breakwater, but it may be possible for the anchor support to make the damping effect strong as much as the fixed support by devising effective arrangement of the anchor ropes and making the spring constant of the anchor rope larger.

CONCLUSION

In the present paper, the improvement on the damping effect of waves by combining the submerged or the floating breakwater with the pneumatic breakwater has been investigated experimentally.

Main conclusions are as follows:

- 1) The combination type breakwater of the submerged and the pneumatic breakwaters is more effective on the wave damping than each breakwater only. The reason why the combination effect appears is explained as follows. When waves pass over the submerged breakwater, a part of the wave energy transfers to higher frequency waves which can be damped by the pneumatic breakwater. This phenomenon is confirmed by investigating the characteristics of waves passing over the submerged breakwater.
- 2) Four kinds of submerged breakwaters were provided for the tests. The permeable type submerged breakwater made of stellersheet is the most effective on the wave damping. However, concerning the combination effect, the impermeable type submerged breakwater is more effective than the permeable one.
- 3) The floating breakwater has similar characteristics to the pneumatic breakwater, so the weak point of the pneumatic breakwater is not improved at all for low frequency waves by combining the floating breakwater. But, for high frequency waves, the combination type breakwater is more effective than each breakwater only.

- 4) The guide plate was set below the bottom of the floating body to guide the horizontal surface flow in the opposite direction to wave propagation. It is found that the velocity of the horizontal surface flow increases by the guide plate. And the result on wave damping also shows the effectiveness of the guide plate.

ACKNOWLEDGEMENT

The authors would like to acknowledge the assistance of Mr.Y.Sudo and Mr.H.Mase in this experiment. A part of the present investigation was accomplished with the support of the Science Research Fund of the Ministry of Education for which the authors express their appreciation.

CHAPTER 132

SCRAP TYRE BREAKWATERS IN COASTAL ENGINEERING
by ROBERT CHARLES MCGREGOR and NEIL SINCLAIR MILLER*

1. INTRODUCTION

The problem of the protection of shorelines and coastal structures from wave action is one of long standing. More recently it has become necessary to examine the feasibility of providing the same sort of wave attenuation for locations further offshore. Where the need for protection is in shallow water, close to the shoreline, bed-based breakwaters are possible and floating breakwaters may only be desirable on the basis of one or more of the following grounds:

- a) cost,
- b) requirement for protection being of short duration,
- c) reduced interference with currents,
- d) adaptability to changing performance criteria,
- e) poor foundations.

As the water depth becomes larger, the costs of a fixed structure become prohibitive whereas only the anchoring fraction escalates for a floating breakwater.

There is an extensive literature extending from 1842 on the floating breakwater concept. Most of the references, however, are postwar following the wartime stimulation of interest in aid of assault landings. Recent sources of state-of-art information are Kowalski (1974) and Adey (1976). The use of scrap automobile tyres has been discussed by Candle (1974), Kowalski (1974, 1976), Noble (1976) and Harms (1978). Candle was proposing what may be called near rigid mats of tyres where neighbouring tyres move relatively little with respect to one another, whereas the Noble, Harms and Kowalski designs use the breakwater flexibility. In the Kowalski breakwater**, the tyres are formed into groups which are known as modules which allow the breakwater to "breathe" and so dissipate more energy by internal movement as well as making construction easier. Several breakwaters of a fairly simple form have been built using this concept. These have been operational in the U.S.A. for several years and have successfully protected at least one marina through hurricane conditions.

* Department of Naval Architecture and Ocean Engineering,
University of Glasgow, U.K.

** The design of breakwaters which make use of the innovations
of Professor Kowalski is proprietary.

The use of worn tyres in seawater is a safe way of reducing an increasingly important pollution problem. In Britain alone, about 25 million tyres are discarded annually and only a fraction of these are recycled at present. In many other countries, environmental regulations are more restrictive and old tyres become a liability and an eyesore. Tyres are completely non-toxic in seawater and do, in fact, attract marine life. (Tyres have been used as submerged reefs, where they are quickly covered by marine growth, and also as fishing islands, where anglers make use of the tyre's attractiveness to fish, by virtue of providing both a haven and a source of food.) The tyre's geometry is particularly convenient because while it can be constrained to float vertically it is bistable and will, if released, topple over in time and sink without causing any damage or becoming a hazard.

2. BACKGROUND

2.1 CONSTRUCTION

The construction of the Kowalski breakwater is in the form of modules (or groups) of tyres which may be tied together and used as prefabricated blocks in the on-site construction of the breakwater as a whole. The basic unit, which is shown in fig. 1 and 2, comprises of 18 tyres which are tied together so that they float with all tyres in a vertical plane. The air trapped in the crown of each car tyre which floats in this way gives a buoyancy force of about forty newtons (40N) giving a module sufficient buoyancy to support the weight of an average man. The heaving motion of the tyres during wave action is sufficient to allow the replenishment of air in the crowns but in some exceptional circumstances where the trapped air may be dissolved during prolonged calms urethane foam or other buoyancy material may be inserted in a fraction of the tyres. Buoyancy may also be reduced by air leaking from the crowns of lacerated tyres or by the growth of mussel spat or weeds.

The modules are fastened together using a minimum number of ties to permit tyres slight movement relative to each other. The choice of tying material depends on the application, environment and required life of the breakwater. It is possible to use nylon, dacron, polypropylene or stainless steel wire rope or chain, but each suffers from some disadvantage with respect to sea water corrosion or abrasion caused by the constant agitation of the tyres. Wire rope and chain have an additional disadvantage because of the weight involved. Since there is a need for structural integrity the use of reinforced rubber belting secured by nylon bolts is to be preferred for situations where durability over long periods is required.

In order to increase the attenuation of higher waves, a deeper module may be created from the basic one with the addition of six more tyres. The unit is three tyres deep.

Both sets of units may be connected into strings, and later mats, by the use of link tyres. This is shown in fig. 3 and, in the case of the basic modules, allows the breakwater great flexibility. This property is beneficial both in wave energy dissipation (the Cockerell raft wave energy device) and in the sharing of loads throughout the breakwater in heavy seas.

fig 2: Module - Plan View

fig 3: Breakwater Mat

2.2 PERFORMANCE

A floating breakwater redistributes the waves energy approaching it in five ways. These are:

- 1) reflections from the forward face(s) of the breakwater,
- 2) dissipation of wave energy within the structure of the breakwater,
- 3) transmission of unsuppressed wave energy,
- 4) diffraction of the waves passing by the ends of the breakwater, into the protected region in the lee of the breakwater, and
- 5) generation of waves by the movement of the breakwater itself on the water behind the breakwater.

Different breakwater concepts give different relative importance to these effects. For example, a fixed concrete breakwater will have nearly total reflection, dissipate only a little as noise and spray, transmit a little by overtopping on occasions and generate none. On the other hand, a tyre breakwater reflects very little energy (depending to some degree on the modules which make up the leading edge), generates a little (depending on the trailing edge), leaving the balance to be shared, between dissipation through its flexibility, internal friction and fluid particle path interference and the unwanted transmission. All breakwaters which terminate at sea will diffract waves in some way and this is frequently an important design consideration since it means that the breakwater shadow zone is encroached on by waves travelling in new directions. These waves may interfere to the detriment of conditions in the protected area.

The measure of performance of a breakwater as a whole must be in terms of energy giving

$$\eta_E = 1 - \frac{\text{energy of waves to leeward}}{\text{energy of incoming waves to seaward}}$$

which is easily calculable in terms of the energy spectra in the two situations. Thus

$$\eta_E = 1 - \left(\frac{H_{SA}}{H_{SF}} \right)^2$$

It is desirable from the design point of view to know the transmission coefficient C_T which in the case of a regular wave train is simply

$$C_T = \frac{H_A}{H_F}$$

In the case of a mixed wave spectrum C_T is given by a ratio of Fourier components averaged from a sufficiently long stationary data record. The transmission coefficient is a function of wavelengths (or frequency since these are uniquely related for water of a given depth).

3. EXPERIMENT

3.1 ARRANGEMENT

The experiments were conducted using 1/4 scale car tyres in the Hydrodynamics Laboratory of the Department of Naval Architecture and Ocean Engineering at Glasgow University. This tank is 77m long, 4.6m wide and 2.4m deep and has a parabolic plunger wavemaker at one end which can be programmed to produce a pseudo-random sea made up nominally of 25 different frequency components with a return cycle of 100 time steps. Wave heights up to 0.4m can be produced.

Twenty-five breakwaters fabricated of basic and deep modules were constructed from the 1,300 tyres available and were tested for wave attenuation and mooring loads. The experimental layout is shown in fig. 4.

Previous breakwater tests (Kowalski 1976) had used several runs at discrete frequencies to analyse a particular breakwater, but on this occasion, because of the large amount of test work to be carried out, a broad spectrum was used and the results for a band of frequencies were analysed simultaneously, using F.F.T.'s. This approach is very efficient for a phenomenon of this type, provided adequate attention is paid to the amplitude errors and the coherence between the two wavetrains. In this experiment, the percentage error, which may be written as

$$\frac{100\%}{\sqrt{N_R N_F}}$$

where N_R is the number of runs and N_F is the number of frequencies averaged, was reduced to about 4%.

fig 4: Experimental Arrangement

3.2 WAVE PERFORMANCE

The analysis converts the digital record into an incoming wave spectrum $S_F(f)$, a transmitted wave spectrum $S_A(f)$ and a transmission coefficient $C_T(f)$. These are related by

$$[C_T(f)]^2 = \frac{S_A(f)}{S_F(f)}$$

An example of the computer output is shown in fig. 5 with some extra annotation to explain features.

fig 5: Sample of presentation of experimental data as provided by PDP 11/40 Computer

To compare breakwaters it is necessary to use the frequency averaged transmission coefficient, given by

$$\overline{C_T} = \frac{H_{SA}}{H_{SF}} = \left[\frac{\int_0^\infty S_A(f) df}{\int_0^\infty S_F(f) df} \right]^{1/2}$$

plotted against a breakwater length which has been non-dimensionalised by a wavelength which is representative of the incoming wave spectrum $S_F(f)$.

When $\overline{C_T}$ was plotted against a breakwater length which was non-dimensionalised by a wavelength representative of the wave spectrum, then each of the breakwater 'families' (i.e. those made up of basic modules only, those with one row of deep modules, etc.) produced a discrete curve (McGregor (1978)). For the spectra used in the experiments, the curves for breakwater 'families' using single depth modules only was curved indicating that energy was passing under the breakwater whereas the curves for breakwaters incorporating the deeper modules were straight lines. If wave heights had been larger then these breakwaters would also have given curved lines but as it was, the depth of the breakwater was sufficient to impede the passage of the depth distributed energy. When the plot is made against a non-dimensional breakwater area (fig. 6) then the curves merge and a single straight line is an adequate representation. Although this suggests a law of dependence for scrap tyre breakwaters, such a conclusion would be premature in view of the non parallel trends discernable for individual 'families.'

3.3 MOORING LOADS

The mooring forces were analysed into histograms which were then compared with the Rayleigh probability distribution.

$$p(F) = \frac{2F}{E(F^2)} \exp\left[\frac{-F^2}{E(F^2)}\right]$$

where F is the force per cable and $E(F^2)$ is the expectation of F . For situations where the Rayleigh curve is a reasonable representation of the histogram the cumulative probability distribution

$$P(F > F_1) = \exp\left[\frac{-F_1^2}{E(F^2)}\right]$$

allows a predication of extreme forces to be made.

The closeness of the fit between the cable tensions and the Rayleigh distribution with the same expectation is illustrated in fig. 7. In each of the families the probability curve skews further towards the higher values for longer breakwaters. Close

comparison of data with the Rayleigh distribution indicated that the data is below the Rayleigh distribution in the tail. This discrepancy is sufficiently small to permit Rayleigh probability to be used for high force statistics at least in the first instance.

If the experimental spectrum were to persist on a breakwater for which the expectation was $300N^2$ then a total mooring load of 75N (approximately 5 times the mean) would be expected to occur once per year but the load could well exceed 64N daily. These are quite low loads on what would be one of the largest model breakwaters.

Further examination of the mooring indicates an apparent dependence on wetted surface area. This parameter often has significance in ship hydrodynamics and suggests the dominance of skin friction in producing drag forces. Further, it can be seen that the amount of energy dissipation is increased only at the expense of an increase in mooring loads. It is inevitable that some of the work done on the breakwater is transmitted to the moorings and it also demonstrates the value of internal friction in wave attenuation.

fig 6: Dependence of overall performance coefficient against a non-dimensional side section area (from McGregor 1978)

fig 7: Comparison of Mooring Load Histogram with Rayleigh Distribution

4. APPLICATIONS

4.1 RANGE

Tyre breakwaters can be used for a wide variety of applications namely

- a) inshore boat marinas,
- b) harbour entrances,
- c) creating safe natural anchorages,
- d) extending existing berths, quays or permanent breakwaters,
- e) temporary protection for work areas,
- f) fish farms,
- g) offshore operations, diving, pipelaying, pollution control,
- h) shoreline erosion.

Each of these requires that a breakwater should be adapted to the local situation using available information on fetch lengths, sea depths, prevalence of wind speeds and directions, tidal ranges, and currents and sea bed conditions. The application to fish farms is discussed in McGregor (1977). This paper will discuss design studies* relating to (c), (b) and (g).

4.2 CREATION OF SAFE ANCHORAGE ON ISLE OF GIGHA

The location of Gigha relative to other land masses is shown in fig. 8. The island lacks a natural anchorage which is secure from all directions. A site survey indicated that the anchorage which could most easily be rendered safe was a channel of about 60m width running from 10° to 190° on the south east of the island (fig. 9).

The northern end of the channel is dry at low tide and is sufficiently shallow to dissipate wave energy at high tide even if there were no bend to the east which has the effect of greatly reducing the fetch in the most vulnerable direction. The southern end of the channel is open to an arc around south. The fetch along the channel's axis is interrupted by Gigha Island (1000m away) and so the most vulnerable direction is due south. The distance to the nearest land along a line of sight is about 20 MM (Mull of Kintyre) but if the line is taken a few degrees to the west the fetch would double (Northern Ireland). The entrance to this anchorage is just deep enough but it is necessary to detour round a submerged rock which may be thought of as an extension to Sgeir Liath and also to avoid fouling with weed on the western side.

Since the most severe weather in this area is likely to be associated with westerly winds, the design condition was reduced to producing tolerable conditions in a sea corresponding to a wind speed of 23ms^{-1} (wind force 9). The waves, in this case, would have a significant wave height, H_s , of 2.2m (giving $H_{\text{max}} \sim 4\text{m}$)

**The breakwaters described have not been constructed at the time of writing.*

fig 8: Fetches to Gigha (km)

fig 10: Performances for three possible breakwaters at Gigha

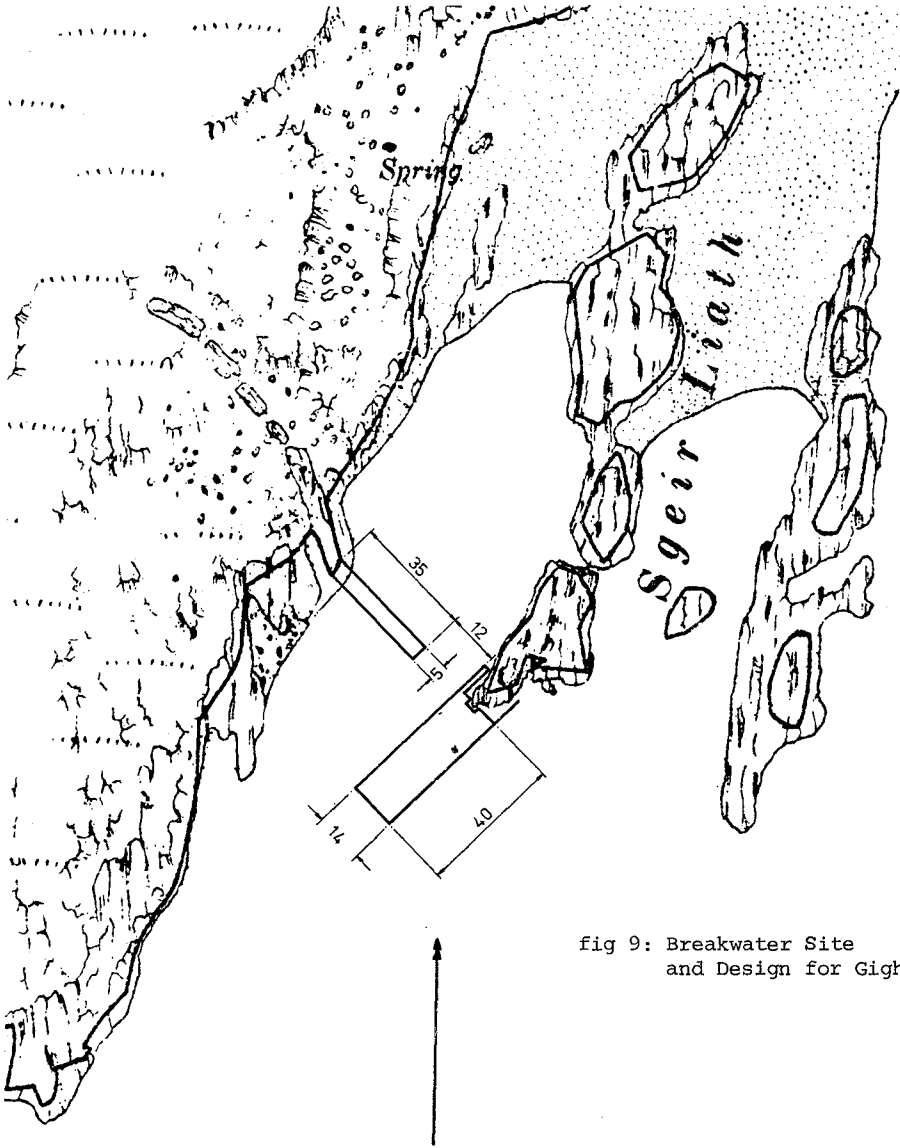

fig 9: Breakwater Site and Design for Gigha

and a significant period, T_s of 5.3s. However, since the channel is shallow and tides are small the wavelengths would be up to about 50m. The energy distribution curve is shown in fig. 10.

The requirement for access limits the breakwater length to about 40m and its width determines its efficiency (see fig. 10). The intermediate breakwater, which consisted of two rows of deep modules and nine rows of basic modules made from car tyres, was predicted to reduce H_s by 50% and would provide adequate protection. This breakwater and a smaller subsidiary one designed to inhibit diffracted and reflected waves are shown in fig. 9.

The maximum mooring load would be below 40 tonnes allowing manageable sizes of anchors to be used.

4.3 IMPROVEMENT OF HARBOUR ENTRANCE CONDITIONS AT WICK

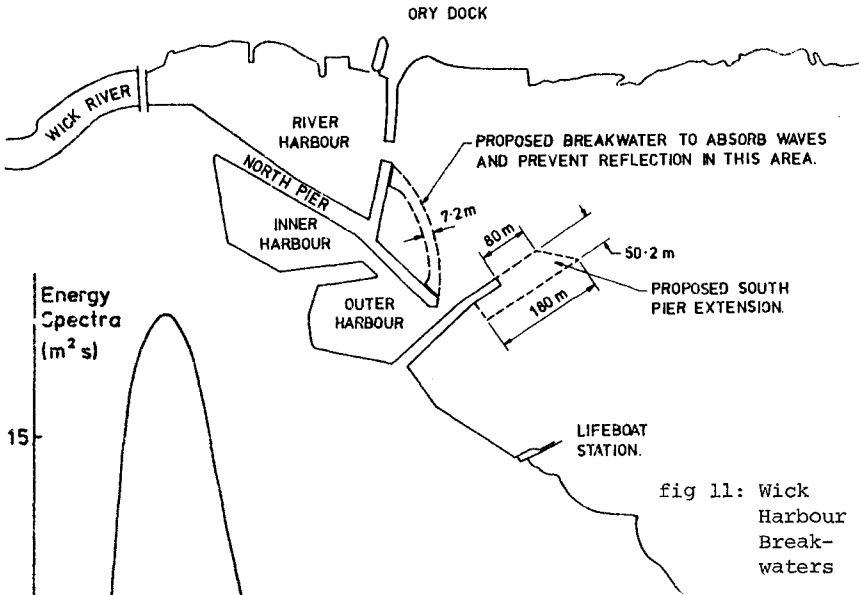

Wick Harbour has been the subject of several studies in recent years because of its location close to the oil fields and potential as a supply base. The 'topography' of the harbour is illustrated in fig. 11. There are two main engineering problems preventing these developments at present, namely

- 1) wave funelling within the bay coupled with reflexions from the river harbour and northern shore make the area close to the end of the south pier difficult to negotiate in easterly storms, and
- 2) sediment is carried into the area adjacent to the outer harbour.

These features inhibit reliability of supply and make harbour maintenance expensive. Solutions which have been proposed using conventional breakwaters, are very costly in an area where the sea is famed for its destruction of the Stevenson breakwater.

The scrap tyre breakwater designed for this situation (and shown in fig. 11) was based on one of the less ambitious proposals for a more normal breakwater. The south pier would be extended by about 80m by the floating breakwater which is also used to "armour" the south pier itself (to decrease overtopping). This breakwater, which would be 52m wide, would reduce H_s from 4m to 1.85m (fig. 12) and because of its relative transparency to the waves reflected from the river harbour it would not aggravate the production of standing wave conditions as a solid breakwater would. The extreme mooring loads would be less than 200 tonnes.

In conjunction with the major breakwater a smaller breakwater between the river and outer harbours would act as a spending beach by reducing the sediment carrying capacity of the waves behind it and stimulating the growth of a beach in this area. This breakwater would also ameliorate the standing wave situation close into the outer harbour entrance.

4.4 ASSISTANCE IN OIL CONTAINMENT

In the case of an oil field close to the shore, as in the Moray Firth, there is an increased danger that any spillage will cause widespread pollution along the coast. This danger may be reduced by an oil boom but these cease to be reliable for $H_s > 1.2\text{m}$ or so. These conditions are exceeded in the Moray Firth for roughly the equivalent of one day a week. This is too high a risk.

The reduction of the risk with a floating breakwater involves a rather different concept to that in either of the previous two examples, since it is now necessary to prevent waves exceeding a specified height from passing out across the perimeter of a large enclosed area.

From directional wind data (Plant 1968) cumulative probabilities of exceedence of wind speeds were drawn and curves of predicted wave heights against wind speed can be superimposed so allowing the probability of wave heights exceeding 1.2m from that direction to be deduced. The modification to this figure by the crescent breakwater required to give protection from this angle can be found by adding in the H_s v U curve when a breakwater is present. Samples of these curves are shown in fig. 13.

The total breakwater is created by taking the maximum of the crescent dimensions at each bearing. Two examples are shown in fig. 14. These reduce the risk of oil crossing the barrier to the equivalent of one day and 18 hours per month respectively. The percentage exceedences can be seen, inside and outside respectively, at the angle of the wave approach.

The total mooring load on such a breakwater would be of the order of 4000 tonnes. For mooring purposes the breakwater would be divided into sections to ensure that the loads were spread and facilitate any maintenance or replacement that may be necessary. A breakwater of this size would also afford a considerable measure of protection to the oil rig in stabilisation from passing ships being off course.

5. CONCLUSION

Scrap tyre floating breakwaters provide a practical, safe and economic option for many wave attenuation problems. There are also occasions when a floating breakwater is the only option.

CHAPTER 133

NON-CONSERVATIVE WAVE INTERACTION WITH FIXED SEMI-IMMERSED RECTANGULAR STRUCTURES

by

Lt. Robert B. Steimer¹
and
Dr. Charles K. Sollitt²

Introduction and Scope

Previous attempts to analytically describe wave reflection and transmission at surface penetrating structures have neglected losses due to flow expansion, contraction, and skin drag along the structure boundaries (Black and Mei, 1970; Ijima, et al., 1972). The model described in this study includes these effects and allows for the inclusion of a dissipative medium such as rubble or closely spaced piles in the region beneath the structure.

The problem of a fixed, two-dimensional structure in a train of monochromatic incident waves is modeled, as shown in Figure 1. The solution allows for 1) variable structure length and draft, 2) different depths in the regions fore, aft, and beneath the structure, 3) variable wave amplitude and period, and 4) turbulent and inertial damping in the region beneath the structure. An equivalent work technique is applied to linearize the damping beneath the structure, yielding a potential flow problem in all three regions. Amplitudes for the resulting series of eigenfunctions in each region are determined by matching pressure and horizontal mass flux at the region interfaces, orthogonalizing these expressions over the depth, and simultaneously solving the resulting equations to yield complex reflection and transmission coefficients. Complex horizontal and vertical force coefficients for the structure are also determined from the integrated Bernoulli equation.

The solution technique is computationally efficient. In general, five modes in the eigen series provide satisfactory convergence for the various hydrodynamic parameters. Approximately six-tenths of a computer system second are required to solve for a single wave-structure condition. The results compare favorably with variational methods used by others.

The effect of skin friction, expansion, and contraction losses tend to reduce both reflection and transmission coefficients by only a few percentage points over a wide range of wave frequencies. The addition

Figure 1. Definition Sketch

of a dissipative medium beneath the structure, however, causes considerable reduction in wave transmission at all wave frequencies while increasing reflection at low frequencies and reducing reflection at high frequencies. Increased inertial damping and decreased porosity in the medium below the structure uniformly decrease transmission and increase reflection.

Comparison with experimental data and other theories is made. New experimental data are presented. Design curves for various structure and wave parameters are presented and discussed.

Theory

Equations of Motion

Newton's Law states that the vector summation of forces acting on a fluid parcel is equal to the resultant vector acceleration of that parcel. The significant forces affecting free surface phenomena may be summarized as

$$\text{acceleration} = (\text{pressure} + \text{gravity} + \text{turbulent friction} + \text{laminar friction} + \text{inertial friction}) \text{ per unit mass}$$

In equation form this statement becomes

$$\frac{dq}{dt} = -\frac{1}{\rho} \nabla(p + \gamma z) - \beta_1 q|q| - \beta_2 q - \beta_3 \frac{\partial q}{\partial t} \quad (1)$$

where q = vector velocity
 ρ = mass density of fluid
 ∇ = gradient operator
 p = pressure
 γ = specific weight of fluid = ρg
 g = acceleration due to gravity
 $\beta_1, \beta_2, \beta_3$ = resistance coefficients

Convective accelerations may be ignored for small amplitude wave motions, thereby reducing the substantial acceleration to the local acceleration or

$$\frac{\partial q}{\partial t} = \frac{dq}{dt}$$

Combining the local acceleration with the inertial damping term in Eq. (1) yields

$$(1+\beta_3) \frac{\partial q}{\partial t} = -\frac{1}{\rho} \nabla(p + \gamma z) - \beta_1 q|q| - \beta_2 q \quad (2)$$

Now let

$$(1+\beta_3) = S \quad (3)$$

where S is an inertial coefficient which includes the effects of local accelerations and additional accelerations caused by local obstructions such as rubble, piles, abrupt corners on the structure, etc.

The laminar and turbulent friction terms are replaced by a single linear friction term which dissipates the same amount of energy over one wave period as the actual friction terms. This simplification permits an analytical solution to the problem without perturbing the equations of motion yet retains a non-linear dependence on wave amplitude. Then

$$-\beta_1 q|q| - \beta_2 q \text{ is replaced by } -f\omega q \quad (4)$$

where f = dimensionless friction coefficient
 ω = wave angular frequency (renders f dimensionless)

An additional condition is required to evaluate f since Eq. (4) is not satisfied by a simple equality. This condition is referred to as Lorentz's Condition of Equivalent Work, and it requires that both friction laws dissipate the same amount of energy over the region of interest during one wave cycle. In equation form this reads

$$f\omega \int_{\text{volume}} dV \int_{\text{period}} dt (q \cdot q) = \beta_1 \int_{\text{volume}} dV \int_{\text{period}} dt (q \cdot q|q|) + \beta_2 \int_{\text{volume}} dV \int_{\text{period}} dt (q \cdot q) \quad (5)$$

Then, on the average, the two friction laws are equivalent. Combining Eqs. (2), (3) and (4) yields

$$S \frac{\partial q}{\partial t} = -\frac{1}{\rho} \nabla(p + \gamma z) - f\omega q \quad (6)$$

A periodic fluid motion is sought for monochromatic waves, hence, the velocity time dependence becomes

$$q(x, z, t) = q(x, z) \exp(-i\omega t)$$

and

$$\frac{\partial q}{\partial t} = -i\omega q \quad (7)$$

Substituting Eq. (7) into Eq. (6) and combining terms

$$\omega(f-iS)q = -\frac{1}{\rho} \nabla(p + \gamma z) \quad (8)$$

The curl of the right hand side of Eq. (8) is identically equal to zero, therefore

$$\nabla \times q = 0$$

and since

$$\nabla \times (\nabla \text{ anything}) = 0$$

it is permissible to replace the vector velocity q with the scalar velocity potential, ϕ , according to

$$q = -\nabla\phi \quad (9)$$

Introducing Eq. (9) into Eq. (8) and combining terms

$$\nabla[-\omega(f-iS)\phi + \frac{1}{\rho}(p + \gamma z)] = 0 \quad (10)$$

The gradient of the bracketed term is equal to zero, therefore the term cannot be a function of spatial location. Requiring that the water surface displacement integrate to zero over one wave length further constrains the bracketed term, establishing that it must equal zero. Therefore, the gradient operator may be removed from Eq. (10), yielding the Bernoulli Equation, which may be solved for the pressure field.

$$\frac{p}{\rho} = -gz + \omega(f-iS)\phi \quad (11)$$

Note that Eq. (11) reduces to the linear wave theory Bernoulli Equation if no damping occurs ($f = 0$, $S = 1.0$).

Water is essentially incompressible in free surface flows. Consequently, conservation of mass reduces to the continuity equation which may be written as

$$\nabla \cdot q = 0 \quad (12)$$

Combining Eqs. (9) and (12) yields Laplace's Equation for irrotational, incompressible flow.

$$\nabla^2 \phi = 0 \quad (13)$$

Equations (11) and (13) are the appropriate equations of motion for the general problem of non-conservative, irrotational, incompressible flow. The velocity field is specified at all times, in all space by Eq. (13). Substitution of the solution to Eq. (13) into Eq. (11) prescribes the pressure field. In order to solve Eq. (11), however, boundary conditions are required to specify the integration constants.

Boundary Conditions

Laplace's Equation is a second order homogenous differential equation requiring two boundary conditions to specify the general solution. A third boundary condition is required to reference the pressure in Bernoulli's Equation. The three boundary conditions are determined by the physical restrictions imposed at the flow field boundaries.

Referring to Figure 1, the bottom boundary condition requires that the vertical velocity component vanish at an impermeable horizontal boundary. Thus

$$w = -\frac{\partial \phi}{\partial z} = 0 \text{ at } z = -h_1, -h_2 \text{ and } -h_3 \quad (14)$$

Similarly, under the bottom of the structure

$$w = -\frac{\partial \phi}{\partial z} = 0 \text{ at } z = -d \quad (15)$$

At the free surface, $z = \eta$, the pressure must be equal to zero. Hence,

$$p = 0 \text{ at } z = \eta \quad (16)$$

Also, the surface must rise and fall at a rate equal to the vertical velocity to maintain continuity at the free surface. Hence

$$\frac{d\eta}{dt} = w = -\frac{\partial \phi}{\partial z} \text{ at } z = \eta \quad (17)$$

Small amplitude wave motions produce negligible convective changes in η and permit an evaluation of w at the still water level to avoid transcendental functions of η . These simplifications reduce Eq. (17) to

$$\frac{\partial \eta}{\partial t} = -\frac{\partial \phi}{\partial z} \text{ at } z = 0 \quad (18)$$

Combining Eqs. (11), (16) and (18) yields the combined kinematic and dynamic free surface boundary condition.

$$\frac{\partial \phi}{\partial z} = -\frac{w}{g} (f - iS)\phi$$

In regions 1 and 3 of Figure 1, $f = 0$ and $S = 1.0$ so that

$$\frac{\partial \phi}{\partial z} = \frac{i\phi}{g} \text{ at } z = 0 \tag{19}$$

Boundary Value Problem

The boundary value problem for each of three regions fore, aft and beneath the structure is summarized in Figure 2. Each boundary value problem is prescribed by Laplace's Equation and the surface and bottom boundary conditions. Flow field boundaries are parallel to the coordinate axes, consequently, variable separation techniques may be used to solve Laplace's Equation. The boundary conditions are applied to evaluate the integration constants. The resulting solutions are presented in detail by Steimer (1977) and are summarized below. The incident wave is described by a single progressive wave in Eq. (20). The reflected and transmitted waves include a single progressive mode each and an infinite series of evanescent modes, as identified in Eqs. (21) and (22). Beneath the breakwater, the solution yields a single wave component corresponding to the progressive mode, Eq. (23), and two infinite series of evanescent modes, one decaying left to right, Eq. (24), and the other decaying right to left, Eq. (25).

$$\phi_i = \frac{ig}{\omega} A_i \exp i[k_{11}(x+b)-\omega t] \frac{\cosh K_{11}(z+h_1)}{\cosh K_{11}h_1} \tag{20}$$

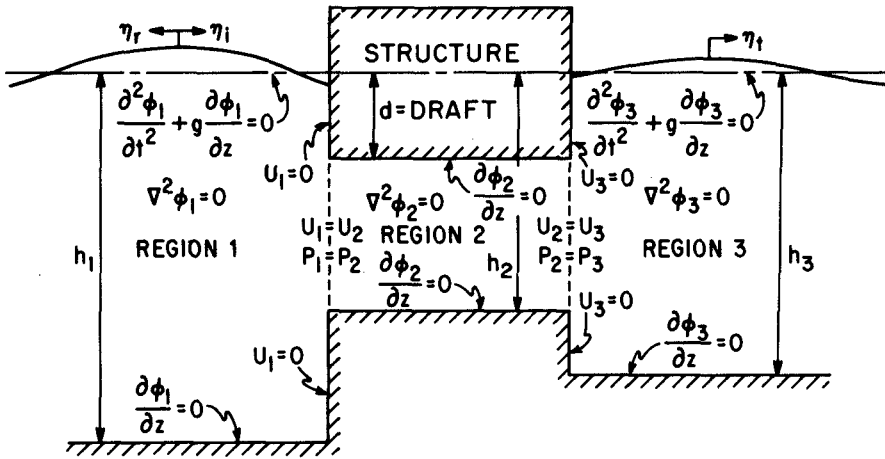

Figure 2. Boundary Value Problem

$$\phi_r = \sum_{N=1}^{\infty} \frac{ig}{\omega} A_{rN} \exp \left(-i[K_{1N}(x+b)+\omega t] \right) \frac{\cosh K_{1N}(z+h_1)}{\cosh K_{1N}h_1} \quad (21)$$

$$\phi_t = \sum_{N=1}^{\infty} \frac{ig}{\omega} A_{tN} \exp \left(i[K_{3N}(x-b)-\omega t] \right) \frac{\cosh K_{3N}(z+h_3)}{\cosh K_{3N}h_3} \quad (22)$$

$$\phi_o = \frac{ig}{\omega} (A_{a1} \frac{x}{b} + A_{b1}) \exp(-i\omega t) \quad (23)$$

$$\phi_a = \sum_{N=2}^{\infty} \frac{ig}{\omega(-1)^{N-1}} A_{aN} \exp[-K_{2N}(x+b)-i\omega t] \cos K_{2N}(z+h_2) \quad (24)$$

$$\phi_b = \sum_{N=2}^{\infty} \frac{ig}{\omega(-1)^{N-1}} A_{bN} \exp[K_{2N}(x-b)-i\omega t] \cos K_{2N}(z+h_2) \quad (25)$$

where: A_{ij} represent wave amplitudes in regions 1 and 3 and pressure head amplitudes in region 2; and K_{ij} represent separation constants or eigenvalue wave numbers in each region. The first subscript identifies the region, while the second subscript identifies the modal number.

The wave numbers are solved from dispersion equations in each region. The dispersion equations result from Eq. (19) in regions 1 and 3 and a combination of Eqs. (14) and (15) in region 2. The appropriate dispersion equation in regions 1 and 3 is

$$\omega^2 = g K_{ij} \tanh (K_{ij} h_i) \quad (26)$$

The K_{i1} wave numbers are the real roots of Eq. (26) and the K_{iN} wave numbers with $N \geq 2$ are the imaginary roots to Eq. (26). The appropriate dispersion equation in region 2 is

$$K_{2N} = \frac{(N-1)\pi}{(h_2-d)} \quad \text{for } N \geq 2 \quad (27)$$

Summarizing, the velocity potential in region 1 is

$$\phi_1 = \phi_i + \phi_r \quad (28)$$

The velocity potential in region 2 is

$$\phi_2 = \phi_o + \phi_a + \phi_b \quad (29)$$

The velocity potential in region 3 is

$$\phi_3 = \phi_t \quad (30)$$

Orthogonalized Interfacial Boundary Conditions

Only the incident wave amplitude in Eq. (20) is known. The remaining amplitudes are unknowns and must satisfy pressure and mass flux

continuity at the interfaces between regions. Pressure continuity requires that the pressure field solutions in each region provide identical results at common boundaries between regions. Thus

$$p_1 = p_2 \quad \text{at } x = -b \quad (31)$$

$$p_2 = p_3 \quad \text{at } x = +b \quad (32)$$

Referring to Eq. (11) and recognizing that $f = 0$, $S = 1.0$ in regions 1 and 3, Eqs. (31) and (32) become

$$\phi_1 = (S + if) \phi_2 \quad \text{at } x = -b \quad (33)$$

$$\phi_3 = (S + if) \phi_2 \quad \text{at } x = +b \quad (34)$$

Mass flux continuity requires that mass be conserved as flow proceeds from one region to another. Recognizing that region 2 may be occupied by a porous medium, the velocities within the pore spaces must increase inversely proportional to the porosity to maintain mass flux continuity at the interface. Thus, if ϵ is the porosity in region 2, the velocities normal to the interfaces will be related according to

$$\frac{\partial \phi_1}{\partial x} = \epsilon \frac{\partial \phi_2}{\partial x} \quad \text{at } x = -b \quad (35)$$

and

$$\frac{\partial \phi_3}{\partial x} = \epsilon \frac{\partial \phi_2}{\partial x} \quad \text{at } x = +b \quad (36)$$

Note that mass flux continuity reduces to velocity continuity if no porous medium exists.

Each interfacial boundary condition includes an infinite series of terms. The terms within the series may be separated to generate $4N$ equations to solve $4N$ unknown amplitudes by utilizing the orthogonal behavior of the z dependent separable functions. The boundary value problems in Figure 2 are all linear, homogenous, second order differential equations with linear, homogenous boundary conditions. Accordingly, they are properly posed Sturm-Liouville problems with orthogonal solutions having the useful property that products of two modal solutions, integrated between boundaries having homogenous boundary conditions, vanish unless the modes are identical (Hildebrand, 1965). Thus

$$\int_0^{-h_1} \phi_{iM} \phi_{iN} = 0 \quad \text{unless } M = N \quad (37)$$

Equation (37) applies equally well to derivatives of ϕ .

This behavior is utilized by multiplying Eqs. (33) and (34) by ϕ_2 and integrating from $z = -h_2$ to $z = -d$. Similarly, Eq. (35) is multiplied by $\frac{\partial \phi_1}{\partial x}$ and integrated from $z = -h_1$ to $z = 0$; and Eq. (36) is multiplied by $\frac{\partial \phi_3}{\partial x}$ and integrated from $z = -h_3$ to $z = 0$.

Note that $\frac{\partial \phi_1}{\partial x}$ and $\frac{\partial \phi_3}{\partial x}$ equal zero above $z = -d$ and below $z = -h_2$.

Evaluating these integrals provides the six equations listed below.

$$\sum_{N=1}^{\infty} C_{rN} \left[\frac{K_{11} \cosh K_{11} h_1}{K_{1N} \cosh K_{1N} h_1} \right] \left[\frac{\sinh K_{1N} (h_1-d) - \sinh K_{1N} (h_1-h_2)}{\sinh K_{11} (h_1-d) - \sinh K_{11} (h_1-h_2)} \right] + (C_{a1} - C_{b1}) \left[\frac{(S+if)(h_2-d) K_{11} \cosh K_{11} h_1}{\sinh K_{11} (h_1-d) - \sinh K_{11} (h_1-h_2)} \right] = -1 \quad (38)$$

$$\sum_{N=1}^{\infty} C_{rN} \left[\frac{\cosh K_{11} h_1}{\cosh K_{1N} h_1} \right] \frac{K_{1N}}{K_{11}} \left[\frac{(-1)^{(M-1)} \sinh K_{1N} (h_1-d) - \sinh K_{1N} (h_1-h_2)}{(-1)^{(M-1)} \sinh K_{11} (h_1-d) - \sinh K_{11} (h_1-h_2)} \right] \left[\frac{K_{11}^2 + K_{2M}^2}{K_{1N}^2 + K_{2M}^2} \right] - [C_{aM} + C_{bM} \exp(-2K_{2M}b)] \left[\frac{(h_2-d)(S+if)(\cosh K_{11} h_1)(K_{11}^2 + K_{2M}^2)}{2K_{11} [\sinh K_{11} (h_1-d) + (-1)^M \sinh K_{11} (h_1-h_2)]} \right] = -1$$

for $M \geq 2$ (39)

$$\sum_{N=1}^{\infty} C_{tN} \left[\frac{K_{11} \cosh K_{11} h_1}{K_{3N} \cosh K_{3N} h_3} \right] \left[\frac{\sinh K_{3N} (h_3-d) - \sinh K_{3N} (h_3-h_2)}{\sinh K_{11} (h_1-d) - \sinh K_{11} (h_1-h_2)} \right] - (C_{a1} + C_{b1}) \left[\frac{(S+if)(h_2-d)(K_{11} \cosh K_{11} h_1)}{\sinh K_{11} (h_1-d) - \sinh K_{11} (h_1-h_2)} \right] = 0 \quad (40)$$

$$\sum_{N=1}^{\infty} C_{tN} \left[\frac{\cosh K_{11} h_1}{\cosh K_{3N} h_3} \right] \frac{K_{3N}}{K_{11}} \left[\frac{(-1)^{(M-1)} \sinh K_{3N} (h_3-d) - \sinh K_{3N} (h_3-h_2)}{(-1)^{(M-1)} \sinh K_{11} (h_1-d) - \sinh K_{11} (h_1-h_2)} \right] \left[\frac{K_{11}^2 + K_{2M}^2}{K_{3N}^2 + K_{2M}^2} \right] - [C_{aM} \exp(-2K_{2M}b) + C_{bM}] \left[\frac{(h_2-d)(S+if)(\cosh K_{11} h_1)(K_{11}^2 + K_{2M}^2)}{2K_{11} (\sinh K_{11} (h_1-d) + (-1)^M \sinh K_{11} (h_1-h_2))} \right] = 0$$

for $M \geq 2$ (41)

$$C_{rM} \left[\frac{\cosh K_{11} h_1}{\cosh K_{1M} h_1} \right] \left[\frac{2K_{1M} h_1 + \sinh 2K_{1M} h_1}{2K_{11} h_1 + \sinh 2K_{11} h_1} \right] + C_{a1} \left[\frac{-4i\epsilon \cosh K_{11} h_1 [\sinh K_{1M} (h_1-d) - \sinh K_{1M} (h_1-h_2)]}{b K_{1M} (2K_{11} h_1 + \sinh 2K_{11} h_1)} \right] + \sum_{N=2}^{\infty} [-C_{aN} + C_{bN} \exp(-2K_{2N}b)] \left[\frac{K_{2N} K_{1M}}{K_{1M}^2 + K_{2N}^2} \right] \left[\frac{-4i\epsilon \cosh K_{11} h_1 [\sinh K_{1M} (h_1-d) + (-1)^N \sinh K_{1M} (h_1-h_2)]}{2K_{11} h_1 + \sinh 2K_{11} h_1} \right] = \delta_{M1} \quad (42)$$

$$\begin{aligned}
& -C_{tM} \left[\frac{\cosh K_{11} h_1}{\cosh K_{3M} h_3} \right] \left[\frac{2K_{3M} h_3 + \sinh 2K_{3M} h_3}{2K_{11} h_1 + \sinh 2K_{11} h_1} \right] \\
& + C_{a1} \left[\frac{-4i\epsilon \cosh K_{11} h_1 [\sinh K_{3M} (h_3-d) - \sinh K_{3M} (h_3-h_2)]}{b K_{3M} (2K_{11} h_1 + \sinh 2K_{11} h_1)} \right] \\
& + \sum_{N=2}^{\infty} [-C_{aN} \exp(-2K_{2N} b) + C_{bN}] \left[\frac{K_{2N} K_{3M}}{K_{3M}^2 + K_{2N}^2} \right] \\
& \left[\frac{-4i\epsilon \cosh K_{11} h_1 [\sinh K_{3M} (h_3-d) + (-1)^N \sinh K_{3M} (h_3-h_2)]}{2K_{11} h_1 + \sinh 2K_{11} h_1} \right] = 0 \quad (43)
\end{aligned}$$

Six equations result, rather than four, because orthogonalizing pressure continuity with respect to the inner modes generates two additional unique equations, one at each interface, for the propagating mode beneath the structure. Each equation is summed on N but is repeated for each M th eigenvalue. Equations (38) and (40) apply to the $M=1$ mode beneath the structure while Eqs. (39) and (41) complete the pressure continuity requirements for $M \geq 2$. Equations (42) and (43) are statements of mass flux continuity, orthogonalized with respect to the outer modes of regions 1 and 3, and apply to all $M \geq 1$. Thus $4M$ equations are produced to solve for $4M$ unknown amplitudes: M reflected waves, M transmitted, and M waves in both the $+x$ and $-x$ directions under the structure.

In Eqs. (38) through (43), the complex amplitudes A_{ij} have been rendered dimensionless by division with the incidental wave amplitude A_i and are denoted as C_{ij} . The Kronecker delta appears as δ_{M1} . The system of $4M$ equations becomes finite by establishing a finite upper limit for the N summation. The amplitude coefficients, C_{ij} , become smaller as j increases and experience with this set of equations, for most practical structural configurations, has demonstrated that summing on five modes is sufficient. Errors due to this finite summation are on the order of a few percent or less. Up to 20 modes have been utilized for unusual configurations such as thin plates.

The $4M$ system of linear algebraic, complex equations is solved via the IBM Scientific Subroutine SIMQ, modified to accept complex coefficients. Amplitudes and phases for each modal amplitude are determined by calculating the modulus and argument, respectively, of each C_{ij} . The reflection and transmission coefficients for the propagating modes are simply $|C_{r1}|$ and $|C_{t1}|$, respectively. Approximately six-tenths of a computer system second are required to solve for a single wave-structure condition described by a five mode series.

Theoretical Behavior

Predicted wave response, quantified as reflection and transmission coefficients, is presented for a hypothetical structure as a function of

dimensionless wave number in Fig. 3-a, b and c. The results show that shorter waves experience more reflection and less transmission at the structure. In addition, as the resistance beneath the structure is increased via an increase in the friction coefficient, f , inertial coefficient, S , or decrease in porosity, ϵ , reflection is increased, attenuation is increased and transmission is decreased. Figure 3-d demonstrates that increased frictional resistance beneath the structure leads to increased energy dissipation. However, an upper limit for energy dissipation is reached at 1/2 the available incident wave energy. Further increases in frictional resistance simply cause 50 percent of the wave energy to be reflected rather than completely absorbed and dissipated beneath the structure.

The results of the present analysis compare favorably with those predicted by other investigators utilizing alternative solution techniques. Sample comparisons are presented in Figs. 4 and 5. Reflection and transmission coefficients results are compared in Fig. 4-a, b, c and d for various structural configurations. The variational technique of Black (1970) in Figs. 4-a, c and d displays essentially identical results to the present theory with negligible resistance ($f=0, S=1.0, \epsilon=1.0$). John's shallow water dock theory (Ippen, 1966) also concurs. The matched asymptotic expansion theory of Tuck (1971) for a narrow slit in a thin, infinitely deep plate also agrees well with the present theory if finite values are used for the depth and plate thickness. Even the long wave behavior is reproduced well, contrasting the variational results in Fig. 4-b.

The horizontal and vertical forces induced by waves acting on the structure are evaluated by integrating the pressure distribution on vertical and horizontal structure surfaces, respectively. The vertical dynamic wave force component is

$$F_{VD} = \int_{-b}^{+b} p dx = \rho\omega(f-iS) \int_{-b}^{+b} \phi_2 dx$$

Substituting for ϕ_2 and evaluating the integral yields

$$F_{VD} = \gamma(S+if) \exp(-i\omega t) \left(2b A_{b1} + \sum_{N=2}^{\infty} \left[\frac{1-\exp(-2K_{2N}b)}{K_{2N}} \right] (A_{aN}+A_{bN}) \right) \tag{44}$$

The horizontal dynamic wave force component is the difference in forces on the two sides of the structure.

$$F_H = \int_0^{-d} p_1 dz - \int_0^{-d} p_3 dz = \int_0^{-d} \rho i \phi_1 (@x=-b) dz + \int_0^{-d} \rho i \phi_3 (@x=b) dz$$

Substituting for ϕ_1 and ϕ_3 and evaluating the integrals yields

Figure 5. Predicted Wave Forces Compared to Other Theories (a) Horizontal Component, (b) Vertical Component

$$\begin{aligned}
 F_H = \gamma \exp(-i\omega t) & \left[\frac{A_1 [\sinh K_{11}(h_1-d) - \sinh K_{11}h_1]}{K_{11} \cosh K_{11}h_1} \right. \\
 & + \sum_{N=1}^{\infty} \frac{A_{rN} [\sinh K_{1N}(h_1-d) - \sinh K_{1N}h_1]}{K_{1N} \cosh K_{1N}h_1} \\
 & \left. - \sum_{N=1}^{\infty} \frac{A_{tN} [\sinh K_{3N}(h_3-d) - \sinh K_{3N}h_3]}{K_{3N} \cosh K_{3N}h_3} \right] \quad (45)
 \end{aligned}$$

Dimensionless force components from Eqs. (44) and (45) have been graphed in Fig. 5-a and b. Results taken from Black (1970) include comparisons with the work of Garrison and Haskind. The comparisons are quite favorable, with only slight differences for very thin plates.

Experimental Results

A small scale experimental program was conducted at Oregon State University to supplement the available data on wave reflection and transmission at rectangular structures. The experiment apparatus is described in Fig. 6-a and the geometric configurations tested are identified in Fig. 6-b. Each model was exposed to a variety of wave amplitudes and frequencies. Incident and reflected waves were resolved with a traversing wave gauge from measurements of the partial standing wave envelope. Transmitted wave measurements were acquired with a stationary wave gauge.

Transmission coefficient results are displayed in Fig. 7. Four combinations of draft, depth and step height are shown with results expressed relative to dimensionless wave numbers. Theoretical results are expressed for frictionless conditions. In general the agreement between experiment and theory is quite good. In Figs. 7-a, b and c, the theory tends to slightly overpredict the transmission coefficient. A non-zero value for the friction coefficient would tend to improve this correlation, indicating that real fluid effects may be modifying the experimental results. Figure 7-d shows the theory underpredicting transmission slightly for long waves. This model configuration has zero draft so that the long wave trough passes under the model without surface contact. The theory does not allow for the separation of the water and model surfaces, a condition which is unlikely to occur in the prototype.

Experimental and theoretical reflection coefficients are presented in Fig. 8-a and b. In general the theory tends to overpredict the measured reflection coefficients. Again, this correlation can be improved by utilizing a non-zero value for the friction coefficient, f , to account for real fluid effects. Small increases in f tend to decrease both the reflection and transmission coefficient as indicated in Figs. 3-a and 8-c. The frictional condition displayed in Fig. 8-c evaluates energy loss due to skin drag over the structure surface and expansion/contraction losses at the abrupt corners of the structure. The corrections indicated improve the correlation with the experimental data, however, larger losses need to be identified to further correct the predicted reflection

coefficients. Evidently the steady flow relationships for skin friction and expansion/contraction losses are not adequate for addressing the same condition instantaneously in unsteady flows. A more complete discussion of friction coefficient evaluation is presented by Steimer (1977).

Design curves for various drafts and step heights have been prepared for the frictionless condition. A sample curve is presented in Fig. 8-d.

Conclusions

The theoretical analyses presented in this study correlates well with other rigorous analytical procedures and with available experimental data. The theory can accommodate a variety of rectangular structural configurations and it provides a rational method for incorporating real fluid losses. The solution technique is numerically efficient in providing reflection, transmission and force coefficients. Additional experimental work is required to validate force predictions and to suggest alternative friction laws to evaluate real fluid effects.

CHAPTER 133

NON-CONSERVATIVE WAVE INTERACTION WITH FIXED SEMI-IMMERSED RECTANGULAR STRUCTURES

by

Lt. Robert B. Steimer¹
and
Dr. Charles K. Sollitt²

Introduction and Scope

Previous attempts to analytically describe wave reflection and transmission at surface penetrating structures have neglected losses due to flow expansion, contraction, and skin drag along the structure boundaries (Black and Mei, 1970; Ijima, et al., 1972). The model described in this study includes these effects and allows for the inclusion of a dissipative medium such as rubble or closely spaced piles in the region beneath the structure.

The problem of a fixed, two-dimensional structure in a train of monochromatic incident waves is modeled, as shown in Figure 1. The solution allows for 1) variable structure length and draft, 2) different depths in the regions fore, aft, and beneath the structure, 3) variable wave amplitude and period, and 4) turbulent and inertial damping in the region beneath the structure. An equivalent work technique is applied to linearize the damping beneath the structure, yielding a potential flow problem in all three regions. Amplitudes for the resulting series of eigenfunctions in each region are determined by matching pressure and horizontal mass flux at the region interfaces, orthogonalizing these expressions over the depth, and simultaneously solving the resulting equations to yield complex reflection and transmission coefficients. Complex horizontal and vertical force coefficients for the structure are also determined from the integrated Bernoulli equation.

The solution technique is computationally efficient. In general, five modes in the eigen series provide satisfactory convergence for the various hydrodynamic parameters. Approximately six-tenths of a computer system second are required to solve for a single wave-structure condition. The results compare favorably with variational methods used by others.

The effect of skin friction, expansion, and contraction losses tend to reduce both reflection and transmission coefficients by only a few percentage points over a wide range of wave frequencies. The addition

Figure 1. Definition Sketch

of a dissipative medium beneath the structure, however, causes considerable reduction in wave transmission at all wave frequencies while increasing reflection at low frequencies and reducing reflection at high frequencies. Increased inertial damping and decreased porosity in the medium below the structure uniformly decrease transmission and increase reflection.

Comparison with experimental data and other theories is made. New experimental data are presented. Design curves for various structure and wave parameters are presented and discussed.

Theory

Equations of Motion

Newton's Law states that the vector summation of forces acting on a fluid parcel is equal to the resultant vector acceleration of that parcel. The significant forces affecting free surface phenomena may be summarized as

$$\text{acceleration} = (\text{pressure} + \text{gravity} + \text{turbulent friction} + \text{laminar friction} + \text{inertial friction}) \text{ per unit mass}$$

In equation form this statement becomes

$$\frac{dq}{dt} = -\frac{1}{\rho} \nabla(p + \gamma z) - \beta_1 q|q| - \beta_2 q - \beta_3 \frac{\partial q}{\partial t} \quad (1)$$

where q = vector velocity
 ρ = mass density of fluid
 ∇ = gradient operator
 p = pressure
 γ = specific weight of fluid = ρg
 g = acceleration due to gravity
 $\beta_1, \beta_2, \beta_3$ = resistance coefficients

Convective accelerations may be ignored for small amplitude wave motions, thereby reducing the substantial acceleration to the local acceleration or

$$\frac{\partial q}{\partial t} = \frac{dq}{dt}$$

Combining the local acceleration with the inertial damping term in Eq. (1) yields

$$(1+\beta_3) \frac{\partial q}{\partial t} = -\frac{1}{\rho} \nabla(p + \gamma z) - \beta_1 q|q| - \beta_2 q \quad (2)$$

Now let

$$(1+\beta_3) = S \quad (3)$$

where S is an inertial coefficient which includes the effects of local accelerations and additional accelerations caused by local obstructions such as rubble, piles, abrupt corners on the structure, etc.

The laminar and turbulent friction terms are replaced by a single linear friction term which dissipates the same amount of energy over one wave period as the actual friction terms. This simplification permits an analytical solution to the problem without perturbing the equations of motion yet retains a non-linear dependence on wave amplitude. Then

$$-\beta_1 q|q| - \beta_2 q \text{ is replaced by } -f\omega q \quad (4)$$

where f = dimensionless friction coefficient
 ω = wave angular frequency (renders f dimensionless)

An additional condition is required to evaluate f since Eq. (4) is not satisfied by a simple equality. This condition is referred to as Lorentz's Condition of Equivalent Work, and it requires that both friction laws dissipate the same amount of energy over the region of interest during one wave cycle. In equation form this reads

$$f\omega \int_{\text{volume}} dV \int_{\text{period}} dt (q \cdot q) = \beta_1 \int_{\text{volume}} dV \int_{\text{period}} dt (q \cdot q|q|) + \beta_2 \int_{\text{volume}} dV \int_{\text{period}} dt (q \cdot q) \quad (5)$$

Then, on the average, the two friction laws are equivalent. Combining Eqs. (2), (3) and (4) yields

$$S \frac{\partial q}{\partial t} = -\frac{1}{\rho} \nabla(p + \gamma z) - f\omega q \quad (6)$$

A periodic fluid motion is sought for monochromatic waves, hence, the velocity time dependence becomes

$$q(x, z, t) = q(x, z) \exp(-i\omega t)$$

and

$$\frac{\partial q}{\partial t} = -i\omega q \quad (7)$$

Substituting Eq. (7) into Eq. (6) and combining terms

$$\omega(f-iS)q = -\frac{1}{\rho} \nabla(p + \gamma z) \quad (8)$$

The curl of the right hand side of Eq. (8) is identically equal to zero, therefore

$$\nabla \times q = 0$$

and since

$$\nabla \times (\nabla \text{ anything}) = 0$$

it is permissible to replace the vector velocity q with the scalar velocity potential, ϕ , according to

$$q = -\nabla\phi \quad (9)$$

Introducing Eq. (9) into Eq. (8) and combining terms

$$\nabla[-\omega(f-iS)\phi + \frac{1}{\rho}(p + \gamma z)] = 0 \quad (10)$$

The gradient of the bracketed term is equal to zero, therefore the term cannot be a function of spatial location. Requiring that the water surface displacement integrate to zero over one wave length further constrains the bracketed term, establishing that it must equal zero. Therefore, the gradient operator may be removed from Eq. (10), yielding the Bernoulli Equation, which may be solved for the pressure field.

$$\frac{p}{\rho} = -gz + \omega(f-iS)\phi \quad (11)$$

Note that Eq. (11) reduces to the linear wave theory Bernoulli Equation if no damping occurs ($f = 0$, $S = 1.0$).

Water is essentially incompressible in free surface flows. Consequently, conservation of mass reduces to the continuity equation which may be written as

$$\nabla \cdot q = 0 \quad (12)$$

Combining Eqs. (9) and (12) yields Laplace's Equation for irrotational, incompressible flow.

$$\nabla^2 \phi = 0 \quad (13)$$

Equations (11) and (13) are the appropriate equations of motion for the general problem of non-conservative, irrotational, incompressible flow. The velocity field is specified at all times, in all space by Eq. (13). Substitution of the solution to Eq. (13) into Eq. (11) prescribes the pressure field. In order to solve Eq. (11), however, boundary conditions are required to specify the integration constants.

Boundary Conditions

Laplace's Equation is a second order homogenous differential equation requiring two boundary conditions to specify the general solution. A third boundary condition is required to reference the pressure in Bernoulli's Equation. The three boundary conditions are determined by the physical restrictions imposed at the flow field boundaries.

Referring to Figure 1, the bottom boundary condition requires that the vertical velocity component vanish at an impermeable horizontal boundary. Thus

$$w = -\frac{\partial \phi}{\partial z} = 0 \text{ at } z = -h_1, -h_2 \text{ and } -h_3 \quad (14)$$

Similarly, under the bottom of the structure

$$w = -\frac{\partial \phi}{\partial z} = 0 \text{ at } z = -d \quad (15)$$

At the free surface, $z = \eta$, the pressure must be equal to zero. Hence,

$$p = 0 \text{ at } z = \eta \quad (16)$$

Also, the surface must rise and fall at a rate equal to the vertical velocity to maintain continuity at the free surface. Hence

$$\frac{d\eta}{dt} = w = -\frac{\partial \phi}{\partial z} \text{ at } z = \eta \quad (17)$$

Small amplitude wave motions produce negligible convective changes in η and permit an evaluation of w at the still water level to avoid transcendental functions of η . These simplifications reduce Eq. (17) to

$$\frac{\partial \eta}{\partial t} = -\frac{\partial \phi}{\partial z} \text{ at } z = 0 \quad (18)$$

Combining Eqs. (11), (16) and (18) yields the combined kinematic and dynamic free surface boundary condition.

$$\frac{\partial \phi}{\partial z} = -\frac{w}{g} (f - iS)\phi$$

In regions 1 and 3 of Figure 1, $f = 0$ and $S = 1.0$ so that

$$\frac{\partial \phi}{\partial z} = \frac{i\phi}{g} \text{ at } z = 0 \tag{19}$$

Boundary Value Problem

The boundary value problem for each of three regions fore, aft and beneath the structure is summarized in Figure 2. Each boundary value problem is prescribed by Laplace's Equation and the surface and bottom boundary conditions. Flow field boundaries are parallel to the coordinate axes, consequently, variable separation techniques may be used to solve Laplace's Equation. The boundary conditions are applied to evaluate the integration constants. The resulting solutions are presented in detail by Steimer (1977) and are summarized below. The incident wave is described by a single progressive wave in Eq. (20). The reflected and transmitted waves include a single progressive mode each and an infinite series of evanescent modes, as identified in Eqs. (21) and (22). Beneath the breakwater, the solution yields a single wave component corresponding to the progressive mode, Eq. (23), and two infinite series of evanescent modes, one decaying left to right, Eq. (24), and the other decaying right to left, Eq. (25).

$$\phi_i = \frac{ig}{\omega} A_i \exp i[k_{11}(x+b)-\omega t] \frac{\cosh K_{11}(z+h_1)}{\cosh K_{11}h_1} \tag{20}$$

Figure 2. Boundary Value Problem

$$\phi_r = \sum_{N=1}^{\infty} \frac{ig}{\omega} A_{rN} \exp \left(-i[K_{1N}(x+b)+\omega t] \right) \frac{\cosh K_{1N}(z+h_1)}{\cosh K_{1N}h_1} \quad (21)$$

$$\phi_t = \sum_{N=1}^{\infty} \frac{ig}{\omega} A_{tN} \exp \left(i[K_{3N}(x-b)-\omega t] \right) \frac{\cosh K_{3N}(z+h_3)}{\cosh K_{3N}h_3} \quad (22)$$

$$\phi_o = \frac{ig}{\omega} (A_{a1} \frac{x}{b} + A_{b1}) \exp(-i\omega t) \quad (23)$$

$$\phi_a = \sum_{N=2}^{\infty} \frac{ig}{\omega(-1)^{N-1}} A_{aN} \exp[-K_{2N}(x+b)-i\omega t] \cos K_{2N}(z+h_2) \quad (24)$$

$$\phi_b = \sum_{N=2}^{\infty} \frac{ig}{\omega(-1)^{N-1}} A_{bN} \exp[K_{2N}(x-b)-i\omega t] \cos K_{2N}(z+h_2) \quad (25)$$

where: A_{ij} represent wave amplitudes in regions 1 and 3 and pressure head amplitudes in region 2; and K_{ij} represent separation constants or eigenvalue wave numbers in each region. The first subscript identifies the region, while the second subscript identifies the modal number.

The wave numbers are solved from dispersion equations in each region. The dispersion equations result from Eq. (19) in regions 1 and 3 and a combination of Eqs. (14) and (15) in region 2. The appropriate dispersion equation in regions 1 and 3 is

$$\omega^2 = g K_{ij} \tanh (K_{ij} h_i) \quad (26)$$

The K_{i1} wave numbers are the real roots of Eq. (26) and the K_{iN} wave numbers with $N \geq 2$ are the imaginary roots to Eq. (26). The appropriate dispersion equation in region 2 is

$$K_{2N} = \frac{(N-1)\pi}{(h_2-d)} \quad \text{for } N \geq 2 \quad (27)$$

Summarizing, the velocity potential in region 1 is

$$\phi_1 = \phi_i + \phi_r \quad (28)$$

The velocity potential in region 2 is

$$\phi_2 = \phi_o + \phi_a + \phi_b \quad (29)$$

The velocity potential in region 3 is

$$\phi_3 = \phi_t \quad (30)$$

Orthogonalized Interfacial Boundary Conditions

Only the incident wave amplitude in Eq. (20) is known. The remaining amplitudes are unknowns and must satisfy pressure and mass flux

continuity at the interfaces between regions. Pressure continuity requires that the pressure field solutions in each region provide identical results at common boundaries between regions. Thus

$$p_1 = p_2 \quad \text{at } x = -b \quad (31)$$

$$p_2 = p_3 \quad \text{at } x = +b \quad (32)$$

Referring to Eq. (11) and recognizing that $f = 0$, $S = 1.0$ in regions 1 and 3, Eqs. (31) and (32) become

$$\phi_1 = (S + if) \phi_2 \quad \text{at } x = -b \quad (33)$$

$$\phi_3 = (S + if) \phi_2 \quad \text{at } x = +b \quad (34)$$

Mass flux continuity requires that mass be conserved as flow proceeds from one region to another. Recognizing that region 2 may be occupied by a porous medium, the velocities within the pore spaces must increase inversely proportional to the porosity to maintain mass flux continuity at the interface. Thus, if ϵ is the porosity in region 2, the velocities normal to the interfaces will be related according to

$$\frac{\partial \phi_1}{\partial x} = \epsilon \frac{\partial \phi_2}{\partial x} \quad \text{at } x = -b \quad (35)$$

and

$$\frac{\partial \phi_3}{\partial x} = \epsilon \frac{\partial \phi_2}{\partial x} \quad \text{at } x = +b \quad (36)$$

Note that mass flux continuity reduces to velocity continuity if no porous medium exists.

Each interfacial boundary condition includes an infinite series of terms. The terms within the series may be separated to generate $4N$ equations to solve $4N$ unknown amplitudes by utilizing the orthogonal behavior of the z dependent separable functions. The boundary value problems in Figure 2 are all linear, homogenous, second order differential equations with linear, homogenous boundary conditions. Accordingly, they are properly posed Sturm-Liouville problems with orthogonal solutions having the useful property that products of two modal solutions, integrated between boundaries having homogenous boundary conditions, vanish unless the modes are identical (Hildebrand, 1965). Thus

$$\int_0^{-h_1} \phi_{iM} \phi_{iN} = 0 \quad \text{unless } M = N \quad (37)$$

Equation (37) applies equally well to derivatives of ϕ .

This behavior is utilized by multiplying Eqs. (33) and (34) by ϕ_2 and integrating from $z = -h_2$ to $z = -d$. Similarly, Eq. (35) is multiplied by $\frac{\partial \phi_1}{\partial x}$ and integrated from $z = -h_1$ to $z = 0$; and Eq. (36) is multiplied by $\frac{\partial \phi_3}{\partial x}$ and integrated from $z = -h_3$ to $z = 0$.

Note that $\frac{\partial \phi_1}{\partial x}$ and $\frac{\partial \phi_3}{\partial x}$ equal zero above $z = -d$ and below $z = -h_2$.

Evaluating these integrals provides the six equations listed below.

$$\sum_{N=1}^{\infty} C_{rN} \left[\frac{K_{11} \cosh K_{11} h_1}{K_{1N} \cosh K_{1N} h_1} \right] \left[\frac{\sinh K_{1N} (h_1-d) - \sinh K_{1N} (h_1-h_2)}{\sinh K_{11} (h_1-d) - \sinh K_{11} (h_1-h_2)} \right] + (C_{a1} - C_{b1}) \left[\frac{(S+if)(h_2-d) K_{11} \cosh K_{11} h_1}{\sinh K_{11} (h_1-d) - \sinh K_{11} (h_1-h_2)} \right] = -1 \quad (38)$$

$$\sum_{N=1}^{\infty} C_{rN} \left[\frac{\cosh K_{11} h_1}{\cosh K_{1N} h_1} \right] \frac{K_{1N}}{K_{11}} \left[\frac{(-1)^{(M-1)} \sinh K_{1N} (h_1-d) - \sinh K_{1N} (h_1-h_2)}{(-1)^{(M-1)} \sinh K_{11} (h_1-d) - \sinh K_{11} (h_1-h_2)} \right] \left[\frac{K_{11}^2 + K_{2M}^2}{K_{1N}^2 + K_{2M}^2} \right] - [C_{aM} + C_{bM} \exp(-2K_{2M}b)] \left[\frac{(h_2-d)(S+if)(\cosh K_{11} h_1)(K_{11}^2 + K_{2M}^2)}{2K_{11} [\sinh K_{11} (h_1-d) + (-1)^M \sinh K_{11} (h_1-h_2)]} \right] = -1$$

for $M \geq 2$ (39)

$$\sum_{N=1}^{\infty} C_{tN} \left[\frac{K_{11} \cosh K_{11} h_1}{K_{3N} \cosh K_{3N} h_3} \right] \left[\frac{\sinh K_{3N} (h_3-d) - \sinh K_{3N} (h_3-h_2)}{\sinh K_{11} (h_1-d) - \sinh K_{11} (h_1-h_2)} \right] - (C_{a1} + C_{b1}) \left[\frac{(S+if)(h_2-d)(K_{11} \cosh K_{11} h_1)}{\sinh K_{11} (h_1-d) - \sinh K_{11} (h_1-h_2)} \right] = 0 \quad (40)$$

$$\sum_{N=1}^{\infty} C_{tN} \left[\frac{\cosh K_{11} h_1}{\cosh K_{3N} h_3} \right] \frac{K_{3N}}{K_{11}} \left[\frac{(-1)^{(M-1)} \sinh K_{3N} (h_3-d) - \sinh K_{3N} (h_3-h_2)}{(-1)^{(M-1)} \sinh K_{11} (h_1-d) - \sinh K_{11} (h_1-h_2)} \right] \left[\frac{K_{11}^2 + K_{2M}^2}{K_{3N}^2 + K_{2M}^2} \right] - [C_{aM} \exp(-2K_{2M}b) + C_{bM}] \left[\frac{(h_2-d)(S+if)(\cosh K_{11} h_1)(K_{11}^2 + K_{2M}^2)}{2K_{11} (\sinh K_{11} (h_1-d) + (-1)^M \sinh K_{11} (h_1-h_2))} \right] = 0$$

for $M \geq 2$ (41)

$$C_{rM} \left[\frac{\cosh K_{11} h_1}{\cosh K_{1M} h_1} \right] \left[\frac{2K_{1M} h_1 + \sinh 2K_{1M} h_1}{2K_{11} h_1 + \sinh 2K_{11} h_1} \right] + C_{a1} \left[\frac{-4i\epsilon \cosh K_{11} h_1 [\sinh K_{1M} (h_1-d) - \sinh K_{1M} (h_1-h_2)]}{b K_{1M} (2K_{11} h_1 + \sinh 2K_{11} h_1)} \right] + \sum_{N=2}^{\infty} [-C_{aN} + C_{bN} \exp(-2K_{2N}b)] \left[\frac{K_{2N} K_{1M}}{K_{1M}^2 + K_{2N}^2} \right] \left[\frac{-4i\epsilon \cosh K_{11} h_1 [\sinh K_{1M} (h_1-d) + (-1)^N \sinh K_{1M} (h_1-h_2)]}{2K_{11} h_1 + \sinh 2K_{11} h_1} \right] = \delta_{M1} \quad (42)$$

$$\begin{aligned}
& -C_{tM} \left[\frac{\cosh K_{11} h_1}{\cosh K_{3M} h_3} \right] \left[\frac{2K_{3M} h_3 + \sinh 2K_{3M} h_3}{2K_{11} h_1 + \sinh 2K_{11} h_1} \right] \\
& + C_{a1} \left[\frac{-4i\epsilon \cosh K_{11} h_1 [\sinh K_{3M} (h_3 - d) - \sinh K_{3M} (h_3 - h_2)]}{b K_{3M} (2K_{11} h_1 + \sinh 2K_{11} h_1)} \right] \\
& + \sum_{N=2}^{\infty} [-C_{aN} \exp(-2K_{2N} b) + C_{bN}] \left[\frac{K_{2N} K_{3M}}{K_{3M}^2 + K_{2N}^2} \right] \\
& \left[\frac{-4i\epsilon \cosh K_{11} h_1 [\sinh K_{3M} (h_3 - d) + (-1)^N \sinh K_{3M} (h_3 - h_2)]}{2K_{11} h_1 + \sinh 2K_{11} h_1} \right] = 0 \quad (43)
\end{aligned}$$

Six equations result, rather than four, because orthogonalizing pressure continuity with respect to the inner modes generates two additional unique equations, one at each interface, for the propagating mode beneath the structure. Each equation is summed on N but is repeated for each M th eigenvalue. Equations (38) and (40) apply to the $M=1$ mode beneath the structure while Eqs. (39) and (41) complete the pressure continuity requirements for $M \geq 2$. Equations (42) and (43) are statements of mass flux continuity, orthogonalized with respect to the outer modes of regions 1 and 3, and apply to all $M \geq 1$. Thus $4M$ equations are produced to solve for $4M$ unknown amplitudes: M reflected waves, M transmitted, and M waves in both the $+x$ and $-x$ directions under the structure.

In Eqs. (38) through (43), the complex amplitudes A_{ij} have been rendered dimensionless by division with the incidental wave amplitude A_i and are denoted as C_{ij} . The Kronecker delta appears as δ_{M1} . The system of $4M$ equations becomes finite by establishing a finite upper limit for the N summation. The amplitude coefficients, C_{ij} , become smaller as j increases and experience with this set of equations, for most practical structural configurations, has demonstrated that summing on five modes is sufficient. Errors due to this finite summation are on the order of a few percent or less. Up to 20 modes have been utilized for unusual configurations such as thin plates.

The $4M$ system of linear algebraic, complex equations is solved via the IBM Scientific Subroutine SIMQ, modified to accept complex coefficients. Amplitudes and phases for each modal amplitude are determined by calculating the modulus and argument, respectively, of each C_{ij} . The reflection and transmission coefficients for the propagating modes are simply $|C_{r1}|$ and $|C_{t1}|$, respectively. Approximately six-tenths of a computer system second are required to solve for a single wave-structure condition described by a five mode series.

Theoretical Behavior

Predicted wave response, quantified as reflection and transmission coefficients, is presented for a hypothetical structure as a function of

dimensionless wave number in Fig. 3-a, b and c. The results show that shorter waves experience more reflection and less transmission at the structure. In addition, as the resistance beneath the structure is increased via an increase in the friction coefficient, f , inertial coefficient, S , or decrease in porosity, ϵ , reflection is increased, attenuation is increased and transmission is decreased. Figure 3-d demonstrates that increased frictional resistance beneath the structure leads to increased energy dissipation. However, an upper limit for energy dissipation is reached at 1/2 the available incident wave energy. Further increases in frictional resistance simply cause 50 percent of the wave energy to be reflected rather than completely absorbed and dissipated beneath the structure.

The results of the present analysis compare favorably with those predicted by other investigators utilizing alternative solution techniques. Sample comparisons are presented in Figs. 4 and 5. Reflection and transmission coefficients results are compared in Fig. 4-a, b, c and d for various structural configurations. The variational technique of Black (1970) in Figs. 4-a, c and d displays essentially identical results to the present theory with negligible resistance ($f=0, S=1.0, \epsilon=1.0$). John's shallow water dock theory (Ippen, 1966) also concurs. The matched asymptotic expansion theory of Tuck (1971) for a narrow slit in a thin, infinitely deep plate also agrees well with the present theory if finite values are used for the depth and plate thickness. Even the long wave behavior is reproduced well, contrasting the variational results in Fig. 4-b.

The horizontal and vertical forces induced by waves acting on the structure are evaluated by integrating the pressure distribution on vertical and horizontal structure surfaces, respectively. The vertical dynamic wave force component is

$$F_{VD} = \int_{-b}^{+b} p dx = \rho\omega(f-iS) \int_{-b}^{+b} \phi_2 dx$$

Substituting for ϕ_2 and evaluating the integral yields

$$F_{VD} = \gamma(S+if) \exp(-i\omega t) \left(2b A_{b1} + \sum_{N=2}^{\infty} \left[\frac{1-\exp(-2K_{2N}b)}{K_{2N}} \right] (A_{aN}+A_{bN}) \right) \tag{44}$$

The horizontal dynamic wave force component is the difference in forces on the two sides of the structure.

$$F_H = \int_0^{-d} p_1 dz - \int_0^{-d} p_3 dz = \int_0^{-d} \rho i \phi_1 (@x=-b) dz + \int_0^{-d} \rho i \phi_3 (@x=b) dz$$

Substituting for ϕ_1 and ϕ_3 and evaluating the integrals yields

Figure 5. Predicted Wave Forces Compared to Other Theories (a) Horizontal Component, (b) Vertical Component

$$\begin{aligned}
 F_H = \gamma \exp(-i\omega t) & \left[\frac{A_1 [\sinh K_{11}(h_1-d) - \sinh K_{11}h_1]}{K_{11} \cosh K_{11}h_1} \right. \\
 & + \sum_{N=1}^{\infty} \frac{A_{rN} [\sinh K_{1N}(h_1-d) - \sinh K_{1N}h_1]}{K_{1N} \cosh K_{1N}h_1} \\
 & \left. - \sum_{N=1}^{\infty} \frac{A_{tN} [\sinh K_{3N}(h_3-d) - \sinh K_{3N}h_3]}{K_{3N} \cosh K_{3N}h_3} \right] \quad (45)
 \end{aligned}$$

Dimensionless force components from Eqs. (44) and (45) have been graphed in Fig. 5-a and b. Results taken from Black (1970) include comparisons with the work of Garrison and Haskind. The comparisons are quite favorable, with only slight differences for very thin plates.

Experimental Results

A small scale experimental program was conducted at Oregon State University to supplement the available data on wave reflection and transmission at rectangular structures. The experiment apparatus is described in Fig. 6-a and the geometric configurations tested are identified in Fig. 6-b. Each model was exposed to a variety of wave amplitudes and frequencies. Incident and reflected waves were resolved with a traversing wave gauge from measurements of the partial standing wave envelope. Transmitted wave measurements were acquired with a stationary wave gauge.

Transmission coefficient results are displayed in Fig. 7. Four combinations of draft, depth and step height are shown with results expressed relative to dimensionless wave numbers. Theoretical results are expressed for frictionless conditions. In general the agreement between experiment and theory is quite good. In Figs. 7-a, b and c, the theory tends to slightly overpredict the transmission coefficient. A non-zero value for the friction coefficient would tend to improve this correlation, indicating that real fluid effects may be modifying the experimental results. Figure 7-d shows the theory underpredicting transmission slightly for long waves. This model configuration has zero draft so that the long wave trough passes under the model without surface contact. The theory does not allow for the separation of the water and model surfaces, a condition which is unlikely to occur in the prototype.

Experimental and theoretical reflection coefficients are presented in Fig. 8-a and b. In general the theory tends to overpredict the measured reflection coefficients. Again, this correlation can be improved by utilizing a non-zero value for the friction coefficient, f , to account for real fluid effects. Small increases in f tend to decrease both the reflection and transmission coefficient as indicated in Figs. 3-a and 8-c. The frictional condition displayed in Fig. 8-c evaluates energy loss due to skin drag over the structure surface and expansion/contraction losses at the abrupt corners of the structure. The corrections indicated improve the correlation with the experimental data, however, larger losses need to be identified to further correct the predicted reflection

coefficients. Evidently the steady flow relationships for skin friction and expansion/contraction losses are not adequate for addressing the same condition instantaneously in unsteady flows. A more complete discussion of friction coefficient evaluation is presented by Steimer (1977).

Design curves for various drafts and step heights have been prepared for the frictionless condition. A sample curve is presented in Fig. 8-d.

Conclusions

The theoretical analyses presented in this study correlates well with other rigorous analytical procedures and with available experimental data. The theory can accommodate a variety of rectangular structural configurations and it provides a rational method for incorporating real fluid losses. The solution technique is numerically efficient in providing reflection, transmission and force coefficients. Additional experimental work is required to validate force predictions and to suggest alternative friction laws to evaluate real fluid effects.

CHAPTER 134

Effects of Wave Grouping on Breakwater Stability

by

R.R. Johnson*, E.P.D. Mansard** and J. Ploeg***

ABSTRACT

It has been found that certain sequences of waves, such as occurring within well defined wave groups, can cause greater damage to rubble mound structures, than equally high individual waves dispersed throughout a wave train. It has therefore been necessary to develop a new wave synthesizing technique, which allows control of the phasing of the wave frequencies, so that a similar degree of wave grouping can be produced in the laboratory as is expected to occur at a particular location in the prototype.

Also, during the course of this investigation, an attempt was made to simulate the strength of concrete armour units to the correct model scale. The breaking of armour units, due to their rocking or being displaced, resulted in a much higher percentage of damage, than would have been possible to predict from tests with commonly used model armour units.

INTRODUCTION

Rubble mound breakwaters undoubtedly belong to the oldest type of coastal structures, and therefore their design procedures have a long history. Simple empirical design criteria were originally based on full scale experiences with these structures. In the more recent past, extensive model testing in hydraulics laboratories throughout the world has modified the criteria considerably, mostly by including more parameters, but still making use of a number of empirical coefficients. This stems mostly from the difficulty of being able to define accurately the physical process of waves breaking on a structure.

Magoon and Baird (1) list some nine parameters affecting the stability of a rubble mound structure, while Bruun

*Assistant Professor, University of Tennessee at Chattanooga, Tennessee, U.S.A.

**Research Associate, Hydraulics Laboratory, National Research Council of Canada, Ottawa, Ontario K1A 0R6 Canada

***Head, Hydraulics Laboratory, National Research Council of Canada, Ottawa, Ontario K1A 0R6 Canada

and Gunbak (2) list a total of twelve parameters, which include most of the nine of the previous authors. Gravesen and Sorensen (3) have attempted to include some of the suggested parameters in their proposed design criteria and have further pointed out the importance of the occurrence of wave grouping, similar to a previous paper by Johnson and Ploeg (4) on this subject. As early as 1966, Carstens et al (5) show damage versus wave height curves for regular and irregular wave trains, with the latter differing in the amount of wave grouping due to different spectral shapes. The curves indicate clearly that the grouped wave train causes greater damage than the non-grouped for the same significant wave heights.

Most of the recently proposed breakwater design formulae are based on laboratory experiments using irregular wave generating equipment. Typically one sees in the literature comparisons between power spectral density functions of naturally occurring sea states and those obtained in wave flumes. Of course the shape of this amplitude spectrum is indeed an essential element in the definition of wave conditions, but if breakwater stability criteria do include a wave period parameter, as well as resonance phenomena as stated by Bruun and Johannesson (6), then the amplitude portion of the power spectral density function alone will not be sufficient to define the sea state. Perhaps somewhat too readily have oceanographers and coastal engineers in the early sixties assumed that a sea state is a continuous random process. Therefore, when a Fourier transform was performed on a recorded wave train, only the amplitude portion of the spectrum was kept and the phase spectrum was ignored as containing no relevant information when dealing with a random process.

It is well known that second order wave forces exerted on floating structures depend heavily on the occurrence of wave grouping. The stability of rubble mound breakwaters appears to be significantly affected by the actual sequence of certain waves in a particular wave train, which tend to occur in wave groups. To test the sensitivity of rubble mound breakwaters to wave grouping, an irregular wave generation technique was developed by Mansard and Funke (7) to allow independent control over the spectrum and the "groupiness" of a wave train, using the information contained in the phase spectrum to control groupiness. With this technique it is then possible to investigate the different modes of failure or stability criteria while maintaining the same energy spectrum, but varying the amount of groupiness. Tests show that different wave trains with similar power spectral density functions and therefore similar RMS values and peak frequencies, and similar wave height statistics, but different wave grouping, do result in rather different stability criteria.

In tests reported previously by Johnson and Ploeg (4), the importance of wave grouping was demonstrated by comparing the effects of a series of artificially constructed wave groups and a non-grouped wave train with the same amplitude spectrum, but randomly assigned phases. These two wave conditions are shown in Fig. 1, and the test results were for a 1:2 slope dolos armoured breakwater, where both wave trains exhibited a significant wave height of 7.6 m, a peak period of 11 s, and a maximum wave height of 11 m. For the non-grouped wave train, some of the dolosse were seen to "rock" in place, but not to the point of being displaced from their locations. However, the sequence of large waves in the artificially grouped wave train (containing no larger wave heights than those encountered in the non-grouped wave train, but consecutively following one another) produced continual displacement of 5 to 7 armour units and severe rocking of most of the armour with each wave group. Since the artificial groups appeared rather unrealistic, the tests

FIG.1 WAVE ENERGY DENSITY SPECTRA
AND GROUPED AND NON-GROUPED WAVE TRAINS

reported in this paper will show a comparison between the effects of a wave train synthesized to have the same degree of groupiness as an actual prototype wave record from a station on the east coast of Canada, and a wave train with the same spectral shape and wave statistics, but randomly assigned phases as commonly used in irregular wave generation.

Of the various types of armour units currently being used for breakwater protection, dolosse seem to be particularly sensitive to certain sequences of waves in a wave train because of the possibility of the units being broken when rocked by wave impact. Visual observations indicate that it appears to be the first wave in a group that loosens the unit, but the second and third waves which produce the damaging motion.

Recently tests have been carried out on a model of the Sines breakwater in Portugal by Ploeg and Mansard (8), where the tensile strength of the concrete in the shank of the dolosse was simulated to the correct model scale, thus allowing a more realistic view of the importance of the breaking of armour units during storm conditions. The tests indicated that for large dolosse, breakage is a key factor in determining a suitable stability criterion and therefore this effect must be taken into consideration when carrying out model tests of rubble mound breakwaters.

FLUME FACILITIES

The wave group effect tests were carried out in a flume described in Fig. 2. A 1:1.5 slope rubble mound breakwater, with dolosse for armour was placed 50 m from the wave board in a 75 m long flume. The 2 m wide flume was divided into a centre channel of 1 m and two side channels each of 0.5 m width. The breakwater was built in the middle channel only. The channel dividers extended from 30 m in front of the breakwater back to the end of a 1:20 slope beach behind the breakwater. The dividers reduced the influence of reflections from the breakwater back to the wave board, and for that reason they were perforated over part of their length. Experiments performed before and after construction of the breakwater showed the arrangement to be quite satisfactory. The hydraulically driven wave machine was computer controlled to generate any specified wave train. Wave height sampling was done with capacitance probes located 2.5 m from the wave board and 3 m in front of the breakwater as shown in Fig. 2. Glass panels in the flume at the location of the breakwater allowed for visual observations and photographic records to be made of the breakwater under wave action. Fig. 3 shows the cross section of the model breakwater, used for these experiments.

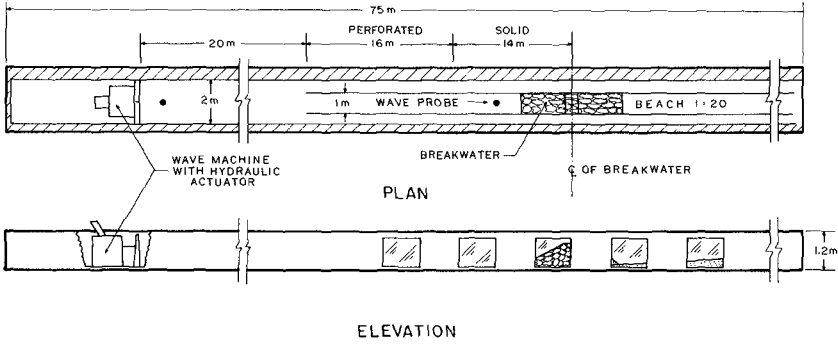

FIG. 2 WAVE FLUME-EXPERIMENTAL SET-UP

FIG. 3 CROSS-SECTION OF THE MODEL BREAKWATER

WAVE GENERATION

An essential part of this study has been the capability to generate at the test section in the wave flume a desired wave train. This has been achieved by means of a phase and amplitude compensated technique described by Mansard and Funke (9). It has also been necessary to use the synthesis technique, referred to earlier (7) which allows control over the phasing of the frequencies and therefore the groupiness of the wave conditions in the flume. The phase spectrum of a wave train has proven to be an important factor and if reproduced can lead to a predetermined amount of wave groupiness in any wave record.

Any periodic time record can be described as a Fourier series with the linear combination of all those cosine and sine functions which have the same period, say as

$$f(t) = a_0/2 + \sum_{n=1}^{\infty} a_n \cos \frac{2\pi n t}{T} + \sum_{n=1}^{\infty} b_n \sin \frac{2\pi n t}{T}$$

where:

$a_0/2$ - mean value

a_n, b_n - Fourier coefficients for the frequency component of the order 'n'

From these Fourier coefficients, the values of the amplitudes A_n , and the phase angles ϕ_n , associated with each frequency component can be derived as follows:

$$A_n = \sqrt{a_n^2 + b_n^2} \quad \text{and} \quad \phi_n = \tan^{-1} \frac{b_n}{a_n} \quad \text{for } n=1,2,3,\dots\infty$$

The variation of these amplitudes over the frequency is referred to as the "Amplitude Spectrum" and that of the phase angles over the frequency as the "Phase Spectrum". Hence any periodic time record can be represented by its Amplitude and Phase spectrum in the frequency domain.

In a laboratory simulation of sea states, very often, importance is attributed to the amplitude spectrum alone, thereby reproducing only the amplitude associated with each frequency component and disregarding the importance of its phase spectrum. One of the main reasons is that the phases appear to be randomly varying within $-\pi$ to π , and are assumed to contain no useful information.

It has been found that the phases can be important and that the use of the amplitude spectrum alone does not give a unique description of the wave record associated with it. A combination of the same amplitude spectrum with different phase spectra can result in entirely different wave trains (grouped or ungrouped). Hence if it is required to reproduce a particular wave record, say as found in the prototype, it is necessary to reproduce the phase spectrum associated with it and it is not sufficient to use randomly selected phases as most of the presently available synthesis techniques do.

In order to illustrate that identical amplitude spectra (Fig. 4a) can lead to different time functions depending on the particular choice of a phase spectrum, the following

two, perhaps somewhat extreme, cases are presented. In the first case, the phase spectrum is defined by means of a random selection via a noise generator with uniform distribution of numbers from $-\pi$ to $+\pi$ and in the second case, the phase is made to vary linearly over a limited range as illustrated in Fig. 4b. The time functions derived from these two identical amplitude spectra, but different phase spectra are, as shown in Fig. 4c, quite different. Further considerations of the relevance of the phase spectra are given in Funke and Mansard (10).

FIG. 4 EFFECT OF THE PHASE SPECTRA ON WAVE TRAINS

A measure of wave groupiness can perhaps be obtained by plotting the "instantaneous wave energy history" (IWEH) of a wave record. This function represents the square of the instantaneous water surface elevations, smoothed by taking a running average over a time interval equal to the period associated with the peak frequency of the energy density spectrum.

There are several steps involved in synthesizing a wave history with the same amount of grouping as observed in a prototype wave record. Sinusoidal waves of a frequency equal to the desired peak spectral frequency are modulated by the prototype IWEH. This modulation will produce a time series similar in grouping to that of the original wave record and may be analysed for the phase spectrum by Fourier analysis. The phase spectrum is then used with the desired amplitude spectrum in an inverse Fourier transform to produce a wave record with the proper wave height statistics

and with the frequencies phased to also give the specified wave grouping. This technique is described in full detail in the earlier referred to report of Funke and Mansard (7).

Three wave generation techniques were applied in the tests reported here. The first followed the technique briefly described above where a wave train was synthesized to have the same degree of wave grouping as a prototype wave record, but with a JONSWAP amplitude spectrum. The result is a well grouped wave history, shown in Fig. 5 with its IWEH, and which realistically simulates a prototype situation. The actual prototype wave record, with the corresponding IWEH is also shown in the same figure. For convenience, this synthesized wave train will be referred to as "grouped".

FIG.5 SYNTHESIS OF WAVE GROUPING FROM A PROTOTYPE WAVE RECORD

The second and more common technique, combined a randomly assigned phase spectrum with the same JONSWAP spectrum in an inverse Fourier transform to obtain a wave history of undetermined wave grouping. In this particular case the result is a wave train with little apparent grouping (Fig. 6), and will for convenience be referred to as "non-grouped". Again the IWEH of this non-grouped wave train has been calculated and is also shown in the figure. Fig. 7 presents a comprehensive comparison of the two wave trains

and their corresponding energy density spectra. It can clearly be seen, that whereas the two amplitude spectra are nearly identical, the wave trains are very different, as far as the degree of wave grouping is concerned. It is important to emphasize that using a randomly assigned phase spectrum can produce wave trains with either more or less grouping than a particular prototype record.

FIG. 6 NON-GROUPED WAVE TRAIN AND ITS INSTANTANEOUS WAVE ENERGY HISTORY

FIG. 7 COMPARISON OF THE GROUPED AND NON-GROUPED WAVE TRAINS

The third technique as presented in the earlier paper by Johnson and Ploeg (4) generated an accentuated and rather artificially grouped wave train, synthesized by an algorithm described by Funke (11) which phases consecutive waves in such a manner that they all focus at a predetermined distance from the wave maker. For convenience, this wave train was referred to as "artificially grouped" and is shown in Fig. 1.

TEST RESULTS AND DISCUSSION

The two examples of the grouped (synthesized to correspond to an observed wave record containing wave grouping) and the non-grouped (generated using a randomly assigned phase spectrum) wave trains, as recorded in deep water conditions, have been shown in Figs. 5, 6 and 7. Both wave trains have a peak period of 11.4 secs and a significant wave height of 6.5 m. To attempt to define the degree of wave groupiness, the RMS value of the instantaneous wave energy history (IWEH) is being proposed. The RMS value of the IWEH of the grouped wave train (Fig. 5) is 0.7 m, while for the non-grouped wave train this value is 0.57 m. The investigation indicates that the breakwater response to the two wave trains is quite different, with the grouped wave train causing severe rocking of the armour and several units to be completely displaced with every wave group (failure mode of 4), but the non-grouped wave train producing only some minor rocking and no displacements (failure mode of 2). A description of modes of failure is given by Baird and Paul (12).

Because the somewhat subjective nature of defining modes of failure, it is difficult to record the results of rubble mound breakwater stability tests precisely, and usable for later reference. The most comprehensive documentation of the results is probably a 16 mm film, made during this study. An edited version of this film was shown at the conference, clearly indicating the differences in the response of the breakwater to the non-grouped and the grouped wave trains.

As mentioned earlier, there does appear to be a mechanism by which the first wave in a group loosens up a unit, the second causes it to be pulled (or pushed) a little out from the armour layer, while the third wave rolls the unit up and down the face of the structure. The non-grouped wave train does not have the same sequence of waves and is therefore not as damaging. It may be possible to relate this partially to the build-up of pressure in the filter layers, and perhaps even the breakwater core, and the resultant stronger down rush.

In Fig. 8 damage factors have been plotted for two types of wave trains, versus the significant wave heights

FIG. 8 DAMAGE CURVES FOR GROUPED AND NON-GROUPED WAVE TRAINS VERSUS SIGNIFICANT WAVE HEIGHTS

for the case of a peak period of 12 s. The dolos weight is 12.2 t (metric) modelled to a scale of 1:34.3 on a slope of 1:1.5 (Fig. 3). For equal damage factors the non-grouped wave train clearly permits a considerably higher design wave condition than the grouped.

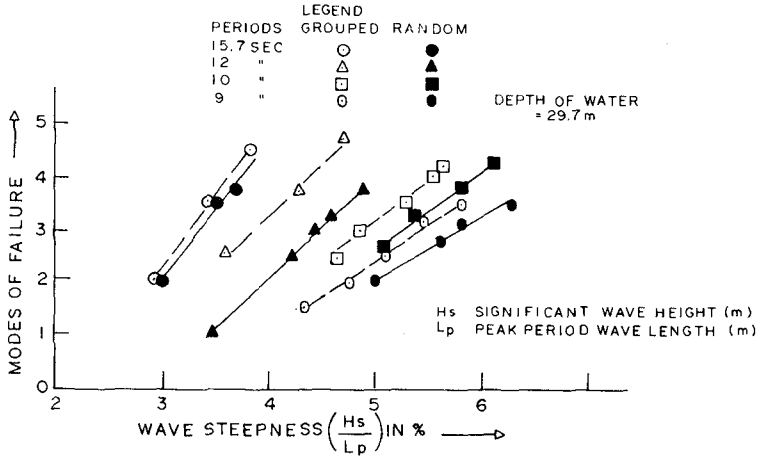

FIG.9 DAMAGE CURVES FOR GROUPED AND NON-GROUPED WAVE TRAINS VERSUS WAVE SLOPES

More extensive tests for different peak periods, dolos weights, water depths and model scales have been carried out and the results are consistently showing a marked difference between the response of grouped and non-grouped wave trains. Fig. 9 is a typical plot of damage factor against wave condition, expressed here as a wave slope parameter in order to include effects related to wave period and water depth. At the time these experiments were performed, however, the method for synthesizing wave grouping was not yet available and the tests were run directly with digitized prototype records, similar to the practice of the Danish Hydraulics Institute (Ref. 13). This means that the peak period variations were achieved by either stretching or compressing the wave history somewhat unrealistically, thus leaving the tests at long and short periods difficult to interpret.

The classification of grouped and non-grouped wave trains is at the present time not clearly defined. It relies mostly on interpretation only. An actual measure of the degree of wave groupiness would ideally come from a

spectral analysis of the IWEH thereby identifying the groups by amplitude, length and frequency of occurrence (and therefore for a given peak frequency, also an indication of the number of waves per group). However, the length of commonly available wave records is usually too short to give an adequate spectral distribution.

With the synthesis technique it is possible to construct wave histories of equal grouping regardless of the width of the power spectral density function, thus showing that spectral width alone cannot be a unique way of determining wave grouping. However, there does seem to be a relationship between the width of the spectrum and the way the amount of groupiness changes with propagation. Further tests are presently under way to consider this aspect.

The tests reported here are all for a dolos armour layer, but the conclusions apply in varying degrees to other types of armour also. The experiments with dolosse did, however, highlight an aspect which applies specifically to this type of unit.

Observing the severe rocking and indeed displacement of dolos units in the model, especially when exposed to the grouped wave trains, leads to the obvious question, how such units will perform when not only the hydraulic parameters are scaled, but also the structural ones. No material has unfortunately been found so far, which has all the correct physical properties to simulate unreinforced concrete (density, elasticity, tensile and compressive strength, friction, etc.) to the correct model scales. Prototype failures of dolos units occur most often through the shank; if it is assumed that this type of failure is mainly caused by exceeding the tensile bending strength of concrete, the model dolos units can be cut and a thin wafer of a material with the correct tensile strength can be inserted. The recent tests on the Sines breakwater (8) were run with a scale of 1:52. To simulate a concrete tensile strength in bending of 35 kg/cm^2 and using the Froude scaling law, a material needed to be used with a tensile strength of about 0.7 kg/cm^2 . A synthetic material, consisting of a mixture of stearic acid and polypropylene, used for artificially modelling the behaviour of ice in the laboratory, has approximately a strength of 0.75 kg/cm^2 . An extensive series of simple and cantilever beam tests was performed to establish the adequacy of inserting a thin wafer of this synthetic material within a much stronger material, to simulate the desired tensile bending strength correctly. Using this simulation technique with the dolos units, the Sines breakwater tests led to an extremely good comparison between prototype and model performance. The results of similar tests, but with commonly used model units, i.e. without scaling any of the strength parameters, were much more difficult to interpret. The actual breaking of the model units

caused immediately the breakage of many other dolosse and a very rapid, general deterioration of the structure. It became quite apparent, that the accepted philosophy of allowing a certain percentage of damage to a rubble mound breakwater as a design condition, can not be relied on when large artificial armour units are used. A 16 mm film of the behaviour of the two types of model units illustrates the differences very clearly. A photograph of the final profile (Fig. 10) shows in the foreground, the completely failed section where dolos units were used which simulated the tensile strength of concrete, but the apparently less damaged section in the background, where the commonly used units were placed.

FIG.10 PHOTOGRAPH OF DAMAGE TO MODEL BREAKWATER
USING MODIFIED DOLOS UNITS

CONCLUSIONS

Firstly, wave grouping has been shown to be an essential parameter in the correct model testing of rubble mound breakwater stability. Since both wave trains considered here had similar spectra and wave statistics, it is evident that one must define the degree of wave grouping as actually observed in nature or as may be expected to occur at a particular location. The typical wave parameters used so far, including a spectral width parameter, are not deemed to give sufficiently accurate description of a particular sea state to allow adequate reproduction in a laboratory wave flume. It is expected that a "groupiness" factor will have to be multi-dimensional, not only taking account of the presence of such groups, but also of the periodicity of their occurrence and their widths.

Secondly, without correctly scaling the strength of concrete of the armour units in model tests of rubble mound breakwaters, it is extremely difficult to determine accurately the percentage of damage. It is not possible to interpret correctly the motions of the armour units, without being able to establish when they will break. As soon as breakage begins to occur, the response of the structure changes drastically, leading very quickly to failure conditions.

LOADINGS ON RUBBLE-MOUND BREAKWATERS DUE TO EARTHQUAKES

by

H. Wang¹, C. Y. Yang², C. Lamison³ and S. S. Chen⁴Introduction

It might reasonably be asked, why study the reaction of a rubble-mound breakwater to earthquake loadings? After all, it is essentially a pile of rubble before an earthquake and is probably only a lower or otherwise deformed pile of rubble afterwards. Repairs are simply a matter of adding more stones. Even if damage occurred, the breakwater might still offer partial protection. This is precisely why, to date, breakwaters are mainly designed for wave loadings. There is practically no documented literature⁽¹⁾ concerning breakwater design for earthquake loading!

However, the oceans are now being tapped as possible locations for industrial installations such as offshore deep water ports, refineries, and power plants. Such facilities must be adequately protected since failures might result in heavy financial losses and cause severe environmental repercussions. Therefore, breakwaters which might be used for this protection can no longer be treated as structures whose failure would only be of secondary consequence. It is thus reasonable to ask whether breakwaters to serve these purposes should also be designed against earthquake loading, since even partial failures might not be acceptable. If they should, then what type of design problems can one expect to encounter and how should one handle them? The present work is aimed at exploring these problems through laboratory experiments.

At present, there is no existing breakwater⁽¹⁾ that has been designed on the basis of earthquake loading. Likewise, observations of breakwaters after continuous earthquakes are also scarce. Okamoto⁽²⁾ reports crumbling of riprap, uneven settlement and loosening or tilting of the upper parts of Japanese breakwaters that have undergone earthquakes. After the large Kanto earthquake of 1927, for instance, breakwaters at the ports of Yokosuka and Yokohama approximately 50 kilometers from the epicenter developed irregularities over their entire lengths. In no cases, however, did any of the breakwaters topple or overturn. During the great Alaska earthquake of 1964, breakwaters at Kodiak City and Seldovia, Kenai Peninsula were badly damaged. The damage to the Kodiak City breakwaters was well documented⁽³⁾ with photographs and surveys taken after the earthquake. The damage was attributed to both earthquake motion and the tsunamis which swept the area. Unfortunately, the

proportion of damage due to each cause could not be determined.

The present work represents an initial attempt to model the breakwater under earthquake loading, to identify failure modes, to determine the trends and degrees of relative importance of various factors and to estimate pressure distributions on the surface. It is an acknowledged fact that the armor layers are the main protection for a breakwater and the current practice in breakwater design is almost exclusively concentrated in the design of armor layer stability against wave force. One of the primary interests of the present tests is, thus, to examine the stability of these armor units against earthquake loading. The dolos was selected for the test program because it is gaining popularity in breakwater construction due to its superior stability against wave attack⁽⁴⁾.

Scaling Laws and Model Design

Breakwater Simulation. It is a well-known fact that proper modeling requires preservation of both geometrical and dynamical similarities. Since a rubble-mound breakwater is not monolithic, but an ensemble of discrete elements, the geometrical similitude requires that both the structural shape and individual elements maintain the same scale ratio.

The model scale is dictated by the model dolosse available for testing, which have dimensions shown in Figure 1. They weigh 210 g. each with specific weight equal to 2.34 g/cm^3 . The overall structure is modeled in accordance with a typical "three-layer breakwater in breaking wave environments" as recommended in the Shore Protection Manual⁽⁵⁾. The cross section of the model is shown in Figure 2. The crushed stones available for sublayer and core constructions have an average specific weight of 1.39 g/cm^3 as measured in air, while in actual breakwaters, heavier stones of approximate unit weight 1.68 g/cm^3 , are usually used. Table 1 provides the weight composition of crushed stones for the sublayer and the core in the model.

Figure 1. Dimensions of Armor Unit Used in the Experiment.

Figure 2. Model Breakwater Cross-Section.

The dynamic effect of an earthquake is mainly an inertia one. The similarity is preserved by the following criterion:

$$\left(\frac{U}{\sqrt{L(1 + C_a \Omega) a_e}} \right)_m = \left(\frac{U}{\sqrt{L(1 + C_a \Omega) a_e}} \right)_p \quad (1)$$

where U = characteristic velocity; L = characteristic length; C_a = added mass coefficient; Ω = density ratio of the fluid to that of the breakwater material and a_e = earthquake acceleration. The subscripts m and p refer to model and prototype, respectively.

If the model and the prototype are geometrically similar and have the same Ω ratio as the present case, the above equation reduces to a modified Froude number provided

$$\left(a_e \right)_m = \left(a_e \right)_p \quad (2)$$

To preserve the similarity of the body force, the Froude criterion should be observed, that is:

$$\left(\frac{U}{\sqrt{gL}} \right)_m = \left(\frac{U}{\sqrt{gL}} \right)_p \quad (3)$$

where g = acceleration of gravity. It is evident that this criterion is automatically satisfied if (1) and (2) are satisfied.

In order to simulate the frictional force of the system, one should first examine the contributing factors. The breakwater is now being looked upon as constructed of solid-fluid structural elements. The frictional force arises from both solid-to-solid contact and fluid-to-solid contact. These two types of frictional forces play opposite roles in breakwater stability. The frictional force due to the relative motion of fluid to solid is an upsetting force, whereas the force due to friction among solids offers the resistance. To model the former force properly, one requires the Reynolds criterion to be preserved:

$$\left(\frac{\rho UL}{\mu} \right)_m = \left(\frac{\rho UL}{\mu} \right)_p \quad (4)$$

where ρ = the density of the fluids and μ = the dynamic viscosity of the fluids.

This criterion is not compatible with the modeling conditions stated above. However, for a structure as bulky as a breakwater, appreciable error will not be introduced by not exactly modeling this force.

The frictional force developed among solid elements, if properly modeled, should follow the criterion below:

$$\left(\frac{ma}{\mu_s W} \right)_m = \left(\frac{ma}{\mu_s W} \right)_p \quad (5)$$

where μ_s = frictional coefficient between solids; m = element mass; and w = element weight. Based on Equation (1), this criterion reduces to

$$(\mu_s)_m = (\mu_s)_p \quad (6)$$

This means that the coefficients of friction in both model and prototype should be the same. The simplest and probably most accurate choice is to build the model with the same materials that one expects to be used in the prototype. In the armor layer, the interlocking behavior may play a dominant role in resisting deformation. Since interlocking among armor units is mainly a function of geometrical shape, there remains little choice but to preserve the shape of the armor units.

As to the elastic restoring force when the structure is subjected to earthquake loading, the apparent shear modulus of elasticity is probably the most pertinent parameter that should be properly modeled. To properly preserve this elastic behavior, the model has to be built with materials of considerably smaller modulus of elasticity than that of the prototype (of the order of the length ratio). Such materials, which at the same time have to satisfy the other modeling criteria as outlined above, are difficult, if not impossible, to find.

In general, the apparent modulus of elasticity affects the amount of energy that can be absorbed before failure. It also affects the natural period of the structure which in turn dictates the frequency at which failure is most likely to occur under vibrating loading. Since a breakwater, being a porous structure of no less than 30% porosity and constructed of discrete particles interacting through friction and interlocking, is a highly damped system the aspect of not being able to match the natural period between model and prototype is not a critical one. In the model the corresponding scaled shear modulus is considerably higher than required. This higher than required model shear modulus was deemed conservative from the point of view of energy absorption.

Earthquake Scaling and Selection. An earthquake can be considered as a vibratory ground motion with components in three orthogonal directions and the random characteristics of "white" noise. Only the horizontal motion was modeled. The principal direction of motion was chosen to be perpendicular to the face of the breakwater. A one-pulse earthquake was selected which corresponds to a prototype frequency of 1.61 Hz with varying amplitude from 0.2 g to greater than 1 g. The frequency was so selected as to provide a time history of motion that envelopes a typical earthquake spectrum similar to that of the El Centro earthquake as given by Newmark and Rosenblueth⁽⁶⁾.

Experiments

Setup. Testing of the model breakwater was done in a tank measuring 1.5 m (depth) by 2.3 m (width) by 37 m (length). A shake table was situated in the center of the tank at an elevation which both minimized the eccentricity of the applied load and allowed a wide range of water levels to be tested. The shake table was designed to support models up to one

ton and to impart horizontal acceleration motions up to 1.6 g. It was actuated by a 20 kip Gilmore hydraulic actuator with a Moog 72-102, 40 gallon per minute Servo valve, controlled by a Gilmore, Model 431B Servo Controller and a Model 112 Wavetek. A variety of wave forms can be generated with capability of all frequencies ranging from 1 to 100 Hz and double amplitudes of from 0.25 to 25 cm. The electronic hookup is shown schematically in Figure 3.

Stability Tests. A total of eight complete breakwaters was built and tested along with one case consisting of the breakwater core only. In general, each breakwater underwent at least four successive shakes. It was intended that each pulse be larger than the one preceding it and this was most often the case. Table 2 summarizes the cases tested.

TABLE 2. SUMMARY OF CASES TESTED

505 Dolosse	VII	0**
505 Dolosse	VIII	1/3

*No Armor or Dolosse

**No Water

In each test case, the dolosse were placed randomly to an even calculated density as in a real breakwater. An exception was made at the toe of each face where the dolosse were placed in a regular fashion for maximum stability against the flat bottom. Detailed test procedures for this part can be found in Ref. (7).

Pressure Distribution Tests. The experiments in this test were divided into two groups. In the first group, a model breakwater with a vertical front face was tested to measure the pressure change on the front face at different elevations. In the second group, a model with a 30° inclined front face was tested. The model with the inclined faces was basically the same as the stability tests with slight front face angle adjustment.

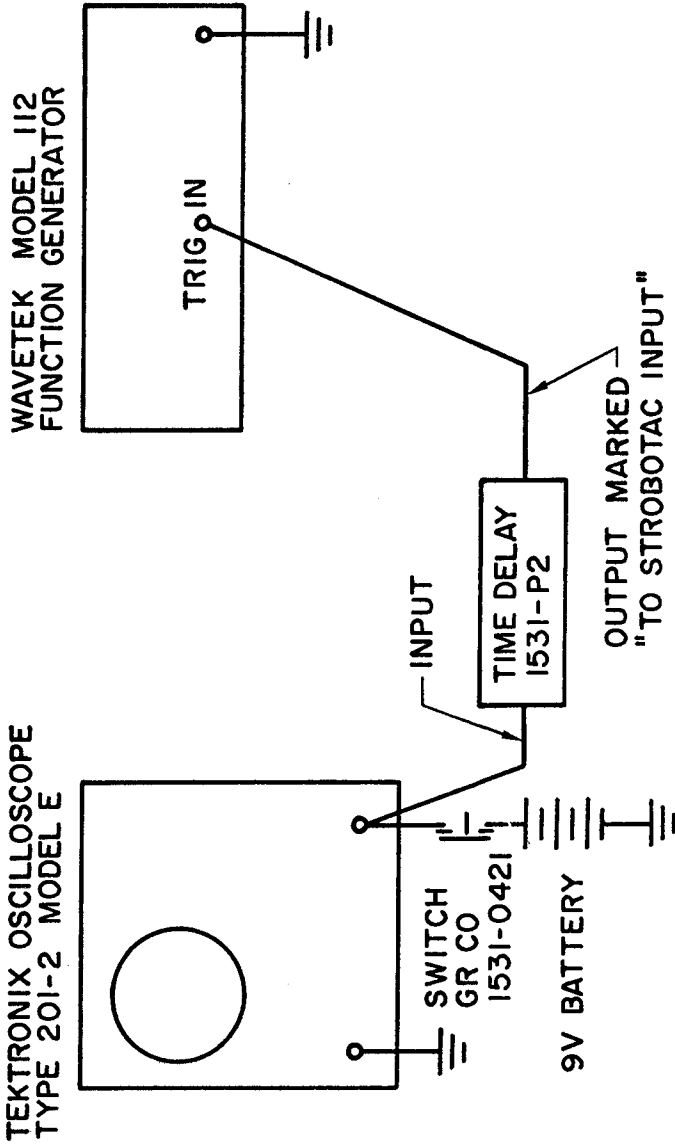

FIGURE 3. Electronic Hookups

For both models, pressure change on the surface of the breakwater at four different elevations were measured by Statham Model P131 and Viatran Model 103 pressure transducers. The water level in all tests was kept at 45 cm. The detailed test program is documented in Ref. (8).

Test Results

Stability. Post test surveys clearly indicated that the dominant mode of damage was settlement. None of the breakwaters tested showed any indications of a catastrophic sliding type failure. It was also apparent that the breakwater crest as opposed to the sides, was most sensitive to the shaking. The crest rounded and settled in much the same way as that of a rock-fill dam under similar conditions⁽⁹⁾. The observed effect of adding more dolosse (Cases VII and VIII) was an increased tendency for some to roll down the face of the breakwater. Possible cracking might have occurred at the crest during a test but none were observed afterwards. Bulging was also noted on the lower and middle parts of some breakwaters. Figure 4 illustrates the breakwater profile changes due to successive shaking.

As one would expect, the steeper slopes were slightly more sensitive to earthquake loading than the milder slopes. In the case tested, more dolos movement was observed on the rear slope (1.25:1) than the front slope (1.5:1) which resulted in, generally, greater outward displacement of the rear toe than the front toe (Figure 4). However, the dolos mat remained intact on both faces under all conditions. Some densification of the dolos layer occurred on the sloping parts of the breakwater at the expense of thinning the crest (less dolosse per unit area than originally).

The thinning in the dolos armor layer would develop into a rift as testing proceeded. On either side of the rift a single sparse layer of dolosse would remain, but this rapidly densified on the breakwater faces. In some cases, the crest became slanted toward the rear. While the crest sometimes remained level it never slanted appreciably towards the front or milder slope.

After examining the physical damages of the breakwater, it became clear that the change in crest elevation is the primary damage indicator. This change in elevation, expressed in terms of the percentage of height prior to the shake, has been plotted in Figure 5 as a function of horizontal acceleration.

As expected, the settlement increases with the acceleration as a trend, but a wide data scattering exists. This wide data scattering is at least partially attributed to the accuracy of the measurement which is about 1% of the total height. If an envelope is drawn around the points on this graph, the intersection of the acceleration lower bound and the zero damage line occurs around 0.4 g. This would indicate that a breakwater of the rubble-mound type is highly resistant to earthquake damage. Clough and Pirtz⁽⁹⁾ reached similar conclusions for rock-fill dams as they found no significant changes in profile until earthquakes produced accelerations of about .4 g. They attribute the relatively high degree of resistance to the flexibility resulting from the discrete nature of a rock-fill dam. Under cyclic loading at

Figure 4. Breakwater Profile Changes Due to Earthquake

○ BREAKWATER DRY
 △ BREAKWATER 1/3 SUBMERGED
 ◇ BREAKWATER 1/2-2/3 SUBMERGED

FIGURE 5. Crest Elevation Change Versus Earthquake Acceleration

earthquake frequencies, the dam would tend to commence shearing in one direction only to find the force reversed and the next shearing displacement cancelling the first. Permanent deformation was mainly produced by shake down; a secondary effect. Further indications of this strength can also be seen in that, for all the earthquakes under about 1.5 g, the settlement is of the order that might be expected from normal shake down over a long period of time. Since settlement is the major mode of damage, one should expect that presettlement prior to the earthquake should also play an important role in addition to the earthquake magnitude. In other words,

$$\text{Settlement} = f(\text{presettlement, acceleration})$$

In the experiments, the best indicator of presettlement is probably the cumulative crest settlement prior to any specific test (defined as the total settlement sustained due to previous shakes, measured from a freshly-built model, prior to the specific test run). If this factor is taken into consideration, the data in Figure 5 can be replotted as shown in Figure 6. It is evident from this plot that a new breakwater is more susceptible to damage than an older one. The presettlement becomes less important for larger ground accelerations. In other words, for a large earthquake, the breakwater will settle the same amount irrespective of the degree of presettlement. This is because, for moderate shocks, the settlement is mainly due to internal densification which is certainly closely related to the initial density, whereas for strong shocks, the crest settlement is caused by change of structural shape and modification of side slopes as were observed during tests. For new breakwaters with little or no initial shake down, Line A-A provides a conservative design criterion; for cases of older breakwaters with more than 4% presettlement, Line B-B is a more reasonable criterion.

The small effect of water level on breakwater response was unexpected. An increased water level would reduce the intergranular effective stresses, here directly proportional to the frictional resistance of the breakwater to deformation. Thus, increased displacement might be expected at high water levels. While the very high water levels did display a tendency in this direction they were interspersed with data from all the lower water levels as well. The tests showing the least settlement for the applied loads were about equally divided between the 0 and 1/3 submerged breakwaters.

It is possible that the reduction in frictional resistance is too small to be apparent. It is also possible that the very nature of the settlement may be fairly independent of the intergranular friction as compared with the resistance due to the armor unit interlocking, which is clearly independent of submergence.

Pressure Distributions

(a) Theoretical Considerations. Westergaard⁽¹⁰⁾ was the first one who in 1933 solved the two-dimensional case of horizontal vibrations of a rigid dam with vertical upstream face placed at one end of an infinitely long reservoir of uniform depth. In the same year, Von Kármán⁽¹¹⁾ developed an approximate but very simple method for the same case. Wang et al.⁽¹²⁾ extended the Von Kármán theory to an inclined surface. The essential results of the latter are summarized here.

A-A DESIGN CURVE
B-B DESIGN CURVE

Figure 6. Effect of Presettlement on Breakwater Damage Due To Earthquakes.

Consider a unit slice of a breakwater with an inclined front face as shown in Figure 7. The following sets of equations can be established:

Continuity Equation

$$y a_x = b a_y \quad (7)$$

Equations of Motion in the x- and y-Directions

$$p = \rho b a_{xf} \quad (8)$$

$$p \cot \theta - p \frac{db}{dy} - b \frac{dp}{dy} = \rho b a_y \quad (9)$$

with the symbols as identified in Figure 8, and the subscript f refers to fluid.

The required boundary conditions are, at the water surface:

$$p = 0 \text{ at } y = h \quad (10)$$

and at the inclined front surface:

$$a_{xf} = a_x \sin^2 \theta \text{ for ideal fluid} \quad (11)$$

or

$$a_{xf} = a_x - a_y \cot \theta \text{ for non-slip boundary} \quad (12)$$

The close form solution for the ideal fluid case is

$$\ln \frac{k}{b} = \frac{1}{2} \ln \left| 2 \left(\frac{y}{b} \right)^2 - \frac{y}{b} \sin 2\theta + \sin^2 \theta \right| - \frac{\cos \theta}{\sqrt{8 - \cos^2 \theta}} \tan^{-1} \frac{4 \left(\frac{y}{b} \right) - \sin 2\theta}{2 \sin \theta \sqrt{8 - \cos^2 \theta}} \quad (13)$$

where k, the integration constant, is:

$$k = \sqrt{2} h \exp \left(- \frac{\pi \cos \theta}{2 \sqrt{8 - \cos^2 \theta}} \right) \quad (14)$$

Once the value of b is determined the pressure can be obtained from Equation (8).

(b) Comparison of Experiment With Theory. In Figure 9, the experimental results of the vertical wall case were compared with the extended Von Kármán theory and the experimental results of Zangar⁽¹³⁾.

Figure 7. A Breakwater With An Inclined Front Face.

Figure 8. Equilibrium of Forces on a Fluid Element.

FIGURE 9. Comparison of Pressure Coefficients at Different Elevations on the Breakwater with a Vertical Front Face

The pressure coefficient, C_p , which appeared in the abscissa, is defined as

$$C_p = \frac{P}{\alpha \gamma h} \quad (15)$$

where γ is the specific weight of water and α is the ratio of horizontal earthquake acceleration to the gravitational acceleration, i.e.

$\alpha = \frac{a_x}{g}$. The experimental results for the inclined-surface case were shown in Figure 10, together with that of Sangar's and the theoretical curve.

It can be seen that for the vertical wall case, the comparisons were reasonably good with the exception that the pressure obtained in the experiment was non-zero at the free surface. This was caused by the surface waves induced by the breakwater motion. This effect was neglected in the theory. The surface-wave induced pressure became larger as the horizontal acceleration increased.

For the breakwater with a 30° inclined surface, the three curves were separated apart with the actually measured pressure significantly larger than that predicted by theory. The effect of surface wave, on the other hand, was not as pronounced as the vertical wall case.

Conclusions

Based on experimental evidence, rubble-mound breakwaters on a rigid foundation are found to be highly earthquake resistant. Extrapolating an envelope on the test result predicts that earthquakes of less than $1/2$ g would not affect a breakwater to any significant extent. Possible failure due to foundation is not included in the consideration.

The fundamental damage mode is clearly the settlement of the crest, coupled with slight slope deformation. Slope steepness has much the influence that might be expected; the crest settled more on the side adjoining the steeper slope, and the horizontal displacement at the toe was also larger on the steeper side. The armor layers, two layers of dolosse in this case, remained largely intact. No hole greater than three clustered units (a commonly-used measure to indicate the extent of core exposure) was observed for all the tests performed, which includes tests with a horizontal acceleration as high as 2.8 g. Under severe or repeated shocks, the dolosse mat tended to settle as a whole down the face of each side, causing thinning or rifting at the breakwater crest. Since settlement is the major mode of damage, presettlement becomes an important factor, which strengthens the resistance against earthquake loading.

Water level does not appear to be an important factor affecting the damage. One may tentatively conclude that the interlocking behavior of armor units plays an important role in earthquake resistance in addition to the internal friction of core material.

The approximate solution of Von Kármán agrees with experiments for the breakwater with a vertical face. For the breakwater having a face

FIGURE 10. Comparison of Pressure Coefficients at Different Elevations on the Breakwater with a 30° Inclined Face

of large inclined angle, an approximate solution from the extended Von Kármán's theory deviates considerably from the experimental result. The maximum pressure is found to be at some distance above the bottom of the breakwater with 30° inclined face but at the base of the breakwater with a vertical face. The magnitude of maximum pressure as induced by earthquakes is not excessive as would result in structural damage. The total force, however, might contribute to the general instability.

In conclusion, rubble-mound breakwaters alone (without foundation consideration) are earthquake resistant in the structural sense. However, this conclusion should not be interpreted as suggesting that earthquake effects can be neglected in design. On the contrary, since crest elevation is an important factor in the functional and structural integrity of breakwaters against wave attack, the degree of possible settlement due to the design earthquake must be established and properly allowed for.

CHAPTER 136

DOLOS-ARMORED BREAKWATERS: SPECIAL CONSIDERATIONS

By

Robert D. Carver¹ and D. Donald Davidson²

INTRODUCTION

Rubble-mound breakwaters are used extensively throughout the world to provide protection from the destructive forces of storm waves for harbor and port facilities. In some locations, a proposed rubble-mound breakwater may be subject to attack by waves of such magnitude that quarrystone of adequate size to provide economic construction of a stable breakwater is not available. Under these circumstances, it is required that the protective cover layer consist of specially shaped concrete armor units.

In 1966, Merrifield and Zwamborn (1) introduced a new shape of armor unit, the dolos (Figure 1) which was acclaimed to have much higher stability characteristics than any existing armor unit. Site-specific model tests conducted at the U. S. Army Engineer Waterways Experiment Station (WES) by Davidson (2); Carver (3); Bottin, Chatham, and Carver (4); and Carver and Davidson (5) have shown dolos to exhibit an excellent stability response when exposed to breaking wave conditions.

Comprehensive stability tests of dolos also have been conducted at WES by Carver and Davidson (6) for a wide range of nonbreaking wave conditions. These tests used randomly placed dolosse with a first underlayer stone weight of $W_r/5$ and a density of units per given area (N/A) equal to $0.83 V^{-2/3}$, i.e., $n=2$, $k_\Delta=0.94$, and $P=56$ percent. It was concluded from this study that the stability response of dolos can be adequately predicted by the Hudson Stability Equation for the range of wave conditions investigated. Their data indicated an average stability coefficient (K) of 33 for dolosse use in a nonbreaking nonovertopping wave environment. Based on the lower limit scatter of their data, a K of 31 was approved for design.

OBJECTIVE

The objective of this paper is to investigate the effects on stability of (1) varying the first underlayer stone weight from $1/5$ to $1/20$ of the armor weight (W_r); (2) placing the dolosse in selected geometric patterns; and (3) reducing the number of dolosse used in the cover layer. As a basis for comparison, $K=33$ will be used.

FIGURE 1

TEST EQUIPMENT AND MATERIALS

All wave action tests were conducted in a flat-bottomed, 1.5-m-wide, 1.2-m-deep, and 36-m-long concrete wave flume with test sections installed in the flume about 27 m from a vertical displacement wave generator. The generator is capable of producing sinusoidal waves of various periods and heights. Test waves of the required characteristics were generated by varying the frequency and amplitude of the plunger motion. Changes in water surface elevation as a function of time were measured by electrical wave-height gages in the vicinity where the toe of the test sections was to be placed and recorded on chart paper by an electrically operated oscillograph. The electrical output of the wave gages was directly proportional to their submergence depth.

The dolos armor units weighed 138 g and had a specific weight of 2.26 g/cm³. Sieve-sized limestone ($\gamma = 2.64$ g/cm³) of angular shape was used for the underlayers (W_1 and W_2) and the core (W_4). Rough granite armor stone (W_3) having an average length of approximately two times its width and an average weight of 172 g was used to armor those areas of the structures not protected by dolosse.

SCALE EFFECT CONSIDERATIONS

Hudson (7) has presented a detailed discussion of the design requirements necessary to ensure the preclusion of stability scale effects in small-scale breakwater models (critical $R_N = 3 \times 10^4$). For all tests reported herein the sizes of model armor units and wave dimensions were selected such that scale effects were insignificant (i.e., R_N was greater than 3×10^4).

METHOD OF CONSTRUCTING TEST SECTIONS

All model breakwater sections were constructed to simulate as nearly as possible prototype breakwater characteristics obtained by usual prototype methods of construction. Typical sections of the breakwater tested (Figure 2) were built as follows. The core material, dampened as it was dumped by bucket or shovel into the flume, was compacted with hand trowels to simulate natural consolidation resulting from wave action during construction of the prototype structure. Once the core material was in place, it was sprayed with a low-velocity water hose to ensure adequate compaction of the material. The underlayer stone was then added by shovel and smoothed to grade by hand or with trowels. No excessive pressure or compaction was applied during placement of the underlayer stone. Armor units used in the cover layers were placed in a random manner, i.e., laid down in such a way that no intentional interlocking of the units was obtained (except for the pattern-placement tests). After each test, the dolosse were removed from the breakwater, all of the underlayer stones and the stones in the cover layer below that portion of the cover layer comprised of dolosse were replaced to the grade of the original test section, and the dolosse were replaced.

FIGURE 2

METHOD OF DETERMINING DAMAGE

In order to evaluate and compare breakwater stability test results, it is necessary to quantify the changes that have taken place in a given structure during attack by waves of specified characteristics. The WES damage-measurement technique requires that the cross-sectional area occupied by armor units be determined for each stability test section. Armor unit area is computed from elevations (soundings) taken at pre-determined locations over the seaward face of the structure before the armor is placed on the underlayer, after the armor has been placed but before the section has been subjected to wave attack, and finally after wave attack. Elevations are obtained with a sounding rod equipped with a circular spirit level for plumbing, a scale graduated in thousandths of a foot, and a ball-and-socket foot for adjustment to the irregular surface of the breakwater slope.

Sounding data for each test section were obtained as follows: after the first underlayer was in place, soundings were taken on the sea-side slope of the structure along rows beginning at and parallel to the longitudinal center line of the structure and extending in 7.5-cm horizontal increments to the junction with the secondary cover layer of armor stone. On each parallel row, 13 sounding points, spaced at 7.5-cm increments, were measured. This distance represented the middle 90 cm of a 152-cm-wide test section; the 31 cm of structure next to each wall was not considered because of the possibility of discontinuity effects between the armor units and the flume walls. Soundings were taken at the same points once the armor was in place and again after the structure had been subjected to wave attack.

Sounding data from each stability test were reduced in the following manner. The individual sounding points obtained on each parallel row were averaged to yield an average elevation at the bottom of the armor layer before the dolosse were placed and then at the top of the armor layer before and after testing. From these values, the cross-sectional armor area before testing and the area from which armor units were displaced (either downslope or off the section) were calculated. Damage was then determined from the following relation:

$$\text{Percent damage} = \frac{A_2}{A_1} (100)$$

where

A_1 = area before testing, cm^2

A_2 = area from which units have been displaced, cm^2

The percentage given by the WES sounding technique is, therefore, a measurement of an end area which converts to an average volume of armor material that has been moved from its original location (either downslope or off the structure). This particular method of measuring damage does not consider the rocking of individual armor units as exercised by some researchers. However, WES visual definition of no-damage from which the less than 5 percent displaced volume criterion determined by the sounding technique was developed is defined such that no significant movement of individual units is allowed after the initial movement of unnested

armor units (which are generally present on any newly constructed structure, but whose displacement does not significantly affect the composite cover layer) occurs, thus the rocking criterion does not play as important a part in our evaluation as those of other researchers.

SELECTION OF DESIGN WAVE HEIGHTS

Design wave heights for the no-damage criterion were determined by subjecting the test sections to monochromatic waves successively larger in height in 0.5-cm increments, until the maximum wave height was found that would produce no more than 5 percent damage. Each test wave was allowed to attack the breakwater for a cumulative period of 30 minutes, then the test sections were rebuilt prior to attack by the next added increment wave. This 30-minute interval allowed sufficient time for the test sections to stabilize, i.e., time for all significant movement of armor material to abate. During the tests, the wave generator was stopped as soon as reflected waves from the breakwater reached it, and the waves were allowed to decay to zero height before restarting the generator in order to prevent the test section from being exposed to uncontrolled wave groups and/or an undefined wave spectrum.

CORRELATION OF TEST RESULTS

Hudson (8) has presented the results of stability tests for the no-damage and no-overtopping criteria on rubble-mound breakwaters in which that part of the breakwater subjected to the most intense wave action was protected by smooth, randomly placed quarry-stone armor units. Based on those data, dimensional analysis and other analytical considerations, the following empirical stability equation (Hudson formula) was derived:

$$W_r = \frac{\gamma_r H^3}{K(S_r - 1)^3 \cot \alpha}$$

This equation is used to correlate the stability test data presented herein.

UNDERLAYER WEIGHT EFFECT TESTS

Underlayer weight effect tests were conducted with randomly placed armor and slopes of 1:2 and 1:3. The number of dolos units per given surface area, A , was $N = 0.83V^{-2/3}$ ($n=2$, $k_\Delta=0.94$, $P=56$ percent). Initially, the structure was built with a 1:2 slope and $W_1 = W_r/5$, and the design wave height for $T = 1.52$ sec was determined to be $H = 20.5$ cm. The breakwater was then reconstructed on the same 1:2 slope and tested for the same wave condition with $W_1 = W_r/10$ and $W_1 = W_r/20$. The stability response of the structure was almost identical in all 3 cases. The structure was then rebuilt at a 1:3 slope with $W_1 = W_r/5$ and the design wave height for $T = 1.52$ sec was determined to be $H = 22.5$ cm. The structure was then rebuilt and tested for the same wave condition with $W_1 = W_r/20$. Test results for the 1:3 slope were almost identical. Figure 3_r shows a plot of relative first-underlayer weight (W_r/W_1) versus the primary coverlayer stability number normalized for slope effects $N_s/(\cot \alpha)^{1/3}$. Thus, considering these

FIGURE 3

two structure slopes, it is concluded that if first underlayer weights in the range of $W_u/5$ to $W_u/20$ have an effect on stability, it is minimal. These data are not presented to recommend changes in the existing underlayer sizing but they are of particular importance when quarry yield is not satisfactory for normal design requirements.

PATTERN-PLACEMENT TESTS

Tests also were conducted to determine if the stability of the dolosse could be increased by placing them in a geometric pattern. It is reasonable to assume that pattern placement will increase prototype placement costs to some extent; however, it was not thought inconceivable that some pattern could be found that would increase stability (reduce the armor weight required for a given design wave height) to the extent that the increased placement costs would be more than compensated for in material savings.

Three patterns were investigated at a 1:1.5 slope. Initially, the structure was built with randomly placed units and the design wave height for wave periods of 1.31 and 2.65 secs was determined to be $H = 18.5$ cm. Patterns were then tested with the design wave height determined for randomly placed units and their stability responses were classed: better, the same, or worse than the stability response of randomly placed units. Details of the patterns tested and general results were as follows:

a. Pattern 1 had the first layer of units placed with the shanks parallel to the slope and the vertical legs alternately upslope and downslope (Photograph 1). The second layer was placed in the horizontal plane of the slope with the shanks perpendicular to those of the first layer (Photograph 2). Attack of 2.65-sec, 18.5-cm, waves produced extensive damage (Photograph 3) with the first underlayer being exposed near the crown. Pattern 1 was less stable than random placement.

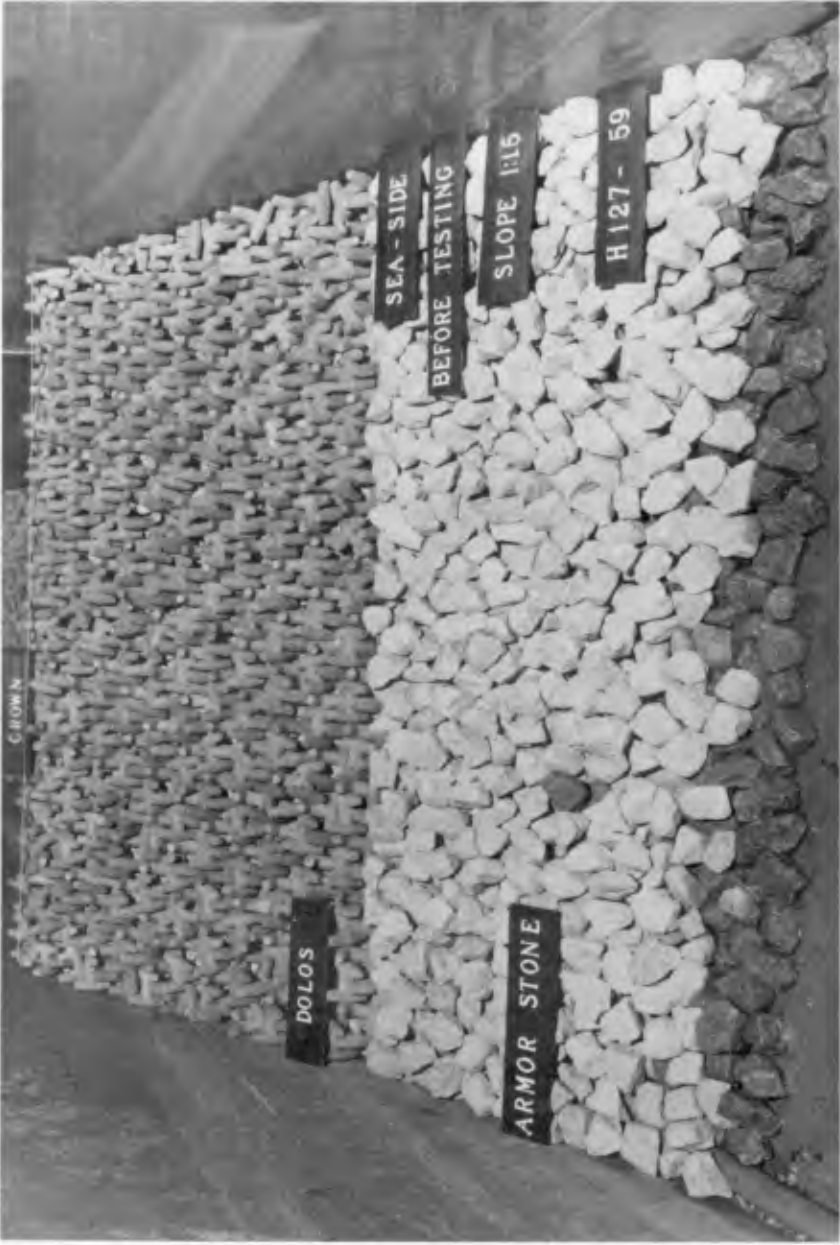

b. Pattern 2 was constructed with the shanks of all units parallel to the slope and the vertical leg downslope. Photograph 4 shows one layer of units in place while Photograph 5 shows the completed structure. Extensive damage was produced by 1.31-sec, 18.5-cm waves (Photograph 6). Pattern 2 was less stable than random placement.

c. Pattern 3 had the first layer of units placed with the shanks parallel to the slope and the vertical legs all upslope or downslope on alternating upslope rows (Photograph 7). The second layer of units was placed in the same manner to yield the complete structure (Photograph 8). Attack of 2.65-sec, 18.5-cm waves produced no damage (Photograph 9). Pattern 3 was more stable than random placement.

The pattern tests described above proved enlightening in that they showed that of the three geometric patterns selected for testing, two proved to be less stable than random placement. Based on these results, designers and construction supervisors are cautioned not to assume that any geometric pattern will increase stability.

Photograph 1. Pattern 1 with one layer of armor units in place

Photograph 2. Pattern 1 with two layers of armor units in place

Photograph 3. Pattern 1 after attack of 2.65-sec, 18.5-cm waves

Photograph 4. Pattern 2 with one layer of armor units in place

Photograph 5. Pattern 2 with two layers of armor units in place

Photograph 6. Pattern 2 after attack of 1.31-sec, 18.5-cm waves

Photograph 7. Pattern 3 with one layer of armor units in place

Photograph 8. Pattern 3 with two layers of armor units in place

Photograph 9. Pattern 3 after attack of 2.65-sec, 18.5-cm waves

Subsequent stability tests showed Pattern 3 to meet the no-damage criterion for wave heights up to 20 cm at the 1:1.5 slope. This was a substantial enough increase over random placement that it was decided to test Pattern 3 at slopes of 1:2 and 1:3. Results of these tests are summarized as follows:

Sea-Side Slope	$H_{D=0}$, cm	K
1:1.5	20.0	42
1:2.0	22.0	43
1:3.0	25.0	44

Recalling that Carver and Davidson's (6) earlier tests yielded an average stability coefficient of 33 for random placed dolosse, the values of K presented above are quite impressive. Considering Pattern 3 as a two-layer system, values of k_A and P were determined to be 0.92 and 50 percent, respectively, or $N/A = 0.92 V^{-2/3}$.

THE EFFECT THE NUMBER OF DOLOS UNITS IN THE COVERLAYER HAS ON STABILITY

Limited tests were conducted using a 1:1.5 slope to determine the effect on stability of using a decreased number of armor units in the cover layers. For these tests, the structures were built using the random placement technique with approximately 25 percent fewer armor units than were used by Carver and Davidson (6) in the stability tests that yielded an average stability coefficient of 33. This armor unit coverage was sparse but could still be considered a two-layer system. Values of k_A and P were 0.62 and 50 percent, or $N/A = 0.62 V^{-2/3}$. These tests yielded a design wave height of 15 cm and thus a stability coefficient of 17, showing that reducing the number of armor units by approximately 25 percent reduced the stability coefficient by approximately 50 percent.

Similar results were found by Vonk (9) for dolos tests where model units representing 4.7 metric ton dolosse were reduced from 0.70 units per square meter ($N/A = 1.07 V^{-2/3}$) to 0.56 units per square meter ($N/A = 0.86 V^{-2/3}$). His data show that for 9-18 sec period waves, the stability coefficient at 2 percent damage dropped approximately 58 and 31 percent for breakwater slopes of 1:1.5 and 1:2, respectively. All these data illustrate the important role the number of armor units play in determining the stability coefficients that are being used today and emphasize the fact that prototype designs should never use less dolosse per given area than recommended by the particular data upon which the stability coefficient is based.

Although the data is limited and it is difficult to relate equivalent stability from different laboratories, Figure 4 indicates the general increase in K as the packing density coefficient (C) increase for dolosse. The data presented in Figure 4 are taken from Carver and Davidson (6), Shore Protection Manual (10); Merrifield and Zwamborn (1), and personal correspondence between Davidson and Zwamborn (11). Reference (6) and (10), K factors are based on the no-damage criteria of less than 5 percent damage by the sounding method previously described, whereas data in

FIGURE 4

References (1) and (11) are based on 2 percent damage by number of displaced units. These data do not necessarily recommend an optimum number of dolosse to use per given area because the safety and economics of each prototype project should be considered on its own merits. They do show, however, that the number of dolosse used per given area is critical to the selection of the stability coefficient and should be considered accordingly.

CONCLUSIONS

Based on the tests and results described herein, in which dolos armor is used on nonovertopping breakwater trunks and subjected to non-breaking waves with a direction of approach of 90° , it is concluded that:

a. For sea-side slopes in the range of 1:2 to 1:3, variations in first-underlayer weights (W_1) from $W_r/5$ to $W_r/20$ do not have a significant effect on stability.

b. Placement of dolosse in geometric patterns may or may not increase stability over that obtained by random placement, depending on the selected pattern; thus caution should be taken not to assume that every geometric pattern will increase stability.

c. The number of dolosse in the cover layer definitely affects the stability coefficient; thus a designer should take precaution to assure that a given stability coefficient is commensurate with the number of dolos units per given area upon which that stability coefficient was developed.

ACKNOWLEDGEMENTS

The data presented in this paper were extracted from part of the model tests described in the Waterways Experiment Station (WES), Technical Report H-77-19, entitled, "Dolos Armor Units Used on Rubble-Mound Breakwater Trunks Subject to Nonbreaking Waves with No Overtopping," which was published for public release in November 1977. The comprehensive study was conducted at WES for the office, Chief of Engineers under the Corps of Engineers Civil Works Research and Development Program. The tests were conducted in the Wave Dynamics Division (Dr. Robert W. Whalin, Chief) of the Hydraulics Laboratory (Mr. H. B. Simmons, Chief); by Mr. R. D. Carver, Research Hydraulics Engineer; and Mr. W. G. Dubose, Engineering Technician, under the immediate supervision of Mr. D. D. Davidson, Chief of the Wave Research Branch.

Grateful acknowledgement is extended to the Office, Chief of Engineers for granting permission to publish this paper.

CHAPTER 137

DOLOS PACKING DENSITY AND EFFECT OF RELATIVE BLOCK DENSITY

by
J.A. ZWAMBORN*

ABSTRACT

Accuracy and compatibility of measuring and testing techniques are discussed briefly and a *plea* is made for *standardisation* to avoid, as far as possible, deviations in test results of different laboratories. One of the main causes of these differences is inconsistency in Dolos *packing densities* and corresponding layer thicknesses or shape factors. In an attempt to alleviate this problem three placing densities, namely 'light', 'mean' and 'dense' have been defined and their physical properties determined. Flume tests with regular waves, and Dolos armour units at these packing densities, showed very little difference in stability and, considering practical limitations during construction, it is suggested that the 'mean' packing density be used for a 'first design', followed by proper model tests. The results of tests with model Dolosse using three different *unit densities* were inconclusive and further tests using a wider range of densities are underway.

INTRODUCTION

The 'Dolos' breakwater armour unit is now used widely for harbour and shore protection works in various parts of the world.²⁰ Model tests on the stability of Dolosse have been carried out at several laboratories but differences in *definitions* and *test techniques* often preclude a direct comparison of the results.

There is, for example, considerable difference of opinion about the *number of Dolosse* required to form a so-called 'double layer' of armouring blocks^{20,11,3,7} and, because the number of Dolosse per unit area affects the economy as well as the stability of a structure, an attempt is made to define more clearly various packing densities. Some tests have also been done to determine the effect of the packing density on the stability of a Dolos armouring, as well as its possible influence on wave run-up.

According to all the known stability formulae, the armour block mass is inversely proportional to the *relative block density* to the third power¹⁴ and it is, therefore, attractive and, in certain cases imperative¹⁶, to use a higher than normal block density. Some doubt has been expressed, however, about the validity of this proportionality in the case of Dolosse¹⁹ and some tests with regular non-breaking waves were, therefore, done to determine the effect of relative block density on the stability of Dolosse.

ACCURACY AND COMPATIBILITY OF MEASURING TECHNIQUES

Definitions and test methods should be completely compatible if comparisons

* National Research Institute for Oceanology, CSIR, Stellenbosch, Republic of South Africa

are to be made between the results of tests on models done in different laboratories and when test data are to be compared with prototype data. This is of particular importance in the case of porosity of the armouring, the block shape factor or the layer thickness, and the damage recorded after wave action.

The *porosity* can be determined in two different ways, firstly, by placing, say, 5 to 10 layers of Dolosse in a container of known dimensions and filling the voids with water ('real' porosity) and, secondly, by determining the percentage voids in the container or of the model slope, from the difference of the 'total volume' and the volume of the Dolosse ('fictitious' porosity). A representative water level, in the case of the container tests, or the thickness of the armour, in the case of a model slope, can be judged by eye (to achieve a reasonable accuracy, 5 to 10 layers are used) or can be determined with the more reliable sounding technique.^{3, 5}

Both methods are used to determine porosity^{11, 18} and a comparison of the values obtained by these methods showed a consistent difference of 3,5 per cent, which is caused by the protrusion above the water surface of parts of the Dolosse. It is thus important to define the basis or method of measurement when values for porosity are given.

The U.S. Army Engineer Waterways Experiment Station (WES) developed a standard *sounding technique* in the early 1950's to measure the extent of damage to stone dumped randomly on a breakwater slope. The size of the original sounding disc was increased for Dolosse to $1,14 V^{1/3}$ with a grid spacing of $1,5 V^{1/3}$, (V is the block volume) to obtain an armour layer thickness "which visually appeared to represent an acceptable two-layer thickness."³ This technique was found to be very useful in determining the average armour thickness; repeat packing and sounding tests in a container showed a maximum variation of ± 3 per cent but repeat soundings of the same packing on Dolos slopes showed a variation of only $\pm 1\frac{1}{2}$ per cent). The *shape factor* $C = t/n V^{-1/3}$ (t being the measured thickness of n layers) follows directly from the armour layer thickness and the block volume and its value is therefore of the same accuracy.

A further check was made of the influence of the grid size and the disc diameter on the measured armour thickness. Container tests showed that for a *grid size* of up to double that specified, that is $3 V^{1/3}$, the thickness is hardly affected, the difference being less than 1 per cent. The layer thickness, however, is reduced slightly, almost linearly, for smaller *disc sizes*, i.e. a disc of one third of the size causes a reduction of just under 10 per cent. The latter should be taken into account when doing *prototype soundings* because normally, a relatively small plate or ball is used which would make the Dolos layer *appear* to be say, 10 per cent, thinner.

A comparison was also made between the *damage* measured according to the WES sounding technique and the damage derived from records of individual blocks which had been displaced. Repeat soundings showed that a 'damage' of 4 per cent (sum of the negative differences) could be obtained even before there had been any wave action. Thus the sounding technique cannot be expected to provide damage figures to an accuracy better than about 4 per cent which is considered a serious drawback, particularly as regards

localised damage. Compared with this, measurement of the movement of individual Dolosse provides a much more detailed and accurate record of damage because the movement of each Dolos can be recorded; with say 500 Dolosse in the test section, damage increments of 0,2 per cent can be differentiated.

In the past, blocks which were seen to be *rocking* continuously were sometimes also included in the measurement of damage because these blocks were assumed to have broken. Compared with the blocks which moved out of position (displaced units) the number of rocking blocks observed was quite small and, since the visual observations were rather subjective, the rocking was often neglected. Observations through glass-sided flumes have indicated, however, that considerable rocking movements do take place and a quantitative measuring technique was therefore developed to record these movements. The technique consists of *time-lapse cine pictures* of the Dolos slope, taken at the time when the wave trough has reached its lowest point on the slope. Subsequent projection of the film clearly shows the change in Dolos positions, representing Dolos movements between successive waves, on the entire exposed slope. The results are analysed by marking and counting the blocks separately which shows

- *continuous rocking or full roll-over* (no displacement)
- *intermittent rocking* (about two-thirds of the time)
- *occasional rocking* (about one-third of the time)

Present knowledge of the Dolos strength is insufficient to define acceptable degrees of rocking and it is *suggested* that, for the time being, all the above modes of movement be recorded separately, together with the number of displaced units, as discussed above. A more detailed description of the measuring techniques is given elsewhere²².

DIFFERENT PACKING DENSITIES

Definitions

The definition of the packing density of breakwater armour blocks is the *number of units* (e.g. Dolosse), N , per unit area of slope. The packing density may be expressed as follows :

$$N_n = \phi_n V^{-2/3}$$

with ϕ_n is the packing density parameter being related to the number of layers (n), the shape factor (C_n) and the 'fictitious' porosity (P_f) as follows : $\phi_n = n C_n (1 - P_f/100)$.

The layer thickness can be expressed as follows :

$$t_n = \tau_n V^{1/3}$$

where τ_n is the layer thickness parameter also related to the number of layers (n) and the shape factor (C_n), i.e. $\tau_n = n C_n$.

Differences of up to 35 per cent in the value of $\phi_{n=2}$ (double layer) are quoted in the literature.^{11,17} Because the number of armour units per unit area, and thus the value of ϕ , has a direct bearing on the economy of the structure and is also expected to influence both the stability as well as the safety of the breakwater, it was decided that a clear and

unambiguous *definition* for the packing density of a *single randomly placed layer* of Dolosse was needed urgently. The following definitions are therefore proposed (see Fig. 1) :

FIG. 1 PACKING DENSITIES

- light packing* - all Dolosse rest on the underlayer with two points (Fig. 1.a.1)
- mean packing* - average packing density judged to provide a proper first layer cover (Fig. 1.a.2)
- dense packing* - every Dolos touches the underlayer with at least one point (Fig. 1.a.3)

Packing tests

To determine the ϕ values for the above packing densities, a total of 65 packing tests were done by 8 different persons using a 0,5m by 0,5m area ($A = 0,25 \text{ m}^2$) and Dolosse with a height $h = 60 \text{ mm}$ ($V = 35,6 \times 10^{-6} \text{ m}^3$).

The following results were obtained :

Packing	Tests	Mean no. Dolosse ($N_{n=1}A$)	Variation max./min.	$\phi_{n=2} = \frac{2N}{n=1} V^{2/3}$
light	23	96	+ 5	0,83
mean	20	115	+ 8	1,00
dense	22	133	+ 8	1,15

As was to be expected, there is a reasonably large variation between the individual packing tests but, on average, the results were found to be very

consistent even with the large number of people involved in the tests. It is thus concluded that, given the above definitions, the three packing densities are reproducible to an acceptable degree of accuracy.

For a breakwater armouring, a 'double layer' of Dolosse is required, that is, $2N_{n=1}$. The corresponding $\phi_{n=2}$ values are included in the last column of the above table.

Placing technique

The packing densities, N , discussed above refer only to the number of units per unit area and *not* to the possible differences in *placing density*, i.e. differences in the number of units per unit of volume. Although it was found in the laboratory to be possible to achieve different placing densities,¹⁸ this is quite impractical in the prototype; the placing density will depend on the placing technique and conditions during placing and can, therefore, not be prescribed.

Since it is not considered possible to achieve a specific placing density in the prototype, a *standard technique* is used in the model whereby the Dolosse are held by the shank and dropped in position from a height of between h to $2h$. This is considered reasonably representative of prototype placing techniques.

On the model slopes, the Dolosse were always placed in *one operation* (full layer thickness) from the bottom upwards. A better interlocking is achieved in this way.

Porosity and layer thickness

The *physical properties*, namely, 'real' (P_r) and 'fictitious' (P_f) porosities, layer thickness (τ) and shape factor (C), were determined for the light, mean and dense packing densities using the results of 12 container tests and 10 tests each for the light and dense packing and 34 tests for the mean packing on a 1 in 1,5 model slope. The average physical properties of Dolosse at different packing densities were found to be as follows :

Packing density	ϕ (n=2)	Porosity in per cent				Relative armour layer thickness			
		Container tests (n=5)		Model slope (n=2)	Container tests (n=1 to 5)		Model slope (n=2)		
		P_r	P_f	P_f	$\tau_{n=2}$	$\tau_{n>2}$	$\tau_{n=2}$	$C_{n=2}$	
light	0,83	55,0	52,8	51,8	1,79	0,85	1,72	0,86	
mean	1,00	55,0	50,9	51,5	2,06	0,94	2,04	1,02	
dense	1,15	55,0	51,4	52,3	2,41	1,14	2,42	1,21	

The 'real' porosity is seen to be independent of packing density which is to be expected. Variations in the fictitious porosity are small and follow no particular trend so that the average value of 51,5 per cent, which applies to both the container and model slope tests, can safely be accepted for all three packing densities.

In the container tests, every layer was sounded from $n = 1$ to $n = 5$. The results showed that the *first layer* was always significantly *thicker* than the following layers because the first layer is packed onto underlayer stone in which the cavities are much smaller than they are in a Dolos layer. Thus $\tau_{n=2}$ is seen to be greater (about 7%) than $2\tau_1$

where t_i refers to the thickness of one layer in a multi-layer packing ($n > 2$). The same applies to the shape factor, C , which is found simply by dividing t_n by n . This should be borne in mind when the armouring in the above table, consists of *more than two layers* ($n > 2$). The model slope double-layer thickness and corresponding shape factor values are seen to agree closely with the container values.

The above physical properties apply strictly only to Dolosse with $r = 0,33$ but it was found that there is no significant difference in porosity or layer thickness for Dolosse with waist ratios varying from 0,30 to 0,35 and they can therefore *safely be used* for all Dolosse with *waist ratios* within this range.

For a normal *double layer*, the number of Dolosse per unit area follows from $N_{n=2} = \phi_{n=2} V^{-2/3}$ but for a large *mound* of Dolosse, consisting of many layers, the packing density per unit of volume (N') becomes :

$$N' = N/t = (1 - P_r/100)V^{-1} = 0,45/V$$

because $P_r = 55,0$ for all three packing densities.

For a structure of *irregular shape* (e.g. breakwater head) in which a *double layer* of Dolosse is used, the number of units per unit of volume may be useful :

$$N'_{n=2} = N_{n=2}/t_{n=2} = 0,485/V$$

which is also independent of packing density accepting $P_f = 51,5$.

Comparison with previous data

Previously reported data on required *number of Dolosse* and corresponding *layer thicknesses* are compared in the following table :

Source	Year	$\phi_{n=2}$	$\tau_{n=2}$
(a) Merrifield and Zwamborn ¹¹	1966	1,04	2,6
(b) CERC, SPM ¹⁷	1973	0,74	2,0
(c) Silva and Foster ¹⁵	1974	0,73	2,00
(d) Davidson ⁵	1976	0,67	1,60
(e) Vonk ¹⁸	1976	1,15	2,36
(f) Vonk ¹⁸	1976	1,08	2,12
(g) Vonk ¹⁸	1976	0,86	2,00
(h) Zwamborn ²⁰	1976	1,0	2,2
(i) Carver and Davidson ³	1977	0,83	1,88
(j) Carver and Davidson ³	1977	0,62	1,24
(k) Present paper : <i>light</i>	1978	0,83	1,72
(l) (based on soundings) <i>mean</i>	1978	1,00	2,04
(m) <i>dense</i>	1978	1,15	2,42

It is clear from the above that smaller layer thicknesses generally go with lower packing densities which is to be expected because $\phi = (1 - P_f/100)\tau$ with P being constant (thus intermediate values for ϕ and τ can be interpolated linearly. Most of the data compare reasonably well, except (a), (b) and (c) for which the τ values are relatively too high. In the tests described in (a) very roughly cast cement Dolosse were used for the original tests. Subsequent tests (h), (k), (l) and (m) were all done with smooth P.V.C. models.

All the Dolos applications in South Africa (involving a total of some 120 000 Dolosse) and several large schemes elsewhere (e.g. High Island Water scheme⁹ and Sines Harbour¹²) were built in accordance with a value $\phi = 1$ whereas in the U.S.A. and Australia values as low as $\phi = 0,67$ and, more recently, $\phi = 0,83$ are used, the latter being the same as the 'light' packing density defined in this paper.

Optimum packing density

Three packing densities have been defined above and the corresponding physical properties determined. The question now is, which density should be used for a particular harbour design?

Obviously, a low packing density reduces the initial cost. On the other hand, some test results indicate that stability of the armour is improved when the number of Dolosse is increased^{3,18}. There are also practical aspects to be taken into account; when a low packing density is used, placing accuracy and control must be very good, otherwise there is a possibility that the armour will have weak spots in it right from the beginning. It is interesting to note that in several instances, *during construction*, the armour was judged to be incomplete or too irregular after the theoretical number of Dolosse had been placed. This occurred, inter alia, at the Cape Town harbour extensions where some 10 per cent cent more Dolosse were used ($\phi \approx 1,13$), for the Port Elizabeth shore protection²⁰ where 2 per cent more Dolosse were used ($\phi = 1,06$) and for the Sines breakwater²¹ where the number of units was increased from $0,16/m^2$ ($\phi = 1,04$) to $0,18/m^2$ ($\phi = 1,17$), that is about 13 per cent more than the theoretical number.

A decision on the packing density to be used should be reached by carefully *weighing up* the initial capital cost, maintenance cost, practical considerations (construction methods and constraints) and the economic effects (interruption in port operation) of a part or complete failure of the structure. In order to be able to perform this type of economic analysis, it will be necessary to know the effect on the stability of different packing densities. Because of the complete lack of comparable data, it was decided to carry out some tests using the three packing densities discussed above.

MODEL TESTS ON EFFECT OF PACKING DENSITY ON STABILITY

Although, as discussed in the previous section, researchers have used various packing densities in stability tests it is virtually impossible, because of the differences in test conditions and the interpretation of damage, to compare directly the results of tests done by different laboratories.

Some *comparative tests* were done, however, by Vonk¹⁸, both with a 1 in 1,5 and a 1 in 2 slope. He found a significant *improvement* in the stability of a Dolos armour by increasing the packing density about 25 per cent from $\phi_{n=2} = 0,86$ to $\phi_{n=2} = 1,08$, particularly for the 1 in 1,5 slope. Carver and Davidson³ also report on some tests carried out with Dolosse on a 1 in 1,5 slope using different packing densities. They report a decrease of about 50 per cent in the stability factor, K_D , for a decrease of 25 per cent in the number of Dolosse (from $\phi = 0,83$ to $\phi = 0,62$) and an increase of 27 per cent in K_D for an increase of 11 per cent in N (from $\phi = 0,83$ to $\phi = 0,92$)^{*}. Silva and Foster¹⁵ found little difference in

* Carver and Davidson³ ascribe this improvement to the fact that the Dolosse were packed in a *pattern* but, considering the improvement in K_D for $\phi = 0,62$ to $\phi = 0,83$, the further increase in K_D could also be ascribed to the increased number of Dolosse.

the initiation of motion of the units but, at higher damage levels, there was a significant increase found with a higher packing density.

Thus, it appears that an *increase in the number of Dolosse per unit area improves stability*. Test data, however, are very sketchy and comparative tests were, therefore, done in the wave flume in Stellenbosch.

In the above, the stability factor is defined by Hudson's formula¹⁷, namely,

$$K_D = \frac{\gamma_s H_D^3}{W \Delta^3 \cot \alpha}$$

where γ_s is mass density, H_D is design wave height, W is block mass, Δ is relative block density i.e. $\gamma_s/\gamma-1$, γ is mass density of water and α is breakwater side slope.

Test facilities

The tests were done in the 160 m long (effective length), 3 m wide and 1,1 m deep wind-wave flume in Stellenbosch. Only *regular waves* were used for this test series which were produced by the translatory wave board. Waves were recorded with temperature compensated probes and wave height meters connected to standard chart recorders. During the wave calibration stage, the waves were measured where the model slope was to be

FIG. 2 MODEL VIEW

positioned in the stability tests (that is, near the intersection of the still water line and the top of the model slope) and a quarter wave length in front. During the actual tests, the waves were recorded from a trolley moving at an approximately constant speed over a distance of two wave lengths in front of the model.

Model lay-out and design

The flume was divided into *three* 0,75 m wide *test sections* leaving two narrow dummy channels of about half that width on either side (see Fig. 2). The core was built of clean 6mm (about 4 g) stone, the model slope

was 1 in 1,5 and the water depth 0,8m.

The particulars of the *model Dolosse* were as follows (based on accurate measurements of a representative sample of 170 Dolosse) :

Model Dolosse	W(g)	V(10 ⁻⁶ m ³)	γ_s	h(mm)	r
Mean	81,2	35,0	2,32	59,2	0,33
Max.deviation(%)	\pm 3,3	\pm 3,0	\pm 2,6	\pm 0,4	\pm 5,3

The 'test areas' were 750 x 750 mm² and 436, 526 and 605 Dolosse were placed in these areas representing a *double layer* of 'light', 'mean' and 'dense' packing respectively. They were placed in six 125 mm (about 2h) wide bands of different colour, three above and three below still water

level, i.e. from 208 mm below to 208 mm above water. Taking $K_D = 25$ ('first design' value²⁰), the design wave height for the model Dolosse follows from Hudson's formula, viz. $H_D = 144,5$ mm and the *area considered for damage* thus extended from $1,44 H_D$ above to $1,44 H_D$ below still water level. Above and below the 'test area', additional 81,2 g Dolosse were placed, but these were not considered for damage.

The underlayer stone mass used was $W = 81,2/5 = 16,2$ g. Sorted stone with a mean mass of 16,5 g was used.^u The thickness of the underlayer follows from $t_u = nCV^{1/3} = 43$ mm, using $n = 2$, $C = 1,15$ and $\gamma_s = 2,64^{20,17}$.

Test conditions and procedures

After the stone had been smoothed out the underlayer was profiled using the standard sounding technique on a 50 mm grid (see Fig. 12.a). The Dolosse were then placed in one operation, working from the bottom upwards, and were sounded on the same grid. The mean difference between the two soundings provided the *average layer thickness*, and the 'fictitious' porosity. The entire Dolos cover was replaced after each test series.

A test series consisted of 24 'bursts' of $2\frac{1}{2}$ min. or a total of 60 min. of wave action for each wave height increment, viz. 83, 100, 117, 134,5, 152, 168,5, 185, 203 and 221. The wave period for the entire series was constant at 1,75 s (the Ursell parameter, $U = HL^2/2d^3$ where L is wave length and d is waterdepth, varied between 1,33 and 4,05; the Iribarren number, $\xi = \tan\alpha/\sqrt{H/L_0}$ where L_0 is the deepwater wave length, varied from 5,06 to 2,90 while for $H_D = 144,5$ mm, $\xi_D = 3,83$ which represents the least stable condition according to Bruun and Günbak²).

Displacement of any units was recorded after each $2\frac{1}{2}$ min 'burst'. Small movements and *rocking* were recorded continuously by the cine technique, except during wave 'bursts' numbers 8 and 16 when the cine camera was used to record the maximum wave *run-up*.

Test results on stability of different packing densities

Because of the inherent variation in tests of this nature, 10 virtually identical *repeat runs* were made using the above-mentioned wave heights. Although a few tests were carried on until complete destruction, most of the test series were stopped when between 20 and 30 per cent damage had been reached, to reduce the time required for reconstruction of the slopes.

The *test results* are shown in Fig. 3 where the percentages of displaced Dolosse are plotted against wave height for each test. The results show considerable differences, particularly for the 'mean' packing density. The more consistent result for the 'light' packing could be ascribed to an, on average, somewhat better interlock between the Dolosse but the 'dense' packing results are equally consistent so that this explanation does not appear to hold.

The *average results* for the three packing densities are shown in Fig. 4. This figure shows the somewhat surprising result that all three packing densities display about the *same stability* and, on the basis of the present tests, stability does not appear to increase with the number of Dolosse, as was expected. There is, however, a difference in the type of collapse of the armour, i.e. the 'light' and 'mean' packing densities collapse more suddenly than the 'mean' and 'dense' packings respectively.

These differences, however, show up only for damage well exceeding 15 per cent.

FIG. 3 PACKING DENSITY TESTS, DOLOS DISPLACEMENT VERSUS WAVE HEIGHT

FIG. 4 COMPARISON OF MEAN TEST RESULTS FOR 'LIGHT', 'MEAN', AND 'DENSE' PACKING DENSITIES

Figure 5 gives the percentages of displaced units as well as the *continuously* and *intermittently rocking* Dolosse. These results were derived from the time-lapse cine measurements. The percentages are not too much greater for the higher damage values but, at the 2 per cent displacement level, the increase due to continuous rocking is seen to be about 50 per cent while continuously plus intermittently rocking units add about 100 per cent to the damage caused by displacement. Although the percentage increase is somewhat smaller for the 'dense' packing, this is not considered to be very significant (see Fig. 5).

FIG. 5 PACKING DENSITY TESTS, MEAN DISPLACEMENT AND ROCKING VERSUS WAVE HEIGHT

The stability factors, K_D given in the following table, also show the lack of increased stability for higher packing densities :

Packing density	'Light', $\phi=0,83$			'Mean', $\phi=1,00$			'Dense', $\phi=1,15$		
	2	5	10	2*	5	10	2	5	10
K_D (displ.)	26,9	39,3	(50)	22,2	36,5	50,3	22,2	37,9	49,9
K_D (displ.+rock.)	16,6	30,2	-	15,4	28,5	-	15,2	29,7	-

The K_D factors, based on displacement, compare with the lowest values reported by Merrifield and Zwamborn¹¹ and are in reasonably good agreement with Carver and Davidson's more recent results³ ($K_D = 33$ for 5% damage, $\phi = 0,83$, best-fit line). The K_D values based on displacement plus continuous and intermittent rocking are seen to be considerably smaller, particularly for the small percentages damage.

As indicated before, the results are somewhat surprising in that there is *no obvious improvement* in stability for the higher packing densities.

The question thus arises whether it is worthwhile to use these higher densities. There are several reasons, however, against using the 'light' packing density, $\phi = 0,83$, namely :

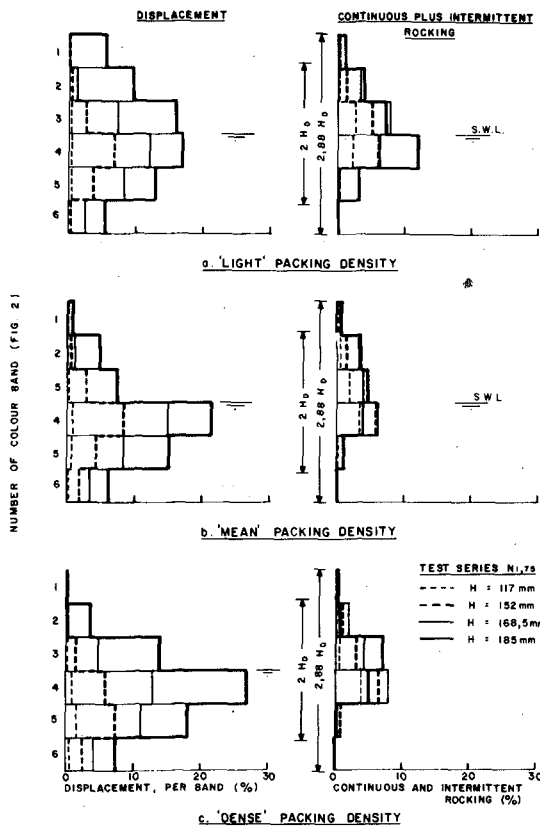

- a large portion of the armour lies underwater so that it is difficult to ensure the 'ideal' packing necessary with the 'light' packing density;
- breakage of more than three Dolosse in a cluster will cause loss of stability with the 'light' packing⁴;
- there is little reserve in the structure, particularly in the case of possible breakage of units;
- the wave run-up is about 5 per cent larger than that for 'mean' packing density (refer following section).

Considering the anchor shape of the Dolos, it would appear that the *optimum*

layer thickness could be $t_{n=2} = h$. In this case, maximum interlocking could be achieved if a certain percentage of the Dolosse came to rest with their shanks about perpendicular to the breakwater slope, acting as anchors. Based on the average measured layer thicknesses, the corresponding packing density would be $N = 0,9 V^{-2/3}$ ($\phi = 0,87 \approx 0,9$). Even so, depending on the type of structure, the method of placing and the quality of the control, it would be prudent to allow for about 10 per cent extra units to ensure an even packing density in practice, increasing the above packing density to $N = 1,0 V^{-2/3}$, that is, 'mean' packing density.

Areal distribution of damage

The average damage per Dolos colour band, for 10 repeat tests, is shown in Fig. 6. This figure shows the percentages damage due to displaced Dolosse as well as for the continuously plus intermittently rocking units.

The results show that the main damage areas are located at and just below the still water line but the 'dense' packing shows maximum damage in band 5 for the waves up to 152 mm. This is thought to be due to the increase in the quantity of run-down water caused by the thicker cover layer. As the wave height increases, the damage becomes more widespread, both below and above water. On average, the 'dense' packing sustained more concentrated damage near the water line whereas the 'light' packing showed the widest distribution of damage. The complete absence of rocking units in band 6 is not necessarily correct because this band remains normally submerged and is therefore excluded from the cine recording.

FIG. 6 PACKING DENSITY TESTS - MEAN AREAL DISTRIBUTION OF DAMAGE

It is clear from the above that significant damage occurs outside the $2 H_D$ area normally considered and it is therefore *recommended* that damage be based on the area of the breakwater slope lying between $1,5 H_D$ above to $1,5 H_D$ below still water level.

Wave reflection and run-up

Some 100 wave reflection measurements for each of the three packing densities were used to compile Fig. 7a. There is seen to be very little variation in the average H_r/H values, that is, 0,27 to 0,30 and there is only a very small increase of reflection from the 'dense' to 'light' packing density.

Wave run-up values measured by the time-lapse cine technique are shown in Fig. 7b. About 70 records for each packing density collected during 7 tests were used to plot this figure. The results show a *significant increase* in wave run-up for increase in wave steepness and for smaller packing densities.

The results for the 'mean' packing density compare well with those obtained previously by Zwamborn and Beute¹⁹ and for the 'light' packing density with the results of Carver and Davidson³.

FIG. 7 WAVE REFLECTION AND RUN-UP VERSUS WAVE STEEPNESS FOR DIFFERENT PACKING DENSITIES

MODEL TESTS ON EFFECT OF BLOCK DENSITY ON STABILITY

All available formulae to determine the mass of armour units include the third power of the relative block density in the denominator, which would indicate that the block mass can be *reduced considerably* if a high relative density is used. This has obvious advantages and, in particular cases, circumstances may *dictate* the use of high-density concrete¹⁶.

A recent study of high-density concrete indicates that *high-strength* concrete can be produced using heavy aggregates, such as magnetite,

goethite, hematite and ilmenite⁶. However, since higher density would result in increased tensile stresses in the armour units, a *thorough strength analysis* should precede the use of such high densities, particularly for large units.

Doubt has also been expressed about the validity of the third power relationship in the case of Dolosse because their stability is, at least, partly the result of the *interlocking* of the units and an evaluation of available test results indicated a power of the relative density below three¹⁹. It was therefore felt that a further investigation of the effect on stability of relative block density, was essential.

Basic stability equation

Castro and Iribarren (1938)¹⁰ developed the first stability equation for rock armouring by equating the *drag force*, caused by the waves, with the resistance force, which depends on the *submerged mass* of the stone and the slope of the armouring. The basic form of their equation is :

$$\frac{V}{H^3} f(\alpha) = \frac{1}{K} \left(\frac{\gamma_s}{\gamma} - 1 \right)^x = \frac{\Delta^x}{K}$$

where $f(\alpha) = (\cos\alpha - \sin\alpha)^3$, K is a constant and $x = -3$. Many researchers have published variations to Iribarren's formula¹⁴, but they all use the same basic form, except for the replacement of H^3 by H^2T in some of the formulae. The main difference between the various formulae is the different forms of $f(\alpha)$. The well-known Hudson formula¹⁷ is obtained by setting $x = -3$, $f(\alpha) = \cot\alpha$ and $V = W/\gamma_s$.

The *inertial forces* on the armour units and *interlocking forces*, applicable to Dolosse, are not taken into account in the above formulae. The inertial force, which depends on the wave period, is estimated to be of the same order of magnitude as the drag force but the effect of interlocking is very difficult to quantify. Armour units are also not necessarily fully submerged when the combination of drag and inertial forces reaches a maximum, which would affect the right-hand term in the above equation.

Previous test results on the effect of unit density

Brandtzaeg has reported on *extensive tests* carried out by Kydland and Sodefjed using stone of different densities (1,725 to 4,72 t/m³), fluids with different densities (1,0 to 1,13 t/m³) and various breakwater slopes (1 in 1,25, 1 in 1,5 and 1 in 2)¹. He plotted relative wave height versus relative unit density for various percentages damage, arriving at a linear relationship of the form $H/V^{1/3} = \xi(\gamma_s/\gamma - \Psi)$, where ξ and Ψ are constants. Although the test results fit in quite well with this equation, the equation has no physical basis and it yields wave heights greater than zero for $\gamma_s = \gamma$, which, of course, is impossible.

The Kydland test results were, therefore, plotted in Fig. 8.a in accordance with the above equation with $f(\alpha) = \cot\alpha$ for 1 and 4 per cent damage. Mean lines have been drawn through the test points which show a *remarkably good fit* for $x = -2,00$, $K = 5,3$ and $x = -2,08$, $K = 9,5$. Hudson ascribes the disagreement with his own formula ($x = -3$) to *scale effects*, because the stability number should be independent of the density. This conclusion, however, appears to be *incorrect* in view of the results shown in Fig. 8.a.

FIG. 8 RELATIVE UNIT VOLUME VERSUS RELATIVE UNIT DENSITY

Sodefjed's test results are plotted similarly in Fig. 8.b for 1 per cent damage. This figure shows different values of x, varying from - 2,08 to - 2,87, for the different breakwater slopes. Thus although it is again found that $x > - 3$, the x values do not agree with Kydland's data. Moreover, the variation of x with slope indicates that $f(\alpha) = \cot \alpha$ does not fully represent the slope effect (replacing $\cot \alpha$ by $(\cos \alpha)^3$ did not reduce the spread of the lines while $(\cos \alpha - \sin \alpha)^3$ made the spread distinctly worse¹⁴).

Some test results with Dolosse of different densities were reported by Gravesen and Sørensen⁹. These are plotted in Fig. 8.c indicating values of $x = - 3,0, - 3,0$ and $- 4,0$ for 1, 2 and 5 per cent damage, respectively. The data, however, are very limited and the drawing of general conclusions should be reserved until more test results become available.

Test facilities, model lay-out and design

The tests were done in the same facilities described before and the models were built in the same position in the flume (see Fig. 2). Three models were again tested side by side, namely Dolosse with specific densities of 2,31, 2,41 and 2,57. The model slopes were 1 in $1\frac{1}{2}$ and the water depth was again 0,8 m.

Details of the model Dolosse, based on representative samples of 50 Dolosse for each density, are given in the following table :

Model Dolosse	W(ρ)	V($10^{-6}m^3$)	γ_s	h(mm)	r
Mean	81,4	35,3	2,31	59,2	0,33
Max. deviation(%)	$\pm 2,1$	$\pm 3,0$	$\pm 1,9$	$\pm 2,4$	$\pm 5,2$
Mean	84,8	35,2	2,41	59,4	0,33
Max. deviation(%)	$\pm 2,3$	$\pm 2,8$	$\pm 2,1$	$\pm 2,5$	$\pm 4,8$
Mean	92,0	35,8	2,57	59,5	0,33
Max. deviation(%)	$\pm 2,5$	$\pm 2,0$	$\pm 2,1$	$\pm 2,1$	$\pm 3,7$

The slope area considered for damage was $750 \times 750 \text{ mm}^2$ on which 513 Dolosse were placed ('mean' packing, $\phi = 1,00$). The 'test area' extended from 255 mm below to 161 mm above still water level ($1,76 H_D$ to $1,11 H_D$ respectively). Below and above the 'test area', 120 g Dolosse were used while the underlayer was 43 mm thick, consisting of 11,4 g stone.

Test conditions and procedures

The same basic test procedures were followed as for the packing density tests. The tests were all done with regular waves of 1,75 s period using $2\frac{1}{2}$ min wave 'bursts' up to a total of 1 hour per wave height.

Tests No's D1 to D 3 and D 8 and D 9 were run with gradually increased wave heights whereas a sudden increase in wave height was used for Tests No's D 4 to D 7²².

Test results on Dolosse with different densities

A total of nine tests were done and the *test results* are shown in Fig. 9 which also shows the mean results for the six *progressive* tests. Considerable variations in the results of individual tests are again evident but the variations are seen to be less for the higher unit density. The 'suddenly' increased wave height tests show, on average, less stability for the $2,31 \text{ t/m}^3$ unit density (Fig. 9.a) but for the other two densities, the results of these tests *agree very well* with the mean of the 'progressive' increase tests (Figs. 9.b and c).

The comparison of the *mean lines* in Fig. 10 show an improvement in Dolos stability for increased unit density, which was expected. Although damage was below 2 per cent, the results compare very well with the results of the different packing density (N) series, for greater percentages damage the D series show greater stability (compare Figs. 4 and 10), which is thought to be mainly due to a shorter test time, i.e. larger wave height steps.^{13,22}

To check on the correctness of the *basic stability equation* the relative Dolos volumes were plotted, versus the relative submerged block density, similar to the plots in Fig. 8, and mean lines were drawn for the 1, 2, 5 and 10 per cent damage cases (displaced Dolosse). The *variation* in individual test results, however, was found to be much greater than for the Kydland and Sodefjed test data (based on stone) and no definite conclusion could be drawn from these test results with regard to the correct value for x . The large variation is probably *typical for Dolosse* because of the inherent differences in packing and subsequent interlocking, which does not apply to the same extent to stone.

It was therefore *concluded* that although increased unit density does increase Dolos stability, further tests with a greater range of unit densities are necessary to determine the correct relationship between stability and unit density. These tests are under way at present.²²

FIG. 10 COMPARISON OF MEAN TEST RESULTS FOR 2,31 ; 2,41 AND 2,57 SPECIFIC DOLOS DENSITIES

MEANS OF PROGRESSIVE TESTS

CONCLUSIONS AND RECOMMENDATIONS

It is absolutely essential to *standardize measuring and testing techniques* to make test results on Dolos stability compatible. Detailed proposals for standardization are made elsewhere²² but the main problem areas were found to be inconsistency in definitions and measurements of packing density, porosity, layer thickness (shape factor) and damage criteria which have led to unavoidable differences in reported test results from different laboratories.

Three *packing densities*, namely 'light' ($\emptyset = 0,83$), 'mean' ($\emptyset = 1,00$) and 'dense' ($\emptyset = 1,15$) have been defined in this paper and the corresponding layer thicknesses were found to be 1,72, 2,04 and 2,42 $V^{1/3}$, respectively, with a porosity of 51,5 per cent, independent of packing density.

Stability tests with a wave period of 1,75 s using these three *packing densities* showed little difference in damage, both based on displaced and displaced plus moving (rocking) units, the stability factor, K_D , being, on average, 24 and 16, respectively, for 2 per cent 'damage'. Wave reflection was found to be between 27 and 30 per cent, independent of placing density, but a difference of between 10 and 20 per cent was found between the wave run-up of the 'light' and 'dense' packing, depending on the wave steepness.

Taking also practical considerations into account, it is *recommended* that the 'mean' packing density be adopted for the 'first design' of a Dolos structure which should be checked by hydraulic model tests, preferably three-dimensional tests. Realistic wave conditions (e.g. irregular waves) should be reproduced in these tests and both displaced and rocking units should be carefully monitored. Tests should preferably include total destruction to determine the inherent safety of the structure.

Tests with model Dolosse having *different unit densities* (2,31, 2,41 and 2,57) showed greater stability for the higher densities but further tests with a greater unit density range are necessary to determine the relationship between stability and unit density.

CHAPTER 138

PERFORMANCE OF DOLOS BLOCKS IN AN OPEN CHANNEL SITUATION

ARTHUR BREBNER*

ABSTRACT

Tests on 100 gm model dolos units on the bed of an open-channel under steady state turbulent flow reveal that the dolos unit has no inherent interlocking property that would make it preferable to ordinary armour stone of the same weight in resisting movement. However interlocking can occur when dolos units are placed on a slope since the natural angle of repose of dolos units is much greater than that of ordinary armour stone, thus accounting for the enhanced K_D of dolosse in a breakwater situation.

INTRODUCTION

Model tests were conducted to compare the stability of dolos blocks, trunk width 0.35 times the overall height and mass 100 gm (0.23 lb) with rock armour of the same density and having an identical mass of 100 gm, in a steady flow of water in an open channel. Such tests could be thought of as tests preliminary to the construction of a barrier across a tidal inlet or as tests to compare the efficiency of dolosse with that of quarystone as protection against scour in a dam situation.

Most coastal laboratories have conducted extensive testing of both rock armour and dolos units for breakwater construction and it is generally agreed, for the same wave-height (approaching normally) and period, the same density of material and breakwater slope, that the weight of armour required for the stable-damage criteria is inversely proportional to K_D , the "hydraulic damage coefficient", which is directly related to the "shape" of the armour unit. Taking K_D as 4 for rock armour and 16 for the dolos block indicates that the latter unit can withstand a wave height

$$\sqrt[3]{\frac{16}{4}} = 1.58 \text{ times that for rock. Conversely a dolos unit of } 0.25$$

times the rock weight could withstand the same height of wave attack. It is assumed here that, for practical purposes, stability equations for rock are applicable to the dolos unit with its interlocking properties and its claimed high drag to weight coefficient and that "structural damage" is absent.

Coastal Engineering Laboratory,
Queen's University at Kingston, Canada.

RESULTS

With the superior behaviour of the dolos unit in an uprush and downrush wave situation one might reasonably expect that, in a free non-oscillatory current, this interlocking property could play a significant role in making the dolos unit more effective in resisting movement than an equal weight of quarrystone unit. However, a solitary unit would not behave much differently unless the drag coefficient was markedly different.

To determine whether the drag coefficients were markedly different many tests were carried out on individual dolosse and rocks in a wind tunnel and in a free stream of water. It was found experimentally that $C_D \times A$ or $C_L \times A$ where A is the projected area normal to the flow were essentially the same for a single dolos or a single rock. On the basis of these tests the effectiveness of the dolos unit is apparently entirely due to its interlocking properties.

Tests were now carried out in a tilting flume with a bed of rocks and a bed of dolosse of identical mass. With a constant flow rate the slope of the flume was gently increased so decreasing the depth over the bed and increasing the velocity.

The "wipe-out" velocity was essentially the same for both the quarrystone bed and the dolos bed. So much for interlocking in this situation! To have put in a dolos bed of 25% of the weight of a quarrystone bed - as one might have deduced from wave tests - would have meant that 25 gm dolos units would have 'wiped-out' at the same velocity as 25 gm rocks, namely, by Froude scaling, at a velocity of 0.8 times the "wipe-out" velocity for the 100 gm rock.

In an effort to discover why the dolos unit is effective as breakwater protection on a slope - usually 1:2 - but not on a horizontal bed, tests were carried out on the natural angle of repose of the rocks and the dolosse, both in air and water.

A box measuring 1 m x 0.5 m x 5 or 6 units thick was filled with either rocks or dolosse and gently vibrated on a concrete vibrating table. The box was then gradually tipped about the bottom edge. The packing angle for both rocks and dolosse was essentially the same, namely 40°. The failure angle of the rock was about 50° whereas the dolosse had an angle of repose of at least 80° - and in one remarkable test 91° (see Figure 1).

CONCLUSIONS

Thus, it may be concluded that the effectiveness of the dolos unit is not materially affected by the drag to weight ratio (which is similar to that of rock), but to its high natural angle of repose. However, this phenomenon can only be brought into play on a relatively steep slope and not on the horizontal. This would explain why dolos units are not as effective when the wave attack is

oblique (see H.R.S. Report IT159, April 1977 by A.F. Whillock" "Stability of Dolos Blocks Under Oblique Wave Attack"), and no more effective for scour protection in a horizontal situation than an equal weight of quarrystone. One can also suggest that the steeper the breakwater slope of dolosse when attacked by normal waves the better the dolos unit appears to be. Further one can also suggest that K_D for dolosse must be a function of breakwater slope.

A MODEL LAW FOR WAVE IMPACTS ON COASTAL STRUCTURES

by

C. Ramkema^{*}ABSTRACT

For the design of the storm surge barrier in the Eastern Scheldt, a study has been carried out on wave impacts against coastal and marine structures. First a review was made of relevant literature, including both wave impacts on coastal structures and slamming of sea-going vessels. From this, the so-called Bagnolds piston model emerged as most appropriate to describe the wave impacts caused by standing waves against protruding elements. This model was then further elaborated to include both adiabatic and isothermal compression of the air cushion and to allow for the compression of the water. Moreover, a model was developed to determine the spatial pressure distribution. Finally, experiments were performed, the results of which were in satisfactory agreement with the mathematical models. Based upon the results of these studies, a scaling law is presented here, from which the pressure magnitude and the time history of the impact in nature may be determined.

1 Scope of the Study

As part of the preliminary investigation for the development of the storm surge barrier in the Eastern Scheldt (Figure 1) tests were carried out to study the wave impacts on the sluice gates in this barrier. As a possible solution caissons placed on a rubble foundation were examined (Figure 2). Wave impacts induced by breaking waves were not observed here because of the relatively large foreshore depth; however, wave impacts might occur locally if the standing wave in front of the gate is impeded by protruding structural elements. Due to the specific shape of the structure, a volume of air is trapped between the protrusion and the rising water level which acts as a spring, resulting in a typical oscillating pattern of the impact pressure history. A literature study was made to find a suitable mathematical model which, after experimental verification, could be used for the conversion of these impacts to an impact in nature.

2 Review of Literature

The first effort to measure wave impacts on maritime structures was made by Stevenson [53] in Scerryvore Rocks 150 years ago. Until 1935 the measurements were performed with instruments unsuitable for these fast phenomena. The first excellent measurements with a high frequency range were executed in Dieppe by Rouville et al [49] and in a laboratory by Bagnold [5]. The development of mathematical wave impact and slamming models started with von Karman's model [31]. Because of the resemblance between the slamming phenomenon and the wave impact a historical review of investigations of both subjects is presented here, showing the relations between the various models (Figure 7).

The various mathematical models for wave impacts and slamming can be com-

bined into one general model (Figure 3), in which M_C is the mass of the construction; M_w is the equivalent hydraulic mass; and k_w , k_A and k_C are the spring constant of water, air and the construction respectively. For civil engineering constructions M_C is mostly much larger than M_w , whereas for ships and gates M_C and M_w are about equal.

The mathematical models in civil engineering can be divided into the way they take into account the importance of the compressed air layer with regard to the elasticity of the structure and the compressibility of water. Bagnolds model apparently is most appropriate to describe the impact against the protrusion, due to the specific air layer between the structure and the equivalent hydraulic mass.

The need for models in naval engineering first became apparent with the evident high pressures on V-shaped seaplane floats during landing. Later on, when the number of seaplanes decreased, impact pressures on high-speed ships stimulated research, as the calculated pressures on V-shaped wedges with the model developed by von Karman [31] were too conservative for these ships. Sellars [50,51] tried to explain the difference by accounting for the elasticity of the ship structure, whereas Verhagen [55] explains the difference by the elasticity of the air layer; the thickness of which is calculated by air flow between ship and water until the velocity of sound (C_A) is reached. For the subsequent stage he uses a Bagnold type piston model, with an air flow determined air layer thickness, for the determination of the impact pressure in which is accounted for the finite structure mass. However, the observed air layer between the caisson's protrusion and the water mass is mostly due to the specific shape of the protrusion and the water surface, so only the last part of Verhagen's model is appropriate for the description of our problem. Verhagen as well as Bagnold are supposing an adiabatic compression of the air layer.

Many experiments have been performed on civil and naval engineering structures, the results of which are generally expressed in the stagnation pressure: $\frac{1}{2} \rho v^2$, where ρ is the density of the water and v is the impact velocity. This is not further considered here, as in the impact process compressibility and air are certainly more important than the gravitational acceleration. Specially worth mentioning are the excellent experiments of Gerlach [21,22,23] in which the influence of liquid and gas properties and model shape on impact pressures of blunt rigid bodies is investigated. A more detailed literature description is in preparation by the author [44].

3 Theory

The observed air layer between the protruding element and the water mass gave evidence for the choice of Bagnold's piston model (in the tests $M_C \gg M_w$). Whether the compression of the air layer is adiabatic, isothermal or somewhere between depends upon such different factors as characteristic time of the phenomenon, the pressure magnitude, the air-water surface with regard to the air layer or bubble layer volume (the heat exchange by evaporation is much more important than by conductivity), the acceleration of the air-water surface and the irreversibility of the process. The significance of this question for model pressure conversion is evaluated in Paragraph 6.

Bagnold's model

The shape of the caisson and the protrusion is such that the phenomenon may be schematized as shown in Figure 4. A two-dimensional mass of water (M_w) with width $2L$ is travelling upward with a velocity v . For $z = \delta$ the

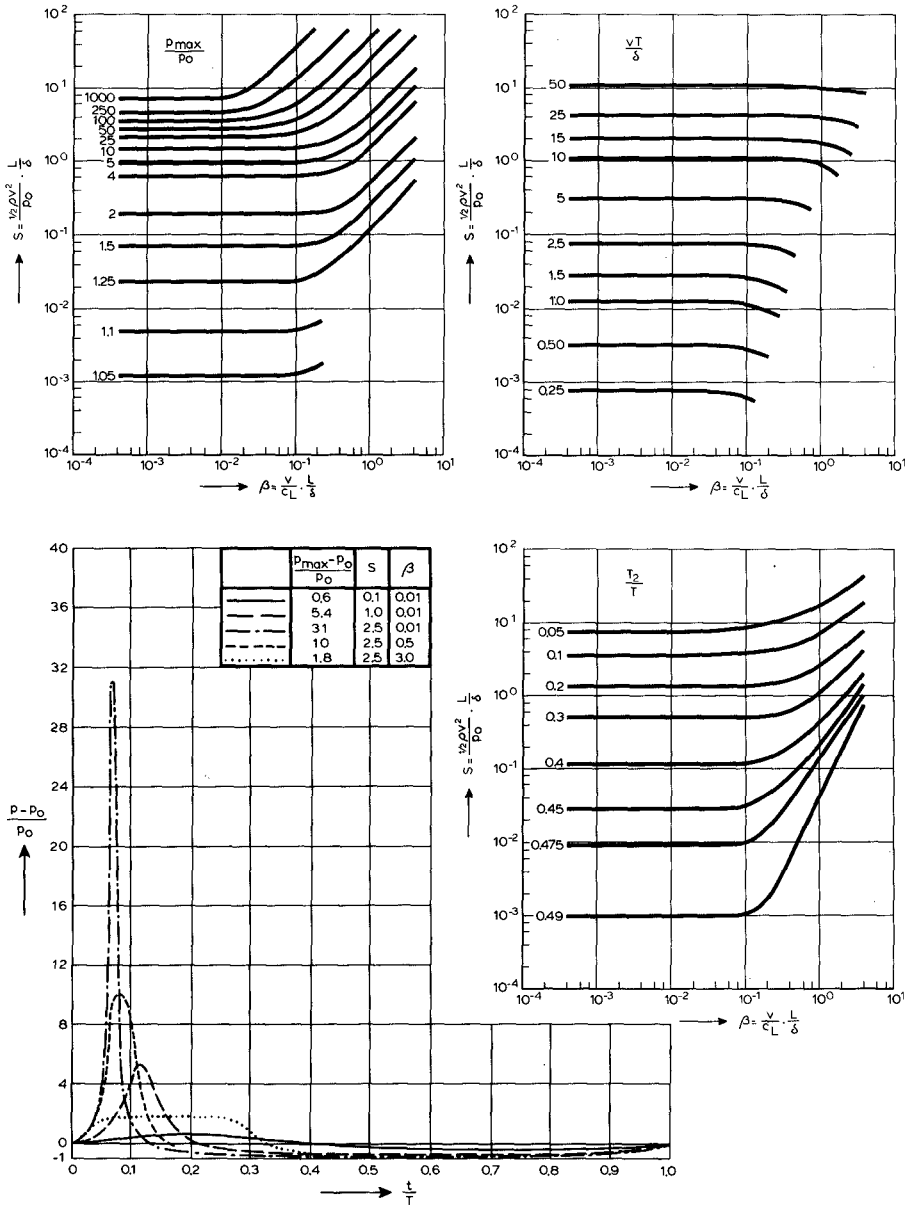

Fig. 8 Piston model with isothermal compression and compressible water: p_{max}/p_0 , $v T/\delta$ and T_2/T as a function of S and β

Fig. 9 Dimensionless peak pressure $(p_{max} - p_0)/p_0$ versus the impact number S for different compression models

Fig. 10 Spatial distribution of the impact-pressure

air layer is blocked from the atmospheric pressure p_0 ; if the hydraulic mass of water per unit length is approximated by ρL^2 [58] the equation of motion can be written as:

$$M_w \frac{d^2 z}{dt^2} = p_2 L - p_0 L. \quad (1)$$

Here, forces due to the acceleration of gravity are neglected because in the time intervals under consideration the weight of the water mass will be small in general compared with the impact load. Moreover, the weight is compensated by the hydrostatic pressure.

The air compression is assumed to vary between adiabatic and isothermal, so:

$$p = p_0 \left(\frac{\delta}{z}\right)^\gamma, \quad (2)$$

where γ is the ratio between the specific heat at constant pressure and that at constant volume. For a linear compression, $|1 - z/\delta| \ll 1$, and with the initial conditions $z = \delta$ and $z = -v$, the following expressions can be derived for the maximum pressure:

$$p_{\max} = p_0 \left[1 + \sqrt{2 \gamma \frac{\frac{1}{2} \rho v^2 L}{p_0 \delta}} \right] = p_0 \left[1 + \sqrt{2 \gamma S} \right]. \quad (3)$$

The frequency of the oscillation is:

$$f = \frac{1}{2\pi} \sqrt{\frac{\gamma p_0}{\delta \rho L}}, \quad (4)$$

where S is defined as the impact number. The general solution for the dimensionless peak pressure $p_{\max} - p_0$, which satisfies Equations (1) and (2) with the mentioned initial conditions, is shown as a function of S in Figure 9. The graph for adiabatic compression is equivalent to Mitsuyasu's [38] and Lundgren's graph [36]. For a more detailed description of this derivation, see Ramkema et al [43].

Bagnold's model with compressible water

One of the basic criticisms of Bagnold's piston model is that for high impact numbers the pressure exceeds $\rho v c_w$ (where c_w is the velocity of sound in water). The one-dimensional mathematical model given below takes into account the compressibility of water. The impulse equation formulated in Lagrange coordinates with the centre on the air-water surface is:

$$\frac{\partial^2 z}{\partial t^2} \cdot \frac{\partial z}{\partial a} + \frac{1}{\rho} \frac{\partial p_w}{\partial a} = 0, \quad (5)$$

and the continuity equation is:

$$\rho \frac{\partial z}{\partial a} = \rho_0, \quad (6)$$

where a is the position of the water particles at $t=0$, ρ_0 is the local density of water at $t=0$, ρ is the local density of water, and p_w is the pressure distribution in the water column. After some rearrangements and the supposition that $\rho^2 \frac{\partial p_w}{\partial \rho}$ can be approximated with $\rho_0^2 c_w^2$, the equations can be written as:

$$\frac{\partial^2 z}{\partial t^2} - c_w^2 \frac{\partial^2 z}{\partial a^2} = 0, \quad (7)$$

with the initial conditions $z = a$ and $\frac{\partial z}{\partial t} = v$ for $-L < a < 0$ and the boundary conditions $p = p_0$ for $a = -L$ and $p_w = p$ (pressure in the air layer) for $a = 0$. The results of this piston model with compressible water are shown in Figure 8. The dimensionless maximum impact pressure p_{max}/p_0 , the dimensionless impact period $v T/\delta$, and the shape parameter T_2/T are given as a function of the impact number S and the compressibility number $\beta = v L/\delta c_w$; the ratio of the characteristic time interval for the impact pressure δ/v and the characteristic time interval for the compression wave L/c_w . For $\beta < 0.1$ and $S < 2$, compressibility of water can be neglected as can be seen from Figure 8. More detailed information is given in Ramkema et al [44].

Spatial pressure distribution

By supposing an homogeneous pressure field in the direction perpendicular to the draft (Figure 6), it is evident that for a wave impact against the whole length of the protruding structural element ($2L$) the pressure distribution over the gate will be almost uniform for large $2L/h$ values. For a small ratio $2L/h$, however, the pressure distribution over the gate will decrease exponentially with increasing z . To quantify this supposition, a mathematical model was used to describe the phenomenon [43]. Supposing a two-dimensional pressure field, zero viscosity, an irrotational motion and an incompressible fluid, this problem is solved by determining the following velocity potential ϕ which satisfies Laplace's equation and the boundary conditions:

$$\frac{\partial \phi}{\partial z} = 0 \text{ at } z = h, x > 0 \text{ and at } z = 0, 0 < x < L_1$$

$$\frac{\partial \phi}{\partial x} = 0 \text{ at } 0 < z < h, x = 0$$

$$p = p_m \cos 2\pi ft \text{ at } z = 0, L_1 < x < 2L.$$

The condition on the free surface ($z = 0$) is generally:

$$g \frac{\partial \phi}{\partial z} + \frac{\partial^2 \phi}{\partial t^2} = -\frac{1}{\rho} \frac{\partial \rho}{\partial t}, \quad (8)$$

where g is the gravitational acceleration. For high frequencies, $g \frac{\partial \phi}{\partial z}$ can be neglected with regard to $\frac{\partial^2 \phi}{\partial t^2}$. The ratio of the pressure amplitude at $z = h$ and at $z = 0$ is shown in Figure 10 as a function of $2L/h$ for different $(2L - L_1)/2L$ values.

4 Experimental Set-up

To verify the frequency behaviour of Bagnold's piston model and the spatial pressure distribution over the gate, a variety of tests has been made. The tests were performed with random waves in a $95 \times 0.90 \times 1.0 \text{ m}^3$ wind wave flume (Figure 11) provided with a flap-type wave generator. A scale model (1:50) was constructed from stainless steel (thickness 20 mm), representing a vertical face fronted by a rectangular protrusion with different lengths (figures 12 and 13). In this model wave impacts were measured at four locations to determine the frequency behaviour, and at six locations for the spatial pressure distribution. The unused holes were filled up with screw bolts flush with the front face of the wall. The wave impacts were measured with Statham PM 131TC pressure cells. The overall accuracy of the amplitude response of the total measuring system was about 90% for a frequency range of 0-2400 Hz. A general impression

Fig. 11 Cross-section through wave channel

Fig. 12 Detail of test section

Fig. 13 Top view of test section

of the instrumental equipment for the tests is shown in Figure 6. The duration of each test was about 1000 zero crossing waves. However, the sensibility for wave impacts fluctuates strongly with the length of the protrusion and the water level with regard to the level of the protrusion. That is why the number of analysed impacts per test is not equal. Besides, only impacts $> 2000 \text{ N/m}^2$ were analysed. The tests for the spatial pressure distribution were limited to about 30 analysed wave impacts.

5 Experimental Results

In the investigation over 100 tests were made, a few of which had a geometry which could be used (see Tables 1 and 2) to test the given mathematical model. However, some general remarks based upon all the tests can be made:

- 1 The time history of the wave impact pressure can generally be described as a damped harmonic vibration. The impact frequency (f) is the reciprocal of the characteristic time of the vibration (Figure 14).
- 2 The impacts in the separated compartments AB and CD are uncorrelated for the frequency and the magnitude of the impact. However, the probability density functions for frequency and magnitude in the separated compartments are equal.
- 3 The pressure distribution in y-direction is about homogeneous in a compartment, with only a slight increase (about 10%) in the angles.
- 4 In general, the exceedance distribution for the impact pressure can be approximated, by a straight line, on logarithmic-linear paper. However, impacts smaller than 2000 N/m^2 are not taken into account (Figure 16).

To predict a maximum impact pressure it is necessary to know the maximum impact velocity, the minimum air layer thickness and the minimum protrusion length involved, but as a result of the mutual interactions this is extremely difficult. It is easier to predict the theoretical minimum impact frequency, which is a function of the maximum protrusion length involved and the maximum air layer thickness.

The impact frequency behaviour has been tested with four different lengths of the protruding element (Table 1). The analysed impacts did not exceed an impact pressure of $10,000 \text{ N/m}^2$ in model and the maximum air layer thickness could be visually estimated during the tests, being $1/10$ of the length of the protrusion. From each impact registration the impact pressure magnitude and the impact frequency were measured (Figure 15); the minimum and maximum value of the impact frequency are shown in the Table 1. With the visually estimated maximum air layer thickness and the length of the protrusion the theoretical minimum impact frequency can be calculated with Equation (4) for adiabatic ($\gamma = 1.4$) and isothermal compression ($\gamma = 1.0$). The linear approximation will be acceptable for impact pressures smaller than $10,000 \text{ N/m}^2$. The results of the comparison between the theoretical and the measured minimum impact frequency values is shown in Figure 18. It is evident that Bagnold's piston model is satisfactory for the prediction of the minimum impacts frequency, but whether the compression is adiabatic or isothermal cannot be concluded from this result.

The theory for the spatial pressure distribution over the gate was tested with the results of 7 tests carried out with 6 pressure cells, several of which were located in the protrusion. Depending upon the length $2L$, about 30 impacts of each test were analysed (as an example see Table 3 and Figure 17), and the coefficients, whose range is given in Table 2, were determined. The result of the comparison between the theoretical and the experimental maximum ratio p_B/p_{BB} is shown in Figure 19. As the theoretic-

Fig. 18 Minimum frequencies as a function of the length of the protrusion ($2L$)

Fig. 19 Extreme spatial pressure distribution for $x = 0$, as a function of $2L/h$

cal curve hardly changes for $0 < \frac{2L - L_1}{2L} < 0.125$, only one curve has been drawn for these values. The second curve in this figure describes the situation in which the whole protrusion is struck by the standing wave, but this situation does not give the maximum coefficients. Due to the limited dimensions of the pressure cell, the mentioned ratio will be slightly larger than the theoretical $p(h)/p(o)$ ratio, but the comparison is still very satisfactory. However, for $2L/h > 1$, the experimental values are substantial smaller than the theoretical values. This was confirmed by the observations, where two impacts could be distinguished: one in front of the gate and a second at the end of the protrusion. The pressure on the gate as a result of this second impact was negligible and difficult to separate from the first. The results presented are spatial pressure distributions for impacts in front of the gate which, consequently, do not confirm the theoretical model.

6 Model Law

Although the agreement between the model experiments and the linear piston model was satisfactory, non-linear effects cannot be neglected for full-scale processes. Therefore the non-linear adiabatic and isothermal compression models have been elaborated (Paragraph 3). In order to use these mathematical models for the conversion of model-to-nature impact characteristics, the type of thermo-dynamic process, the influence of compressibility and the scaling factor of the impact-number S have to be determined. Because the shape of caisson and water surface is determinant for the air layer thickness and the hydraulic mass involved, the scaling factor for δ and L is linear ($n_\delta = n_L$; $n_v = n_l$). The external water movement obeys Froude's law, so $n_v = \sqrt{n_l}$ where the atmospheric pressure is equal in model and nature ($n_{p_0} = 1$). This results in a linear scale for the impact number S , or $n_S = n_l$. The thermodynamic similarity is difficult to evaluate. Due to the larger air volume and the higher pressure, the process in nature will be more adiabatic, whereas as a result of the larger air-water surface, the longer characteristic period and the state of the water surface the process in nature will be more isothermal than in model tests. However, in general the non-linear isothermal conversion is a little (10% for $p_{max} < 10 p_0$) more conservative, so this model was chosen. The influence of the compressibility can be evaluated with the compressibility number ($\beta = vL/\delta c_w$). For the model investigation $v < 1$ m/s, $2L < 0.40$ m and $c_w = 1540$ m/s; the minimum air layer thickness will be estimated with Verhagen's [55] first approximation for one-sided outflow $\delta = v \cdot 2L/c_A$, where c_A is the velocity of sound in air (≈ 340 m/s). So the compressibility number in model (1:50) has a maximum value of 0.11 and a minimum value, for $\delta = 1/10.2 L$, or 0.007. In nature this value will vary between 0.11 and 0.05. As can be seen from Figure 8, the influence of compressibility can be neglected, for $\beta < 0.1$ and $p_{max}/p_0 < 10$. The isothermal compression model law is presented in Figure 20 for $\beta < 0.1$ and $p_{max}/p_0 < 10$. If a similar time history of the impact in model and nature is supposed, the time scale can be related to the pressure scale if the total momentum obeys Froude's law. However, in general the full-scale time history is not similar to that in model due to the effect of the atmospheric pressure p_0 , which is equal in model and nature. Pressure amplitudes in model will generally be small with respect to the atmospheric pressure whereas in nature minimum values may approach zero pressure. Therefore the shape of the pressure fluctuation in full-scale may show sharp crests and flat troughs contrary to the sinusoidal fluctuation in model. Elaboration of the dimensionless fluctuation period vT/δ with Figure 21 shows that

Fig. 20 Model-law for isothermal compression

Fig. 21 Example of impact conversion

Example: impact conversion for a scalefactor 50

Model impact : $p_{max} - p_0 = 20 \text{ kN/m}^2$
 $f_{model} = 400 \text{ Hz}$

$S_{model} = 0.015$

length scalefactor: 50

$S_{nature} = 0.75$

Nature impact : $p_{max} - p_0 = 380 \text{ kN/m}^2$
 $p_{min} - p_0 = 65 \text{ kN/m}^2$
 $f = 8 \text{ Hz}$
 $T_2/T = 0.26$

$n_{yT}/\delta = n_S^{1/2}$ for practical impact pressures ($p_{\max} < 10 p_0$).

With the help of Figure 20, p_{\max} , p_{\min} , T_2/T and T of the given model impact pressure can be converted to an impact in nature. See as an example Figure 21 for $n_S = 50$.

The spatial pressure distribution over the gate in nature will be geometrically similar to the impact in model.

7 Discussion and Comments

As a result of the fact that the minimum impact frequency can well be predicted with Bagnold's linear piston model a non-linear isothermal compression model law is presented. The conversion of model impact pressures can easily be done with the help of Figure 20. However, it is questionable whether the described model law for an impinging standing wave against the protrusion is comparable, for example, with a breaking wave against a composite breakwater.

A striking feature of the described impact pressures was the damped oscillation, but this phenomenon was also seen by Bagnold [5], Mitsuyasu [38] Rouville et al [49], Ross [48], Gerlach [21], Chuang [12] and many others. The observed combination of an air layer and a maximum impact pressure at the same location was also observed in investigations from Richert [45], Ross [48], Gerlach [21], etc. However, the observed damping of impact pressures by breaking waves against breakwaters is much larger, which can be explained by the larger pressure radiation for flat structures like a breakwater front compared with the "hollow" structure used for the present tests. The conversion of a wave impact of breaking waves against a breakwater is dominated by the question: which part of the wave height (H) is involved in the process in nature compared with that in model? Supposing the breaking wave in a scale model ($M_C \gg M_w$) has all the features (geometrical and kinematic) of the wave in nature, then the wave height involved is on a linear scale and so is the thickness of the air layer resulting from the concave part of the breaking wave front. At the limit (but hardly imaginable) the thickness of the air layer is determined by the air flow (see Verhagen [55]). The flatness of the water surface (parallel to the breakwater front) required for this air flow process, however, has a very low probability of occurrence, especially in breaking wave fronts and has therefore been neglected. So the scale factor for the impact number S is n_1 , under the supposition of a linear scale for the involved wave height and the air layer thickness. The measured impact on the breakwater model can now be converted to an impact in nature as far as peak pressure, characteristic time and shape of the impact are concerned. With the help of Weggels' or Richert's mathematical model, or with the model presented here with modified boundary conditions, the spatial pressure distribution can be calculated. The response function of the structure will finally determine the response to this impact force.
