Coastal Engineering

1976 PROCEEDINGS

RAD

PROCEEDINGS
OF THE
Fifteenth
Coastal Engineering
Conference

July 11-17, 1976 • Honolulu, Hawaii

Sponsored by the
State of Hawaii
University of Hawaii
American Society of Civil Engineers
through its Coastal Engineering Research Council
American Shore and Beach Preservation Association

Published by the American Society of Civil Engineers
345 East 47th Street, New York, N.Y., 10017

Price \$50.00

ACKNOWLEDGMENTS

The following served as the Organizing Committee for the Fifteenth International Conference on Coastal Engineering:

Charles L. Bretschneider
(Chairman)
Department of Ocean Engineering
University of Hawaii

J. Thomas O'Brien
J.K.K. Look Laboratory of
Oceanographic Engineering
University of Hawaii

Harold P. Brown
Conference Center
University of Hawaii

David S. D. Chung
U. S. Naval Facilities
Engineering Command
Pearl Harbor, Hawaii

Ada Marie B. O'Brien
Honolulu, Hawaii

S. Joseph Amaki
Department of Transportation
State of Hawaii

Howard A. Schirmer
Dames and Moore, Engineers
Honolulu, Hawaii

Karl V. Keller
Pacific Division, Corps of
Engineers, U. S. Army
Honolulu, Hawaii

Frederick A. Zobrist
Neighbor Island Consultants

Appreciation is expressed to the Department of Planning and Economic Development of the State of Hawaii and the Hawaii Visitors Bureau for providing the many photographs appearing on the title pages for the various parts of the proceedings.

REVISIONS IN WAVE DATA PRESENTATION

LAURENCE DRAPER

Institute of Oceanographic Sciences
Wormley, Godalming, U.K.

In 1966 the author proposed, at the Tenth Conference on Coastal Engineering, methods (Reference 1) of presentation of wave data which were thought likely to be useful to the engineering user. Data obtained from many recording stations have been processed and presented in the formats proposed, and appear to have been able to provide answers to many of the wave questions posed by engineers. However, from time to time additional questions arise, and improvements in technology enable answers to more sophisticated questions to be given. The purpose of this paper is to describe the additions thought necessary to cope with these changes; there are no alterations to the 1966 presentation methods, only additions.

Extreme waves

In the last decade the ability to estimate the likely height of the highest individual wave in some long period of time, say 50 or 100 years, has assumed a new importance. The methods employed all rely on the extrapolation of measured sets of data, but as no one method has an impeccable theoretical parentage several methods have to be resorted to. Considerable effort has been put into such work by this Institute and at present the log-normal, Gumbel and Weibull distributions are used on each set of data.

Persistence

In the original paper the only recommendation made concerning persistence dealt with the persistence of wave conditions with heights at and above given thresholds; this is used mainly in connexion with the estimation of downtime, and is now known as the Persistence of Storms. However, in rougher sea areas it becomes necessary to quantify the number and duration of quiet spells, so that working time on operations such as pipelaying, which can only proceed in prolonged calm conditions, can be estimated. This is known as the Persistence of Calms. It is not possible to derive the Persistence of Calms from the Persistence of Storms, or vice versa.

Figure 1. Presentation of hypothetical wave spectra illustrating the characteristics of swell and locally-generated waves

One-dimensional spectra

The most important improvement stems from the arrival of data-logging equipment and the ability to produce spectra on a routine basis at an acceptable cost. A publication listing spectral data for 3000 wave records, the number commonly obtained in a year, would not be easy to comprehend unless the spectra could be extremely condensed. It now seems likely that spectra for a month can be presented on one page in a form which can be assimilated by visual inspection and yet which can give quantitative results. This is an extension suggested by M.J. Tucker to the method used by Snodgrass et al. (Reference 2) in the Pacific swell attenuation study. Each spectrum is presented as a column of numbers giving the energy density in $\text{metres}^2/\text{Hz}$ each plotted at its appropriate frequency level. Subsequent spectra are displayed in the same way one after another and then contours of wave energy are drawn. A hypothetical result is given in figure 1. Apart from giving the actual data, the method identifies immediately where the waves are under generation and where swell is arriving from a distant storm. The arrival of swell is characterized by the appearance of low-energy long-period waves whose energy gradually increases as the frequency increases (period decreases) so that the contours are aligned upwards to the right; in contrast, with locally generated waves the energy and wave period increase together and the contours align downwards to the right. This presentation is a powerful method for the identification of the wave regime at any given time. Once a potentially dangerous time (for the engineer) is defined, the full details of the spectra can be obtained from the original data. Returning to the figure, which is a hypothetical demonstration of this type of presentation, it shows the appearance of swell between days 1 and 3; the slope of a line drawn along the ridge can enable the distance of the source (storm) to be calculated. About noon on day 4 a local storm is beginning to generate waves of increasing period; this continues to day 6, after which calm conditions return.

Actual examples are given in Figures 2 and 3. These present data from a Waverider Buoy situated 6 miles to the west of the island of South Uist in the Outer Hebrides, north west Scotland. Figure 2 illustrates fairly rough conditions with significant heights up to 5.72 m. The highest energy concentrations lie between about 9 and 16 seconds period. The figure covers the time between 10.59 hours on day 100 (9 April) and 0759 hours on day 105 (14 April). The second illustration, figure 3, covers the time between 10.56 hours on day 115 (24 April) and 0459 on day 120 (29 April). It is a time of lower waves, significant heights up to 1.24 m, with a swell of about 9 seconds dying away and another swell of 15 or 16 seconds arriving, reducing in period and dying away. There is a

Fig 2

Actual spectra for five days with significant wave height and zero-crossing period calculated from each spectrum

WEST OF SOUTH UIST, OUTER HEBRIDES

Fig 3

Actual spectra for five days with significant wave height and zero-crossing period calculated from each spectrum

small amount of local wave generation at about 3 seconds, probably due to winds of around 10 knots. In these cases, to make the presentation more complete, the significant wave height in metres and the zero crossing period in seconds are given below each column. In these two figures the data are not as condensed as in the hypothetical case, figure 1, and because there were several sources of wave energy in the North Atlantic at the time the picture is not as simple as in the idealized figure 1.

Sea-bed waves

With the improvement in techniques there is the possibility of presenting on a routine basis information on the magnitude of the wave motion at the sea bed. This can be done either as spectra in an analogous way to the presentation of surface data, or in a more condensed way as was done for some wave data around the U.K. This is by means of an exceedance diagram for wave-induced particle speeds at the sea bed (Reference 3).

Titles of graphs at present proposed for data presentation:

- | | |
|---|-----|
| (1) Wave Height Exceedance - one for each season. | |
| (2) Zero-crossing Period Histogram - one for each season. | |
| (3) Spectral Width Parameter - annual. | |

| (5) Persistence of Storms - annual. | |
| (6) Persistence of Calms - annual. | New |
| (7) Extreme Waves - several methods - annual.
1 method at present. | New |
| (8) Spectra if available. | New |
| (9) Sea Bed Spectra if available and desirable. | New |
| (10) Sea Bed particle speed exceedance if surface
spectra available. | New |

ACKNOWLEDGEMENTS

The author gratefully acknowledges the willing assistance of several consultant and university engineers who discussed the proposals in detail and made valuable suggestions. The cooperation of his colleagues, especially Mr E.G. Pitt in the provision of the examples of the spectral presentation, is very much appreciated.

CHAPTER 2

WAVE CLIMATE ANALYSIS FOR ENGINEERING PURPOSE

by Hans H. DETTE ¹⁾ and Alfred FÖHRBÖTER ²⁾

ABSTRACT

The North Sea (Fig. 1) is known as a random sea with depths in the southern part between 40 m and 100 m so that in contrary to the Atlantic and Pacific coastlines deep sea wave conditions do not exist. After four years of comprehensive wave measurements in the offshore area of the Island of Sylt near the Danish border a general analysis of the wave climate in that region was possible. In this paper results and suggestions will be presented under the aspect of replacing qualitative judgements by quantitative statements which are derived from the knowledge of the adjacent wave climate. Because the wave action varies from year to year a general time unit is not advisable for the evaluation of shore processes; therefore the time scale should be substituted by the integral of incoming wave energy occurring after a certain time. The investigated method of expressing the total energy of one season or one year in the electrical unit Kilowatthour (kWh) per meter (m) width of shoreline could prove in future as a feasible way of classifying the irregular seasonal and yearly wave intensities.

It is further shown that wave measurements over a period of several years can be sufficient for the investigation of correlations between the wind velocities occurring from all directions and the resulting wave heights. In case of satisfying correlation factors it will then be possible to carry out feedback operations for periods from which only records of wind velocities and directions are available and even to hindcast the wave heights for certain not yet measured wind velocities.

¹⁾ Oberingenieur Dr.-Ing., ²⁾ Prof. Dr.-Ing. and Director of Leichtweiss-Institut für Wasserbau of the Techn. Univ. Braunschweig, Germany, Div. of Hydrodyn. and Coastal Eng.

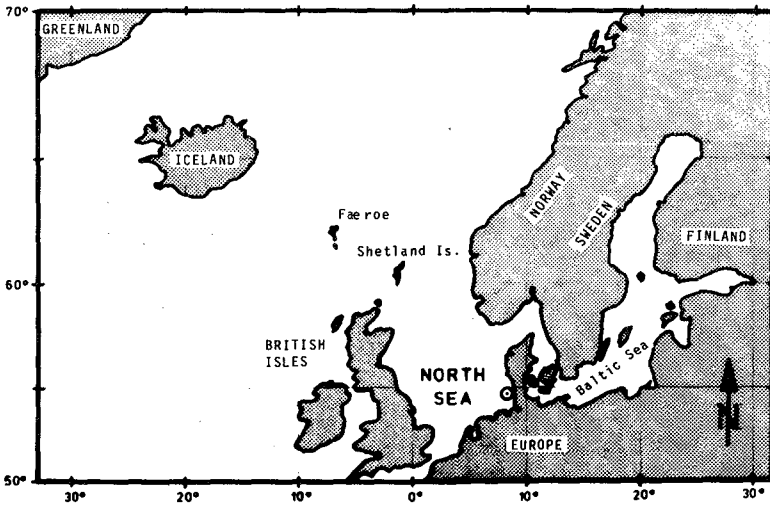

Fig. 1: Location of the North Sea with the region of wave climate analysis

INTRODUCTION

The analysis of the wave climate at a certain location by means of longterm measurements is usually aimed at the investigation of extreme wave parameters and the exceedance frequencies of the maximum or significant wave heights. These informations are needed for the design of offshore structures and coastal protection works. Besides it is often desirable to get some further information about the wave pattern which will normally have to be expected or taken into consideration during certain months or seasons within the year. This is of interest for the determination of the execution time.

Another point of interest is the knowledge of the wave intensity during a certain period or after the completion of an activity. Such informations are especially needed with regard to the feasibility of mobile coastal protection works - e. g. beach nourishments in which sand is used in large amounts as material of construction. As such measures do not grant a protection for ever they will have to be repeated from time to time depending upon the intensity of waves in that region. For this purpose it is necessary to find quantita-

tive statements as it has been for example suggested by the definition of a "half decay time" of a nourishment (FOHRBÖTER 1974) as that point when a nourishment should be renewed.

WAVE RECORDS AND ANALYSIS

With regard to the above mentioned necessities and in order to evaluate an artificial beach nourishment with more than $1.000.000 \text{ m}^3$ of sand dumped in 1972 at Sylt through an extensive surf zone a comprehensive wave measuring program was carried out from 1971 to 1974. Four ultrasonic wave recorders were laid out up to a distance of 1.3 km from the shoreline; from which three stations were located seaward of a longshore bar extending at a distance of 300 m from the shoreline, whereas the fourth was placed in the trough between longshore bar and the beach (Fig. 2).

Fig. 2: Wave measuring profile

At least twice a day, about high and low water the waves were recorded simultaneously for a period of 15 minutes. According to a special program, depending upon the actual prevailing wave heights, records were carried out at shorter intervals up to continuous records during heavy storm surges.

For the determination of the statistical wave height parameters (H_{max} , H_s , and H_m) and the wave periods a sequence of 100 waves within the 15 minute record was selected and the zero-up crossing method was applied as suggested by DRAPER, 1966.

Within the four years of measurements a maximum wave height $H_{max} = 7.2$ m was measured at a distance of 1.3 km from the shoreline at position W_4 (Fig. 2).

From a series of several hundred single records the following statistical relationships were obtained (position W_3):

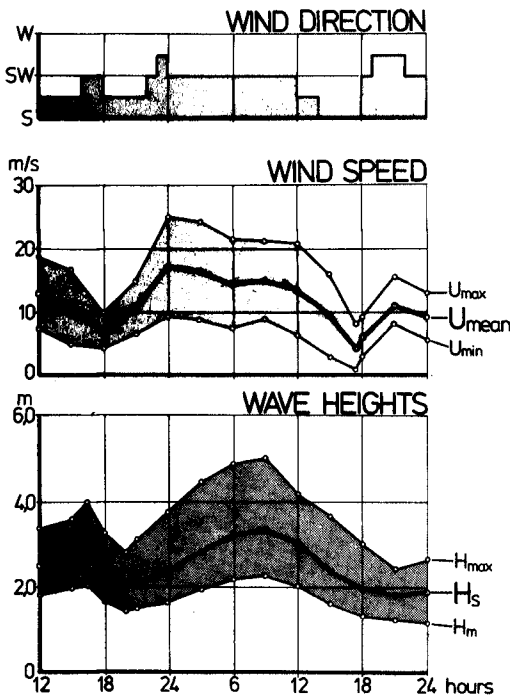

$$H_{max} / H_m = 2.07$$

$$H_{max} / H_s = 1.44$$

$$H_s / H_m = 1.44$$

WIND-WAVE CORRELATIONS

Based on the high number of single records relations between the mean

local wind velocities and the wave heights measured seaward of the longshore bar at position W_3 (Fig. 2) could be carried out by means of electronic computations. For this purpose the hourly records of wind direction and velocity were available from a meteorological station near the wave measuring profile for the period from 1965 to April 1976. General relationships between wind and waves are shown on Figure 3 for a storm period in February 1973. Besides a phase shifting of several hours can be seen between the maxima and minima of wind and wave height records.

Fig. 3: Wind and Wave height conditions during a storm in February 1973

Figure 4 demonstrates the frequency and directional distribution of the hourly wind records in the years from 1965 to 1976. During nearly 20 per cent of the considered time wind velocities higher than $U_{\text{mean}} = 10 \text{ m/s}$ with significant wave heights $H_s \approx 2 \text{ m}$ were predominant. The storm causing wind directions are ranging from South of Southwest (SSW) up to West of Northwest (WNW) with a resultant direction lying in between WSW and W.

Fig. 4: Frequency and directional distribution of wind records (1965 to 1976)

For wind sectors of 22.5° correlations between the wave generating wind directions ranging from South to Northwest (Fig. 4) and the significant wave heights measured at position W_3 (Fig. 2) were carried out for time differences from one hour up to six hours and besides for the mean wind velocity and direction prevailing during the first to third, the second to fourth and the third to fifth hour before the wave measurement.

The best correlations for all sectors were found for the mean wind direction and velocity prevailing during the second to fourth hour,

The following correlation coefficients were obtained:

Wind Direction	Correlation Coefficient R
S	0.55
SSW	0.80
SW	0.79
WSW	0.91
W	0.96
WNW	0.88
NW	0.49

For the different wave generating wind sectors the measured significant wave heights H_s are plotted as function of the mean wind velocities U_{mean} on Figure 5. Within the wave measuring period from 1971 to 1974 the following highest mean wind velocities lasting for three hours and associated wave heights occurred:

Wind Direction	Mean Wind Velocity for 3 Hours	Significant Wave Height
-	m/s	m
S	12.0	2.7
SSW	14.5	3.2
SW	15.0	3.8
WSW	23.5	5.2
W	22.0	5.2
WNW	20.5	4.9

Additionally the regression lines are drawn for the single wind directions in Figure 5, so that for higher not yet recorded wind velocities the significant wave heights may be extrapolated. The maximum wave heights can be determined by using the already mentioned relationship

$$H_{\text{max}} = 1.44 H_s$$

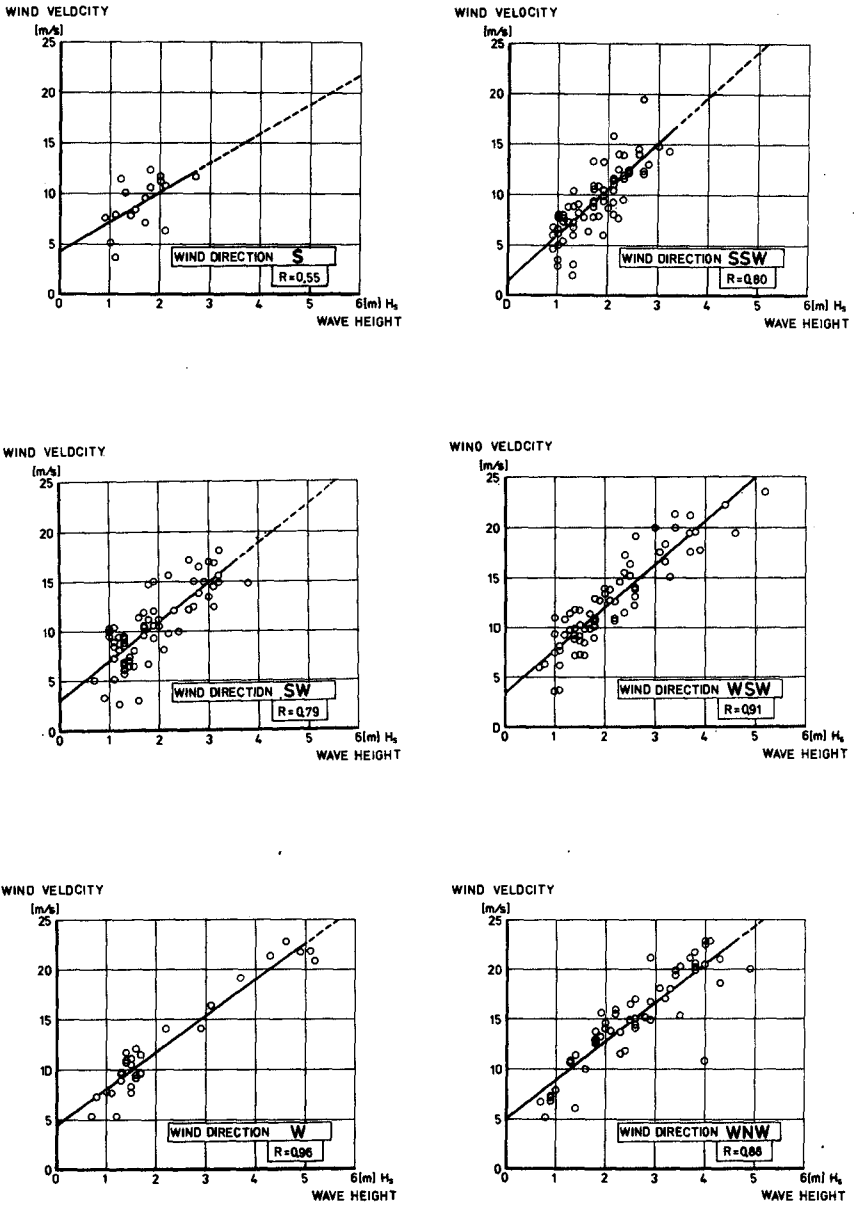

Fig. 5: Correlations between local wind velocities and significant wave heights

Based on the above investigated relationships which yielded satisfying correlations it could be proved that a wave measuring period of a few years can be sufficient in order to find reliable statistical parameters between the wave generating factors and the existing wave heights. The wave measuring period can be regarded as the calibration phase within the effort to evaluate the longterm wave climate in the years before (= feedback operation) and after the wave measurements when only wind data are available which can be obtained with a minimum of efforts and expenses.

In the following a further application of the suggested concept will be presented with regard to the aim of finding objective statements for the evaluation of processes caused by wave action.

WAVE ENERGY LOAD

Because the wave action varies from year to year a general time unit is not advisable for the evaluation of the durability of an offshore structure or a coastal protection work. The time scale should be substituted by a distorted time scale by means of computing the integral of the incoming wave energy load per unit width of wave front. The method of expressing the total wave energy load of one season or one year in the electrical unit Kilowatthour (kWh) per meter width of shoreline is regarded as a feasible way of classifying in future the irregular seasonal wave intensities.

By application of the linear wave theory and inserting the significant wave height $H_{s(j,i)}$ computed from the hourly wind records by the above mentioned correlation the single hourly wave loads \bar{N} were determined for the period from 1965 to 1976 and classified according to different criteria.

The incoming wave load \bar{N} , expressed in the electrical unit kWh per meter width of shoreline was determined in the following way:

$$\bar{N} = 1.225 \cdot c \cdot \Delta t \sum_{j=1}^{24} \sum_{i=1}^{365} H_s^2$$

with $H_s = H_{s(j,i)}$ = wave height at the hour j in the year i

$c = \sqrt{g \cdot d}$ = wave velocity at position W_3 (Fig. 2)

$d = 10$ m = constant = mean water depth at position W_3

$\Delta t = 1$ = one hour

It is no doubt that the above assumptions incorporate uncertainties and rough assumptions with regard to a quantitative reliability. Therefore the calculated wave energy loads are not considered from the quantitative point of view, the method is mainly regarded as a reliable basis for the demonstration of the irregular seasonal wave intensities as it is shown on Figure 6 for the period from 1965 (starting with the month of April) up to the end of March 1976

Fig. 6: Monthly wave energy load at position W_3 within the period from 1965 up to 1976

With regard to the classification of the yearly wave energy load as it is demonstrated on Figure 7 the total wave energy load per year (left axis on Figure 7) should be neglected as already mentioned; instead the mean of the

considered period (= 100 per cent) should be determined and deviations from the mean should be expressed in percentage (right axis).

Fig. 7: Yearly wave energy loads in the years from 1965 to 1976

So for example the wave intensity could be classified by means of deviations from the mean wave load as follows:

- > 110 % = high
- 90-110 % = normal
- < 90 % = low

The next figures may help to estimate depending upon the long-term wave climate the risks when a work has to be carried out for example during a certain month or season within the year. Figure 8 shows the classification of the single monthly wave energy loads according to the months and seasons of the year for the period from 1965 to 1976. On Figure 9 the sum of the monthly wave energy loads over the same period has been summarized and the deviations from the mean can be seen.

Finally the consideration of incoming wave energy load can be useful with regard to the resultant direction of wave attack which will give an idea into which longshore direction there will have to be expected a net transport of sediments. From Figure 10 it is obvious that there will be surplus of movements in northern direction for the period from 1965 to 1976.

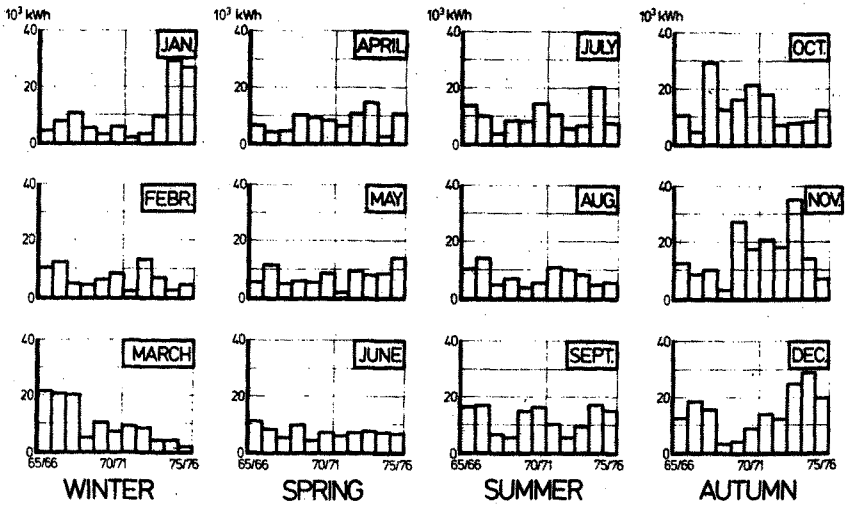

Fig. 8: Classification of the wave energy load according to the months of the year within the period from 1965 to 1976

Fig. 9: Total wave energy loads for the months of the year for 1965 to 1976

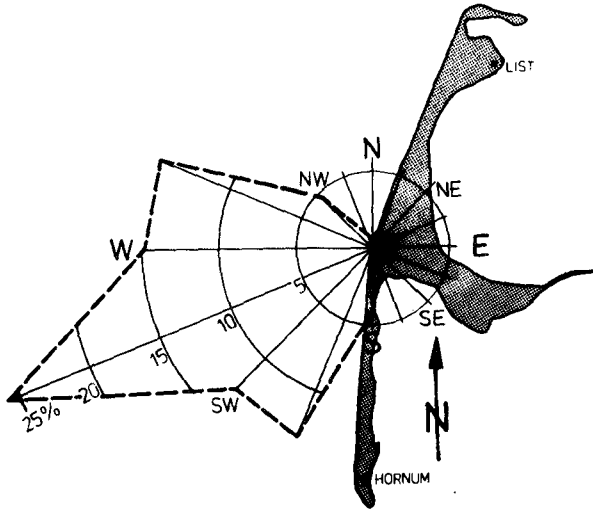

Fig. 10: Frequency and directional distribution of wave energy load for the period from 1965 to 1976

CONCLUSIONS

The attempt to point out relationships between wind velocities occurring from different directions and the wave heights was possible by means of extensive electronic computations. In case it is possible to prove also satisfying correlations for other places of interest the suggested method could be applied in order to receive an objective knowledge of the long-term wave climate and to facilitate the evaluation of processes caused by wave action for an engineer.

CHAPTER 3

WAVES USED FOR INTER-TIDAL DESIGN AND CONSTRUCTION

BY

D. C. KEILLER and T. D. RUXTON,

BINNIE & PARTNERS, LONDON

Introduction

1. The selection of suitable design criteria and methods of construction for works on inter-tidal sand flats has played an important part in a recently completed study (1) which examines the feasibility of storing fresh water in bunded reservoirs built on the foreshore of the Wash bay in the east coast of England (figure 1). Wave, wind and tide conditions have been monitored in the bay for 3 years to provide the information needed for design and construction. Experience gained during the construction of a 15m high trial embankment (figure 2) located 1m below mean sea level and 5 km from the sea defence bank has enabled us to examine the economy of construction methods. Short and long term observations on the bank will provide data on the performance of rip rap surface protection in field conditions.

2. The Wash is an approximately square bay extending over an area of 600km^2 with an entrance 20km wide. Mean spring tides in the bay have a range of 6.4m and tides with ranges above 8.0m are predicted to occur once or twice a year. The large tidal range is associated with extensive foreshores. At low water of a spring tide approximately half the area of the bay is exposed revealing sand and mud flats which in places extend 8km from the sea defence banks. The problems associated with the accurate measurement of water levels in this area with its extensive sand flats have been described by Pugh and Waller (7).

Wave measurement programmes

3. At the commencement of the study there was very little information available on wave conditions in the Wash. To remedy this situation we initiated two separate programmes of wave observation. Three wave recorders were mounted on the foreshore in an area exposed at low water to record wave conditions over the inter-tidal sand flats. These records were obtained for a 15 minute period each tide close to high water. Anemometers installed on the edge of the bay provided a continuous record of wind conditions. The installation and early results from these instruments have been described by Driver and Pitt (3). The second programme of wave observation was the visual estimation of wave height by the skippers of the pilot cutter serving the port of King's Lynn. These seamen observed wave conditions almost every tide at 3 buoys marking the shipping channel which

cuts through the inter-tidal sand flats. Data were obtained from both instrumental and visual programmes for a period of 3 years (1972 - 1975)

4. The aims of the two wave observation programmes were complementary. The storm wave data obtained by the wave recorders were to be used in conjunction with the locally measured wind data and also wind data from long established recording stations to define the wave conditions that should be used for the design of rip rap surface protection for permanent reservoir embankments founded on the foreshores of the southern Wash. The visual estimates of wave height were to show the distribution of typical wave heights experienced in the Wash and the significance of seasonal variations. These results combined with the experience of contractors working in the Wash would enable us to estimate the likely proportion of time wave conditions would limit construction work on the inter-tidal sand flats.

Storm wave conditions on the SE foreshore of the Wash

Wind conditions associated with storm waves

5. An analysis of the operation of the wave recorders during the 3 year study period showed that waves with a significant height of at least 0.5m were recorded on 48 separate tides. The largest waves were as expected associated with NW, N and NE winds since the longest overwater fetches are from these directions. In general, larger waves were associated with stronger winds, though this effect was masked by the influence of tide level on wave height. The largest waves were recorded during storms which coincided with the high waters of spring tides.

6. On every recorded occasion except one a 10m/s wind from the NW, N or NE at high water resulted in 0.5m waves at one or more recorders. The exception occurred at a time when only one recorder (site 1) was operational. There are however many occasions when similar wind speeds and directions occurring at low water failed to generate 0.5m waves at any of the recorders the following high water. This highlighted the fact that waves are generated over the inter-tidal foreshore only when a storm coincides with high water. On such occasions the maximum waves associated with the wind are quickly generated because of the short fetches which exist in almost all directions. For example a NW wind of 20m/s at high water would generate fetch-limited waves at the recorder sites after about $1\frac{1}{2}$ hours.

Analysis of storm wave records

7. The wave recorder output was analysed using the method proposed by Tucker (9) as modified by Draper (2). The data are summarised in figure 3 which shows the significant wave heights and zero crossing periods

recorded at each site. Results have only been included for those occasions (tides) at each site when the recorded significant wave height was at least 0.5m. There were 33 such tides at site 1, 20 at site 2 and 35 at site 3 between September 1972 and May 1975.

8. The wave heights and periods recorded at each site are broadly similar with the highest waves generally being recorded at site 3. The two largest individual values of significant wave height were, however obtained from the recorder at site 1 where significant heights of 2.4m and 1.6m were recorded. The wave heights at site 2 were latterly generally lower than elsewhere. This is thought to result from a 1m increase in bed level during the winter 1973/74.

9. There is only a very weak correlation between the height and period of recorded waves.

10. The wave height distributions (figure 3) cannot be compared in detail because the waves recorded at each site did not all occur on the same occasions. Comparisons may better be made by comparing the differences between the observed waves and those predicted for each occasion by a standard wave-forecasting routine. Although deep-water wave prediction routines cannot be expected to give accurate answers in shallow water, they do provide a standard for comparison taking account of wind speed, duration, direction and fetch length. The differences between the observed and predicted wave conditions will indicate the influence of the shallow and varying water depth on wave generation, refraction, shoaling and friction.

11. Wave hindcasts have been made using the Sverdrup-Munk-Bretschneider (S-M-B) deep water wave forecasting charts (6) for each site on every tide that the significant wave height was at least 0.5m. The waves were hindcast using the average wind speed over a period long enough to generate fetch limited waves. On each occasion the fetch was calculated for high water of a spring tide assuming all wave generation to occur within the confines of the bay. No allowance was made for the effects of refraction in the calculation of fetch.

12. The ratio of observed significant wave height (H_s) to hindcast significant wave height (H_o) has been plotted against water depth for site 1 alone and sites 2 and 3 together on figure 4. The best fit straight lines to each set of wave height data are shown. The results show a rapid increase in wave height ratio with water depth at site 1 but much smaller changes in wave height ratio with water depth at sites 2 and 3. Bounding lines spaced two standard deviations from the mean are also included. Consideration was given to plotting the H_s/H_o ratio against water level relative to Ordnance Datum and using this relationship for the subsequent analysis and design instead of one incorporating water depth. The observed reduction in wave heights at site 2 (paragraph 8) following the rise in sea bed level suggested the use of water depth rather than water level. Furthermore in considering

wave heights at different foreshore levels the use of water depth proved to be more convenient than water level. The bed configuration seaward of the reservoir sites does not include banks or bars that would invalidate the use of water depth and the increase in fetch with increasing depth (due to higher water levels) was shown to have no marked effect on the results at site 2.

13. The magnitude of the random errors that have been introduced into the calculation of wave height by the method of analysis of the wave records (paragraph 7) are fairly significant. These random errors alone are estimated to cause a standard deviation in the wave height ratio of around 13%. The measured standard deviation for the observations from sites 2 and 3 is about 20%. The standard deviation of the observations for site 1 is greater at about 27%, due largely to the two occasions when the wave height ratio exceeded 1.4.

14. These two occasions are interesting as these were also the occasions of the largest waves recorded during the study. The operation and calibration of the wave recorder appeared normal on both occasions. The most likely explanation for these exceptional wave heights is that the recorder was situated close to a point where wave energy was concentrated by wave refraction during both storms. The greater sensitivity of wave height ratio to water depth at site 1 when compared to sites 2 and 3 may also be indicative of a concentration of wave energy resulting from wave refraction as such concentrations depend on water depth as well as wave period.

Extreme storm conditions

Extreme wind conditions

15. The installation of anemometers on the shore of the Wash in 1972 provided the first continuous records of winds in the bay. In the past wind records have been collected at Spurn Head (figure 1) which is 50km north of Gibraltar Point. Wind records are also available at several nearby inland sites including a long record at Cranwell (figure 1) 55km west of Gibraltar Point. As the Wash anemometers have only operated for three years there are insufficient data available for them to be used to give reliable estimates of wind speeds occurring less frequently than once in 5 years.

16. The British Meteorological Office was commissioned to examine the relationship between wind speeds at Gibraltar Point and Cranwell with a view to using the long record available at Cranwell to estimate extreme winds at Gibraltar Point. Cranwell was chosen for this comparison as it was the site nearest the Wash with broadly similar wind characteristics and a long record. Initial comparisons indicated that wind direction and strengths at the two sites were usually similar.

17. The results of the comparison of hourly mean wind speeds confirmed that on average the differences in wind speed between Gibraltar Point and Cranwell were fairly small. Despite this apparent similarity the main significance of the regression equations linking the two stations was that the estimates of wind speed at Gibraltar Point using Cranwell data were poor. If corrections were made to the regression equations based on the wind direction, the difference between the observed and estimated wind speed at Gibraltar Point was reduced. Even with this improvement the standard error of estimate was between $1\frac{1}{2}$ and 2m/s . The use of Cranwell data to estimate wind speeds at Gibraltar Point on particular occasions is thus ruled out.

18. The regression equations linking wind speeds at Gibraltar Point with those at Cranwell are considered adequate to estimate the broad characteristics of winds at Gibraltar Point. The evidence from Cranwell suggests for example that gale force winds (speeds 17m/s) from the NE are rare at Gibraltar Point. The examination showed that large errors would result from the use of the regression equations during individual storms. This prevents us estimating extreme wind conditions at one site on the basis of extreme conditions at the other and is due to many complex effects which influence the relationship on particular occasions. These effects may be expected to be especially pronounced during extreme storms.

19. The meteorological office considered that more reliable estimates would be provided from wind maps prepared by Hardman, Helliwell and Hopkins (4). These wind maps have been updated to take account of extreme winds in East Anglia up to June 1975 and the estimates for the Wash (figure 5) taken off these maps show a wind speed of 29.2m/s (57kt) to have a return period of 50 years. The wind speed frequencies apply to a point in the centre of the entrance to the Wash.

20. The wind directions associated with very high wind speeds cannot be estimated in the same way as the extreme wind speed. Some indication of the most likely directions of extreme winds is provided by the records from Spurn Head from 1922 to 1958. An examination of the directions associated with hourly mean wind speeds of at least 21m/s showed (Table 1 below) that although the most common direction for high winds was W, almost half the occurrences were associated with N or NW winds which are able to generate some of the largest waves in the Wash. There were no recorded occasions of similar NE or S winds at Spurn Head. The large proportion of high winds associated with W, NW and N winds is a feature of observations made along the NE coast of England. Although there may be some differences between the winds at Spurn Head and the Wash, the Spurn Head data are used in the subsequent analysis.

Wind direction	S	SW	W	NW	N	NE	E	SE
Percentage of occasions	0	7	33	30	19	0	7	4

Table 1: Directions associated with mean wind speeds \geq 21 m/s at Spurn Head.

Extreme wind speeds at high water

21. The probability that extreme wind conditions will occur during a high water period is lower than the probability of these winds occurring at any state of the tide. There is only a 1 in 4 chance that the maximum hourly mean wind speed during a storm will coincide with a three hour period at high water. From an analysis of storms recorded at Lerwick, Shellard (8) has estimated the ratio of maximum wind speeds averaged over varying numbers of hours to the maximum speeds over one hour. Shellard considered that these ratios could be used to estimate the wind speeds which, when averaged over different numbers of hours, had the same frequency of occurrence each year as the maximum mean hourly wind speed.

22. The wind ratios derived by Shellard (8) for Lerwick have been applied to the Wash data to estimate the frequency of occurrence of combinations of wind speed and duration (figure 5). In our calculation of duration, the wind speed was assumed to be above the average for half the averaging period. The lower wind speeds which occur more frequently for long periods of time have a greater chance of occurring during a high water period. The frequency of occurrence of particular wind speeds at high water may be obtained by combining the frequency of occurrence of the wind speed for a particular number of hours with the probability that this will coincide with high water and summing the frequencies derived for periods up to 9 hours. All periods of 9 hours or more are considered together as they will all coincide with at least one high water period. No account has been taken of periods which overlap two or more high water periods as these rare occasions are unlikely to increase the derived frequency of particular wind speeds by more than 1%. The estimated frequency of occurrence of various wind speeds at high water is also shown on figure 5. The figure shows that for the same frequency of occurrence each year the maximum hourly mean wind speed at high water is about 2m/s lower than the maximum hourly mean speed recorded at any state of the tide.

23. The frequency of occurrence of a given wind speed from a particular wind direction at high water is estimated by combining the results contained in figure 5 with those in table 1 (paragraph 20).

Extreme wave heights

24. The frequency of occurrence of a particular large wave height at high water in deep water in the southern Wash is estimated by summing the frequency of occurrence at high water of the winds from W, NW, N and E that are capable of generating the desired wave height. The available fetch is taken as the site 3 fetch within the confines of the bay at high water of a spring tide and the relationship between wind speed and wave height in deep water is taken from the S-M-B wave forecasting charts (6). The deep water wave height frequencies were used with the empirical relationship (figure 4) between wave height and water depth for sites 2 and 3 to obtain shallow water wave frequencies for a range of water depths.

25. The calculations we undertook indicated that N winds would probably cause the largest waves in the SE Wash. The greater frequency of occurrence of strong NW winds compared to N winds (Table 1) does not outweigh the effect of the longer N fetch. The longer fetch allows less strong and therefore more frequent N winds to generate large waves more often than NW winds.

26. Up to this point the calculations of wave height frequencies referred to particular water depths. These depths will occur at different foreshore levels as the tides change from springs to neaps. To provide estimates of the frequency of occurrence of large waves at particular foreshore levels, we have combined the probability that high water will reach a particular level with the frequency of occurrence of the required wave height in the appropriate water depth. The results are then summed for all tide levels. The probability that the predicted tide will reach a given level was derived from the annual distribution of predicted tide levels; the assumption has been made that there would be an average tidal residual of +0.5m at high water whenever large waves occurred. This is because strong NW and N winds generally raise water levels in the southern Wash and are quite often associated with North Sea storm surges. The calculations indicated that at foreshore levels above -1m OD large waves are most likely to occur during high spring tides when predicted high water levels are at least +3.3m OD. This is because the frequency of occurrence of wind needed to generate large waves in this depth of water is much higher than that of the wind needed to generate the same size of wave in the shallower water that is more often present.

27. Wave heights which are estimated to have particular frequencies of occurrence at various foreshore levels are shown in figure 6. This figure indicates that at all depths the wave height with a frequency of occurrence of 0.001 each year is only about 2.3 times larger than the wave height that occurs on average once a year. The wave height expected at a foreshore level of -4m OD is about 2.4 times the wave height expected at +2m OD with the same frequency of occurrence.

28. In some areas of the foreshore, wave energy will be concentrated or dispersed by the effects of wave refraction. These local variations in wave energy concentration will change the height of the waves. In areas of severe concentration the wave height may be up to twice that experienced generally. The occurrence of severe concentration of wave energy will be critically dependent on the wave period and water depth on each occasion as well as the offshore bed topography.

Rip rap design for sea-facing reservoir banks

29. The extreme wave heights derived for the southern Wash (figure 6) have been used as the basis for design of rip rap surface protection for the Westmark and Hull Sand reservoir shapes (figure 1). The method of relating wave height to surface protection is based on recent model studies by the British Hydraulics Research Station (HRS) (5). The studies indicate that for a given embankment slope, the amount of damage sustained by a randomly placed quarry stone rip rap layer of given stone size depends principally on the significant height and number of waves attacking the embankment. In the model studies the rip rap was placed over suitable filter material in a layer whose thickness was twice the median size of the rip rap. Failure of the modelled slope protection was deemed to occur when a hemispherical foot with a diameter equal to the median size of rip rap under test could just touch the underlying filter layer.

30. The rip rap design for the proposed sea facing reservoir embankments in the Wash was based on the requirement that the surface protection should not require maintenance even after a design storm containing 2000 waves with a significant height estimated to have a probability of occurrence each year of 0.001 at the level of the foreshore upon which the bank was sited. The number of waves in the design storm was calculated as the maximum number likely to attack the bank during the three hour period around high water when water depth would be greatest. The wave heights experienced on the preceding and following high water are likely to be significantly smaller during such an extreme storm because of the improbability of a sufficiently strong wind being maintained for upwards of 12 hours (figure 5). A further reason for confidence in the restriction of the design storm to 2000 waves is that model tests with up to 5000 waves generally showed little additional damage to that caused by 2000 waves (5). The requirement that no maintenance be needed was interpreted as meaning that during the design storm the damage should be less than 15% of that

causing failure, as defined above, of the rip rap protection. The assumption has been made in this definition that the results of the model studies may be directly applied to the proposed Wash reservoirs. From figure 6 the design wave height for an embankment founded close to 0m OD on the SE foreshore of the Wash is 2.3m. Rip rap with a median size exceeding 950mm placed on a 1:4 slope will satisfy the no-maintenance requirement defined above for this wave height.

31. A second requirement for the rip rap design was that in areas subjected to concentrations of wave energy, the protection should not fail, though greater damage requiring maintenance would be permissible. In such areas the significant wave height will increase and greater damage will be experienced during storm with a given frequency of occurrence.

32. For the Westmark reservoir which is founded at and above 0m OD a median stone size of 950mm satisfying the first requirement is considered adequate. This size of stone should withstand, without failure, waves 1.75 times the height experienced generally during the design storm. Such a measure of concentration of wave energy is unlikely to be exceeded on the flat gently shelving foreshore seaward of the reservoir. This area of foreshore has been stable for 100 years and is accreting in a fairly uniform manner.

33. On the line of the Hull Sand reservoir embankment which crosses a series of channels and areas of complex topography, wave heights up to twice the height experienced generally are considered possible. This implies that in some areas during the design storm waves with a significant height of 4.6m could attack an embankment founded at 0m OD. To resist such waves without failure, rip rap laid on a 1:4 slope should have a median size of at least 1050 mm. As a result of the dependence of the wave height on the foreshore level for a storm with a particular frequency of occurrence (figure 6) the size of rip rap used for surface protection should vary with foreshore level. The size of rip rap required for both Westmark and Hull Sand reservoirs at various foreshore levels is shown in Table 2.

Foreshore level (mOD)	Median size of rip rap (mm)		Top level of protection (mOD)	
	Hull Sand Reservoir	Westmark Reservoir	Heavy	Light
+2	750	650	+8.5	+10.0
0	1050	950	+9.75	+12.0
-2	1450	-	+10.75	+14.0
-4	1700	-	+11.5	+15.75

Table 2: Rip rap design for proposed Wash reservoirs
(Note: design maximum still water level +5.8mOD)

34. The vertical height to which surface protection should be taken depends on the expected extreme still water level and the height above this which may be damaged during a storm which almost causes failure of the protection. The HRS model studies (5) indicated that at failure of a 1:4 slope damage extended for a vertical distance of 3 median stone diameters above and below the still water level. This finding is applied to the full scale embankment design with an added 0.5m allowance for free board. The recommended top level of rip rap protection (table 2) assumes an extreme water level of +5.8mOD which is estimated to have a frequency of occurrence each year of 0.001 at Roaring Middle.

35. Above the main surface protection, lighter protection is required against wave run up. The HRS model studies (5) indicated that wave run up would occasionally reach a level 1.25 times the significant wave height above still water level. Using this information for reservoir design in the Wash, with a similar allowance for free board and an extreme water level of +5.8mOD gives the top levels of lighter protection (table 2).

The trial bank as a test for the rip rap design

36. The trial bank constructed in the Wash (figure 2) is circular in plan with a diameter of 284m enclosing a small area of foreshore. The bank consists of 412,000m³ of sandfill won with a cutter-suction dredger from a nearby foreshore borrow pit. The sand fill is protected against wave attack and erosion by quarry stone rip rap and two filter layers of coarse sand and crushed furnace slag from a phosphate process. The rip rap on the seaward side of the bank consists of hard durable limestone with a median size of 660mm laid in a layer 1300mm thick. On the landward side similar though smaller rip rap is used. The protection on the seaward side is taken from sea bed level (-1m OD) to +7.5m OD. Above this level the bank is protected to +9m OD by slag. The top 5m of the bank is grassed.

37. The surface protection used for the trial bank is less heavy than that recommended for the permanent banks of the Westmark reservoir although the trial bank and the proposed Westmark reservoir are founded at similar levels. If the design assumptions used for the proposed reservoir prove to be accurate the rip rap on the trial bank will suffer damage requiring maintenance during storms with a significant wave height exceeding 1.7m. The frequency of occurrence of such waves at the bank site is thought to be about 0.1 each year if wave energy is not concentrated onto the bank.

38. The surface protection of the trial bank should not fail even if attacked by waves with a significant height of 2.7m which are thought to have a frequency of occurrence of about 0.001 each year. If wave energy was heavily concentrated onto the trial bank by wave refraction, failure may occur during storms with a frequency of occurrence of 0.1. Such concentrations of wave energy are thought unlikely as the bed topography seaward of the bank is flat and gently shelving.

39. The long term performance of rip rap on the trial bank will indicate the validity of the design methods we propose for the main reservoir embankment. To this end a continuing programme of wave, wind and tide measurement has been recommended with associated studies on the performance of the surface protection. The performance of the rip rap will be judged on the basis of stone movement.

Visual wave observations to estimate inclement weather

40. Three of the buoys marking the King's Lynn shipping channel were chosen as sites for visual wave observations (figure 1); No 13 indicative of conditions on the upper foreshore, No. 7 indicative of lower foreshore conditions and No. 1 in deep water at the mouth of the channel. Estimates of wave period were not made, although the skippers reported the presence of swell.

41. The wave height frequency distribution is shown in figure 7 which compared the wave height distribution at buoys 13, 7 and 1 for the year June 1974 to May 1975. Large waves are encountered much more frequently at buoy 1 than at the more landward buoys. For example in 1974/5 waves exceeding 0.6m (2ft) were reported on almost 20% of observations at buoy 1, almost 10% of observations at buoy 7 and less than 3% of the observations at buoy 13. At each buoy there were also a large number of occasions when wave heights less than 0.075m (3ins) were recorded. The proportion varied from 10% at buoy 1 to over 20% at buoy 13.

42. The information provided by the skippers of the pilot cutter was of great value to us in assessing typical wave conditions in the Wash, principally because of the regularity of the observations. Over a period of 3 years December 1973 - November 1975 the skippers recorded their wave height estimates at buoy 7 on 92.5% of the 2116 high waters. The wind conditions on the high waters when no observations were made at buoy 7 were compared with conditions on other high waters and found to be very similar suggesting that severe wave and wind conditions did not usually prevent the pilot cutter putting to sea. On the majority of occasions when the pilot cutter remained in port the reason was the absence of shipping requiring pilotage.

43. There were only four recorded occasions in the 3 years when stress of weather was given as the reason for remaining in port or turning back before reaching buoy 7. On 7 of the 9 occasions when waves above 1.5m were noted at buoy 7, however, no readings were made at buoy 1 suggesting that wave height was a contributory factor in causing the pilot cutter to turn back or meet ships before reaching buoy 1. On one of these occasions the cutter reached buoy 1, but the conditions were so severe that the skipper felt unable to estimate the wave height accurately.

44. The seasonal variations in wave height estimates over the 3 year period at buoy 7 are shown in figure 8. This figure shows that the wave height distribution is fairly similar at all seasons of the year with the exception of the 3 summer months of June, July and August when wave heights are noticeably lower, making these months the prime building period.

45. The seasonal estimates of wave height distribution (figure 8) do not indicate for how long the waves remained above a height which could hinder or damage work nor the length of time between periods of inclement weather when building may proceed. This information is conveyed on figure 9 which shows that the number of separate periods each season when waves exceed 0.22 and 0.30m remained between 20 and 25 with no significant reduction in the summer. The average persistence of small waves was however about $1\frac{1}{2}$ days longer in the summer than during the remainder of the year. There are also likely to be much longer periods with no waves above 0.45 and 0.6m in summer than at other times of the year. Although the other months generally have longer periods of inclement weather, even these months contain occasional long calm spells.

46. Data from the anemometer at Cranwell indicate that the period of the study was fairly windy. In the two years June 1973 to May 1975 there were 45 percent more hours when the wind speed exceeded 10m/s (UK Beaufort force 6) than the average over the nine years July 1966 to June 1975. During a typical construction period, the amount of time that will be lost due to inclement weather would normally be somewhat lower than the proportion of time indicated by the wave height frequency distribution (figure 7).

47. The effects of variations in wind conditions from year to year may be illustrated by considering the wave and wind data from the spring months of March, April and May during the 3 years 1973 to 1975 (figure 10). During these spring months the weather is often dominated by moderate northerly winds which can generate fairly large waves in the Wash. The proportion of time the wind exceeded 8m/s (UK Beaufort force 5) from the NW, N or NE ranged from 3 to 5% in 1973 and 1974 to 15% in 1975. At the same time wave heights exceeding 0.45m (18ins) were reported on 7 to 8% of tides in 1973 and 1974, but 20% of tides in 1975.

48. Experience gained by contractors using using small craft for survey and building purposes suggested that operations were hindered when wave heights exceeded 0.23m (9 ins).

49. The contractor for the trial bank (HAM Dredging Ltd) imported large quantities of rip rap stone and filter material through an offshore transshipment site in which the materials were moved from coasters to barges by floating cranes. The operation of this site was occasionally affected by the inclement weather experienced in the spring of 1975 (figure 10) which delayed the programme 5 days in 7 weeks. The periods

when weather conditions halted the transshipment operation coincided with reports from the pilot skippers of 0.5m waves at buoy 7.

Conclusions

50. For the design of the surface protection for the reservoir embankments proposed in the recent feasibility study for water storage in the Wash we have attempted to estimate the frequency of occurrence and extent of storm damage. To this end we have measured wave and wind and tide conditions at the site for three years to derive empirical relationships between water depth, wave height and wind speed, direction and fetch.

51. We were advised not to use a direct correlation between local recorded wind conditions and the conditions recorded 55km away at a long term anemometer station as the basis for derivation of extreme winds. Instead extreme wind maps based on all available regional wind data have been used as these are considered more reliable than a direct correlation between two individual stations.

52. To assess the frequency of occurrence of various wave heights on the inter-tidal foreshore we have taken into account the duration and direction of extreme wind speeds and the probable incidence of these winds with high water. Our estimates of wave height, based on the empirical relationship between wind, wave and tide conditions, take account of the variation in high water levels between spring and neap tides. We have been able to estimate wave heights with a given frequency of occurrence at foreshore levels ranging from mean high water springs to mean low water springs in an area with a spring tide range of 6.4m.

53. Our estimates of the frequency of occurrence of wave heights at various foreshore levels have been combined with the results of recent model studies at HRS to produce a rip rap design. The frequency of damage and probability of failure of this surface protection has been estimated.

54. Long term tests on the trial bank rip rap combined with continuing wave wind and tide measurements will indicate the validity of the design methods proposed.

55. Estimates of the amount of time that will be lost during construction of the reservoir bank due to wave activity may be made as a result of regular visual observations of wave height over a three year period. These observations enable the frequency and probable duration of waves likely to hinder building operations to be estimated on a seasonal basis.

ACKNOWLEDGEMENTS

This work has formed part of the feasibility study of the Wash Water Storage Scheme undertaken for the Central Water Planning Unit, Reading, England, by Binnie & Partners, London. Thanks are due to O. Gibb, Director of the Planning Unit and Binnie & Partners for permission to publish the paper.

DATA COLLECTION AND ANALYSIS

FOR

COASTAL PROJECTS

INTRODUCTION

Modern design concepts for coastal engineering works make increasingly heavy demands in respect of the number of variables to be investigated, of the accuracy of the field measurements and of subsequent methods of analysis. In general the larger the projects the greater the demand for accurate site data but frequently, whatever the field data requirement might be, environmental conditions impose severe limitations upon the quality and quantity of the obtainable information.

Before field measurements commenced on the two projects reported in this paper (see Figures 1 and 2) careful consideration was given to the relation between the probable status of the data, the level of statistical analysis to be applied and the constraints the results might impose upon research objectives or upon projected works. Such appraisal was specially relevant since the projects drew upon results from both physical and mathematical models and, in one case, involved assessments of extreme sea conditions related to nuclear safety. This approach provided sufficient flexibility to adjust the method or extent of data collection to take advantage of optimum conditions in the field and changing requirements for input to models and designs.

The time and energy expended in obtaining data of the correct order of confidence was justified by its direct applicability to alternative designs in the face of rapidly inflating construction costs. It was considered essential that the planning and control of data collection be co-ordinated by the design engineer for relating individual items to the project as a whole. It was found equally important that the hydrographic surveyors and oceanographers, familiar with the physical aspects involved, understood how their results were to be applied and hence appreciated the necessity of achieving appropriate tolerances for different parts of the work.

OUTLINE OF CASE STUDIES

The paper describes two data collection programmes which had significant analogies despite being devised for sites remote from each other and for quite different purposes. Both sites had gently shelving sandy shores and seabed and in each case the severity of the wave climate and degree of exposure determined the choice and operating methods of field equipment. These were

FIGURE 1. POOLE AND CHRISTCHURCH BAYS RESEARCH STUDY. POSITIONS FOR DATA RECORDING.

constraints that greatly affected the value of the data collected and established the tolerance standards for the data requirements.

Poole and Christchurch Bays Research Study

In the first project programme the primary study site was Poole Bay on the south coast of England, fronting the flourishing holiday resort of Bournemouth, where the beach was not only an amenity but provided protection to the promenade and cliffs. A secondary study site covered a short length of an adjoining bay where the beach was very small and had been insufficient to prevent rapid erosion of clay cliffs. As can be seen from Figure 1 both bays faced south, both had limited protection from the prevailing south-westerly storms, and both had fairly shallow shelving seabeds and beaches, the levels of which had been lowered during recent years.

Many of the problems at Poole Bay were analogous to those in other British coastal areas. Therefore the United Kingdom Department of the Environment agreed to sponsor a research project aimed at analysing the beach feeding parameters. The Authors were involved as Project Co-ordinators, being responsible for preparing Contract Documents and ensuring that the data was collected at the required time and was of an adequate standard for subsequent analysis by the Hydraulics Research Station, Wallingford. Collection of data from the two bays extends over a period of three years in association with the following schemes for coast protection:

- a) In Poole Bay, renourishment of the beaches was undertaken by dredging about one million cubic metres of sand from an offshore bank and pumping this onto the beaches.
- b) At the west end of the bay information on beach response was sought to the construction of two long semi-permeable groynes.
- c) The headland between the two bays at the eastern end of 'B' area (see Figure 1) contained bands of ironstone which gave it a greater resistance to erosion than the surrounding material. Information was required on movement trends of mobile material past such a headland and its associated inshore shelf.
- d) In Christchurch Bay, cliffs composed of overconsolidated clay were receding through a pattern of slumps, mud slides and mud flows. More information was required on the rate of recession related to the degree of beach protection at the toe and on the most suitable methods for beach development in this context.

(i) Hydrographic and Topographic Surveys

The surveys extended along 14 km of coastline (see Figure 1) and consisted of 43 survey sections at approximately 400 m intervals. Each section profile began at the toe of the sea wall or cliff and terminated some 500m offshore or at the 9 m contour (5 fathom mark), whichever was the greater. These surveys were carried out immediately before and after the beach feeding and subsequently three times within the first year following completion of the sand replenishment. Further surveys were made at the end of the first year and then at six monthly intervals thereafter.

Each survey section was in fact a combination of topographic and hydrographic surveying carried out during a spring tide, the topographic survey at low water (LWST) and the hydrographic survey at high water (HWST). It was specified in the Contract that the topographic surveys were to be carried out within $1\frac{1}{2}$ hours of LWST, and that the hydrographic survey was to be an extension of the topographic survey line carried out within $1\frac{1}{2}$ hours of HWST. This method of operation ensured that there was a length of profile over which levels were repeated, this overlap serving as a useful check on accuracy achieved, in particular that of the hydrographic work. It was also specified that the surveys had to be carried out within 24 hours of each other to ensure that recorded changes of beach levels were kept to a minimum between the hydrographic and topographic surveys. In the hydrographic work horizontal and vertical tolerance limits were specified not to exceed ± 1 m and ± 80 mm respectively. For the topographic work it was obviously possible to obtain closer limits and the Specification required the points on a section to be within 1 in 5000 horizontally and ± 20 mm vertically.

A recording tide gauge was installed at Bournemouth. This single installation was found to be insufficient to establish a datum for all the hydrographic surveying. The research area was under the influence of two amphidromic points and experienced flood peaks of varying height along its length. Consequently other temporary gauges had to be established along the frontage.

Current velocity measurements were taken every half hour at five stations and at four depths throughout a complete spring tide.

Some 200 bed samples were also taken, both onshore and offshore at regular intervals and their grain size distributions established. The depths of the deposits above the clay bed were also recorded at regular intervals at the various sampling stations. These were repeated at the same time as the surveys.

(ii) Wave Analyses

A waverider buoy was positioned in Poole Bay (see Figure 1). The buoy recorded for 20 minutes every 3 hours, producing information on parameters such as H_1 , H_2 , H_S , T_C , T_2 and E . The buoy had to be inspected once a month, taken out of the water, checked and cleaned, It was recalibrated every six months. The receiver was serviced every two weeks.

Wind data was also analysed from two recorders in the area and the wave data plotted in relation to the wind. Wave directions were observed visually from the cliff top once a day.

(iii) Aerial Survey

This provided stereographic coverage of some 20 km of coastline at a scale of 1 to 2500, the photographic coverage starting and finishing 1 km either side of the boundaries specified on Figure 1. The photography was to be carried out at LWST at six monthly intervals for a period of three years, with a cloud cover less than 10 per cent. Limiting tolerances with regard to crab and tilt were specified.

The aerial survey was later extended to cover the entrance to Poole Harbour to the west of the project area to assist in determining any tendency for the beach feed sand to drift in a westerly direction.

(iv) Film

A film lasting some 20 minutes was commissioned in order to have a record of the research project. The various subjects to be recorded and the minimum duration of viewing time to be allocated to each item were specified. An allowance was made for additional footage of film.

Koeberg Nuclear Power Station

The site area, which lies some 27 km north of Cape Town on the west coast of South Africa (see Figure 2), consists of a zone of active dunes behind a gently sloping beach and sea bed. It is intended that a multi-stage development of nuclear power stations will be constructed at the site which together will generate some 6000 MW for the Electricity Supply Commission (ESCOM). The cooling water for the reactors is to be taken from a dredged basin, protected from wave activity by rubble mound breakwaters, and discharged as a low velocity jet south of the southern breakwater arm (see Figure 2). The site is exposed to the full force of the south Atlantic Ocean, the sea is rarely calm, and throughout most of the year there is a wide surf zone. During the

summer, the site is affected by waves generated from the south and occasionally by storms travelling from this direction. In the winter, storm generation and waves from the north-west appear to predominate. Although the beach and offshore sea bed undergo seasonal changes there is no apparent net change from year to year (1).

On the west coast of South Africa the sea water temperatures are some 10°C below that of the ambient temperatures of freshwater lakes. According to Shannon (2) the main reason for this is that as the cold Benguela current, originating in the Antarctic, passes northward along the Continental shelf, upwelling is generated by the predominant southerly winds. However, this effect could be temporarily modified by north-westerly winds and therefore merited a detailed study as the upwelling of cold water has a direct bearing on the efficiency of the stations.

Mathematical models were used to predict siltation patterns in and around the intake basin (1), the susceptibility of the basin layout to seiche, resonance and recirculation patterns and temperatures for various discharge conditions. Physical models were used to establish the criteria for breakwater design and wave conditions within the intake basin.

Initially studies involving oceanographic measurements were carried out by the Institute of Oceanography of the University of Cape Town as early as 1968, as experience was gained using the data collected and, the project requirements were defined, it became apparent that a more intensive site investigation was required. A definitive data collection and processing programme was evolved by the Authors' firms with relation to the cooling water intake basin and discharge works. Data-gathering procedures were agreed and jointly developed with the National Research Institute for Oceanology (NRIO), together with the University of Cape Town who undertook this work.

(i) Hydrographic and Topographic Surveys

These surveys were undertaken on a quarterly basis for a period of 2 years using the survey markers shown on Figure 2. However, allowances were made for additional ad-hoc surveys after periods of extended calms or severe storms. It was intended that there should be an overlap between the beach and hydrographic surveys but, because of the almost continual occurrence of surf, this overlap was rarely achieved. In fact difficulties of surveying in the surf zone imposed severe restrictions on the data collection and on the accuracy of the survey. This problem was resolved during the course of the studies by the use of a ski boat fitted with a recording echo-sounder and a calibrated vertical pole fixed on it as a mast. When the ski boat indicated that it was making a fix on its echo-sounding trace a shore-based surveyor

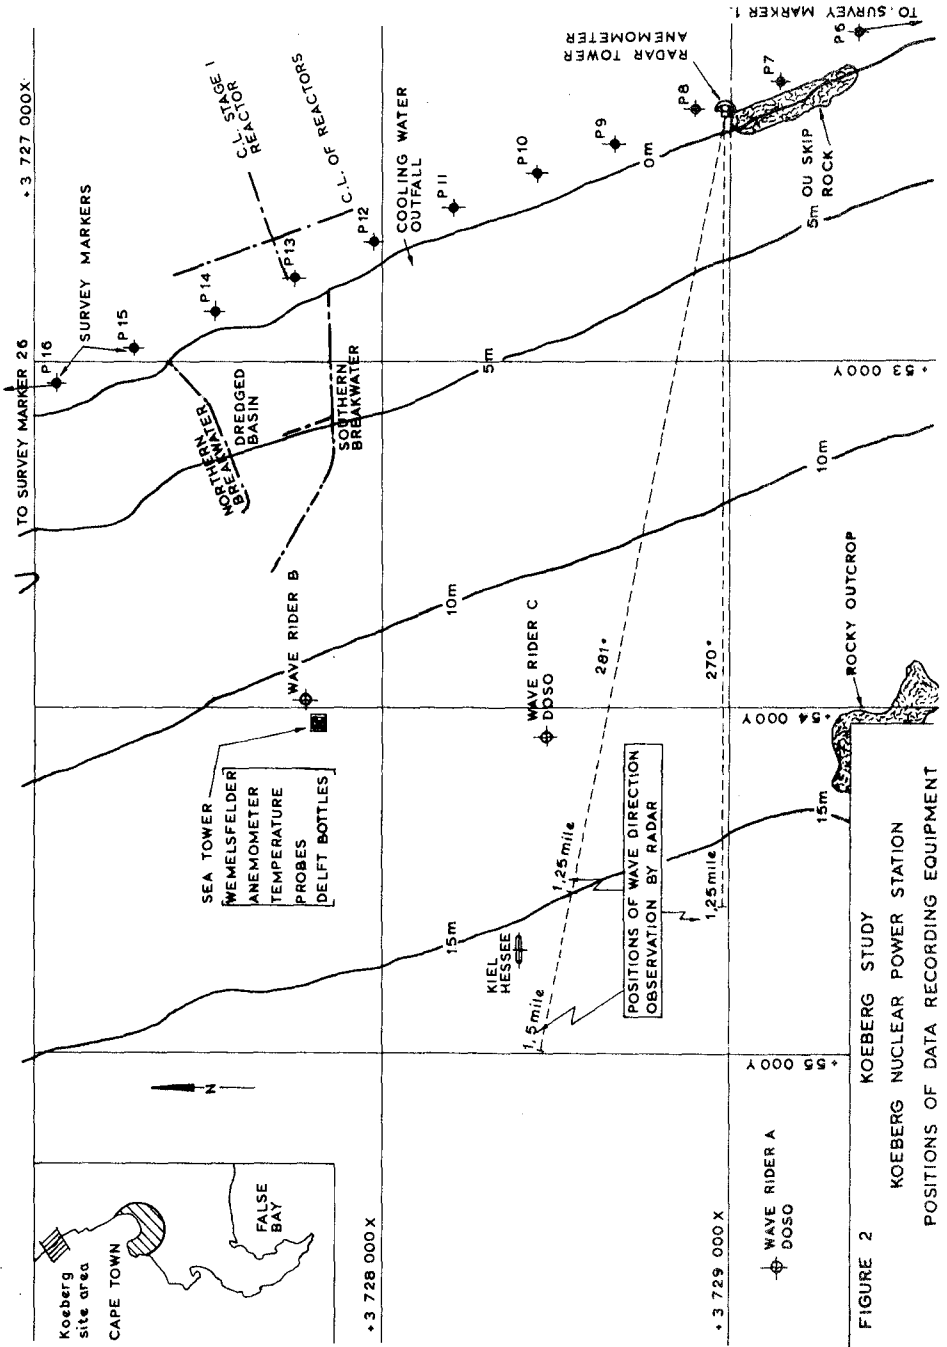

FIGURE 2
 KOEBERG STUDY
 KOEBERG NUCLEAR POWER STATION
 POSITIONS OF DATA RECORDING EQUIPMENT

with a theodolite and camera attachment established the boat's position and elevation. This innovation ensured that the tolerances for the vertical accuracy of the echo survey were kept to an acceptable level.

In addition to the survey markers a series of beach poles was installed opposite the Sea Tower between low water and the dune area. Measurements of beach levels relative to the top of the poles were taken at weekly intervals and enabled a detailed picture of beach erosion and accretion to be established.

(ii) Wave Height and Period Data

Early in the data collection programme it was decided to install a Sea Tower in about 10 m of water (see Figure 2) and to operate it as a data collection centre. A Wemelsfelder float-operated wave height recorder, type W.R.67, which was installed on the Sea Tower in March 1972, provided basic wave data such as H_s , H_{max} , H_{10} , H_{rms} and E .

Wave measurements were also taken using an NIO ship-borne recorder on board the research vessel "Thomas B. Davie" during survey voyages, together with visual observations of wave direction. In general these records of the deep water wave spectra were discontinued once wave recorders were established at the site.

The main information on the wave spectra was provided by Waverider buoys A and B, installed early in 1974, and Waverider buoy C which later replaced buoy B. The buoys recorded for 20 minutes every 6 hours and produced an almost continuous record of wave conditions on the site. The buoys were calibrated and maintained regularly and the records were analysed to give wave parameters, in the same way as on the Poole Bay Project.

(iii) Wave Direction

In 1974 a Decca radar system type RM 919, which is the smallest of the commercial shipping range, was established in a recording hut on Ou Skip rocks at the south end of the study area. This system was based on that developed by the Institute of Oceanographic Sciences (3), with the scanning dish on top of a tower some 33 m (100 feet) above mean sea level. The radar was operated for 10 minutes every 5 hours and recorded the wave patterns photographically, with an exposure time equal to the time of a complete sweep of the radar scanner. This unique method of recording enabled the whole wave front pattern to be recorded as far as 2 km ($1\frac{1}{2}$ miles) seaward of the site. In addition, by recording the photographs on successive frames of a cine film the resulting time-lapse photographs presented a two-dimensional picture of the wave fronts as they were refracted and diffracted. By timing the radar photographs to coincide with wave buoy

recordings, wave direction was added to the other parameters obtained.

The radar system could not be arranged, economically, to record wave directions as far out as Waverider buoy A. Consequently, a Doso meter (4) was introduced in 1975 as an additional tool for measuring these directions in deep water beyond the range of the radar. This recorder, which is a simple bottom-mounted flow direction indicator, was positioned initially next to Waverider buoy C for two months and calibrated against the radar records. Once calibrated it was stationed next to Waverider buoy A.

Observations of wave height, period and direction were also taken from data recorded under the international system operated by Voluntary Observation Ships (VOS) (5). Records for a limited sea area of Marsden Square No.45 were obtained and analysed for use in conjunction with the data obtained on the site in order to improve confidence in the deep water wave spectra. Predictions regarding wave directions were also made by correlating the spectral energy plots obtained for the waves with the low pressure areas in the south Atlantic which generated the waves.

(iv) Wind

Measurements of wind speed, direction and duration were taken both at the Sea Tower and on the observation tower on Ou Skip rocks using Lambrecht recorders. These wind readings were compared with longer term records at nearby airports and at a refinery, as an independent check on the results and as a method of extending the 3 years of site measurements.

(v) Currents

The spring tidal range was 1.5 m (4.9 feet) on this stretch of the South African coast, but the co-tidal lines were almost parallel to the coast. Consequently the tidal currents were small, and not normally measurable on conventional current meters. A Bendix current meter was installed at the Sea Tower and a Keil Hassee current meter was installed on the sea bed near Waverider buoy A, but each meter only recorded current velocities outside instrumental error range during full flood of a spring tide or at times of strong onshore winds.

Most of the data on currents was collected by using free and fixed drogue systems. Measurements using the free drogue system were taken either on an ad-hoc basis or to examine in greater detail the pattern of currents resulting from a specific wind condition. Current data from fixed drogues was obtained by measuring the distances and angles between three drogues connected in series. This was done each morning and evening, and from the

observations the current speeds and directions could be calculated. The results were analysed together with wind records and a relationship between winds and currents was established.

(iv) Bed Samples

A number of samples were taken and analysed during the programme. The bed material throughout the area was in general fine sand with a D₅₀ of about 0.1 mm, but occasionally the bed material was coarser in areas where rip currents predominated.

(vii) Suspended Sediment

Samples were taken initially using Delft bottles, attached to the legs of the Sea Tower, at a number of levels. This sampling method was too crude for prediction of sediment in suspension, needed as essential input data to the sediment transport model that was being developed. However, Professor Kilner was developing a vacuum-operated sediment sampler at the University of Cape Town (6) and it was decided to use this, though at the time it was untried. Initially samples were collected instantaneously in a vacuum bottle, but as this was unsatisfactory as a record for long period storm waves, a later development of the equipment enabled a continuous sample to be taken during the passage of several waves. To operate in the breaker zone the sampler was suspended from a helicopter which, although an expensive method, enabled samples to be collected at a number of depths within the water column and for a variety of wave conditions, without too much difficulty. A more complete description of the method can be found in Professor Kilner's paper to this Conference.

(viii) Sea Water Temperatures

Initially measurements using thermometers were taken at monthly intervals on research vessels within the area. However, this was found not to provide a representative sample and later conductivity type temperature probes were installed at three depths at the Sea Tower. Also, additional measurements were taken regularly over a period of two years at a number of positions by wading into the surf zone. These measurements proved to be most interesting and a clear relationship was established between the sea water temperatures and the wind driving the upwelling current.

PROBLEMS ENCOUNTERED

For major coastal engineering projects which merit extensive data collection programmes the problems encountered are numerous. The cost is high and, as Wright (7) has pointed out, the tender prices for the surveys can vary considerably depending on the engineer's specification and the contractor's assessment of the

actual requirements. Any specification must not only allow for the logistics of collecting each set of data under a variety of sea and weather conditions, but also define the tolerances which can be applied in practice. In addition, it is generally necessary for the different types of data to be collected simultaneously. One set of data alone may be interesting, but to be of use it needs to be time-related to other different sets of measurements, e.g. hydrographic and topographic surveys require the continuous measurement of the wave climate and current patterns if the former are to be successfully analysed. For this it is essential not only to have back up equipment but also to adopt different methods of approach, so that any missing data may be filled in with some degree of confidence from alternative sources, or so that it can be used to correlate with other longer term records.

The limits of achievement of data collection from the two survey programmes of the projects described were dependent upon measurement of the wave-dominated environmental climate, the status of the project and the purpose intended for the use of individual observations.

At Koeberg, predictions of extreme events were required in relation to the safety of the nuclear plant. An intensive programme of investigations was called for in order to provide reliable input data for the complex physical and mathematical models. Even so the results obtained were limited by the severe marine environment.

At Bournemouth, the wave climate was far less severe and it was possible to use a much less intensive programme of investigations. However, on occasions important records could still not be obtained during the winter months.

Considering the problems that arise from the wave climate, some of the basic wave parameters can be relatively easy to collect. Waverider buoys were successfully employed on both projects and achieved a very high rate of useful collection. A buoy broke loose during the worst storm on both projects, resulting in a gap in the wave record while the buoy was reinstated. This also meant that the peak wave energy condition went unrecorded and consequently affected the predictions of wave and surge conditions which were dependent upon them. The Wemelsfelder recorder on the Koeberg Sea Tower also failed to provide a continuous record because, during major storms, waves broke over the tower and tended to force the instrument's float into the top of the well chamber.

The VOS observations were useful in that they provided relatively long-term records and gave an indication of the deep water climate.

FIGURE 3. WAVE FRONT PATTERNS RECORDED PHOTOGRAPHICALLY USING RADAR.

Establishing the direction of waves has always been a problem. Visual observation from cliff tops, such as at Bournemouth, proved satisfactory but only represented the near-shore, refracted, waves at one point along the 14 km coastal study area. Although this information could be used to back-track the wave rays in order to derive the deep water spectra, which could then be refracted in elsewhere along the coast, this process can pose many problems principally arising from the nature of the model grid. At Koeberg good results were obtained by combining radar records (see Figure 3), which also required a high vantage point, with Doso records. On their own the radar records were not entirely satisfactory as, even in the severe wave climate at Koeberg, only about 35% of the waves were recorded during a year, i.e. those waves which were sufficiently high and steep with, in general, 'fluffy' crests. However the radar faithfully recorded sufficient wave fronts over a fairly wide sea area and, by use of time-lapse photography, the refraction pattern of a wave as it shoaled could

be checked against calculated values. Radar equipment had the further advantage that it was entirely land-based and could be easily serviced. This was not the case with the Doso meter, for which a diver was required to retrieve the records and to service the instrument. If subsequent analysis showed a fault in operation to have occurred, a section of the readings might have been omitted and lost. However, in general the Doso meter gave an excellent point recording of wave direction and proved to be a powerful tool when used in conjunction with radar recordings.

At the time of the project study an alternative concept for determining wave direction was fortunately being developed by Dr Harris of the University of Cape Town and this was expanded in private correspondence.

In brief the deep water wave directions were established by comparing synoptic weather bulletins with contoured plots of spectral wave energy arrivals against wave frequency and the time of recording.

These contoured plots, normally covering a period of about one month, showed a series of high and low areas, representing times of peak energy arrival or of relatively quiescent periods respectively. The scales of the plot were calibrated so that a line drawn through the major axis of the peak area intersected the time abscissa at the date on which the generated storm waves had originated, and the included angles gave the distance to the storm centre in degrees of latitude. Examination of the weather bulletins showing the location of the isobars of the low and high pressure areas for the period preceding the arrival of the peak energy condition provided an essential check on the calibration.

This method was proved by comparing the results against those of the other methods of measuring wave direction and, once proved, was used to fill in missing data.

It was found that the hydrographic and topographic surveys were greatly influenced by wave activity. This was because wave energy not only alters the onshore and offshore topography and bathymetry but, as has been mentioned earlier, also affects the practical aspects of the survey itself. Cross (8) who discusses the many sources of error that can occur in inshore surveying also acknowledges the important influence of the wave climate. At Bournemouth the surveys were timed to coincide with spring tidal conditions to ensure that there was an adequate area of overlap between the topographic and hydrographic surveys.

On at least two occasions, rough seas led to a postponement of the surveys and only three out of eleven surveys were fully completed in the time specified. At Koeberg one of the surveys

was abandoned altogether due to sea conditions. It was found that the zone of overlap on each line could be extended and thus the accuracy of the survey improved by using a survey pole with disc base for topographic surveying which could be taken into the water by a man in a wet suit. This technique was successfully employed at Poole Bay to extend the topographic survey by some 20 m, but at Koeberg the surf conditions rapidly halted progress outwards and overlap was rarely achieved. Even under ideal conditions, as can be seen from Figure 4, the overlap does not always give a good solution.

FIGURE 4. POOLE AND CHRISTCHURCH BAYS RESEARCH STUDY. OVERLAP OF HYDROGRAPHIC AND TOPOGRAPHIC SURVEYS.

The overlap between the two surveys cannot be relied upon to provide a datum line for the hydrographic survey. The reference level must be related to datum using the tidal level at the time of the survey, especially at the seaward end of the section. This presented few problems at Koeberg which has a small and reasonably regular tide. The Bournemouth coast, however, under the influence of two amphidromic points (see Figure 5), caused tidal differences in the two bays which were not only notable from tide to tide but also varied during a tide. A careful check had to be made of the tidal level variation along the coast by the installation of additional tide boards.

FIGURE 5. POOLE AND CHRISTCHURCH BAYS RESEARCH STUDY.
SPRING TIDAL OBSERVATIONS FOR 17 FEBRUARY 1976

It was realised that the mathematical model for sediment transport, developed specially for the Koeberg project, would rely heavily upon site data records, especially on suspended sediments in relation to wave height. When the studies commenced, no reliable method was known for obtaining suspended sediment samples in the surf zone. Fortunately the 'Kilner' sampler was developed, providing suspended samples in waves up to 6 m high which showed good correlation with those developed from theory (1).

In areas where tidal current predominated conventional current meters were adequate and, if used during spring and neap tidal cycles, the tidal current pattern could be easily established. Where the tidal currents were low or non-existent the current pattern had to be established using drogues. This required at least one year's data, preferably taken on a daily basis, which was possible using a fixed drogue system. A relationship had then to be established between the currents and the wind driving them. This proved possible at Koeberg and the relationship was used together with the continuous records of wind to predict flow patterns.

CONCLUSION

It can be said with confidence that a data collection programme can be accurately planned only when the parameters to be measured are known. Clearly this is an unrealistic situation and consequently latitude must be allowed in the collection programme for lack of knowledge by, if possible, providing for more than one method of measuring the data. This requires thought, planning, finance and an assessment of what the answers will be. A complete set of data taken at the same time is essential to any project, especially if models are employed. No matter how sophisticated the theory or advanced the modelling technique that is adopted, the quality of the answer will directly reflect the quality of the data fed in.

It is also essential that, when planning data collection, the engineer understands the technique to be used and the practical difficulties involved. He must not demand a level of accuracy that is impossible or, unless he makes provision for it, extremely expensive to achieve. On the other hand the hydrographer or University Department must realise how the data which they collect is to be used and what influence it has on the project as a whole. The engineer must not be afraid to experiment but should not rely entirely on new untried equipment which tends to produce results later than expected.

In general the cost of taking measurements of the coastal environment are high but their true value is not always apparent at the beginning. The Authors have found that because of this high cost many institutions are willing to undertake analyses of

data on a shared use basis. Co-operation of this kind between research personnel and practising engineers can be very beneficial to a project as a whole.

ACKNOWLEDGEMENTS

The authors would like to thank both ESCOM and the U.K. Department of the Environment for providing the necessary funds for the projects, for their understanding that data collection is in part an evolutionary process, and for their permission to publish this paper.

They would like to thank personnel from the following South African Institutions; University of Cape Town, the National Research Institute for Oceanology, the Department of Fisheries (VISKOR) and the Atomic Energy Board, and personnel from the following U.K. Institutions; The Hydraulics Research Station, University of Southampton, Longdon and Brownings Surveys Ltd and Huntings Surveys Ltd.

CHAPTER 5

REGIONAL NETWORK FOR COASTAL ENGINEERING DATA

Richard J. Seymour*
Meredith H. Sessions**

A. Introduction

The California Department of Navigation and Ocean Development (DNOD), responsible for shoreline protection within the state, was particularly aware of the lack of coastal wave statistics to support their beach erosion program. As a direct result of the 1974 ASCE-sponsored New Orleans Conference on Ocean Wave Measurement and Analysis, discussion was initiated within DNOD and then with the Scripps Institution of Oceanography (SIO) at La Jolla, on the feasibility of establishing a regional wave monitoring network for California. The initial specification presented by DNOD was for a 200-station network reporting directional wave spectra twice daily for a period of ten years. SIO ocean engineering personnel responded with a system concept employing low-cost pressure transducers hardwired to shore with a dialup telephone data gathering link to a central station. The initial cost estimates appeared attractive when compared with Corps of Engineers experience as reported in Peacock (1974).

As a result, a small program was funded in February 1975 at Scripps to demonstrate critical hardware items through the breadboard stage. With the successful completion of this work, additional funds were allocated by DNOD as matching funds for a California Sea Grant Project.

The first station in the network began operation on 3 December 1975 at Imperial Beach, California. A second station was added at Ocean Beach (San Diego) on 27 March 1976, a third at SIO (La Jolla) on 18 May 1976 and the fourth at Oceanside, California on 2 June 1976. The locations of these initial stations are shown in Figure 1.

Considerable effort has been directed during the past 10 years toward the development of numerical models to predict deep-water wave conditions from meteorological data. Reasonable results have been obtained and sufficient accuracy achieved to allow routing of both commercial and military ship traffic. There has been some hope by users

* California Department of Navigation and Ocean Development

** Scripps Institution of Oceanography

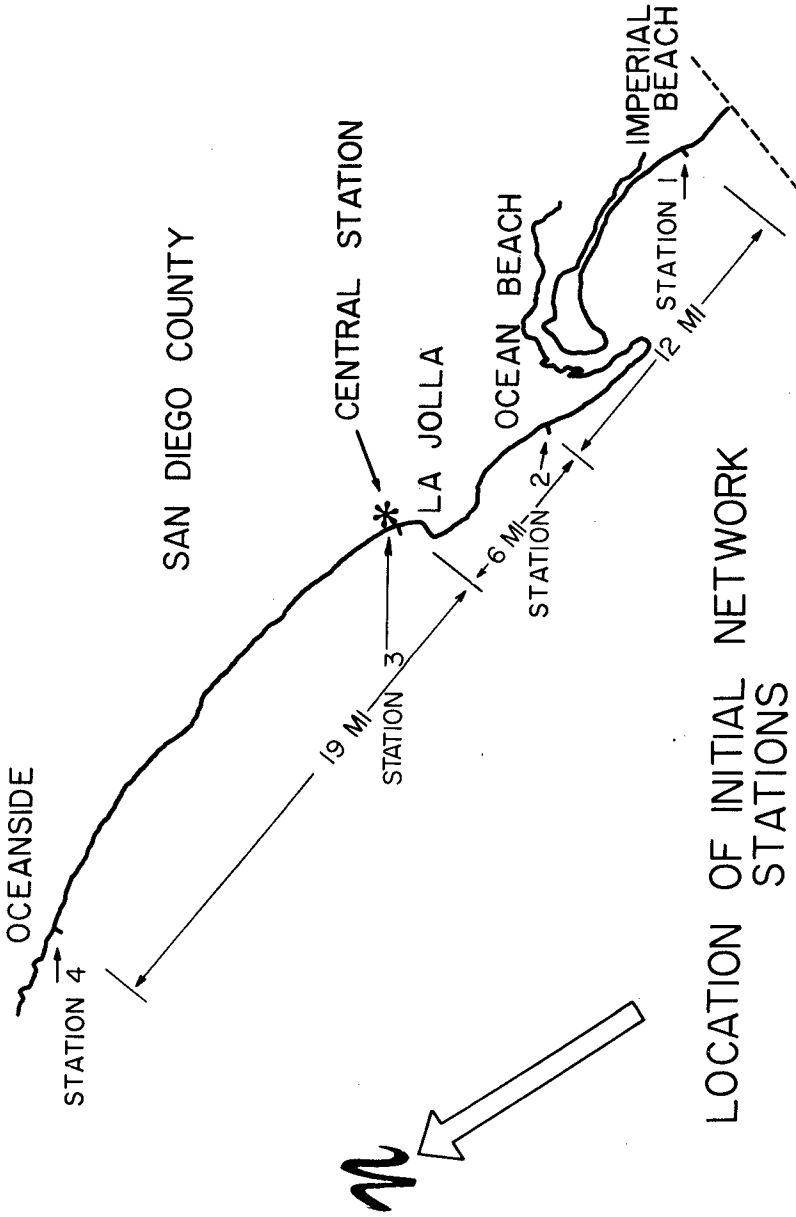

FIGURE 1

of nearshore wave data that hindcasting of meteorological records would allow a relatively low-cost method of accumulating long-term coastal wave statistics. However, the realities of the situation indicate that this may never be possible. Because of the irregularities in the continental shelf topography, a very marked difference in the refracted wave intensity at a particular location results from a small change in the deep-water wave approach angle. Accuracies on the order of one-half degree are needed in predicting offshore directional spectra in order to achieve reasonable estimates of local nearshore wave climates. The best obtainable accuracy that may eventually be expected is still at least an order of magnitude poorer than this.

The situation existing in Southern California is even more difficult than in most coastal regimes. The deep-water waves are not only refracted by the very irregular bathymetry of the shelf but are reflected, scattered and diffracted by a chain of large offshore islands.

Since the observed local wave climate is the sum of the deep-water swell that diffracts around the islands, and the locally generated wind waves, these factors combine, in the case of Southern California, to make wave prediction for coastal areas an extremely difficult task. Therefore, in this region of the coastline, it is even more imperative to find an affordable method for acquiring wave statistics through local nearshore measurements at closely spaced sites.

Any effort by man to alter the coastline shape, to prevent the erosion of valuable shoreline property, to manage the sediment budget within a coastal province -- all require the ability to predict the local capacity of the waves to transport sediment onshore, offshore, and longshore. Since man is most often concerned with the long-term cumulative effect of such sediment transport, only long-term statistics on the wave climate will allow meaningful predictions to be made.

Nearshore currents -- tidal, wind-driven or caused by fresh water flows -- can be significant factors in sediment transport and the dispersion of pollutants. Temperature variations with depth and time can provide data on such stable phenomena as thermoclines and such transient events as internal waves and bores. Both features are important in the engineering of the mixing patterns of outfalls. The wind field over the water can be of value in verifying wave generation models and for atmospheric pollution studies. Thus, a variety of additional sensors might be utilized at certain locations in addition to the basic wave gaging.

B. Objectives of the System

1. Coastal Wave Climate Statistics:

The primary objective of the system is to provide an affordable means of gathering directional wave statistics, at least twice each day, from closely placed stations along the coast of California. These stations are to be selected to allow both a characterization of the wave climate along the entire coastline and to highlight areas of specific interest -- such as a coastal reach undergoing critical erosion. These statistics are to be available in a timely manner to the users (reports containing monthly data are mailed no later than the third working day of the following month). Further, the data are to be archived so that raw data tapes and spectra tapes can be used at a future time by investigators.

The data can also be available in nearly realtime for surf reports and boaters' advisories if desired.

It is an objective of the program to collect these data for a minimum of ten years to establish seasonal trends.

2. Sediment Transport Estimates:

The second priority objective is to make estimates of the longshore sediment transport from the wave data in all locations where this would be appropriate. This prediction will utilize the best available model relating the measured wave characteristics and the sediment transport. Since the original wave data are preserved, these estimates can be updated later with improvements in the transport model.

3. Support of Scientific Experiments:

The ability of the network to provide nearly simultaneous observations over a very broad reach of coastline provides a unique data gathering tool to many coastal experiments. It is an objective of the program to support such work whenever possible, either as the primary data source or as an adjunct to the basic data retrieval system.

C. General Description of the System

1. Station Locations:

As of 30 June 1976, four stations have been installed in the network as shown in Figure 1. All are in San Diego County and have been added in a northerly progression. The Imperial Beach location was chosen as the southernmost site

in California because a critical beach erosion problem has been experienced here. In addition, a beach renourishment project is now underway and the wave data obtained may be of value in monitoring the effectiveness of the sand placement. The Ocean Beach site is just north of the Sunset Cliffs area, which has suffered damaging erosion. The gaging station is also very close to the entrance to Mission Bay, which will be studied by the Corps of Engineers for possible solution to the dangerous entrance conditions due to breaking waves which are encountered several times each year. The site at SIO is close to the Scripps Submarine Canyon, the terminus for a major littoral cell. The Oceanside location is in an area with chronic problems caused by interrupted littoral drift and localized erosion.

2. Central Station Configuration:

When the multiplexed signal is received at the central station, channel separation is achieved by tuned filters at the carrier frequency. The signal is then demodulated and digitized. The multiplexed data from as many as seven instruments are transmitted over an ordinary voice-grade, dial-up commercial telephone line. The data quality is at least as high as experienced with more costly leased lines over comparable distances.

At the central station, a dedicated minicomputer is interfaced to a receiver and autocall system. Under real-time computer control, a preprogrammed telephone number corresponding to the desired field station is dialed. Each station is called in sequence once every ten hours. This provides a minimum of two reports per day and eliminates the bias possible with fixed polling times. Upon connection to the field site, the digitized words are written to the computer buffer and then to magnetic tape for permanent storage.

The system block diagram is shown in Figure 2.

3. Field Station Configuration:

The initial stations utilize existing piers to bridge the surf zone. In the updated configuration, wave measurements are obtained with very stable LVDT (linear variable displacement transformer) pressure transducers which are molded directly on the end of a specially designed high performance armored cable as shown in Figure 3. This construction eliminates the cost and reliability hazards associated with connectors and housings. A single transducer providing one-dimensional wave spectra is the basic station. Three transducers in an array are now being

**BLOCK DIAGRAM,
DATA TRANSMISSION SYSTEM**

FIGURE 2

GULTON WAVE SENSOR ASSEMBLY

FIGURE 3

installed at each station to provide a directional estimate. The underwater cables are terminated in a data control box on the end of the pier. This unit performs the functions of signal conditioning, multiplexing signals from the various sensors, and responding to telephone requests for data from the central computer. The installed cost of the complete field station with an array of three pressure transducers, the underwater cabling and the data control box is projected to be less than \$3,000. Current meters, temperature probes, anemometers and other continuously reporting instruments can be accommodated in addition to the wave measuring devices. The output of each instrument is amplified at the point of measurement and converted to a frequency in the kHz range. At the shore station, this is divided down and used to modulate a carrier tone in the voice range.

4. Reports and Data Analysis:

These data are available for immediate analysis, if required. Normally Fourier transforms of wave data are made once a month and stored on a permanent transform archive tape. From these, a monthly wave climate statistical report is made, including one-dimensional spectra and significant wave height estimates for each data sampling.

D. Data Archiving

It is anticipated that the appropriate federal agency will, at some later time, take over the function of archiving the wave data obtained with this network. Initial discussions with NOAA personnel indicate that they plan a national wave statistics program beginning before the end of this decade. This would meet the needs for a central repository, capable of specifying the format for standard inputs and of meeting the requests of investigators for duplicate tapes or tabulations of data. Until this arrangement is available, the present project organization will attempt to meet the needs of interested investigators for raw data, transforms or tabulations.

Following is a tabulation of data outages which have occurred since the system went into operation in December 1975:

<u>Date</u>	<u>Data Lost</u>	<u>Cause</u>
December 1975	2 runs from 1 site	Power supply failure in central station
April 1976	2 runs from 1 site	Vandalism

<u>Date</u>	<u>Data Lost</u>	<u>Cause</u>
June 1976	2 runs from 1 site	Phone line damaged by construction work
June 1976	1 run from 1 site	Pier power outage

During this time over 1,000 runs have been made, so the data outage rate is 0.7%. Considering only equipment failures, the rate becomes 0.2%.

E. Plans For Expanding Capabilities

1. Additional Stations

As funds become available, other stations will be added to the network. As in the selection of the existing stations, the advice of the Corps of Engineers, the California Department of Navigation and Ocean Development, and other interested agencies will be solicited to aid in selecting future sites.

2. Wave Direction Measurement Capability

During the second half of 1976, the existing stations (and additional stations as they are installed) will have multiple channel capability. This will allow the installation of a minimum of three sensors in an array to estimate wave directional properties.

Two alternate approaches are being evaluated at this time. The first is to calculate a conventional directional spectrum estimate. With the limited array size, this will necessarily result in a poor estimate of actual wave direction. The second approach involves an approximation of the longshore momentum flux, defined by Longuet-Higgins (1970) as the sum over frequency of the products of the energy, the ratio of the phase and group velocities and the sine and cosine of the approach angle. This is expressed symbolically as

$$S_{xy} = \sum E_n \sin \theta \cos \theta$$

This parameter, which can be related to the longshore current induced by waves along straight coastlines, may be a more valuable and concise means for describing the overall directionality of the wave field.

Regardless of which method is employed in monthly reporting, the raw data will be preserved for use in other types of analyses.

3. Wind Measurements

Wind will be measured at pier sites utilizing an aerovane-type sensor which has had wide application on ships and oceanographic buoys. Data will be sampled periodically and a number of samples stored in a temporary memory until called by the central station. Upon receipt of a command from the central computer, data will be converted to a frequency proportional to the values stored in the memory and sent as a sequential series. The entire contents of the temporary memory will be sent upon command but the contents will be retained until overflow occurs with the most recent value pushing the oldest data out of the stack. Sample intervals and durations are programmable and can be varied to suit the experiment requirements.

F. Results and Preliminary Conclusions

The first seven months of operation of the network have shown gratifying progress. The hardware cost goals have been met or exceeded. The data retrieval reliability has been greater than 99%, including causes beyond the control of the project. Every monthly report has been mailed to users within the first three working days of the following month.

A sufficient data bank has already been acquired to allow some tentative conclusions on the eventual usefulness of these measurements:

.....The ability to discriminate low amplitude, long-period oscillations has been dramatically illustrated by the record of a tsunami reverberation made on 4 December 1975, four days after the earthquake on Hawaii. The uncorrected bottom pressure time history is shown in Figure 4. Although the original tsunami arrival had been detected by the tide gaging station at Scripps Institution of Oceanography, this reverberation was not detectable.

.....The influence of tides on spectral shape is significant when wind waves are small. Figure 5 shows a pressure record in which the mean sea level shift caused by the tide can be easily distinguished.

.....It has long been reasoned that point-to-point variations in nearshore wave climate are large. The present record of the network indicates that these variations may be even larger than anticipated. Figure 6 shows qualitatively the intense spatial variability within an 18-mile stretch of coastline during a single month. The "vertical" dimension suggested by

FIGURE 6

this plot is absolute energy plotted at the same scale for all stations.

This variability, both temporal and spatial, reinforces the need for closely spaced nearshore wave measuring stations reporting more than once per day in order to characterize the impact of the wave climate on the shoreline.

CHAPTER 6

WAVE MEASUREMENTS IN OPEN OCEAN

Davidson T. Chen, Benjamin S. Yapple, Donald L. Hammond
and Paul Bey

Space Science Division
Naval Research Laboratory
Washington, D. C. 20375

I. INTRODUCTION

The ability to measure the wave spectra in the open ocean from a moving vessel has met with varying degrees of success. Each sensor to date has suffered in its performance due to environmental conditions or due to its physical placement aboard the vessel for measuring the unperturbed sea. This paper will discuss the utilization of a microwave sensor on a moving vessel for measuring the open ocean wave spectra. Employing microwaves, some of the limitations of other sensors are not experienced.

Tucker [1] developed the Tuckermeter for measuring the wave spectra from a moving ship by sensing changes in water pressure due to surface wave conditions. The Tuckermeter is placed below the water line and thus requires calibration for each wave frequency, ship speed, and depth. Since the sensor operates on pressure, it performs as a low pass filter and will not sense the higher frequencies.

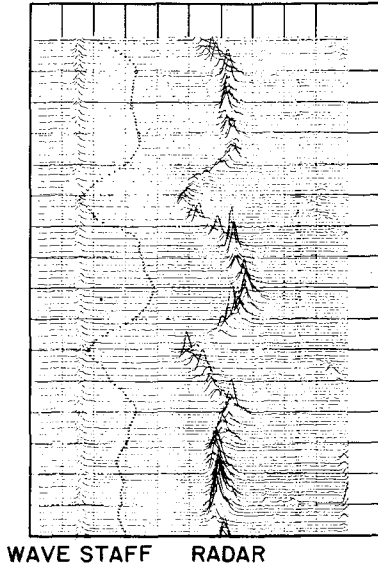

A microwave shipboard wave height radar sensor for measuring the ocean wave spectra was developed by the Naval Research Laboratory (NRL) and was installed on the S.S. McLean in February 1975 and its performance, design, and analysis of data for one data run will be discussed.

II. RADAR SYSTEM

A profile of the ocean waves by measuring their height variations can be used to calculate the ocean wave spectral components. A radar with high angular and range resolution is an ideal sensor for profiling the waves because the narrow antenna beam illuminates a small spot on the ocean surface and the narrow transmitted pulse resolves the vertical height of the waves.

A radar system employing these features was operated from a Coast Guard navigation tower to demonstrate its capability to measure ocean wave spectra as indicated by

Yaplee, et al. [2]. The radar system illuminated a one meter spot with a one-nanosecond pulse permitting a height resolution of 15 centimeters. The radar range measurements were compared with a wave staff mounted around the spot illuminated by the radar. A sample of the radar and the wave staff wave profiles are shown in Figure 1.

Figure 1 Measurements from Chesapeake
Light Tower

The encouraging results of the tower measurements led to a radar system designed to be operated from a ship to profile ocean waves. It was desirable to point the antenna beam out at a slight angle to avoid the ship's bow wake to measure the unperturbed sea. However, since the radar in this look angle is not viewing the nadir, the question arises as to what effect the phenomenon of wave foreshortening will be on the wave spectrum. Therefore, a set of tower radar

measurements were made to profile the sea at different look angles between nadir and forty-five degrees. The wave spectra of the tilted radar and wave staff data were obtained and these spectra were almost identical at all look angles from nadir to forty-five degrees [3]. Therefore it was concluded that the results of the shipboard radar would not be compromised as the result of changing look angles.

The principal parameters for the shipboard radar are listed in Table 1. The functional block diagram of the radar system is shown in Figure 2.

TABLE 1

Parameters for Shipboard Radar

Wavelength	3 centimeters
Pulse Width	2 nanoseconds
Peak Transmitted Power	100 watts
Pulse Repetition Rate	10,000 per second
Antenna Diameter	61-centimeter parabola
Receiver Noise Figure	7 db
Equivalent Pulse Processing Rate	100 per second

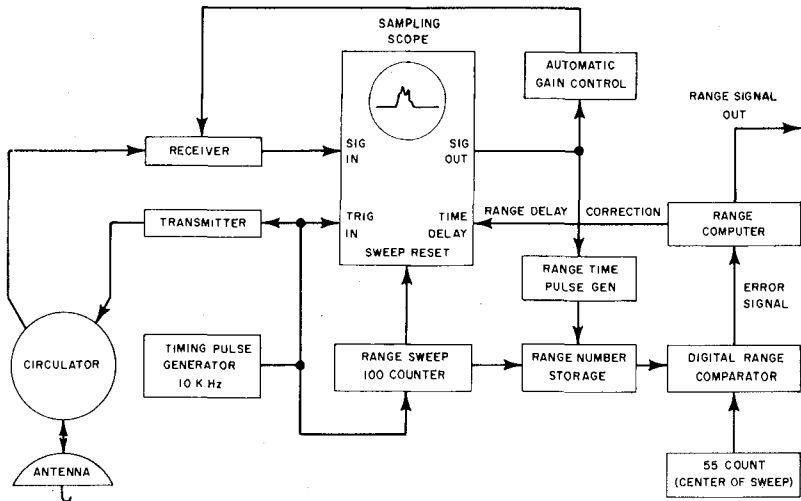

Figure 2 Radar System

The radio frequency components for the transmitter and receiver are mounted in a watertight enclosure on an antenna pedestal located about 23 meters above the ship's water line. The antenna is pointed abeam and tilted down and out about 15 degrees with respect to nadir. Figure 3 is a photograph of the antenna mounted on the starboard side of the ship's bridge and the figure to the right shows a sample of the measured data before processing.

SHIPBOARD WAVEHEIGHT RADAR ON-BOARD SS - McCLEAN

Figure 3

The 10 Kilohertz (KHz) timing generator, shown in Figure 2, triggers the transmitter and synchronizes the receiver signal processing. The radio frequency transmissions consist of 2-nanosecond wide pulses at the 10 Gigahertz (GHz) carrier frequency with a peak power of 100 watts and with a pulse repetition rate of 10,000 per second. The radar pulses reflected by the ocean surface are amplified in the receiver to a usable level. An envelope detector following the amplifier results in a 2-nanosecond wide video pulse.

Processing the 2-nanosecond wide pulses requires circuitry in the system with bandwidths of 500 Megahertz (MHz). It is desirable to operate at a lower bandwidth where components are more easily used and obtained. By using a sampling scope for display and signal processing, it is possible to make this bandwidth transformation to an equivalent video pulse that is 200 microseconds wide or a bandwidth of 5 KHz. Thus the use of standard low speed

logic circuits can be used for signal processing resulting in a simpler and more reliable system. The principle of operation of a sampling scope is well known and will not be discussed. See references [4, 5, 6] for the particular scope used in this radar.

III. EXPERIMENTAL TESTS

The nanosecond radar is located starboard on the bridge of S.S. McLean and adjusted to view the ocean at a look angle of 15 degrees from nadir and away from the bow wake. On February 6, 1975, while the ship was underway from Elizabeth, New Jersey to Portsmouth, Virginia, simultaneous ocean surface data were taken by the shipboard radar while an airborne laser profilometer and airborne nanosecond radar were measuring the same seas. The object of this effort is to establish the validity of the shipboard measured data.

The shipboard radar data were recorded at 30 minute intervals starting at 8:20 A.M. EST on February 6, 1975 and ended at approximately 2:00 P.M. of the same day. Each file of data started with about a minute of zero level setting and followed by a minute of calibrations. The ship was travelling at 14.9 meters per second at 214 degrees heading. Approximately 9:26 A.M. the aircraft intercepted the ship's track at $38^{\circ}3' N$ in latitude and $74^{\circ}41' W$ in longitude. Airborne data were recorded at 152.4 meters and at 304.8 meters altitude in the immediate vicinity of the ship's path. At 152.4 meters altitude, a laser profilometer [7] and an airborne nanosecond radar were used to profile the ocean surface. At 304.8 meters altitude, NRL's airborne nanosecond radar was operated in the wave spectrometer mode. Aircraft data were recorded continuously at intervals of about 90 seconds as the aircraft was flying at 75.2 meters per second ground speed. Exact coincidence of data taking was not possible and comparison of the data is based on approximate times from the ship and aircraft logs.

IV. ANALYSIS

The dynamics of the two platforms (aircraft and ship) while recording ocean surface data was significantly different. In addition to their peculiar motion characteristics, the data were recorded in different manners. One, is continuously in analog and the other, is intermittently and digitally. To effect a better comparison of the data, it was necessary that the data be reduced to some common base.

The analog shipboard data were recorded in real time, and then sampled and digitized at 8 Hertz (Hz) off-line. This digitizing rate was a compromise, taking into account the longest ocean wavelengths expected to be experienced by

the ship and the storage capacity of in-house computers to process the data. The aircraft data were digitized at 90 Hz rate in real time but was utilized at 15 Hz rate off-line. Again a compromise was made with the high frequencies which were not overly significant being truncated and at the same time trying to maintain equal spatial resolution with the shipboard data.

The largest amount of dynamic motion or movement other than forward velocity of a ship is its roll. In Figure 3 was shown a sample of the shipboard radar output and the output of the roll sensor. The magnitude and the period of the roll which affect the determination of the true ocean wave spectra must be removed before any real analysis can be conducted. However other motions also need to be corrected for unless they become second order in magnitude and can be ignored.

By assuming rigid body motion the geometry of the radar aboard ship is shown in Figure 4. The upper figure

(A) VERTICAL UPRIGHT POSITION

(B) ROLL POSITION

Figure 4 Rigid Body Motion due to Roll

shows the direction of the ship moving into the paper and in still water thus remaining in the upright position. The radar measures $R(t)$, the distance from the radar to the surface of the water at an angle α with respect to the vertical. It is the magnitude and frequency of these radar distance variations that yields information for determining the ocean spectra. As mentioned earlier, ship motions, particularly roll, affects the magnitude of these variations yielding an erroneous wave height change. In the lower illustration of Figure 4 is shown an instantaneous roll position that the ship can assume. In this situation, the change in radar distance $R(t)$ is not due to waves but is due to the ship's motion and the radar then measures the distance R_θ instead of R_0 . The magnitude of the change in R_0 to R_θ needs to be determined. Symbols used in Figure 4 for determining this change are defined as

- H_0 - distance from radar antenna to water surface, in the direction of ship's symmetric axis, and 0 degrees roll angle; 23.2 m for H_0 in these calculations;
- H_θ - distance from radar antenna to water surface in the direction of ship's symmetric axis, caused by θ degrees roll angle;
- L_0 - horizontal distance of radar antenna from center of gravity of the ship at 0 degrees roll angle; 12.2 m for L_0 in these calculations;
- θ - angle of roll; positive in clockwise direction, from vertical upright position, by looking into the direction of ship's heading;
- R_0 - radar distance of 0 degrees roll angle;
- R_θ - radar distance at θ degrees roll angle;
- α - look angle of radar antenna, 15 degrees;
- CG - center of gravity of the ship;
- MC - metacenter of the ship;
- BC - buoyant center of the ship.

From the Law of Sine's, it can be shown that

$$R_\theta = (H_0 - L_0 \tan\theta) \frac{\cos\theta}{\cos(\theta - \alpha)} \quad (1)$$

Using Equation (1) the values for $R_\theta(t)$ can be determined from H_0 , L_0 , α , and θ which can be obtained from the ship's roll sensor.

Using $R_{\theta}(t)$ in the radar distance measurements, the following relationship can be established:

$$R_R(t) = R_{\theta}(t) - \zeta(t) \sec(\alpha - \theta) + \Delta R(t) \quad (2)$$

where

$R_R(t)$ - the radar distance measurement to the water surface;

$\zeta(t)$ - the instantaneous apparent wave height, positive in upward direction from the mean sea surface;

$\Delta R(t)$ - the radar distance changes due to ship motion other than roll.

It is worth noting that, as it has been shown by Hammond, et al. [3], for $|\alpha - \theta| \leq 45^\circ$ the term $[\zeta(t) \sec(\alpha - \theta)]$ will indeed give the correct ocean wave spectrum as calculated from $\zeta(t)$. Thus, for simplicity in data processing, Equation (2) can be approximated as

$$R_R(t) = R_{\theta}(t) - \zeta(t) + \Delta R(t) \quad (3)$$

This relationship shows the effect of ship motion in conjunction with wave motion and their effect on the radar range measurements, but assumes that any flexural and torsional motions which change the distance between the radar antenna and the center of gravity are negligible. All other motion changes such as yaw, pitch and heave, etc. are combined into $\Delta R(t)$. The term of interest, $\zeta(t)$, in describing the sea surface, is small in magnitude and it modulates the distance $R_R(t)$ which is large. The shipboard equipment was designed only to record this modulation and as a result a large distance bias, D , remains.

Let

$$R_A(t) = R_R(t) - D \quad (4)$$

where $R_A(t)$ is called the relative radar range measurement and D is a constant. Substituting Equation (3) into Equation (4),

$$R_A(t) = R_{\theta}(t) - \zeta(t) + \Delta R(t) - D \quad (5)$$

Rearranging the terms

$$R_{\theta}(t) - R_A(t) = \zeta(t) - \Delta R(t) + D. \quad (6)$$

Define

$$R_1(t) = R_{\theta}(t) - R_A(t) \quad (7)$$

where $R_1(t)$ is the relative radar range without the effect of ship's roll. Rearranging the terms

$$\zeta(t) = R_1(t) + [\Delta R(t) - D]. \quad (8)$$

This results in $\zeta(t)$ describing the sea surface variations. There still exist $[\Delta R(t) - D]$ which has not been accounted for because D is basically a DC term. This however can be removed by filtering the data. The term $\Delta R(t)$, as defined, consist of all the other ship motions affecting the radar range measurements. The high frequency components of $\Delta R(t)$ are of such low magnitude that their effects on the wave measurements are negligible, whereas the low frequency components can be effectively removed with a high pass filter. In the reference by Linnette [8] the filtering process employed to remove the $[\Delta R(t) - D]$ term is discussed. After the process $\zeta(t)$ still contains a Doppler term and it must be taken care of before it is possible to study the ocean surface characteristics.

The term $\zeta(t)$ describing the amplitude variations of the waves as the radar profiles the surface while the ship is underway includes a Doppler term. Due to the velocity of the ship and the Doppler effect, the waves encountered are foreshortened. Thus the wavelengths measured are not the true ocean wavelength but an apparent wavelength. If the radar's instrumentation had incorporated a coherent radio frequency signal, the effect of the ship's velocity can, by appropriate instrumentation, be subtracted directly. Since this is not the case, it is necessary to correct the apparent spectra to a true spectra. In order to accomplish this, it is no longer possible to operate in the time domain but one must resort to working in the wave number or frequency domain.

It is straight forward to evaluate the apparent wave number spectrum, $\psi_A(k_A)$, from the foreshortened wave height, $\zeta(t)$, where k_A is the apparent wave number because of the Doppler effect. Neglecting the effect of the direction of propagation of the wave component under consideration, it can be shown, in Appendix, that $\psi_A(k_A)$ can be transformed to $\phi(\sigma_T)$ where $\phi(\sigma_T)$ is the true wave frequency spectrum

and σ_T is the true wave frequency. The spectra shown in the results were calculated by using Equation (10) in Appendix.

Significant wave heights were determined by employing equation (9), [ref. 9],

$$H_{1/3} = 4\sqrt{E} \quad (9)$$

where $H_{1/3}$ is the significant height and E is the total energy of the waves.

V. SPECTRAL BANDWIDTH WITH SPECTRAL RESOLUTION

The 0.61-meter parabolic antenna illuminates a footprint [10] about 0.95 meters in diameter at a radar range of 24.4 meters. This footprint size can only resolve wavelengths longer than 1.83 meters which is equivalent to an apparent cutoff frequency of 0.908 Hz. The true cutoff frequency is 0.358 Hz after removing the Doppler effect. Translating this true cutoff frequency into a true wave period results in wave period of not less than 2.8 seconds. The high pass filter, discussed earlier, removes waves with periods longer than 7 seconds in the data. The wave spectra shown in the results are calculated for the wave period window of 2.8 to 7 seconds.

If different spectral bandwidths are desired, the upper frequency bound can be raised by increasing the antenna size. The lower frequency bound can also be extended but this requires removing the ship's motions without the use of high pass filter. The analysis requires ship motion sensors at the site of the antenna to record the actual excursions of the antenna. In this manner it is possible to resolve the longer wavelengths of the spectra.

VI. RESULTS

Wave spectra from the shipboard measurements are presented in Figures 5 to 12. The significant wave heights for files 1 to 8 of the data, respectively, are 2.10, 2.22, 2.23, 2.17, 2.16, 1.99, 1.99, and 1.94 meters. Since the sea was not in steady state conditions, it is not possible to make comparison with the Pierson-Moskovitz spectrum [11]. Figure 13b shows the analyzed results from the airborne measurements made by laser profilometer and the nanosecond radar. Laser profilometer registered 1.84 meters and the nanosecond radar registered 1.43 meters as the significant wave height based on data taken at the altitude of 152.4 meters. At the altitude of 304.8 meters, operating the nanosecond radar in wave spectrometer mode

yielded significant wave height of 2.01 meters. All airborne measurements were made in the vicinity of the ship during part of the time the shipboard radar was recording data for file 2. Accordingly Figure 13b, of the airborne measurements and Figure 6 of the shipboard measurements are combined in Figure 13 for comparison. The shapes are very similar. The significant wave heights of all the measurements are shown in Figure 14. The data are in reasonable agreement, especially when time coincidence of the data is not possible and the aircraft covers such large area about the ship.

Figure 14 Significant Wave Height Measurements, Feb. 6, 1975

VII. DISCUSSIONS

In any system, one can always find areas for improvement, and this radar is no different. After conducting the analysis of the data, several points should be noted.

1. Future radars for this purpose should record the total range as well as the range modulation by the waves. The advantage is to enable one to make absolute corrections for the ship motions; otherwise, only relative corrections can approximately be made for ship motions, and still leave the DC offset as an unknown quantity.

2. A shipboard radar measurement of wave spectra permit viewing the undisturbed area of the sea. With better time and spatial resolution and by employing accelerometers on the antenna, the ship motion effects can be removed directly. Three accelerometers and three angular sensors at the site of the radar are recommended for future measurements.

3. Shipboard radars can operate in all types of weather, twenty-four hours a day.

ACKNOWLEDGMENTS

The authors of this paper wish to thank Kalen J. Craig for his indomitable spirit in developing the radar system and also the testing and evaluating it at sea. The assistance of James Kenney in preparing the equipment for use in the 1974-1975 season is greatly appreciated. Mr. Charles Buhler's skill in the assembly of the antenna package was an excellent example of assistance from the support services at NRL. Mr. E. A. Uliana's programming assistance made the data analysis possible. The cooperation from the personnel from the Teledyne Materials Research and the crew of the S.S. McLean made our task much easier. The authors also wish to make special thanks to Mr. J. T. McGoogan, of NASA Wallops Flight Center, for his encouragement of the study and for permitting NRL to use the C-54 aircraft for measuring the waves independently and simultaneously with the shipboard measurements.

The research reported herein was supported by Naval Sea Systems Command under Contract N00024-75-WR-51625 and U. S. Coast Guard under Contrast MIPR Z-70099-43693.

APPENDIX

The changing pitch of the sound from, say, a fire-engine siren as it moves by at high speed is familiar to all; this effect, the Doppler effect, is one of the most obvious influences of relative motion between the source and the medium. Similarly, if a wave train of ocean waves propagating at the surface of the ocean is observed by a radar in motion, a Doppler change of frequency also will result. The Doppler effect is purely a kinematic phenomenon and can be evaluated without resorting to dynamical equations of wave motion. By kinematic argument [12], it can be shown that

$$\sigma_T = \sigma_A + \frac{\sigma_T^2}{g} v \cos \xi \quad (10)$$

where

σ_T - true wave frequency, $2\pi/T$ or ck_T ;

k_T - true wave number, $2\pi/\lambda_T$;

λ_T - true wavelength;

σ_A - apparent wave frequency;

k_A - apparent wave number, $2\pi/\lambda_A = (\sigma_T^2/g) + (\sigma_T/v \cos \xi)$;

T - wave period;

λ_A - apparent wavelength;

ξ - angle between the ship's heading and the direction of the wave propagation;

v - speed of the ship;

c - phase speed of wave component;

g - gravitational acceleration.

By employing Equation (10) and Jacobian transformation from the apparent wave number domain to true wave frequency domain in Euclidian space yields

$$\phi(\sigma_T) = \frac{2\sigma_T}{g} \left(1 + \frac{1}{2} \frac{g}{\sigma_T v \cos \xi} \right) \psi_A(k_A) \quad (11)$$

where $\phi(\sigma_T)$ is the wave frequency spectrum and $\psi_A(k_A)$ is the apparent wave number spectrum.

Since data is already digitized, the equations are modified to take into account that the information is sampled at some rate and not continuous. Thus following changes are incorporated to perform the calculations:

by defining

M - total number of lags;

J - lag number;

Δx - distance between observations; $v \cos \xi \Delta t$;

Δt - time between observations, then

$$k_A(J) = \frac{J}{M \Delta x} = \frac{\sigma_T^2(J)}{g} + \frac{\sigma_T(J)}{v \cos \xi}$$

and also

$$\sigma_T(J) = - \frac{g}{2v \cos \xi} + \left[\frac{g^2}{4(v \cos \xi)^2} + \frac{g \pi J}{M \Delta x} \right]^{1/2}$$

from Equation (10).

CHAPTER 7

GREAT LAKES WAVE INFORMATION

By

D. T. Resio¹ and L. W. Hiipakka²

I. Introduction.

The lack of reliable Great Lakes wave information has long been a problem for the Corps of Engineers and others involved in planning and design along Great Lakes coasts. In recent years this need has been accentuated by increased water levels and increased demand for coastal land use. The Corps need for wave information became critical with the passage of the River and Harbor Act of 1970 (Public Law 91-611) Section 123 of this legislation authorized design and construction of contained spoil disposal facilities having a ten-year capacity to hold polluted dredged material.

The North Central Division of the Corps of Engineers (NCD) is responsible for dredging 117 navigation projects and connecting channels in the Great Lakes. Of these, 59 are considered polluted, necessitating construction of 41 diked disposal sites at an estimated cost of over \$300,000,000. With a program of this magnitude, it was apparent that unnecessary conservatism in design had to be minimized through development of the best wave information base that the state-of-the-art could provide.

A project was initiated at the Corps of Engineers Waterways Experiment Station (WES) under the sponsorship of NCD to supply design wave information. After a review of all possible sources of available wave information and the potential for obtaining additional gage data, it was determined that a wave hindcast program might best meet the immediate needs of NCD. The actual study has been divided into four phases:

- a. The estimation of over-lake winds,
- b. The establishment of a wave hindcast technique,
- c. The analysis of waves from model outputs, and
- d. The evaluation of errors in Phases a, b, and c.

11. Winds Over A Lake.

Cole (1967) evaluated three methods for estimating winds over Lake Michigan. He compared estimates from these three methods to winds observed at a tower located about a mile offshore from Muskegon, Michigan. Table 1 gives the results of these comparisons to the three techniques in terms of correlation coefficients. The method based on the reduction of geostrophic wind speeds to surface wind speeds produced the highest

correlation coefficient, 0.63. Methods based on the reduction of gradient winds to surface winds (Jacobs, 1965) and on the transformation of over-land wind speeds to over-water wind speeds produced substantially lower correlation coefficients. However, as shown in Figure 1, although the correlation coefficient is high for the geostrophic method there is a pronounced bias toward overestimation of wind speeds, particularly at high velocities. A detailed study of the relationship between geostrophic wind speeds and anemometer-level wind speeds over large lakes (Resio and Vincent, 1976) indicated that this bias is due to the lack of velocity-dependence in the constant used to reduce geostrophic velocities to surface velocities in this method.

During this study two methods were found to produce unbiased estimates of wind speeds over the Great Lakes--a method based on the transformation of geostrophic winds to surface winds using numerical techniques similar to those of Cardone (1969) and a method based on the transformation of wind speeds measured at land sites to over-water wind speeds. The latter of these methods was chosen for application to hindcasting due to its simplicity and the lack of long-term meteorological records at a time and space scale suitable for obtaining accurate geostrophic level winds.

The derivation of the transformation coefficients is discussed in detail in an earlier paper (Resio and Vincent, 1976a). In this paper, the wind speed over water was related to the wind speed over land by

$$U_w = U_L \psi \phi_n \bar{F} \quad (1)$$

where U_w is the over-water wind speed, U_L is the over-land wind speed, and ψ , ϕ_n , and \bar{F} are dimensionless conversion factors accounting for the effects of the velocity-dependence of lake surface roughness, air-sea temperature difference and over-water fetch, respectively. Figures 2 and 3 give the determined forms of ψ and ϕ_n along with corroboratory evidence from other studies for Lake Erie and Lake Ontario. The fetch factor was found to be approximated by

$$\bar{F} = \begin{array}{ll} 0.411 F^{0.297} & \text{for } F < 20 \text{ miles} \\ 1.0 & \text{for } F > 20 \text{ miles} \end{array} \quad (2)$$

where F is the over-water fetch in miles. Whereas the relationships for ψ and ϕ_n were based on more than 52,000 ships observations, the relationship for \bar{F} is based on a limited number of observations tabulated by Richards et al. (1966) and should probably be regarded only as a first estimate.

Using Equation 1 to estimate winds over Lake Erie and Lake Ontario the rms error was found to be a function of velocity (Figure 4). As seen here, the error for wind speeds of importance to design and planning is beneath 5 knots.

Figure 2. Variation in Ψ with observed land velocity

Figure 3. Variation in Φ_n with air-sea temperature difference

Figure 4. RMS error in wind speed estimate as a function of observed land wind speed

It can be shown (Resio, 1976) that the bias introduced by a random error in wind velocity is represented by

$$\frac{\hat{H}}{H} = \frac{(U^2 + \sigma_e^2)}{U^2} \quad (3)$$

where \hat{H} is the estimated mean wave height for conditions with wind speed U , H is the actual mean wave height for conditions with wind speed U and σ_e^2 is the variance of wind estimates around U . Figure 5 shows the value for \hat{H}/H as a function of wind speed for an rms error of 5 knots. For wind speeds above 25 knots over the water, there is less than 5 percent bias due to the random error in wind estimates.

Further evidence that the wind transformation is reliable even during high wind conditions can be seen in Figures 6a, 6b, and 6c. These figures show comparisons of winds estimated from data obtained at Cleveland and Toledo airports during storms on Lake Erie and simultaneous observations of winds by ships in the lake.

III. The Wave Model.

Three hindcast techniques were evaluated for application to the Great Lakes. These are as follows:

- a. The significant wave method contained in the Shore Protection Manual.
- b. A numerical model of the growth and decay of wave spectra as formulated by Inoue (1966, 1967), Cardone (1969), and Pierson et al. (1966).
- c. A numerical model of the growth and decay of wave spectra as formulated by Barnett (1966).

The first technique has been evaluated in previous studies by Cole (1967) and Brebner and Kennedy (1962) on Lake Michigan and Lake Ontario, respectively. Figure 7 shows the results of their comparisons along with some additional comparisons performed during this study for waves in Lake Ontario and Lake Erie. This figure indicates a pronounced tendency to over estimate wave heights in high wind conditions. Regression coefficients suggest that there is about a 35 percent bias in this method. However, since the winds used for hindcasting in this method appear to be too high (Figure 1), the bias might be more a function of errors in wind speed rather than a discrepancy in the wave hindcast curves. The standard deviation of the scatter about the regression line was 2.5 ft.

As indicated in the previous discussion, the lack of precise measure of wind speed over a fetch complicates the comparison of hindcast wave heights to observed wave heights. Therefore, instead of basing a decision regarding the optimal model for hindcasting in restricted fetches on such comparisons, the results of field efforts (Hasselmann et al., 1973;

Figure 5. Estimate of bias due to random wind error

a.

b.

c.

Figure 6. Comparison of wind speeds by ships to wind speeds estimated by equation (1)

Figure 7. Composite chart showing results of comparison of observed wave heights and wave heights hindcast by SMB methods on the Great Lakes

Mitsuyasu, 1968), which formulated functional relationships between non-dimensional fetch and wave height parameters were used for comparisons. These studies have supported Kitaigorodskii's (1962) similarity theory for the development of wave spectra along a fetch. Figure 8 shows a plot of non-dimensional wave height, defined as

$$\tilde{H} = \frac{g\sqrt{E}}{U_*^2} \quad (4)$$

where U_* is the friction velocity of the wind, E is the total energy in the wave spectrum, and g is the acceleration due to gravity, versus nondimensional fetch defined as

$$\tilde{F} = \frac{gF}{U_*^2} \quad (5)$$

where F is the fetch measured in the same units as g and U_* . This figure indicates that none of the available models produce results in accord with recent observational evidence for limited fetches.

Of the three models, the Barnett model came closest to reproducing the desired relationship between non-dimensional fetch and non-dimensional wave height. Consequently, this model was chosen for modification in an effort to achieve a better fit between predicted and expected values. A review of the field studies by Mitsuyasu (1968) and Hasselmann *et al.* (1973) indicated that a major factor not considered in the Barnett model was the variation in the Phillips equilibrium constant with non-dimensional fetch. This constant was originally proposed by Phillips (1958) as a "universal constant" in the relationship between wave frequency and energy density in that portion of the surface waves dominated by wave breaking. On dimensional grounds, he hypothesized that such a relationship should be of the form

$$S(f) = Bg^2 f^{-5} \quad (6)$$

where S is the energy density of waves with frequency f and B is a constant. Later work by Mitsuyasu (1966, 1968), Hasselmann *et al.* (1973), and DeLeonibus *et al.* (1974) have demonstrated that although the f^{-5} proportionality is almost always preserved in the equilibrium range, B varies systematically with non-dimensional fetch and non-dimensional wave height. Figure 9 shows that this variation can be quite important in the Great Lakes regions where non-dimensional fetches can range over several orders of magnitude. Consequently, an implicit formulation of B was programmed into the wave model to compensate for this effect. Figure 10 indicates that this brings the theoretical growth rates into much better agreement with observation.

In several tests of the modified Barnett model against deepwater gage observations in the Great Lakes, the model performed well. Figure 11

Figure 10. Comparison of rate of change of nondimensional wave height with nondimensional fetch with rates of change observed by Mitsuyasu (1968) and Hasselmann et al. (1973)

Figure 11. Comparison of maximum significant wave heights for individual storms as recorded by gages (Point Pelee, Lake Erie; and Toronto, Cobourg, and Main Duck, Lake Ontario), and significant wave heights hindcast by the numerical model using Barnett's parameterizations

is a compilation of the comparisons between observed peak significant wave heights and hindcast peak significant wave heights for storms on Lake Erie and Lake Ontario. The input to this model was taken from land winds transformed as described in the previous section. There was only a small positive bias in this sample (4 percent), and the standard deviation of hindcasts around the best fit regression line was about 1.5 ft.

It should be noted that the wave heights calculated in the model are considered to be deepwater wave heights and must be transformed by refraction, shoaling, diffraction and bottom friction before a nearshore wave estimate can be made.

IV. Analyses Of Model Outputs.

Lake Erie, Lake Ontario, and Lake Michigan have now been completed under the present program at WES. Between 200-500 storms, covering a period of 69 years, have been hindcast for each lake. For each storm hindcast, a time series of two-dimensional spectra at 1-hour intervals was retained on magnetic tape for grid points located at about 10-mile intervals along the shoreline. These data permit an extensive set of analyses into the organization of the wave climate on these lakes. A typical set of data analyses is presented here for Cleveland, Ohio, which is on Lake Erie.

a. Analysis of extreme significant wave heights by season and direction of approach:

Since many harbors and design sites in the Great Lakes are protected by ice during the winter, the analysis of extremes was stratified into seasons defined as January-March (winter), April-June (spring), July-September (summer), and October-December (fall). Similarly, since the design of structures requires information on approach direction, the analysis separated the wave heights into direction classes as shown in Figure 12.

The largest significant wave height within each season-direction category was determined for each storm. It is assumed that the maximum significant wave height in one storm is uncorrelated with a maximum significant wave height in another storm. A preliminary study of the return periods of these wave heights indicated that they were adequately described by a Fisher-Tippett Type I distribution; and hence, the logarithm of the return period could be expected to be a linear function of wave height

$$\ln T \sim a + bH \quad (7)$$

where T is the return period of the significant wave height H and a and b are two constants. Figure 13 shows that this is a reasonable assumption for deepwater wave heights in the Cleveland area. In this figure, the return periods were estimated by the USGS method (Dalrymple, 1960)

$$T = \frac{m+1}{n} \quad (8)$$

Figure 12. Definition of shoreline angles used in study

Figure 13. Linear variation of log T with wave height

where m is the total number of years in the sample and n is the rank of the magnitude (i.e., for the largest wave height $n=1$, for the second largest $n=2$, etc.).

Table 2 gives the return periods for deepwater significant wave heights in the Cleveland area for the four seasons and three angle classes previously defined. The return periods for all directions combined within each season are also given in this table along with the confidence bands for each of these estimates calculated from the relationship (Gringorten, 1961)

$$S_x = S\sqrt{\frac{1.1000y^2 + 1.1396y + 1}{N}} \quad (9)$$

where S is the standard deviation of the annual maxima of significant wave heights, S_x is the confidence band estimate (one standard deviation wide) and y is the reduced variate in the Fisher Tippett Type I distribution.

b. Recurrence intervals for wave heights within an arbitrary time interval during a year.*

Although the stratification by seasons is adequate for some purposes, many planning and design criteria at sites around the Great Lakes require other intervals during the year for consideration. To obtain estimates of recurrence within arbitrary time intervals, all extremes were first categorized by 5-day increments within the year. Thirty-day overlapping periods were used to filter some of the irregularities from the distributions, and then the largest 10 significant wave heights in each time interval and direction class were plotted against recurrence intervals using the USGS method. Least squared error regression lines were calculated for each of these sets of data. Table 3 gives a matrix with the recurrence intervals for each 5-day period within the year calculated in this manner. The recurrence interval, T_k , for k 5-day periods can be calculated from the relationship

$$T_k = \frac{1}{1 - \prod_{i=1}^k (1 - 1/T_i)} \quad (10)$$

where T_i is the recurrence interval for a five-day period. As an example of the application of this table, the mean recurrence interval for a 10-ft wave in the angle class 2 in the month of July is 122 years.

*The only constraint on this is that the time interval must be some multiple of 5 days.

100	8,5(2,0)	18,0(2,0)	15,7(1,0)	18,3(2,1)

c. Significant period as a function of significant wave height and approach direction.

Two factors--significant wave height and over-water fetch--were found to explain the majority of the variations in significant periods. At each site, the over-water fetch is related directly to an angle of wave approach; consequently, mean significant period is well represented as a function of significant wave height within each previously defined angle class (Figure 14).

d. The expected duration of significant wave heights.

The amount of water transported over a dike during a storm is related not only to the peak significant wave height but also to the durations of significant wave heights above particular levels. A simple measure of this latter parameter is taken to be the mean duration of wave heights above any level H for all storms in which that wave height or higher occurs. Figure 15 shows the results of this calculation for the Cleveland data for the months of October through December.

e. Probabilities of higher order wave heights.

Estimates of the average wave heights for the highest 10 percent ($H_{1/10}$) or highest 5 percent of the waves in a spectrum are related directly to estimates of $H_{1/3}$ by a simple constant of proportionality. Consequently, recurrence intervals for these wave heights can be obtained by a transposition of the line for the recurrence intervals for $H_{1/3}$ (Figure 16). However, the statistics for the largest single wave in a spectrum also involve the duration of wave heights. As shown by Longuet-Higgins and Cartwright (1956), the probability of a particular wave height occurring is directly related to the wave height, the rms deviations of the surface elevation, and the duration of the sample. Since many storms have been hindcast in this study, there is no need to assume an average duration, but rather the probabilities can be calculated from the time histories.

V. Discussions and Conclusions.

An important question regarding the usefulness of hindcast wave data is the accuracy of the wave height distributions produced by the hindcasts. The answer to this question must be determined on an individual basis for each different type of probability estimate based on the hindcast data set. For example, as shown in Figure 5, the bias created by an error in wind estimates can create a significant bias at low wave heights. The importance of the type of relative bias demonstrated in Figure 5 is dependent on the magnitude of the bias created in the wave height estimates. Consequently, the extreme bias at winds under 10 knots is not significant in most cases, since the estimated wave heights for these winds are still less than a ft. On the other hand, if more accuracy is needed in this very low wave height range, an analysis similar to Figure 5 could provide a simple means of filtering the distribution of hindcast wave heights to obtain a better estimate of actual wave conditions.

Figure 14. Significant wave period as a function of angle class and wave height

Figure 16. Linear shift in log T between $H_{1/3}$ and $H_{1/10}$

Figure 17. Relationship between $\Psi(Z)$ and Z

At the other end of the distribution, the extremes, the results shown in Figure 5 indicate very little bias; however, as shown in Resio and Vincent (1976b), an additional source of error encountered in this range comes from the effects of the convolution of the extremal distribution and a Gaussian error distribution. This bias can be considered in terms of the ratio of mean recurrence interval estimated from the extremal distribution with the error term \hat{T} , to the mean recurrence interval for the extremal distribution alone, T . In Resio and Vincent (1976b) this was shown for a Fisher-Tippet Type 1 distribution to be given by

$$\frac{\hat{T}}{T} = \frac{1 - F(H)}{1 - F(H)\psi(z)} \quad (10)$$

where the form of $\psi(z)$ is shown in Figure 17 with z defined as

$$z = \frac{\sigma}{B} ,$$

where σ is the rms error in the wave estimates and B is a coefficient of variation in the extremal distribution.

The importance of the above relationships is that it indicates that the possible bias can be quantified. For design wave calculations on Lake Ontario, this bias was shown (Resio and Vincent, 1976b) to be less than 10 percent. Additionally, the implication is that the confidence bands are not seriously affected by the random errors in individual hindcasts for these data. Thus, Equation 9 still provides a good estimate of the confidence bands when using hindcast wave heights, and the width of the confidence band still decreases as the square root of the record length.

This paper has demonstrated the utility of a numerical hindcast model in providing a set of data which can subsequently be analyzed to obtain a wide range of information on the organization of the wave climate at a site. Although there are errors in specific hindcasts, these errors do not appear to create significant bias in many of these statistical estimates. Furthermore, the ability to obtain a long-term, synthetic record of two-dimensional spectra permit an extensive analysis into even complex phenomena with higher confidence than could be obtained from an exact record obtained from exact measurements over a shorter period of time.

CHAPTER 8

APPLICATIONS OF EMPIRICAL FETCH-LIMITED SPECTRAL FORMULAS TO GREAT LAKES WAVES¹

Paul C. Liu, M. ASCE²

ABSTRACT

Two episodes of Great Lakes waves for which both wind and wave data are simultaneously available are used to examine the applicability of the empirical fetch-limited spectral wave formulas developed by JONSWAP, Mitsuyasu, Liu, and Sverdrup-Munk-Bretschneider. Comparing the results hindcast from the formulas with those recorded shows that, for hindcasting significant wave heights, Liu's formula gives better results for less than fully developed waves, while formulas by JONSWAP, Mitsuyasu, and Sverdrup-Munk-Bretschneider give better results for fully developed waves. In hindcasting average wave periods and peak-energy frequencies, all the formulas result in a deviation of up to 2 s and 0.5 rad s⁻¹, respectively. These results can be used as a reference in evaluating and interpreting wave predictions made by these formulas as applied to the Great Lakes.

1. INTRODUCTION

Various surface wave studies in recent years have results in the development of several sets of empirical fetch-limited spectral formulas of practical interest in wave predictions. These formulas are all characterized by the dimensionless fetch parameter $X_0 = gX/U_*^2$, where g is the acceleration of gravity, X the fetch distance, and U_* the frictional wind velocity. In terms of X_0 , the significant wave height $H_{1/3}$, peak-energy radian frequency ω_p , and spectral energy density $S(\omega)$ as a function of frequency ω can be expressed by

$$H_{1/3} = A \frac{U_*^2}{g} X_0^a \quad (1)$$

$$\omega_p = B \frac{g}{U_*} X_0^{-b} \quad (2)$$

$$S(\omega) = C g^2 \omega^{-5} X_0^{-c} \exp[-DX_0^{-d} (\frac{U_* \omega}{g})^{-4}] F \quad (3)$$

in which A , B , C , and D = the empirical coefficients; a , b , c , and d = the empirical exponentials; and F = an empirical spectral shape function. Several authors have developed various sets of numbers for these empirical constants. Table 1 represents a summary of the results obtained from these studies. Data

collected from many oceans and lakes, as well as laboratory wave tanks, were used. Table 1 reveals that some of the constants derived by these authors are quite close; some of the constants, however, differ significantly. It is of interest to note that, although the authors used their own wave measurements in developing their empirical formulas, they all made an effort to incorporate the results of well-known wave studies published during the past 20 years. Obviously, some of the differences in the coefficients can be attributed to the authors' subjectivity in adjusting the regression line to fit their own data. Because of these differences and because of the simple nature of the formulas, case studies have been made to examine the applicability of the formulas by using available wave data from the Great Lakes. This paper presents two episodes of wave conditions for which recorded data are compared with those hindcast by the formulas of JONSWAP, Mitsuyasu, and Liu. In addition, conventional hindcasts from the Sverdrup-Munk-Bretschneider formulas (Shore Protection Manual, Vol I, 1973) are also included for further comparisons.

2. CHARACTERISTICS OF THE FORMULAS

Before proceeding to the case studies, it is of interest to examine some of the basic characteristics of the formulas that use hypothetical wind conditions. Because frictional wind velocity was not available for this study, logarithmic wind profile and a drag coefficient, C_{10} of 10^{-3} have been used in this paper for converting wind speed at different levels to U_* . Fig. 1 presents a set of examples of wave spectra calculated by empirical formulas (3) for 10-m level wind speeds of 5 and 40 m s^{-1} and fetch distances of 10 and 100 km. As the four cases shown in the figure combine long and short fetches with high and low wind speeds, respectively, the magnitude of spectral energy and peak-energy frequency varies significantly from case to case. However, the relative differences among the three empirical spectra are similar for all cases. In general, JONSWAP and Mitsuyasu spectra are fairly close, especially at high wind speeds, while Liu spectra yield much lower energy content. The energy at the spectral peaks for JONSWAP and Mitsuyasu are approximately an order of magnitude larger than those of Liu. An explanation for this great difference lies in the fact that the wave data used in developing the JONSWAP and Mitsuyasu formulas are from fully developed seas, whereas the wave data from Lake Michigan used in Liu's formula are not.

With energy spectra calculated from the empirical formulas, the spectral moments can be readily obtained. The basic parameters, such as significant wave heights and average wave periods, can then be derived from the moments, based on the theoretical results of Longuet-Higgins (1952) and Rice (1945), as:

$$H_{m_0} = 4m_0^{1/2} \quad (4)$$

and

$$T_{m_{0,2}} = 2\pi(m_0/m_2)^{1/2} \quad (5)$$

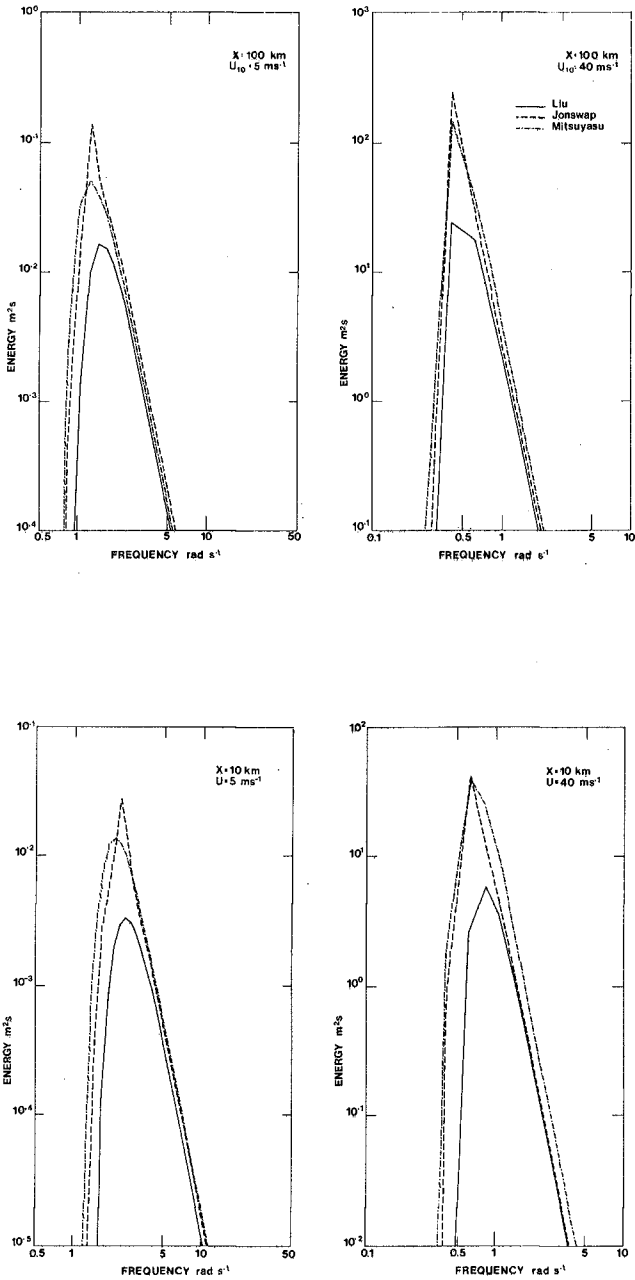

Fig. 1 Examples of wave spectra calculated by empirical formulas.

in which the n th moment of a wave spectrum is given by

$$m_n = \int_0^{\infty} \omega^n S(\omega) d\omega. \quad (6)$$

Here the average wave period $T_{m0,2}$ is presumably equivalent to the wave period given by the Sverdrup-Munk-Bretschneider method. The significant wave height H_{m0} calculated by Eq. (4) should approximate $H_{1/3}$, calculated by (Eq. 1). A correlation of calculated H_{m0} and $H_{1/3}$ is given in Fig. 2. In the case of the JONSWAP method, H_{m0} tends to be larger than $H_{1/3}$. A slightly greater trend is also shown in Mitsuyasu's case. Since Liu's empirical equation for $H_{1/3}$ was a direct derivation from the spectral moments, the close correlation shown is not surprising. In the following discussions, $H_{1/3}$, ω_p , and $T_{m0,2}$ will be calculated from the various empirical formulas and compared with actual data.

3. APPLICATIONS OF THE FORMULAS

Two episodes of Great Lakes waves, with both wind and wave data available, are used to examine the applicability of the various empirical formulas. The first episode occurred in Lake Michigan. Wave data were recorded by a staff gage installed on a research tower located 2 km offshore from Muskegon, Michigan, in 16 m of water (Fig. 3). The wind anemometer was located at 10 m above the lake surface on the same tower. The episode covered approximately 4 days during October 25th through 28th of 1971. The wind conditions, which are typical of the Great Lakes, are shown in Fig. 4. The wind speeds during this episode were quite unsteady with the predominant direction from the south and south-southeast providing moderate fetch distances of the order of 50 km.

Fig. 5 represents the significant wave heights $H_{1/3}$ recorded during this episode as compared with those hindcast by empirical formulas. Here and in the following figures in this paper, the heavy solid lines indicate recorded data; the dotted lines, the long-short dashed lines, the dashed lines, and the light solid lines indicate the hindcast data by Sverdrup-Munk-Bretschneider, Mitsuyasu, JONSWAP, and Liu, respectively. The results of Sverdrup-Munk-Bretschneider, Mitsuyasu, and JONSWAP, shown in Fig. 5, are strikingly close. In this episode, they all overestimated the recorded data by a factor of 2. Liu's results are relatively lower than the others since the energy contents given by Liu's formula are generally less than the others. In this case, Liu's results are closer to the recorded results than the others.

Fig. 6 shows the comparisons for the average wave period $T_{m0,2}$. The relative differences between the results of different authors seem quite similar and distinctive. Sverdrup-Munk-Bretschneider, for the most part, furnished the highest estimate, followed in order by Mitsuyasu and JONSWAP. Liu hindcast relatively lower average wave periods for the same wind condition.

The results for the peak-energy frequency ω_p are shown in Fig. 7. The Sverdrup-Munk-Bretschneider formula does not give estimations for ω_p ; hence,

Fig. 7 Comparison of hindcast and recorded ω_p during Lake Michigan episode.

only JONSWAP, Mitsuyasu, and Liu are compared. The relative differences are again quite similar and distinctive. Liu hindcast a higher ω_p , followed by JONSWAP and then Mitsuyasu.

The second episode is from Lake Ontario. The wave gage, a waverider buoy manufactured by Datawell of Holland, was located 30 km northeast of Oswego, New York, in 150 m of water. The solid circle labeled Oswego-2 on the map, Fig. 8, indicates the waverider location. The open circle on the map shows the location of an instrumented buoy where the wind data used in this analysis were recorded. The wind anemometer on the buoy was 4 m above the lake surface.

Fig. 9 gives the wind conditions during this 4-day episode of October 7-11, 1972. The wind speeds were typically unsteady, with directions starting from the north, with a moderate fetch of 40 km, changing to west with a long fetch of 200 km or more when the storm intensified, and gradually switching back to north after the storm subsided.

The comparisons for the hindcast and recorded significant wave heights for this episode are shown in Fig. 10. The relative differences between the empirical results remain the same. The results of this episode are different from the first episode, however, in the sense that Liu's hindcasts, which were closer to the recorded results than the others in Fig. 5, are clearly underestimated in Fig. 10. The hindcasts of Sverdrup-Munk-Bretschneider, Mitsuyasu, and JONSWAP are again close to each other in this episode and also close to the recorded data during the growth part of the storm. All the empirical formulas significantly underestimated $H_{1/3}$ when the wind field decayed and directions switched from long fetches to short fetches.

Figs. 11 and 12 show the comparisons for $T_{m0,2}$ and ω_p , respectively, for this episode. The results are generally similar to those discussed in Figs. 6 and 7. It seems that, at any given time, one of the formulas tends give a better hindcast than the others, but none of the formulas is able to maintain the close hindcast throughout the episode. The inconsistency, therefore, casts doubt over the applicability of all the formulas.

Two examples of comparing computed spectra with the recorded spectra are shown in Fig. 13. The accuracy of the spectrum hindcast by the formulas depends mainly on the accuracy of corresponding formulas in hindcasting significant wave height and peak-energy frequency. If the hindcast significant wave height and peak-energy frequency values are close to those recorded, then the hindcast spectrum will certainly be close to that recorded and vice versa. The comparisons of spectra shown in the figure represent the typical results that can be expected from these empirical formulas.

4. SUMMARY AND CONCLUDING REMARKS

It has been the intent of this paper to present an assessment of the usefulness and applicability of the various empirical formulas in connection with surface waves in the Great Lakes. The assessment has been performed by comparing waves that were hindcast by the formulas with those actually recorded during two storm episodes in Lakes Michigan and Ontario. Based on the detailed

Fig. 8 Location of wave gage in Lake Ontario.

Fig. 9 Wind conditions during Lake Ontario episode.

Fig. 10 Comparison of hindcast and recorded $H_{1/3}$ during Lake Ontario episode.

Fig. 13 Examples of hindcast and recorded wave spectra.

comparisons for the three parameters $H_{1/3}$, $T_{m0,2}$, and ω_p , results can be summarized as follows:

a. Significant Wave Height, $H_{1/3}$. The hindcasts by the JONSWAP, Mitsuyasu, and Sverdrup-Munk-Bretschneider methods are generally close to each other and greater than Liu's hindcast by about 50 percent. During the Lake Michigan episode, Liu's results were closer to the recorded results than the others; thus, the other formulas yielded overestimations. During the Lake Ontario episode, JONSWAP, Mitsuyasu, and Sverdrup-Munk-Bretschneider's results were closer to the recorded results than Liu's during the growth part of the storm; hence Liu's results appear to be underestimations.

At first glance, the results rendered by the two episodes seem to be inconsistent. The inconsistency, however, can be clarified by further examination of the two respective wind fields. During the Lake Michigan episode, the 10-m wind speeds started at 2 m s^{-1} and gradually increased to 10 m s^{-1} and higher; thus, the wave spectra were mostly under development. During the Lake Ontario episode, on the other hand, the wind speeds at the 4-m level had reached over 10 m s^{-1} at a very early stage of the storm. The wave spectra under this wind field tended to be fully developed. From these facts, it appears that Liu's formula is applicable for the less than fully developed waves, whereas JONSWAP, Mitsuyasu, and Sverdrup-Munk-Bretschneider formulas are applicable for the fully developed waves. This is consistent with the characteristics of the data from which the corresponding formulas were derived.

The above discussions apply only to the growth part of the storms. All the formulas underestimated the significant wave height when the wind field decayed, especially when the decay involved changes in wind direction as well as reductions in fetch distances. As the formulas were neither derived from, nor intended for, decaying processes, the results are by no means unexpected.

b. Average Wave Period, $T_{m0,2}$. The difference between high and low estimates as hindcast by the formulas for a given time is about 2 s. The recorded data generally lie within this range. Therefore, the error in hindcasting average wave periods by any formula is about 2 s or less. None of the empirical results can be considered substantially close to the recorded results throughout either of the two episodes.

c. Peak-Energy Frequency, ω_p . The difference between high and low ω_p hindcast for a given time is about 0.5 rad s^{-1} . With the exception of the low wind portion of the Lake Michigan episode and the decaying portion of the Lake Ontario episode, the recorded ω_p lies within the range of the empirical hindcasts. An accurate hindcast of ω_p will lead to accurate hindcasting of wave spectra if the hindcast of significant wave height is also accurate. None of the formulas seems to be able to provide an accurate ω_p . During both episodes, Liu's hindcasts were relatively close to the recorded results through a major portion of the storm. JONSWAP and Mitsuyasu's hindcasts came closer to the recorded results at the peak of the storm.

These results, while generally fulfilling most of the objectives of this paper, are by and large both disappointing and encouraging. These results are disappointing because they demonstrate that simple fetch-limited spectral formulas have not provided substantial applicability to the prediction of Great

Lakes waves. Undoubtedly, parameters neglected by the formulas, such as duration and atmospheric stability, play important roles not known at the present time and need to be further explored. On the other hand, these results are encouraging because they provide information on the limitations and error ranges that can be expected in the application of these formulas to predicting Great Lakes waves. Until further developments and additional studies are made, the results presented in this paper will continue to be useful.

CHAPTER 9

WAVES OFF TAICHUNG COAST OF TAIWAN

by

Charles C.C. Chang¹, M.H. Wang² and J.T. Juang³

SYNOPSIS

Many coastal engineers have made studies on the characteristics of waves, but most of them concentrated on waves of the open ocean. Due to the environmental difference, the result drawn for open ocean waves may not be applied to straits or the continental shelf. Based on the observed data, the authors intend to obtain some characteristics or tendency of wave condition in the Taiwan strait. Correlation among wave parameters and meteorological factors is also examined. Comparisons to the result for open ocean waves are made to supply information for planning, design and construction of coastal structures on the coast of the strait. These studies are also useful for wave prediction in the strait area.

GEOGRAPHICAL AND METEOROLOGICAL CONDITIONS

The Taichung coast, on the central-west part of the island of Taiwan, faces the Taiwan strait as shown in Fig. 1. The climate in this area may be classified as winter monsoon, summer and the transitional seasons. The speeds of NNE-NE winds prevailing during the monsoon season beginning in October to the next March are generally higher than those of S-SW winds in summer season from May to August. Due to frequent change of

 2. Former Assistant Engineer, Taichung Harbor Bureau, Taiwan, Rep. of China.
 3. Assistant Engineer, Hydraulics Laboratory, Taichung Harbor Bureau, Taiwan, Rep. of China.

wind directions, the months of April and September are regarded as the transitional season. However, during the period of July to September, this island is frequently hit by typhoons. Paths of seven typhoons from 1971 to 1975 were plotted in Fig. 2.

DATA COLLECTION

An ultrasonic wave gauge was set at a water depth of 19 meters below low water level in the Taichung harbor construction area off the coast. The gauge was installed in July 1971 to record waves of 20 minute intervals for two hours. Among the wave series, 150 waves were chosen to represent to wave record of this time interval. Parameters of the average wave, the one-third highest wave or the significant wave, the one-tenth highest wave and the maximum wave were calculated. The reference wind speed was compiled from the anemometer records established on this coast. Location of the wave gauge and the anemometer are shown in Fig. 3.

ANALYSIS

The relative occurrence frequency of the significant wave height and that of the significant wave period were calculated by month, by season and finally by 4 years, the duration of all records. In order to investigate the central value and the scatter of probability distribution, both mean and variance of wave characteristics were computed. Since the waves change with the meteorological factors, thus, the difference of wave height statistics for each month and each season is examined. The same procedure is followed for studying the probability distribution of the significant wave period. Moreover, the correlation coefficient between the significant wave height and its reference wind speed for each month was calculated. The coefficient is useful to wave prediction. Because wave steepness plays an important role on the development of coast, the deepwater wave steepness H_0/L_0 has been studied.

For comparisons of the wave condition of this

strait area with the open ocean. Two sources of open ocean wave data are selected. One was obtained by Hogben and Lumb (1966) in the ocean area off the north and east coasts of Taiwan and also analyzed by Bretschneider (1973). The other was collected by Jade Dattatri (1973) off the Mangalore harbor located on the west coast of India as shown in Fig. 4.

Because typhoon waves control the design condition of coastal structures, seven typhoon wave sequences as shown in Fig. 2 have been studied. Correlation coefficient between typhoon wave height and wind speed was calculated and discussed. The relationship between the significant wave height $H_{1/3}$ and period $T_{1/3}$ is also examined with the equation suggested by Bretschneider (1973).

$$T_{1/3} = 3.86 \sqrt{H_{1/3}} \quad (1)$$

The above equation is derived from wave data of open ocean. The unit of $H_{1/3}$ is meter and $T_{1/3}$ is second.

In order to check whether the theoretical Rayleigh's law will apply to strait waves, ratios among wave heights of the significant wave, the one-tenth highest wave, the average wave and the maximum wave are studied. The results are compared with the equations presented by Longuet-Higgins (1952)

$$H_{1/3} = 1.6 H_{ave} \quad (2)$$

$$H_{1/10} = 1.27 H_{1/3} \quad (3)$$

$$H_{max} = 1.583 H_{1/3} \quad (4)$$

RESULTS AND DISCUSSIONS

1. Periodicity of Wave Condition

The distributions of the significant wave height for each season are shown in Fig. 5 and Fig. 6. The accumulated probability of wave height is also shown in Fig. 7. All deviate slightly from the Rayleigh's curves.

The significant wave period for each season was

shown in Fig. 8. The accumulated probability is also shown in Fig. 9. The distribution of $T_{1/2}$ for each season nearly follows the normal law. It seems that the variation of meteorological condition in each season doesn't change the type of wave period distribution as illustrated in these diagrams.

Mean values of monthly significant wave heights and periods with their 90% confidence interval are shown in Fig. 10 and 11 respectively. The periodicity of monthly occurrence of $H_{1/2}$ and $T_{1/2}$ is also shown in Fig. 12. Oceanic condition in summer is quite calm. From May to August, monthly mean of wave height is less than 0.8 meter and wave period less than 5.5 second. Concerning the transitional season, both mean values of monthly wave height and period in September are larger than those in April. As to the monsoon season, mean values of wave heights in October has the largest confidence interval while that in March has the smallest. Comparison of the variance coefficients of wave heights and periods for each month is made in Fig. 13. It is clear that the variation coefficient of $H_{1/2}$ is always larger than that of wave period. Since the typhoon hits this island occasionally, the variation coefficient of wave height in summer is quite high. However, the yearly recurrence of the significant wave period is quite obvious. Typhoons also affect the monthly mean value of wave height, but it has little effect on that of wave period. Meanwhile, the monthly correlation coefficients between wave height and wind speed are also calculated as shown in Table 1 which shows no distinct difference for winter and summer seasons.

2. Monthly Variation of Wave Steepness

The monthly mean of deepwater wave steepness with 90% confidence interval is shown in Fig. 14. During the winter monsoon season from October to March, the wave steepness is rather high, beach erosion might occur. However, due to large tidal range, only a few sand bars appear in this coast.

3. Typhoon Waves and Winds

Wind direction generally changes from NNE through N, NNW, W, WSW and SSW to S during a typhoon assault. The wind is rather steady and duration is long during the former stage. The NNE and N winds are dominant at

this stage. The longest duration of N wind ever recorded is 24 hours and that of NNE wind is 20 hours. Relationships between the significant wave height and the reference wind speed for NNE and N are plotted in Fig. 15 and Fig. 16 respectively. The short vertical line, drawn in Figures, indicates the standard deviation of wave heights from their mean. The wave height increases linearly with wind speed when the peak of typhoon wave sequence is over, unsteady wind is usually observed except from SSW direction. At a later stage, the wind direction changes rapidly from time to time, as a result the duration becomes very short, no definite relationship between wave height and wind speed can be formed except the SSW direction.

Using 90% confidence interval, the ratios of the significant wave height $H_{1/3}$ to the reference wind speed $U_{Ref.}$ for NNE, N and SSW wind are obtained as follows.

$$\begin{aligned} \frac{H_{1/3}}{U_{Ref.}} &= 0.110 - 0.130 && \text{for NNE wind} \\ &= 0.133 - 0.147 && \text{for N wind} \\ &= 0.112 - 0.128 && \text{for SSW wind} \quad (5) \end{aligned}$$

where $H_{1/3}$ is in meter and $U_{Ref.}$ is in meter per second.

The relationship of the wave height and SSW wind speed is shown in Fig. 17. The null hypothesis may be accepted in 1% significance level as follows.

$$H_{1/3} = 0.130 U_{Ref.} \quad (6)$$

The correlation coefficient between wind speed and wave height for each typhoon is listed in Table 2. Typhoon Nina whose center passed by the harbor has the largest correlation coefficient, while Typhoon Gloria passed the Bashi strait, southward of the island, has the least. It may be assumed that a stronger relationship between winds and waves would result if the typhoon path is closer to the location of the wave recorder.

4. Typhoon Wave Height Distribution

The ratios among $H_{1/3}$, H_{ave} , $H_{1/10}$ and H_{max} of typhoon waves have been studied in order to ascertain the conformity to the Rayleigh distribution of wave

height. In accordance with Fig. 18, 19 and 20, the relationship may be expressed as follows:

$$H_{1/2} = 1.41 H_{ave} \quad (7)$$

$$H_{1/10} = 1.20 H_{1/2} \quad (8)$$

$$\begin{aligned} H_{max} &= 3.04 H_{1/2} && \text{for } H_{max} \leq 5.8^m \\ &= 1.16 H_{1/2} && \text{for } H_{max} \leq 4.5^m \end{aligned} \quad (9)$$

The first relationship in Eq. (9) is regarded as the upper limit and the second one, the lower limit. These equations (7, 8 and 9) indicate that the strait wave height distributions may not follow exactly Rayleigh's law. The small wave in the strait has higher probability of occurrence than that in the ocean. The mean value of H_{max} to $H_{1/2}$ ratio for each typhoon wave sequence and its standard deviation are shown in Table 3.

5. Typhoon Wave Height and Period

The correlation curve between typhoon wave height and period of 90% confidence interval is shown in Fig. 21. The scatter diagram of wave height and period is shown in Fig. 22. The most probable relationship may be represented by Eq. (10)

$$T_{1/2} = 4.56 \sqrt{H_{1/2}} \quad (10)$$

It indicates that for the same wave height, the wave period in the strait is longer than that in the ocean. Such a phenomenon is worth further study.

6. Recurrence Period of Wave Height

Based on the wave height distribution compiled from 4-year records, the recurrence period of the specified significant wave height has been calculated. Comparison of the recurrence period of wave height in the strait with that in the ocean (Bretschneider, 1973) has also been made. Bretschneider's result was drawn from ship observation of waves on the north and east coasts of Taiwan (Hogben and Lumb, 1966) as shown in Table 4 and Fig. 23. The wave height in the strait is approximately one half of that in the ocean. However, the curves shown in Fig. 23 may be modified by further observation and analysis, this study may still be used as the

criteria for waves in the strait sheltered area.

7. Comparison of Monsoon Wave Distribution

The wave height and period distribution of the Taichung coast is compared with that of the Mangalore harbor on the west coast of India. It is noted from Fig. 24 and Fig. 25 that the monsoon wind on the west coast of India generates waves heavier than those generated on the Taichung coast. Nevertheless, the wind speed recorded at the Mangalore harbor was lower than that at the Taichung harbor.

CONCLUSIONS

The meteorological factors have little effect on the monthly distribution of wave period, which has a clear recurrence month by month. The significant wave period may be estimated from the significant wave height by Eq. (10). The wind acts as a dominant factor to the wave height. Therefore, the wave height distribution of winter monsoon differs from that of summer season. It is found that the wave height on this coast is approximately one half of that on the north and east coasts of Taiwan based on a comparison with Bretschneider's (1973) results. This phenomenon is also verified by comparing the waves off west coast of India. Though the wind speeds in the India coast area are lower, heavier seas are also observed. However, waves in the straits would have rather a longer period for a given magnitude of wave height. The distribution of strait wave height may not follow the Rayleigh's law. So that the strait wave will be overestimated by means of the result drawn by Longuet-Higgins (1952). The recurrence interval of various significant wave height shown in Table 4 and Fig. 23 may be used as the wave criteria for the structure design on the coast of the strait. Of course, the result is needed to be modified by further study.

ACKNOWLEDGMENT

The authors express their appreciation to Admiral M.C. Chen, director of the Taichung Harbor Bureau, for

kind permission to use the wave and wind records. Acknowledgment is also made to Mr. C.L. Wang, chief engineer of the Taichung Harbor Bureau, and Dr. L.W. Tang, Professor of National Cheng-kung University, for their constant instruction in the presentation of this study. Besides, much of the calculation work herein was done by Mr. Y. C. Huang. The authors are very grateful for all the help which was given and has made this study possible.-

CHAPTER 10

EXTREME WAVE PARAMETERS BASED ON CONTINENTAL SHELF STORM WAVE RECORDS

by

R. E. Haring*, A. R. Osborne* and L. P. Spencer*

SUMMARY

Measured storm wave records from several Continental Shelf areas were used to test the adequacy of estimating formulae for individual wave parameters. In all, 376 hours of storm wave records were analyzed, and their properties nondimensionalized by fundamental spectral parameters. Results are presented for surface deviation statistics, individual wave height statistics and individual wave period statistics. The results can be used by ocean engineers to eliminate unintended bias from wave parameters selected for the design of offshore facilities. The most significant result is that measured rare wave heights in the storm wave records are on the order of 10 percent less than predicted by the Rayleigh distribution at the 1 in 1000 probability level.

INTRODUCTION

Severe storms on the Continental Shelf produce a complex series of waves in time and space. The condition of the ocean's surface which exists over a short time interval is assumed to be a stationary process called a sea state. The spectral definition, a distribution of the amplitude energy density in the frequency domain, contains the necessary information to define the sea state. Fundamental properties derived from the spectral definition are the total energy content (or variance of the sea surface) and the dominant frequency (or frequency of maximum energy density). The shape of the spectral density function is also important because it characterizes the wave amplitude record. Modern wave prediction methods estimate the energy content of the sea surface as a function of both frequency and direction [1]. Instrumental measurements of the stationary, time-varying sea surface can be analyzed mathematically to produce the spectral density as a function of frequency. Such instrumental measurements are often used to verify or calibrate numerical wave prediction models. Figure 1 illustrates the typical sea state spectrum and the derived properties which will be used in this paper.

Conventional engineering design practice for fixed offshore structures requires the specification of an individual wave in terms of trough-to-crest height and zero-crossing period [2]. This design wave should be a realistic estimate of the extreme, rare wave in a severe storm sea state whose return period is appropriate for the design

* Exxon Production Research Company, Houston, Texas.

problem at hand and whose properties are consistent with real sea surface behavior. Selection of design wave parameters is often based on the assumption that the distribution of wave heights in a storm sea state is described by the theoretical Rayleigh distribution. Practical formulae for the selection of wave parameters have been proposed based on this assumption. These formulae can be expressed in terms of the fundamental derived properties from the amplitude energy density spectrum. However, an idealized sea surface is assumed; that is, the distribution of surface deviations about the mean is Gaussian and the energy is narrow-banded in the frequency domain. Neither of these assumptions is satisfied for storm wave records on the Continental Shelf. Jahns and Wheeler [4] have shown that substantial deviations from the Gaussian assumption occur in water depths up to 100 ft. Furthermore, reported storm wave spectra and spectral hindcasts made by modern wave prediction methods may not be sufficiently narrow-banded to justify that assumption. A study was undertaken using measured storm wave records from several Continental Shelf areas to test the adequacy of estimating formulae for individual wave parameters. The results reported in this paper will allow the designer to avoid any unintended bias in selecting design wave parameters. The results also provide a basis for the development of empirical compensation factors for practical use.

DATA SOURCES AND ANALYSES

The offshore petroleum industry has undertaken several measurement programs in areas of present and future interest. Valuable wave records have been obtained in the Gulf of Mexico through the Ocean Data Gathering Program [5], in the North Sea through a measurement program sponsored by the United Kingdom Offshore Operators Association and through the Gulf of Alaska Wave and Wind Measurement Program [6]. Exxon has also obtained storm wave data in conjunction with offshore operations. Analysis of these data is restricted to digitized storm wave records. The arisen sea states provide the opportunity to examine greater deviations from the idealized sea surface than would be expected under ambient wave conditions. Compensation factors developed from the measured storm data should be applicable to design problems because the underlying physical phenomena are similar to those that occur under design level conditions.

Table 1 summarizes the data sources utilized in this study. Widely different geographic areas, water depths, and measurement systems are combined in the results presented in this paper. Altogether, approximately 376 hours of storm wave records were analyzed.

Many investigators have presented characteristic spectra based on wave measurements. The principal ones applied to continental shelf storms are due to Pierson and Moskowitz [7], Robinson, Brannon and Kattawar [8] and Hasselmann et al [9, 10, 11]. These spectra are compared in a nondimensionalized form in Fig. 2. The dimensionless groups used here place the dominant spectral frequency at unity and require that the area under the spectrum be unity. Thus, the spectral density shapes in the frequency domain can be compared directly. The storm wave data analyzed in this study exhibit a broad range of spectral shapes which include all three of the model shapes illustrated in Fig. 2. This is not unexpected because of the variety of meteorological conditions represented by the data. The storm waves in the Gulf of Mexico are produced by tropical storms with their attendant high winds and rapidly changing wind fields. North Sea and Gulf of Alaska storms are produced by large extratropical disturbances which have lower wind speeds but greater fetch lengths and durations. In some cases there is swell propagating into the wind fetch area which alters the character of the storm spectra.

Statistical analyses of the storm wave records were conducted in a hierarchy outlined below:

Data Blocks - Continuous water surface deviation records were digitized, and approximately 20-minute segments were analyzed as a block. A 20-minute wave record is considered long enough to obtain statistically meaningful results, but short enough to warrant the assumption of a stationary, ergodic process. The data were screened to insure that no noise spikes, DC drifts or original analog signal lapses would be inadvertently incorporated into the statistical analysis. An amplitude energy density spectrum was computed for each block of storm wave data. This defined the dominant spectral frequency and the spectral moments for the block. The spectral calculations were conducted by the methods of Blackman and Tukey

[12] with the number of lag products used for the autocorrelation function calculation equal to approximately $100/\Delta t$. Statistics on individual wave crest elevations, heights and zero-crossing periods were accumulated from the wave record. Other special parameters which will be discussed later were also computed for each block of data. Quantities derived from the wave record analysis were nondimensionalized by fundamental spectral parameters. Wave crest and height parameters were nondimensionalized by $\sigma = \sqrt{m_0}$ and wave period parameters were nondimensionalized by T_1 .

Stormy Interval - The stormy intervals analyzed had reasonably constant spectral shape characteristics over the interval of significant wave heights used (cf. Table 1). Statistics for the nondimensional parameters were compiled based on the values accumulated for each block of data within each stormy interval.

Composite Statistics - The results from each stormy interval were combined by area, spectral characteristic (such as bandwidth parameter), water depth or other combinations of data. These are the results that are presented in this paper. In all, approximately 148,000 zero-crossing waves were processed digitally and their statistics accumulated. The results presented below are broadly divided into three categories: surface deviation statistics, individual wave height statistics, and individual wave period statistics.

SURFACE DEVIATION STATISTICS

The non-Gaussian behavior of surface deviations are water depth dependent. Jahns and Wheeler [4] demonstrated that fact with shallow water storm wave records obtained in the Gulf of Mexico. For the data available there is no important non-Gaussian behavior discernible in water depths greater than about 350 ft. However, imperfections in the wave measurement systems utilized could easily mask the small deviations that are expected in these water depths. The non-Gaussian behavior of the sea surface manifests itself as a surplus of rare wave crests and a deficit of rare wave troughs relative to those predicted by the theoretical developments of Cartwright and Longuet-Higgins [3]. For the case of zero-crossing waves only, the rare crests (large η^*/σ) are predicted to follow the Rayleigh distribution.

Jahns and Wheeler [4] suggested a correction to the Rayleigh distribution in the following form.

$$P [\text{wave crest } \eta_c \leq \eta^* | \sigma] = 1 - \exp \left\{ -\frac{1}{2} \left(\frac{\eta^*}{\sigma} \right)^2 \left[1 - B_1 \frac{\eta^*}{d} \left(B_2 - \frac{\eta^*}{d} \right) \right] \right\} \quad (1)$$

This correlation is shown in Fig. 3 along with the composite shallow water data presented by Jahns and Wheeler [4] and Gulf of Mexico data from hurricane Camille in 340-ft water depth [13]. The form of this correlation suggests that the probability of rarely occurring crest heights relative to the storm wave record σ will increase gradually with increasing crest height-to-water depth ratio (η^*/d) and reach maximum

near 0.3. The parabolic form of the correlation reflects the fact that crest heights of breaking waves will be about 0.55-0.60 of the water depth. Thus, the water depth effect cannot continue indefinitely with increasing η^*/d .

Another aspect of surface deviation analysis relates to commonly used methods for estimating the fundamental wave record property σ from an instrumentally-recorded analog wave record. It is often not convenient to digitize and process a large volume of analog wave surface deviation recordings from wave measuring instruments. Two methods are evaluated as part of this study. The mean-rectified deviation is easy to record electronically [14]. This recording procedure was simulated using the digitized storm wave data available. Tucker [15] proposes a method that utilizes the highest crest and lowest trough (or second highest crest and second lowest trough) in an analog wave record. These parameters can often be determined quickly by inspection of a paper chart record of 100 or so waves. This procedure was also simulated digitally.

The equations that apply are found in the paper by Tucker [15]. His equations can be rearranged to provide the following estimates of the RMS surface deviation σ of the wave record, σ_r , σ_1 , and σ_2 , based on the mean-rectified deviation and Tucker's definition of H_1 and H_2 , respectively.

$$\sigma_r = \bar{H}_r \sqrt{\pi/2} \quad (2)$$

$$\sigma_1 = H_1/[2\sqrt{2\theta} (1 + 0.289 \theta^{-1} - 0.247 \theta^{-2})] \quad (3)$$

$$\sigma_2 = H_2/[2\sqrt{2\theta} (1 - 0.211 \theta^{-1} - 0.103 \theta^{-2})] \quad (4)$$

For each block of wave data, the three estimates of σ were calculated and used to normalize the true σ of the wave record. The mean and coefficient of variation of the accumulated ratios were determined. These results are presented in Table 2.

Table 2. Estimates of RMS Surface Deviation

	σ/σ_r	σ/σ_1	σ/σ_2
Range for 4 Areas (Table 1)			
Mean	0.997-1.018	0.996-1.028	0.997-1.026
Coefficient of Variation	1.0-1.4%	8.5-10.1%	5.6-6.6%
Composite Data			
Mean	1.001	1.011	1.013
Coefficient of Variation	1.3%	8.7%	6.1%

It is evident from the results that all three methods on the average give an essentially unbiased estimate of the true RMS surface deviation. However, the method based on mean-rectified wave height produces a much smaller coefficient of variation. The relatively large coefficients of variation obtained for the H_1 and H_2 methods could cause significant error in the estimate of σ (and hence of the spectral estimate of significant wave height $H_s = 4 \sigma$) by infrequent sampling of analog wave records. These errors would compensate over a long time period such as is the case when processing ambient wave statistics. Isolated, severe storm wave records could have true values of H_s substantially different than those assigned by infrequent sampling of the wave record by the H_1 or H_2 method.

INDIVIDUAL WAVE HEIGHT STATISTICS

Proper assessment of individual wave height statistics requires that a consistent definition be adopted for wave height determination. As indicated in Fig. 4, wave height can be defined as the difference between the trough and crest elevation between two successive zero crossings in either the upward direction or in the downward direction. One can also assign a wave height based on the average trough depths about a given crest. Of course, the idealized waves assumed in design practice are symmetric about the crest unlike most large rare waves in a storm sea state. The rare wave heights for all possible wave height definitions were normalized to σ and compared with the commonly accepted Rayleigh distribution. These results are presented in Fig. 5. This analysis is concentrated on the highest 1/10th waves which are in excess of the nominal significant wave height $H_s = 4 \sigma$ for the sea state. The probability of exceeding rare waves on the order of twice the significant wave height was consistently much less for the instrumental storm wave records analyzed than predicted by the Rayleigh distribution. This finding contradicts many publications which assume wave heights are approximately Rayleigh distributed. However, those assumptions are not based on detailed examination of the extreme right-hand tail of data.

A commonly accepted practice for estimating the maximum wave height in a storm sea state is to derive the wave which would be exceeded on the average once in N_z zero-crossing waves. This is given by the following well-known expression:

$$H_{\max} = H_s \sqrt{\frac{1}{2} \ln N_z} \quad (5)$$

which can be derived from Equation 3 for large N_z . Table 3 shows the height actually exceeded based on all the normalized storm wave records (Figure 5) relative to the height that is predicted to be exceeded by the Rayleigh distribution (Equation 5) for the probability level of 1 in 1000 waves.

TABLE 3 Compensation of Rayleigh Height Statistics

	$\frac{H \text{ Actual}}{H \text{ Rayleigh}}$, for $P[H^* \sigma] = 0.999$		
	<u>Downcrossing</u>	<u>Upcrossing</u>	<u>Average</u>
Range for 4 Areas (Table 1)	0.87-0.92	0.89-0.94	0.86-0.92
Composite Data	0.892	0.920	0.867

The results are consistent for all areas from which data are available and show on the average the true rare wave height is about 10 percent less than predicted at the 1 in 1000 probability level. The form of the composite statistics shown in Fig. 5 suggests a linear compensation to the Rayleigh distribution as follows.

$$P[\text{wave height } H \leq H^*|\sigma] = 1 - \exp \left\{ -\frac{1}{8} \left(\frac{H^*}{\sigma} \right)^2 \left[C_1 + C_2 \left(\frac{H^*}{\sigma} \right) \right] \right\} \quad (6)$$

Thus, the exceedance probability for increasingly rare nondimensional wave heights H^*/σ will increasingly depart from the Rayleigh distribution. The extreme wave heights could be renormalized to the true significant wave height ($H_{1/3}$) as measured by the highest one-third waves in the wave records. Of course, the data would then agree with the Rayleigh distribution at a height equal to the significant wave height. However, there would still be a downward compensation of the true wave height distribution relative to Rayleigh statistics required for increasingly rarer waves as a consequence of Equation 6. Furthermore, the true significant wave height $H_{1/3}$ is not necessarily equal to the fundamental property of the wave record, $H_s = 4\sigma$. Only $\sigma = \sqrt{m_0}$ is predicted by spectral wave models, and is related to the energy content of the sea surface. Therefore, the most useful scaling parameter for individual wave height statistics would be based on the wave record RMS surface deviation σ as shown in Fig. 5.

INDIVIDUAL WAVE PERIOD STATISTICS

The design engineer must also estimate the zero-crossing period associated with a design wave height. The kinetics of water particle motion in space and time calculated for design waves can vary significantly with wave period. It is also necessary to estimate the zero-crossing period of all waves so that the number of waves per hour for the duration of a nominal storm sea state can be estimated. If the storm wave spectra were extremely narrow-banded ($\epsilon = 0$), then all wave periods should be essentially equal to the dominant spectral period. Therefore, it is intuitive that the deviations from this ideal situation should be dependent on the bandwidth parameter ϵ . The definition of ϵ which we use is based on the ratio of the number of zero-crossing waves to the total number of double-amplitude waves in the block of wave data N_z/N_w .

$$\epsilon = \sqrt{1 - (N_z/N_w)^2} \quad (7)$$

This is a more stable estimate of ϵ because it does not depend on the higher spectral moments, which depend strongly on the higher frequency energy and which are subject to some uncertainty due to wave recording and digitization procedures. This subject has been treated in detail by Goda [16].

Figure 6 illustrates the average zero-crossing period normalized to the dominant spectral period over each stormy interval versus the average bandwidth parameter ϵ for that interval. The results, while empirical, provide a useful correlation to relate the average number of zero-crossing waves in a storm wave record to the bandwidth. Figure 6 shows that even for relatively narrow-banded storm spectra the zero-crossing periods will average about 0.8 of the dominant spectral period. The standard deviation of the ratio T_z/T_d between individual blocks of wave data within a stormy interval is 0.071.

A similar correlation is shown in Fig. 7 for rare wave zero-crossing periods. Here the rare wave period definitions are the average of the downcrossing periods of the highest one-third waves, of the highest one-tenth waves, and of the maximum wave in the particular block of wave data. The same trend is exhibited for all of the large well formed waves in a storm sea state. This confirms results reported by Goda [16]. Consequently, we can conclude that the average period of the significant waves and larger exhibit an essentially constant ratio to the dominant spectral period of the sea state in which they occur. The ratio is less than unity and is bandwidth dependent. This result implies that the extreme wave heights in a sea state are associated with steeper waves of essentially the same zero-crossing periods on the average as the less rare waves in that sea state. Comparison of Fig. 6 with Fig. 7 shows that the average period of the large waves is always greater than the average zero-crossing period of all the waves in the record. As indicated by the dashed lines in Fig. 7, these correlations are not exact. The standard deviation of the wave periods normalized to the dominant spectral period between individual blocks of data increases as the wave rarity increases.

The empirical results presented in Figs. 6 and 7 also can be presented in terms of wave periods derived from properties of each storm sea state spectrum. Formulae have been suggested [1,3,16] for estimating average wave record properties as follows:

$$\bar{T} = 2\pi m_0/m_1 \quad (8)$$

$$T_0 = 2\pi \sqrt{m_0/m_2} \quad (9)$$

$$\epsilon_s = \sqrt{1 - m_2^2/m_0 m_4} \quad (10)$$

These formulae should account for finite spectral width ($\epsilon \neq 0$) by incorporating the higher spectral moments. These spectral estimates

were normalized by their corresponding true values for each block of data and compiled over each stormy interval analyzed. These results are presented in Figs. 8 and 9 versus the bandwidth parameter. The spectral estimates consistently underpredict the true values of wave period as derived from the wave records, particularly for the wider-banded wave spectra. Note that the standard deviation of the normalized ratios is substantially less than for the results shown in Figs. 6 and 7. There is no consistent correlation between the spectral estimate ϵ_S with that derived from the wave counts. On the average the spectral estimate of bandwidth parameter ϵ_S is about 5 to 15 percent greater than the value defined by Equation 7 for the storm wave records analyzed.

CONCLUSIONS

1. The properties of storm waves that are rare in their sea state show uniform, correlatable behavior when nondimensionalized by the fundamental spectral properties derived from the wave records. This result covers a wide range of geographic locations, water depths, and storm characteristics.
2. Surface deviation statistics are non-Gaussian and exhibit a surplus of rare crests relative to the Rayleigh distribution out to at least 340-foot water depth as determined by hurricane Camille wave records from the Gulf of Mexico.
3. Simplified methods to estimate the true RMS surface deviation σ of a storm wave record are unbiased on the average, but some methods can lead to substantial error when applied to a small sample of wave record.
4. The statistics of extreme wave height, as measured by elevation difference between trough and crest, deviate substantially from the Rayleigh distribution at the 1 in 1000 wave probability level. The true observed wave heights are on the order of 10 percent less than predicted.
5. The zero-crossing wave periods for the entire record and for the rare waves in a sea state can be nondimensionalized by the dominant spectral period and correlated with bandwidth parameter ϵ . The wave periods relative to the dominant spectral period decrease as bandwidth increases.
6. The approximate formulae for individual wave periods and bandwidth parameter based on higher spectral moments do not agree well with results obtained directly from the wave records.

ACKNOWLEDGMENTS

The authors wish to thank the Oceanographic Committee of the United Kingdom Offshore Operators Association and the participants in the Gulf of Alaska Wave and Wind Measurement Program for permission to utilize their proprietary storm wave records in this study. We also acknowledge the efforts of M. A. Williams of Rice University who assisted with the digital wave record processing.

CHAPTER 11

CONSECUTIVE HIGH WAVES IN COASTAL WATERS

by Winfried Siefert^{*)}

Abstract

The problem of statistics of numbers of consecutive high waves has not yet been treated in detail. Some numerical results (Goda, 1970) and evaluations of prototype data in water depths of 100 m (Rye, 1975) and 40 m (Wilson and Baird, 1973) respectively were published. Data from measurements in nearshore coastal waters, with unbroken, breaking and broken waves, obtained in the Elbe estuary, are treated in this paper.

Introduction

For the design of coastal structures as well as for the understanding of coastal processes a lot of prototype wave data is necessary. During the last decade research has been intensified all over the world. Usually the wave climate at a certain position is characterized by representative heights and periods (\bar{H} , $H_{1/3}$, \bar{T} , $T_{H_{1/3}}$) and energy spectra. By correlation with wind data, functions of wave height, period, and spectra occurrence and exceedance can be given. In addition to that distribution functions of wave heights and periods for any wave stage can be derived, as has been done by evaluation of about 15.000 wave records in the Elbe estuary at the German North Sea coast (Siefert, 1974) (Fig. 1).

Concerning stability problems of structures extended to wave attack there is another criterion: the number of waves in a run that exceed a predetermined value. There are

^{*)} Dr.-Ing., Strom- und Hafengebäude Hamburg, Coastal Eng. Res. Group "Neuwerk", 2190 Cuxhaven, West Germany

Fig. 1
Wave Investigations in the Elbe Estuary

not yet transfer functions between distributions of heights and periods or energy spectra and the numbers of consecutive high waves. So this problem has to be analyzed separately as an additional information.

The static wave force on a structure is usually characterized by the design water level plus highest wave height. The dynamic force - evaluated by one or the other good or bad formula - is usually derived from the significant wave height or $H_{1/10}$ or something similar. The realistic force, caused by a run of waves of a certain height and generating vibrations and perhaps resonance, is not yet subject to wave design.

Analysis

Numerical treatments of the problem of statistics of consecutive high waves were done by Goda (1970), for wide spectra, with additional derivations for narrow band spectra by Ewing (1973); evaluations of prototype data in water depths of 100 m by Rye (1975) and 40 m by Wilson and Baird (1973). These results are shown together with some results from the Elbe estuary in linear scale on Fig. 2.

The presented values for waves in a run higher than $H_{1/3}$ show large agreement, though there seem to be some specific differences.

Most of the "runs" with waves $>H_{1/3}$ occur in runs of only one wave, i.e. preceded and followed by smaller waves (70 to 85%). About 10 to 20% of the runs consist of 2 waves, up to 7% of 3 waves, up to 2.5% of 4 waves. More than 5 waves $> H_{1/3}$ in a run are not yet identified.

For further analysis this graph will be presented in semi-logarithmic scale. Before that it seems to be useful to do some remarks on the evaluation and the definition of a group or "run". Table 1 gives the height numbers of consecutive waves in a record with the notification of waves $>H_{1/3}$ and numbers of wave groups. In general, one "event" is

understood as a "group" of consecutive waves above a chosen limit, a "group" consisting of one or more waves in a row.

On the left side of Fig. 3 we see the before mentioned results. Theory seems to give too small probabilities for the occurrence of 3 and more waves $>H_{1/3}$ in a run. The results from the outer Elbe and in greater depths are more or less identical.

Fig. 3

Probability of Wave Group Formation with Waves Greater than $H_{1/3}$

The comparison on the right side of Fig. 3 shows that in very shallow water the probability of long runs is diminished and nearly the same as Goda's theory.

Some hints of changes of wave group behaviour with mean wave height can be given on Fig. 4. In three different topographic areas with different water depths it turns out that the probability of longer runs with $H > H_{1/3}$ raises with mean wave height. As possible mean wave height raises with water depth, the tendency is the same as on Fig. 3: increase of probability of long runs with high waves with increasing water depth.

The analysis of wave groups $> 1.8 \bar{H}$ shows on the left side of Fig. 5 the same tendency as was seen with groups $> H_{1/3}$: In shallow water the probability of long runs of high waves becomes smaller.

On the right side we see that the probability of long runs diminishes with increasing predetermined height. But this result has to be considered in detail, as is shown on Fig. 6.

These graphs show the probability of wave group formation versus the relation of predetermined and mean wave height.

A certain number of records was evaluated as follows: All waves higher than H^* are 100%. Now each run contains a certain amount of these 100%.

The dots indicate the percentage of waves with $H > H^*$ that occurred in the longest run of a record.

In connection with this the increase of wave periods with wave heights has to be taken into account, i.e. on Table 2 from the right to the left:

 (Longest Run of Each Record with j_{max} Consecutive Waves $H > H^*$)

Table 2
Connections Between Wave Periods Of
Different Wave Height Groups

<u>SOUTHERN NORTH SEA</u>	<u>SURF ZONE</u>	<u>TIDAL FLATS</u>
$T_{H_{1/3}} = 1.25 \bar{T}$	$T_{H_{1/3}} = 1.19 \bar{T}$	$T_{H_{1/3}} = 1.15 \bar{T}$
$T_{H_{1/10}} = 1.33 \bar{T}$	$T_{H_{1/10}} = 1.30 \bar{T}$	$T_{H_{1/10}} = 1.22 \bar{T}$
$T_{H_{\max}} = 1.46 \bar{T}$	$T_{H_{\max}} = 1.30 \bar{T}$	$T_{H_{\max}} = 1.28 \bar{T}$

Moreover, the formation of wave groups influences oscillations of wave set-up, and this way of wave analysis will also give some hints about the reliability of laboratory test results with monochromatic waves.

Not treated in this paper is the mean number of small waves between runs of high waves. Some informations on this problem are given by Ewing (1973).

Summary

The result of Figs. 3 to 6 is:

1. The greater H^* - the lower limit of the heights in the run - is, the lower is the number of waves above H^* ;
2. The greater H^* is, the greater is the probability that a lot of the waves $>H^*$ occur in one run: Waves greater than $1.6 \bar{H}$ appear in a run of 2 or 3 as often as in a "run" of 1 wave. Groups of 2 and 3 waves of a height greater than 1.7 or $1.8 \bar{H}$ have been recorded.
3. The greater the relation of design wave height and mean wave height is, the more important becomes the dynamic force by consecutive design wave heights.

PARAMETRIC REPRESENTATION OF A WIND-WAVE FIELD

by Henrik RYE^x and Roald SVEE, Dr. techn.^{xx}

The River and Harbour Laboratory (VHL) at
the Norwegian Institute of Technology,
7034 - Trondheim - NTH, Norway

SUMMARY

The applicability of various spectral shape parameters is discussed. The wave height distribution from 60 actual wave recordings is computed and compared to the Rayleigh distribution. The behaviour of various wave period parameters is discussed. Based on results from field data as well as numerical computations, it is concluded that some of the spectral wave parameters frequently used today may not be suitable for characterizing the wave field.

INTRODUCTION

Offshore activity in the North Sea has increased the need for wave data for the design of offshore structures. To overcome the increasing amount of wave data collected in the field, a parametric representation of the data is highly preferable.

This paper considers the usefulness of certain currently used wave parameters and distributions such as wave spectra, spectral width parameters, wave period parameters, and wave height distribution. It should be noted that the International PIANC Commission in their recent wave study /1/ recommended and stressed the need for such studies wherever possible.

The literature on this topic is relatively extensive and the results do not appear to be consistent. Some of the discrepancies from the past may be explained from the fact that reliable wave data from the field may be difficult to collect, especially during severe weather conditions, and that the wave recording equipment applied may not have been reliable. A recent test of the shipborne Tucker wave recorder /2/ concludes that "the pressure signal contains a relatively high level of noise of any kind, in particular in cases of

^x Senior scientist

^{xx} Head, section of harbour and coastal engineering

high wave conditions" /3/.

However, the accelerometer buoy produced by Datawell, Netherlands (the "Waverider" buoy), appears to be reliable /4/.

THE WAVE ENERGY SPECTRUM

It is generally believed today that the wave energy spectrum is able to express all the linear statistical properties of a wind-wave surface. However, the shape of the wave energy spectrum appears to be controversial. Based on the wave data available in 1964, Pierson and Moskowitz /5/ proposed a spectrum of the type

$$S_{PM}(f) = \alpha g^2 2\pi^{-4} f^{-5} \exp \left[-\frac{5}{4} \left(\frac{f}{f_p} \right)^{-4} \right] \quad (1)$$

where $S_{PM}(f)$ is the spectral density, f is the frequency (inverse of the wave period), f_p is the peak frequency (the frequency at which the spectral density reaches its maximum value) and α is Phillips' constant. This spectrum is widely used today for engineering applications /6, 7, 8, 9/.

More recently, K. Hasselmann et.al. /10/ arrived at another spectral formulation for fetch-limited, wave-growth conditions during the first Joint North Sea Wave Project (JONSWAP). This spectrum was shown to be much more sharply peaked than the corresponding Pierson Moskowitz type of spectrum. K. Hasselmann et. al. were able to fit the spectral shape of their observations to the following analytical expression:

$$S(f) = \alpha g^2 (2\pi)^{-4} f^{-5} \exp \left[-\frac{5}{4} \left(\frac{f}{f_p} \right)^{-4} \right] \gamma \exp \left[\frac{-(f-f_p)^2}{2\sigma^2 f_p^2} \right] \quad (2)$$

where $\sigma = \begin{cases} \sigma_a & \text{for } f < f_p \\ \sigma_b & \text{for } f > f_p \end{cases}$

where $S(f)$ is the spectral density of the spectrum (denoted the JONSWAP spectrum), α is the Phillips' /11/ constant (which was shown to vary considerably with the fetch and the wind speed), g is the acceleration of gravity, γ is the ratio of the maximal spectral energy to the maximum of the corresponding Pierson-Moskowitz spectrum (1) with the same values of α and f_p ; σ_a and σ_b define the left and right side widths, respectively, of the spectral peak. Fig. 1 illustrates the physical interpretation of the parameters α , f_p , γ , σ_a and σ_b . It is noted that for $\gamma = 1$, the JONSWAP spectrum reduces to a Pierson-Moskowitz type spectrum.

Fig. 1. Illustration of the definition of the five parameters α , f_p , γ , σ_a and σ_b in the JONSWAP spectrum (2). From ^p/10/.

The shape factor γ was found to have values up to 7 with an average value of 3.3. Therefore the wave energy spectrum appears to be much more peaked during wave growth conditions than in the PM-spectrum. Fig. 2 illustrates the JONSWAP spectrum with a γ factor equal to 7 and the corresponding Pierson-Moskowitz spectrum. For a brief review of the JONSWAP results see /12/.

The JONSWAP results were obtained during short-fetched, light wind conditions. However, recently obtained storm wave energy spectra indicate that the spectral shape compares reasonably well to the JONSWAP spectrum during more severe wave conditions also /13, 14, 15, 16/.

The spectral shape of the wave energy field is important to consider for a number of engineering applications. When transfer functions for linear systems are applied, a too low spectral peak in the wave-spectral input may underestimate the forces on an oscillating structure tuned to the peak frequency. D. Hoffmann /9/ stresses the importance of varying the spectral shape when wave loads on ship structures are considered. Wave group formation (i.e. that large waves tend to succeed each other in one single run) tends to be more pronounced for a narrow (or sharply peaked) spectrum /17, 18, 19, 20/. P. Bruun /21/ stresses the importance of wave-group occurrences in the wave field for the breakdown of breakwaters exposed to extreme sea states. Also, for the slow-drift oscillations of moored structures (i.e. oscillations with periods much larger than the periods present in the wave spectrum) the shape of the wave spectrum appears to be an important factor /16, 22/. These oscillations tend to respond to the wave height envelope period /23, 24, 25/ rather than to the individual wave period.

Fig. 2. Illustration of the sharply peakedness of the JONSWAP spectrum. α = arbitrary. The frequency scale is normalized to the peak frequency f_p . Two values of γ are shown, $\gamma = 7$ (full line) and $\gamma = 1$ (broken line). $\sigma_a = 0.07$ and $\sigma_b = 0.09$ which correspond to the average values found during the JONSWAP experiment /10/.

SPECTRAL SHAPE PARAMETERS

The large variations in the spectral shape found for field data /8, 9, 10, 26/ indicate the need of spectral shape parameters. One parameter which has been applied extensively is the spectral width parameter ϵ defined by

$$\epsilon^2 = 1 - \frac{m_2^2}{m_0 m_4} \quad (3)$$

where the moment m of the wave-energy spectrum is defined by

$$m_n = \int_0^{\infty} S(f) f^n df \quad (4)$$

The spectral width parameter was introduced by Cartwright and Longuet-Higgins /27/ in order to describe whether the wave energy was concentrated within a narrow frequency band ($\epsilon \rightarrow 0$) or not ($\epsilon \rightarrow 1$).

Another parameter ν , applied by Longuet-Higgins /17/ to describe the narrowness of the spectrum, is defined

$$\nu^2 = \frac{m_2 m_0}{m_1^2} - 1 \quad (5)$$

A similar parameter ν_1 , also suggested by Longuet-Higgins /29/, is defined

$$\nu_1^2 = 1 - \frac{m_1^2}{m_2 m_0} \quad (6)$$

A parameter Q_p to describe the peakedness of a wave spectrum, was introduced by Goda /18/ and is defined by

$$Q_p = \frac{2}{m_0^2} \int_0^{\infty} f [S(f)]^2 df \quad (7)$$

All these parameters are supposed to characterize the distribution of the wave energy on the frequency scale. However, it appears that some of these parameters depend on the choice of the high-frequency cut-off when the moments (4) are computed. Figs. 3-6 show the dependency of these parameters on the choice of the high-frequency cut-off frequency. The JONSWAP spectrum (2) was applied for $S(f)$, and the integrations were carried out numerically.

It turns out that the parameter Q_p is the only one which is not dependent on the high-frequency cut-off choice. In addition, the parameter seems to distinguish very well between a very sharply peaked JONSWAP spectrum ($\gamma=7$) and a Pierson-Moskowitz type spectrum ($\gamma=1$). It is therefore recommended that this parameter be applied rather than the parameters ϵ , ν or ν_1 .

From Fig. 6, it may even be considered to establish a relationship between γ and Q_p . This relationship is shown graphically in Fig. 7 for a specific choice of σ_a and σ_b .

The reason why ϵ varies with the choice of the high-frequency cut-off in the numerical integrations, is that the wave energy spectra are found to have a high-frequency tail proportional to f^{-5} . When the fourth moment of such a

Fig. 6. The peakedness parameter Q_p as a function of the high-frequency cut-off choice. Q_p is computed from (7). α = arbitrary. The frequency scale is normalized to the peak frequency f_p . Three values of γ are shown. $\sigma_a = 0.07$. $\sigma_b = 0.09$.

Fig. 7. The relationship between the spectral peakedness parameter Q_p and the spectral shape parameter γ in the JONSWAP spectrum. The other parameters in the JONSWAP spectrum are: α = arbitrary, f_p = arbitrary, $\sigma_a = 0.07$, $\sigma_b = 0.09$.

spectrum is computed, the result will be proportional to the natural logarithm of the high-frequency cut-off. In fig. 3, ϵ is shown to vary between 0.4 and 0.8 for a Pierson-Moskowitz type spectrum, dependent on the cut-off frequency. In addition, ϵ appears to distinguish poorly between a very sharply peaked ($\gamma=7$) wave energy spectrum and a Pierson-Moskowitz type spectrum ($\gamma=1$). These facts may explain some of the conflicting results reported in the literature /14, 30, 31/.

It is possible to obtain a rough estimate of ϵ directly from a wave record /18/ by applying the formula

$$\epsilon^2 = 1 - \left(\frac{N_0}{N_1} \right) \quad (8)$$

where N_1 is the number of maxima and N_0 is the number of zero-up-crossings in the wave record. However, the number N_1 will depend on the resolution of the wave recorder; a recorder with a large resolution will record more maxima than a recorder with a small resolution and thus enlarge the value of ϵ . This effect will be similar to the effect of choosing a larger high-frequency cut-off when ϵ is computed from the moments of the spectrum.

THE WAVE HEIGHT DISTRIBUTION

When the spectrum is narrow, it can be shown that the wave height distribution is approximately a Rayleigh distribution /32/. This distribution has been compared to the actual distribution of the wave heights recorded, and the agreement appears to be good /18, 28, 30, 32, 33/.

In order to compare wave height distribution from actual wave recordings to the Rayleigh distribution, 60 recordings of wind-generated waves were examined. The data were collected with a "Waverider" accelerometer buoy located outside Utsira, Norway. The location is shown in Fig. 8. The water depth was about 100 m. The duration of each recording was between 8 and 20 minutes.

Fig. 8. Location of the "Waverider" wave recorder. From /16/.

The data applied for the analysis were collected from three storms, occurring in October, November and December 1970. All of the recordings were selected so that some waves larger than 4 m were present in each recording.

Wave heights lower than 0.5 m were excluded because these waves were expected to be affected by the resolution of the recording instrument. By excluding these waves, the results were expected to improve /33/.

Fig. 9 shows that the wave heights follow the Rayleigh distribution comparatively well. In order to include all of the 60 recordings on the same diagram, the average wave height \bar{H} was used as unity for each of the recordings.

Fig. 9. The distribution of the wave heights from 60 wave recordings. The wave heights are determined from the zero-up-cross method. The heights are normalized to the average wave height of each recording.

THE WAVE PERIOD PARAMETERS

The distribution of the wave periods appears to be more controversial than the distribution of the wave heights. Bretschneider /34/, using semi-empirical relationships, proposed a Rayleigh distribution of the zero-up-crossing wave period squared (T_z^2) which has been applied with variable success /18, 33/. Recently, however, Longuet-Higgins /28/ has arrived at a theoretical wave

Fig. 10. Illustration of the average periods T_{m01} and T_{m02} for a very sharply peaked JONSWAP spectrum. $\alpha = \text{arbitrary}$. The frequency scale is normalized to the peak frequency f_p . $\gamma = 7$. $\sigma_a = 0.07$. $\sigma_b = 0.09$. T_p is determined according to (11). T_{m01}^a is determined from $P(9)$. T_{m02} is determined from (10).

Fig. 11. Illustration of the average periods T_{m01} and T_{m02} for a Pierson-Moskowitz type spectrum. $\alpha = \text{arbitrary}$. The frequency scale is normalized to the peak frequency f_p . $\gamma = 1$. $\sigma = 0.07$. $\sigma_b = 0.09$. T_p is determined according to (11). T_{m01}^a is determined from (9). T_{m02} is determined from (10).

period distribution which seems to compare well with observations.

A number of wave period parameters have been proposed for practical applications. Based on the moments of the spectrum, an average wave period T_{m01} may be defined /9, 28/.

$$T_{m01} = \frac{m_0}{m_1} \quad (9)$$

Sometimes the average periode T_{m02} is also defined /9, 30, 35, 36/.

$$T_{m02} = \left(\frac{m_0}{m_2}\right)^{\frac{1}{2}} \quad (10)$$

In /9/, T_{m02} is denoted "the average apparent period".

The peak period T_p (inverse of the peak frequency f_p) is obtained by derivating the wave spectrum equation:

$$\frac{d}{df} [S(f)] = 0 \quad (11)$$

This period corresponds to the frequency of maximum energy density in the wave spectrum /9, 10/.

The period parameters T_{m01} and T_{m02} were computed by numerically integrating the JONSWAP spectrum. Figs. 10 and 11 show the results from the computation. For a very sharply peaked JONSWAP spectrum ($\gamma=7$), T_{m01}/T_p was found to be ~ 0.885 while T_{m02}/T_p was found to be ~ 0.850 . For a Pierson-Moskowitz type spectrum ($\gamma=1$), $T_{m01}/T_p \sim 0.785$ while $T_{m02}/T_p \sim 0.735$.

The results were also found to depend on the high-frequency cut-off choice as shown in Fig. 12. The numbers above are given for a high frequency cut-off choice approximately equal to $4 f_p$.

For the JONSWAP spectrum, the main part of the energy will be concentrated within a narrow frequency band about the peak frequency. The largest waves (the most important for engineering purposes) will have their periods very close to the peak period because these waves are expected to contribute most to the wave spectrum. However, the computations in this paper show that for a relatively narrow, single-peaked wave energy spectrum with a peak period of, say, 10 seconds, the "average period" (T_{m01} or T_{m02}) is expected to fall within the range 7.1 - 8.9 seconds, dependent of the high-frequency cut-off choice and the peakedness of the spectrum. This computation therefore suggests that the average wave periods computed by means of the moments of the spectra will tend to underestimate the period of the largest waves by about 10 - 25%. This conclusion is consistent with Goda /30/ which states that T_{m02} "requires a correction of +20% on the average when applied for sea waves".

Another wave period parameter frequently applied is the average "zero-up-cross" wave period T_z . This parameter is defined as the ratio between the number of zero-up-crossing of the wave trace and the total duration of the wave record. This parameter depends on the resolution of the recorder. A larger number of zero-up-crossing will be recorded if the resolution is improved. By means of numerical simulation, it has also been shown by Goda /18/ that T_z varies with the spectral shape.

Fig. 12. The "average" wave periods T_{m01} and T_{m02} as a function of the spectral shape parameter γ and the high-frequency cut-off choice. T_{m01} is normalized to the peak period T_p and the high-frequency cut-off choice is normalized to the peak frequency f_p . The following parameters in the JONSWAP spectrum were applied: α = arbitrary, f_p = arbitrary, $\sigma_a = 0.07$, $\sigma_b = 0.09$.

Based on field data, a low correlation has been found /37, 38, 39/ between T_z and the period of the maximum energy density. It is therefore concluded that the period T_z does not appear to be a convenient parameter to characterize the periods of the sea waves.

However, recent findings indicate that the periods of the highest waves in a wave record might be applicable. Thompson /37/ suggests that the average period in trains of large waves in the wave record might be a useful period parameter to apply, and he shows that this period will be very close to the spectral peak period T_p . Goda /30/ concludes that the significant wave period is statistically stable. This parameter appears to be only about 5% smaller than the spectral peak period.

The number 5% is in good agreement with the relation between the peak period T_p and the significant wave period given by Bretschneider /40/.

$$T_p = \sqrt[5]{5/4} T_S \tag{12}$$

$$\approx 1.06 T_S$$

Also, Earle /41/ considered the relationship between the period of the max. wave height T_{HMAX} , T_S and \bar{T} . He also finds that \bar{T} needs a correlation of about + 20%; $\bar{T}_S \approx 0.8 T_{HMAX}$. For T_{HMAX} , he finds it approximately equal to T_S , but T_{HMAX} is less statistically stable than T_S .

A small check on these results was applied on wave data from the North Sea. A quarter of the 60 recordings previously mentioned were selected for spectral analysis. Wave recordings from a growing wind-wave field were digitized and the spectrum computed by means of an FFT algorithm. The peak period T_p was determined from the spectrum and the period of the maximum wave height T_D was found directly from the wave record. Fig. 13 shows the results. Also shown, is the significant wave height determined from $4\sqrt{m_0}$. Fig. 13 indicates that the period of the maximum wave tends to slightly underestimate the period of the spectral peak. The finding is consistent with the results from Goda's investigation /30/, where the period of the maximum wave was found, on the average, to be only about 5% lower than the period of the spectral peak.

Fig. 13. Comparison of the spectral peak period T_p and the period of the maximum wave height for 15 actual wave recordings from Utsira. The recordings are selected from a growing wind-wave field.

It is concluded that the peak period T_p and the significant wave period T_S characterize the periods of the largest waves in the recording better than the various average wave periods \bar{T} , T_{m01} or T_{m02} do. It is therefore recommended that T_p or T_S are applied rather than the various "average" periods.

CONCLUSIONS

The results derived in this paper may be summarized as follows:

1. The spectral width parameter is shown to vary considerably with the high-frequency cut-off choice. The spectral peakedness parameter Q_p , introduced by Goda /18/, appears to be a more convenient parameter with which to characterize the spectral distribution.
2. The wave height distribution from a wind-wave field compares very well to a Rayleigh distribution.
3. The period of the spectral peak or the significant wave period will correspond relatively close to each other and will characterize the period of the largest waves present in the recording better than the "average" wave periods do.

ACKNOWLEDGEMENTS

APPENDIX - NOTATION

- f = frequency or the inverse of the wave period
 f_p = frequency of the spectral peak
 g = acceleration of gravity
 \bar{H} = average wave height
 m_n = n'th moment of the spectrum
 N = number of zero-up-crossings in a wave record
 N = number of maxima in a wave record
 Q_p = spectral peakedness parameter
 S = spectral energy density distribution
 T_{m01} } "average" wave periods
 T_{m02} }
 T_p = period corresponding to the spectral peak frequency f_p
 T_s = significant wave period
 T_z = zero-up-crossing wave period
 \bar{T}_z = average zero-up-crossing wave period
 α = Phillips' constant in the wave energy spectrum
 γ = spectral shape factor in the JONSWAP spectrum
 ϵ }
 ν } = spectral width parameters
 ν_1 }
 σ }
 σ_a } = parameters to describe the broadness of the spectral
 σ_b } peak in the JONSWAP spectrum

CHAPTER 13

HURRICANE WIND AND WAVE FORECASTING TECHNIQUES

BY CHARLES L. BRETSCHNEIDER¹ AND ELAINE E. TAMAYE²

ABSTRACT

Measurements needed to calibrate both significant wave and wave spectrum methods. These concern extreme waves hence related more to design than operations.

Ratio of one-dimensional wave spectrum $S(f)$ as function of wave frequency (f) to that as function of frequency (f_0) of maximum energy density with slope, $m + 1$ is:

$$\frac{S(f)}{S(f_0)} = e^{-\frac{m+1}{m} \left(\frac{f}{f_0}\right)^{-(m+1)}} - \frac{m+1}{m} \left(\frac{f}{f_0}\right)^{-m}$$

Ratio of period of maximum density (f_0^{-1}) to wind speed (U) in knots with significant wave height (H_s) in feet as a parameter is:

$$\frac{f_0^{-1}}{U} = 0.4 \tanh \left\{ \ln \left[\frac{1 + \frac{40 H_s}{U^2}}{1 - \frac{40 H_s}{U^2}} \right]^{1/2} \right\}^{0.6}$$

and ratio of wind speeds at radial distances r and R in nautical miles from center of stationary hurricane is:

$$\frac{U_r}{U_R} = -\frac{1}{2} \frac{fR}{U_R} \frac{r}{R} + \sqrt{\left[1 + \frac{fR}{U_R} \right] \frac{R}{r} e^{(1-R/r)} + \left[\frac{1}{2} \frac{fR}{U_R} \frac{r}{R} \right]^2}$$

Significant wave heights [H_{Rv} and H_{rv}] in hurricane moving at forward speed [V_F] for significant wave heights [H_R and H_r] for stationary hurricane are:

$$H_{Rv} = H_R \left[1 + \frac{1}{2} \frac{V_F \cos \theta}{U_{Rs}} \right]^2 \quad \text{and} \quad H_{rv} = H_r \left[1 + \frac{1}{2} \frac{V_F \cos \theta}{U_{rs}} \right]^2$$

θ is angle between wind and hurricane forward speed; $H_R = K' \sqrt{R \Delta P}$ and H_r/H_R and K' are functions of fR/U_R where f = coriolis parameter = $2 \times$ Earth's angular velocity \times Sine (average latitude); ΔP = central pressure reduction from normal in inches of mercury; and subscript "s" denotes surface wind speeds.

This technique predicts at one station (N29W89) during Hurricane Camille (11 Aug 69) maximum wave of 42.4 ft compared to 43.1 ft measured and an envelope-of-spectra similar to one from measurements in North Sea (JONSWOP, 15 Sept 68).

Hurricanes in Hawaiian waters have recurrence interval of about 1 in 50 years. One in 1959 [DOT] caused considerable damage especially on island of Kauai.

This paper supported in part by the Univ. of Hawaii Sea Grant College Program of the National Oceanic and Atmospheric Administration (NOAA), Office of Sea Grant, Department of Commerce of the U.S.A. Government under its "Wave Statistics for Extreme Wave Conditions".

¹ Professor and Chairman and ² Graduate Student;
both in Department of Ocean Engineering; University of Hawaii.

FORWARD

The various methods of wave forecasting are summarized briefly including wave spectra and its application to hurricane waves. The latest relationships are presented. Knowledge of the art of forecasting extreme wave conditions is important since tropical cyclones occur in most of the tropical areas of the world, including the Gulf of Mexico and Atlantic Coast of the U.S.A.

WAVE FORECASTING PHILOSOPHIES

Of the various methods of wave forecasting, there are primarily only two concepts: the Significant Wave (Bretschneider, 1970, 72a, 72b) and the Wave Spectrum (Pierson and Moskowitz, 1964; Cordone, Pierson, Ward, 1975).

1. The Significant Wave Concept is a very simple method which forecasts the principle parameters, i.e. the significant wave height, H_S and the significant wave period, T_S , or else the modal period of the frequency spectrum

$$f_o^{-1} = \sqrt[4]{5/4} T_S .$$

The normal unit form of the theoretical spectrum can be used to estimate the wave spectrum; and the normal form of the directional spectrum, frequency dependent, can be used to estimate the complete directional spectrum.

2. The Wave Spectrum concept is on reverse to the significant wave method, i.e., the wave spectrum method predicts the directional spectrum, from which the one-dimensional spectrum and the significant wave are determined.

3. In both methods the Rayleigh distribution is used to determine the most probable maximum wave height.

4. Both methods are based upon use of measured wave data for calibration. If the same or similar wave data are used for calibration, then both methods should give essentially the same results in regard to directional spectrum, the one-dimensional spectrum, the significant wave height and period, and the period (f_o^{-1}) of maximum energy density.

5. The significant wave method is easier to use and certainly less costly, whereas the wave spectrum method requires a highly sophisticated and expensive computer program.

6. Both methods are needed to compliment each other, and also serve as calibration techniques for each other.

7. The methods concern only the extreme wave conditions associated with design criteria, and not associated necessarily with the day by day or operational wind and wave criteria.

Presently, there are about seven methods used in wave forecasting and some methods are not better necessarily than others. Wave

forecasting, or wave hindcasting as the case may be, is an art as well as a science. The accuracy of any method depends upon practice, experience, verification, and correlation. Both the Significant Wave Method and the Wave Spectrum methods are taught at the University of Hawaii, and it is up to the student to make a choice. These methods are presented in Bretschneider, 1967, 68, 72, 73 and Pierson, Moskowitz, 1964, and Silvester, 1974.

OCEAN WAVE SPECTRUM

ONE-DIMENSIONAL WAVE SPECTRUM,--There is very little that can be added to the state-of-the-art on ocean wave spectrum analytical expressions. Opinions have been generated on what is the best form of the wave spectrum. Only minor details exist between the various semi-empirical methods; none are of any significance to ocean engineering. The problem is to select the design wave spectrum for a particular situation, area of operation, and the recurrence interval. The only thing lacking is data for obtaining statistical extremes in some places.

The generally accepted form of the unit wave spectrum is as follows:

$$S(f) = Af^{-(m+1)}e^{-Bf^{-m}} \quad (1)$$

where $S(f)$ = energy density, and f = wave frequency in hertz (sec^{-1}). The form of equation (1) is similar to that of the Weibull distribution function (Weibull, 1951) as used in Bretschneider (1959).

There are three parameters involved in equation (1), namely: the coefficients A and B , and the slope $(m+1)$ of the high frequency end of the spectrum. They can be obtained, either by theory, wave forecasting relationships, or by use of measured wave spectrum data.

Based on past experience, enough information is available to postulate the form of equation (1). For example the value of maximum energy $S(f_0)$ and the wave frequency f_0 at which it occurs can be determined by performing the following simple operation on equation (1):

$$\frac{d[S(f)]}{df} = 0 \quad (2)$$

whence

$$B = \frac{m+1}{m} f_0^m$$

$$A = S(f_0) e^{\frac{m+1}{m}} f_0^{m+1}$$

thus

$$\frac{S(f)}{S(f_0)} = e^{\frac{m+1}{m}} \left(\frac{f}{f_0}\right)^{-(m+1)} e^{-\frac{m+1}{m} \left(\frac{f}{f_0}\right)^{-m}} \quad (3)$$

Note that when $(m+1) = 5$, equation (3) becomes:

$$\frac{S(f)}{S(f_0)} = e^{5/4} (f/f_0)^{-5} e^{-5/4} (f/f_0)^{-4} \tag{4}$$

Equation (4), whose solution is shown in Fig. 1, is a special form of the wave spectrum given in Bretschneider (1959) as is the Pierson-Moskowitz (1964) spectrum. Sometimes engineers prefer the so-called period (T) spectrum, which can be obtained as follows:

$$S(T) dT = -S(f) df$$

where $T = f^{-1}$

and $dT = -f^{-2} df$

This is a simple operation and leads to:

$$\frac{S(T)}{S(T_0)} = e^{\frac{m-1}{m}} \left(\frac{T}{T_0} \right)^{m-1} e^{-\frac{m-1}{m}} \left(\frac{T}{T_0} \right)^m \tag{5}$$

where $S(T_0)$ is maximum with dimension $\ell^2 t^{-1}$ at wave period T_0 , and $(m-1)$ is the slope for very low periods of the period spectrum.

Note that the dimension of $S(T)$ is $\ell^2 t^{-1}$ and $S(f)$ is $\ell^2 t$. When $(m-1) = 3$, equation (5) becomes:

$$\frac{S(T)}{S(T_0)} = e^{3/4} \left(\frac{T}{T_0} \right)^3 e^{-3/4} (T/T_0)^4 \tag{6}$$

Equation (6) is a special form of the period spectrum given in Bretschneider (1959); see Fig. 2.

All of the above equations are special forms of the Weibull Distribution function (Weibull, 1951).

Equations (4) and (6) [figures 1 and 2] are related as follows:

$$f_0^{-1} = \sqrt[4]{5/4} T_s$$

and $T_0 = \sqrt[4]{3/4} T_s$

or $f_0^{-1} = \sqrt[4]{5/3} T_0$

$$T_s = \sqrt[4]{4/3} T_0 = \sqrt[4]{4/5} f_0^{-1} \tag{7}$$

where T_s is a definite definition of the significant wave period, not necessarily as the characteristic period used in the past.

From actual data on frequency spectrum, the corresponding period spectrum can be obtained by use of two operations:

$$\begin{aligned} S(T) &= S(f) \cdot f^2 && \text{(for the ordinate)} \\ T &= f \cdot f^{-2} && \text{(for the abscissa)} \end{aligned} \quad (8)$$

The area under the spectrum in either case remains the same.

The design wave spectrum can be obtained by Froude scaling of measured wave spectrum, but with caution. For example:

$$\left. \begin{aligned} S_p(f) &= \lambda^{5/2} S_m(f) \\ f_p &= \lambda^{-1/2} f_m \end{aligned} \right\} \quad (9)$$

where λ is the linear scale parameter, and p stands for predicted and m stands for measured. This assumes that g^2 and t are the same from one section of gF/U^2 to the next section, which is not necessarily always true; $g = 32.16 \text{ ft/sec}^2$, $F = \text{fetch (feet)}$, and $U = \text{wind speed (ft/sec)}$.

DIRECTIONAL SPECTRUM.—The earliest directional spreading function was the one published by Cote, et al., (1960) as obtained from the Stereo Wave Observation Project (SWOP). Since then, other forms of the directional spectrum have evolved including those by Ou, et al., (1974), Silvester (1974) and Longuet-Higgins, et al., (1963). The choice of the directional spectrum depends upon the engineering solution required. Certainly, more experimental data on the directional spectrum is required especially for engineering problems such as the reaction to wave excitation of ships and of flexible fixed and floating offshore structures. For all practical engineering purposes, it does not seem to make very much difference which of the proposed directional spectrum methods are used. (See Silvester, 1974, Fig. 3.34.)

THE ENVELOPE OF SPECTRA.—The "overshoot" of the high frequency energy during early wave generation has been observed in measurements made in both laboratory and field. The classical field observations were made during JONSWOP, that is the Joint North Sea Wave Project (Barnett, 1972 and Fig. 3), while the classical laboratory observations were made by Mitsuyasu (1968 and Fig. 4). These as well as measurements made on Lake Michigan (Liu, 1971) and on North Atlantic (Miles, 1972) are notable.

The Envelope of Spectra is of the same form as Equation (3) and for demonstration purposes the same as Equation (4), except now the value of maximum energy and the corresponding wave frequency are respectively $S(f_o^*)$ and f_o^* .

The Envelope Spectrum, as discussed by Bretschneider (1975) in fact should be termed "the Envelope of Spectra"; it takes the high frequencies into account and thus includes these "overshoots"

All the spectra under the Envelope of Spectra is preferable to the fully-developed sea spectrum for design purposes because the Envelope of Spectra yields more energy at the high frequencies.

Both the Envelope of Spectra and the fully-developed sea spectrum should be cut off at the particular low frequency defined by the fetch length and wind duration, which limit the length of the wave which can be generated.

As an example, the Envelope of Spectra is superimposed in Fig. 3 on the JONSWOP spectra obtained from measurements at 11 stations situated in the North Sea offshore the Island of Sylt, Germany. The spectra at all stations would be similar if the fetch length at all stations were replaced with the time growth which actually occurred at the station farthest offshore (#11). Thus, the design spectrum should be based on all spectra under the Envelope of Spectra and not on the spectrum at final time of maximum peak. This same effect is apparent in the North Atlantic spectra (Miles, 1972, Figs. 5 and 6). Perhaps a better selection of m would give a better fit, but this demonstration, given of the Envelope of Spectra, seems adequate.

The area under the Envelope of Spectra is considerably more than the area under the fully-developed spectrum $(1/4 H_s)^2$. This is very important for engineering design purposes. In fact, it is for this reason that small boats are swamped and sunk in small lakes, such as those 2 miles in diameter under 40-knot winds, rather than in the open ocean in the roaring forties. A number of challengers have rowed across the Atlantic and the Pacific Ocean, surviving seas 40-foot high, 12-second period. Many so-called pioneers have drowned trying to get ashore during a gale on a small inland lake with waves 2- to 3-foot high, and 1- to 3-second periods. The Envelope of Spectra supports these conclusions.

DEEP WATER WAVE FORECASTING

EQUATIONS FOR PREDICTION OF DEEP WATER WAVES.--The latest Significant Wave forecasting relationships for constant wind speed and direction are as follows (Bretschneider, 1973):

$$\frac{gH_s}{U^2} = A_1 \tanh \left[B_1 \left(\frac{gF}{U^2} \right)^{m_1} \right] \dots\dots\dots (10)$$

$$\frac{C_o}{U} = \frac{gT_s}{2\pi U} = A_2 \tanh \left[B_2 \left(\frac{gF}{U^2} \right)^{m_2} \right] \dots\dots\dots (11)$$

$$t_{min} = 2 \int_0^{F_{min}} \frac{1}{C_o} dx \dots\dots\dots (12)$$

where:

$$\begin{aligned} A_1 &= 0.283 & A_2 &= 1.2 \\ B_1 &= 0.0125 & B_2 &= 0.077 \\ m_1 &= 0.42 & m_2 &= 0.25 \end{aligned}$$

H_s = significant wave height, feet

T_s = significant wave period, sec

F = fetch length, feet

U = U_s (10-min average surface wind speed), ft/sec at 10-meter water level

t = wind duration, sec

C_o = wave crest speed, ft/sec

The form of these equations was given originally by Wilson (1954); only the coefficients have been changed. Graphical solutions of them are given in Bretschneider (1970) and Shore Protection Manual (1973).

The expression gF/U^2 in equations (10) and (11) can be eliminated, and using the above coefficients and expressing U in knots and g as 32.2 ft/sec^2 the following is obtained:

$$\frac{T_s}{U} = 0.4 \tanh \left[1.07 \left(\operatorname{arctanh} \frac{40 H_s}{U^2} \right) 0.6 \right] \quad (13)$$

REVISIONS OF SIGNIFICANT WAVE PERIOD.--Equation (13) seems to give significant wave periods for high wind speeds about 10% too high. Based on wave spectra measured in the North Atlantic, for example, Fig. 5, from Miles (1972), equation (13) has been changed to read:

$$\frac{f_o^{-1}}{U} = 0.4 \tanh \left\{ \ln \left[\frac{1 + \frac{40 H_s}{U^2}}{1 - \frac{40 H_s}{U^2}} \right]^{1/2} \right\} 0.6 \quad (14)$$

where f_o^{-1} = sec. = period of maximum energy density, U = knots and H_s = feet and the significant wave period T_s , from equation (7) is $T_s = \sqrt[4]{4/5} f_o^{-1}$. Hence, equation (13) is needed no longer. The solution to equation (14) is given in Table I.

Incidentally, the Envelope of Spectra given by equation (4) was applied to the wave spectra measured in the North Atlantic (Miles,

1942) and the results plotted in Figs. 5 and 6. It is interesting to note that the Envelope of Spectra is almost in exact agreement with the +90% confidence limit of the mean International Ship Structures Committee (ISSC) spectrum (Fig. 6).

FORECASTING HURRICANE WIND FIELDS

INTRODUCTION.--A method is presented for determining hurricane wind fields and resulting deep water wave field, as proposed by Bretschneider. A detailed development of the hurricane model is given in Bretschneider, 1972 a and b. The wind field itself is based in part on work by the National Weather Service; see Meyers (1954) and Graham and Nunn (1959).

Graphs, formulae and procedures are presented by Bretschneider (1972-b) which make it possible to calculate the entire deep water wave field from model hurricane wind fields. They have been applied successfully to historical hurricanes along the U.S. East and Gulf of Mexico coasts and to U.S. National Weather Service standard project and probable maximum hurricanes for deep water conditions.

BASIC RELATIONSHIPS FOR STATIONARY HURRICANE WIND FIELD.--The balance of the pressure gradient, Coriolis, and centrifugal forces of the equation of motion leads to the non-dimensional stationary hurricane wind field, which is given as:

$$\frac{U_r}{U_R} = -\frac{1}{2} \frac{fR}{U_R} \frac{r}{R} + \sqrt{\left(1 + \frac{fR}{U_R}\right) \frac{R}{r} e^{(1-R/r)} + \left(\frac{1}{2} \frac{fR}{U_R} \frac{r}{R}\right)^2} \quad (15a)$$

where U_r and U_R are the wind speeds at radial distance r and R (radius of maximum winds) from the hurricane center, $f = 2\omega \sin\phi$ (Coriolis parameter) $\omega = 7.29 \times 10^{-5}$ rad/sec (angular velocity of earth), and ϕ is the latitude.

$$P = P_O + (P_N - P_O) e^{-R/r} \quad (15b)$$

where P = atmospheric pressure at radial distance r , P_O = central pressure, P_N = normal pressure = 29.92 inches of mercury, and R = radius to maximum wind.

Figure 7 gives the non-dimensional solution for equation (15a) for values of $r/R \geq 1.0$ vs fR/U_R . Note that r/R did not necessarily occur where U_r/U_R is a maximum. Graham and Nunn (1959) recognized this shortcoming and made modifications based in part on experience and data. The significant change is their recommendation of a single relationship as shown in Figure 7 for $r/R \leq 1.0$. The example which follows utilizes The Graham and Nunn model for $r/R \leq 1.0$ and

the National Weather Service model given by equation (15a) for $r/R \geq 1.0$ (Fig. 7).

The maximum sustained wind speed will occur at R, radius of maximum wind, and refers to a value, averaged over a time of 10-20 minutes, and reduced to the 10-meter elevation above mean sea level. The geostrophic wind speed U_R is given by:

$$U_R = K\sqrt{\Delta P} - 0.5 fR \quad (16)$$

where U_R is in knots, $\Delta P = P_N - P_O$ is the central pressure reduction from normal in inches of mercury, and the constant K varies with latitude from 67 at 20-25°, to about 63 at 45° latitude (see Table II).

The 10-minute average wind speed, U_{RS} , at the 10-meter reference level is given by:

$$U_{RS} = k^* U_R \quad (17)$$

where $k^* = .865$ for all U.S. East Coast and Gulf Coast Zones A and C, and $k^* = .886$ for Gulf Coast Zone B [see Graham and Numm (1959) for zone designations].

CORRECTION DUE TO FORWARD MOTION OF HURRICANE.--The stationary model hurricane wind field is coupled directly to the corresponding model hurricane wind field. Thus, any change in the wind field will result in a directly related change in the wave field. For a moving hurricane, the change in the wind speed component is:

$$\Delta U = \frac{1}{2} V_F \cos \theta \quad (18)$$

thus

$$U_{RS}^* = U_{RS} + \Delta U \quad (19)$$

where θ is the angle of wind deflected from the direction of the incurvature angle of the wind speed and V_F is average forward speed of the hurricane.

Hurricanes moving faster than the critical forward speed are not considered herein. This condition needs further study.

EXAMPLE CALCULATIONS FOR 1969 HURRICANE CAMILLE.--The following are some simple sample calculations for Camille according to parameters obtained from Cordone, Pierson & Ward (1975).

- R = radius of maximum wind = 10 nautical miles
- ΔP = atmospheric pressure reduction at hurricane center from normal = 105 milli-bar = 3.1" mercury
- V_F = average forward speed of hurricane = 10 knots (this increased as Camille moved inland)
- ϕ = approximate average latitude for maximum wave generation = 29°
- f = $.525 \sin \phi$ = coriolis parameter = .255 radians/hour
- β = 25° incurvature angle for stationary hurricane

Determinations of maximum sustained wind speed at R

$$K = 66 \text{ (from Table II)}$$

$$U_R = K\sqrt{\Delta P} - 0.5 fR = 114.9 \text{ knots}$$

$$U_{RS} = .886 U_R = .886(114.9) = 102 \text{ knots}$$

This is for the stationary hurricane and U_{RS} is the 10-minute average wind speed at the 10-meter anemometer level above mean sea level.

WIND FIELD FOR CAMILLE MOVING AT 10 KNOTS.—1. The change in wind components, ΔU , due to the moving hurricane for radii at 20° incremental angles is:

$$\Delta U = 5 \cos \theta$$

2. Thus, the 10-minute average wind speed at 10-meter level (U_{RS}^*) for a moving hurricane is:

$$U_{RS}^* = U_{RS} + \Delta U = .886 U_R + \Delta U = 102 + 5 \cos \theta$$

3. Various values for the isotachs were chosen ($U_{RS} = 20, 40, 50, 60, 70, 80, 90, 100$ knots), and the parameter U_{rs}/U_{RS}^* calculated for each U_{RS}^* .

4. From Fig. 7 the corresponding values of r/R were determined for the calculated parameter $fR/U_R = 0.022$.

5. The wind field was then constructed for the values of U_{rs} and their corresponding radius (Fig. 8).

FORECASTING HURRICANE DEEP WATER WAVES

STATIONARY MODEL HURRICANE WAVE FIELD.—Relationships have been developed in Bretschneider (1972) for obtaining the model hurricane wave field:

$$H_R = K' \sqrt{R\Delta P} \quad (20)$$

where R and ΔP have been defined and K' , a function of fR/U_R , can be obtained from Table III.

The general relationships for the entire stationary hurricane wave field, where $H_r/H_R =$ function of fR/U_R , is shown in Fig. 9.

FORWARD MOTION OF A HURRICANE.—

$$H_{RV} = H_R \left[1 + \frac{1}{2} \frac{V_F \cos \theta}{U_{RS}} \right]^2 \quad (21)$$

$$H_{rv} = H_r \left[1 + \frac{1}{2} \frac{V_F \cos \theta}{U_{rs}} \right]^2 \quad (21A)$$

where H_R is obtained by use of equation (20), H_T is obtained by use of Figure 9, H_{RV} and H_{TV} are a result of the forward speed, V_F , and the direction of wind in relation to direction of forward speed as given by the angle θ . The limitation of equation (21) is that $V_F \leq V_C$, where V_C is the critical forward speed.

CAMILLE DEEP WATER WAVES

FOR SIGNIFICANT WAVES.--Calculate $fR/U_R = .255 (10)/114.9 = 0.0222$. From Table III, $K' = 6.64$, $R =$ radius at maximum wind.

FOR THE STATIONARY HURRICANE.-- $H_R = k' \sqrt{R \Delta P} = 6.64 \sqrt{31} = 37.0$ feet. Calculate

$$\frac{40 H_R}{U_{RS}^2} = \frac{40 (37.0)}{(102)^2} = 0.142$$

From Table I [or equation (14)], $f_0^{-1}/U = 0.121$. Therefore, $f_0^{-1} =$ period of maximum energy = 12.34 sec. And, $T_S =$ significant period = $\sqrt[4]{4/5} f_0^{-1} = 11.67$ sec.

HURRICANE MOVING AT FORWARD SPEED, $V_a \leq V_C$ WHERE $V_C =$ CRITICAL FORWARD SPEED.--The modified significant wave height for actual forward speed is:

$$H_a = H_R \left[1 + \frac{1/2 V_F}{U_{RS}} \right]^2 = 37.0 \left[1 + \frac{5}{102} \right]^2 = 40.7 \text{ feet}$$

The wave period f_0^{-1} may be found by first calculating:

$$\frac{40 H_a}{(U_{RS} + 1/2 V_F)^2} = \frac{40(40.7)}{(107)^2} = 0.142$$

From Table I (or equation 14), $f_0^{-1}/U_i = 0.121$. Therefore, $f_0^{-1} = .121 \times (107) = 12.95$ sec. And, $T_S = \sqrt[4]{4/5} f_0^{-1} = 12.25$ sec.

Similarly the critical forward speed, V_C in knots can be calculated from $V_F = V_C = 1.515 T_C$.

Table IV summarizes the results of the above calculations.

SIGNIFICANT WAVES AT $r/R = 1.8$ TO 2.0 .--Refer to figures 7 and 9. The maximum value of the significant wave does not occur at $R =$ radius of maximum wind, but at 1.8 to $2.0 R$, where $H_{2R} = 1.04 H_R = 37 \times 1.04 = 38.5$ feet and $U_{2RS} = 0.9 U_{RS} = 0.9 (102) = 91.8$ knots.

$$\frac{40 H}{U^2} = \frac{40 (38.5)}{(91.8)^2} = 0.182$$

$$\frac{f_o^{-1}}{U} = 0.139$$

$$f_o^{-1} = 0.139 (91.8) = 12.76 \text{ sec}$$

$$T_S = 12.76 \sqrt[4]{4/5} = 12.07 \text{ sec}$$

For a hurricane moving at 10 knots:

$$U_{2RS} = 91.8 + 5 = 96.8 \text{ knots}$$

$$H_{2RS} = 38.5 \left[1 + \frac{5}{91.8} \right]^2 = 42.8 \text{ feet}$$

$$\frac{f_o^{-1}}{U} = 0.139$$

$$f_o^{-1} (2R) = 0.139 (96.8) = 13.46 \text{ sec}$$

$$T_S = 13.46 \sqrt[4]{4/5} = 12.73 \text{ sec}$$

A summary of the above calculations for $r = 2R$ is given in Table V.

CAMILLE DEEP WATER WAVES AT "2R"

The path of Hurricane Camille and the location of the six wind and wave measuring stations are shown in Fig. 10 taken from Cordone, et al. (1975) as part of the Ocean Data Gathering Program (ODGP) of the Shell Development Co.

The height of the maximum significant wave corrected for a moving hurricane was determined for each ΔU corresponding to radii at 20° incremental angles according to:

$$H_{Rv} = H_R \left[1 + \frac{1}{2} \frac{V_F \cos \theta}{U_{RS}} \right]^2 = 36.97 \left[1 + \frac{\Delta U \cos \theta}{101.8} \right]^2$$

Values of H_T/H_{RV} were determined for the parameter $fR/U_R = 0.022$ and set values of r/R using Fig. 9.

The values of H_T corresponding to the given radius r were then calculated for each H_{RV} and the results plotted in Fig. 11.

The wave field was then constructed for chosen values of H_T (in this example, $H_T = 10, 15, 20, 30, 35, 40$ feet) using Fig. 11.

The results of the above wave predictions are shown in Figure 8, superimposed on the wind field. A comparison is made in Figure 12 between these predictions and measurements made at six stations off the Louisiana coast as part of the ODGP.

In order to make the comparison between the predicted and the measured significant wave heights at the ODGP stations, the predicted wind and wave field was placed along the storm track with forward direction 10° W of N and centered at time 1800 CDT. The predicted significant wave heights are for an instantaneous wave field. The comparison made here is not absolute since the wave heights will change as a function of time with the moving hurricane. The maximum measured significant wave height was 43.13 feet compared to 42.4 feet predicted in the field generally and not necessarily at one of the stations.

A comparison between the measured spectrum (Cordone, et al., 1975) and two predicted spectrum (Cordone, et al., 1975 and Bretschneider, 1970) at ODGP Station 1 at 1600 hours CDT, August 11, 1969, is presented in Fig. 13. Both predictions are well within the measured $\pm 90\%$ confidence limit (Fig. 10 of Cordone, et al., 1970). Fig. 13 includes the Envelope of Spectra (equation 4) based on the measured values (at the maxima where $f_0^{-1} = 14.3$ seconds, $S(f_0) = 4,030 \text{ ft}^2 \text{ sec} = 374.4 \text{ m}^2 \text{ sec}$) in contrast to the predicted spectra which are based upon predicted values of the wave height. This Envelope of Spectra is very similar to that from the JONSWOP measurements (Fig. 3). For example, if Camille were a design hurricane, the design spectrum would be all the spectra under the Envelope of Spectra as shown in Fig. 13 rather than the actual measured spectrum, in order to account for the "overshoot" of early wave generation in time, fetch, and wind speed. Some other value of m might be more appropriate in equations (3) and (4) and thus might fit better the measured spectra.

The purpose was not to determine the proper value of m for the Envelope of Spectra, but was to illustrate the importance of the "overshoot". There is need for more research in this area.

HAWAIIAN DEEP WATER WAVES

The tracks of the major hurricanes near Hawaii for the period 1950-1974 are shown in Figure 14. They include DOT (1959), NINA (1957) and HIKI (1950).

Note that most hurricanes approach the Islands from either the east or south. Although most have done little or no damage, a few

have been devastating such as Hurricane DOT (1959) which did over 5.5 million dollars worth of damage to crops and buildings on the island of Kauai with gusts over 100 mph recorded at Kilauea Point Lighthouse and \$150,000 in damage on the Islands of Oahu and Hawaii. In 1972 Hurricane DIANA generated waves estimated to be 30 feet high along the SE (Puna) coast of the Island of Hawaii.

Using the technique described in "Wind Field for Camille" a graphical presentation was prepared (Fig. 15) which when applied to Figure 14 provides predictions of the wind and wave field that may be expected to occur in the open ocean during a hurricane off the Hawaiian Islands. Its recurrence interval is estimated to be once in fifty years.

As a hurricane approaches the land, the winds are reduced by 1% per mile within 10 miles of the coast and correspondingly the waves are decreased in height, except very close to shore where the waves begin to break. However, the effect of the Islands is fairly negligible since their extent is small compared to that of the hurricane. Therefore, it is reasonable to expect significant waves of up to 30 feet and greater in height with 60 knot (69 mph) winds. In addition, instantaneous gusts of 84 knots (97 mph) may occur, and individual maximum waves could exceed 50 feet in height. Winds in the usually windy Pali (cliff) on the Island of Oahu can be expected to exceed 87 knots (100 mph).

DISCUSSION AND SUMMARY

There is an abundance of information available for calculating in deep water (1) the standard project and probable maximum hurricane wind and wave fields as verified adequately by use of the Ocean Data Gathering Project measurements (2) the maximum sustained wind speed, U_R , and maximum significant wave height, H_R , at radius of maximum wind, R , as applied successfully to historical hurricanes along the U.S. East and Gulf of Mexico coasts and to the standard project and probable maximum hurricanes of the U.S. National Weather Service (Bretschneider, 1972-b). The method is limited to a hurricane moving at speed equal to or less than its critical forward speed. Those faster need further study.

Winds and waves due to a hurricane moving over the Continental Shelf and the Coastline are modified by bottom friction percolation, refraction, shoaling, breaking, and water depth change caused by storm surge and/or tide. These must be taken into account.

ACKNOWLEDGEMENT

This paper was supported in part by the task "Wave Statistics for Extreme Wave Conditions" which is sponsored by the University of Hawaii Sea Grant College Program, National Oceanic and Atmospheric Administration (NOAA), Office of Sea Grant, Department of Commerce of the U.S.A. Government.

NOTE CONCERNING FIG. 4: "D" is wind damper opening in percent and "F" is the fetch in meters. Thus, the index 15-8 denotes a fetch of 8 meters subject to a wind generated when damper is 15% open.

LIST OF SYMBOLS

ΔH	Change in significant wave height due to a change in wind speed and fetch length, moving hurricane	U_{RS}	Surface wind speed at distance R from hurricane center, stationary hurricane
H_r	Significant wave height at r, stationary hurricane	U_{RS}^*	Surface wind speed at distance R from hurricane center due to change in wind speed, moving hurricane
H_R	Significant wave height at R, stationary hurricane	V_F	Forward speed of hurricane
H_{Rv}	Significant wave height at R due to change in wind speed, moving hurricane	β	Incurvature angle of wind vector
H_x	Component of H along x-axis	θ	Angle of the radius measured counterclockwise from the x-axis
H_y	Component of H along y-axis	ϕ	Latitude
K	Coefficient used in expression for U_R	ω	Angular velocity of earth
K'	Coefficient used in expression for H_R	P	Atmospheric pressure at radial distance r
k^*	Coefficient used in expression for U_{RS}	P_0	Central pressure
ΔP	Central pressure reduction from normal, inches mercury	P_N	Normal pressure = 29.92 inches H_g
r	Radial distance from center of hurricane	ℓ	Length
R	Radius of maximum wind	t	Time
s	A subscript to denote surface wind speed	T	Wave period in general
ΔU	Change in wind speed due to moving hurricane	T_s	Significant wave period
U_r	Geostrophic wind speed at distance r from hurricane center, stationary hurricane	T_c	Critical period
U_s	10-minute average surface wind speed at 10 meters above water surface	f_0^{-1}	Period of maximum energy density
U_R	Geostrophic wind speed at distance r from hurricane center, stationary hurricane	f	Wave frequency; also Coriolis parameter
U_{rs}	Surface wind speed at distance r from hurricane center, stationary hurricane	f_0	Frequency of maximum energy density
		f_0^*	Frequency of maximum energy density for the Envelope Spectrum

CHAPTER 14

OCEAN WAVE STATISTICS FROM FNWC SPECTRAL ANALYSES

Warren C. Thompson, Professor of Oceanography
F. Michael Reynolds, Lieutenant, U. S. Navy
Department of Oceanography, Naval Postgraduate School
Monterey, California 93940

ABSTRACT

Climatological wave data that may be shoaled and refracted from a deep-water wave station can be compiled in two forms from spectral ocean wave analyses produced by the Fleet Numerical Weather Central at Monterey, California: (1) significant wave statistics, which are similar to statistical tables currently in use, and (2) spectral element statistics, which give the frequency of occurrence of energy densities contained in a matrix of 15 frequency bands and 12 direction bands. Experimental formats of both types of statistical compilations are presented, their properties are examined, and the coastal engineering applications of these statistics are discussed.

BACKGROUND

For certain purposes coastal engineers require frequency-of-occurrence statistics on ocean waves compiled for a selected deep-water wave station located offshore from the coastal sector of interest. These wave climatology tables characteristically give the statistical frequency with which height-period-direction ($H-T-\psi$) data elements occur per average month or average year. They are of particular value in beach erosion studies because of the fact that the $H-T-\psi$ elements can be shoaled and refracted from deep water to any location in intermediate or shallow depths up to the breaker point. The gradient of the statistical wave field in deep water is generally sufficiently small along the coast that wave statistics prepared for a given deep-water wave station may be carried into shoal water depths for many miles in either direction from the station.

Frequency-of-occurrence statistics are derived from synoptic weather maps by the wave-hindcast method. Heretofore, the analysis of weather maps for wave generation parameters (wind velocity, fetch, and wind duration) has been performed manually. Because of the large amount of labor involved, climatological data of this type are not available for most coasts of the open oceans. Statistical tables have been compiled by the hindcast method for the Atlantic, Gulf, and Pacific coasts of the United States, however, and these have had wide use (tables currently in use were prepared by Saville, 1954; Newmann and James, 1955; Bretschneider and Gaul, 1956; Marine Advisers, 1961, and National Marine Consultants, 1960, 1961). The effort involved in making manual hindcasts has also limited these compilations to three years of weather maps. The yearly variability of the statistical wave field at a given open ocean wave station in middle and higher latitudes is known to be

appreciable; accordingly, a three-year data base for long-term average statistics must be considered minimal.

In December 1974 the Fleet Numerical Weather Central (FNWC) of the United States Navy at Monterey, California put into routine operation a spectral ocean wave computer model that produces "real-time" computations, termed analyses, of the deep-water wave field in spectral form 12-hourly for a grid-point field covering the major oceans of the Northern Hemisphere (waves are not computed for the Southern Hemisphere). The wave field is computed in 3-hour time steps from the surface wind field, which in turn is derived from the observed sea-level pressure field. The grid-point spacing is approximately 150 nautical miles. Details concerning the FNWC Spectral Ocean Wave Model, including comparisons between FNWC wave computations and open-ocean observations, are given by Lazanoff and Stevenson (1975).

In addition to issuing daily wave analyses and forecasts, FNWC has begun running historical weather maps through their spectral wave program and is in the process of storing the 6-hourly wave field for the Northern Hemisphere oceans on magnetic tapes. Present plans call for the production of 20 years of 6-hourly analyses for the period 1955-1974. When the project is completed, which will require many months, the archived wave data will provide the potential to extend the present wave statistics coverage geographically to most coasts and islands of the open North Pacific, North Atlantic, and North Indian Oceans, and to increase the time base nearly an order of magnitude as well.

Wave statistics for coastal engineering use have not previously been produced from FNWC spectral wave computations. In this paper, formats for presenting frequency-of-occurrence statistics are illustrated and applications of the statistics are discussed. Additional information is given by Reynolds (1976).

DEVELOPMENT OF THE TABLES

The approach taken by the authors to develop wave-occurrence statistics from FNWC spectral analyses was to mock up suitable formats manually from a short series of FNWC computer printouts for a given wave station. This permitted experimentation with the format design, including the selection of suitable scales. The wave station chosen is a FNWC grid point located at latitude 50.9°N and longitude 145.6°W near Ocean Weather Station Papa in the open Gulf of Alaska (a deep-water site along an open ocean coast could have been chosen). A summer month and a winter month, August 1974 and February 1975, were selected for extremes in seasonal wave activity and with the expectation of a dominance of swell during one month and sea in the other. The statistical tables for February only are presented here. The equivalent tables for August can be found in Reynolds (1976). It may be noted that the August wave statistics reveal much lower wave activity, shorter wave periods,

and a higher incidence of swell versus sea than occurred in February. Because of missing synoptic analyses, the data for February that are shown in the tables were drawn from 45 12-hourly computer printouts totalling 22½ days of time.

SYNOPTIC SOURCE DATA

Familiarity with the FNWC wave analysis printout is required for a full understanding of the design and characteristics of the tables presented herein. A sample printout for the selected wave station for 00Z on 31 August 1974 is shown in Table 1.

The 15 wave-frequency values shown across the top of the printout (Item 1) each represent the central frequency of a given FNWC frequency band. The central frequencies are seen to cover a period range from 6.1 seconds (0.164 Hz) to 25.7 seconds (0.039 Hz). The limits and width of each frequency band are given in Table 2. The 12 wave-direction values shown in the right-hand column in degrees (Item 2) and in the left-hand column in coded form (Item 3) each represent the central direction of a 30° directional band. The geographical directions are seen to be irregular. They vary from grid point to grid point because of the global map projection used by FNWC (Lazanoff and Stevenson, 1975).

The block of 180 numbers forming the body of the table (Item 4) constitutes the frequency-direction ($f-\psi$) spectrum of the wave field. Each number represents the wave energy density, expressed as variance (ft^2), contained in the frequency and direction bands indicated. The sums of the columns (Item 5) represent the wave energy contained in the 15 frequency bands irrespective of wave direction and constitute the familiar f -spectrum. The sums of the rows (Item 6) give the wave energy contained in the 12 direction bands irrespective of wave frequency, and collectively represent the less familiar ψ -spectrum.

The sums of the component variance values contained in the $f-\psi$ spectrum, the f -spectrum, and the ψ -spectrum (Items 4, 5, and 6) are identical, and for the waves being considered are seen to total 3.145 ft^2 (Item 7). It is of interest to note that two well-defined wave trains from different sources are revealed in the printout. The larger set is a swell train with a dominant period of about 15.0 seconds (0.067 Hz band) and a dominant direction from the West (259° band); the other set is sea of about 9.7 second period (0.103 Hz) from the South (199°).

At this point, some comment is needed regarding the wave frequency bands (Item 1) represented in the printout. The 15 bands have been carefully selected by FNWC to minimize computing time and yet cover the full frequency range for ordinary gravity waves with suitable bandwidths. It may be noted in Table 2 that the bands below a frequency of 0.080 Hz are of constant width (0.0055 Hz), but that at higher frequencies the bandwidth has been widened by multiples of 2, 3, 4, and 18. A consequence of this design is

that in order to properly compare the magnitude of two energy density values, the values must be adjusted to a common frequency bandwidth. Choosing the common or standard bandwidth to be $\Delta f = 0.0055$ Hz, this can be done by multiplying the energy density values in the printout by the appropriate energy density factors listed in Column 4 of the table. By way of example, the secondary peak of the f-spectrum (Item 5 of Table 1) appears to lie at a frequency of about 0.133 Hz, whereas this maximum actually lies at about 0.103 Hz (the primary peak of the f-spectrum lies at about 0.067 Hz). The energy content of these two frequency bands are seen from the printout to have values of 0.41 ft^2 per $\Delta f = 0.0165$ Hz (from Table 2) and 0.33 ft^2 per $\Delta f = 0.0110$ Hz, or about 0.14 ft^2 and 0.16 ft^2 respectively, when adjusted to the common bandwidth of $\Delta f = 0.0055$ Hz. The component variance values of the f- ψ spectrum (Item 4) must be similarly adjusted for direct comparison of their energy contents.

It should be further noted that if the variance values composing the f-spectrum shown in the printout (Item 5) were plotted on a linear frequency scale, the resulting graph would be exaggerated at the high-frequency end of the spectrum because of the choice of variable frequency bandwidths. Nevertheless, the sum of these variance values, 3.145 ft^2 , correctly represents the total energy content computed for the waves present. For a correct graphical representation of the frequency spectrum (to the accuracy permitted by the widths of the frequency bands), the variance values must first be adjusted to a common frequency bandwidth through use of the energy density factors. No such difficulty arises with the ψ -spectrum because of the use of equal directional bandwidths.

The FNWC decision to represent the frequency spectrum by unequal bandwidths affects the way in which statistical tables may be formatted and the statistics compiled, and requires care by the user in order to assure correct interpretation of the data. This is commented upon further in the discussion of the individual tables.

Returning to the spectral printout in Table 1, the waves computed to be present at the station at the designated time are seen to be described in considerable detail by 180 ΔV - Δf - $\Delta \psi$ elements, each being a component, ΔV , of the total variance of the wave field (V) contained in a specific frequency band, Δf , and direction band, $\Delta \psi$. These wave data are referred to herein as spectral element data. The wave information in the printout may also be summarized by designating the significant height, $H_{1/3}$, the period of maximum energy density, T_{\max} , and the direction of maximum energy density, ψ_{\max} . For the wave field shown in the printout, $H_{1/3} = 6.8$ feet ($H_{1/3}^2 = 4V^2$ where $V = 3.145 \text{ ft}^2$), T_{\max} lies in the frequency band centered at 15.0 seconds (or 0.67 Hz), and ψ_{\max} lies in the direction band centered at 259 degrees. Thus, the ψ_{\max} wave field can be described in a gross way by a single $H_{1/3}$ - T_{\max} - ψ_{\max} data unit. Wave data in this form will be significant wave data.

It is evident that wave statistics derived from a time series of FNWC spectral analyses may be compiled as (1) significant wave statistics, consisting of one $H_{1/3} - T_{max} - \psi_{max}$ data unit per FNWC analysis, and as (2) spectral element statistics, composed of $180 \Delta V - \Delta f - \Delta \psi$ data units per FNWC analysis (or fewer than 180 units when variance values of 0.00 ft^2 are excluded from the statistical tabulation). Example formats of each are given in the following sections.

In the statistical tables and the discussion herein, wave frequency and wave period are used interchangeably, in a reciprocal sense, according to convention; frequency is used when reference is made to the FNWC spectral model and period when operational wave products are of interest.

SIGNIFICANT WAVE TABLE

The significant wave statistics compiled for the selected station for February 1975 from FNWC spectral wave analyses are presented in Table 4. Because of the sparsity of the data in the individual direction bands, the entries for all 12 directions have been combined into a single table for illustration purposes in this paper; tables intended for practical use would display each direction component separately. The values in the table represent the number of 12-hourly synoptic analyses occurring during the $22\frac{1}{2}$ day data period. The height scale, coded for brevity (code given in Table 3), is linear with an increment of 2 feet. Regarding the period scale, wave occurrences were compiled from the printouts by the FNWC frequency bands shown in Table 2, but for purposes of convention each column of Table 4 is labelled for the period equivalent to the central frequency of each FNWC frequency band. The equivalent period bandwidths are seen from Table 2 to be variable and to lie mostly in the range of 1 to 2 seconds.

The design of Table 4, except for the use of frequency as a base instead of period, is essentially identical to existing frequency-of-occurrence tables, but with one important exception. In compiling wave statistics derived from the manual analysis of weather maps, wherein wave trains generated in individual wind areas are computed and propagated separately, it has been the general practice to record each set of waves as an independent occurrence whenever two or more trains are present simultaneously at the wave station. This results in tables containing more hours of wave occurrence in a month than actually occurs, particularly when separate tables for sea and swell are compiled. This presents the user with the problem of how to adjust the data to 100% occurrence. In addition, higher wave heights must occur in nature than these tables generally indicate because multiple wave trains are a common occurrence at open ocean wave stations. In the FNWC Spectral Ocean Wave Model, the growth of sea and the propagation of swell are complexly inter-related and individual wave trains are not differentiated in the $f-\psi$ spectrum. Accordingly, the statistics compiled from the

FNWC spectral analyses reflect wave heights associated with the statistical occurrence of multiple wave trains, and the super-occurrence problem does not exist.

In using significant wave tables compiled from FNWC spectral analyses, it may be desirable for some purposes to distinguish swell from sea and to estimate the relative age of the swell, i.e., whether it has travelled over a short, moderate, or long decay distance. Because swell steepness diminishes with increasing travel distance from the generating area, some measure of the steepness of the wave field, γ_s , can be used for this purpose. In this study, γ_s is defined in terms of $H_{1/3}$ and T_{max} by analogy to monochromatic waves as shown in Table 5. The relationship selected between wave age and γ_s is given in the lower part of the table. Thus, young swell has a statistical steepness in the range of about 1/40 and 1/100, has travelled 0 to 250 nautical miles from the location where it was generated, and has been reduced in significant height by a factor of 1.0 to 0.5. It may be observed that because significant wave tables are a matrix of values of $H_{1/3}$ and T_{max} , they are also tables of γ_s and accordingly of wave age. This permits wave-age boundaries to be superimposed, as in Table 4.

It may be recalled that the term "wave age" was introduced by Sverdrup and Munk (1947) to describe the growth stages of sea during wave generation. They defined it as the ratio of wave speed to surface wind speed, C/U , and related it to wave steepness. In extending use of the term to swell, which has considerable practical merit, wave age is defined differently than for sea but remains related to the steepness of the wave field.

The zone labelled "sea" in Table 4 contains all synoptic occurrences where sea is the dominant component of the wave field present, regardless of the wind speed generating the sea or of its stage of growth. The zone is seen to have a cutoff such that wave heights greater than a certain value do not occur for a given period. Young seas, because they are of maximum steepness, should lie along this data envelope, whereas fully arisen seas should fall near the inner margin adjacent to the zone labelled "young swell". A well-defined data cutoff should be expected whenever a significant number of synoptic entries represent seas, but may not be evident in statistics where swell is dominant.

SPECTRAL ELEMENT TABLES

Spectral element statistics compiled for the selected station for February 1975 from FNWC synoptic wave analyses are shown in Table 6. The entries in the table were read directly from the 180 component variance values contained in each of the 45 12-hourly printouts available for the month (eg., Item 4 of Table 1). The entries for all 12 direction bands have been combined into a single table for purposes of comparison with Table 4.

Table 6 is identical to Table 4 with respect to the period scale and the manner of representing frequency of occurrence (i.e., by the number of 12-hourly analyses); however, the significant-height scale is replaced by a variance scale chosen to give a reasonable spread to the data. The variance scale is coded (Table 3) to simplify the table. It should be noted that the units of variance in Table 6 are ft^2/FNWC frequency bandwidth.

Tables 6 and 4 were derived from the same FNWC printouts and the total energy content represented by their entries is identical. Nevertheless, there are no values common to both distributions, and consequently, there are no means by which the data in the two tables can be equated numerically. Neither can one table be derived from the other. These circumstances arise from the fact that although the energy in the waves at a given place and time can be separated analytically into spectral components and can subsequently be reconstituted to yield a significant wave height representing that sea surface, the same spectral components when distributed in a statistical table with components from other synoptic analyses can no longer be identified and re-assembled to produce the significant height.

A comparison of these two tables offers some interesting contrasts, however, and gives some feeling for the coarseness of significant wave data as a descriptor of ocean wave climatology. The spectral element table contains some fifty times more data than the significant height table; specifically, 2126 variance entries ($> 0 \text{ ft}^2$) versus 45 height entries. The variance entries are distributed in a wider range of period bands, from 6.1 to 25.7 seconds versus 9.7 to 18.0 seconds, and extend into what are ordinarily considered very long periods. Further, the entry of maximum energy is centered in the 20.0 second band for the spectral element statistics versus the 16.4 second band for the significant wave statistics. It should additionally be noted that the wave activity in February 1975 was appreciable; this is indicated in Table 4 by the small number of occurrences of waves under 10 feet (Code 05 and under), but is not apparent in Table 6 where most of the entries are in the lowest energy categories.

A peculiarity of Table 6 is that a given energy category or code number does not represent the same energy density for all frequency bands. This is due to the variable widths of the FNWC frequency bands. For example, Code 03 represents an energy level of $0.50\text{-}0.74 \text{ ft}^2/0.0055 \text{ Hz}$ bandwidth in the 12.0 second band but $0.50\text{-}0.74 \text{ ft}^2/0.0110 \text{ Hz}$ bandwidth in the adjacent 10.9 second band, giving the 10.9 second band about half the energy density of the 12.0 second band. Accordingly, energy density values cannot readily be compared across the table. This circumstance would complicate the use of this type of table and would likely result in incorrect interpretation of the statistics.

This difficulty may be avoided by reducing the component variance values to the standard frequency bandwidth, $\Delta f = 0.0055$

Hz, through multiplication by the energy density factors given in Table 2. This operation may be applied either to the 180 variance values in each FNWC printout, or with a slight reduction in statistical accuracy to the statistics compiled directly from these values. Table 7 was derived from Table 6 by the latter method. The variance scale of Table 7 thus has the units of $\text{ft}^2 / 0.0055 \text{ Hz}$ standard bandwidth for all periods in the table.

Table 7 has the desirable quality that a given energy code number represents the same energy level for all frequency bands. On the other hand, the table contains less total energy than Table 6. This is due to the fact that in adjusting the energy of the FNWC frequency bands to the standard bandwidth in the periods from 6.1 to 10.9 seconds, segments of the frequency spectrum lying outside the 0.0055 Hz bandwidth centered about each period are in effect excluded.

A feature of the spectral element tables of particular interest that is best seen in Table 7 is the well-defined energy cutoff extending diagonally across the table. The cutoff represents the energy-saturated frequencies of sea spectra associated with the strongest winds occurring during the month. The cause and nature of the cutoff can be more readily visualized from consideration of Table 8 which shows the spectral entries such as might be extracted from a single FNWC printout for a fully arisen sea of 50 knots (in the absence of swell). The entries in this table show the energy density per 0.0055 Hz and 30° bandwidths (as in Table 7) for the condition in which the mean wind direction coincides with the center of the direction band (this condition gives the maximum variance values possible for the 50-knot sea). The reader may recognize this distribution as a frequency spectrum graph in tabular form that has been rotated 180° about both the energy density and frequency axes. If one now imagines a graph of nested frequency spectra for fully arisen seas generated over a range of wind speeds, the spectra are seen in the higher frequencies to occupy a relatively narrow band on the graph, with the outermost spectrum being associated with the strongest wind and representing the energy cutoff in the equivalent statistical tables. If non-fully developed spectra for the same wind speeds are added to the imagined graph, the unsaturated portions of each will lie inside this band, as will also the saturated low-frequency tails of fully arisen spectra associated with weaker winds.

It is evident from these considerations that the entries in Table 7 lying inside the cutoff zone may represent (1) saturated frequency components associated with fully arisen seas produced by weaker winds, (2) unsaturated components of seas produced by strong or weak winds, or (3) swell. There is no way to associate these entries with sea or swell however, whether or not this might be desired for practical purposes. All that can be said in this vein is that the entries lying in a band along the data envelope clearly represent dominantly sea. It should be

mentioned here that the energy cutoff in Table 7 is not fully analogous to the height cutoff in Table 4; occurrence entries representing sea may be found anywhere inside the data envelope of Table 7 but lie only in the zone labelled "sea" in Table 4.

The wave statistics for February are presented in still another form in Figure 1. This figure was constructed by cumulating the occurrences in Table 7 from high to low energy density within each period band (cumulative table not shown), and plotting the cumulated values against the period. The curves in the graph are isopleths of energy density coded according to Table 3. Figure 1 combines the advantage of Table 6 in that the total energy represented is correct, and Table 7 in which the energy densities are referenced to the standard 0.0055 Hz bandwidth. This graphical presentation gives the user a distinctly better visual impression of the statistical distribution than do the two tables; however tables directly provide the numerical values a user needs.

Figure 1 is of particular interest not so much as a format in which spectral element statistics may be presented but because of the possibility which it suggests for describing climatological wave data by a mathematical function, at least for some ocean regions and seasons. The energy-occurrence curves in the figure are seen to resemble nested wave frequency spectra for fully arisen seas associated with a range of wind speeds, with the dashed curve being the counterpart of the T_{\max} curve for the spectra. The fact that the pattern of this T_{\max} small-sample distribution is so well defined suggests that the long-term average pattern for February is similar at this station. It may be expected, on the basis of continuity, that similar wave climatology patterns occur in adjacent months and over adjacent regions of the North Pacific Ocean; accordingly, it seems possible that all of these distributions might be described by a function having variable coefficients that provide for seasonal and geographical gradients. From a practical standpoint, the availability of wave climatology models for ocean regions would greatly improve data packaging, allow greater versatility in data manipulation, and improve the prediction of infrequently occurring wave conditions.

Consideration of the spectral characteristics of sea and swell further suggests that in ocean regions and seasons where swell is dominant, the wave climatology may not be amenable to mathematical description. A graph similar to Figure 1 prepared for August (not shown) when the swell-to-sea ratio is substantially higher at the selected station is inconclusive on this point because of the low frequency of wave occurrence in that month. It should be recalled that Figure 1 is a data composite of all 12 direction bands. If long-term average statistics for February were displayed for each direction band, it is reasonable to expect that a pattern similar to that in the figure would appear for all or some of the component directions.

USES OF THE STATISTICS

Significant wave statistics tables derived from FNWC spectral analyses are similar in construction to climatology tables currently in use, except for tabulation of the wave data by variable period increments. This design feature may appear untidy but should not restrict the uses of the statistics.

The coastal engineering applications which would be made of these tables appear to be identical to those of existing wave climatology tables. Reasons for favoring use of the FNWC-derived significant wave statistics, however, are that they are free of the familiar super-occurrence problem in which tables contain more total hours of wave occurrence than actually occurs, and that they take into account simultaneous occurrence of wave trains arriving at a wave station and therefore contain higher wave heights.

With regard to spectral element statistics, there are considerable uncertainties concerning their uses and apparently no experience available to provide guidance. The following comments are therefore limited to the more obvious things that can and cannot be done with these statistics.

The $\Delta V - \Delta f - \Delta \psi$ values composing spectral element tables compiled for a deep-water wave station can be shoaled and refracted in the same manner as the spectrum of a given set of waves (described by Pierson, Neumann, and James, 1955); thus, the spectral element climatology can be determined for a selected shoal-water site (except near the surf zone since the breaker height cannot be identified in the spectral statistics). These statistics cannot be converted into wave height statistics, however, and so cannot be used to compute design wave heights, wave forces, breaker-height statistics, or littoral-drift rates by current methodology; these quantities must still be calculated using the more gross significant wave statistics.

The principal uses for wave statistics in spectral element form, both in coastal waters and the open ocean, appear to lie in the realm of resonant reaction of structures to waves. Practical applications can readily be visualized involving piling platforms, spar platforms, tethered breakwaters, floating causeways, surface vessels, and surface-effects craft. The nature of the transform from spectral wave information to structures response and how the transform can be applied quantitatively appear to be little understood, however.

Although specific uses for spectral element climatology are not now developed, the marked differences which these statistics display from the significant wave statistics derived from the same synoptic source data, along with the possibility of modelling these spectral distributions mathematically, compels further attention to these data.

CHAPTER 15

Application of Fetch Area Method in Monsoon Wave Hindcasting

Nai-Kuang Liang¹, Shih-Tsan Tang²
and Ben-Juen Lee³

ABSTRACT

The Fetch Area Method (FAM) derived from Elementary Wave Model is used to analyze the winter monsoon wave of Taichung Harbour. The empirical wind-wave energy transfer coefficient $\bar{\xi}$ determined by FAM for this area is 7.25×10^{-4} . A relationship between $g T_{1/3} / 2\pi\bar{U}$ and $g t_d' / \bar{U}$ is also found, where \bar{U} is the average wind speed and t_d' the duration. A comparison of the wave hindcasting of FAM has shown that the latter is better than the former, and the former is valid only as the wind velocity increases, once the wind decreases the SMB Method is no more valid.

INTRODUCTION

The Fetch Area Method based on Elementary Wave Model (Liang 1973a, 1973b) is applicable to the wave forecasting or hindcasting, in which the influence of the whole wind field is considered.

The limited water field and the continental shelf of Taiwan Straits make us believe that the wave generated in this area should be different from that of the open sea like Pacific Ocean (Fig. 1). There are some coastal stations in Taiwan where both wind and wave data are available. Among them, we are most satisfied with the completeness and perfectness of the data in the vicinity of Taichung Harbour. The hindcast work of this paper has been made on the basis of the data on the point observation of Taichung Harbour and the weather maps analyzed by Central Weather Bureau. In this paper we analyzed the wave and wind data according to the Elementary Wave Model to determine the empirical coefficient $\bar{\xi}$ and the relationship of $T_{1/3}$, the average wind speed of influencing area \bar{U} and the duration t_d' adapted for Taichung Harbour. Using this coefficient and the relationship, one can hindcast or forecast the monsoon waves of this area.

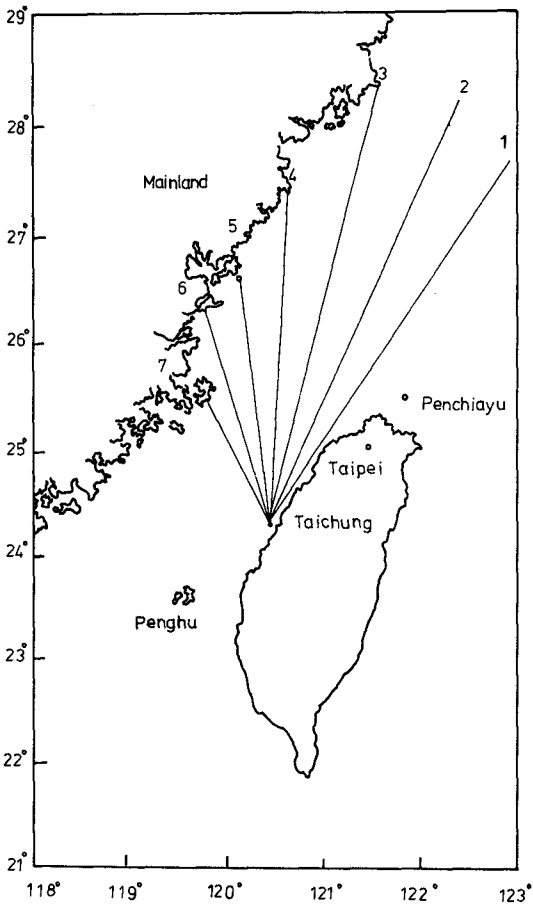

Fig.1 Taiwan Straits

BASIC THEORY

According to the Elementary Wave Model (Liang 1973b, 1975) and some modifications, the wave energy at the observation point 0 (Fig. 2) is as follows:

$$E = \frac{2}{\pi G} \int_r \int_\theta \bar{\Phi}(r, \theta) U^2(r, \theta) \cos^2[\beta(r, \theta)] \exp\left(-\frac{0.08}{U^2} r\right) dr d\theta \quad (1)$$

where G is the equivalent group velocity and defined as

$$G = \frac{g}{2} \frac{\int_0^\infty \bar{\Phi}(\sigma) \sigma^{-1} d\sigma}{\int_0^\infty \bar{\Phi}(\sigma) d\sigma} \quad (2)$$

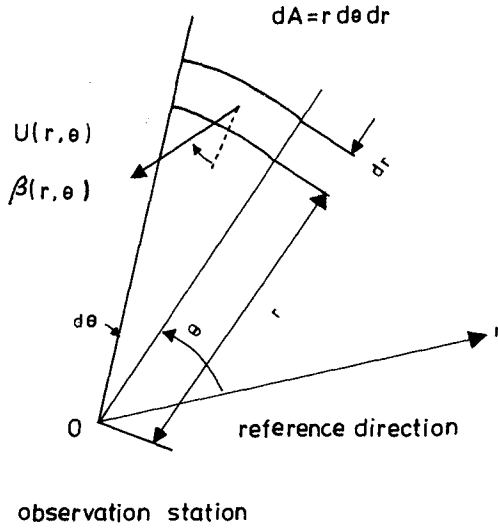

Fig.2 The coordinate system of the wind field.

in which $\bar{E}(\sigma)$ is the wave spectrum. $\bar{\xi}$ is a parameter which characterizes the energy transfer from wind to wave. U (m/s) is the wind velocity at 10m above sea level. $\cos^2 \beta$ is the angular spreading function which is verified by an experiment (Liang 1973a,b). $\exp (- \frac{0.08}{U^2} r)$ is an e-exponential decay term, which is determined by the 100% developed seas after C. L. Bretschneider, i. e.,

$$\frac{gr}{U^2} = 600,000. \tag{3}$$

or
$$r = \frac{600,000}{g} U^2 = \frac{600}{g} U^2 \text{ (km)} \tag{4}$$

It is then supposed that the elementary wave energy at the end of the fetch of this 100% developed seas is decayed to 1/100 of the original amount, as it propagates to the observation point 0,

$$e^{-\alpha r} = \frac{1}{100} \tag{5}$$

$$\alpha r = 4.605 \tag{6}$$

From eq.(4) $\alpha \approx \frac{0.08}{U^2}$ (7)

For simplicity, we take

$$G_{1/3} = \frac{gT_{1/3}^2}{4\pi}, E_{1/3} = H_{1/3}^2 \tag{8}$$

Instead of G and E and assume $\bar{\xi}$ is a constant, then we have

$$H_{1/3}^2 = \frac{2}{\pi G_{1/3}} \bar{\xi} \int_r \int_\theta U^2 (r, \theta) \cos^2 [\beta (r, \theta)] \exp (\frac{-0.08}{U^2} r) dr d\theta \tag{8}$$

$$\text{or, } \bar{\xi} = \frac{H_{1/3}^2}{2 / (\pi G_{1/3}) \int_r \int_\theta U^2 (r, \theta) \cos^2 [\beta (r, \theta)] \exp (\frac{-0.08}{U^2} r) dr d\theta} \tag{9}$$

ESTIMATION OF WIND FIELD AND DETERMINATION OF INFLUENCING WIND FIELD

The preliminary data for wave forecasting or hindcasting is the information of

wind field over sea areas. Unfortunately, there are few wind data available in these areas and it is believed that there are still some difficulties to determine the wind field over the ocean (Bunting, 1970). Hence, we have made some objective judgement of the wind field over these sea areas. Estimates of wind field over sea areas are made on the basis of the isobaric pattern of synoptic weather charts and the wind data of nearby meteorological stations. The sea areas can be roughly divided into two regions, i.e., the region to the north of Pengchiayu and the region in the Taiwan Straits. Since the region to the north of Pengchiayu belongs to an open sea where the isobaric pattern is less influenced than that in the Taiwan Straits, the wind field in this area is estimated from the calculated wind speed and the wind data of the nearby stations.

The calculated wind speed is obtained from the geostrophic balance equation

$$U_g = \frac{1}{f a f} \frac{\Delta p}{\Delta n} \quad (10)$$

and some corrections with geostrophic surface-wind relationship given by

$$U = aU_g + b \quad (11)$$

where $a = 0.54$ and $b = 2.5$ (Hasse and Wagner, 1970)

In the region of Taiwan Straits the isobaric lines are greatly curved and the pressure gradient is too great to be determined precisely from the weather chart. However the wind was observed offshore of Taichung Harbour at 2 hour interval. Hence, the observed wind data at this area will be used to represent the wind field over the Straits.

The 6-hr weather map is always changing, we should assume that the wind is steady during the six hour interval. Since the winter monsoon blows steadily from the north or northeast, it's appropriate to say that the wave in the generating area is quasi-fully-developed. It is then assumed that the elementary wave energy propagates at the speed of the fully-arisen equivalent group velocity determined by the local wind, i.e, $0.5 U$ after Neumann. The authors use a series of surface synoptic charts to determine the influencing wind field. For example, if we try to hindcast the wave at 1400Z, Feb. 26, 1974, the weather chart at 1500Z should be checked at first. The weather charts are available at 0300Z, 0900Z, 1500Z and 2100Z. Since the weather system is assumed unchanged during the 6-hr interval, the wind field is stationary from 1200Z to 1800Z. The wind speed of Taichung Harbour at 1500Z Feb. 26, 1974 is $U_1 = 17.4$ m/s, the first influencing sector has a radius (Fig.3)

$$\begin{aligned} r_1 &= 0.5 \times 17.4 \times \Delta t_1 \\ &= 0.5 \times 17.4 \times 2^1 \times 3600 \text{ (m)} \\ &= 0.6 \text{ (lat.)} \end{aligned}$$

Then we check the former chart (Fig.4) of 0900Z on which the wind speed near r_1 is $U_2 = 11$ m/s, Hence,

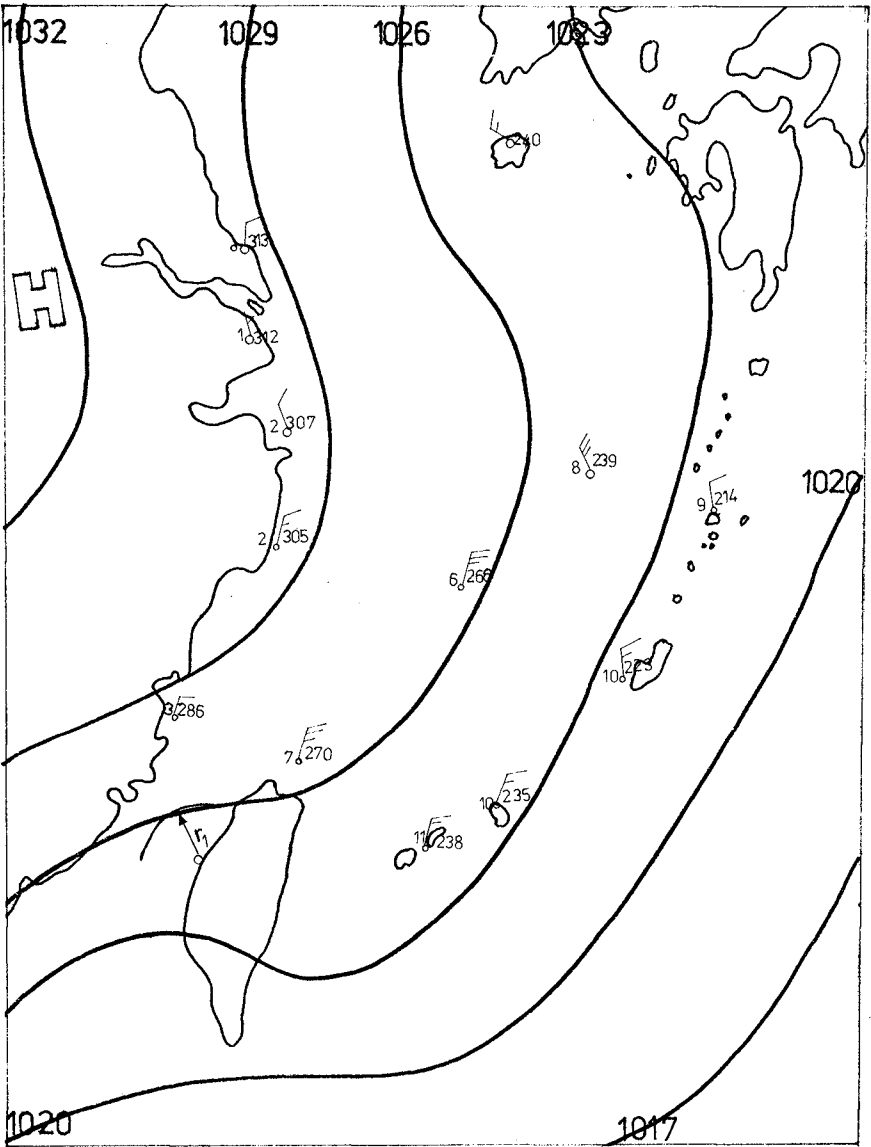

Fig.3 Surface synoptic chart for 1500Z, Feb. 26, 1974

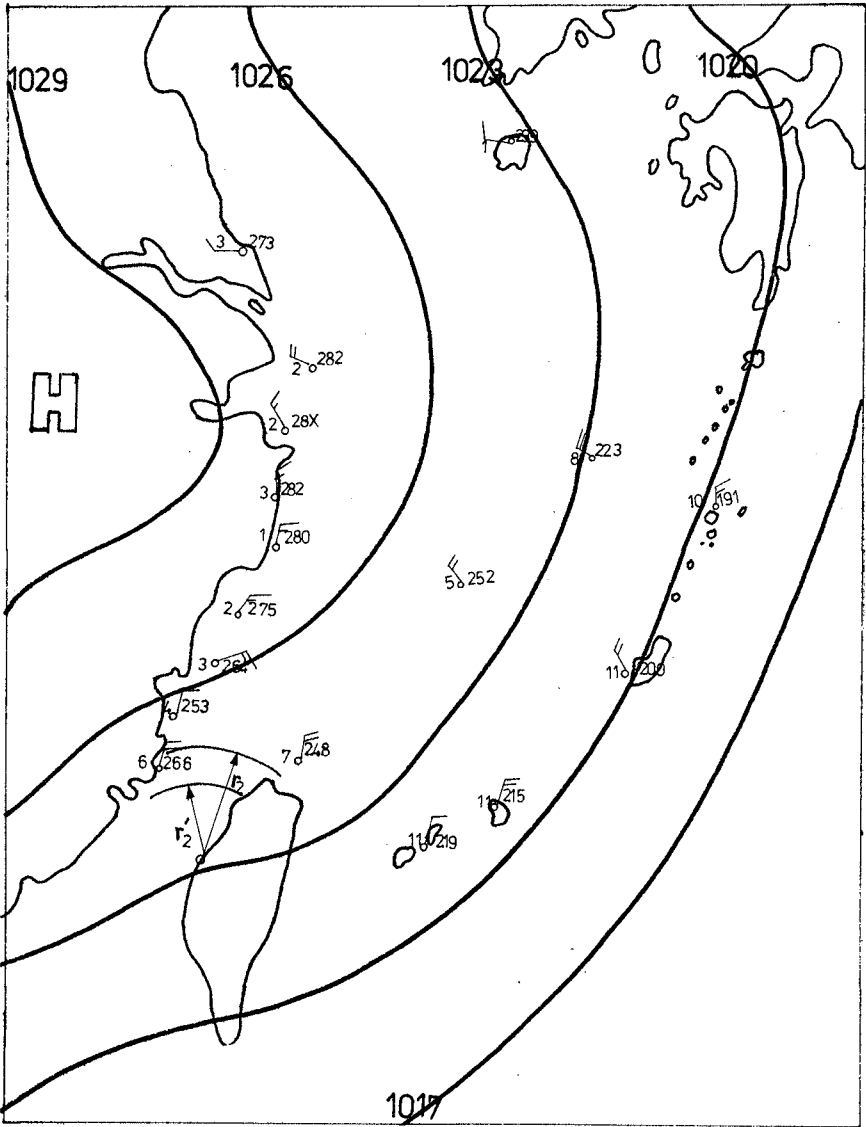

Fig.4 Surface synoptic chart for 0900Z, Feb. 26, 1974

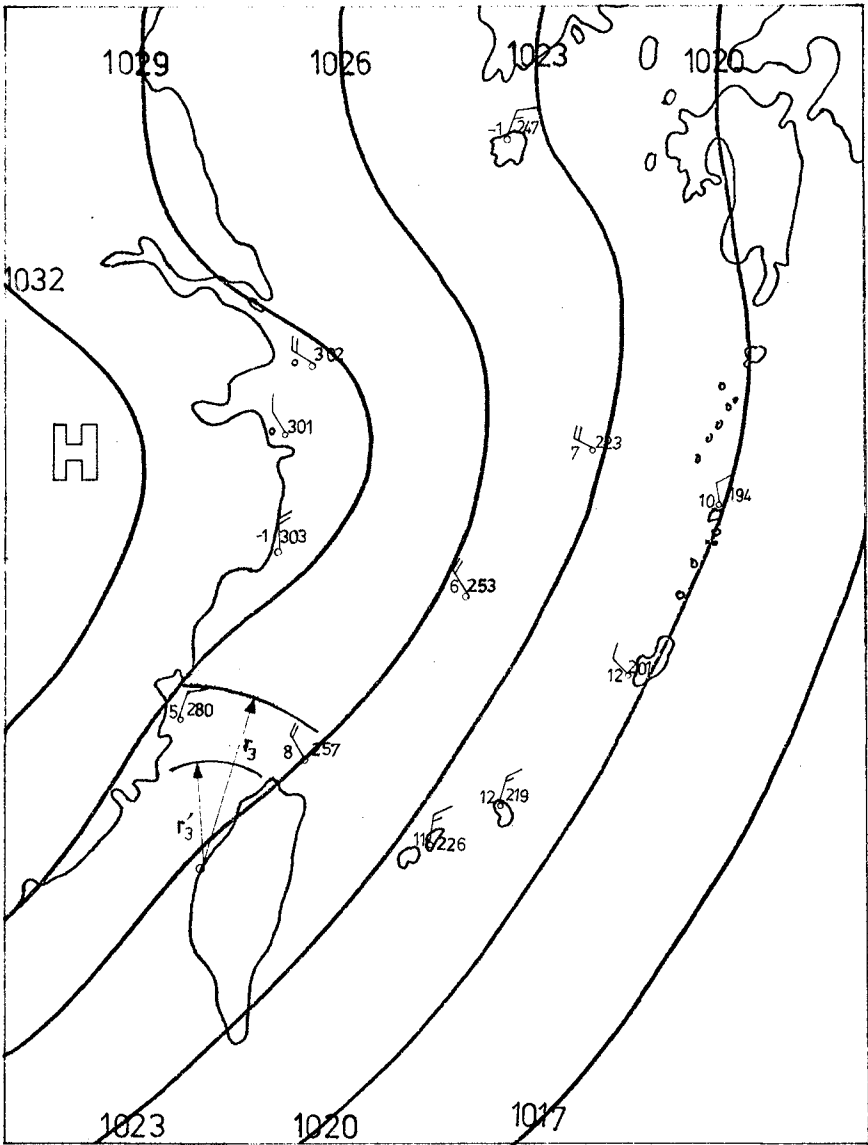

Fig.5 Surface synoptic chart for 0300Z Feb. 26, 1974

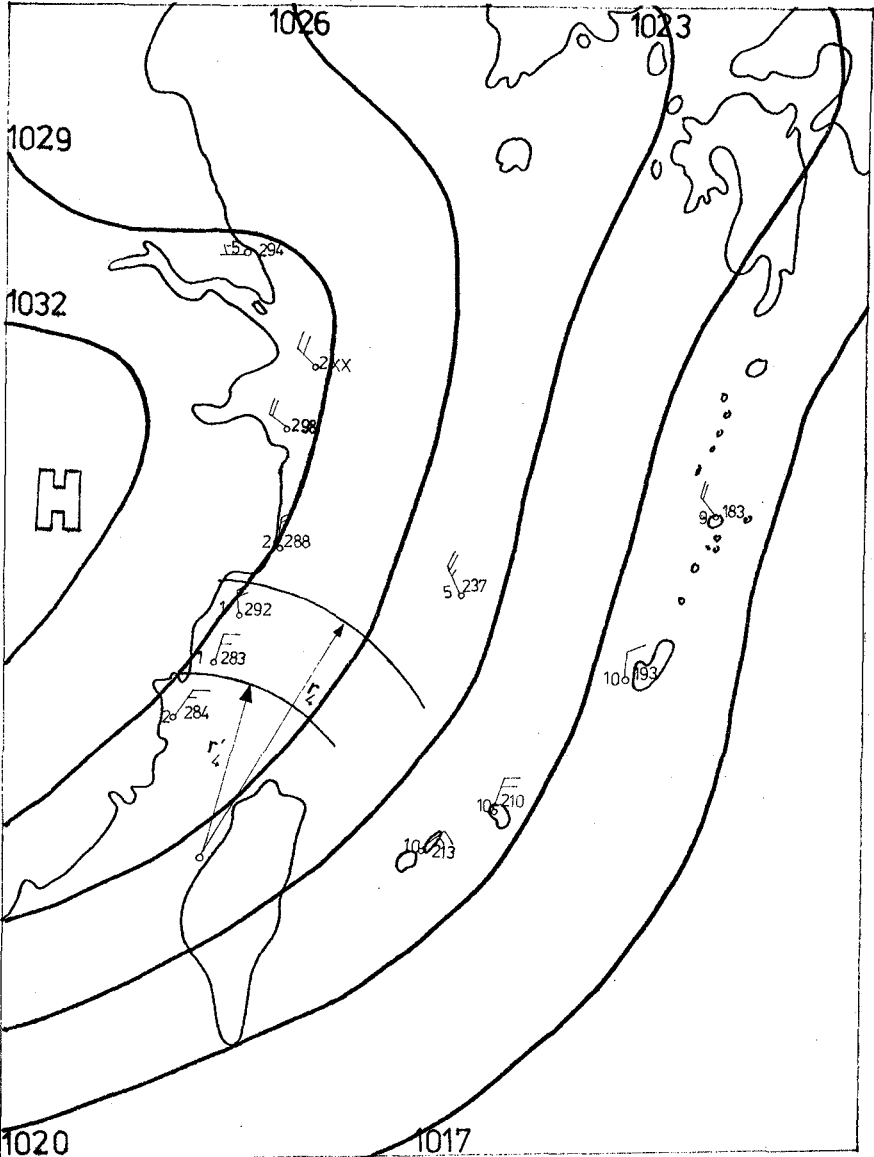

Fig.6 Surface synoptic chart for 2100Z Feb. 25, 1974

$$\begin{aligned} r_2 &= 0.5 \times 11 \times (\Delta t_1 + \Delta t) \\ &= 0.5 \times 11 \times (2 \frac{1}{2} \times 6) \times 3600 \text{ (m)} \\ &= 1.4 \text{ (lat.)} \end{aligned}$$

$$\begin{aligned} r_2' &= 0.5 \times 11 \times \Delta t_1 \\ &= 0.5 \times 11 \times 2 \frac{1}{2} \times 3600 \text{ (m)} \\ &= 0.4 \text{ (lat.)} \end{aligned}$$

Since the wind data to the north of Pengchiayu is not valid for Taiwan Straits of which the radius is about 1.0 lat., we should take $r_2' = 1.0$ lat.

In Fig. 5, the weather chart of 0300Z shows the wind speed near r_2 is $U_2 = 10$ m/s. Then

$$\begin{aligned} r_3 &= 0.5 \times 10 \times (\Delta t_1 + 2\Delta t) \\ &= 0.5 \times 10 \times (2 \frac{1}{2} \times 2 \times 6) \times 3600 \text{ (m)} \\ &= 2.3 \text{ (lat.)} \end{aligned}$$

$$\begin{aligned} r_3' &= 0.5 \times 10 \times (\Delta t_1 + \Delta t) \\ &= 0.5 \times 10 \times (2 \frac{1}{2} \times 6) \times 3600 \text{ (m)} \\ &= 1.3 \text{ (lat.)} \end{aligned}$$

In the weather chart of 2100Z, Feb. 25, 1974 (Fig. 6) the wind speed near r_3 is $U_4 = 11$ m/s, therefore

$$\begin{aligned} r_4 &= 0.5 \times 11 \times (\Delta t_1 + 3\Delta t) \\ &= 0.5 \times 11 \times (2 \frac{1}{2} \times 3 \times 6) \times 3600 \text{ (m)} \\ &= 3.7 \text{ (lat.)} \end{aligned}$$

$$\begin{aligned} r_4' &= 0.5 \times 11 \times (\Delta t_1 + 2\Delta t) \\ &= 0.5 \times 11 \times (2 \frac{1}{2} \times 2 \times 6) \times 3600 \text{ (m)} \\ &= 2.5 \text{ (lat.)} \end{aligned}$$

EVALUATION OF \bar{F} and $T_{1/3} - \bar{U} - t_d'$ - RELATIONSHIP.

The detail to calculate eq. (9) is illustrated in Fig. 1. It consists of 7 radials from the wave station at intervals of 10° and extending these radials until they intersect the shoreline.

With the influencing wind field determined we can calculate the integral along each radial. All the work is finished by a computer program. 233 data during the time from Feb. 7, 1974 till March 15, 1974 are selected to evaluate the $\bar{\xi}$ -value. It seems to have no correlation between $\bar{\xi}$ and wind speed.

The average value of $\bar{\xi}$ of these 233 cases is 7.24990×10^{-4} , its standard deviation is 2.19916×10^{-4} .

Two definitions have been made: \bar{U} is the area average wind speed from the observation point to the sea area where the e-exponential decay term $\exp(-\frac{0.08}{U^2} r) = 0.6$ and the duration t'_d is defined as the time interval between the first and the last weather chart we used to evaluate the average wind speed \bar{U} . A relationship of $T_{1/3}$, \bar{U} and t'_d is expressed as a dimensionless phase velocity $gt'_{1/3} / 2\pi\bar{U}$ and dimensionless duration gt'_d / \bar{U} on log-log plot (Fig. 7). A linear relationship in log-log plot is suggested:

$$\frac{gt'_{1/3}}{2\pi\bar{U}} = 0.00488 \left(\frac{gt'_d}{\bar{U}} \right)^{0.4472} \tag{12}$$

Fig. 7 Dependence of dimensionless phase velocity on dimensionless duration

COMPARISON OF SMB AND FAM

49 wave data during the time from Oct. 28, 1975 to Nov. 1, 1975 are selected to illustrate the comparison of SMB (U.S. Army, Corps of Engineering) and FAM hindcasting. The FAM hindcasting is finished by a computer. We need only give the wind velocities in specified areas at 6-hr interval. The result is shown in Fig. 8. and Fig. 9. It can be seen clearly that SMB has a little better result as the wind velocity increases. Once the wind velocity decreases, SMB is no more valid. In general, FAM has a much better hindcasting. The percentage of $H_{1/3}$ and $T_{1/3}$ within specified percent error by both methods is shown in Table I.

Table I Accuracy of hindcasting

Percent Error	Percentage of $H_{1/3}$ within Percent error		Percentage of $T_{1/3}$ within Percent error	
	SMB	FAM	SMB	FAM
5	8	39	22	16
10	22	61	33	43
15	27	71	53	63
20	35	88	73	84
25	47	92	82	88
30	51	94	90	96
35	57	98	96	100
40	63	100	100	100

CONCLUSION

1. SMB is a good method to predict or hindcast waves when the wind is increasing. Once the wind decreases, SMB is no more valid, at least for limited water field such as Taiwan Straits.
2. In general, FAM is much better than SMB, because the former has considered the influence of the whole wind field.
3. FAM can be used for routine work, such as Fishery Weather Forecasting of the Central Weather Bureau, Taiwan, Rep. of China, if one can precisely predict the wind in the Taiwan Straits.

ACKNOWLEDGEMENT

The authors wish to acknowledge the invaluable assistance rendered by Mr. C. H. Shu in the preparation of data analysis. Thanks also extended to Miss P.L. Chien for drawing the figures and typing the text.

CHAPTER 16

CHARACTERISTIC WAVE PERIOD

By

M. Manohar (1), I.E. Mobarek (2) & N.A. El Sharaky (3)

ABSTRACT : The wave period estimates obtained from different procedures are not consistent unlike statistical distribution analysis of wave heights. Thus not one definition of wave period is satisfactory for engineering analysis of coastal processes.

There are at least 10 different measures of wave periods including the zero up-crossing period, the average wave period, significant height period and peak of the energy density spectrum period.

For the analysis of periods, 20 min. records were obtained from offshore pressure recorders. Summer and winter records were analysed separately.

In the analysis, zero up-crossing period and average period were taken as reference periods. There were significant differences between the wave periods and they were found to depend also on the spectral width parameter.

Finally comparison was made between the energy flux obtained under the spectral diagrams and energy flux obtained using various wave periods and heights.

Study shows that if the total energy flux is desired, then the most appropriate values to be used are the root mean square wave height and period corresponding to that wave height. Use of significant wave height, along with zero up-crossing period gives higher values.

INTRODUCTION : Ocean waves are extremely complex in character. The period, celerity, wave length and wave height are irregular. Though individual wave heights vary considerably, they are easier to define statistically and the expected wave heights can be predicted reasonably. Such consistency does not, however, occur with wave periods and therefore, not one definition of wave period is sufficient in wave analysis.

There are, at least, 10 measures of wave periods, at present, in use namely (i) average period of all waves called period of wave crests, (ii) zero up-crossing period, (iii) average period of one-third the highest waves, (iv) average period of one-tenth the highest waves, (v) period of root mean square wave height, (vi) average period contained in a single wave group, (vii) period of the highest wave, (viii) period most prominent in the record, (ix) period corresponding to the peak of the energy density spectrum and (x) period of the maximum energy density.

THEORY : At a given point on the ocean surface, the water surface elevation y is a function of time and can be assumed as the sum of an infinite number of sinusoidal waves, each with a frequency

$\omega_i = \frac{2\pi}{T_i}$ and phase angle ϕ_i where ω_i = angular frequency of the i th component of the wave spectrum. Thus

$$y(t) = \sum_i^N a_i \cos(\omega_i t + \phi_i) \quad (1)$$

where $y(t)$ is a stationary random function. The probability density of $y(t)$ is a Gaussian distribution

$$p(y) = \frac{1}{\sqrt{2} m_0} e^{-\frac{y^2}{2 m_0}} \quad (2)$$

where $\sqrt{m_0}$ = square root of the zero moment or area of the energy density spectrum and

$$H_{\text{rms}} = 2 \sqrt{2 m_0} \quad (3)$$

where H_{rms} = root mean square wave height.

Not going into mathematical details of the Raleigh Distribution, it can be stated that consideration of the energy of the component waves leads to the energy density spectrum. The energy of each component

$$e_i = \frac{1}{2} \rho g a_i^2$$

where e_i varies with angular frequency ω depending upon wave characteristics. The energy density of the spectrum $E(\omega)$ is the energy contained in the frequency limits ω , and $(\omega + d\omega)$. Thus :

$$E(\omega) d\omega = \frac{1}{2} \sum_{\omega}^{\omega + d\omega} a_i^2$$

and the total energy in the whole spectrum is

$$m_0 = \int_0^{\infty} \epsilon(\omega) d\omega = \sum_1^N \frac{1}{2} a_i^2 \tag{3}$$

Statistical analysis (3, 4) also shows that average zero up-crossing period T_z of the sea surface and the average crest period T_c can be determined from the wave spectrum. Thus :

$$T_z = 2\pi \sqrt{\frac{m_0}{m_2}} \tag{4}$$

$$T_c = 2\pi \sqrt{\frac{m_2}{m_4}} \tag{5}$$

The spectral width parameter ϵ is given by :

$$\epsilon = \sqrt{1 - \frac{m_2^2}{m_0 m_4}} \tag{6}$$

where m_2 and m_4 are spectral moments of 2nd and 4th order respectively.

If the spectrum has a constant shape, then it may be characterised by a single wave height directly related to the wave energy described by m_0 and a single wave period. The characteristic period (T_0) adopted is often corresponding to the frequency ω_0 of the spectral peak and can be obtained from the energy spectrum (with $\epsilon(\omega)$ on the y axis and $\omega = \frac{2\pi}{T}$ on the x axis). The above period of the maximum energy density obtained from spectral analysis is also useful in finding the average period of the waves composing the dominant wave groups in a swell (7, 8).

ANALYSIS : In the study, waves were recorded by offshore pressure operated recorders (OSPOS) anchored at the bottom in 6 m to 7 m depths at three stations off the Nile Delta Coast.

Draper/Tucker (3,9) method of manual analysis was made of the pressure charts, each record of which was of 20 min. duration recorded at intervals of 4 hours. Analysis was made separately for summer and winter seasons

since the former usually experienced swells from wind waves more or less continuously and the latter generated storms separated by lull periods.

To obtain a more objective analysis and since it represents an integration of waves present in the 20 min. record, the period of zero up-crossing was taken as the characteristic period and other periods were compared to that period. However, since zero up-crossing method depends on a practical method for determining the zero line, the wave crest period was also used as reference period in some cases.

There were significant differences between the various wave periods. Further the differences depended on the type of waves namely swells or storm waves or whether the waves occurred with one or more peaked spectra. Comparing the zero up crossing period with significant period, the former was found to be normally more than the latter, the ratio for summer and winter waves being 1.2 and 1.13 respectively (Fig. 1). The reason for this is probably because a large wave results when several of the spectral components are in phase at a given point and time. The period of the resulting wave will be influenced most by the higher frequencies present and therefore will be less than the zero up-crossing period T_z . Also larger values of ϵ occur for storm waves since wide range of z frequencies are present. Comparison of period of maximum wave height with zero up-crossing period (fig.2) shows similar trend (for the same reasons) but to a lesser extent. Their ratios (T_{Hmax} to T_z) are also dependent upon on the spectral width parameters which vary from 0.4 to 0.8 with summer swells (ϵ small) having smaller values than storm waves (ϵ large). Analysis of the period of the peak of the energy spectrum with zero up-crossing period gave a relationship $T_o = 1.12 T_z$ (fig.3) which corresponds to Bretschneider spectrum (1) for wind generated z waves such as those of Pierson and Moskowitz (6). The above relation was found to be mostly true for swells and for fully risen storm waves. This relationship will, however, differ if a spectrum of different form or of more than one peak occur. Comparison of significant wave height periods with those of maximum wave heights showed periods to be more or less equal though slightly less for swells. Considering spectral peak period in relation to the significant wave period, the former was higher than the latter varying from 1.22 to 1.32 (fig.4), the higher value representing summer waves.

Using wave crest period as reference, the significant wave height period, the spectral peak period, maximum wave height period, period corresponding to the root mean square wave height period were then analysed (figs.5 to 8). The spectral peak period showed the largest variation with the root mean square wave height period showing the least variation and the period of the maximum wave height equalling the period of the wave crests for swells (ϵ small). The fact that the spectral peak period showed the largest variation is not surprising since it represents a single peaked spectra of higher frequencies.

Studies were also made between the period of maximum energy density and the period corresponding to the peak of energy density spectrum. There seemed to be no correlation between them and therefore, no further study was made of the former.

Groups of waves (not swell trains) present in wind waves during storms were then examined and their periods determined. Similarly periods of prominent waves during storms were also analysed. Fig. 9 shows that they are related to T_z in some way or other. The analysis of these is not complete since swell trains have yet to be studied. However, the present indications are that for wind waves, zero up crossing period is fair representation of wave group period.

Unlike the earlier study of Harris⁽⁵⁾ which showed very little correlation of different wave period definitions, this study seems to indicate the existence of relations between some of them and that fact has been made use of to evaluate the total energy flux correctly using various wave height and period definitions.

Fig.10 shows the comparison between the energy flux obtained under the spectral diagrams and energy flux obtained using the various wave periods and heights. It shows that if the correct total energy flux is desired, then the most appropriate values to be used are the root mean square wave height and the period corresponding to that wave height. Use of significant wave height along with the zero up crossing period or spectral peak period results in considerably higher values representing higher energies present in the wave train. Though they may be useful in the study of wave dynamics, they will certainly give higher sediment transport rates than the actual. Lines representing the various energy fluxes using different wave periods have been drawn for the purpose of comparison.

CONCLUSIONS : An extensive study of the various definitions (ten) of wave periods was made. It showed that for wind waves and for swells associated with such wind waves, certain relations exist between some wave period definitions. It also showed that use of zero up-crossing period to represent the period of a wave recording is not to be recommended in all cases. Comparison of the actual energy flux from wave spectrum with the various wave periods and wave heights showed that the most appropriate combinations are those involving root mean square wave height and period corresponding to that height and that combinations involving significant wave height and zero up crossing period gave considerably higher values.

CHAPTER 17

OCEAN WAVE RECORD ANALYSIS BY TUCKER'S METHOD - AN EVALUATION

J. Dattatri¹ and I. V. Nayak²

INTRODUCTION

The planning and design of any Coastal Engineering structure requires adequate knowledge of the wave characteristics. It is desirable that this knowledge of waves is based on instrumentally recorded data over a number of years, so that reliable values could be used for the computation of the design wave. Analysis of instrumentally recorded data to yield the relevant wave characteristics like the significant wave height, though not complicated is too time consuming. A simple method of analysis has been proposed by Tucker (9, 10), wherein the relevant information is obtained with only a few measurements of the larger waves. This method is also recommended by Draper (6) in his plea for uniformity of the analysis and presentation of wave data. This paper deals with the application of the Tucker's method to analysis of waves recorded off the Mangalore Harbour on the West Coast of India.

ANALYSIS OF WAVE RECORDS - TUCKER'S METHOD

Tucker (9, 10) has provided a simple method for obtaining the pertinent information of waves in any wave record, by only a few measurements of the larger waves, the theoretical basis of which is given by Cartwright and Longuet-Higgins (1), and by Cartwright (2). The measurements required

¹Asst. Prof., Dept. of App. Mech. and Hydraulics, Karnataka Regional Engineering College, SURATHKAL (S.K.)-574157, India.

²Prof. and Head, Dept. of App. Mech. and Hydraulics, Karnataka Regional Engineering College, SURATHKAL (S.K.)-574157, India.

for the Tucker's method of analysis are: A, the height of the highest crest; B, the height of the second highest crest measured from the mean water level line; C, the depth of the lowest trough; and D, the depth of the second lowest trough from the mean line as shown in Fig. 1. In addition the number of zero-crossings N_z , that is, the number of times the record trace crosses the mean line in an upward direction in the duration considered (Fig. 1) is also required. From these measurements, Tucker defines $H_1 = A + C$, and $H_2 = B + D$.

Using these measured values, the other wave height parameters can be estimated from H_1 and H_2 . D_{RMS} , defined as the root-mean-square value of the instantaneous distance of the water surface from the mean line, is estimated as follows:

$$D_{RMS} = \frac{1}{2} H_1 (2\theta)^{-\frac{1}{2}} [1 + 0.289 \theta^{-1} - 0.247 \theta^{-2}]^{-1} \dots (1)$$

$$D_{RMS} = \frac{1}{2} H_2 (2\theta)^{-\frac{1}{2}} [1 - 0.211 \theta^{-1} - 0.103 \theta^{-2}]^{-1} \dots (2)$$

$$\text{in which } \theta = \text{Log}_e N_z \dots (3)$$

It should be noted that in the original papers (9, 10), Tucker had used H_{RMS} instead of D_{RMS} , to indicate the root-mean-square value of the displacements of the water surface from the mean line. This results in some confusion as H_{RMS} is also used to indicate the root-mean-square value of the crest to trough heights of waves. To overcome this confusion, Tucker in the closure (5) of one of his paper (10) had suggested the use of D_{RMS} and H_{RMS} to indicate the r.m.s. value of wave displacements and wave heights respectively. For a wave system containing only a narrow band of frequencies, $H_{RMS} = 2\sqrt{2} D_{RMS}$ (5). Introducing this, Eqs. 1 and 2 can now be modified to:

$$H_{RMS} = \sqrt{2} H_1 (2\theta)^{-\frac{1}{2}} [1 + 0.289 \theta^{-1} - 0.247 \theta^{-2}]^{-1} \dots (4)$$

$$= K_1 H_1 \dots \dots \dots (4(a))$$

$$\text{in which } K_1 = \sqrt{2} (2\theta)^{-\frac{1}{2}} [1 + 0.289 \theta^{-1} - 0.247 \theta^{-2}]^{-1} \dots (4(b))$$

$$H_{RMS} = \sqrt{2} H_2 (2\theta)^{-\frac{1}{2}} [1 - 0.211 \theta^{-1} - 0.103 \theta^{-2}]^{-1} \dots (5)$$

$$= K_2 H_2 \dots \dots \dots (5(a))$$

in which $K_2 = \sqrt{2} (2\theta)^{-\frac{1}{2}} [1 - 0.211 e^{-1} - 0.103 e^{-2}]^{-1} \dots (5(b))$

It can be seen from Eqs. 4(b) and 5(b) that K_1 and K_2 are functions of θ only, which in turn is a function of N_z from Eq. 3. Hence K_1 and K_2 can be evaluated as functions of N_z and this is shown in Fig. 2.

The analysis of wave records is now reduced to a simple process of determining H_1 , H_2 and N_z from the wave record and then determining K_1 and K_2 from Fig. 2 using the measured value of N_z . From these values, H_{RMS} can be evaluated using Eq. 4(a) or Eq. 5(a). Once H_{RMS} has been evaluated, the other wave height parameters like the significant wave height can be determined using the relations given by Longuet-Higgins (8). Analysis of ocean wave records in India (3) and abroad (7) have shown that the relations between the various wave height parameters as given by Longuet-Higgins, to be substantially the same for the records analysed.

Tucker (10) recommends that the zero-crossing period T_z , (= duration of record, in seconds/ N_z) could be the relevant period to be used with the above wave heights.

APPLICATION OF TUCKER'S METHOD

The primary objective of the present investigations was to study the applicability of the Tucker's method to waves recorded along the Indian Coasts. For this purpose, the wave records obtained by the Mangalore Harbour Project authorities on the West Coast of India were utilized. About 12 months' records were available for analysis and the results of the analysis regarding the wave height and wave period distributions etc., has been reported in an earlier paper (3). For the present investigations about 50 samples of the wave records of 15 minutes duration, picked at random were utilized for analysis by the Tucker's method.

For each sample, the heights A, B, C and D were directly read from the records. From these values $H_1 = A+C$

and $H_2 = B+D$ were evaluated. For each sample the number of zero-crossings, N_z was also noted. From the known value of N_z , the values of the constants K_1 and K_2 , H_{RMS} was evaluated from Eqs. 4(a) and 5(a), and this H_{RMS} will hereafter be referred to as the H_{RMS} estimated from H_1 or H_2 .

For each wave record sample, the crest to trough heights of the individual waves were also read and the root-mean-square wave height, H_{RMS} , was also directly computed from these individual heights.

As the wave recorder used, was of the sub-surface pressure type, all the wave heights read from the wave records were corrected to account for the attenuation of wave pressure with depth and the frequency response of the instrument as per standard procedures (3).

PRESENTATION AND INTERPRETATION OF DATA

Eqs. 4 and 5 can only give the estimate of the value of H_{RMS} , since a statistical average value like H_{RMS} is being evaluated based on a single reading of H_1 or H_2 . As stated by Tucker (9), the statistical errors in these estimates are less than what might be expected and are not much worse than that of the mean of the highest one third waves in the records. Tucker (9) mentions that the proportional standard error in the estimate of H_{RMS} from H_1 could be approximately 13 percent and from H_2 about 10 percent, under certain conditions. The direct computation of any statistical average like H_{RMS} , from the individual wave heights itself is subject to error depending on the length of the record (4). In view of these considerations, perfect agreement cannot be expected between the H_{RMS} , estimated from H_1 or H_2 , and the H_{RMS} directly computed from all the individual wave heights in the record.

In Fig. 3 the H_{RMS} estimated from H_1 and H_2 is compared with the H_{RMS} directly computed. As discussed

earlier, perfect agreement is absent. But, it can be seen that the H_{RMS} estimated from H_1 or H_2 is within ± 15 percent of the directly computed value. There is a strong tendency for the H_{RMS} estimated from H_2 , to be more than the directly computed value. The spectral width parameter ϵ , for the samples analysed ranged from 0.2 to 0.8. The possibility of the variation in the spectral width parameter being a reason for the deviations of the data was also considered, but no systematic variation was noticed. A possible reason for the scatter could be that crest to trough heights are used in the computation instead of water surface heights from the mean line, and the theoretical relationships are derived using the latter.

Assuming the H_{RMS} directly computed to be the correct value, analysis was made of the percentage error in the estimation of the wave height from the single measurement of H_1 or H_2 , and these results are presented in Fig. 4. It can be seen in Fig. 4, that in nearly 90 percent of the cases, the estimated H_{RMS} differed from the directly computed value by less than 15 percent. These studies show that the H_{RMS} estimated from H_1 or H_2 is close enough to the H_{RMS} directly evaluated, for practical purposes. This supports the usefulness of the Tucker's method as a rapid means of obtaining the pertinent wave characteristics without a detailed and time consuming analysis of the wave records.

Another aspect studied was the relation between H_{Max} (the maximum crest to trough wave height in the sample under investigation) and, H_1 and H_2 . Actually Tucker recommends that for many civil engineering purposes, the relevant wave height could be H_1 and the period T_z .

In Fig. 5 is plotted H_{Max} versus H_1 and H_{Max} versus H_2 . For the data analysed, it can be seen that H_1 is generally greater than H_{max} and $H_2 = H_{Max}$. In general, for records containing only a narrow band of frequencies, H_{Max} should be

nearly equal to H_1 . This is because the narrow band assumption implies that the highest crest is associated with the deepest trough and in that case, it follows that H_{Max} should be equal to H_1 . But the present set of wave records, with the spectral width parameter ranging from 0.2 to 0.8, cannot be regarded as belonging to the narrow band process. For the wide band process, the highest crest is not associated with the deepest trough and it is to be expected that H_1 will be greater than H_{Max} and the results in the present analysis confirm it.

CONCLUSIONS

Tucker's simple method of obtaining the pertinent information of waves in any wave record by only a few measurements of the larger waves is found to be applicable to waves recorded on the West Coast of India. The error involved in such computations in comparison with more refined calculations is found to be generally below 15 percent.

ACKNOWLEDGEMENTS

The data analysed was made available to the authors by the Mangalore Harbour Project authorities and authors express their thanks of gratitude to them. To Prof. Evald Nielsen, formerly UNESCO Professor in Coastal Engineering at the college, who initiated these coastal engineering studies, the authors owe their debt of gratitude. The paper is published with the permission of the college authorities.

SIX-PARAMETER WAVE SPECTRA

by

Michel K. Ochi* and E. Nadine Hubble*

ABSTRACT

In an attempt to develop a systematic series of wave spectra covering a variety of spectral shapes observed in the ocean, this paper presents a newly developed series of wave spectra which involves six parameters. In the development of the six-parameter wave spectra, the spectra are decomposed into two parts. Each part is expressed by a mathematical formula with three parameters, and the total spectrum is expressed by the combination of two sets of three-parameter spectra. Results of analysis have shown that the six-parameter wave spectra thus derived appear to represent almost all stages of development of a sea during a storm. Then, from the statistical analysis of 800 spectra observed at the North Atlantic Ocean, the values of the six-parameters are expressed in terms of significant wave height so that a family of spectra for a desired sea severity can be generated.

INTRODUCTION

Recent progress in application of statistics to ocean and coastal engineering enables us to evaluate responses of ocean structures in a seaway at an early design stage by carrying out spectral analysis. In applying the linear superposition principle for prediction, however, wave spectra in desired seas have to be prepared in advance, and the magnitude of responses of ocean structure is significantly influenced by the shape of wave spectra for a given sea severity.

The shape of wave spectra observed in the ocean varies considerably (even though the significant wave heights are same) depending on the duration and fetch of wind, stage of growth and decay of a storm, and existence of swell. For example, Figure 1 shows a variety of shapes

*David W. Taylor Naval Ship Research and Development Center,
Washington, D.C., U.S.A.

of wave spectra all of which have the same significant wave height of 3.5 m (11.48 ft) (+1%), and wind speeds are between 20 to 25 knots.

Figure 1 Variety of wave spectra for significant wave height of 3.5 m (11.48 ft)

As can be seen in the figure, the spectrum JHA 40 has a very sharp single peak at the lower frequencies, while some spectra (JHC 128, NW 23, NW 39) have double peaks. Furthermore, three spectra (JHC 113, NW 228, and JHC 128) have the same modal frequency of 0.58. Thus, even though two parameters (significant wave height and modal frequency) are the same, the shape of the spectra are significantly different, and this may result in a significant difference in the evaluated magnitude of responses of ocean structures. This indicates that additional parameters are required for more accurate representation of wave spectra to provide useful information for more rational design of ocean structures.

In an attempt to develop a systematic series of wave spectra covering a variety of spectral shapes, this paper presents a newly developed series of wave spectra which involves six parameters.

In the development of the six-parameter wave spectra, the wave spectra are decomposed into two parts--one which includes primarily the lower frequency components of the wave energy and the second which covers primarily the higher frequency components of the energy. Then, each wave spectrum is expressed in a mathematical formula with three parameters; i.e., significant wave height, modal period, and shape parameter, and the entire spectrum is expressed by a combination of two sets of three-parameter spectra. The parameters are determined numerically such that the difference between the theoretical six-parameter and observed spectra is minimal.

The six-parameter representation of ocean waves is made on a total of 800 observed spectra, and the results are classified into 10 groups depending on the severity. Then, for each group a statistical analysis is carried out on the parameters taking into account the correlation between them. Finally, the results are presented in a family of spectra including the most probable spectrum expected to occur for a specified sea state as well as the limiting spectral shapes which may occur with a confidence coefficient of 0.95. The values of the six-parameters for this set of mathematical spectra are expressed in terms of significant wave height so that a family of spectra for a desired sea severity can be generated.

DERIVATION OF SIX-PARAMETER WAVE SPECTRA

In the development of the six-parameter wave spectra, the spectra are decomposed into two parts as illustrated in Figure 2; one which includes primarily the lower frequency components of the wave energy and the second which covers primarily the higher frequency components of the energy. This concept of decomposing the wave spectrum into two parts was also proposed by Strekalov et. al. in 1972 in their analysis of measured wave spectra [1]. In the present analysis, the spectrum of each part is expressed by a mathematical formula with three parameters so that the total spectrum is expressed by the combination of two sets of three-parameter spectra.

It may be of interest to note here the shape of wave spectra which have been most frequently observed to date. Although numerous shapes of wave spectra have been observed, the results of analysis made on available data indicate that spectral shapes similar to those shown in Figure 3 through 5 have been most frequently observed. In a broad sense, the shape of these spectra have a peak at the lower frequencies which decreases exponentially to a plateau at the higher frequencies. Thus, it is very difficult to express the entire spectral shape in a simple mathematical formula. The lower frequency part of the spectra

Figure 2 Decomposition of wave spectra

Figure 3 Example of wave spectrum (sig. height 2.89 m, 9.47 ft)

Figure 4 Example of wave spectrum (sig. height 7.47 m, 24.5 ft)

Figure 5 Example of wave spectrum (sig. height 10.09 m, 33.1 ft)

shown in these figures may be well expressed by some currently available spectral formulations; however, in the presently existing formula, the wave energy at the higher frequencies decreases exponentially with increase in frequency and hence the energy at the plateau is not represented. Although the wave energy at the higher frequencies is usually much less than that at the lower frequencies, its contribution to responses of marine vehicles and structures may be significant depending on their size and vehicle speed. Thus, it is highly desirable to represent the shape of the entire spectrum as closely as possible, and this may be achieved by separating the spectra into two parts.

First, we may derive the three-parameter representation for both the low and high frequency part of the spectrum as follows:

From results of dimensional analysis of ocean waves, Phillips has derived the following form of the spectrum of ocean waves over a range of frequencies between the modal frequency and that at which capillary waves become significant [2]:

$$S(\omega) = \alpha g^2 \omega^{-5} \quad (1)$$

where, α = equilibrium range constant
 g = gravity acceleration

The validity of this spectral presentation for wind-generated waves has been shown by Kitaigorodskii [3] from an analysis of Burling's observed data, and many formulae currently available for spectral representation of ocean waves are expressed in the following form [4] [5] [6]:

$$S(\omega) = \frac{A}{\omega^5} e^{-B/\omega^4} \quad (2)$$

Since it is commonly assumed that ocean waves comprise a Gaussian process with a narrow-band spectrum, it can be shown that the significant wave height, ζ , defined as the average of the highest one-third waves becomes,

$$\zeta = 4\sqrt{m_0} = \sqrt{\frac{4A}{B}} \quad (3)$$

where, $m_0 = \int_0^{\infty} S(\omega) d\omega = \frac{A}{4B}$

Next, let the spectrum, $S(\omega)$, be divided by the area, m_0 , so that the spectrum has a unit area. That is,

$$S'(\omega) = \frac{4B}{\omega^5} e^{-B/\omega^4} \quad (4)$$

The unit area spectrum, denoted by $S'(\omega)$, can be considered as if it were a probability density function, since $S'(\omega)$ is a positive, continuous, and integrable function with unit area, and thereby satisfies all conditions required for the probability function. $S'(\omega)$, in fact, yields the exponential probability density function by letting $\omega^4 = 1/x$. Hence, it can be generalized in the form of a new probability density function with an additional parameter, λ , which yields the gamma probability function. That is,

$$S'(\omega) = \frac{4}{\Gamma(\lambda)} \frac{B^\lambda}{\omega^{4\lambda+1}} e^{-B/\omega^4} \quad (5)$$

Under the assumption that the spectrum is narrow-banded, $S'(\omega)$ may be converted to the dimensional wave spectrum $S(\omega)$ which satisfies the condition that the area under the spectrum is equal to $(\zeta/4)^2$ given in Equation (3). Then, we have,

$$S(\omega) = \frac{1}{4} \frac{B^\lambda}{\Gamma(\lambda)} \frac{\zeta^2}{\omega^{4\lambda+1}} e^{-B/\omega^4} \quad (6)$$

The constant, B , in Equation (6) can be expressed in terms of the modal value, ω_m , by setting the differentiation of $S(\omega)$ with respect to ω to be zero. That is,

$$B = \left(\frac{4\lambda+1}{4} \right) \omega_m^4 \quad (7)$$

Thus, from Equations (6) and (7), the following spectral formulation can be made:

$$S(\omega) = \frac{1}{4} \frac{\left(\frac{4\lambda+1}{4} \omega_m^4 \right)^\lambda}{\Gamma(\lambda)} \frac{\zeta^2}{\omega^{4\lambda+1}} e^{-\left(\frac{4\lambda+1}{4} \right) \left(\frac{\omega}{\omega_m} \right)^4} \quad (8)$$

The spectrum given in Equation (8) has three parameters; namely, significant wave height, ζ , modal frequency, ω_m , and a parameter λ .

The parameter, λ , controls the shape (sharpness) of the spectrum when the other two parameters are held constant, and hence it may be called a spectral shape parameter. For example, Figure 6 shows computer printout of a family of wave spectra for various λ while the other two parameters, ζ and ω_m , are held constant at 3.0 m (9.8 ft.) and 0.6 rps, respectively. As can be seen in the figure, the spectral shape becomes sharper with increasing λ .

Let $\lambda = 1$ in Equation (8). Then, we have,

$$S(\omega) = \frac{1.25}{4} \zeta^2 \frac{\omega_m^4}{\omega} e^{-1.25 \left(\frac{\omega_m}{\omega}\right)^4} \quad (9)$$

The spectrum given in Equation (9) is the Bretschneider two-parameter wave spectrum expressed in terms of significant wave height and modal frequency. Thus, the three-parameter spectrum given in Equation (8) includes the Bretschneider two-parameter spectrum as a special case ($\lambda = 1$), and this in turn also includes the Pierson-Moskowitz one-parameter spectrum ($\lambda = 1$ and $\omega_m = 0.4 \sqrt{g/\zeta}$).

By combining two sets of three-parameter spectra, one representing the low frequency components and the other the high frequency components of the wave energy, the following six-parameter spectral representation can be derived:

$$S(\omega) = \frac{1}{4} \sum_j \frac{\left(\frac{4\lambda_j+1}{4} \omega_{mj}\right)^{\lambda_j}}{\Gamma(\lambda_j)} \frac{\zeta_j^2}{\omega^{4\lambda_j+1}} e^{-\left(\frac{4\lambda_j+1}{4}\right) \left(\frac{\omega_{mj}}{\omega}\right)^4} \quad (10)$$

where, $j = 1, 2$ stands for the lower and higher frequency components, respectively.

The six parameters, $\zeta_1, \zeta_2, \omega_{m1}, \omega_{m2}, \lambda_1,$ and λ_2 , involved in Equation (10) are determined numerically such that the difference between theoretical and observed spectra is minimal. For this, appropriate initial values are chosen for each parameter, and then the computation is carried out for various combinations of the parameters in order to determine the final values for which the difference between theoretical and observed spectra is minimal. An example of the computer output is shown in Figure 7. The heavy line in the figure is the measured spectrum and the line with the circles is the six-parameter spectral representation. The values of the parameters for this example are $\zeta_1 = 4.14$ m (13.59 ft.), $\zeta_2 = 3.27$ m (10.73 ft.), $\omega_{m1} = 0.58$, $\omega_{m2} = 1.00$, $\lambda_1 = 2.67$, and $\lambda_2 = 1.37$.

Recently, a computer program has been developed by applying a nonlinear least square fit technique by which the six parameters can be evaluated directly from the information on wave spectra stored on tape. This eliminates the need to generate individual spectra in visual form from the tape to which mathematical formula is fitted.

Examples of comparisons between observed spectra and mathematical six-parameter spectra are shown in Figures 8 through 11. For example, Figure 8 shows a comparison for the case when swell coexists with wind-generated waves and hence the spectrum has double peaks. Figure 9 shows an example of the case when the wind-generated waves are growing and are nearly fully-developed, and spectral shapes similar to this are

frequently observed as mentioned earlier. On the other hand, Figure 10 shows an example for seas of mild severity with a relatively broad-band spectrum while Figure 11 shows a comparison for a very severe sea of significant wave height 14.5 m (47.7 ft) in which the sea is partially developed by strong wind, and has a very sharp peak at the lower frequencies in the spectrum. As can be seen in these examples, the six-parameter spectra derived in Equation (10) appear to represent almost all stages of development of a sea during a storm.

STATISTICAL ANALYSIS OF PARAMETERS

It was shown in the preceding section that the six-parameter spectra represent fairly well a variety of spectral shapes observed in the ocean. Perhaps one of the most useful applications of the spectra is to carry out a statistical analysis on each parameter so that a family of spectra for a given sea severity will be generated with a preassigned probability of assurance. For this purpose, a total of 800 available spectra observed in the North Atlantic Ocean [7] [8] [9] are classified into ten groups depending on severity as given in Table 1. Then, for each group a statistical analysis is carried out on the parameters, except for the last two groups IX and X where the number of samples is small.

First, consider the statistical properties of significant wave heights ζ_1 and ζ_2 , for the low and high frequency components, respectively, for a given severity. Consider the i -th group in Table 1 in which the wave spectra with significant heights ranging from $(\zeta_i)_{\min}$ to $(\zeta_i)_{\max}$ are included in the sample. Then, the significant heights for the low and high frequency components (ζ_1 and ζ_2 , respectively) cannot exceed $(\zeta_i)_{\max}$. In other words, the probability density function of ζ_1 and ζ_2 have to be truncated at $(\zeta_i)_{\max}$. The results of the analysis have shown that the significant heights ζ_1 and ζ_2 both obey the normal probability law, and that the concept of truncation is necessary only for ζ_1 , the significant height for the low frequency component.

Figure 12 shows a comparison between the histogram obtained from the data and the truncated normal probability distribution curve of ζ_1 , for Group IV (a nominal significant height $\zeta = 4.57$ m, 15 ft.). Figure 13 shows an example of the comparison for ζ_2 for the same Group IV. Still other examples, Figures 14 and 15 show similar comparisons

made for more severe seas, Group VII ($\zeta = 9.15$ m, 30 ft.). As can be seen in these figures, the significant wave heights ζ_1 and ζ_2 obey the normal probability law from which the confidence band of each parameter can be established. However, for a given sea severity, it is not necessary to consider the confidence band for ζ_1 and ζ_2 individually. This is because the two significant wave heights ζ_1 and ζ_2 , and the significant wave height of the entire spectrum, ζ , are functionally related as discussed in the following:

If it is assumed that the low and high frequency component spectra are both narrow-banded and that their sum (namely, the entire spectrum) is also narrow-banded, then the following simple relationship holds:

$$\zeta^2 = \zeta_1^2 + \zeta_2^2 \quad (11)$$

If one of the component spectra (perhaps, the high frequency component spectrum) is not narrow-banded, then the significant wave height of the entire spectrum is analytically derived as outlined in Appendix A. In order to compare the difference between the two approaches, Figure 16 is prepared.

Table 1 Group of significant wave heights used for analysis

GROUP	SIGNIFICANT WAVE HEIGHT	
	NOMINAL	RANGE
I	4.0 ft (1.22 m)	Less than 5.5 ft (1.68 m)
II	6.5 (1.98)	5.5 ft (1.68 m) ---- 7.5 ft (2.29 m)
III	10.0 (3.05)	7.5 (2.29) ---- 12.5 (3.81)
IV	15.0 (4.57)	12.5 (3.81) ---- 17.5 (5.34)
V	20.0 (6.10)	17.5 (5.34) ---- 22.5 (6.86)
VI	25.0 (7.62)	22.5 (6.86) ---- 27.5 (8.38)
VII	30.0 (9.15)	27.5 (8.38) ---- 32.5 (9.91)
VIII	35.0 (10.67)	32.5 (9.91) ---- 37.5 (11.43)
IX	40.0 (12.20)	37.5 (11.43) ---- 42.5 (12.96)
X	45.0 (13.72)	Higher than 42.5 ft (12.96 m)

Figure 16 Relationship between significant wave heights ζ_1 , ζ_2 , and ζ

The solid lines in Figure 16 show the relationship between significant wave heights, ζ_1 , ζ_2 , and ζ , as obtained from Equation (A-10) in Appendix A, while the dashed lines show the relationships obtained from Equation (11). Included also in the figure are the results of the analysis of measured wave spectra whose significant wave heights are within ± 2.5 percent of the specified height. For example, for significant wave height, $\zeta = 9.1$ m (30 ft.), the results of the analysis of wave spectra with significant heights from 8.9 m (29.3 ft.) to 9.4 m (30.8 ft.) are plotted in the figure. As can be seen in the figure, the two lines obtained from Equations (A-10) and (11) do not differ appreciably, and that the results of analysis of the measured spectra fall on these lines. Hence, the simple formula given in Equation (11) may be used for the functional relationship between ζ_1 and ζ_2 . Thus, for a given sea severity of significant wave height ζ , the six parameters involved in Equation (10) can be reduced to five parameters by taking the ratio of the two significant wave heights, ζ_1/ζ_2 . For convenience, let $\zeta_1/\zeta_2 = \tan \theta$, and the statistical property of θ will be discussed hereafter.

$\theta = \tan^{-1}(\zeta_1/\zeta_2)$ (where, $0 < \theta < 90$) is outlined in Appendix B, and comparisons between histogram and the probability density function given in Equation (B-3) are shown in Figures 17 and 18 which pertain to Groups IV and VII, respectively. As can be seen in these examples, the derived probability density function agrees well with the histograms and hence the statistical analysis will be made using this probability function.

Figure 17 Histogram and probability density function of parameter θ for Group IV

Figure 18 Histogram and probability density function of parameter θ for Group VII

Figure 19 Histogram and probability density function of parameter ω_{m1} for Group IV

Figure 20 Histogram and probability density function of parameter ω_{m2} for Group IV

Next, the probability density function of the modal frequencies, ω_{m1} and ω_{m2} , will be obtained. In the determination of the modal frequencies for a given wave spectrum, no limitation is set for the value of ω_{m1} , namely, $0 < \omega_{m1} < \infty$. However, the modal frequency, ω_{m2} , has to be greater than ω_{m1} , and furthermore, the restriction is made such that ω_{m2} should not be less than 0.6 in order to avoid the possibility of an unrealistic representation of the spectral shape. For example, suppose a spectrum has triple peaks, two of which are in the frequency range below 0.6, then the computer program may take these two peaks (even though the energy is not appreciable) and discard the third peak in the higher frequency range which is associated with the wind-generated seas. In this case, it may be more appropriate to represent the two peaks in the frequency range less than 0.6 by one peak, and consider the energy in the higher frequency range.

The results of analysis of the available data have indicated that ω_{m1} and ω_{m2} both obey the normal distribution law, although ω_{m2} is truncated at 0.6. As an example, comparisons between histogram and the probability density function for Group IV are shown in Figures 19 and 20.

The value of the shape parameter, λ_1 , is much higher than that of λ_2 , in general; however, it appears that both follow the gamma probability law. Comparisons between the histogram and the gamma probability density function for λ_1 and λ_2 for Group IV are shown in Figure 21 and 22, respectively. Other examples of the comparisons for Group V ($\zeta = 6.10$ m, 20 ft.) are shown in Figures 23 and 24.

FAMILY OF WAVE SPECTRA

In this section, a family of wave spectra will be developed for a desired sea severity using the probability function applicable for each parameter in an attempt to represent various shapes of spectra associated with a storm.

In the development of the family of spectra, an attempt was made first to divide each probability density function into seven divisions as shown at the top of Figure 25. The figure is an example for the modal frequency, ω_{m_1} for Group IV (nominal significant height 4.75 m, 15 ft.). Then six values were determined by which 50%, 80%, and 95% of the probability density function was covered as shown at the top of the figure. For each value of ω_{m_1} , the value of each of the other parameters was determined from the original data by taking their respective averages in the region of $\pm 5\%$ of ω_{m_1} . For example, the θ -value for $\omega_{m_1} = 0.65$ (the upper value for 80% coverage) was determined by taking the average value of θ from a sample which belonged to $\pm 5\%$ of $\omega_{m_1} = 0.65$ ($0.62 < \omega_{m_1} < 0.68$) in Group IV. Since there are five parameters, θ , ω_{m_1} , ω_{m_2} , λ_1 , and λ_2 , this procedure resulted in a family consisting of a total of 25 spectra for a given sea severity. Judging from the results of this procedure, however, it appears that 25 wave spectra are too many to be considered since many of the shapes look alike.

To reduce the number of spectra involved, another approach is to choose three values for each parameter; namely, the modal value, the upper and the lower values determined from a confidence band for a confidence coefficient of 0.95. For example, the most probable ω_{m_1} is obtained as 0.53 for Group IV as shown in Figure 25, and the upper and lower bound values are 0.71 and 0.36, respectively. Similarly, three ω_{m_1} -values are evaluated for all other groups (except Groups IX and X) listed in Table 1, and the results are plotted in Figure 26 as a function of significant wave height, ζ . Included also in this figure are the formulae representing the data points so that the ω_{m_1} values for a desired sea severity can be evaluated.

Next, the values of the other parameters for each ω_{m_1} are determined for all groups in the same fashion as mentioned earlier, the results of which are plotted in Figures 27 through 30 as a function of ζ . It is noted that the parameter values shown in these figures are all associated with the parameter ω_{m_1} . The formulae representing the data points are also included in these figures. Although the formulae are derived without consideration of data points for severe seas ($\zeta = 12.2$ m, 40 ft. or above), the formulae may still be applicable for severe seas; since the data does not show serious scatter in relatively severe seas. Thus, a set of three spectra associated with the parameter ω_{m_1} can be drawn for an arbitrarily specified sea severity. As an example, Figure 31 shows a set for a significant wave height of 4.0 m (13.1 ft.). As can be seen in the figure, the dominant peaks of the spectra range from $\omega_{m_1} = 0.38$ to 0.74, and the spectral shape becomes more broad as the modal frequency ω_{m_1} increases.

The above discussion along with Figures 25 through 31 pertain to the parameter ω_{m_1} . The same procedure as that to derive a set of three spectra associated with ω_{m_1} , is carried out for the other four parameters, and thus a total of fifteen mathematical spectra can be established for a given sea severity. Of these fifteen spectra, five are associated with the mode value of the five parameters. The results of the analysis have

Figure 26 ω_{m1} -values as a function of significant height

Figure 28 ω_{m2} -values for probable, upper and lower-bound values of ω_{m1} as a function of significant height

Figure 30 λ_2 -values for probable, upper and lower-bound values of ω_{m1} of significant height

Figure 27 θ -values for probable, upper and lower-bound values of ω_{m1} as a function of significant height

Figure 29 λ_1 -values for probable, upper and lower-bound values of ω_{m1} as a function of significant height

indicated, however, that the shapes of these five spectra are nearly the same as shown in Figure 32. Hence, the spectrum associated with the mode value of the parameter θ may be chosen as representative of the five spectra determined from the mode values of the parameters.

ζ = significant wave height in meters

Thus, a total of eleven spectra derived in the above are considered as a family of wave spectra for a specified sea severity. The values of six parameters for these eleven spectra are expressed in terms of significant-wave height, ζ , and are tabulated in Table 2 so that a family of spectra for a desired sea can be generated from Equation (10). In these eleven spectra, one is considered as the "most probable spectrum" representing a specified sea, and the remaining ten spectra are those expected to occur with 95 percent confidence.

Examples of the family of spectra thus derived are shown in Figures 33 through 36. Figures 33 and 34 are for significant wave heights of 1.25 m (4.1 ft.) and 3.0 m (9.8 ft.), respectively, and the shapes of wave spectra vary considerably in these seas of relatively mild severity. The frequency domain where the predominant wave energy exists varies to a great extent (from 0.4 to 1.2) depending on the shape of spectra. On the other hand, Figure 35 is for a significant wave height of 9.0 m (29.5 ft.), and the frequency domain where the predominant wave energy exists varies to a much less extent (from 0.3 to 0.7) in this severe sea although a variety of spectral shapes may still be observed.

Figure 36 is for a significant wave height of 13.0 m (42.6 ft.), an example of very severe seas. A family of spectra shown in this figure is of particular interest since the values of all parameters for this fam-

ily of spectra are determined by extending the lines of the analysis of data, examples of which are shown earlier in Figures 26 through 30. In order to examine whether or not the family of spectra thus generated represents the measured spectra, Figure 37 is prepared. The figure shows an observed spectrum which has the same significant wave height as that of the family shown in Figure 36, 13.0 m (42.6 ft.). Included also in the figure is the computer-generated six-parameter spectrum. From the comparison of these two figures, it can be seen that the example given in Figure 37 agrees well with one of the members of the family (the most probable spectrum) given in Figure 36. Thus, it appears that the families of spectra generated using the parameter values obtained from the extension of the lines in the analysis of the data can be considered to represent realistic sea spectra.

Figure 38 Significant amplitudes of the vertical bow motion of a catamaran in various seas (10-knot speed)

APPLICATION OF SIX-PARAMETER SPECTRA

The six-parameter wave spectra can be applied to evaluate responses such as motions and wave-induced forces, etc., of marine vehicles and structures in a seaway for design consideration. Figure 38 shows, as an example of the application, the significant values of the vertical bow motion relative to waves of a catamaran (length 67 m, 220 ft.) for 10-knot speed in various sea severities. Included also in the figure are the responses evaluated by using the Pierson-Moskowitz fully-developed sea spectra, and those due to individual wave spectra (about 300) observed at Station India in the North Atlantic Ocean [9].

As can be seen in the figure, for a specified sea severity, there are 11 responses (one for each member of the family of the six-parameter spectra), and one of the family members yields the largest response, and another yields the smallest response. The most probable spectrum given in Table 2 yields the most probable response. By connecting the points obtained in each sea severity, we may establish the most probable response, the upper-bound and the lower-bound responses which will provide useful information for design. The upper and lower-bounds cover the majority of the responses obtained from using the measured wave spectra, and it may safely be said for this case that the values of the six parameters obtained from a statistical analysis of the data yield a family of spectra representing realistic seas reasonably well with 95 percent confidence.

The results of a similar application made for predicting extreme wave-induced loads on an ocean structure may be found in Reference [10].

The six-parameter wave representation may be used for the analysis of wave spectra associated with particular situations such as breaking waves, wave run-up, etc. The measured spectra may be expressed in terms of six parameters and a statistical analysis may be carried out on the parameters to find significant factors which influence the spectra.

Another application of the six-parameter representation is to store or file a massive amount of measured data for statistical analysis. In the case where consecutive measurements are made within a certain time interval, the data may be stored in the form of six variables, the values of which change gradually with time, and hence the sea condition associated with the growth and decay of a storm may be discussed from a statistical analysis of the parameters.

CONCLUSIONS

Consideration of various shapes of wave spectra for a given sea severity is of particular significance for evaluation of response of ocean and coastal structures to waves, since the magnitude of responses is greatly influenced by the relative location of the modal frequencies of waves and response of individual structures. In an attempt to develop a systematic series of wave spectra covering a variety of spectral shapes, a series of wave spectra which involves six parameters are newly developed.

In the development of the six-parameter wave spectra, the spectra are decomposed into two parts, and each part is expressed by a mathematical formula with three parameters; i.e., significant wave height, modal frequency, and shape parameter, and the entire spectrum is expressed by the combination of two sets of three-parameter spectra. The parameters are determined numerically such that the difference between theoretical and observed spectra is minimal. The six-parameter spectra thus obtained appear to represent almost all stages of the sea condition associated with a storm.

Then, a total of 800 spectra observed in the North Atlantic Ocean are classified into 10 groups depending on severity, and for each group a statistical analysis is carried out on the parameters taking into account the correlation between them. From the results of analysis, a family consisting of eleven sets of mathematical spectra is established for a given sea severity. In these eleven spectra, one is considered as the "most probable spectrum" representing a specified sea, and the remaining ten spectra are those expected to occur with 95 percent confidence. The values of six parameters for these eleven spectra are expressed in terms of significant wave height, and are tabulated in Table 2 of the paper so that a family of spectra for a desired sea severity can be generated from the formula (Equation 10) given in the paper.

APPENDIX A: SIGNIFICANT WAVE HEIGHT FOR A SPECTRUM CONSISTING OF HIGH AND LOW FREQUENCY COMPONENTS

Let $x(t)$ be the wave profile of an irregular sea which is a normal random process with zero mean and a narrow-band spectrum, and let $x(t)$ be comprised of two components; $x_1(t)$ and $x_2(t)$, which correspond to the wave profile of the low frequency and the high frequency components, respectively. Here, $x_1(t)$ and $x_2(t)$ are both normal random processes; however, in the following it is assumed that $x_1(t)$ is a narrow-banded but $x_2(t)$ is not necessarily narrow-banded. The amplitude, frequency, and variance are denoted by A , ω , and σ^2 , respectively, and the subscripts 1 and 2 refer to the low and high frequency components, respectively.

Then, from the assumption described above, the wave profile $x(t)$ may be written in the following form:

$$x(t) = A(t) \cos(\omega_2 t - \theta(t)) \quad (A-1)$$

The low-frequency component wave profile becomes,

$$x_1(t) = A_1(t) \cos(\omega_1 t - \theta_1(t)) \quad (A-2)$$

On the other hand, the high frequency component wave may be expressed in the following form:

$$x_2(t) = x_{2c}(t) \cos(\omega_2 t) + x_{2s}(t) \sin(\omega_2 t) \quad (A-3)$$

where,

$$x_{2c}(t) = \sum \left[a_n \cos(n\omega - \omega_2)t + b_n \sin(n\omega - \omega_2)t \right]$$

$$x_{2s}(t) = \sum \left[a_n \sin(n\omega - \omega_2)t - b_n \cos(n\omega - \omega_2)t \right]$$

and

$$a_n = \frac{2}{T} \int_0^T x_2(t) \cos(n\omega t) dt$$

$$b_n = \frac{2}{T} \int_0^T x_2(t) \sin(n\omega t) dt$$

Here, $x_{2c}(t)$ and $x_{2s}(t)$ are independent normal processes, and their joint probability density function can be written as,

$$f(x_{2c}, x_{2s}) = \frac{1}{2\pi\sigma_2^2} e^{-\frac{x_{2c}^2 + x_{2s}^2}{2\sigma_2^2}} \quad (A-4)$$

From the condition that $x(t) = x_1(t) + x_2(t)$, Equations (A-1),

(A-2), and (A-3) yield:

$$x(t) = [x_{2c}(t) + A_1(t) \cos \psi] \cos \omega_2 t + [x_{2s}(t) - A_1(t) \sin \psi] \sin \omega_2 t \quad (\text{A-5})$$

where,

$$\psi = (\omega_1 - \omega_2)t - \theta_1$$

Thus, from Equations (A-1) and (A-5), we can derive the following relationship:

$$\begin{aligned} x_{2c} &= A \cos \theta - A_1 \cos \psi \\ x_{2s} &= A \sin \theta + A_1 \sin \psi \end{aligned} \quad (\text{A-6})$$

Since the joint probability density function of x_{2c} and x_{2s} is given in Equation (A-4), the joint probability density function of A and θ can be obtained from Equations (A-4) and (A-6) by transformation of two random variables (x_{2c}, x_{2s}) to (A, θ) , and therefrom the marginal probability density function of A can be obtained. This part of the work was done by Middleton [A-1], and he derived the following formula:

$$f(A) = \int_0^{2\pi} f(A, \theta) d\theta = \frac{A}{\sigma_2^2} e^{-\frac{A^2 + A_1^2}{2\sigma_2^2}} I_0\left(\frac{AA_1}{\sigma_2^2}\right), \quad 0 \leq A < \infty \quad (\text{A-7})$$

The probability density function of the amplitude, A , given in the above, however, is expressed in terms of the amplitude of the low frequency component waves, A_1 . Hence, Equation (A-7) can be considered as a conditional probability density function $f(A|A_1)$. In order to express the probability density function of A in terms of the variance of the two component waves σ_1^2 and σ_2^2 , the condition is used that the low frequency wave component has a narrow-band spectrum and hence its amplitude follows the Rayleigh probability law. Thus, the probability density function of A can be written as follows:

$$\begin{aligned} f(A) &= \int_0^\infty f(A|A_1) f(A_1) dA_1 \\ &= \frac{A}{\sigma_2^2} e^{-\frac{A^2}{2\sigma_2^2}} \int_0^\infty I_0\left(\frac{AA_1}{\sigma_2^2}\right) \frac{A_1}{\sigma_1^2} e^{-\frac{1}{2}\left(\frac{1}{\sigma_1^2} + \frac{1}{\sigma_2^2}\right)A_1^2} dA_1 \end{aligned} \quad (\text{A-8})$$

By carrying through the integration involved in the above equation, the following formula can be derived:

$$f(A) = \left(\frac{1}{1+\mu} \right) \frac{A}{\sigma_2^2} e^{-\frac{A^2}{2\sigma_2^2}} \times \left(1 + \sqrt{\frac{\pi}{2}} \sqrt{\frac{\mu}{1+\mu}} \frac{A}{\sigma_2} e^{\left(\frac{\mu}{1+\mu} \right) \left(\frac{A}{2\sigma_2} \right)^2} I_{\frac{1}{2}} \left(\frac{\mu}{1+\mu} \left(\frac{A}{2\sigma_2} \right)^2 \right) \right) \quad (A-9)$$

where,

$$\mu = \left(\frac{\sigma_1}{\sigma_2} \right)^2, \quad I_{\frac{1}{2}}(Z) = \sqrt{\frac{2}{\pi Z}} \sinh Z$$

Equation (A-9) is the probability density function of the amplitude, A , in terms of two variances, σ_1^2 and σ_2^2 , which are equal to the area under the low and high frequency components, respectively, of the wave spectrum. The significant wave height of the spectrum, ζ , is then obtained numerically from Equation (A-9) as follows:

$$\zeta = 3 \int_{A_*}^{\infty} A f(A) dA \quad (A-10)$$

where, A_* can be found from

$$\int_0^{A_*} f(A) dA = 2/3$$

APPENDIX B: DERIVATION OF PROBABILITY DENSITY FUNCTION OF $\theta = \tan^{-1}(\zeta_1/\zeta_2)$

In the text it is discussed that the significant wave heights ζ_1 and ζ_2 both obey the normal probability law, and that the concept of truncation is necessary for the significant height for the low frequency component, ζ_1 .

Let μ_1 and σ_1^2 be the mean and variance, respectively, of the significant height ζ_1 belonging to the i -th group in Table 1 given in the text, and let μ_2, σ_2^2 be the mean and variance of the significant height ζ_2 . Since ζ_1 and ζ_2 may not necessarily be statistically independent, let ρ be the correlation coefficient which can be evaluated from the sample

belonging to the i -th group. Then, by taking into account the truncation of ζ_1 at $(\zeta_1)_{\max}$, the joint probability density function of ζ_1 and ζ_2 belonging to the i -th group can be written as.

$$f(\zeta_1, \zeta_2) = \frac{1}{1 - \int_{(\zeta_1)_{\max}}^{\infty} f(\zeta_1) d\zeta_1} \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}} - \frac{1}{2(1-\rho^2)} \left\{ \left(\frac{\zeta_1 - \mu_1}{\sigma_1} \right)^2 - 2\rho \left(\frac{\zeta_1 - \mu_1}{\sigma_1} \right) \left(\frac{\zeta_2 - \mu_2}{\sigma_2} \right) + \left(\frac{\zeta_2 - \mu_2}{\sigma_2} \right)^2 \right\} \quad (\text{B-1})$$

x e

$$0 < \zeta_1 < (\zeta_1)_{\max}, \quad 0 < \zeta_2 < \infty$$

where, $f(\zeta_1)$ is the probability density function of the significant height ζ_1 which is a normal distribution with mean μ_1 and variance σ_1 .

Let $\eta = \zeta_1/\zeta_2$. Then, from Equation (B-1), the probability density function of η becomes,

$$f(\eta) = \frac{1}{1 - \int_{(\zeta_1)_{\max}}^{\infty} f(\zeta_1) d\zeta_1} \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}} \int_0^{\infty} \zeta_2 - \frac{1}{2(1-\rho^2)} \left\{ \left(\frac{\zeta_2\eta - \mu_1}{\sigma_1} \right)^2 - 2\rho \left(\frac{\zeta_2\eta - \mu_1}{\sigma_1} \right) \left(\frac{\zeta_2 - \mu_2}{\sigma_2} \right) + \left(\frac{\zeta_2 - \mu_2}{\sigma_2} \right)^2 \right\} d\zeta_2 \quad (\text{B-2})$$

x e

$$0 < \eta < \infty$$

Next, let $\theta = \tan^{-1}\eta = \tan^{-1}(\zeta_1/\zeta_2)$. Then, the probability density function of θ can be obtained numerically using Equation (B-2) as follows:

$$f(\theta) = \left[f(\eta) \right] \sec^2 \theta, \quad 0 < \theta < 90 \quad (\text{B-3})$$

$\eta = \tan \theta$

CHAPTER 19

DIRECTIONAL SPECTRA OF OCEAN SURFACE WAVES

by

H. Mitsuyasu and S. Mizuno

Research Institute for Applied Mechanics

Kyushu University, Fukuoka, Japan

ABSTRACT

From 1971-74 seven cruises were made to measure the directional spectrum of ocean waves by using a cloverleaf buoy. Typical sets of wave data measured both in open seas and in a bay under relatively simple conditions have been analyzed to clarify the fundamental properties of the directional spectrum of ocean waves in deep water.

It is shown that the directional wave spectrum can be approximated by the product of the frequency spectrum and a unimodal angular distribution with mean direction approximately equal to that of the wind. The normalized forms of the frequency spectrum show various forms lying between the Pierson-Moskowitz spectrum and the spectrum of laboratory wind wave which has a very sharp energy concentration near the spectral peak frequency. The form of the JONSWAP spectrum is very close to that of laboratory wind waves. The concentration of the spectral energy near the spectral peak frequency seems to decrease with increasing the dimensionless fetch and the spectral form finally approaches to the Pierson-Moskowitz spectrum which can be considered as the spectrum with the least concentration of the normalized spectral energy. However, the definite relation between the shape of the normalized spectrum and the dimensionless fetch has not been obtained.

Concerning the angular distribution, it is shown that the shape of angular distribution of the single-peaked wave spectrum in a generating area can be approximated by the function $G(\theta, f) = G'(s) \left| \cos(\theta - \bar{\theta})/2 \right|^{2s}$ proposed originally by Longuet-Higgins et al. (1963). Here $G'(s)$ is a normalizing function, $\bar{\theta}$ is the mean direction of the spectral component, and s is a parameter which controls the concentration of the angular distribution function.

The significant results of this study are that $\bar{\theta}$ is very close to the wind direction irrespective of the wave frequency, and that the parameter s can be uniquely determined from the dimensionless frequency. The angular distribution is very narrow for the frequencies near the dominant peak of the frequency spectrum, whereas it widens rapidly towards high and low frequencies. Thus, the major energy-containing frequency components of the ocean waves propagate in almost the same direction as the wind with the least angular spreading.

An idealized form of the angular distribution function of the ocean wave spectra is proposed for practical purposes. Qualitatively, the idealized form proposed here has a property which is similar to that of the SWOP spectrum, although they are different quantitatively.

INTRODUCTION

To a first approximation, ocean surface wave can be regarded as a linear superposition of statistically independent free waves and is consequently described by two-dimensional wave spectrum (directional spectrum). During the last twenty years great many studies have been made to clarify the properties of ocean wave spectra. However, in contrast with numerous studies of the one-dimensional (frequency) spectrum, only a few studies have been made of the two-dimensional (directional) spectrum of ocean waves. Particularly, reliable data for estimating the directional spectra of ocean waves are remarkably lacking except for the data reported by Côté et al. (1960), Longuet-Higgins et al. (1963), Ewing (1969) and recently by Tyler et al. (1974). These situations may be partly attributed to the technical difficulties for the measurement of the directional wave spectrum as compared to that of the one-dimensional spectrum. Therefore, many studies on the directional wave spectrum have been concentrated on the measuring techniques and their accuracies rather than the measurements and analysis of the directional wave spectra in various conditions.

In order to save these situations, in 1971 we have developed the cloverleaf buoy which is almost the same as that of the National Institute of Oceanography (Cartwright and Smith 1964). From 1971 to 1974 seven cruises were made to measure the directional spectrum of ocean waves by using the cloverleaf buoy. Typical wave data measured both in open seas and in a bay have been analyzed to clarify the fundamental

properties of the directional spectrum of ocean waves in fairly simple generating conditions. A new standard form of directional wave spectrum is proposed on the basis of typical sets of measured data. The proposed form of the directional spectrum is further verified by the additional data obtained in the East China Sea during the period of AMTEX'75.*

WAVE DATA AND ANALYSIS

Waves were measured by using a cloverleaf buoy which is almost the same as that of the National Institute of Oceanography (Cartwright and Smith, 1964). It can measure the

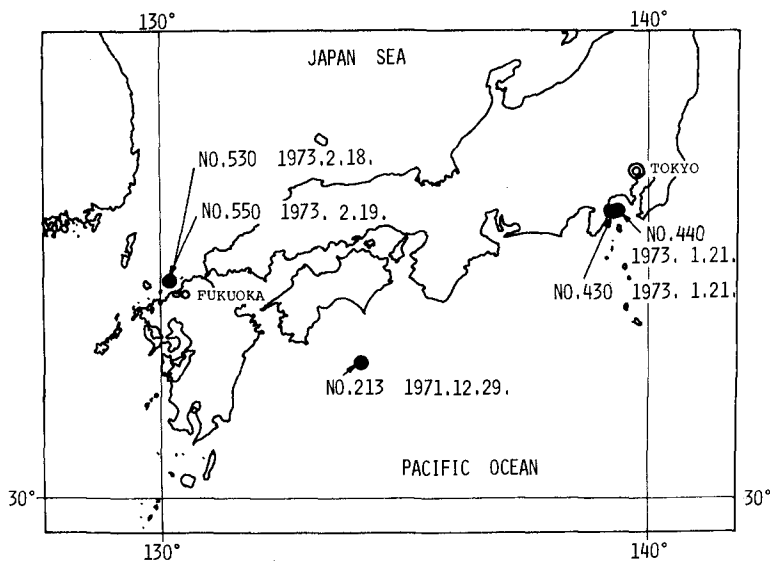

Fig. 1. Locations and dates of the wave observations.

* AMTEX'75 (Air-Mass Transformation Experiment in 1975) is one of the international sub-program of GARP (Global Atmospheric Research Programme).

vertical acceleration η_{tt} , slope η_x , η_y , and curvature η_{xx} , η_{yy} , η_{xy} of the wave surface $\eta(t, x, y)$. The detailed description of the instrumentation including the buoy and of the observational procedures has been given elsewhere (Mitsuyasu et al., 1973a,), and will not be repeated here.

From approximately 50 cases, only five typical data sets (identified as Nos.213, 430, 440, 530 and 550) have been analyzed; each is a continuous record of about 1 h. These data were obtained under the fairly simple generating conditions. That is, the wind speeds and directions are fairly constant within the duration time. Fig.1 shows the locations and dates of the wave observations.

Data sets 213, 530 and 550 correspond to wave data in open seas and data sets 430 and 440, to those for a bay.

Table 1 gives the wind direction θ_w , speed U , and approximate duration t_d , which have been measured from the tending ship near each observation station; H and T are the significant wave height and period, respectively, measured by the cloverleaf buoy.

Data set	θ_w	parameter				
		U ($m s^{-1}$)	t_d (h)	H (m)	T (s)	H/L
213	E-NE	10	26	1.49	6.20	0.025
430	ENE-NE	7	2	0.80	4.45	0.026
440	ENE-NE	7	4	0.74	4.11	0.028
530	NNE	9	4	0.84	4.50	0.027
550	N-NE	10	24	2.34	8.30	0.022

Table 1. Wave parameters from the five data sets.

The wind speeds measured at the observation stations have been determined by taking the mean of the measured wind speeds during the duration. Table 2 gives similar kind of data which have been measured in the East China Sea ($28^{\circ}19'N \sim 28^{\circ}36'N$, $125^{\circ}17'E \sim 125^{\circ}42'E$) and are used for verifying the conclusions derived from the first series of data shown in Table 1.

Original wave data recorded on magnetic tapes in analogue form were digitized by using a high-speed A-D converter. The cross spectral analysis of the data was done on the

computer system FACOM 270-20 using a standard program based on fast Fourier transform procedures. Fundamentals of the mathematical procedure of the data analysis are almost the same as those used by Longuet-Higgins et al. (1963) and by Cartwright and Smith (1964). Condensed descriptions of the data analysis have been given also in our previous papers (Mitsuyasu et al. 1973a, and 1975).

Data set	θ_w	parameter				
		U (m s^{-1})	t_d (h)	H (m)	T (s)	H/L
801	0°	10	55	2.33	7.80	0.025
804	340°	13	18	2.79	8.00	0.028
805	350°	14	23	2.67	7.80	0.028

Table 2. Wave parameters from the additional three data sets

Cross spectra $C_{em}(f) - Q_{em}(f)$ were computed using the measured six signals from the ocean waves. The directional spectrum $E(f, \theta)$ is conveniently expressed in the form

$$E(f, \theta) = \phi_1(f)G(f, \theta), \quad (1)$$

where $\phi_1(f)$ is the one-dimensional wave spectrum and $G(f, \theta)$ an angular distribution function. The one-dimensional spectrum $\phi_1(f)$ is determined from the acceleration spectrum $C_{11}(f)$, i.e.,

$$\phi_1(f) = (2\pi f)^{-4} C_{11}(f). \quad (2)$$

The coefficients A_n and B_n in the Fourier expansion of an angular distribution function $h(f, \theta) [= \pi G(f, \theta)]$ can be determined up to $n = 4$, from the measured cross-spectral elements C_{ym} and Q_{em} . From these Fourier coefficients the angular distribution function $h(f, \theta)$ can be expressed approximately as

$$h_4(f, \theta) = \frac{1}{2} + \sum_{n=1}^4 w_n (A_n \cos n\theta + B_n \sin n\theta), \quad (3)$$

for $w_1 = 8/9$, $w_2 = 28/45$, $w_3 = 56/165$, $w_4 = 14/99$

where the weights w_n are introduced to make $h_4(f, \theta)$ non-negative. The partial Fourier sum with the weights w_n corresponds to the smoothed average of $h(f, \theta)$ by the weighting function $W_4(\theta)$ which is very approximately proportional to $\cos^4 \theta/2$ and has an rms width $\pm 29^\circ$.

RESULTS

a. One-dimensional spectra of ocean waves

In a previous study one of the present authors studied the similarity of the one-dimensional spectra of wind-generated waves by using accurately measured wave data for three different groups A, B and C (Mitsuyasu et al., 1973c). Wave data for groups A and B were obtained in two quite different wind-wave facilities under various conditions. The wave data of group C were obtained in Hakata Bay, where the water depth is approximately 5 m and the fetch is approximately 5 km to the north.

It was found that wave spectra normalized in the form

$$\frac{\phi_1(f) f_m}{E} = \phi\left(\frac{f}{f_m}\right) \quad (4)$$

were quite similar and stable within each the groups; here f_m the spectral peak frequency and E the total energy of the wave spectrum defined by

$$E = \int_0^{\infty} \phi_1(f) df = \int_0^{\infty} \int_0^{2\pi} E(f, \theta) d\theta df \quad (5)$$

Moreover, there were no differences in the normalized spectra between groups A and B. However, the normalized spectra of group C were slightly different from those of groups A and B. These results can be clearly seen in Fig.2 which is reproduced from the previous paper (Mitsuyasu et al., 1973c), and shows the mean form of the normalized spectra of each group together with the normalized spectrum of Pierson and Moskowitz (1964). As can be seen from Fig. 2, the concentration of the normalized spectral energy near the spectral peak is lower in the data of Group C than

Fig.2 Similarity of the one-dimensional wave spectrum.

in those of groups A and B. The concentration of the normalized spectral energy of the Pierson-Moskowitz spectrum is much smaller than that of group C. The dimensionless fetch gF/u_*^2 is approximately 10^2-10^3 for the wave data of groups A and B, 10^5-10^6 for those of group C, and approximately 10^7 for the Pierson-Moskowitz spectrum. Therefore, within the range of our previous data, it was concluded that the concentration of the normalized spectral energy of wind waves seems to decrease with increasing dimensionless fetch gF/u_*^2 .

The normalized spectra shown in Fig.2 are used as a kind of reference for discussing the present data of one-dimensional spectra measured under various conditions. All of the measured spectra were normalized in the form (4) and compared with the previous results. Some typical examples of the normalized forms of the measured wave spectra are shown in Figs. 3-5.

The dashed line in each figure shows the spectral form which is selected from the typical spectra shown in Fig.2 and which has the closest resemblance to each measured spectrum. It can be seen from these figures that the wave spectrum of No. 430/1 is quite similar to the spectrum of laboratory wind waves, the wave spectrum of No. 550/1 is quite similar to the spectrum observed in Hakata Bay, and the wave spectrum of No. 213/1 is quite similar to the Pierson-Moskowitz spectrum. All of the other spectra were scattered between the spectral form for laboratory wind waves and that of Pierson-Moskowitz (1964), though they are not shown in the figures. Furthermore,

Fig.3. Normalized form of the one-dimensional wave spectrum: Continuous curve, ocean wave data set No. 430/1; dashed curve, laboratory wave data (group A).

within the range of our observed spectra, it was shown that the Pierson-Moskowitz spectrum is the spectrum with the smallest energy concentration, in other words, the spectrum with the largest spectral width. Within the range of the present data, however, a definite relation between the normalized spectral form and the dimensionless fetch has not been obtained.

Recently, a new spectral form, the JONSWAP spectrum, has been reported (Hasselmann et al. 1973). The JONSWAP spectrum has very high concentration of normalized spectral energy, which is comparable to that for laboratory wind waves. Fig.6 shows the comparison of the JONSWAP spectrum, the Pierson-Moskowitz spectrum and the idealized form of laboratory wind wave spectra (Mitsuyasu 1973b). As shown in Fig.6, the JONSWAP spectrum is quite similar to the spectra of laboratory wind waves in the normalized form (4). Therefore, we

Fig.4. As in Fig.3 except for ocean wave data set No. 550/1, and the wave data of Hakata Bay (group C).

Fig.5. As in Fig.3 except for ocean wave data set No. 213/1, and the Pierson-Moskowitz spectrum.

can say that many of the ocean wave spectra scatter between the JONSWAP spectrum and the Pierson-Moskowitz spectrum. In fact, almost every wave spectra of our additional data sets 801, 804, 805 were just between these two extem forms of the wave spectra. As an example, normalized spectra of wave data No. 805 is shown in Fig.7.

Fig.6. Similarity of the one-dimensional wave spectrum

Fig.7. Normalized form of one-dimensional wave spectrum: dats set No. 805, the Pierson-Moskowitz spectrum and the JONSWAP spectrum.

b. The angular distribution function

Fig.8 shows an example of the measured angular distribution $h_4(f, \theta)$ together with $h_2(f, \theta)$ which is given by

$$h_2(f, \theta) = \frac{1}{2} + \sum_{n=1}^2 w_n' (A_n \cos n\theta + B_n \sin n\theta) \quad (6)$$

for $w_1' = \frac{2}{3}$, $w_2' = \frac{1}{6}$.

Here, $h_2(f, \theta)$ is an angular distribution which can be determined only from the signals of η_{tt} , η_x and η_y , and corresponds

Fig.8. Angular distribution functions of the directional spectrum (wave data case 430/1, 2, 3): continuous curve, $h_4(f, \theta)$; dashed curves, $h_2(f, \theta)$.

to the data measured by a "pitch-roll buoy". Eq. 6, the partial Fourier sum with weights w_n , corresponds to the smoothed average of $h(f, \theta)$ by the weighting function $W_2(\theta)$ which is proportional to $\cos^4 \theta/2$. Since the width of $W_2(\theta)$ is approximately twice as large as that of $W_4(\theta)$, $h_2(f, \theta)$ is smoother than $h_4(f, \theta)$ as shown in Fig.8. In the figure $h(\theta)$ for each frequency component is shown separately. It can be seen from Fig.8 that $h(f, \theta)$ can be well approximated by an unimodal distribution function except for some exceptional cases which are considered to be affected by some errors.

In order to investigate $h(f, \theta)$ more quantitatively, the following function, originally proposed by Longuet-Higgins et al. (1963), is fitted to the measured angular distributions;

$$h(\theta) = G'(s) \left| \cos \frac{1}{2} (\theta - \bar{\theta}) \right|^{2s}, \quad (7)$$

where $G'(s)$ is a normalizing function to make

$$\int_0^{2\pi} h(\theta) d\theta = \pi,$$

i.e.,

$$G'(s) = 2^{2s-1} \chi \frac{\Gamma^2(s+1)}{\Gamma(2s+1)}. \quad (8)$$

The parameter s is, in a general case, a function of the wave frequency f , and $\bar{\theta}$ is the mean direction defined by

$$\bar{\theta} = \tan^{-1} B_1/A_1. \quad (9)$$

In Eq. (8) Γ is the gamma function.

The form of $h(\theta)$ given by the above equation is shown in Fig.9 for different values of s . As can be seen, $h(\theta)$ tends to a narrower distribution with an increase of the parameter s . That is, s can be

Fig.9. An idealized angular distribution function.

considered as a parameter which controls the concentration of the directional distribution of the wave energy.

If Eq. (7) were a perfect fit to the measured angular distribution, the parameter s would have to satisfy all of the expressions

$$C_n = \frac{s(s-1)\dots(s-n+1)}{(s+1)(s+2)\dots(s+n)},$$

$$n = 1, 2, 3, 4 \quad (10)$$

where

$$C_n = (A_n^2 + B_n^2)^{\frac{1}{2}} \quad (11)$$

By using Eqs. (10) and (11) the parameter s_n can be determined from the corresponding Fourier coefficients A_n and B_n , respectively, for $n = 1, 2, 3, 4$. Furthermore, if Eq. (7) were a perfect fit to the measured angular distributions, all s_n ($n = 1, 2, 3, 4$) should be equal. In fact, s_2 was found to be approximately equal to s_1 , but s_3 and s_4 were somewhat different from s_1 and s_2 . These might be attributed to the fact that the higher terms of the Fourier coefficients of angular distribution function contain non-negligible errors, due to the poor accuracy in the measurement of wave curvature. Therefore, the parameter s_1 and s_2

Fig.10. The one-dimensional wave spectrum $\phi_1(f)$, mean direction $\bar{\theta}$, and the spreading parameters s_1 and s for wave data set 550.

will be used for the following discussions.

Fig.10 shows typical set of values of $\phi_1(f)$, $\bar{\theta}$, s_1 and s , where s is the mean of the values of s_1 and s_2 . The location of the arrow shows the frequency of the maximum spectral density. It can be seen from this figure that the value of s_1 or s is very large near the maximum spectral density frequency. However, it decreases rapidly toward higher and lower frequencies. In other words, the angular distribution is very narrow for the frequency components near the spectral peak frequency, whereas it widens rapidly toward higher and lower frequencies. It can also be seen that the mean direction of the dominant spectral component is almost the same as that of the wind (cf. Table 1). Similar results have been obtained from the other sets of data.

Therefore, it can be said that in a generating area, frequency components near the dominant peak of the frequency spectrum, i.e., the most energy-containing frequency components, propagate in almost the same direction as the wind direction and their angular spread is very narrow. However, the angular spreading increases toward higher and lower frequencies as the spectral energy decreases.

AN IDEALIZED FORM OF THE ANGULAR DISTRIBUTION FUNCTION

In order to find the relation between the parameter s and the dimensionless frequency \tilde{f} [$= 2\pi fU/g = U/C$], s [$= (s_1+s_2)/2$] and \tilde{f} are plotted in Fig.11 on a log-log scale. It can be seen that values of the parameter s are almost uniquely determined from the dimensionless frequency \tilde{f} on the high-frequency side of the spectrum, although the data are somewhat scattered due to the insufficient accuracy of the measurements. In Fig.11 the arrow marks the location of the dimensionless frequency \tilde{f}_m that corresponds to the spectral peak frequency f_m . It can also be seen from Fig.11 that in each spectrum the parameter s shows its maximum value near \tilde{f}_m as already shown in Fig.10, and s decreases rapidly with decreasing \tilde{f} at $\tilde{f} < \tilde{f}_m$. Similar results can also be obtained from the data on s_1 .

These facts suggest that for the high-frequency side of the spectrum the parameter s shows an equilibrium form which is given approximately by

$$s = 11.5 \tilde{f}^{-2.5} . \quad (12)$$

In the frequency range below the spectral peak, $\tilde{f} < \tilde{f}_m$, an approximate expression for s can be given by

$$s = k \tilde{f}^m, \quad (13)$$

where k and m are dimensionless constants. The power m in the above expression seems to depend somewhat on \tilde{f}_m . That is, as shown in Fig.11, m is slightly larger in the cases of smaller \tilde{f}_m than in those of larger \tilde{f}_m . At this time, however, since the scatter of the data are considerable, these differences in m are neglected and m is assumed to be

$$m = 5.$$

The constant k can be determined from the condition that s has its maximum value s_m at \tilde{f}_m where Eq. (13) coincides with Eq. (12).

Approximate expressions for s for $\tilde{f} < \tilde{f}_m$ and for s_m are

$$s = 11.5 \tilde{f}_m^{-7.5} \tilde{f}^5, \quad (14)$$

$$s_m = 11.5 \tilde{f}_m^{-2.5}. \quad (15)$$

On the other hand, the dimensionless frequency \tilde{f}_m of the spectral peak can be determined from the dimensionless fetch $F [= gF/U^2]$ by using the so-called fetch relation. For example, the fetch relation (Mitsuyasu 1968)

$$\tilde{f}_m = 1.00 \hat{F}^{-0.330}, \quad (16)$$

Fig.11. The parameter s as a function of the dimensionless frequency \tilde{f} . \tilde{f}_m is the dimensionless frequency of the maximum density of the one-dimensional wave spectrum.

where

$$\hat{f}_m = u_* f_m / g, \quad \hat{F} = gF / u_*^2 \quad (17)$$

where u_* is the friction velocity of the wind, can be transformed into

$$\hat{f}_m = 18.8 \hat{F}^{-0.330} \quad (18)$$

by using the approximate relation

$$25 u_* = U_{10} = U. \quad (19)$$

From Eqs. (7), (12), (14) and (18) we can derive an idealized form of the angular distribution function that can be used for practical purposes. That is, the angular distribution is given by

$$G_1(f, \theta) = G_1(s) |\cos \theta / 2|^{2s} \quad (20)$$

where

$$G_1(s) = \frac{1}{\pi} 2^{2s-1} \frac{\Gamma^2(s+1)}{\Gamma(2s+1)}. \quad (21)$$

The parameter s is given by Eq. (12) for $\hat{f} > \hat{f}_m$ and by Eq. (14) for $\hat{f} < \hat{f}_m$, and \hat{f}_m can be determined from Eq. (18). Fig.12 shows further check of the proposed relations (12) and (14) by the data sets 801, 804 and 805. Coincidence between the prediction and observation is generally satisfactory.

Fig.12. As in Fig.11 except for wave data sets No.801, 804 and 805.

From Eqs. (12), (14) and (15) the other expressions for s are as follows:

$$s/s_m = (\tilde{f}/\tilde{f}_m)^{-2.5}, \quad \text{for } \tilde{f} \geq \tilde{f}_m, \quad (22)$$

$$s/s_m = (\tilde{f}/\tilde{f}_m)^5, \quad \text{for } \tilde{f} \leq \tilde{f}_m. \quad (23)$$

It should be mentioned here that the parameter s at the spectral peak frequency f_m increases with an increase in the dimensionless fetch \tilde{F} . In other words, the angular distribution becomes narrower as the dimensionless fetch increases. This is a rather unexpected result, because it would appear that the angular distribution should broaden with increasing fetch due to the fluctuation of the wind direction in a generating area.

COMPARISON OF VARIOUS ANGULAR DISTRIBUTION FUNCTIONS

Finally, the proposed form of the angular distribution

Fig.13. The angular distribution functions $G_0 = (2/\pi)\cos^2\theta$; G_1 , proposed spectrum and G_3 , SWOP spectrum, as a function of the dimensionless frequency \tilde{f} .

function, $G_1(f, \theta)$, is compared with the other forms which have been used frequently for practical purposes. Typical forms of the angular distribution are

1. PNJ type (Pierson et al., 1955)

$$G_0(\theta) = \frac{2}{\pi} \cos^2 \theta \quad (24)$$

2. SWOP spectrum (Coté et al., 1960)

$$G_3(f, \theta) = \begin{cases} \frac{1}{\pi} (1 + a \cos 2\theta + b \cos 4\theta), & \text{for } |\theta| \leq \pi/2 \\ 0, & \text{for } |\theta| > \pi/2 \end{cases} \quad (25)$$

where

$$a = 0.50 + 0.82 \exp \left(-\frac{1}{2} \tilde{f}^4 \right) \quad (26)$$

$$b = 0.32 \exp \left(-\frac{1}{2} \tilde{f}^4 \right). \quad (27)$$

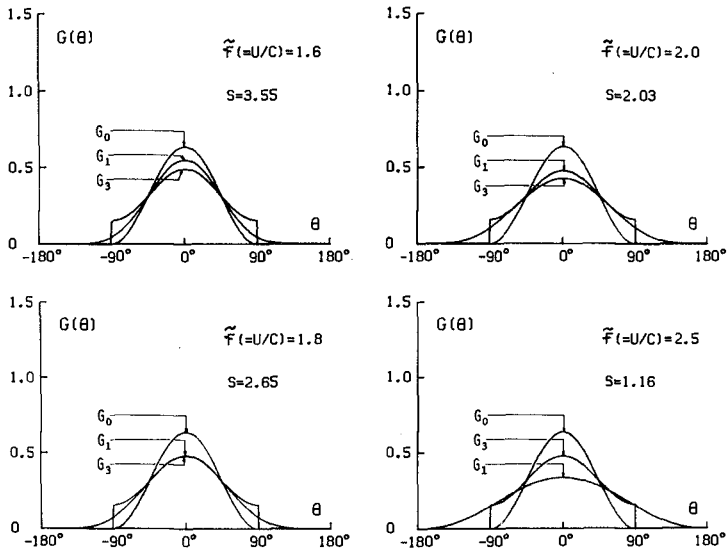

Fig.14. As in Fig.13 for other values of \tilde{f} .

Figs. 13 and 14 show the comparisons of the various forms for the angular distribution functions, $G_0(\theta)$, $G_1(f, \theta)$ and $G_3(f, \theta)$, by taking $\tilde{f} [= U/C]$ as a parameter. Here, $G_1(f, \theta)$ shown in the figures corresponds to angular distributions of the spectral components in a frequency range $\tilde{f} > \tilde{f}_m$. It can be seen from Figs. 13 and 14 that $G_0(\theta)$ is an appropriate form for the spectral components near the frequency $\tilde{f} [= U/C] \doteq 1.5$, but it has a wider angular distribution for the frequency components $\tilde{f} < 1.5$ and narrower angular distribution for the frequency components $\tilde{f} > 1.5$, as compared $G_1(f, \theta)$; $G_3(f, \theta)$ is very close to $G_1(f, \theta)$ for the frequency components $\tilde{f} \doteq 1.8-2.0$, although there exist some discontinuities of the distributions at $|\theta| = \pi/2$. Furthermore, $G_3(f, \theta)$ shows a wider angular distribution for the frequency components $\tilde{f} < 1.8$ and a narrower angular distribution for $\tilde{f} > 2.0$.

In some cases the following form of the angular distribution function has been used for practical purposes:

$$G_2(f, \theta) = G_2'(n) \cos^n \theta, \quad (28)$$

where

$$G_2'(n) = \frac{1}{\pi^{\frac{1}{2}}} \frac{\Gamma(1 + \frac{n}{2})}{\Gamma(\frac{1}{2} + \frac{n}{2})}. \quad (29)$$

It can be shown by comparing $G_2(f, \theta)$ with $G_1(f, \theta)$ that $G_2(f, \theta)$ becomes very close to $G_1(f, \theta)$ if we assume

$$n = 0.46 s, \quad (30)$$

and use Eqs. 12 and 14 for the values of s . The relation (30) is only an approximate relation which gives consistent results for the frequency components $\tilde{f} < 1.6$ or $s > 4$.

CONCLUSIONS

Using typical wave data measured by the cloverleaf buoy we have determined the directional spectrum of ocean waves, in particular, the form of the one-dimensional frequency spectrum and that of the angular distribution function. While final conclusions have not been obtained for the frequency spectrum, an idealized form of the angular distribution function has been determined, which can be used for practical purposes.

The most important findings of the present study are the following properties of the angular distribution of wave energy. The angular distribution is very narrow for the frequency components near the spectral peak, whereas it widens

toward high and low frequencies. Furthermore, the angular distributions of the frequency components near the spectral peak become narrower with increasing dimensionless fetch and, thus, with the growth of the wind waves. These properties are included in the proposed form of the idealized angular distribution function. Finally, it should be mentioned that, in many cases, the variabilities in the angular distribution functions are fairly large. Particularly, the scatter of the parameter s is considerable for the low frequency components ($f < f_m$) of the spectrum. This may be attributed to the effects of background swell and nonlinear wave-wave interactions. It should be also mentioned that the idealized form of the angular distribution function is based only on the ocean wave data and not on the laboratory wave data. Therefore, the extension of the formula to the laboratory wind wave is uncommendable.

ACKNOWLEDGEMENTS

Basic data used in the present study were obtained in a project entitled "Studies on techniques for ocean wave measurements". We are grateful to many members of this project, particularly, to Prof. F. Tasai and Prof. T. Suhara. We also wish to acknowledge to Mr. K. Eto and Mr. M. Tanaka for their constant supports in the study, and Miss N. Uraguchi for typing the manuscript.

CHAPTER 20

WAVE DIRECTION COMPUTATIONS WITH THREE GAGE ARRAYS

by

D. Esteva¹

INTRODUCTION. Wave direction is an important parameter in the solution of many coastal engineering problems such as the estimation of sediment transport and the response of coastal structures. Wave-gage arrays are among the most widely proposed systems for measuring wave direction. In late March 1970, the U.S. Army Coastal Engineering Research Center (CERC) installed an array of five pressure sensors off the California coast.

Figure 1 gives the location of the array, its geometry and dimensions. The water depth at the site was approximately 9.14 meters (30 feet) and the gages were positioned .76 meters (2.5 feet) from the bottom.

One use for the array data would be to compare redundant values of wave direction and estimate the level of accuracy of the computations. Redundant values of direction were obtained from the ten three-gage arrays possible with five gages. Three-gage arrays offer some advantages over arrays involving a larger number of gages and have been proposed by many investigators. An obvious advantage involves economics. Non-linear arrays offer the advantage over linear arrays that straight forward mathematical expressions can be derived for the unambiguous computation of direction. These expressions involve the phase differences between gage pairs for the waves present, no recourse to two-dimensional spectral analysis is necessary. However, it is necessary to assume long and relatively straight crested waves, traveling in well determined directions, and geometrically stationary over the array. The first two assumptions are supported by high altitude aerial photographs, Figure 2 and, by radar scans of the wave field, Figure 3. Fujinawa (1975) conjectures that narrow directional spread is responsible for the incomplete recovery of the true directional spectrum from field records in his computations using high directional resolution.

Direction estimates for all bands .01 hz wide between approximately 30 and 3 seconds were obtained from the ten arrays using cross spectra between gage pairs. The lower limit on period is estimated from the water column over the pressure sensors. The resulting directions at bands of maximum energy disagreed by 20° to 160° . It had been expected that the array would yield directions to better than 20° .

¹Mathematician/Oceanographer, U.S. Army Coastal Engineering Research Center, Ft. Belvoir, VA

The computational model was applied to computer simulated narrow-banded wave trains propagating across the array. Because of the narrow-bandedness of the simulated trains, the frequency resolution used in these computations was increased to approximately .001 hz. It was found that the directional results depend highly on the spectral width, both, in frequency and direction, of the wave train involved and on the relationship between wavelength at the site and gage separations.

The same higher frequency resolution was used to analyze field wave pressure records having standard deviations above 2 feet. Average discrepancies of 20 degrees among computed directions were obtained for narrow-banded trains with periods longer than 10 seconds. Larger discrepancies resulted for shorter periods. Thus, accuracies no better than 20 degrees can be expected for wave directions resulting from three-gage arrays.

ARRAY OPERATION AND DATA SUMMARY. The gages in the array were developed mostly at CERC. The heart of the system is a Fairchild pressure transducer which is potted inside a two-inch plexiglass tube, (Williams 69, Peacock 74). A plastic tube filled with silicone oil transmits the sea water pressure to the transducer. A rubber diaphragm separates the silicone oil from the sea water. A teflon scouring pad dipped in anti-fouling paint separates this rubber diaphragm from the end of the package which admits the sea water pressure. The instrument is mounted vertically on a tripod. The signals from the pressure transducers are brought by cables to a recording and transmitting station on shore.

The water pressure at each of the five gages was registered continuously at four samples per second on digital magnetic tape. The recording proceeded with few interruptions during most of 1970. It can be shown (Kinsman, 1965), that the potential energy in the wave field is proportional to the variance of the time history of sea surface elevation at a fixed location. This energy is also proportional to the square of the wave height. Thus, the standard deviation of sea surface elevations (or of the pressure at a certain depth) is a good measure of wave height. Four times the standard deviation approximately equals the significant wave height.

The standard deviation of the wave pressure in each gage was computed for observations consisting of simultaneous 20-minute recordings. The mean standard deviation was found for each observation. Table 1 gives a breakdown of the largest difference of individual standard deviations in an observation from their mean for 871 observations processed in 1970 regardless of magnitude. This breakdown indicates the system operated in a consistent way. The field wave records used for computing wave direction were chosen from those observations in this Table for which the standard deviations in the five gages differed by 3% or less from their mean and for which the uncompensated significant wave height was above 2 feet.

TABLE 1. PERCENT OF OBSERVATIONS FOR WHICH THE LARGEST DEVIATION OF INDIVIDUAL STANDARD DEVIATION IN THE OBSERVATION FROM THEIR MEAN WAS AS INDICATED. EIGHT-HUNDRED AND 71 OBSERVATIONS IN 1970.

Deviation from mean	Percent of Observations
$\leq 2\%$	41
(3 - 10%)	52
(11 - 20%)	1
$\geq 20\%$	6

COMPUTATION OF WAVE DIRECTION

For a long crested sinusoidal wave with frequency σ_i , propagating in direction α_i , the phase difference between locations 1 and 2 with coordinates (x_1, y_1) and (x_2, y_2) respectively, is given by:

$$\phi_{12} = K_i [(x_1 - x_2) \cos \alpha_i + (y_1 - y_2) \sin \alpha_i] \quad (1)$$

where $K_i = 2\pi/L_i$, is the wave number associated with frequency σ_i , and L_i is the wave length.

Expressions for the phase differences between two pairs of gages in a three-gage array allow solving for the sine and cosine of the direction of wave travel α_i . Thus the angle is determined uniquely. Estimates of a representative phase difference between gage pairs for bands of constant frequency width are easily computed from cross-spectra of the wave (pressure) records. These spectra give average values of the covariance of the wave records along two perpendicular directions for each band. The expediency in these computations is appealing provided the resulting directions are of engineering value.

The co-spectrum (Co) and quad spectrum (Quad) may be defined as, (Jensen and Watts, 1968):

$$C_{o\Delta} = \sum_{\Delta} X_1 X_2 \cos \phi_{12}$$

$$Quad_{\Delta} = \sum_{\Delta} X_1 X_2 \sin \phi_{12} \quad (2)$$

where X_1 and X_2 are the frequency spectral estimates from wave records 1 and 2 and the \sum_{Δ} indicates summation over the adjacent spectral periods combined

to make up a band. The representative phase difference for the band is given by expression 3 below, where the sign of numerator and denominator must be taken into account.

$$\phi_{12\Delta} = \tan^{-1} \left[\frac{\text{Quad}_{\Delta}}{\text{Co}_{\Delta}} \right] \quad (3)$$

Cross spectra between gage pairs were computed for bands approximately .01 hz wide for a few observations. A representative wave direction was computed for each band between 30 and 3 seconds for the 10, arrays. The agreement among these redundant values is an indication of the degree of confidence that can be placed on the resulting directions.

Disagreements on the order of 20° were obtained for bands of maximum energy with central periods above 10 seconds. For bands with maximum energy at shorter central periods disagreements on the order of 160° were obtained.

It had been expected that the array would yield directions to better than 20 degrees and for periods between 25 and 7 seconds.

SIMULATED OBSERVATIONS

To gain understanding of the problems involved, wave records arising from narrow-banded wave trains propagating through the array in a specified direction were simulated in the computer. Each simulated observation consisted of values of the wave profile at the five locations computed at 1/4 second intervals for slightly over 17 minutes (1024 seconds) to simulate the sampling rate and record duration customarily used at CERC for the field data.

Fast Fourier Transform (Cooley and Tukey 1967) computations yield the contribution to the variance at each of a set of frequencies ω_m 's, which are harmonics of a fundamental given by the inverse of the record duration, T. The frequencies of these harmonics will be referred to as *spectral frequencies* and the corresponding periods, given by their inverse the *spectral periods*. The resulting spectrum will be termed the *high resolution spectrum*. For records 1024 seconds in duration, this high resolution approximately equals .001 hz.

Assume a sinusoid with frequency given by

$$\sigma = \frac{2\pi(m + \delta)}{N\Delta t} \quad (4)$$

where Δt is the interval of time between samples and δ is less than or equal to 1/2. This expression provides for assigning frequencies which

differ from the spectral frequencies. The contribution to the variance at the spectral frequencies, of the sampled record is given by:

$$S_m^2 = a_m^2 + b_m^2 \quad m = 1, \dots, N/2 \quad (5)$$

where a_m and b_m are the Fourier coefficients. Harris shows (Harris 1974) that for values of m near \hat{m} ; i.e., for ω_m near the frequency of the sinusoid, and for \hat{m} far removed from one and $N/2$, the expressions below are good approximations to the coefficients.

$$a_m \approx \frac{A \sin \pi \delta \cos (\phi - \pi \delta)}{\pi (\hat{m} - m + \delta)} \quad (6)$$

$$b_m \approx \frac{A \sin \pi \delta \sin (\phi - \pi \delta)}{\pi (\hat{m} - m + \delta)}$$

It is clear that slow convergence of the energy toward the spectral period closest to the assigned period is indicated. Thus the energy is spread over adjacent spectral periods. This spreading, due to the finiteness of the record is usually referred to as spillover.

The technique routinely used at CERC to decrease spillover is to apply the cosine bell data window as indicated below:

$$\hat{Y}_i = \frac{1}{2} \left(1 - \cos \frac{2\pi t_i}{T} \right) Y_i \quad i = 1, \dots, N \quad (7)$$

where Y_i are the values in the original record. The Fourier coefficient for the resulting \hat{Y}_i are given by:

$$\hat{a}_m \approx \frac{A \sin \pi \delta \cos (\phi - \pi \delta)}{2\pi (\hat{m} - m + \delta) [(m - m + \delta)^2 - 1]} \quad (8)$$

$$\hat{b}_m \approx \frac{A \sin \pi \delta \sin (\phi - \pi \delta)}{2\pi (\hat{m} - m + \delta) [(m - m + \delta)^2 - 1]}$$

Thus convergence is greatly increased and spillover is effectively reduced to three adjacent spectral periods.

The cosine bell data window was applied to all records discussed here. Thus, in simulating records it was sufficient to consider wave trains consisting of three sinusoids with nearby periods spread over at most six adjacent spectral periods. Central periods near 16 and eight seconds were chosen to simulate a relatively long period swell and a shorter period swell. Swells with these periods are common in the West Coast.

Figures 4 and 5 are plots of the high resolution spectra for two of the simulated observations. Energy density at each spectral frequency is plotted versus a linear frequency scale in Hz. The corresponding period values are given along the top axis. All of the spectral plots shown here have been plotted in the same way and to the same scale. The spectra in these two figures resulted from combining only three sinusoids; yet, energy contributions appear at from five to nine adjacent periods. In Figure 4 three relative maxima separated by two minima can be identified. The energy shown at these two minima may be interpreted as due to spillover since no sinusoids were combined with the appropriate periods.

Energy minima can easily be identified in the high resolution spectra of field wave observations. The energy at these minima may be used as a measure of spillover and noise in these spectra.

Table 2 gives the characteristics of the first eight simulated observations and Table 3 the computational results at spectral periods closest to the assigned periods.

The last column in Table 3 gives the average resulting directions from the ten arrays. For wave trains 1 thru 3 the computed directions agree for the ten arrays and with the input directions to within 1 degree. Directional results for wave train No. 4 are correct only for spectral period number 62. The main difference between this train and No. 2 is the narrower spectral width. Wave train No. 2 gave the correct direction for all spectral periods while No. 4 did not.

Directional results seem meaningless for simulated wave trains 5 through 8. To determine whether these poor results were due to some programming deficiency another eight sets of simulated records were generated interchanging periods and directions.

The directional results for the sinusoids with periods clustered around 16 seconds were of the same quality regardless of the assigned direction. The directional results for the 8 second sinusoids, however, indicate that the capability to sense the correct direction for these shorter waves depends on the orientation of the three-gage array relative to the direction of propagation of the incoming wave. This is not surprising when it is realized that the effective gage separation for the different gage pairs varies with this relative orientation.

Additional simulated records were generated using the same periods as for observation No. 5 but assigning the additional directions listed in

Table 4. At the top of each column the orientation and shape of the corresponding array is given. Computed directions omitted differed by 87° and more from the assigned directions listed on the left hand column. It is apparent from Table 4 that the more nearly equilateral arrays give correct directions for a wider range of periods.

The effect of angular spread in the 16 second wave train was investigated by introducing angular spreads among assigned directions and keeping frequency separations among sinusoids constant (three spectral frequencies). Input angular spreads of 5° , 10° , and 20° gave rise to angular spreads of 0° , 16° , and 32° respectively.

FIELD WAVE OBSERVATIONS

To better evaluate directional results from field observations, spectral periods at or near which wave trains may be present in the field were isolated in the high resolution spectra of 44 field observations. The

average uncompensated significant wave height in each observation was over two feet and discrepancies of individual standard deviations from their mean was 3% or less.

TABLE 3. COMPUTATIONAL RESULTS AT CLOSEST SPECTRAL FREQUENCIES FOR SIMULATED WAVE TRAINS

Table 4 Directional results of high resolution spectral computations for 2 second wave.

Results differing by 87° or more from the assigned directions on the left hand column have been omitted.

structure suggests more than one wave train present in that period range. The spectra in Figure 7 display bimodality - a large portion of the energy appearing at shorter periods. A "background" energy was estimated for each observation by systematically averaging the energy at minima between 25 and seven seconds in the spectrum. Adjacent spectral periods in this range showing energy content twice the background or above were identified and considered arising from the same wave train. The number of adjacent periods in each train was used as a measure of the *spectral width* of the train. The energy had to be above the chosen level at all five gages for the spectral period to be included in the group. The spectral period among these showing maximum energy was taken as the "period" of the wave train.

Directions were computed at all the spectral periods in each train for the ten arrays. The total spread among these directions was found; and, an average total spread was computed for trains having the same spectral width. The same was done for the spread in computed directions at the "period" of the train.

Twenty-five percent (25%) of the identified wave trains had total directional (computed) spreads above 100° and were not considered any further. For 89% of the discarded trains, the "period" of the train was under 9.4 seconds. Thus trains with "period" under this value were also discarded.

Table 5 shows the results for the different spectral widths for the 280 trains retained.

TABLE 5. AVERAGE SPREAD IN COMPUTED DIRECTIONS FOR 280 WAVE TRAINS IDENTIFIED IN THE HIGH RESOLUTION SPECTRUM OF 44 FIELD WAVE OBSERVATIONS

Spectral Width (hz)	Average Total Spread in Direction (for all Periods) (Degrees)	Average Spread in Direction for "Period" of Train (Degree)	No. of Cases
.001		21.8	96
.002	30.9	22.9	58
.003	33.6	20.2	41
.004	41.5	20.4	22
.005	38.7	19.8	21
.006	43.8	19.8	16
.007	48.2	17.0	5
.008	84.5	17.6	8
.009	53.0	15.3	6
.010	49.3	13.7	3
.011	38.0	18.0	1
.012	81.0	15.0	1
.013	48.5	15.2	2

These results indicate that narrow peaks consisting of from one to three spectral periods are most frequent. The total spread in direction increases with frequency width. The spread in the direction at the "period" of the train remains relatively constant. Since the average spread at this "period" for narrow-banded trains ($< .003$ hz) is 21.8 degrees; it is to be expected that three-gage arrays cannot yield directional results to any better accuracy.

There are various possible explanations for the large spreads observed in the directions computed from field records. For the long crested wave model to be applicable, it is important that:

- o The phase differences be known accurately or that the probable error in their computed values be known; from expressions 6 and 8 it is clear that the analysis yields accurate phase differences for strictly monochromatic conditions. For each component with nearby period in a wave train the value of δ in expressions 6 (or 8) will be different; thus, no accurate value of the phase difference for the train nor of the error involved can be estimated;
- o the wave crests over the array site be long and straight; waves with periods between 20 and eight seconds had and are undergoing refraction at the site of the array; thus, their crests are not exactly straight; for the longer waves, with wave lengths at the array site several times the gage separations, the curvature will not introduce much error; this is not the case for the shorter waves, and orientation of the array becomes important;
- o the sea surface be stationary in time for the duration of the record, and in space over the span of the array. Stationarity of the wave field is assumed in most wave directional models. The extent and frequency of its applicability either in the open ocean or in coastal waters has not been established.

These three factors are sufficient to account for the discrepancies found in computed directions.

CONCLUSIONS

The results of directional computations both for simulated and field wave data records indicate three-gage arrays have some capability to determine wave direction under certain conditions. This capability depends on:

- o the dimension of the array and the water depth at the site which

place a lower limit on the wave period for which possibly accurate directions may be computed;

- o the orientation of the array for the shorter periods;
- o the nature of the wave field; directional results for wave trains with a narrow frequency distribution and/or for which the computed directions differ little at adjacent spectral periods might be meaningful.

For wave trains with narrow frequency and directional spreads; and, period above 10 seconds, the Pt. Mugu arrays yield directions to an estimated accuracy of 20° .

CHAPTER 21

RANDOM WAVE SIMULATION IN A LABORATORY WAVE TANK

Akira Kimura

Research Assistant

and

Yuichi Iwagaki

Professor

Department of Civil Engineering
Kyoto University
Kyoto, Japan

ABSTRACT

Most of coastal engineering problems have been studied with monochromatic waves. However, sea waves which arrive at the coast are random. It is very difficult to estimate exactly the influence of these random waves to coastal structures. Then the model tests in a laboratory wave tank using random wave simulation techniques seem to be most desirable way to estimate the influence of randomness of sea waves. For this purpose, the accomplishment of random wave simulation system, which make possible generating random waves having statistically same properties as those of sea waves, has long been desired. The authors achieved to establish such a new wave simulation system. In this paper, the characteristics of this system are demonstrated experimentally through several cases of random wave simulations.

INTRODUCTION

Random wave simulations are usually performed with a random wave generator in a laboratory wave tank. Then the important problem is how to drive the random wave generator to simulate random sea waves. In other words, how to generate random signals by which the random wave generator is driven becomes important. There are two ways of generating random signals, classifying random wave simulation techniques roughly. One is an analog method and the other is a digital method. In both methods, we must define at first what kind of properties of random waves should be simulated. Power spectrum shapes, Gaussian distribution of the water surface elevation and Rayleigh distribution of the wave height are well known representative properties for random sea waves. Simulated random signals must have the above properties at least. Especially the power spectrum shape of the simulated random signal must be same as that of sea waves.

It is known experimentally that other properties besides the power spectrum shape are almost same as those of sea waves if the power spectrum shape of simulated random waves is similar to that of sea waves. So the main purpose of random wave simulation is how to simulate the power spectrum shape of sea waves.

The analog method is the electrical simulation technique using band-pass filters. Random noise generated electrically is transmitted into a band-pass filter unit which consists of many band-pass filters with slightly different central frequencies. Gains of each filter are controlled so as to make equal the power of the output signal from each filter to the initially specified function in each frequency band. This initially specified function will be called as a target spectrum. Output signals from each filter are superimposed each other. Then the power spectrum of the output signal becomes equal to the target spectrum consequently. Finally this signal is transmitted into the random wave generator (1),(2).

The digital method is usually carried out by means of a digital computer. Random numbers generated by the computer are averaged using a numerical filter with a weighted moving average method. Averaged values are converted into analog record by a D-A converter and transmitted into the random wave generator. In this method, the procedure for designing the numerical filter mathematically, which transforms random numbers to random signals of specified properties, becomes important. Usually this problem can be deduced to solving Wiener-Hopf's integral equation, which is necessary and sufficient conditions that input and output signals must satisfy. But this procedure is very complicated and laborious and there is no assurance of the existence of an analytical solution in any case (3),(4).

From the fundamental knowledge about the Fourier transformation theorem, the numerical filter can be calculated easily by the reverse Fourier transformation of a linear spectrum. This numerical filter does not satisfy Wiener-Hopf's equation. In spite of mathematical discrepancy this method has been used frequently for convenience (5),(6),(7).

Beside these numerical filter methods, the wave superposition method has been treated by Borgman (5) and Goda (8). This is the most simple method to simulate random waves. But the simulated random waves by this method repeat themselves periodically every certain time interval. In order to avoid this periodicity several methods have been examined. Goda (8) recommended that the number of component waves is more than fifty. However, it can be said that when the number of component waves becomes so large it takes more time to calculate random signals than by the numerical filter method.

The authors propose herein a new method to calculate numerical filters. The procedure of this method is very simple and the numerical filter obtained satisfies Wiener-Hopf's equation.

NUMERICAL FILTER

The problem to obtain a numerical filter can be deduced to design mathematically an optimum circuit system which transforms a white noise $x(t)$ to a random wave profile $y(t)$ of desired statistical properties. In Fig.1 showing a linear circuit system, $h(\tau)$ and $g(\tau)$ mean unit impulse response functions in the normal and reverse directions of the circuit respectively. The relations between $x(t)$ and $y(t)$ are expressed as

$$y(t) = \int_0^{\infty} h(\tau) x(t-\tau) d\tau \dots\dots\dots(1)$$

$$x(t) = \int_0^{\infty} g(\tau) y(t-\tau) d\tau \dots\dots\dots(2)$$

Eqs.(1) and (2) can be written as follows in digital form expressions:

$$y_t = \sum_{\tau=0}^{\infty} h_{\tau} x_{t-\tau} \dots\dots\dots(3)$$

$$x_t = \sum_{\tau=0}^{\infty} g_{\tau} y_{t-\tau} \dots\dots\dots(4)$$

where $x_t, y_t, h_{\tau}, g_{\tau}, x_{t-\tau}$ and $y_{t-\tau}$ are digitized values of $x(t), y(t), h(\tau), g(\tau), x(t-\tau)$ and $y(t-\tau)$ with a time interval dt . Substituting Eq.(4) into Eq.(3) gives

$$\begin{aligned} y_t &= \sum_{\tau=0}^{\infty} h_{\tau} \sum_{n=0}^{\infty} g_n y_{t-n-\tau} = \sum_{\tau=0}^{\infty} h_{\tau} \sum_{n=-\infty}^{t-\tau} g_{t-\tau-n} y_n \\ &= \sum_{n=-\infty}^t y_n \sum_{\tau=0}^{t-n} g_{t-n-\tau} h_{\tau} \dots\dots\dots(5) \end{aligned}$$

Then from the condition that y_t appearing in both sides of Eq.(5) are always equal, the following relation is derived:

$$\sum_{\tau=0}^t g_{t-\tau} h_{\tau} = \delta_t \quad (t=0, 1, 2, \dots, \infty) \dots\dots\dots(6)$$

where δ_t is Dirac delta function

$$\delta_t = 1 \quad (t=0), \quad \delta_t = 0 \quad (t \neq 0) \dots\dots\dots(7)$$

In Eq.(6), if either h_{τ} ($\tau = 0, 1, 2, \dots, \infty$) or g_{τ} are known, the other can be determined easily. But h_{τ} and g_{τ} are not yet defined independently. Then other conditions are introduced to define h_{τ} and g_{τ} separately. In Eqs.(3), (4) and (6), it is impossible to sum up τ infinitely in real computation, then the upper boundary of summation is replaced by a sufficiently large number N . Now the white noise having the following characteristics is introduced newly as a random input:

$$E[x_t] = 0, \quad E[x_t x_{t-\tau}] = \delta_{\tau} \dots\dots\dots(8)$$

where $E[]$ means time averaging procedure.

If it is assumed that h_{τ} ($\tau = 0, 1, 2, \dots, N$) are given, g_{τ} are known from Eq.(6). y_t ($t = 0, 1, 2, \dots, \infty$) can be determined by substituting the white noise x_t into Eq.(3). Newly defined white noise x'_t obtained by substituting these y_t into Eq.(4) must be equal to x_t , but there are little differences between them, because the upper value of the

summation is replaced by a sufficiently large but finite number N in Eqs.(3),(4) and (6). Then let us try to obtain h_t and g_t which will minimize the mean squares of the difference between x_t and x_t^1 .

$$D^2 = E[(x_t - x_t^1)^2] = E[x_t^2] - 2E[x_t x_t^1] + E[x_t^1^2] \dots\dots\dots(9)$$

From Eqs.(3), (4) and (8) and the condition $h_i = 0$ when $i < 0$, Eq.(9) can be written as

$$D^2 = 1 - 2 \sum_{\tau=0}^N g_\tau E[x_t y_{t-\tau}] + \sum_{\tau=0}^N \sum_{n=0}^N g_\tau g_n r_{\tau-n} = 1 - 2h_0 g_0 + \sum_{\tau=0}^N \sum_{n=0}^N g_\tau g_n r_{\tau-n} \dots\dots\dots(10)$$

where r_i ($i = 0, 1, 2, \dots, N$) are digital values of the autocorrelation function of the output y_t . In order to obtain g_i ($i = 0, 1, 2, \dots, N$) which minimize D^2 , differentiating Eq.(10) with respect to g_i and putting each equation to be equal to zero, the following equation can be derived:

$$\sum_{\tau=0}^N g_\tau r_{\tau-n} = h_0 \delta_n \quad (n=0, 1, 2, \dots, N) \dots\dots(11)$$

This equation can also be expressed in matrix representation as

$$\begin{pmatrix} r_0 & r_1 & r_2 & \dots & r_N \\ r_1 & r_0 & r_1 & \dots & r_{N-1} \\ r_2 & r_1 & r_0 & \dots & r_{N-2} \\ \dots & \dots & \dots & \dots & \dots \\ r_N & r_{N-1} & r_{N-2} & \dots & r_0 \end{pmatrix} \begin{pmatrix} g_0 \\ g_1 \\ g_2 \\ \vdots \\ g_N \end{pmatrix} = \begin{pmatrix} h_0 \\ 0 \\ 0 \\ \vdots \\ 0 \end{pmatrix} \dots\dots(12)$$

As h_0 appearing in the right hand side of Eq.(12) is still unknown, then an attempt to solve the equations except the top ones including h_0 is made. This means to solve the matrix of rank $N-1$.

$$\begin{pmatrix} r_0 & r_1 & r_2 & \dots & r_{N-1} \\ r_1 & r_0 & r_1 & \dots & r_{N-2} \\ r_2 & r_1 & r_0 & \dots & r_{N-3} \\ \dots & \dots & \dots & \dots & \dots \\ r_{N-1} & r_{N-2} & r_{N-3} & \dots & r_0 \end{pmatrix} \begin{pmatrix} g_1/g_0 \\ g_2/g_0 \\ g_3/g_0 \\ \vdots \\ g_N/g_0 \end{pmatrix} = - \begin{pmatrix} r_1 \\ r_2 \\ r_3 \\ \vdots \\ r_N \end{pmatrix} \dots\dots(13)$$

Now denote the solution of this matrix by g_i^1 ($i = 1, 2, \dots, N$), which are the ratios of g_i to g_0 as seen in Eq.(13).

Putting $n = 0$ in Eq.(11) gives

$$g_0 r_0 + g_1 r_1 + g_2 r_2 + \dots + g_N r_N = h_0 \dots\dots\dots(14)$$

If both sides of Eq.(14) are divided by g_0 , Eq.(14) is written as

$$r_0 + g_1' r_1 + g_2' r_2 + \dots + g_N' r_N = h_0 / g_0 \quad \dots (15)$$

The left hand side of Eq.(15) can be determined by solving Eq.(13). Denoting the total summation of Eq.(15) by q , g_n can be expressed as follows:

$$g_n = \frac{h_0}{q} g_n' \quad \dots (16)$$

Substituting these relations into Eq.(10), the following equation can be obtained:

$$D^2 = 1 - \frac{h_0^2}{q} \quad \dots (17)$$

If q is positive, D^2 has a minimum value zero when $h_0^2 = q$. From Eq.(16), g_n can be finally determined as

$$g_0 = \frac{1}{\sqrt{q}}, \quad g_n = \frac{g_n'}{\sqrt{q}} (n=1, 2, \dots, N) \quad \dots (18)$$

Substituting these g_n into Eq.(6), then h_n ($n = 0, 1, 2, \dots, N$) can be determined. h_n are the numerical filters which transforms the white noise into random signals of a target spectrum.

NUMERICAL SIMULATION

In this section numerical simulations using the method explained previously are treated, and the results are compared with target spectra.

In addition random wave simulations by the Fourier transformation method are compared with those by this method. Two types of numerical filters can be defined by the Fourier transformation method. One is a numerical filter and the other is an asymmetrical one. From the results of numerical simulations in the preceding study, it was found that the asymmetrical filter gives better results than the symmetrical one. Then the results of random wave simulations by the newly proposed method herein will be compared with those by the asymmetrical filter.

Random signals by the Fourier transformation method are calculated by the relation

$$y_t = \sum_{i=-N/2}^{N/2} a_i \cdot x_{t-i} \quad \dots (19)$$

where a_i ($i = -N/2, \dots, 0, \dots, N/2$) are the numerical filters defined by the sine transformation of a linearized target spectrum. Eq.(19) has a similar form to Eq.(3) except lower limit of the summation.

The spectrum for random sea waves is frequently expressed as

$$S(f) = c_1 f^{-m} \exp(c_2 f^{-n}) \quad \dots (20)$$

where c_1, c_2, m and n are constants determined by wave conditions. This equation can be normalized using the peak frequency f_p and the spectral value $S(f_p)$ as follows:

$$S(f) = S(f_p) (f/f_p)^{-m} \cdot \exp\left\{\frac{m}{n} [1 - (f/f_p)^{-n}]\right\} \dots\dots\dots (21)$$

Values of f_p and $S(f_p)$ used in this numerical simulation are tabulated in Table-1. Target spectra are determined by substituting these values into Eq.(21). Autocorrelation functions are calculated by Wiener-Khintchine's theorem.

By substituting the digitized autocorrelation function into Eqs.(6), (13), (15) and (18), numerical filters can be determined. Fig-2 shows the examples of the numerical filters tabulated in Table-1. These numerical filters transform the random numbers, which have flat characteristics of power spectrum density, into the random signals of a target spectrum.

Fig-3 shows a part of uniform random numbers used in these numerical simulations. These random numbers are generated by the mixed congruence method using the computer subroutine. Fig-4 shows a part of numerically simulated random waves in Case-I-b.

Fig-5(a)~(d) and Fig-6(a)~(f) show the plots of the power spectra of simulated random waves by the proposed method and the Fourier transformation method (dotted lines) with the target spectra (solid lines). It is known from these figures that the proposed method gives better results than the Fourier transformation method.

These numerical simulations were performed in same conditions. N in Eq.(3) and Eq.(19) is 128 and the time interval dt is 0.05 sec. So the same degree of accuracy can be obtained by this new method with a smaller value of N than by the Fourier transformation method.

Goda (8) concluded, based on his experimental study that the time interval dt is preferable to satisfy the following relation:

$$dt \leq \frac{0.05}{f_p} \dots\dots\dots (22)$$

This relation is satisfied in all cases. However, dt must be selected not so as to be too little because when the time interval becomes small, N in Eq.(3) must be large. It is known from the accuracy of the simulated random waves that the moderate size of N is 100 or so and dt is desirable to be equal to $0.05/f_p$ which is the largest value that satisfies Goda's criterion.

The numerical filters as shown in Fig-2 must satisfy the following Wiener-Hopf's integral equation which is necessary and sufficient conditions:

$$\psi_{xy}(\tau) = \int_0^\infty h(\sigma) \cdot \psi_x(\tau-\sigma) d\sigma \quad (23)$$

where ψ_{xy} is the crosscorrelation function between the input $x(t)$ and the output $y(t)$, ψ_x is the autocorrelation function of the input $x(t)$ and $h(\sigma)$ is the filter or weighting function.

This equation can be expressed in digital form as

$$E[x_{t-\tau} \cdot y_t] = \sum_{\sigma=0}^N h_{\sigma} \cdot E[x_{t-\tau} \cdot x_{t-\sigma}] \quad \dots \quad (24)$$

The left hand side of Eq.(24) can be written using Eq.(3) as follows:

$$E[x_{t-\tau} \cdot \sum_{s=0}^N h_s \cdot x_{t-s}] = \sum_{s=0}^N h_s \cdot E[x_{t-\tau} \cdot x_{t-s}] \quad (25)$$

This is equal to the right hand side of Eq.(24). Therefore, h_{τ} ($\tau = 0, 1, 2, \dots, N$) satisfy Wiener-Hopf's integral equation.

RANDOM WAVE SIMULATION SYSTEM

Fig-7 shows the flow chart of the random wave simulation system. Two types of information can be available as an input of this system. One is a theoretical expression of the power spectrum or autocorrelation function. The other is the power spectrum or autocorrelation of observed sea waves or records of water surface itself. This system only needs basically the digitized autocorrelation function to simulate random waves. Either power spectra or autocorrelation functions can be available, because both are related each other by Wiener-Khintchine's theorem.

If the observed sea surface elevations are selected as input of this system, the right hand side of this flow chart will be used. This part of the flow chart is mainly aimed to generate random numbers. Because it is a very difficult problem to determine the randomness of sea waves, this part is attached to introduce the randomness in the simulation procedure from the observed sea waves. Reverse numerical filter g_{τ} in Eqs.(4)

and (6) are used to generate random numbers. Other procedures are the same as those at the left hand side of the flow chart.

Random waves in prototype must be reduced to a moderate size in order to generate in a laboratory wave tank. Usually the Froude similitude law is used to reduce the power spectra to a moderate scale. Then this reduced power spectrum will be called as a target spectrum. In the next step, the target spectrum must be modified because the random wave generator does not have flat response characteristics of frequency. Therefore, the wave making characteristics must be considered. In this system, Biesel-Suquet's theoretical relation between the movement of a wave making paddle and generated waves in a wave tank is adopted. Although this relation is for periodic small amplitude waves, it will be valid for random waves as the paddle movement is small. Fig-8 shows the experimental results for the ratio of the component amplitude of random waves to that of paddle movement. Plotted data agree well with the theoretical relations. Biesel-Suquet's theoretical relations shown in Fig-8 are expressed as

for piston type,

$$\frac{H}{2R} = \frac{2 \sinh^2 kh}{\sinh kh \cosh kh + kh} \quad \dots \dots \dots (26)$$

for flatter type $\frac{II}{2K} = \frac{2 \sinh kh}{kh} \frac{1 - \cosh kh + kh \sinh kh}{\sinh kh \cosh kh + kh}$ (27)

The modified target spectrum $S^*(f)$ will be defined by

$S^*(f) = S(f) \cdot [F(f)]^2$ (28)

where $S(f)$ is a target spectrum and $F(f)$ the inverse expression of Eq.(26) or Eq.(27).

Pierson-Moskowitz and Neuman spectra are selected to demonstrate the feasibility of this system. Target spectra are determined by Eq.(21). f_p and $S(f_p)$ of each spectrum are shown in Table-2. Fig-9 shows an example of the target spectrum and modified target spectrum.

Numerical filters were calculated in the same manner as used in the former section. Random numbers were averaged with the numerical filter, and these averaged values were transmitted into a D-A converter. The output signal from the D-A converter should be arranged to the smooth signal with the low pass filter. Then finally the random signals were transmitted into the wave generator.

Magnetic tapes and data recorders included in Fig-7 are attached to store digital and analog signals for future experiments.

Fig-10 shows the wave tank used in this system. This wave tank is 27 m long, 50 cm wide and 75 cm deep with glass side walls. At one end of this tank a random wave generator is furnished. At the other side of the wave tank, a wave absorber is installed and a wave gauge is set at the position of 10 m apart from the wave making paddle. Photo-1 and Photo-2 show the wave tank and random wave generator respectively.

The random wave generator is of servo-controlled electro-hydraulic system. Some typical properties of this wave generator are listed in Table-3. The wave generator has two actuators, which are connected with a piston type wave making paddle and a flatter type one respectively. Each actuator can be controlled independently. When the peak frequency of the target spectrum is higher than 1.0 Hz, random wave simulations will be performed with the flatter type wave making paddle, and if the peak frequency is lower than 1.0 Hz, the piston type wave making paddle is used. Furthermore, each paddle can be controlled simultaneously with different random signals.

A band pass filter unit not included in this system with fifteen band pass filters of 1/3 oct. frequency band from 0.2 to 5.0 Hz is attached as an optional faculty to this random wave generator. Therfor, the random wave simulations by an analog method can be made (2).

Fig-11 (a) ~ (d) and Fig-12 (a) ~ (d) show the experimental results of Pierson-Moskowitz and Neuman spectral simulations. The plotted data in each figure denote the results of power spectral analysis of water surface elevation measured by the wave gauge, and the solid lines show target spectra. From these figures, it is known that the power spectra of simulated waves are very close to the target spectra except in the region of low frequency.

The difference between the data and the target spectra at low frequency may be mainly caused by the surf beat which is usually observed in random waves near the coast.

This random wave simulation system aims to simulate a random wave spectrum. At the same time, other properties such as probability distributions of surface elevation and wave height must resemble those of sea waves.

Fig-13 shows some examples of the probability distributions of water surface elevation of simulated waves for Case-1-b and Case-2-a shown in Table-2. Plotted values are slightly skew to the minus side compared with the Gaussian distribution shown in a solid line, but this tendency is always observed in sea wave data. This is owing to the non-linear characteristics of wave motion.

Fig-14 shows wave height distributions defined by the zero-up-cross method for Case-1-b and Case-2-a. Agreement of data with the Rayleigh distribution is very well. These results means that the simulated waves in a wave tank have the same characteristics as those of sea waves.

CONCLUSION

The random wave simulation system has been discussed with several cases of random wave simulations in a wave tank. New, simple and accurate method to determine the numerical filter in this system has been proposed. The numerical simulation of random waves and experiments in a laboratory wave tank have shown that this system is very satisfactory.

There are some restrictions of wave making in extremely low and high frequency regions not only for this system but also for a regular wave generator, even though the random wave generator adopted in this system is much improved so as to equipt two types of wave making paddles. It is, therefore very difficult to estimate random waves in wide frequency range, for example, random waves of widely separated multiple peaked spectrum by a usual random wave generator only.

The ideal random wave simulation system will be consist of an extremely low frequency random wave generator like a tsunami generator and an ordinary random wave generator and a wind tunnel.

This random wave simulation system was completed in 1973. Since then, more than 40 cases of random wave simulation have been performed, and the statistical characteristics of random waves, such as distributions of the wave period, wave height and wave period and also combined distributions, have been studied using these simulated random waves (9), (10)

CHAPTER 22

WAVE HEIGHT DISTRIBUTION OF WIND WAVES OVER LONG WAVES

Shan-Hwei Ou¹ and Frederick L.W. Tang²

ABSTRACT

Influence of long wave on the wave height distribution of wind waves was studied through the laboratory experiment. Experiments were conducted in a wind-wave tank where the wind waves were generated by a wind blower and the long waves were developed by an oscillating pendulum type wave generator.

The wave height distribution of the wind waves over long wave is slightly different from the Rayleigh distribution in the small steepness of long wave. The ratios between the average of highest 1/n-th waves vary with the steepness of long waves. The magnitude and the location of the spectral peak of wind waves are altered. The amount of the attenuation of wind wave energy is larger than the results of Mitsuyasu (1966).

1. INTRODUCTION

The design of marine structures have often been done with the concept of representative wave. Offshore structures are mostly designed against the maximum probable wave at the structure site. Coastal structures are usually designed against the significant wave at the locality. However, marine structures are subjected to the action of irregular waves. The analysis of irregular wave action on marine structures requires the information of statistical distribution of wave heights. Ito, et.al.(1966) employed the wave height distribution function to estimate the possible sliding distance of the breakwater. This method has been adopted in the practical breaker design (The Japan port and Harbour Association, 1970). Goda(1970) calculated the rate of wave overtopping of sea walls from the wave height distribution.

In this kind of analysis, the detailed distribution function of wave heights is needed. Theoretical distribution of wave heights, defined by the crest-to-trough method, was developed by Longuet-Higgins(1952) as the Rayleigh distribution, under the assumptions of narrow spectrum and random phases. There are lots of investigators confirm this wave height distribution. However, it is uncertain in case where the wind waves are propagated over the surface of long waves such as ocean swell or tidal currents.

The interaction of short wave and long wave has been studied by Longuet-Higgins and Stewart(1960) for the case of same wave type and by Mitsuyasu(1966) for the case of different wave type. In this paper, the influence of long wave on the wave height statistics of wind waves is presented.

2. EXPERIMENTAL EQUIPMENT AND PROCEDURE

The experiment was conducted in a wind - wave tank of 75 m long, 1m wide and 1.2 m deep as shown in Fig.1. The long waves were generated by an oscillating pendulum type wave generator at one end of the tank. Wind waves are generated in the same direction by a 10 Hp motor, located at 10 m down the pendulum wave generator. The cross section of the outlet of wind blower is 1m in width and 0.5 m in height. The bottom of the duct is 0.2 m above the still water level such that the regular waves may pass through the gap. The wind velocity at the center of the wind passage was measured by a pitot - static tube in conjunction with a micromanometer. The micromanometer was allocated in a slope of $\sin \theta = 1/4$, and filled with two insoluble liquids of ink solution and colorless benzene, each has the specific gravity of 0.998 and 0.875 at the temperature of 20°C respectively. The pressure difference bearing at the pitot - static tube can be read out easily and hence the wind velocity was obtained. Waves were measured by the resistance type wave gauge and recorded on the visigraph.

Wind waves were generated by three free stream wind velocities, i.e. 8.10m/s, 10.73m/s and 12.45m/s. The regular long waves were produced by three periods and five wave heights. The properties of regular long waves used in the present experiment were listed in the table 1. The steepnesses of the long waves are all below 0.01. Each experimental condition includes the case of three wind velocities, that makes altogether 45 experimental runs.

Table 1. Regular long waves used in the experiment

Mean period (sec)	Mean wave height (cm)	Steepness

2.51	3.64	0.0037
2.48	4.99	0.0052
2.48	5.91	0.0062
2.48	8.10	0.0084

In the experiments the regular long wave was generated first, and then wind was sent over the surface of long wave. Each run lasts for five minutes, and the co - existent system was recorded for last two minutes. The wave data at fetch 16.4 m were presented here.

3. EXPERIMENTAL RESULTS

3.1 General features of the combined wave field

Figure 2 shows the examples of the wave record. In the figure, (a) is the record of wind wave unaffected by the long wave; (b) is the record of mechanically generated long wave; (c) is the record of co- existent system in almost steady state. Figure 3 shows the examples of co - existing system under different wave steepness of long waves. The wave heights are taken as crest-to-trough wave height through out this analysis. The wave statistics of wind waves and long waves are calculated separately, and the combined wave field of wind waves and long wave was also computed as given in Table 2, where the values in bracket denoted the wave statistics for wind waves only.

3.2 Wave height statistics

The theoretical wave height distribution derived by Longuet - Higgins for a narrow band spectrum is given as

$$P(H)dH = \frac{1}{4} \frac{H}{\sigma^2} \exp \left(-\frac{H^2}{8\sigma^2} \right) dH \dots \dots \dots (1)$$

where σ^2 is the variance of surface elevation. The ratios of average heights of the highest 1/n-th waves have been calculated as

$$\frac{H_{1/3}}{H_a} = 1.598, \quad \frac{H_{1/10}}{H_{1/3}} = 1.270 \quad \text{and} \quad \frac{H_{max}}{H_{1/3}} = 1.601 \quad (\text{for } N=160) \dots \dots (2)$$

Although several reasons could affect the wave height distribution, such as the nonlinear wave - wave interaction, the breaking effect, the instrument of wave recorder, and the use of a finite number of component wave heights, etc., the wave height distribution observed in the field (Grodnight, 1963; Collins, 1967; Koele, 1960; Goda, 1974; etc.) has been shown generally in good agreement with the Rayleigh distubution.

In the present analysis, the distributions of crest - to - trough wave heights of wind waves over the long wave are computed. Figure 4 is the wave height distribution of wind waves over the long wave as given in Figure 3. It is seem that the wave height distributions do not deviate too much from the Rayleigh distribution, except for the wind waves only and the low wave steepness. All the experimental data of wave beight distribution are summarized into four groups According to the steepness of long wave, i.e., $H/L = 0, 0.001-0.003, 0.003-0.006, 0.006-0.009$. The data in the same group are averaged and formed the representative wave height distribution as given in Figure 5. Seeing that the wave height distributions vary with the steepness of the long

wave. The wave height distribution of wind waves in absence of long wave does not follow the Rayleigh distribution. As the steepness of long wave increases, the densities in the lower part of the distribution function begin to grow, and the wave height distribution of the co-existent system of wind waves and long wave show slightly close to Rayleigh than before, as in the case of $H/L = 0.001-0.003$ and $H/L = 0.003-0.006$. However, when the steepness of long wave continue to increase as in the case of $H/L = 0.006-0.009$, the distribution shows deviate from Rayleigh again.

Figure 6 shows the values of ratios among various wave height in relation to the steepness of long waves. It is noted that the values of $H_{1/3}^1 / H_a$ and $H_{1/10} / H_{1/3}$ are smaller than the theoretical values given by Equation (2), but the ratio of $H_{\max} / H_{1/3}$ is larger, comparing the theoretical values. The ratios of $H_{1/3} / H_a$, $H_{1/10} / H_{1/3}$, $H_{\max} / H_{1/3}$ are increased in proportion to the steepness of long wave.

Figure 7 shows the relations between $H_{1/10} / H_a - U/C_0$ and $H_{1/10} / H_{1/3} - \epsilon^2$, where U is the free stream velocity, C_0 is the phase velocity of long wave, ϵ is the bandwidth of the co-existent system computed from power spectrum. It is seen that $H_{1/10} / H_{1/3}$ increases with ϵ^2 , and $H_{1/3} / H_a$ seems has nothing to do with U/C_0 .

3.3 The spectrum and the attenuation of wind wave energy

Spectra of wind waves alone and the co-existent system of wind waves and long waves are analysed in order for the better understanding of the detailed properties of wind waves on long waves. Each record of two minutes in length is digitized with 0.1 sec interval. The computation of wave spectrum was done by the IBM 1130 digital computer. Each run consumes 7 minutes of computer time. The adopted program was based on Blackman and Tukey method with sample size $N=1024$, maximum lag $M=102$, Nyquist frequency $f_N = 5.0$ c/s, resolution $f=0.049$ c/s.

In Fig. 8, the solid line shows the power spectrum of wind waves for wind velocity equals to 12.45 m/s. As long waves appear, the spectrum of co-existent system shows a double peaks, which can clearly separated each other. The high frequency peak represents the wind wave spectrum, and the low frequency peak represents the long wave spectrum. Fig. 8 shows that the wind wave spectrum is attenuated gradually with increasing the steepness of long waves. The scale of ordinate in the figure is changed in the high frequency range so as to see more clearly the changes of wind wave spectrum.

The total energy in each run as listed in Table 2 is computed through the spectrum calculation. In Table 2, $(E)_0$ indicates the total energy of wind waves in the absence of long waves; E represents the total energy of the co-existent system of wind waves and long waves. The total energy of the co-existing system is increased in most cases due to the appearance of long waves. But that part of wind waves energy in the co-existent system is decreased, as has shown in Fig. 8. Let E' be the energy contained

in the wind waves of the co-existent system. E' can be obtained by the numerical integration of each spectrum. Fig.9 shows the attenuation of wind wave energy as relation to steepness of the long waves. The attenuation rate according to long wave steepness is larger than the result of Mitsuyasu (1966). The attenuation of wind waves energy might due to the breaking of wind waves near the crest of the long wave, as has pointed out by Longuet-Higgins and Stewart (1960). The other reason of attenuation is due to the change of wind field induced by the passing long waves. The peak of wind wave spectrum is also altered. Fig.9 shows the results.

4. CONCLUSION

The interaction between short wind-generated waves and the long mechanically-generated waves involves complicated energy transfer in the wind field and wave field. The experimental results show the influence of long wave on the wave statistics of wind waves. The wave height distributions of wind waves over small steepness of long waves show not much deviate from the Rayleigh distribution, but the ratios of various wave heights are varied both with the steepness of long waves and the band width of the co-existent spectrum. The attenuation of wind wave energy is directly proportion to the steepness of long wave. The peak of wave wave spectrum is shifted.

CHAPTER 23

INTERACTION OF WAVES AND A TURBULENT CURRENT

by

J. D. A. van Hoften¹ and S. Karaki²

ABSTRACT

An experimental investigation was made to study wave-current interaction. Wave amplitude attenuation was measured along a laboratory wave channel to compare wave dissipation with and without flow. Mean, wave, and turbulent velocities were also measured to determine the modifications of the flow imposed by the gravity waves propagating with the current. The process of energy transfer in the wave-current system was studied. Energy was found to be extracted from the waves, diffused downward and dissipated by an increase in bottom shear stress.

INTRODUCTION

The development of a model to accurately describe the generation and decay of ocean surface waves has been a primary objective of oceanographers for decades. In present wave forecasting formulas there is far more agreement on empirical wave growth than on wave dissipation. Numerous studies have dealt with the aspect of laminar wave energy dissipation such as the early theoretical work of Lamb (1932) and Hunt (1952). Experimentally, a large variety of studies have been made relating wave dissipation to near-surface viscous effects or to the oscillatory boundary layers. In real situations, waves seldom travel across non-turbulent waters. Thus an account must be made of the interaction which results as orbital wave velocities work against the shear current and turbulence which likely exist.

This paper describes a laboratory study of the interaction of waves and current as mechanically generated, monochromatic, intermediate-depth gravity waves propagate on a turbulent open channel flow. The two areas of primary concern are:

1. Wave modification - the change in wave form, mainly wave amplitude, resulting in increased wave energy dissipation.
2. Current modification - the alteration of mean and turbulent flow parameters due to the wave interactions, as well as changes in the resistance to flow and energy transport properties.

THEORETICAL ANALYSIS

In order to create a set of baseline data for wave attenuation analysis, it is first necessary to examine wave energy dissipation without the effect of channel flow. Hunt (1952) utilized the basic laminar wave dissipation equations and integrated the effects of the oscillatory boundary losses for the side and bottom and derived an expression for a wave attenuation modulus,

$$\alpha = \frac{2k}{b} \sqrt{\frac{\nu}{2\sigma}} \left(\frac{kb + \sinh 2kh}{2kh + \sinh 2kh} \right) \quad (1)$$

where b is channel width, h is flow depth, k is wave number ($2\pi/\text{wave length}$), ν is kinematic viscosity and σ is wave frequency ($2\pi/\text{period}$) derived from $\sigma^2 = gk \tanh kh$. Wave amplitude attenuation is then defined by the exponential form

$$a = a_0 e^{-\alpha x} \quad (2)$$

where a_0 is the initial wave amplitude and a is the attenuated amplitude at distance x .

The analysis of the wave-current amplitude attenuation utilizes a control volume of unit width bounded by upstream and downstream vertical sections, the channel bottom and the free water surface. Whitham (1962) applied the concept of the radiation stress (introduced by Longuet-Higgins and Stewart (1960)) to the momentum and energy flux in water waves. Application of Whitham's concepts to the case of attenuating monochromatic waves propagating on a uniform open channel flow begins with the integral momentum equation,

$$\frac{d}{dx} (\rho h U_m^2) + \rho g h \sin \theta + \frac{dS_{xx}}{dx} = - \bar{\tau}_b \quad (3)$$

$$\text{where } S_{xx} = E \left(\frac{2kh}{\sinh 2kh} + \frac{1}{2} \right) \quad (4)$$

is the longitudinal component of radiation stress, $\sin \theta$ is channel slope, $\bar{\tau}_b$ is the mean bottom shear stress, a is wave amplitude, E is wave energy density ($1/2 \rho g a^2$), and U_m is the mass transport velocity defined by

$$U_m = \bar{u} + \frac{E}{\rho h c} \quad (5)$$

where \bar{u} is mean uniform flow velocity, and c is phase speed. By substituting equations (4) and (5) into (3), differentiating and retaining terms to the order of a^2 and assuming an exponential wave attenuation of the form of equation (2), the resulting equation for bottom shear stress is

$$\bar{\tau}_b = \rho gh \sin \theta + \rho g \alpha a^2 \left[\frac{2}{c} (\bar{u} + c_g) - \frac{1}{2} \right] \quad (6)$$

where c_g is the group velocity defined by

$$c_g = \frac{C}{2} \left[1 + \frac{2kh}{\sinh 2kh} \right] \quad (7)$$

Note that for $\theta = 0$, and $\bar{u} = 0$, equation (6) reduces to the form

$$\bar{\tau}_b = \rho g \alpha a^2 \left[\frac{2c_g}{C} - \frac{1}{2} \right] \quad (8)$$

which is just dS_{xx}/dx . In other words for the case of waves on still water the shear stress on the bottom is balanced by the rate of change of the radiation stress. Also note that if $\theta \neq 0$, $\bar{u} \neq 0$, and $\alpha = 0$, or the case of waves propagating on a current without attenuation,

$$\bar{\tau}_b = \rho gh \sin \theta \quad (9)$$

which is the bottom shear stress without waves.

In the same manner, the equation for the energy flux through the control volume is

$$\frac{d}{dx} \left[\frac{\rho h U_m^3}{2} + \rho gh^2 U_m + S_{xx} U_m + E U_m + E c_g \right] = -D \quad (10)$$

where D is the energy dissipation defined as dE/dt . Again substituting and retaining terms of the order a^2 gives the total dissipation as

$$D = \rho gh \sin \theta \bar{u} + E \left[\frac{g \sin \theta}{c} + \alpha \bar{u} \left(1 + \frac{3\bar{u}}{c} \right) + 2\alpha c_g \left(1 + \frac{2\bar{u}}{c} \right) \right] \quad (11)$$

The first term on the right is the energy dissipation due to channel flow alone as the product of shear stress and mean velocity. The remaining terms represent the additional dissipation due to wave-current interaction and will be denoted D_w . For the case of no flow, $\bar{u} = 0$, $\theta = 0$, and noting that $da/dx = -\alpha a$, equation (11) reduces to

$$D = c_g \rho g \alpha a^2 \quad (12)$$

$$\text{or } D = -c_g \frac{dE}{dx} \quad (13)$$

Thus the energy dissipation in still water is a product of the group velocity and the longitudinal wave energy density gradient.

The above analysis provides a basis for the experimental measurements. Terms of equation (11) may be directly measured and an estimate may be computed for the total dissipation between successive sections of the channel. Limitations are imposed by the

assumption of a uniform velocity profile and the neglect of side-wall losses. Also neglected is the integral effect of the turbulent interaction. A possible improvement may be made to the analysis by the use of the energy equation derived by Brink-Kjaer and Jonsson (1975) which assumes a linear shear profile.

EXPERIMENTAL APPARATUS AND PROCEDURES

Figure 1 shows a schematic of the wind-wave facility at Colorado State University. The flume is 15.8 m long, 60 cm wide and 70 cm deep. Flow was recirculated at a constant depth of 15.2 cm and waves were generated by a vertical plunger of the upstream end. Mean flow velocities ranged from 15.0 to 60.0 cm/sec and wave frequencies varied from 1.3 to 2.5 Hz.

An initial study of wave attenuation in still water was made to compare the experimental results to the theoretical laminar dissipation of equation (1). Water surface elevations were measured with a capacitance probe mounted on a moving carriage. Average or rms wave heights were measured at 15 cm intervals along the centerline of the 10 m test section. Wave lengths were measured directly by longitudinally separating two capacitance probes and observing the corresponding Lissajous figure on an X-Y oscilloscope plot. Integral wave locations were recorded when the figure repeated itself.

Waves were next generated on a series of steady currents and wave profiles were measured. Artificial bottom roughness elements assured a fully developed turbulent flow. Velocity measurements were made with a split hot-film anemometer at various depths in the flow field both with and without waves. Simultaneous wave and velocity data were digitized and stored on magnetic tape.

Iterative computer techniques were used to analyze the split-film data due to the large intensities of the velocity fluctuations. Phase averaging techniques were next used to compute flow quantities relative to the average wave profile. Quantities computed at each depth included mean velocity, wave velocity, longitudinal and vertical turbulence intensities, and turbulent and wave induced Reynolds stress.

To separate the velocity components the instantaneous velocity, u_i , is written as a sum of a time mean, \bar{u}_i , a wave induced component, \tilde{u}_i , and a random component, u_i' . Thus

$$u_i(x, z, t) = \bar{u}_i(x, z) + \tilde{u}_i(x, z, t) + u_i'(x, z, t) \quad i = 1, 2 \quad (14)$$

By first time averaging, the mean signal is removed. The process of phase averaging then identifies wave induced and turbulent velocities as a function of wave phase. Phase averaging is symbolized by brackets ($\langle \bullet \rangle$).

WAVE MODIFICATION

Figure 2 shows three typical mean wave amplitude variation curves for waves in still water. Figure 3 illustrates similar measurements for waves on a flowing channel. The rms amplitudes are normalized by the amplitude at the beginning of the test section. Reflected wave energy creates the regular variation in rms wave amplitude throughout the channel. In most still water cases the pattern obeyed the one-half wave length theory presented by Ursell et.al. (1959). For waves on a current the pattern was distorted due to the modification of wave parameters by the flow, but a regular sinusoidal pattern still existed in the channel.

Attenuation, or wave energy dissipation is demonstrated by the gradual decay of wave amplitude along the channel. The measured exponential decay modulus, α_m , was calculated by a least squares fit of equation (2) to the measured profiles. It is readily apparent that neglecting wave reflection would seriously affect attenuation measurements. Figure 4 is a plot of representative measured attenuation coefficients on still water against the viscous theory of Hunt (1952). In nearly all cases the theory slightly underestimates the measured attenuation modulus, a fact that many investigators have previously noted (Eagleson (1962), and Grosch et.al. (1960)).

In order to compare wave attenuation on still and moving water it is necessary to analyze the wave-current results from a reference system convected with the mean velocity. The results then show a reduced relative frequency and decreased fetch. Figure 5 shows wave dissipation as a function of wave amplitude on still water. Note again that the dissipation is slightly underestimated by viscous theory but increases nearly as the square of the amplitude. Figure 6 is a similar plot of waves on a current, where D_w is the wave dissipation from the convected reference system, calculated from equation (11). Note in this case the large increase in wave dissipation due to the wave-current interaction and the divergence from the A^2 variation as amplitude increases. Figure 7 shows the dissipation as a function of wave steepness, ak , with mean velocity, \bar{u} , as a third variable. Steeper waves on the same flow are shown to dissipate energy faster, probably due to the added-stretching of vortex lines as described by Phillips (1959).

FLOW MODIFICATION

Figure 8 illustrates the effect on the velocity profile of increasing frequency and amplitude of waves superposed on a constant mean velocity. Mean velocities at each relative depth, z/h , are normalized by the bulk mean velocity. As the frequency and amplitude increase, the mean velocity profile flattens near the surface and steepens near the bottom. Equation (16) predicts that $\bar{\tau}_b$ will increase as the wave amplitude and attenuation modulus increase. The increase in velocity gradient near the bottom indicates the relative increase in average boundary shear.

The modification of mean velocity and turbulence quantities for a typical run is shown in Figure 9. Dotted profiles are those measured without waves. Quantities for the wave-current profiles are an average over a wavelength of the phase averaged results. The mean velocity profiles indicate a strong interaction with a large increase in gradient near the bottom. The local longitudinal and vertical turbulence intensities show an increase near the surface and relative reduction in the middle regions. The Reynolds stress becomes positive near the surface due to the reversal of the mean velocity gradient, and its magnitude is lower throughout the depth. It is apparent that the interaction of the waves and shear flow produce turbulence near the surface and that it diffuses downward, likely through the action of wave induced pressure terms. A further analysis of the energy transfer mechanism is given in van Hoften (1976).

Local flow characteristics give insight into the magnitude of the interaction. Figure 10 shows the longitudinal wave induced velocity at various relative depths. Velocity variations are typical of intermediate-depth waves with finite velocities near the bottom. Figure 11 is a plot of the phase averaged longitudinal turbulence intensity and Figure 12 is the turbulent Reynolds stress. Note that both exhibit double frequency behavior and both become less phase dependent as depth increases.

One-dimensional energy spectra of the longitudinal velocity fluctuation, with and without waves, were computed. Figure 13 shows spectra computed at four relative depths without waves. The inertial subrange where the slope obeys the $-5/3$ law appears as a narrow band due to the relatively low flow Reynolds number ($R_e = 36,900$). The high frequency portions of the spectra conform closely to the -7 slope where viscous effects determine energy transfer. A -1 slope at $z/h = 0.07$ is mildly indicated in the region where Tchen (1953) predicts large turbulence production, near solid boundaries. Figure 14 shows spectra of the total longitudinal velocity ($u + u'$) with waves. The large peaks in the plots correspond to the wave induced velocity component at 1.88 Hz. Note that relative peaks decrease with depth, as the velocity plots from Figure 10 indicate. The spectrum at $z/h = 0.95$ appears to have a range of low frequencies where the -1 slope applies, representing a production range. Chang and Cheng (1972) studied turbulent airflow over water waves and predicted that the -1 power law should apply from the dominant wave frequency to the lower bound of the inertial subrange. The low Reynolds number of the present flows, however, prevents an accurate assessment of this concept.

CONCLUSIONS

Waves propagating on an open channel flow are shown to be altered by a combination of the interaction of the waves with the shear gradient and the existing turbulence. The effect is to extract energy from the waves resulting in an increased wave attenuation.

The flow itself is altered by the superposed waves. The induced orbital wave velocities distort the mean velocity profile increasing the gradient near the bed. Turbulence energy is produced near the surface by the interaction of the wave induced Reynolds stresses and the fluctuating velocity gradients. The energy diffuses downward where it is dissipated on the bottom by an increase in apparent boundary shear stress.

CHAPTER 24

TRANSFORMATION OF NONLINEAR LONG WAVES

by

Nobuo Shuto

Chuo University, Tokyo, Japan.

SYNOPSIS

Kakutani's equation is extended to include the effects of variable width of the channel and the bottom friction. Based on the equation, several solutions are derived and compared with experimental results. For example, Green's law is obtained if the nonlinearity, dispersion and bottom friction are neglected. With the nonlinearity included, it is shown that the wave amplitude follows Green's law and at the same time the wave profile deforms due to the nonlinear effect.

Discussion of the present paper is mainly focused on the effect of the bottom friction. From the experimental results of cnoidal waves in a channel of constant depth and width, on the bottom of which artificial roughnesses are planted, it is shown that the friction coefficient estimated from Kajiura's theories gives good agreements, thus confirming the validity of the method of conversion, proposed in the present paper, between sinusoidal and cnoidal wave motions.

Change in height of cnoidal waves on a slope is also solved. The friction coefficient determined from wave characteristics and bottom conditions, by means of Kajiura's theories and the method of conversion stated above, is used in the comparison with experimental results. Theoretical prediction agrees very well with experimental results.

INTRODUCTION

In shallow water, long waves transform under several effects such as nonlinearity, dispersion, topography and bottom friction. As for the first three effects, the present author has derived an equation and solved in one of his previous papers [1].

In the present paper, an equation which includes all four effects is derived and, therefore, is considered a fundamental equation for water waves in shallow water. In other words, the equation is an extension of Kakutani's equation [2], because if the bottom friction and the effect of the variable width are neglected, it is reduced to Kakutani's one.

The bottom friction here is assumed to be proportional to the square of the horizontal velocity of water particle. This is normally done if the flow is turbulent near the bottom. We encounter two questions as for the expression of the bottom friction. The one is how we select the representative horizontal velocity, and the second problem is how we can estimate the magnitude of the friction coefficient.

In the following derivations, the horizontal velocity of the first order approximation, that is, the horizontal velocity of the linear long waves is used as the representative velocity. Since it has a uniform vertical distribution, it is easy to connect it with the water surface elevation η , for which the equation is derived. At the same time, there is neither ambiguity nor complexity in the definition of the bottom friction.

For the friction coefficient in an oscillatory flow, Jonnson's empirical formula [3] and Kajiura's theories [4], [5] are available. In the present paper, an attempt is made to connect cnoidal waves with Kajiura's theories which assumed sinusoidal waves. It is assumed here that the mean energy dissipation is the same for sinusoidal and cnoidal waves, thus providing the method of conversion of the friction coefficients.

Kajiura derived his first theory, on assuming that the boundary layer thickness is very big and covers the whole water depth. This corresponds to tsunamis or storm surges in natural conditions.

Kajiura's second theory is for wind waves or swells in shallow water. It is assumed that the boundary layer thickness is very thin compared to the water depth.

In the experiments, artificial rectangular roughnesses are planted on the bottom of the channel and on the slope. For a given size and spacing of the roughnesses, Adachi's empirical formula [6] is used to calculate the coefficient of the bottom friction and the roughness length z_0 in steady flow. The friction coefficient thus obtained is always smaller than that required for unsteady flow. Therefore, the roughness length is used to estimate the friction coefficient for unsteady flow, combined with the horizontal velocity of linear long waves, by Kajiura's theories.

Decay of cnoidal waves in a channel of constant depth and width are at first tested in order to examine the validity of the expression of the bottom friction. Dimensions of the roughnesses used in the experiments are big for the water depth, compared with the natural condition. The friction coefficients computed from experimental results are quite big compared with that estimated for steady flow and fall between two Kajiura's theories. Therefore, it is concluded that the present theory combined with Kajiura's theories provides reasonable basis for transformation of nonlinear long waves in shallow water.

Experiments are also carried out on a slope of 1 on 20, on which the same artificial roughnesses are planted. Mean value of the friction coefficient is used to predict the change in wave height and the results agree very well with experimental results.

FORMULATION

The equations to be solved are;

$$\left. \begin{aligned}
 u_x + v_y + w_z &= 0 \\
 u_t + uu_x + vu_y + wu_z &= -\frac{1}{\rho} p_x + \frac{1}{\rho} \tau_z \\
 v_t + uv_x + vv_y + wv_z &= -\frac{1}{\rho} p_y \\
 w_t + uw_x + vw_y + ww_z &= -\frac{1}{\rho} p_z - g
 \end{aligned} \right\} \text{----- (1)}$$

in which the x-axis is taken horizontally and parallel to the direction of wave propagation, the y-axis horizontally and normal to the x-axis, and the z-axis vertically and positive upwards. It is assumed that the bottom friction mainly contributes in the x-direction only.

Boundary conditions are as follows.

On the free surface $z = h_0 + \eta$,

$$\left. \begin{aligned}
 p &= 0 \\
 \eta_t + u\eta_x + v\eta_y &= w \\
 \tau &= 0
 \end{aligned} \right\} \text{----- (2)}$$

On the sea bottom $z = h(x)$

$$\left. \begin{aligned}
 uh_x &= w \\
 \tau &= \tau_b
 \end{aligned} \right\} \text{----- (3)}$$

At the side wall of the channel $y = \pm b(x)$,

$$ub_x = \pm v \quad \text{----- (4)}$$

In these expressions, it is assumed that the centerline of the channel coincides with the x-axis and the water depth does not vary in the y-direction.

Equations and conditions are expressed in dimensionless form by using Johnson's method [7] and are expanded into series by Kakutani's method of perturbation [2]. The details are not stated here because they are almost the same as are given in one of the author's previous papers, except that the bottom friction is developed as $\tau = \epsilon^{1/2} \tau_0 + \epsilon^{3/2} \tau_1 + \text{----}$. With this expression, the effect of the bottom friction does not appear in the first order approximation but in the second approximation.

Solutions of the first order approximation are given as follows.

$$u_0 = \frac{1}{V_0} \eta_0, v_0 = 0, w_0 = \frac{1}{d} \eta_0 \xi (1 - d - z), p_0 = \eta_0$$

----- (5)

where every quantities are expressed in terms of the elevation of free surface η_0 . Up to this point, no restriction is given to the wave profile.

Second order approximation is solved and every terms are expressed again in terms of η_0 and are integrated once with respect to the y-direction in order to include the side wall condition in the equation, and vertically once thus taking into consideration the bottom and free surface conditions. Finally we have the following equation for the first order surface elevation in dimensional expression.

$$\eta_x + \frac{3}{2} g^{-1/2} d^{-3/2} \eta \eta_\xi + \frac{1}{6} g^{-3/2} d^{1/2} \eta_{\xi\xi\xi} + \frac{1}{4} d^{-1} d_x \eta$$

$$+ \frac{1}{2} b^{-1} b_x \eta + \frac{1}{2} C_1 d^{-2} \eta |\eta| = 0$$

----- (6)

in which the subscript 0 is omitted for simplicity. Letter subscripts in the equation denote differentiation with respect to them.

The first term in the equation denotes the spatial rate of change in wave profile and others are the causes. The second term is the effect of finite amplitude, referred hereafter, as the effect of nonlinearity. The third is the effect of dispersion. The fourth is the effect of the variable water depth. With these four terms only, the equation is reduced to Kakutani's equation.

The fifth term gives the effect of the variable width of the channel. With this term included, the equation is extended to two dimensional cases which are important in practical problems such as refraction problem. The bottom friction is given by the last term in which the bottom friction is expressed as $\tau = \rho C_1 u |u|$.

Notations used are as follows. The term x denotes the horizontal distance, ξ a modified time defined by $\xi = \int (1/\sqrt{gd}) dx - t$, t the actual time, g the acceleration of gravity, d the undisturbed water depth, b the width of the channel and C_1 the friction coefficient.

EXAMPLES OF SOLUTION

Decay of linear long waves

Equation (6), with the second and third terms neglected, is reduced to

$$\frac{\eta_x}{\eta} + \frac{1}{2} \frac{b_x}{b} + \frac{1}{4} \frac{d_x}{d} + \frac{C_1}{2} \frac{|\eta|}{d^2} = 0$$

----- (7)

and the solution is

$$\eta b^{1/2} d^{1/4} = \eta_0 b_0^{1/2} d_0^{1/4} \exp\left[-\int_{x_0}^x \frac{C_1}{2} \frac{|\eta|}{d^2} dx\right] \quad \text{----- (8)}$$

If the friction term is neglected, the equation is reduced to Green's law of shoaling.

For a sinusoidal wave in a channel of constant depth and width, when the effect of bottom friction is assumed small enough to be replaced by an equivalent linear friction, then for a small travel distance x , the wave profile is given by

$$\eta = \eta_0 \exp\left[-\frac{4a_0}{3} \frac{x}{d^2}\right] \quad \text{-----(9)}$$

where a_0 is the initial wave amplitude.

Decay of shallow water waves due to bottom friction

It is assumed here that the depth and width of the channel are constant. Equation (6) is reduced to the following expression.

$$\eta_x + \frac{3}{2} g^{-1/2} d^{-3/2} \eta \eta_\xi + \frac{C_1}{2} d^{-2} \eta |\eta| = 0 \quad \text{----- (10)}$$

For the positive η , the equation is simply expressed by

$$\eta_x + A\eta \eta_\xi + B\eta^2 = 0 \quad \text{----- (11)}$$

and its solution which satisfies the boundary condition $\eta = f(-t)$ at $x = x_0$ is given by

$$\eta = \frac{f\left[\xi + \frac{A}{B} \ln\{1 - B\eta(x - x_0)\}\right]}{1 + B(x - x_0) f\left[\xi + \frac{A}{B} \ln\{1 - B\eta(x - x_0)\}\right]} \quad \text{----- (12)}$$

For the negative η , B in the equation is replaced by $-B$. In these expression $A = 3/2 \cdot g^{-1/2} d^{-3/2}$, and $B = C_1 d^{-2}/2$.

CHANGE IN WAVE HEIGHT OF CNOIDAL WAVESEquation

For simplicity, equation (6) is written as

$$\eta_x + \alpha_1 \eta \eta_{\xi} + \alpha_2 \eta_{\xi} \eta_{\xi} + \alpha_3 \eta |\eta| + \alpha_4 \eta = 0 \quad \text{----- (13)}$$

The wave profile is divided into two parts; the one is the principal part η_0 which is cnoidal waves and the other minor part a modification.

$$\eta_0 = H \operatorname{cn}^2 \beta + \delta, \quad \beta = A[\xi - Bx], \quad A = \frac{1}{k} \left[\frac{3gH}{4d^2} \right]^{1/2} \quad \text{----- (14)}$$

It is assumed that the principal part of the wave profile always keeps the cnoidal shape. Main change can occur in its wave height, phase and the position of wave trough. And even if the higher order term is included, the latter should not increase secularly with respect to x . Otherwise, at some time later, the magnitude of the higher order term exceeds that of the basic cnoidal waves and, then, the perturbation applied here is no longer valid. As for the details of the manipulation, one can refer References [1], [8] and [9].

Under this assumption, the following equation is derived and gives the change in wave height.

$$\frac{1}{H} \frac{dH}{dx} - \frac{1}{2U} \frac{dU}{dx} + \alpha_4 + \frac{\delta}{H} \frac{I_2}{I_1} \left[\frac{1}{H} \frac{dH}{dx} - \frac{1}{U} \frac{dU}{dx} + \alpha_4 \right] + \alpha_3 H \frac{I_0}{I_1} = 0 \quad \text{----- (15)}$$

where U^2 is a kind of Ursell's parameter defined by gHT^2/d^2 , and others are as follows.

$$\left. \begin{aligned} \alpha_3 &= \frac{C_1}{2} d^{-2} \\ \alpha_4 &= \frac{1}{2} b^{-1} b_x + \frac{1}{4} d^{-1} d_x \\ \delta &= -\frac{H}{k^2} \left[\frac{E}{K} - k'^2 \right] \\ I_0 &= \int_{-k}^k \left(\operatorname{cn}^2 \beta + \frac{\delta}{H} \right)^2 \left| \operatorname{cn}^2 \beta + \frac{\delta}{H} \right| d\beta \\ I_1 &= \int_{-k}^k \operatorname{cn}^4 \beta d\beta \\ I_2 &= \int_{-k}^k \operatorname{cn}^2 \beta d\beta \end{aligned} \right\} \quad \text{----- (16)}$$

There are difficulties in the above equation if one want to solve it analytically. They are due to two terms, $\delta I_2/HI_1$ and I_0/I_1 .

Approximations of $\delta I_2/HI_1$ and I_0/I_1 for large Ursell's parameter

For Ursell's parameter larger than 50, the following approximation was obtained in Ref. [1],

$$\frac{\delta I_2}{HI_1} = - \frac{2\sqrt{3}}{U} \quad \text{----- (17)}$$

and if we allow errors of 3.5 % at most, this approximation is extended down to $U^2 = 40$.

As for another coefficient I_0/I_1 , we have to approximate it in a form convenient for integration. At first the integral I_0 is rewritten as follows for convenience of numerical computation.

$$\begin{aligned} I_0 &= \int_{-k}^k (cn^2\beta + \frac{\delta}{H})^2 |cn^2\beta + \frac{\delta}{H}| d\beta \\ &= 2 \int_0^k (cn^2\beta + \frac{\delta}{H})^2 |cn^2\beta + \frac{\delta}{H}| d\beta \\ &= 2 \int_0^{\beta_1} (cn^2\beta + \frac{\delta}{H})^3 d\beta - 2 \int_{\beta_1}^k (cn^2\beta + \frac{\delta}{H})^3 d\beta \\ &= 4 \int_0^{\beta_1} (cn^2\beta + \frac{\delta}{H})^3 d\beta - 2 \int_0^k (cn^2\beta + \frac{\delta}{H})^3 d\beta \end{aligned} \quad \text{----- (18)}$$

where β_1 is the value which satisfies

$$cn^2\beta_1 + \frac{\delta}{H} = 0 \quad \text{----- (19)}$$

The above equation is approximated for large Ursell's parameter, that is, for large K, by

$$I_0 = \frac{16}{15} - \frac{16}{\sqrt{3}} U^{-1} + 32 U^{-2} \quad \text{----- (20)}$$

Figure 1 shows the comparison between numerical value of I_0 and its approximation, Eq.(20). Taking into consideration the fact that Eq.(20) is no longer applicable down to $U^2 = 100$ and is still inconvenient for integration, a set of I_0/I_1 shown in Table 1 is proposed as the approximation for integration.

Fig.1. I_0 as a function of Ursell's parameter

U^2	I_0 / I_1
40 - 200	$0.05254 U^{4/5}$
200 - 1 000	$0.1516 U^{2/5}$
1 000 - 2 500	$0.3025 U^{1/5}$
2 500 -	$\frac{4}{5} (1 - \frac{5\sqrt{3}}{U})$

Table 1. Approximate values of I_0/I_1

Case 1. Constant depth and constant width

To examine the validity of the expression of the bottom friction and to correlate the friction coefficient for cnoidal waves to Kajiura's theories, solutions without the topographical effect are derived and are to be compared with experimental results. Since d is constant in this case, Ursell's parameter varies with wave height H . Then, we have

$$U^2 = \frac{gT^2}{d^2} H = \frac{H}{D}, \quad \frac{H}{x} = 2 \frac{U}{x} \quad \text{----- (21)}$$

where D is d^2/gT^2 and takes a constant value, because the wave period T is also considered constant.

For Ursell's parameter between 40 and 2500, the coefficient I_0/I_1 is expressed by

$$\frac{I_0}{I_1} = F U^m / 5 \quad \text{----- (22)}$$

where F and m are constant for given ranges of Ursell's parameter and are given in Table 1.

Equation (15) is now reduced to

$$\frac{3}{2} [U^{-1} - \frac{4}{\sqrt{3}} U^{-2}] \frac{dU}{dx} + \alpha_3 DFU^{(10+m)/5} = 0 \quad \text{----- (23)}$$

or further to

$$[U^{-1-(10+m)/5} - \frac{4}{\sqrt{3}} U^{-1-(15+m)/5}] dU + \frac{2}{3} \alpha_3 DF dx = 0 \quad \text{----- (24)}$$

and the solution is given by

$$\begin{aligned} & \left(\frac{U_0}{U} \right)^{(10+m)/5} \left[1 - \frac{4}{\sqrt{3}} \frac{10+m}{15+m} \frac{1}{U} \right] - \left[1 - \frac{4}{\sqrt{3}} \frac{10+m}{15+m} \frac{1}{U_0} \right] \\ & = \frac{10+m}{15} \frac{C_1}{gT^2} F x U_0^{(10+m)/5} \quad \text{----- (25)} \end{aligned}$$

where the subscript $_0$ denotes the value at a reference point $x = 0$.

Although the wave height is given by Eq.(25), the equation is still a little complicated. More simple relationship, if obtained, is convenient for practical purpose. Therefore, the Ursell's parameter in the first square bracket is replaced by U_0 . A numerical examination shows that if the wave height H remains larger than $0.8H_0$, this replacement yields 3 % errors at most. The wave height H_0 is the wave height at the beginning of an interval where the bottom friction is not negligible and H is the wave height at its end. With the distance x of the interval well chosen so as to satisfy this restriction, wave height can be predicted by simple formulae as shown in Table 2.

For Ursell's parameter larger than 2500, Eq.(15) becomes of the following form.

$$\left(\frac{3}{2} \frac{1}{U} - \frac{2\sqrt{3}}{U^2} \right) \frac{dU}{dx} + \frac{4}{5} \left(1 - \frac{5\sqrt{3}}{U} \right) \alpha_3 DU^2 = 0 \quad \text{----- (26)}$$

For this range of Ursell's parameter, $5\sqrt{3} U^{-1}$ is not larger than 0.17 and the following approximation is used in the integration.

$$\left(1 - \frac{4}{\sqrt{3}} \frac{1}{U} \right) / \left(1 - 5\sqrt{3} \frac{1}{U} \right) \approx 1 + \frac{11}{\sqrt{3}} \frac{1}{U}$$

The solution is given as follows.

$$\left(\frac{U_0}{U}\right)^2 \left[1 + \frac{22}{3\sqrt{3}} \frac{1}{U}\right] - \left[1 + \frac{22}{3\sqrt{3}} \frac{1}{U_0}\right] = \frac{16}{15} \alpha_3 D U_0^2 x \quad \text{----- (27)}$$

Again the fact that $22/3\sqrt{3} \cdot U^{-1}$ is smaller than 0.15 is taken into consideration and U in the first square bracket is replaced by U_0 . The result is also listed in Table 2.

For a solitary wave as a limit when Ursell's parameter tends to infinity, we have

$$H = H_0 / \left(1 + \frac{8}{15} \frac{C_1 H_0 x}{d^2}\right) \quad \text{----- (28)}$$

If one prefer Manning's n in place of C_1 used in the present paper, he can replace C_1 by $gn^2 d^{-1/3}$ although there is an unsolved problem, that is, how to determine the value of n for unsteady flow.

$$40 < gHT^2/d^2 < 200$$

$$\left(\frac{H_0}{H}\right)^{7/5} - 1 = 0.0490 \frac{C_1 x}{gT^2} \left(\frac{gH_0 T^2}{d^2}\right)^{7/5} / \left[1 - 1.70 \left(\frac{gH_0 T^2}{d^2}\right)^{-1/2}\right]$$

$$200 < gHT^2/d^2 < 1000$$

$$\left(\frac{H_0}{H}\right)^{6/5} - 1 = 0.121 \frac{C_1 x}{gT^2} \left(\frac{gH_0 T^2}{d^2}\right)^{6/5} / \left[1 - 1.63 \left(\frac{gH_0 T^2}{d^2}\right)^{-1/2}\right]$$

$$1000 < gHT^2/d^2 < 2500$$

$$\left(\frac{H_0}{H}\right)^{11/10} - 1 = 0.222 \frac{C_1 x}{gT^2} \left(\frac{gH_0 T^2}{d^2}\right)^{11/10} / \left[1 - 1.59 \left(\frac{gH_0 T^2}{d^2}\right)^{-1/2}\right]$$

$$2500 < gHT^2/d^2$$

$$\frac{H_0}{H} - 1 = \frac{8}{15} \frac{C_1 H_0 x}{d^2} / \left[1 + 4.23 \left(\frac{gH_0 T^2}{d^2}\right)^{-1/2}\right]$$

Table 2. Decay of wave height in case of $\alpha_4 = 0$

Case 2. Cnoidal waves in general case

Almost similar calculation is possible for this case except that the water depth in Ursell's parameter is also variable. The following relationship should be substituted in place of Eq.(21).

$$\frac{2}{U} \frac{dU}{dx} = \frac{1}{H} \frac{dH}{dx} - \frac{2}{d} \frac{dd}{dx} \quad \text{----- (29)}$$

The equation to be solved is

$$\begin{aligned} & \frac{1}{U} \frac{dU}{dx} + \frac{1}{3} \frac{1}{b} \frac{db}{dx} + \frac{3}{2} \frac{1}{d} \frac{dd}{dx} + \frac{2}{3} \frac{\delta}{H} \frac{I_2}{I_1} \left[\frac{1}{U} \frac{dU}{dx} + \frac{1}{2} \frac{1}{b} \frac{db}{dx} + \frac{9}{4} \frac{1}{d} \frac{dd}{dx} \right] \\ & + \frac{2}{3} \alpha_3 H \frac{I_0}{I_1} = 0 \quad \text{----- (30)} \end{aligned}$$

For Ursell's parameter between 40 and 2500, the equation is further reduced to the following with the aid of Eqs.(17) and (22).

$$\begin{aligned} & \frac{1}{U} \frac{dU}{dx} \left[1 - \frac{4}{\sqrt{3}} \frac{1}{U} \right] + \frac{1}{2} \left[\frac{1}{b} \frac{db}{dx} + \frac{9}{2} \frac{1}{d} \frac{dd}{dx} \right] \left[\frac{2}{3} - \frac{4}{\sqrt{3}} \frac{1}{U} \right] \\ & + \frac{2}{3} \frac{C_1}{2gT^2} F U^{(10+m)/5} = 0 \quad \text{----- (31)} \end{aligned}$$

The solution is given by

$$U^2 (U - 2\sqrt{3}) b d^{9/2} \exp \left[\int \frac{C_1 F}{gT^2} \frac{U^{(15+m)/5}}{U - 2\sqrt{3}} dx \right] = \text{const.} \quad \text{----- (32)}$$

The value of U in the exponential function of the equation can be replaced by U₀ under the same consideration as in case of constant depth and width of the channel. In terms of wave height H, the relationships are shown in Table 3.

For Ursell's parameter larger than 2500, the equation is given by

$$\frac{2}{U} \frac{dU}{dx} + \frac{1}{U - 2\sqrt{3}} \frac{dU}{dx} + \frac{1}{b} \frac{db}{dx} + \frac{9}{2} \frac{1}{d} \frac{dd}{dx} + \frac{4}{5} \frac{C_1}{gT^2} U^2 \frac{U - 5\sqrt{3}}{U - 2\sqrt{3}} = 0 \quad \text{----- (33)}$$

and the solution is

$$\frac{U^2(U - 2\sqrt{3}) b d^{9/2}}{U_0^2(U_0 - 2\sqrt{3}) b_0 d_0^{9/2}} = \exp\left[-\frac{4}{5} \frac{C_1}{gT^2} U^2 \frac{U - 5\sqrt{3}}{U - 2\sqrt{3}} dx\right]$$

----- (34)

In terms of H, the result is also shown in Table 3.

With C_1 set equal to zero, that is, with no friction, the right-hand sides of the results in Table 3 are reduced to unity and they coincide with the result of the author's previous paper which discussed the shoaling of cnoidal waves.

$$\frac{Hb d^{5/2} (\sqrt{gHT^2/d^2} - 2\sqrt{3})}{H_0 b_0 d_0^{5/2} (\sqrt{gH_0 T^2/d_0^2} - 2\sqrt{3})}$$

$$40 < gHT^2/d^2 < 200$$

$$= \exp\left[-\frac{0.05254 C_1 x}{gT^2} \left(\frac{gH_0 T^2}{d_0^2}\right)^{9/5} / \{\sqrt{gH_0 T^2/d_0^2} - 2\sqrt{3}\}\right]$$

$$200 < gHT^2/d^2 < 1000$$

$$= \exp\left[-\frac{0.1516 C_1 x}{gT^2} \left(\frac{gH_0 T^2}{d_0^2}\right)^{17/10} / \{\sqrt{gH_0 T^2/d_0^2} - 2\sqrt{3}\}\right]$$

$$1000 < gHT^2/d^2 < 2500$$

$$= \exp\left[-\frac{0.3025 C_1 x}{gT^2} \left(\frac{gH_0 T^2}{d_0^2}\right)^{8/5} / \{\sqrt{gH_0 T^2/d_0^2} - 2\sqrt{3}\}\right]$$

$$2500 < gHT^2/d^2$$

$$= \exp\left[-\frac{4C_1 H_0 x}{5 d_0^2} \{\sqrt{gH_0 T^2/d_0^2} - 5\sqrt{3}\} / \{\sqrt{gH_0 T^2/d_0^2} - 2\sqrt{3}\}\right]$$

Table 3. Change in wave height of cnoidal waves under the effects of variable water depth, variable channel width and bottom friction

EXPERIMENTAL PROCEDURE

Experiments were carried out in a wave flume 50 m long, 1 m wide and 1 m high. First series of the experiments was carried out in a channel of constant depth. Water depths during the experiments were kept 10 cm, 20 cm and 30 cm. Wave period was kept constant as 2 sec. Wave heights were varied between 2 cm at minimum and 12 cm at maximum. At the end of the channel, a permeable slope of 1 on 25 was installed, packed with waste films. Even with this wave absorber, we had normally 7-8 % reflection from this end of the channel. The maximum reflection observed during experiments was about 10 %.

Artificial rectangular roughnesses were planted on the bottom in the middle part of the channel. Height and width of a roughness are the same and 8 mm. Its length is 1 m and can cover the whole width of the channel. Spacing of the roughnesses is 8 cm. The roughnesses were arranged at right angles to the direction of wave propagation. Total length of roughened bed measured along the direction of wave propagation is 10 m. From the beginning of this area, wave heights are measured at every 1 m intervals. Since the reflection is not completely negligible, we draw, by using the experimental results, average curves of the change in wave height, from which the friction coefficient C_f is estimated.

In the second series of the experiments, a slope of 1 on 20 was installed. Total horizontal length of the slope was 6 m. Water depths at the toe of the slope were 40 cm, 45 cm and 50 cm. From the upper end of the slope, continues another horizontal bed, on which water depths during the experiments were 10 cm, 15 cm and 20 cm. The same roughnesses as in the first series of experiments were planted on the surface of the slope. Wave height was measured at every 50 cm intervals on the slope. Wave periods were varied between 2 sec and 10 sec. Wave heights at the toe of the slope were varied from 1.5 cm to 10 cm.

COMPARISON BETWEEN THEORY AND EXPERIMENTCharacteristics of roughness in steady flow

According to Adachi's empirical formula [6], the effect of the rectangular ribs arranged at right angles to the stream is expressed in terms of Nikuradse's equivalent sand roughness k'_s by the following relationship.

$$k'_s = 30 k m (R_1 / k)^{-\theta} \quad \text{----- (35)}$$

where R_1 is the hydraulic radius of the channel, k is the height of a roughness, s is the spacing of the roughnesses, m and θ are functions of s and k which were experimentally determined by Adachi.

$$m = 0.79 (s/k)^{-0.26} \quad \text{-----} \quad (36)$$

$$\theta = 0.02 (s/k)^{0.8}$$

The roughness length z_0 is defined by $k'_s/30$. For example, $z_0 = 0.23$ cm for $d = 30$ cm, $k = 8$ mm and $s = 8$ cm.

The friction coefficient C_1 for steady flow is computed by

$$C_1 = [6.0 + 5.75 \log_{10} (d/k'_s)]^{-2} \quad \text{-----} \quad (37)$$

and is 0.0227, 0.0137 and 0.0108 for water depth 10 cm, 20 cm and 30 cm, respectively, in the first series of the experiments.

Estimation of the friction coefficient by Kajiura's theories

Field data and experimental results obtained by many researchers show that the friction coefficient under wave action is different from that in steady flow. Kajiura established two theories, on considering the average state of turbulence over one wave period and adopting the assumption of the eddy viscosity analogous to that for the steady turbulent flow. According to his theories, the frictional coefficient is given as a function of certain dimensionless parameters constructed from known quantities of wave and bottom conditions.

Kajiura's theories are based on the assumption that the oscillatory motion is sinusoidal and the present theory used the cnoidal waves. Direct substitution of the results of Kajiura's theory is not recommended. In order to connect two different definitions of the friction coefficients, mean energy dissipation of sinusoidal motion is equated with that of cnoidal waves.

For the case of long period waves [4], in which the flow is fully turbulent, the mean energy dissipation is

$$\langle E \rangle = \frac{\rho}{2} \frac{8}{3\pi} \hat{C}_{k1} \cos \theta \hat{U} \hat{u}^2 \quad \text{-----} \quad (38)$$

where \hat{u} is the amplitude of the mean velocity vertically averaged over the water depth. The angle θ denotes the phase lead of the bottom stress relative to the vertically averaged velocity and \hat{U} is the amplitude of a formally defined velocity corresponding to the pressure gradient.

For the case of short period waves [5], in which the thickness of the bottom frictional layer is very thin compared with the total depth of water, the mean energy dissipation is given by

$$\langle E \rangle = \frac{\rho}{2} \hat{C}_{k2} \cos\theta \hat{U}^3 \quad \text{-----} \quad (39)$$

where \hat{U} is the amplitude of the horizontal velocity at the top of the bottom frictional layer. The angle θ denotes the phase lead of the bottom stress relative to the velocity at the top of the frictional layer.

For cnoidal waves in the present paper, the mean energy dissipation is given by

$$\langle E \rangle = \frac{\rho}{2} 16 I C_1 \hat{u}^3 \quad , \quad I = I_0 / 2K \quad \text{-----} \quad (40)$$

where \hat{u} is the amplitude of the horizontal velocity which is vertically uniform and I is given in Table 4 in simple expressions convenient for practical application.

Equating these three formulas, the coefficient used in the present paper can be estimated from Kajiura's theories.

$$\hat{C}_{k2} \cos\theta = \frac{\rho}{3\pi} \hat{C}_{k1} \cos\theta \left(\frac{\hat{u}}{\hat{U}} \right)^2 = 16 I C_1 \left(\frac{\hat{u}}{\hat{U}} \right)^3 \quad \text{----} \quad (41)$$

$gHT^2/d^2 = U^2$	I
40 - 200	$0.08089 U^{-1/5}$
200 - 1000	$0.2334 U^{-3/5}$
1000 - 2500	$0.4657 U^{-4/5}$
2500 -	$\frac{32}{15\sqrt{3}} \left(1 - \frac{5\sqrt{3}}{U} \right) \frac{1}{U}$

Table 4. Values of I

Experimental results in case of horizontal bottom

The friction coefficients are determined from the experimental results, converted, by means of Eq.(41), to Kajiura's definition of the friction coefficient, and plotted in Fig.2. In the same figure, Kajiura's theories are given by two oblique lines, and three short horizontal lines correspond to the friction coefficients in steady flow.

Fig. 2. Friction coefficients compared with Kajiura's theories and Adachi's formula

The friction coefficients in steady flow show very small values and are unable to be used for practical estimation of decay of water waves in shallow sea. The experimental results fall between Kajiura's theories. This suggests that the conversion formula given above is practically valid.

Taking into account the fact that the size of the roughness in the experiments is very big compared to the water depth and this condition does not frequently occur under natural conditions, it is concluded that the present theory with the friction coefficient converted from Kajiura's first theory can be used to predict the change in height of tsunamis and storm surges, while if combined with Kajiura's second theory it can be used to compute the case of wind waves and swells in shallow water.

Change in wave height on a slope

Since the method of evaluating the friction coefficient from given wave and bottom conditions is established, the present theory is compared with the second series of experiments. Figure 3 shows an example. Although values of friction coefficient varies with water depth on the slope, average value, 0.1 for this case, is used in calculation. Broken line in the figure shows the shoaling of cnoidal waves when no friction is taken into account. Solid line is with friction and agrees fairly well with experimental results. Scattering of the experimental data is considered due mainly to the reflection from the slope and the wave absorber installed at the end of the flume.

Fig.3. Change in wave height on a slope.

CONCLUSIONS

A fundamental equation for long waves is derived by using Kakutani's and Johnson's methods. The equation includes the effects of nonlinearity, dispersion, water depth, width of the channel and bottom friction.

In addition to several solutions obtained in analytical form, the change in wave height of cnoidal waves is given and listed in Tables 2 and 3. In order to obtain as simple and convenient formulas as possible, imposed, during the derivation, were restrictions which should be remembered at application. The length of an interval, x , should be well chosen so as that the wave height H at the end of the interval remains larger than 0.8 times H_0 , the wave height at the beginning of the interval. If this restriction is not welcome, Eqs.(25) and (27) should be used in place of formulas in Table 2, or H_0 in the right-hand sides of the equations in Table 3 should be replaced by H .

The friction coefficient C_1 is estimated from known quantities of wave and bottom conditions. In the present experiments, artificial rectangular ribs are used, the roughness length, z_0 , of which is evaluated from Adachi's empirical formula. This roughness length and wave characteristics gives the friction coefficient for sinusoidal waves, if one follows Kajiuura's theories. Kajiuura assumed sinusoidal waves and the present theory cnoidal waves. Conversion of the friction coefficient between the two different motions is possible through Eq.(41), provided that the mean energy dissipation is the same for the two motions.

From the first series of experiments, the method of estimation of the friction coefficient is confirmed. Results of the second series of the experiments show that the theoretical prediction of the change in wave height on a slope agrees very well with experiments.

It is concluded that the present theory combined with Kajiura's first theory which assumes that the flow is fully turbulent gives good estimation of the change in wave height of tsunamis and storm surges, and that with Kajiura's second theory which assumes a thin bottom frictional layer the theory predicts the change in height of swells and wind waves in shallow water.

CHAPTER 25

RECENT DEVELOPMENTS IN THE STUDY OF BREAKING WAVES

by

Michael S. Longuet-Higgins

Oceanographic Sciences, Wormley, Godalming, Surrey

1. INTRODUCTION

The sight and sound of breaking waves and surf is so familiar and enjoyable that we tend to forget how little we really understand about them. Why is it, that compared to other branches of wave studies our knowledge of breaking waves is so empirical and inexact?

The reason must lie partly in the difficulty of finding a precise mathematical description of a fluid flow that is in general nonlinear and time-dependent. The fluid accelerations can no longer be assumed to be small compared to gravity, as in Stokes's theory for periodic waves and the theory of cnoidal waves in shallow water, nor is the particle velocity any longer small compared to the phase velocity.

The aim of this paper is to bring together some recent contributions to the calculation both of steep symmetric waves and of time-dependent surface waves. These have a bearing on the behaviour of whitecaps in deep water and of surf in the breaker zone.

Since spilling breakers in gently shoaling water closely resemble solitary waves, we begin with the description of solitary waves of limiting amplitude, then discuss steep waves of arbitrary height. The observed intermittency of whitecaps is discussed in terms of the energy maximum, as a function of wave steepness. In Sections 6 and 7 a simpler description of steady symmetric waves is proposed, using an asymptotic expression for the flow near the wave crest. Finally we describe a new numerical technique (MEL, or mixed Eulerian-Lagrangian) with which it has been found possible to follow the development of periodic waves past the point when overturning takes place.

2. THE LIMITING SOLITARY WAVE

A simple and very accurate approximation to the limiting solitary wave has recently been given by Longuet-Higgins (1974). If x and y are horizontal and vertical coordinates and h the undisturbed depth of water, then the surface profile on one side ($x > 0$) is approximated by

$$y/h = Ae^{-\lambda x/h} + Be^{-\mu x/h} \quad (2.1)$$

The constants A , B and λ , μ are determined by the conditions, first, that the particle at the crest moves with the phase-speed $c = F\sqrt{gh}$. So from Bernoulli's equation,

$$y/h = \frac{1}{2}F^2 \quad (x = 0), \quad (2.2)$$

Secondly, the angle of inclination at the surface is -30° , so

$$dy/dx = -1/\sqrt{3} \quad (x = 0). \quad (2.3)$$

We know thirdly (see Lamb, 1932 § 252), that in the outer fringes of the wave ($x \rightarrow \infty$) the profile behaves asymptotically like $e^{-\lambda x}$, where

$$\frac{\tan \lambda}{\lambda} = F^2 \quad (2.4)$$

exactly. This is satisfied by (2.0) if $0 < \lambda < \mu$. Fourthly we have Starr's exact relation

$$3V/g = (F^2 - 1) M \quad (2.5)$$

where V is the potential energy and M the mass:

$$V/g = \int_{-\infty}^{\infty} \frac{1}{2} y^2 dx, \quad M = \int_{-\infty}^{\infty} y dx;$$

and lastly an exact relation

$$\int_{-\infty}^{\infty} \left[(1 + y/h)(1 - 2F^{-2}y/h)^{\frac{1}{2}}(1 + dy/dx^2)^{\frac{1}{2}} - 1 \right] dx = 0 \quad (2.6)$$

proved by Longuet-Higgins (1974). Equations (2.2) to (2.6) are five relations to determine the constants A , B , λ , μ and F , giving

$$\left. \begin{aligned} A &= 1.5389, & \lambda &= 1.0495 \\ B &= -0.7093, & \mu &= 1.4630 \\ F^2 &= 1.6592. \end{aligned} \right\} \quad (2.7)$$

The resulting profile, plotted in Figure 1, agrees numerically with that given by Yamada (1957) to within 1% everywhere, and generally to within 0.2%.

Figure 1. (from Longuet-Higgins, 1974). The profile of the highest solitary wave as given by equation (2.1) (solid line) compared with the numerical calculations of Yamada (1957) (circles) and Lenau (1966) (crosses).

3. SOLITARY WAVES OF ARBITRARY HEIGHT

The properties of solitary waves of arbitrary amplitude a in water of undisturbed depth h have been studied in two recent papers by Longuet-Higgins and Fenton (1974) and by Byatt-Smith and Longuet-Higgins (1976) using quite different methods.

It is convenient to define a parameter ω for the family of solitary waves by the equation

$$\omega = 1 - q^2/gh$$

where q is the particle-speed at the wave crest, in a frame of reference moving along with the phase-speed. For waves of small amplitude, $q \approx \sqrt{gh}$ so ω is small, whereas for limiting waves q vanishes, so $\omega = 1$. In general

$$0 < \omega \leq 1 \tag{3.1}$$

and the complete range of ω is precisely known.

Figure 2 shows a succession of wave profiles, computed precisely for moderate values of ω . The height of the waves increases monotonically with ω . This is in qualitative agreement with the approximate Rayleigh-Boussinesq theory, in which

$$\left. \begin{aligned} y/h &\approx \frac{1}{3} \alpha^2 \operatorname{sech}^2(\frac{1}{2} \alpha x) \\ F^2 &= 1 + \frac{1}{3} \alpha^2 \end{aligned} \right\}$$

and so

$$\omega = 1 - (F^2 - 2a/h) \frac{1}{3} \alpha^2 \approx a/h \tag{3.2}$$

and ω increases almost linearly with a/h . As the wave height increases, so the horizontal width of the profile decreases, like $1/\alpha$ or $(a/h)^{-1/2}$. This implies that successive profiles must intersect each other, and from Figure 2 it is clear that as the amplitude increases, so the point of intersection gradually moves in towards the wave crest.

Figure 2. (from Byatt-Smith and Longuet-Higgins, 1976). Profiles of solitary waves at moderate values of the parameter ω .

At finite values of the wave steepness the acceleration near the crest becomes comparable with g and the approximate Rayleigh-Boussinesq theory is no longer valid. An exact theory was however calculated by two methods. In Longuet-Higgins and Fenton (1974) the Rayleigh-Boussinesq theory was treated as the first term in an infinite series in powers of ω , which was carried to high order and then summed by rational approximants (Padé sums). All integral properties converged, up to and including $\omega = 1$, and from these it was possible to calculate also the dimensionless phase-speed F .

Figure 3 shows the dimensionless phase-speed calculated by means of Padé sums, and plotted as a function of the wave steepness a/h . After increasing steadily with a/h , F reaches a maximum and then actually decreases at higher values of a/h . The maximum speed $F = 1.294$ occurs when $a/h = 0.790$, whereas the speed of the highest wave is only $F = 1.286$.

The presence of a maximum in the phase-speed is at first sight surprising, since it implies that over a certain range of steepnesses there can exist two distinct solitary waves in the same depth of water, having the same phase-speed. The reason becomes

Figure 3. The dimensionless phase-speed $F = c/\sqrt{gh}$ for solitary waves, as a function of the relative crest height a/h .

Figure 4. (from Byatt-Smith and Longuet-Higgins, 1976). The form of steep solitary waves close to the wave crest.

Figure 5. Comparison of the profiles of two steep solitary waves ($\omega = 0.90$ and 0.96).

apparent from Figure 4. This shows some accurately calculated profiles near the wave crest, from $\omega = 0.90$ to $\omega = 0.96$. Evidently the trend begun at the lower wave amplitudes in Figure 2 continues, and as ω increases the point of intersection moves up close to the wave crest. The situation is shown more clearly in Figure 5, from which it will be seen that the higher of the two waves, corresponding to $\omega = 0.96$ actually lies below the lower wave ($\omega = 0.90$) over most of the wave profile. This implies that the average elevation of the higher wave is actually less than that of the lower wave.

Now Starr's exact relation (2.5) can be written in the form

$$(F^2 - 1) = \frac{3}{2} \bar{y}/h \quad (3.3)$$

where \bar{y} is the average surface elevation, defined by

$$\bar{y} = \frac{\int_{-\infty}^{\infty} y^2 dx}{\int_{-\infty}^{\infty} y dx} \quad (3.4)$$

So if \bar{y} decreases as ω increases, so also must F decrease, by equation (3.2).

Although the completeness of the Rayleigh series was questioned by Witting (1975), nevertheless the existence of the maximum speed has been confirmed by a quite different method of calculation based on the integral equation of Byatt-Smith (1970) for solitary waves. In his first paper, Byatt-Smith took the phase-speed F as an independent parameter in the integral equation, and from it calculated the wave height and profile. He was unable to obtain solutions with F greater than about 1.294, and in this neighbourhood convergence was slow. The explanation is apparently that in this neighbourhood a small change in F corresponds to a large change in the profile. But in a second paper (Byatt-Smith and Longuet-Higgins, 1976) ω was taken as independent parameter, and the wave speed F as dependent variable. The solutions converged rapidly and the maximum in F was verified (see Figure 6).

Figure 6. (from Byatt-Smith and Longuet-Higgins, 1976). The dimensionless phase-speed F at high values of ω , calculated by two different methods.

4. WAVES ENTERING SHALLOW WATER

In addition to the maximum in the phase-speed, Longuet-Higgins and Fenton (1974) also found maxima in the mass, momentum and energy of solitary waves, as a function of a/h or of ω (see Figure 7). This has implications for waves entering gradually shoaling water. For, in the absence of appreciable dissipation, the energy E_1 of a solitary wave might be expected to remain a constant. As the mean depth h diminished, the dimensionless energy $E = E_1/\rho gh^3$ would be expected to increase, at first. So, provided the wave remained symmetrical it would be represented by a point travelling up the curve in Figure 7, with both E and a/h increasing.

Before the maximum value of E is reached, however, the wave must leave the energy curve, which it generally does by becoming unsymmetrical and then spilling or plunging forwards (see Section 8). If it plunges heavily, it becomes radically altered. But if it spills gently, it may thereby dissipate enough energy to travel on down the curve more or less as a symmetric wave damped by a whitecap on the forward face. This

Figure 7. (from Longuet-Higgins and Fenton, 1974). The normalised mass M , momentum I and energy E of a solitary wave, as a function of the relative height a/h .

presumably is a spilling breaker, for which a theory has recently been given by Longuet-Higgins and Turner (1974). In their model, the whitecap was represented as a gravity-current, of density ρ' less than unity, riding down the forward face of an irrotational wave and exchanging mass and momentum by entrainment across the interface. Calculations showed that the flow could exist provided that ρ'/ρ was of order 0.7 (similar to the ratio observed in hydraulic jumps) and that the surface slope exceeded an angle of about 20° .

In this model, however, and also according to observation, the length of the whitecap tends to increase continually*, so producing a disproportionate damping of the wave. What happens when the point in Figure 7 reaches the right-hand edge of the graph, representing the steepest symmetric wave? Longuet-Higgins and Fenton (1974) suggested that it may jump back to a point lower down the curve, representing a wave with almost the same mass and momentum, but with a slightly lower energy. This wave would have a rounded crest and a lower value of a/h . The process might then be repeated.

Some support for this suggestion comes from an analysis of the film of shoaling solitary waves made by Kjeldsen and Olsen (1974). Measurements of the length ℓ of the whitecap as a function of the time t (see Figure 8) show that it increases not continuously but in a series of jumps. At each jump, the crest becomes rounded and a part of the whitecap is lost by being left behind the travelling crest. The remnant appears on the near face of the wave as a patch of aerated water, which quickly subsides.

Figure 8. (from Longuet-Higgins and Turner, 1974). Measurements of the length ℓ of the whitecap on shoaling solitary waves as a function of the time, showing intermittency.

*No allowance was made in this model for loss of buoyancy by air bubbles rising through the upper surface.

5. PERIODIC WAVES

For progressive waves in deep water, it has been shown by Schwartz (1974) that the well-known Stokes expansion in powers of the first harmonic a_1 , which is satisfactory at low wave amplitudes, fails to converge at larger wave amplitudes, short of the highest. This is because the waves become markedly non-sinusoidal, developing narrow crests and broad troughs, and the amplitude a_1 of the first harmonic in fact reaches a maximum and then diminishes before the highest wave is reached. So for steepnesses greater than about 0.1 even the higher-order Stokes expansions are divergent and misleading.

Schwartz (1974) overcame this difficulty by using as expansion parameter the wave steepness H/L itself, which increases monotonically throughout the range of possible waves. However, the limiting value of H/L is not accurately known a priori. As an alternative Longuet-Higgins (1975) used the parameter

$$\omega = 1 - \frac{q^2 q'^2}{c^2 c_0^2} \tag{5.1}$$

where q and q' denote the particle speeds at the crest and trough, in a frame moving with the wave, and where c and c_0 are the wave speed and the speed of infinitesimal waves respectively. This parameter is similar to (3.1) and indeed reduces to (3.1) when the depth is finite and the wavelength infinite. The range of ω is from 0 to 1, the value 1 corresponding precisely to the highest wave.

Figure 9. (from Longuet-Higgins, 1975). The square of the wave amplitude a and wave speed c for progressive waves in deep water, as a function of the parameter ω (equation 5.1). The units are chosen so that $g = 1$ and the wavelength $L = 2\pi$. The wave steepness H/L equals a/π .

By using Padé sums, Longuet-Higgins (1975) obtained convergence up to and including the highest wave ($\omega = 1$). Precisely similar effects as for solitary waves, namely maxima in the speed, energy, momentum, momentum flux, etc., as functions of the wave steepness, made their appearance (see Figure 9).

This result is particularly significant since the Stokes series (with ω as parameter) is formally quite different from the Rayleigh-Boussinesq series for the solitary wave. Yet for Stokes's series no question of completeness arises, since Levi-Civita proved actual convergence, for waves of sufficiently small amplitude.

More recently, Cokelet (1976) has calculated and tabulated the speeds, momenta and other integral properties of symmetric gravity waves of arbitrary amplitude and in waves of arbitrary depth h . His method is to use the general Stokes series for waves in finite depth, with an expansion parameter similar to (5.1). For all ratios of the wavelength to depth, he finds maxima in the phase speeds as a function of the wave steepness. There are maxima also in the momentum, momentum flux, energy and energy flux. These accurate calculations may be of considerable use for practical purposes.

6. ASYMPTOTIC SHAPE OF WAVE CREST

The wave crests in Figure 5 suggest that as $\omega \rightarrow 1$ the profile approaches the 120° corner-flow predicted by Stokes. But when $\omega < 1$, and while the crests are still rounded, is there any smooth asymptotic form which the free surface assumes in some neighbourhood of the crest? A natural length-scale for such an asymptotic form

Figure 10. The crests of steep solitary waves (from Figure 5) after rescaling by $l = q^2/2g$, where q is the particle speed at the crest.

is the length

$$\ell = q^2/2g \tag{6.1}$$

where q denotes the particle speed at the crest in the frame moving with the wave. Comparison with equation (3.1) shows that ℓ is directly related to ω by

$$\ell = \frac{1}{2}h(1 - \omega). \tag{6.2}$$

As a test of the conjecture, Figure 10 shows the same wave profiles as in Figure 5 ($\omega = 0.90$ to 0.94) now drawn on the new scale ℓ . When ω approaches 1 they do indeed tend to fall along the same curve.

To define our limiting flow we may take radial coordinates (r, θ) with the origin O at a distance $\ell = q^2/2g$ above the wave crest, and with the line $\theta = 0$ vertically downwards. The Bernoulli condition at the free surface is then

$$\left| \frac{dX}{dz} \right|^2 = 2gr \cos \theta \tag{6.3}$$

where $X = \phi + i\psi$ is the complex velocity potential and $z = re^{i\theta}$. We require a solution which, as $r/\ell \rightarrow \infty$, tends to the Stokes corner-flow:

$$X \rightarrow \frac{2}{3} g^{1/2} z^{3/2} \quad \text{as } r \rightarrow \infty, \quad |\theta| \leq \frac{\pi}{3}. \tag{6.4}$$

This problem has been solved numerically in a recent paper by Longuet-Higgins and Fox (1976). The resulting profile is shown in Figure 11 (and also by the broken line in Figure 10). Not unreasonably, the free surface crosses its asymptote at about $r/\ell = 3.32$ and then approaches it very gradually from the outside. It can be shown analytically that for large values of r/ℓ the normal displacement n of the surface from the straight-line asymptote must have the form

$$n/\ell \sim K(\ell/r)^{1/2} \cos [(3\mu/2) \ln r - \epsilon] \tag{6.5}$$

where K and ϵ are amplitude and phase constants and μ is the positive root of the equation

$$\frac{\mu\pi}{2} \tanh \frac{\mu\pi}{2} = \frac{\pi}{24\sqrt{3}} \tag{6.6}$$

In fact $K = 0.60$, $\epsilon = 0.47$ and $\mu = 0.714$. This means that the free surface approaches its asymptote in a very slowly damped oscillation. There is a second crossing of the asymptote at $r/\ell = 68.5$, a third at $r/\ell = 1286$, and so on.

Figure 11. (from Longuet-Higgins and Fox, 1976a). The asymptotic profile of the crests of a steep gravity wave, on a scale $\ell = q^2/2g$.

The results can be checked not only by a direct comparison with the profiles of wave crests calculated independently (such as in Figure 10) but also by a consideration of the maximum surface slope. From Figure 11 it will be seen that between the two crossings of the asymptote at $r/l = 3.32$ and $r/l = 68.5$ the maximum angle of slope must slightly exceed 30° . The actual value is 30.37° . This should correspond to the maximum slope of almost-limiting gravity waves.

Now independent calculations of the complete profiles of steep solitary waves have been made both by Sasaki and Murakami (1973) and by Byatt-Smith and Longuet-Higgins (1976). Their values for the maximum surface slope are plotted against ω in Figure 12. It can be seen that a linear extrapolation of the plotted points passes very close to the asymptotic value that we have obtained independently.

Figure 12. (from Longuet-Higgins and Fox, 1976). The maximum surface slope of steep solitary waves, as a function of the parameter ω . The limiting value at $\omega = 1$ corresponds to the profile of Figure 11.

Figure 13 shows a similar comparison for periodic waves in deep water. The agreement is again very close.

Figure 13. (from Longuet-Higgins and Fox, 1976). The maximum surface slope of progressive waves in deep water, as a function of the parameter ω' .

The acceleration of a fluid particle at the wave crest is given by

$$\ddot{y} = -q^2/R$$

where R is the radius of curvature. From the present profile this is found to be $0.39 g$. In the far-field, as $r/l \rightarrow \infty$, the acceleration tends to the value $\frac{1}{2} g$ directed radially outwards, as in the Stokes corner-flow.

7. IMPROVEMENT IN THE CALCULATION OF STEEP GRAVITY WAVES

The maximum slope will in theory exceed 30° only for very steep, symmetric waves and in a limited region near the crest, which may be affected by instabilities, wind pressures and surface tension. Nevertheless the asymptotic solution found in Section 6 may have practical uses. At present the only accurate calculations of steep, symmetric gravity waves have been obtained by mathematical tour-de-force, either by carrying small-amplitude expansions to very high order or by numerical techniques, such as Fourier series or integral equations, which involve lengthy and complicated numerical schemes. The main value of the asymptotic solution just described is that it may be used as an inner solution, valid near the wave crest, and matched asymptotically to an outer solution representing the flow in the remainder of the wave.

The appropriate matching has already been carried out for periodic waves in deep water by the present author and M.J.H. Fox (1976). As a sample of their results, Figure 14 shows a comparison of the square of the wave speed c^2 plotted against the wave steepness. The peculiar shape of the top of the velocity curve is accurately checked, showing that it is certainly not due to some quirk of the Padé approximants.

Such an approach thus promises to simplify our calculations of steep, symmetric waves, and to improve our understanding of them.

Figure 14. Square of the velocity c for progressive waves in deep water, as a function of ω . The plotted points correspond to the values obtained from Padé sums (Longuet-Higgins, 1975; see also Figure 9). The curve is found independently by matching the asymptotic solution in Section 6.

8. A METHOD FOR CALCULATING UNSTEADY SURFACE WAVES

In natural conditions the occurrence of a steady, steep wave is somewhat exceptional. Even symmetric waves tend to become unsteady and asymmetric long before their energy reaches the theoretical maximum. However, a new and general method for calculating the development of an unsteady wave has recently been given by Longuet-Higgins and Cokelet (1976). So far it has been applied only to waves in deep water but it could readily be extended to waves in water of finite depth.

Figure 15. Axes and notation for space-periodic waves in deep water.

The motion is assumed to be irrotational and periodic in space (see Figure 15) though not generally periodic in time. All calculations are carried out with the surface values of the space coordinates (x, y) and of the velocity potential ϕ . For the rates of change of these quantities one has

$$\begin{aligned} \frac{Dx}{Dt} &= \frac{\partial \phi}{\partial x} \\ \frac{Dy}{Dt} &= \frac{\partial \phi}{\partial y} \end{aligned} \tag{8.1}$$

$$\frac{D\phi}{Dt} = -p - gy + \frac{1}{2}(\nabla\phi)^2$$

where D/Dt denotes differentiation following the motion. The last equation follows from the time-dependent Bernoulli equation and the fact that $D\phi/Dt = \partial\phi/\partial t + (\nabla\phi)^2$. Hence, given the surface values of x, y, ϕ and $\nabla\phi$ at some instant t on the surface $C(t)$ one can calculate x, y and ϕ at time $(t + dt)$ on the displaced surface $C(t + dt)$.

To proceed to the next time-step we need to know both components of the velocity on $C(t + dt)$. We can obtain the tangential component $\partial\phi/\partial s$ immediately, by differentiating $\phi(t + dt)$ along the new surface. However we still lack the normal component of velocity $\partial\phi/\partial n$ on $C(t + dt)$.

Now because of the space-periodicity we can transform C into a closed contour C' (Figure 16) simply by writing

$$e^{ik(x + iy)} = \zeta, \quad (k = 2\pi/L). \tag{8.2}$$

Figure 16. One wavelength in the (x, y) plane transformed to a closed domain in the z -plane.

The domain of the fluid goes into the interior of C' and the points at infinite depth go into the origin $z = 0$. We then have to solve, in effect, the well-known Dirichlet problem, namely to find $\partial\phi/\partial n$ on a contour C' , given ϕ on C' and

$$\nabla^2\phi = 0 \quad (8.3)$$

everywhere inside C' .

This problem can be solved as follows (see Figure 16). Let (R, α) denote the polar coordinates of a running point P on the boundary, relative to a fixed point Q , also on C' . Then it follows from Green's theorem that

$$\int_{C'} \frac{\partial\phi}{\partial n} \ln R \, ds = \pi\phi_Q + \int_{C'} \phi_P \, d\alpha \quad (8.4)$$

where in the right-hand integral we take the principle value. Since ϕ is known everywhere on C' , the right-hand side is given, and equation (8.4) is then a linear integral equation for $\partial\phi/\partial n$, with given kernel $\ln R$. Solution of this equation gives us $\partial\phi/\partial n$ on $C(t + dt)$, and the time-stepping can proceed.

Numerical solution of equation (8.4) has been carried out by Longuet-Higgins and Cokelet (1976) replacing the boundary by a finite number N of integration points. Typically $N = 60$ for one wavelength. Details of the method, which are vital for its accuracy and success, are given in their paper. The method was first tested for accuracy on a free symmetric wave of finite amplitude for which the form and phase-velocity were calculated independently by the method of Section 5, and good agreement was obtained. Then the following experiment was performed. As initial state was chosen a progressive wave of fairly large amplitude, whose energy was 0.80 times the maximum E_{\max} for a steady symmetric wave of that wavelength. The energy was then raised by applying to the surface (numerically) a pressure of the form

$$p = \left\{ \begin{array}{l} p_0 \sin(kx - \sigma t) \sin \sigma t, \quad (0 < \sigma t < \pi) \\ 0 \quad (\sigma t < 0 \text{ and } \sigma t > \pi) \end{array} \right\} \quad (8.5)$$

through the boundary-conditions (8.1). This represented a sinusoidal distribution of pressure, in quadrature with the fundamental harmonic of the surface elevation, increasing and dying away smoothly over half a wave period (π/σ). After the surface pressure had fallen to zero, the wave was supersaturated, that is its level exceeded E_{\max} . It was then allowed to run free. Its subsequent development can be followed in Figure 17.

Figure 17. (from Longuet-Higgins and Cokelet, 1976). Development of a progressive wave in deep water. From (a) to (c) a surface pressure (8.5) is applied to the rear face of the wave. From (d) to (e) the wave is free.

Figure 18 gives a close-up view of the free surface near the instant of overturning. The figure shows successive positions of the free surface (actually every 3 time-steps) in a frame moving with the speed c_0 of infinitesimal waves. The plotted points refer always to the same marked particles, so that a line through a succession of points defines a particle trajectory, in this reference frame.

Figure 18. (from Longuet-Higgins and Cokelet, 1976). Successive profiles of the free surface near the instant of overturning, seen in a reference frame moving with speed c_0 .

The particles have a welcome tendency to congregate near points of high surface curvature, which is precisely where they are needed for computational accuracy.

It will be seen that the crest remains rounded until well past the instant when the surface becomes vertical. Thereafter the curvature near the tip of the breaker increases rapidly. The free surface can be followed by this method only so long as the separation between adjacent particles does not exceed a fraction of the local radius of curvature. The question whether the curvature becomes infinite in finite time cannot be decided by this method.

In practice the tip of the jet will be much influenced both by surface tension, which we have neglected, and by air currents. Both these may cause it to break up into spray. Both effects could possibly be included in the calculation. The present calculations were intended to apply only to waves on a sufficiently large scale.

Though the computation involves only the surface values of x , y and ϕ , the pressure and velocity components in the interior may also be found from the surface values, by the use of Cauchy's theorem. The pressure gradients in the tip are small, but there is no evidence of a reversed normal gradient of the pressure.

Because it uses the velocity potential ϕ yet follows marked particles, the above technique may be called MEL (mixed Eulerian and Lagrangian). The example just discussed illustrates only one possible application of the general method. Various other initial conditions might be chosen so as to correspond, for example, to a standing wave, or to a partially reflected wave, or to a mixture of progressive wave trains having rationally related wavelengths. These would constitute a wave group with slowly varying wave envelope. It will be of interest to see how the resulting energy and momentum lost in the jet of the breaking wave are related to the different initial conditions.

9. EXPERIMENTAL CONFIRMATION

Although the above computations were for deep water, nevertheless one would expect the local behaviour of the wave crest to be asymptotically similar whether in deep or shallow water. To test whether the surface could remain smooth and continuous after the tangent became vertical, the author and N.D. Smith, with the collaboration of Dr. N. Hogben, made a high-speed film of waves breaking on a 1:6 beach slope, in the No. 2 Towing Tank of the National Physical Laboratory at Teddington. Figure 19 shows one frame from a film taken at 500 frames/sec. The grid-spacing is 5.0 cm. The film confirms that the free surface can indeed remain smooth and rounded until after overturning takes place.

ABSTRACT

Measurement of waves, and vertical and horizontal water particle velocities were made of spilling, plunging and surging breakers at sandy beaches in the vicinity of Monterey, California. The measured breaking waves, derived characteristically from swell-type waves, can be described as highly nonlinear. Spectra and cross spectra were calculated between waves and velocities. Secondary waves were noted visually and by the strong harmonics in the spectra. The strength of the harmonics is related to the beach steepness, wave height and period. The phase difference between waves and horizontal velocities indicates the unstable crest of the wave leads the velocities on the average by 5-20 degrees. Phase measurements between wave gauges in a line perpendicular to the shore show breaking waves to be frequency nondispersive indicating phase-coupling of the various wave components. The coherence squared values between the sea surface elevation and the horizontal water particle velocity were high in all runs, ranging above 0.8 at the peak of the spectra. The high coherence suggests that most of the motion in the body of breaking waves is wave-induced and not turbulent.

INTRODUCTION

Wave theories can be applied outside the surf zone with some degree of certainty, and can be tested in laboratory and field situations. The various theories can be used to carry the waves from deep water through the shoaling process up to the point of near breaking. At the breaker point, however, there is a transition from ordered to apparent turbulent motion and the theoretical description of wave kinematics becomes difficult. One of the greatest deficiencies in our understanding of the surf zone is an appropriate description of breaking waves. The experimental study of the kinematics of breaking waves in the surf zone has progressed slowly due to the problems encountered in making direct field measurements and the difficulty in modeling the surf zone in the laboratory.

The most direct approach to the problem of describing the kinematics of surf zone breaking waves is by field measurements. Advances in instrument design have led to simple, sturdy, devices for measuring waves and velocities with rapid response time. Miller and Ziegler (1964) used both acoustic and electromagnetic flow meters to determine the particle motion

in the surf zone. Walker (1969) made studies using propeller-type flow meters. Wood (1973) measured waves and currents in the surf zone using movies of dye movement and capacitance wave gauges. Fhürbötter Büsching (1974) utilized a two-component electromagnetic current meter and pressure-type wave meters to measure simultaneous orbital velocities and water levels. Thornton (1968) used an electromagnetic flow meter and pressure transducers to measure waves inside the surf zone. Steer (1972), Thornton and Richardson (1973), Bub (1974) and Galvin (1975) used pressure meters, capacitance wave gauges and electromagnetic current meters to measure surface profiles and particle velocities within the surf zone; the work presented here is a synthesis of these latter studies.

EXPERIMENT

The experiments were designed to measure kinematics of various types of breaking waves including spilling, plunging and surging breakers. The manner in which waves break depends very much on the characteristics of the beach and near-shore bottom slope. The experimental sites were in the vicinity of Monterey, California. The beaches here were some of the first intensively studied to gain an understanding of amphibious warfare techniques and were described and popularized by Bascom (1964).

The Del Monte Beach, within Monterey Bay, was chosen to measure plunging and spilling breakers. The waves at this location are generally topographically sheltered and severely directionally filtered due to refraction by the geometry of the bay often resulting in swell type waves impinging perpendicular to the shore. Hence, a simplification to a two-dimensional narrowbanded wave description is allowed. A second experimental site was Carmel River Beach, five miles to the south, where the beach is very steep and often has surging type breakers. Again here, the beach is within an embayment, Carmel Bay, and the generally narrow-banded waves impinge almost perpendicular to the shore.

The median grain size at Del Monte Beach is approximately 0.2 mm (taken at the water line), and the beach slope varies between 1:14 to 1:40. The median grain size at the Carmel River Beach is approximately 0.6 mm and the beach slope varies between 1:6 to 1:12. A typical beach profile and instrument location for Del Monte Beach is shown in Figure 1.

Instrumentation. The surf zone is a formidable environment in which to make measurements. The instruments must be rugged and reliable but at the same time be accurate and have a good time response. The instrumentation set-up described below evolved over a number of experiments.

Measurements at Del Monte Beach were made using two electromagnetic flow meters and three capacitance wave gauges. One flow meter and two wave gauges were used at Carmel River Beach. The instruments were mounted on the towers within the surf zone. All equipment was calibrated in the laboratory prior to the experiments.

The electronics package for each of the 2.5 m capacitance wave gauges was constructed using the design of McGoldrick (1969). The electronics package was housed in a water-tight brass case which was mounted on the tower. This enabled the connecting leads to be less than 30 cm, thereby minimizing wire-to-wire capacitance. Accuracy is estimated to be ± 0.005 m.

The flow meters were Marsh-McBirney Model 721 and 722 Electromagnetic Current meters. The flow meter operation is based on Faraday's principle of electromagnetic induction. Each probe measures water velocity in two orthogonal directions. The flow meters were calibrated with an oscillating platform attached to an eccentric arm driven by a variable speed motor. Measurement accuracy was determined to be ± 0.005 m/sec during calibration.

The instrument towers are 6.3 cm outside diameter steel pipes which were 3.6 m high with a 1.0 m baseplate and 0.6 m steel pipe bottom extension. A typical tower and sensor arrangement is shown in Figure 2. The towers were placed on a line perpendicular to the shore and were erected during low tide when the beach was easily accessible. The measurements were then conducted at high tide. The tidal range in the Monterey area is typically two meters. The towers were supported by steel guy wires fastened to the one meter long blade type anchors. Several types of anchors were tried; the blade anchor was chosen because it works quite satisfactorily in the relatively coarse sand and is easily installed. The flow meters were positioned directly under the wave gauges with the axes aligned horizontally and vertically. A carpenter's level was used to establish axis alignment with an estimated error of ± 2 degrees.

A number of problems arose in the course of the experiments. The greatest difficulties in the field are encountered during periods of storms and large waves, a time when the measurements are often of most interest. Flotsam and, in particular, the giant kelp, *Macrocystis*, torn loose from its hold-fasts are thrust ashore during storms. The kelp at times becomes entangled in the instrument towers, greatly increasing the drag, and making the towers susceptible to being knocked down.

The beaches are composed of fine to coarse sand. During wave conditions when the beaches are being eroded and cut back, considerable scour can occur around the anchors and instrument towers causing towers to topple on several occasions.

The first capacitance wave gauge wires were manufactured from one cm diameter stripped RG-11 coaxial cable, (Bub, 1974); these wave wires were susceptible to strumming and broke soon after installation. The construction of the wave wire was modified to a three-eighths inch outside diameter stainless steel rod as the center conductor covered with a jacket of polyurethane plastic tubing as the dielectric; these wave gauges can withstand the severe forces in the surf.

Wave gauges penetrating the surface were used to obtain a true measure of the surface elevation. Pressure transducers, although easier to install and maintain, do not represent the water surface in breaking waves. Breaking waves are highly nonlinear and the conventional technique of converting the pressure measurements to water surface elevation using the spectral transfer function derived from linear theory results in substantial error. As will be shown, the velocities, and hence dynamic pressures beneath breaking waves, are much greater than calculated using linear theory. Further, pressure does not support sharp discontinuities beneath the sharp crests of breaking waves, hence, the pressure records are much smoother and rounded off compared with the capacitance wave gauge measurements.

FIGURE 1. LOCATION OF INSTRUMENTS.

FIGURE 2. INSTRUMENTATION TOWER.

All signals were cabled ashore and recorded on a Vidar Corporation 32-channel digital data acquisition system. A Sangamo Model 3500 14-channel FM tape recorder was utilized as a secondary recording system. A Brush 8-channel strip chart recorder was used to monitor the instrumentation performance during recording and as a means to select the appropriate data sections to be analyzed.

Analysis. A mean value was calculated for all data sets and the data were linearly detrended to exclude the rise and fall of the tide. The variance, standard deviation and average period were calculated. The average period was determined by calculating the time between zero up-crossings.

Correlation functions were calculated for signals and smoothed with a Parzen window. The smoothed correlation functions were Fourier transformed to obtain the power and cross spectra. The coherence and phase were calculated from the cross spectral estimates.

The maximum lag time in calculating the correlation functions was taken as five percent of the record giving a spectral bandwidth resolution of 0.0055 Hz and resulting in 40 degrees of freedom for each spectral estimate. The 90 percent confidence limits for 40 degrees of freedom using a chi-square distribution are found to be between 0.72 and 1.51 of the measured power spectral estimates.

Measurements in the surf zone are not only hampered by the difficulties of a physically hostile environment, but can present conceptual analysis difficulties. The wave heights and spectral characteristics continually change as the waves shoal, break and dissipate across the surf zone. Changes in the wave profile occur over short distances compared to the wave length within the surf zone which does not allow spatial averaging within the surf zone. Point measurements are also troublesome because the breaker position is continually changing. Thus, the waves in the surf zone are spatially nonhomogeneous and tend to be temporally nonstationary.

As the wave height stochastically varies, the wave set-up changes resulting in a change in the mean water level at a particular location in the surf zone. The breaker position is approximately related to the wave height and local depth. Hence, the breaker position tends to wander, depending on the wave conditions. The breaker position tends to wander more on flatter beaches as was evident at Del Monte Beach experiment site. The shoaling processes on steeper beaches occur much more rapidly and over shorter distances, resulting in the breaker position being relatively fixed. The waves broke at nearly the same position for a particular tidal stage at the steeper Carmel River Beach site.

The spatial nonhomogeneity and temporal nonstationarity results in a smearing of spectral information of the breaking processes. This difficulty must be kept in mind when interpreting the results, but does not appear to be a severe limitation.

WAVES AND HORIZONTAL VELOCITY MEASUREMENTS

Qualitative Description. A number of universal similarities of wave form can be observed for various types of breakers occurring on different beaches. Figure 3 is a typical analog record of plunging-spilling breaking waves and horizontal velocities beneath the waves obtained from Del Monte Beach. In general, there is a quick drawdown of water just before the breaker arrives, followed by a steep, vertical leading edge, and a sloping profile toward the trailing edge, giving a generally sawtoothed shape. On the trailing edge, one or more secondary waves are often noted. The secondary waves are harmonics of the primary wave frequency and are indicative of strongly nonlinear waves. The authors have had the opportunity to see in the field the secondary waves develop by standing on an instrument tower as the waves break past the tower. As the wave shoals, the secondary waves start to grow and, as the waves steepen rapidly just before breaking, the secondary waves likewise rapidly develop on the back of the primary wave. The rapid transfer of energy from the primary wave frequency to the secondary wave is "mother nature's" means of maintaining the potential energy across the surf zone rather than converting to kinetic energy in the breaking process. The broken primary wave often reforms and continues toward shore closely followed by the secondary wave; this often results in two waves breaking close behind each other as the beach face is approached.

Surging breakers generally occur on steeper beaches in which the shoaling wave becomes unstable and forms a bore-like profile as the water progresses up the beach face. The breaking process on steep beaches occurs rapidly and secondary waves generally do not have time to develop.

On steep beaches, the swash zone is much more important in the surf zone processes, and on very steep beaches can constitute a major extent of the surf zone. A strong interaction of the backwash of the proceeding breaker and the new breaker can occur which complicates the wave processes. Wave reflection from steep beaches is greater which further complicates the processes.

The water particle velocity trace shown in Figure 3 reflects the general characteristics of the sea surface. The water cannot support sharp discontinuities which results in the velocities being considerably more smoothed. It should be emphasized that the smoothing in the velocity records is real and not a result of the frequency response of the flow meters.

In a spilling breaker, the crest becomes unstable and slides down the face of the wave; the turbulent region is generally confined to the area above the trough and does not penetrate into the body of the flow. The crest of the plunging breaker curls over and penetrates deeper into the water column, although the velocities still have an appearance similar to the wave surface. Surging breakers, which are bore-like, are apparently turbulent on the small scale throughout the water column, but the body of the fluid translates with the wave profile. Hence, the primary motion even under the surging breakers can be associated with the surface and is wave-induced. The important point is that the velocities under breaking waves and in the surf zone appear to be primarily associated with the wave surface and not turbulent, disorganized motion.

FIGURE 3. TYPICAL ANALOG RECORD OF WAVES AND HORIZONTAL VELOCITIES BENEATH THE WAVES FROM DEL MONTE BEACH.

Comparing Measured and Calculated Velocity Spectra Using Linear Wave Theory. A velocity spectrum was calculated from the wave spectrum using the transfer function derived from linear wave theory. Previous work in deeper water by Simpson (1969), Bowden and White (1966), and Thornton and Krapohl (1974) has shown that using linear wave theory to derive the spectral transfer function gave very good results in calculating the water particle velocity spectra under waves. It was not expected that as good results would be obtained in the surf zone, but would serve as a basis for comparison with other theories. Further, spectral analysis assumes superposition of the spectral component which only allows using a constant parameter linear theory for the transfer function.

The elevation of the surface $\eta(t)$ can be described as the superposition of an infinite number of sinusoids of the form:

$$\eta(t) = \sum_{n=1}^{\infty} a_n \cos(\vec{k} \cdot \vec{x} - \sigma_n t + \epsilon_n) = \sum_{n=1}^{\infty} \eta_n \quad (1)$$

where a_n is the amplitude, x is the horizontal Cartesian coordinate, t is the time, ϵ_n is an arbitrary angle, \vec{k} is a horizontal vector wave number, and σ is the frequency related in linear theory to k by

$$\sigma_n^2 = gk_n \tanh k_n h \quad (2)$$

where g is the acceleration of gravity. The $\eta(t)$ represents the sum total of all component wavelets. Summing in the manner of (1) implies a linear system and restricts the analysis to the use of linear wave theory to describe the wave-induced motion.

Linear wave theory can be used to calculate the wave-induced water particle velocities. The equation for the horizontal velocity is

$$\begin{aligned} u(t) &= \sum_{n=1}^{\infty} a_n \sigma_n \frac{\cosh k_n (h+z)}{\sinh k_n h} \cos(\vec{k}_n \cdot \vec{x} - \sigma_n t + \epsilon_n) \\ &= \sum_{n=1}^{\infty} \frac{\sigma_n \cosh k_n (h+z)}{\sinh k_n h} \eta_n = \sum_{n=1}^{\infty} H_n(\sigma, z) \eta_n \end{aligned} \quad (3)$$

where h is the total depth and z is the vertical coordinate measured positively upward from the still water level. The solution says that the amplitude of the velocities is a function of wave amplitude, frequency and depth, and that the water surface and horizontal water particle velocities are in-phase. The term in (3) in braces represents the complex spectral transfer function, $H_n(\sigma, z)$, and is used to calculate the wave-induced horizontal velocity spectrum, $S_u(\sigma)$, from the wave spectrum $S_\eta(\sigma)$:

$$S_u(\sigma) = |H(\sigma, z)|^2 S_\eta(\sigma). \quad (4)$$

In the formulation of linear wave theory, the boundary conditions are linearized in order to obtain an analytical solution. In the linearization, it is assumed that the amplitude is small in comparison with the wavelength, that is, $ak \ll 1$. Higher-order solutions to the boundary value problem, generally obtained by perturbation analysis, give a better representation of a constant profile wave. However, the nonlinearities introduced in the solution preclude their use where the principle of superposition is invoked.

Figure 4 shows typical spectra of the measured and calculated water particle velocities using Eq. 4 for the case of plunging-spilling breakers in the surf zone taken at Del Monte Beach. The waves are narrow-banded with a primary frequency of 0.06 hz (16.6 second period).

Strong harmonics of decreasing energy density are evident. The measured horizontal velocities were always greater than the calculated by 20-100 percent. That is to say, linear theory underpredicts the horizontal velocities. This is not surprising because of the steepness of the waves, but the amount of underestimation is surprising. The amount of deviation from linear theory demonstrates the strength of the nonlinearities of shallow water waves and some contribution by turbulence.

The strong harmonics are both real and artifices. The secondary waves are real harmonics of the primary wave and show up as energy at harmonic frequencies. Due to the very peaked wave form of the primary wave, spectral analysis will also show energy-density at harmonic frequencies as a result of viewing the breaking waves as an infinite sum of sinusoidal wave components.

Also shown in Figure 4 are the coherence squared (here-after referred to simply as coherence) and the phase difference between waves and horizontal velocity. The coherence between waves and horizontal water particle velocities was high, ranging above 0.75 at the peak of the spectrum and decreasing at higher and lower frequencies. The generally high coherence indicates the water particle motion is primarily wave-induced.

The decrease in coherence can be attributed primarily to the velocities being converted to turbulence during breaking and the nonlinearities associated with finite amplitude wave motion. The decrease in coherence due to turbulence can be demonstrated by considering the horizontal velocity, u , as being decomposed into wave-induced, U , turbulent, u' , and mean, \bar{u} , contributions, such that the velocity is given by

$$u = U + u' + \bar{u}. \quad (5)$$

Assuming the wave-induced and turbulent velocity spectral component are statistically independent, the horizontal velocity spectrum is given by

$$S_u(\sigma) = S_U(\sigma) + S_{u'}(\sigma). \quad (6)$$

The wave-induced velocity spectrum is calculated from the wave spectrum using equation (4). For a constant parameter linear system the coherence is identically equal to unity,

FIGURE 4. MEASURED AND CALCULATED HORIZONTAL VELOCITY SPECTRA UNDER SPILLING-PLUNGING BREAKERS, 4 MARCH 1975.

$$\gamma_{U\eta}^2(\sigma) = \frac{|S_{U\eta}(\sigma)|^2}{S_U(\sigma) S_\eta(\sigma)} \equiv 1 . \quad (7)$$

Since the turbulent and wave-induced velocities are assumed to be statistically independent, then

$$S_{U\eta}(\sigma) = S_{U\eta}(\sigma) . \quad (8)$$

The substitution of (6), (7) and (8) into the definition of coherence between the total horizontal velocity and waves results in

$$\gamma_{U\eta}^2(\sigma) = \left[1 - \frac{S_U(\sigma)}{S_U(\sigma)} \right]^{-1} = \frac{S_U(\sigma)}{S_U(\sigma)} \leq 1 . \quad (9)$$

Increasing lack of coherence is due to an increasingly high ratio of turbulence (noise) to coherent wave-induced velocity fluctuations (signal). Using this interpretation for the coherence, the results of Figure 4 suggest that 94% of the spectral energy at the primary wave frequencies (peak of the spectrum) is wave-induced.

The phase difference between waves and horizontal velocities for all runs varied between 5-30 degrees at the primary frequency. Theory states that the waves and horizontal velocity are in phase, or have a zero phase difference. The measured phase difference is interpreted as showing the breaking wave crest leading the wave-induced velocities beneath.

Wave and velocity spectra characteristic of collapsing breakers taken at Carmel River Beach are shown in Figure 5. Wave No. 1 and horizontal velocity spectra were measured at the breaker line. Wave No. 2 spectrum was measured 3.5 meters shoreward. The spectra do not exhibit the strong harmonics on this steeper beach because the secondary waves do not have time to develop during rapid shoaling. The energy density is greatly attenuated in the breaking process from Wave No. 1 to Wave No. 2. The coherence and phase difference shown are between Wave No. 1 and horizontal velocity. The phase difference shows the waves leading the velocities at the primary frequency by 15 degrees. The coherence is high, again indicating the motion to be primarily wave-induced.

Wave Celerity. The wave speed, or celerity, was measured using two wave gauges separated in a line perpendicular to the propagating wave crests. Consider a spectral wave component propagating perpendicular to the beach in the x direction measured at point, $x_1 = 0$, and a point shoreward by an amount, $x_2 = \Delta x$, given by

$$\begin{aligned} \eta_1(\sigma) &= a_1(\sigma) \cos \sigma t , \\ \eta_2(\sigma) &= a_2(\sigma) \cos(k\Delta x - \sigma t) . \end{aligned} \quad (10)$$

The phase difference of the waves between the two measurement points is given by

FIGURE 5. WAVE AND VELOCITY SPECTRA CHARACTERISTICS OF COLLAPSING BREAKERS, 29 MAY 1975.

$$\phi(\sigma) = k\Delta x = \frac{\sigma\Delta x}{c} \quad (11)$$

where the celerity, $c = \sigma/k$.

Figure 6 shows two wave spectra measured at Del Monte Beach within the surf zone. Wave gauge one was at the approximate breaker line and wave gauge two was 11 meters shoreward. The wave spectra exhibit strong harmonics. The energy density is shown to decrease as the waves break and progress shoreward. The coherence is high at the primary frequency and decays from the peak. The phase difference between the wave gauges continuously increases with frequency.

Expected phase differences were calculated using both the linear wave theory relationship

$$c = \left(\frac{g}{k} \tanh kh\right)^{1/2} \quad (12)$$

and the shallow water relation assuming nondispersive waves

$$c = \sqrt{g(h + \alpha H)} \quad (13)$$

where h is the total depth of water, H is the wave height and α a constant. It should be noted that even though the water is shallow, the higher frequency wave components can be considered intermediate or even deep water waves.

The phase differences calculated using equation (11) are shown on Figure 6. The dashed line is the phase difference calculated using the nondispersive wave speed, equation (13), for α equal to 0.5. The comparison of all measured and calculated phase differences shows that linear theory wave speed is not valid, but that the waves are nondispersive. The nondispersiveness of the waves across the frequency band of significant wave energy is because the wave components are phase-coupled to the primary frequency wave, i.e., the higher frequency wave components travel at the phase speed of the primary frequency wave. The phase-coupling of the wave components is another indication of the strong nonlinearities of breaking waves.

CONCLUSIONS

The measured breaking waves, derived characteristically from swell-type waves, can be described as highly nonlinear, although the kinematics are more orderly than intuitively presupposed. The measured wave and velocity spectra show strong harmonics of the peak frequency of the waves. The harmonics are secondary waves of the primary wave frequency and are indicative of strongly nonlinear waves. As the wave shoals, the secondary waves start to grow and, as the waves steepen rapidly just before breaking, the secondary waves likewise rapidly develop on the back of the primary wave. The development of secondary waves indicates a transfer of energy to higher frequencies.

FIGURE 6. WAVE SPECTRA SEPARATED BY 11 METERS IN THE SURF ZONE, 4 MARCH 1976.

Spectra and cross spectra were calculated between waves and velocities measured directly beneath the waves. The wave energy-density spectral components were converted to velocity spectral components using linear wave theory. The measured horizontal velocities were always greater than the calculated by 20-100 percent. The amount of deviation from linear theory demonstrates the strength of the nonlinearities of shallow water waves.

The measured phase difference between waves and horizontal velocities indicates the waves generally led the velocities on the average by 5-20 degrees, implying that the "curling" crest of the wave arrives prior to maximum water particle velocity. The coherence values between the sea surface elevation and the horizontal water particle velocity were high in all runs, ranging above 0.8 at the peak of the spectra and decreasing at higher and lower frequencies. The decrease in coherence can be attributed primarily to the velocities being converted to turbulence during breaking and the nonlinearities associated with finite amplitude wave motion. The high coherence suggests that most of the motion in the body of the breaking waves was wave-induced. Hence, breaking waves may be more amenable to theoretical treatment than previously thought, although still very nonlinear.

The wave speed was measured using two wave gauges separated in a line perpendicular to the propagating wave crests. The measured phase difference was compared with theoretical values calculated using celerity relations from linear wave theory and the shallow water relation assuming nondispersive waves. The measurements show that the breaking waves are frequency nondispersive; this is further evidence of the strength of the nonlinearities of the waves in the surf zone.

CHAPTER 27

DEFORMATION UP TO BREAKING OF PERIODIC WAVES ON A BEACH

Ib A. Svendsen* and J. Buhr Hansen*

ABSTRACT

An experimental description is presented for the transformation of periodic waves which approach breaking on a gently sloping beach. The data include the variation of wave height, phase velocity, wave surface profiles, and the maximum value of the wave height to water depth ratio $(H/h)_{\max}$ around the breaking point.

The results are compared with the theories of sinusoidal and cnoidal wave shoaling, and the latter is shown in most cases to agree remarkably well when the laminar energy loss along the walls and bottom of the wave tank is included.

An empirical relation is established between wave length to water depth ratio L/h at the breaking point and the deep water wave steepness H_0/L_0 . Also the maximum wave height to water depth ratio at breaking shows considerably less scattering than found previously, when plotted versus $S = h_x L/h$, h_x being bottom slope.

1. INTRODUCTION

The literature shows a considerable number of experimental investigations of the slow transformation of waves on a sloping bottom, which is denoted shoaling. In particular, data for the variation of the wave height have been reported.

Most of these results, however, do not confirm each other. Thus no definitive conclusion has been obtained so far neither about the real variation of the wave height nor as to which theory will predict the variation sufficiently accurately.

Iversen (1952)[†] presented experimental data which showed that the height of periodic waves on a sloping bottom grows much faster than predicted by the sinusoidal wave theory, and Brink-Kjær and Jonsson (1973) showed that actually the variation resemble a cnoidal wave shoaling.

Similar experiments were made by Ippen and Eagleson (1955), and Eagleson (1956) arrived at the same conclusion though the pattern was

*Assoc. Prof., Institute of Hydrodynamics and Hydraulic Engineering (ISVA), Technical University of Denmark.

[†]The paper by Iversen (1953), 'Waves and breakers in shoaling water,' Third Conf. Coastal Engrg., Cambridge, Mass. 1952, is almost identical with Iversen (1952).

less pronounced, partly due to considerable scattering. Also the experiments by Vera-Cruz (1965) should be mentioned.

Iwagaki (1968) compared his experiments with the theory of hyperbolic waves, in which the wave profiles are approximated by parts of solitary wave profiles. As far as it has been possible to ascertain from the graphical presentation in the paper, the agreement is good for waves with small deep water steepness ($H_0/L_0 < 0.005$), (though the theoretical curves have not been extended to the full region of water depths for which measurements are presented). Actually it may be shown (Svendsen, 1974) that to the first order the hyperbolic wave height varies as h^{-1} , i.e. as a shoaling solitary wave. Further, in particular waves of small deep water wave steepness (swell-type) will more and more resemble a solitary wave in shape as the water depth decreases. Hence the best agreement with hyperbolic waves should be expected for swell-type waves. For steeper waves the comparison seems inconclusive as should also be expected, as the theory does not apply to such waves.

Against this stand the solitary wave experiments by Ippen and Kulin (1954) and by Camfield and Street (1969) indicating that although a solitary wave is as far from a sinusoidal wave as well possible, the variation of its height is much better predicted by the $h^{-1/4}$ rule valid for long sinusoidal waves. This is further confirmed by the numerical calculations by Madssen and Mel (1969), which agree quite well with the results of Camfield and Street.

Finally, Wiegel (1950) claims that in general his experimental results for periodic waves on slopes 1:10.8 and 1:20 follow the linear theory.

One possible reason for these discrepancies is that all the experiments for pure solitary waves, and Wiegel's with periodic waves, have been performed on slopes which are actually too steep to allow the shoaling assumption to be valid. Another important factor is the friction losses, which can be shown to have a considerable effect on the shoaling process, in particular in a relatively narrow laboratory wave flume.

Also part of the surprisingly large scattering which appears in many experimental results for wave quantities is most likely due to the free second harmonic waves generated by the sinusoidal motion of a piston-wave-generator.

The aim of the present investigation has been to try to clear up some of these uncertainties, using the facilities for generation of waves of extremely regular and permanent form, described by Buhr Hansen, Schiolden and Svendsen (1975).

In addition to the wave height, the phase velocity and the mean water level ('set-down') have been measured, and records have been obtained for the wave surface profiles. The results are compared with theory, and since it is rather evident from previous investigations that the linear theory is doomed to fail, the major emphasis is placed on a comparison with cnoidal wave theory. Perhaps it should be added for completeness that a second or higher order Stokes theory will be out of question, too, when the Ursell parameter U (defined as HL^2/h^3)

(as in most cases) grows far beyond 30 or 40, which is about the limit for which a higher order Stokes theory is applicable.*

In each case will be discussed outcome of the comparison, and an analysis will be attempted of the possible reason for discrepancies.

2. DESCRIPTION OF EXPERIMENTAL FACILITIES AND PROCEDURE

The waves are generated by a flap-type wave generator in a flume 33 m long, 60 cm wide, with a plane beach sloping 1:35 (see Fig. 1). The motion of the wave generator is controlled by a PDP 8 mini-computer, which generates a command signal of the form

$$\xi = e_1 \sin \omega t + e_2 \sin(2\omega t + \beta_2) \quad (1)$$

(Buhr Hansen and Svendsen, 1974). Fig. 2 shows a comparison between a resulting measured wave profile (with almost no free second harmonic components) and a second order Stokes wave. The parameter $U = HL^2/h^3$ is about 2. It appears that even for U as large as 40-50 (which is far up in the cnoidal region), the waves generated by (1) remain of clean and constant form.

This is important because the waves in the constant depth part of the wave flume represent the initial conditions for the shoaling process. (It may be noticed that it has no meaning to consider whether the wave produced by (1) is a 'Stokes' or a 'cnoidal' wave, as long as it is of constant form.)

The water surface variation is recorded by a resistance wave height transducer (two silver wires, 0.17 mm diameter, 5 mm apart), the signal of which is scanned by the computer 400 times per second. The transducer is mounted on a carriage which is moving slowly along the flume. Vertical irregularities of the rails for the carriage are eliminated by storing in the computer a zero level correction, which is obtained from the wave transducer during a carriage-run without waves.

In the experiments, the computer determines on line the height H of each wave, the mean water level $\bar{\eta}$, and by means of an additional wave height transducer, the phase velocity c . At the same time selected wave profiles are stored. After each experiment the results may be plotted out on an ordinary pen-recorder.

In all experiments reported, the still water depth was 36.0 cm and the plane slope was 1:35. The wave frequency varied between 0.3 Hz and 1.2 Hz, the wave height in the constant depth part of the flume between 3.5 cm and 10 cm.

The calibration factor for the wave transducers was determined by linear regression on 10-12 data points corresponding to 1 cm increments in the submergence of the transducer. In all experiments the minimum submergence was more than 1.5 cm, corresponding to a regression coefficient larger than 0.999.

*The limit referred to corresponds to the largest value of H for which there is no secondary wave crest in the trough. In the second order this means that $U < (L/h)^3 \pi^{-1} (3 \coth^3 kh - \coth kh)^{-1}$, the maximum of which is 26.3 for $kh \rightarrow 0$ (see Svendsen and Jonsson, 1976). For higher order theories U may be slightly larger.

Fig. 1 Experimental facility

Fig. 2 Comparison between profile measured in front of the wave generator and Stokes second order approximation with the same wave height and period

Fig. 3 Illustration of reproducibility of experiments

The reproducibility of the experiments is illustrated in Fig. 3 showing two records of the same experiment. The figure also shows that even most of the small and apparently inexplicable irregularities in the records are obviously repeated exactly the same way. Some may be due to irregularities in the wave flume (though the accuracy of alignment of sides and bottom is well below 1 mm) but most of them seemed to be generated by either capillary waves, secondary waves generated by the breaking process, and perhaps the rest of the free second harmonics.

3. THE SHOALING ASSUMPTION

The notion of wave shoaling or wave transformation on a beach was introduced on an intuitive basis by Rayleigh (1911). In his approach there are three more or less independent assumptions involved:

- (a) The wave will — to the first approximation in bottom slope — continuously adjust its form so that surface profile, phase and particle velocities, pressure variation, etc. can be determined from the horizontal bottom theory, applying the local values of water depth and wave height.
- (b) The wave energy flux through a vertical section is constant, which implies that the reflection is negligible.
- (c) The number of waves remain constant during the shoaling process so that the wave period T is conserved.

Essentially each of these assumptions requires a 'sufficiently gently varying water depth', but how gently will actually depend on the wave theory considered. This question can be analysed theoretically by rigorous perturbation expansions including the effect of the bottom slope h_x .

Rayleigh, of course, presented the ideas in terms of the linear wave theory, and for that case it may be shown that the shoaling assumptions will be satisfied provided the relative change in water depth over a wave length is of the same order of magnitude as the wave steepness (or smaller), i.e.

$$S \equiv h_x L/h = O(H/L) \quad (2)$$

For higher order Stokes waves only smaller values of h_x are allowed (depending on the order considered), and for (first order) cnoidal waves, Svendsen (1974) showed that a consistent shoaling theory requires $S = O(h/L)^3$.

In conclusion we notice that in all cases the parameter S occurs and that shoaling conditions imply that S is too small to be of importance. This will be discussed further later on.

4. THE WAVE HEIGHT VARIATION

Experimental Results

Since the wave period is assumed to be constant, one of the principal problems in wave shoaling is to determine the wave height H as a function of the water depth h .

Figs. 4 and 5 show the recorded variation of the wave height for deep water wave steepnesses ranging from 0.0039 to 0.064. Both dimensionless wave period $T\sqrt{g/h}$, wave height to water depth ratio H/h in the constant depth part of the flume, and the theoretically determined deep water wave steepness H_0/L_0 are given in each figure.

There are two experimental curves in each figure. One represent each individually measured wave height, the other a moving average over the length of the reflection pattern.

Though the curves for the individual wave heights seem to show a continuous variation they are actually step-curves. This is because the carriage with the wave transducer moves 2 - 4 cm (depending on the wave period) along the wave flume during one wave period, i.e. between each new result for the wave height.

In the following the origin of the theoretical curves is described and discussed, but first we consider the effect of energy loss due to friction.

Energy Loss due to Friction

This effect was taken into account in the theoretical curves by reducing the energy flux at each station with the energy lost since the previous station in the calculation, due to friction along the bottom and along the side walls.

In these calculations laminar boundary layers were assumed in all cases although the longest and highest waves according to Jonsson (1966) should have turbulent boundary layers, at least close to the breaking point. The effect, however, of introducing the turbulent value of the wave energy loss on the last part of the slope appears to be insignificant.

In the calculation of friction losses were used wave particle velocities determined by the linear theory. This also applies to the region where the wave height variation was calculated from the cnoidal theory. In fact it is a reasonable simplification since the friction only 'eats' a minor part of the energy flux anyway.

Linear Wave Shoaling

It is not surprising that the present results confirm the conclusion quoted in the introduction from other investigations, namely that shoreward of the point of minimum wave height, i.e. roughly $h/L_0 = 0.10$, the linear theory predicts divergingly smaller wave heights than measured. This is evident from Fig. 4b where the linear curve is shown through to breaking.

On the other hand we notice that as long as the deep water steepness is less than 3-4% (Figs. 4a and 5a), the linear wave theory seems to work quite well in deeper water. This is of particular interest because the cnoidal theory cannot be applied for $h/L_0 \gtrsim 0.10$.

In fact, for the small wave steepnesses the agreement is better than in the interpretation of Iversen's measurements given by Brink-Kjær and Jonsson (1973). They found that even for smaller wave steepnesses an appreciable discrepancy seemed to develop between the linear theory and

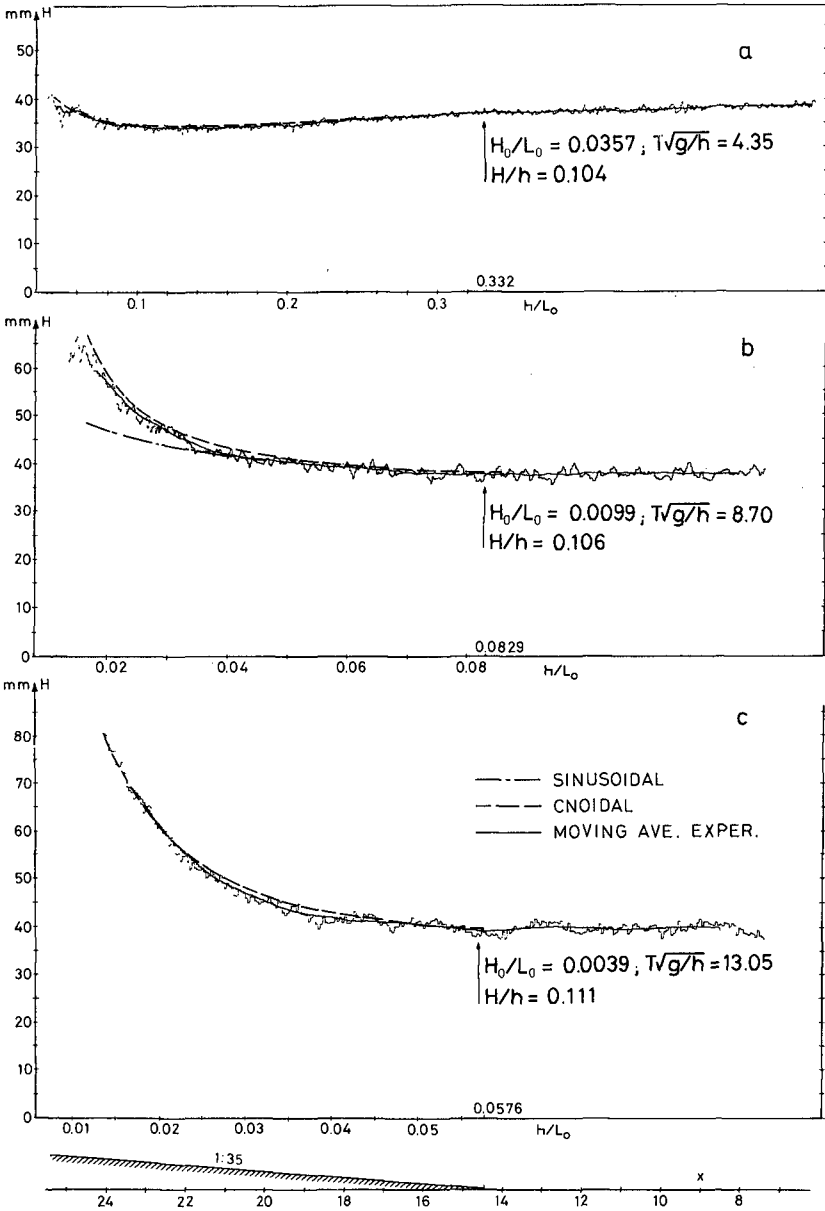

Fig. 4 Variation of wave height for three different wave steepnesses

Fig. 5 Variation of wave height, rather steep waves

the measurement as h/L_0 decreased towards the value 0.10. Fig. 6 shows an example of this where H_0/L_0 is 3.58%, and the linear theory yields results up to 8% higher than the measurements (i.e. a minimum value of $H/H_0 = 0.913$ against 0.85 measured).

It has turned out that the major reason for this discrepancy is that friction has been neglected in Brink-Kjær and Jonsson's calculation of the theoretical curves. In particular in Iversen's case, with a wave flume only 30 cm wide and a horizontal bottom depth of 77.8 cm in the case considered, the friction along the side walls has a considerable effect. Taking this into account brings the theoretical minimum value of H/H_0 down to 0.869 in the case shown in Fig. 6, and this must be considered in fair agreement with the measured value. The theoretical variation with friction included is shown in the figure. It may also be noticed that the wave heights measured by Iversen are most likely influenced by the fact that the first 4.6' (= 1.40 m) of Iversen's slope are steeper (1:5.75 = 0.174) than the value 1:13.8 = 0.072 referred to as the slope for the experiment.

Fig. 6
The effect of friction losses on Iversen's results

For the experiment shown in Fig. 4 a, H_0/L_0 is almost the same (3.57%) and here the measured minimum value of H/H_0 is 0.875 against the calculated value (including friction) of 0.889.

From Fig. 5 a-c, however, we see that if the deep water steepness increases, the wave height to water depth ratio will grow to large values already outside the cnoidal region. In the case of $H_0/L_0 = 6.4\%$ (Fig. 5 c) the wave actually breaks at $h/L_0 \approx 0.10$, so that the entire shoaling process has been determined by the linear theory. And quite obviously, linear theory cannot handle the large values of H/h .

Since we here at the breaking point have $U_{\max} \sim 45$ ($H/h \sim 0.71$ and $L/h \sim 8$) it seems likely that the problem could be overcome by using a second or third order Stokes shoaling theory.

Cnoidal Wave Shoaling

The theory of cnoidal wave shoaling used here was developed by Svendsen and Brink-Kjær (1972) who on the same intuitive basis as Rayleigh

solved and tabulated the variation of the wave height. A more direct presentation of the results can be found in Skovgaard et al. (1974).

Perhaps it should be mentioned that this theory is based on (8) (see Sect. 6). A slightly different version will appear if (10) (in which $\sqrt{1+AH/h}$ is substituted by $1+\frac{1}{2}AH/h$) is used, and other differences of similar nature are possible too. Formally all these versions (as e.g. Shuto (1974) and Ostrovskiy and Pelinovskiy (1970) are equal in that they only differ in the way the small terms are handled. For practical applications, however, where H/h is not really as small as envisaged in the theory they result in considerable differences in the numerical results for e.g. the wave height variation, in particular as we approach the breaking point. In our numerical calculations we have found that the best fit to the measurements is obtained by using the version developed by Svendsen and Brink-Kjær.

As appears from Fig. 4 b and c, the combined linear-cnoidal shoaling model fits the experimental data surprisingly well in those cases where the H/h -ratio remains small for $h/L_0 > 0.10$. The predictions even follow the development all the way to the breaking point, although the theory should not be applicable there.

It should be emphasized, however, that essentially this only indicates that the relationship between cnoidal energy flux and wave height shows a realistic variation with water depth. The absolute value of the energy flux is determined from the wave height in the constant depth part of flume and may not be correct (and other cnoidal wave properties as e.g. the position of the mean water level may be even rather inaccurately predicted by the same theory). This must be recalled in those experiments where $h/L_0 \gtrsim 0.10$ in the constant depth part of the flume. Then linear wave theory is applied for $h/L_0 > 0.10$, and at $h/L_0 = 0.10$ the theoretical result must be matched with the cnoidal shoaling, which is used shoreward of that point.* Svendsen and Brink-Kjær (1972) matched the two theories by assuming continuity in energy flux. However logical this approach seems it results in a discontinuity in wave height at the matching point.

Since, however, neither of the two theories yields the exact energy flux for a given wave height it may be argued that it is equally correct to match the wave heights, which we know are continuous, and accept a discontinuity in the theoretically determined energy flux (which is approximate anyway) at the matching point. This is actually the method chosen here. Finally it is mentioned that in the numerical evaluations the still water depth has been corrected for wave set-down.

Discussion

As mentioned the figures show a reasonable agreement, though discrepancies up to 6-8% in wave height develop close to the breaking point. This cannot surprise, however, since the energy flux used for the calculations was based on the assumptions that $H \ll h$, that the horizontal velocity u is constant over the water depth, and that the excess pressure p^+ due to the wave is constant too, and proportional to the local

*In principle any point shoreward of $h/L_0 \sim 0.10$ could be chosen as the matching point between the two theories.

value of the surface elevation. As is evident from e.g. velocity measurements in waves near breaking (see e.g. Iwagaki and Sakai, 1976), the velocity is far from constant over the water depth, and the constancy of p^+ actually represents neglect of the vertical accelerations in this context.

A few comments will also be appropriate about the matching procedure between linear and cnoidal wave theory.

The wave tables prepared by Skovgaard et al. (1974) are based on continuity in energy flux. The tables may also be used, however, for calculations with continuity in wave height at the matching point, if it is noticed that the corresponding shift in energy flux is represented by a formal shift in the deep water wave steepness. The procedure is illustrated in the appendix.

As mentioned in Sect. 3, a proper measure of the steepness of the sloping bottom is the parameter $S = h_x L/h$.

Since L is approximately proportional to \sqrt{gh} , a plane slope will correspond to $S \sim h_x h^{-1/2}$ so that for fixed h_x the value of S grows with decreasing water depth, indicating that the slope appears steeper and steeper to the waves as they propagate shoreward. Hence the shoaling condition (which requires S small) will sooner or later be invalidated. With reference to the assumptions in Sect. 3 this would cause appreciable reflection and disintegration of the wave form (T not constant). No such phenomena were observed in the experiments recorded here, which suggests that S in all cases have been small enough.

5. WAVE SURFACE PROFILES

Let us assume that a rigorous perturbation expansion is carried out for waves on a sufficiently gently sloping bottom. Then the shoaling of the wave will represent the first approximation, but even though the slope of the bottom does not directly influence this first order solution, a second order solution exists which will represent the first approximation to the effect of the bottom slope, which has the effect of making the wave skew.

Svendsen (1974) carried out the calculations for this second order solution in the case of cnoidal waves, and the result for the skew wave profiles can be written

$$\eta = \eta^{(0)} + \eta^{(1)} \quad (3)$$

where $\eta^{(0)}$ is the constant depth cnoidal wave profile

$$\eta^{(0)} = H \left(\beta(m) + cn^2(2K\theta, m) \right), \quad \theta = \frac{t}{T} - \frac{x}{L} \quad (4)$$

K being the complete elliptic integral of the first kind, m its parameter, and β a function of m . $\eta^{(1)}$ is the above mentioned first approximation to the effect of the sloping bottom. $\eta^{(1)}$ is given by

$$\frac{\eta^{(1)}}{h} = 3 S \frac{L}{h} T \sqrt{g/h} f\left(\theta; U, \frac{H}{h}\right) \quad (5)$$

where

$$f\left(\theta; U, \frac{H}{h}\right) = \frac{\eta_{\theta}^{(0)}}{\sqrt{gh}} \int \eta_{\theta}^{(0)-2} \int \eta_{\theta}^{(0)} \int \left[2(cn^{(0)})_h - c_h \eta^{(0)} \right] d\xi d\zeta d\theta \quad (6)$$

Fig. 7 Wave profiles for wave with $H_0/L_0 = 0.0165$ on slope $h_x = 1:35$

Fig. 8 Wave profiles for wave with $H_0/L_0 = 0.0114$ on slope $h_x = 1:35$

with indexes θ and h denoting partial differentiation with respect to θ and h , respectively, under the restriction that the energy flux E_f is constant. This solution has been evaluated for a number of cases corresponding to wave profiles measured in the experiments. As input for the evaluation of the theoretical profiles has been used the wave period, the local measured wave height, the water depth (including set-down), and the bottom slope.

Figs. 7 and 8 show a comparison between measured and calculated profiles, in each case for three different phases of the deformation of a wave towards the breaking point.

It is immediately evident from the figures that the agreement is good even for wave height to water depth ratios as large as 0.75. It should, however, also be noticed that all the cases in the figures correspond to situations where the deviation from the symmetrical (ordinary) cnoidal wave profile is small. In other words, situations where the shoaling assumption about a local equilibrium is still valid. This is required also in the theory for $\eta^{(1)}$ because $\eta^{(1)}$ has to be a small perturbation on $\eta^{(0)}$. Consequently the large deformations which rapidly develop just before breaking cannot be predicted by this theory.

An interesting feature is that the skewness of the surface slopes is not so pronounced in the wave crest. The major effect of sloping bottom is concentrated in the wave trough, which has its deepest point right in front of the next wave crest.

6. PHASE VELOCITY

The measurements of the phase velocity c were obtained by measuring the time (in milliseconds) it took the wave crest (identified digitally by the computer) to travel the distance between two wave gauges placed 20.0 cm apart in the direction of wave travel.

The results obtained in this way are rather sensitive to small changes in the shape of the wave crest between the two wave gauges. As a consequence, the individual measurements show a considerable scattering ($\pm 10 - 25\%$). This is particularly pronounced for the very small wave steepnesses. Consequently the scattering is much reduced when the waves steepen on the slope.

The results for c presented in Fig. 9 a - d represent a moving average over a number of waves. The results have further been confirmed by a different method based on measuring electrically the time it takes the wave to travel between two pointed metal-rods placed 20 cm apart. The mean value of the measurements obtained in this way confirmed that the results obtained from the computer when the pointed ends of the metal-rods were placed at a level close to the wave crest.

It can be mentioned that one of the reasons for the large scattering in the experimental results is that small free second harmonic waves still exist in the flume. Such disturbances result in phase velocities which are constant in time, but vary from point to point. Hence the tendency mentioned in Sect. 2, that even the irregularities are reproduced when an experiment is repeated.

The measurements are compared with linear and cnoidal results for the phase velocity. From linear theory we have

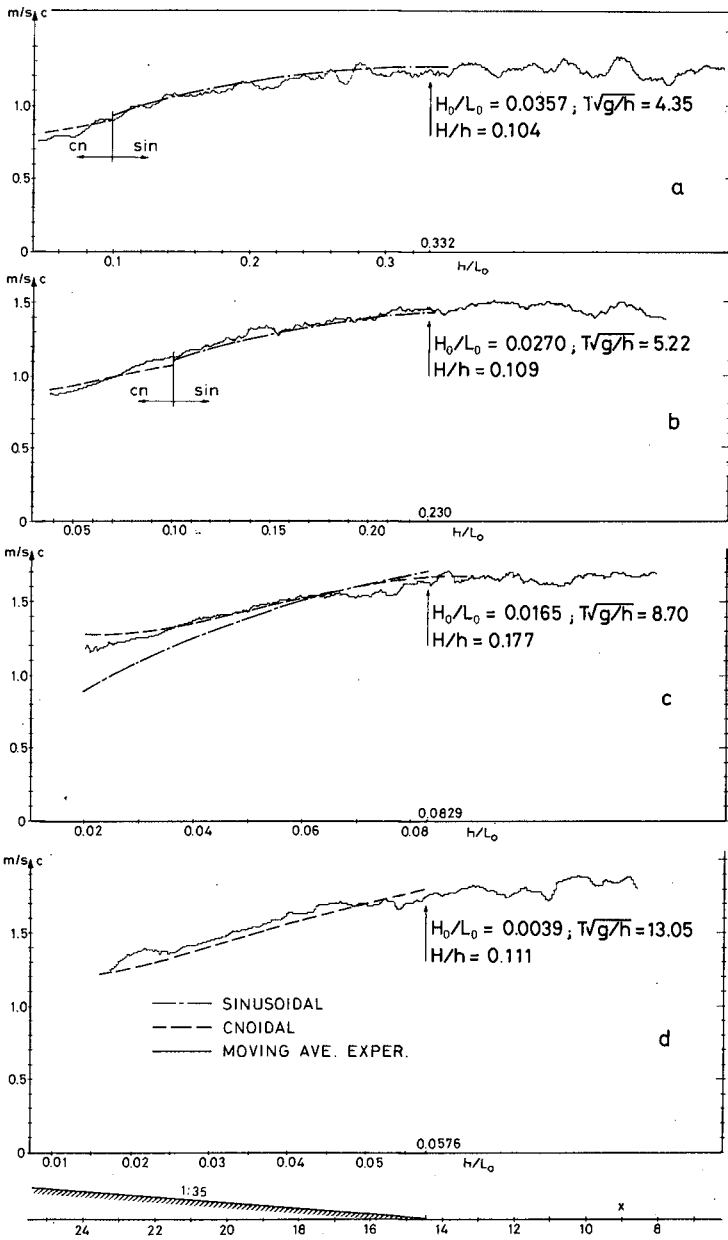

Fig. 9 Variation of phase velocity

$$c = \frac{g}{\omega} \tanh kh \quad (7)$$

which is used for all values of $h/L_0 > 0.10$. As the cnoidal result for c is used (for $h/L_0 < 0.10$)

$$c = \left(g h \left(1 + A \frac{H}{h} \right) \right)^{1/2} \quad (8)$$

$$A = \frac{2}{m} - 1 - \frac{3E}{mK} \quad (9)$$

where E is the complete elliptic integral of the second kind.

Since cnoidal theory assumes $H/h < 1$, (8) may also be written

$$c = \sqrt{g h} \left(1 + \frac{1}{2} A \frac{H}{h} \right) + O\left(\frac{H}{h}\right)^2 \quad (10)$$

which is equally valid. In the analogy with the wave height variation we realize that for waves near breaking the numerical results obtained for (8) and (10) differ appreciably. It turns out that the results obtained from (8) fit the measurements better. In (8) the theoretically determined wave height (i.e. from the shoaling process) has been used.

In general the conclusion is positive. The two theories predict the phase velocity to within a few per cent, the linear theory for $h/L_0 > 0.10$, the cnoidal shoreward of that point. The only exception is close to breaking, where the cnoidal theory overestimates the finite amplitude effect and yields results somewhat above the measurements. In Fig. 9 c is for comparison given the linear curve even though $h/L_0 < 0.10$ everywhere.

7. WAVE BREAKING

The last topic to be discussed in this paper is the characteristics of the waves at the breaking point, including the prediction of the position of this point, e.g. in terms of the water depth where breaking is initiated.

Even though cnoidal theory seems to predict the wave height variation reasonably well, no information can be deduced from that theory (or any other known theory) about where the breaking occurs. In that question we must rely entirely upon empirical data.

One of the problems is to define exactly where the breaking has started. Often breaking is defined to start 'where the front of the wave becomes vertical', though in the case of a spilling breaker there is no such point. Also the initiation of foam may be a very uncertain definition in small scale experiments where the surface tension will cause scale effects for the foam production.

In consequence of these arguments we have chosen to define the breaking point as the point where H/h is maximum. Since the wave height has a maximum close to the point where the energy dissipation starts and h is decreasing, H/h appears to have a rather sharp maximum. In the evaluation of h the set-down is incorporated. The choice of H/h to identify the breaking point has the advantage that from an engineering point of view the maximum of H/h is one of the primary information about the wave breaking.

Part of the large scatter in breaking data for earlier experiments is believed to be due to free second harmonics in the waves (Battjes, 1974). And even when this irrelevant effect is removed, as in our experiments, each breaking wave will generate wavelets which influence the breaking of the next wave etc. This is particularly pronounced for plunging breakers and represents an effect which must be expected also in the nature.

In the attempt to find coherence in the data obtained, many different plots and relationships among the parameters have been tried. One of the most promising is shown in Fig. 10.

It shows the value of the wave length to water depth ratio $(L/h)_B$ at the point where H/h is maximum. Since all the experiments were performed with a slope 1:35, Iversen's (1952) data for slopes, 1:10, 1:20, 1:30 and 1:50, and those reported by Iwagaki and Sakai (1976) for slopes, 1:10, 1:20 and 1:30 have been included, too. For all the points, L has been determined from the cnoidal wave theory using the wave period, and the wave height and water depth at the breaking point.

The abscissa in Fig. 10 is the theoretically determined deep water wave steepness H_0/L_0 . It appears from the figure that within the accuracy expected by the experiments (and the more advanced ISVA-experiments show a smaller variation, as they should) the data can be described by the relationship

$$(L/h)_B = 2.30 (H_0/L_0)^{-1/2} \quad (11)$$

From this relationship several deductions follow. Since L/h is increasing monotonously shorewards, this relation means that breaking starts when the wave length to water depth ratio grows to a value which depends only on the deep water wave steepness.

It is of particular interest to note that $(L/h)_B$ does not depend on the bottom slope h_x , and that the scattering is considerably smaller than for any other correlation between breaking parameters. The first suggests that shoaling conditions are satisfied in most of the experiments (Iversen's 1:10-data showing a weak tendency to larger values of $(L/h)_B$). Since L/h varies rapidly with the position in the breaking zone, the small scattering indicates that the initiation of breaking depends strongly on the value of L/h .

Once the relation (11) has been established, the wave height at the breaking point H_B is actually *theoretically* fixed too for a wave with a given deep water steepness H_0/L_0 . From (11) we get $(L/h)_B$, and since L/h is a monotonous function of h/L_0 for given H_0/L_0 (Svendsen and Brink-Kjær, 1972) this means that $(L/h)_B$ corresponds to one particular value of h_B/L_0 . This value can in principle be determined, though none of the tables published so far are suited for this purpose.* Finally, from h_B/L_0 and H_0/L_0 the value of $(H/h)_B$ can be determined (using e.g. Table 3 in Skovgaard et al., 1974).

Notice that if only H_0/L_0 is given we cannot determine the absolute value of h_B and H_B , only the ratios described above. Often, however, the wave period will be given too, and then $L_0 = g/(2\pi) T^2$ yields the

*The table required should have the entries L/h and H_0/L_0 and yield values of h/L_0 .

Fig. 10 Wave length to water depth ratio $(L/h)_B$ at the breaking point versus deep water wave steepness H_0/L_0

Fig. 11 Maximum value of wave height to water depth ratio $(H/h)_B$ versus slope parameter $S = h_x(L/h)_B$

length required to specify the absolute values from the dimensionless ratios.

In Fig. 11 a the values of $(H/h)_B$ are plotted versus $S = h_x(L/h)_B$. A comparison between theoretical and experimental results here would yield no information, which could not be drawn from Figs. 4 and 5.

The measurements of Iversen, and Iwagaki and Sakai (Fig. 11 b) do not quite fit into the pattern of the present investigation but the tendency is the same. Their results all correspond to smaller values of $(H/h)_B$ and the scattering is considerable. As mentioned before, this is probably to a large extent due to the free second harmonics generated by their wave generator. The scattering, however, is considerably decreased by using S instead of $(L/h)_B$. Thus the value of H/h at the breaking point is actually a function of the bottom slope h_x .

It will be seen that the values of the $(H/h)_B$ are in general somewhat larger than the height $0.827 h$ considered the largest possible for a solitary wave on a horizontal bottom (Longuet-Higgins and Fenton, 1974), and other results usually quoted for the maximum possible height of periodic waves. Also, the largest values of $(H/h)_B$ correspond to the largest values of S .

In both these respects, the results seem to fit into the pattern found by Camfield and Street (1969) who for solitary waves (i.e. theoretically infinitely long waves) found $(H/h)_B$ -values up to 2.

8. CONCLUSION

Linear ('sinusoidal') and cnoidal wave theories are compared with experimental results obtained with waves without free second harmonic disturbance on a plane slope $h_x = 1:35$. It is shown that:

- (a) Linear theory can predict the shoaling as long as the wave height to water depth ratio H/h is small (Fig. 4 a).
- (b) Cnoidal theory, which can only be used for $h/L_0 < 0.10$ (L_0 being deep water wave length), predicts the variation of the wave height quite well even close to breaking (Fig. 4 b and c).
- (c) Linear theory is used for $h/L_0 > 0.10$, and wave height is matched with cnoidal theory at that point. For waves with large deep water steepness H_0/L_0 ($> 3-4\%$) the value of H/h is not small for $h/L_0 > 0.10$. Hence linear theory fails (Fig. 5 b and c). Second or higher order Stokes theory is recommended in this case for $h/L_0 > 0.10$.
- (d) The skew shape of the wave profiles is well predicted by a theory taking into account the effect of the bottom slope (Figs. 7 and 8). The theory cannot predict breaking.
- (e) Both the linear and the cnoidal formulae for phase velocity c fit remarkably well to the data for $h/L_0 > 0.10$ and < 0.10 , respectively (Fig. 9).
- (f) At the breaking point the wave length to water depth ratio $(L/h)_B$ appears to be independent of bottom slope, for bottom slopes less than 1:10, i.e. $(L/h)_B = f(H_0/L_0)$, Fig. 10, whereas $(H/h)_B$ is primarily a function of the slope parameter $S = h_x(L/h)_B$ (Fig. 11).

The authors wish to acknowledge help and guidance from Jørgen Christensen and Paul Prescott in the experimental work, and from Ivar G. Jonsson in the calculations of friction losses.

APPENDIX

Given a wave with period $T = 12$ s, and $H_0/L_0 = 0.01$.

Find the wave height H at $h = 7$ m.

Since $L_0 = gT^2/2\pi = 225$ m, we have $h/L_0 = 0.031 > 0.10$ so that cnoidal wave theory is appropriate to use for this wave at $h = 7$ m.

Continuity in energy flux at the matching point, Table 3 in Skovgaard et al., yields directly (using h/L_0 and H_0/L_0 as entry) that $H/H_0 = 1.133$, or $H = 2.55$ m, since $H_0 = 2.25$ m.

Continuity in wave height at the matching point requires that we stage the calculation through that point. Linear theory yields (h_m denoting the depth at the matching point)

$$h_m/L_0 = 0.10 \Rightarrow H/H_0 = 0.933 \quad H = 0.933 \cdot 0.01 \cdot 225 = 2.10 \text{ m}$$

$$h_m = 0.10 \cdot 225 = 22.5 \text{ m}$$

At this point the table for linear (i.e. sinusoidal) waves yields $H_{\sin}/H_0 = 0.933$, whereas the cnoidal result for $H_0/L_0 = 0.01$ is $H_{\text{cn}}/H_0 = 0.867$. If we now require that at the matching point $H_{\text{cn}} = H_{\sin}$, we find that in the cnoidal calculation we must formally use a deep water wave height $H_{0,\text{cn}} = H_0 \cdot 0.933/0.867 = 2.43$ m, i.e. in the cnoidal computation the deep water steepness must be $H_{0,\text{cn}}/L_0 = 0.01076 \sim 0.0108$. The wave height at $h = 7$ m can then be found from Table 3 (Skovgaard et al.) using $h/L_0 = 0.031$ and $H_0/L_0 = 0.0108$ as entry. We get

$$H/H_0 = 1.140 \quad H = 1.140 \cdot 2.43 = 2.78 \text{ m}$$

against 2.55 m obtained by the other matching procedure.

ABSTRACT

Wave shoaling is calculated, based on finite amplitude wave theories on a uniform depth which were extended by the authors using the Stokes second definition for wave celerity. Change of wave characteristics with decrease in water depth is discussed from numerical computation, and difference in shoaling characteristics is considered in comparison with results obtained from usual wave theories by the first definition. Theoretical results are compared with preliminary experimental ones on the wave transformation in shoaling water conducted by the experimental facilities satisfying the physical conditions corresponding to the definition for wave celerity as well as possible, and the validity of each theory for practical purposes is investigated.

INTRODUCTION

There appears to be some problems in calculating wave shoaling by finite amplitude wave theories on a uniform depth under the assumption that energy flux of waves and wave period are invariable with change in water depth. One of them is the fact that as already pointed out by Stokes (1880), the physical definition is necessary to determine the wave celerity in the extension to the higher order approximate solution of finite amplitude wave theory. The one is the Stokes first definition for wave celerity, which means that the average horizontal water particle velocity over a wave length vanishes, and the other is the Stokes second definition for wave celerity, which means that the average momentum over a wave length vanishes by addition of a uniform motion.

The authors (1972) already calculated finite amplitude wave theories such as Stokes waves and cnoidal waves using the Stokes second definition for wave celerity and investigated the applicability by comparison with experimental results for wave celerity and water particle velocities.

In the calculation of wave shoaling, Le Méhauté and others (1964 and 1966) used usual Stokes wave theories of the third and the fifth orders by the first definition. Iwagaki and Sakai (1967) also used the hyperbolic wave theory of the second approximation. The hyperbolic wave theory was derived by Iwagaki (1968) from Laitone's cnoidal wave theory (1961), in which the wave celerity is calcu-

lated by the second definition.

In this paper, change of wave height and wave length with decrease in water depth is calculated using the above-mentioned theories by the second definition, and difference in shoaling characteristics is considered in comparison with results obtained from the usual wave theories by the first definition. Nextly, the applicability of each theoretical result is briefly discussed by the comparison with a preliminary experimental one.

ENERGY FLUX OF FINITE AMPLITUDE WAVES

According to Whitham (1961), mean energy flux of waves over a wave period \bar{W} is defined as

$$\bar{W} = \frac{1}{T} \int_{-T/2}^{T/2} \int_{-h}^{\zeta} \left(\frac{1}{2} \rho (u^2 + w^2) + p + \rho g z \right) u dz dt \dots \dots \dots (1)$$

in which T is the wave period, h the depth of water, ζ the surface displacement from the still water level, p the wave pressure, ρ the density of fluid, g the acceleration of gravity and u and w are the horizontal and vertical water particle velocities respectively. Eq. (1) is transformed into Eq. (2) from Bernoulli's theorem, in which ϕ is the velocity potential.

$$\bar{W} = -\frac{1}{T} \int_{-T/2}^{T/2} \int_{-h}^{\zeta} \rho \frac{\partial \phi}{\partial t} u dz dt \dots \dots \dots (2)$$

Mean energy flux of waves calculated from the Stokes wave theory of the fourth order by the second definition \bar{W}_{S2} is given as

$$\begin{aligned} \bar{W}_{S2} = & \frac{\rho c^2 \lambda^2}{8k} \left[A_{11}^2 (2kh + \sinh 2kh) + 8\lambda^2 \left\{ kh \left(A_{32}^2 + \frac{1}{2} A_{11} A_{13} + A_{11}^3 \right) + \frac{A_{11}^2 B_{22}}{8} + A_{22} A_{11} \cosh kh + \frac{A_{11} A_{22}}{2} \right. \right. \\ & \cosh kh + \frac{A_{11} A_{13}}{4} \sinh 2kh + \frac{3}{16} A_{11}^3 \sinh 2kh + \frac{A_{11}^2 B_{22}}{8} \cosh 2kh + \frac{A_{11} A_{22}}{2} \cosh 3kh \\ & \left. \left. + \frac{A_{11}^2}{4} \sinh 4kh \right\} \right] + O(\lambda^6) \end{aligned} \dots (3)$$

in which c is the wave celerity, λ the small expansion parameter corresponding to the wave steepness, k the wave number and A_{ij} and B_{ij} are the function of kh respectively. In the calculation, the contribution of the higher order terms than the fourth order term to the result is neglected. Eq. (3) agrees exactly with Le Méhauté's result by the usual Stokes wave theory if $A_{22} = 0$.

On the other hand, mean energy flux of Chappelard's cnoidal wave theory (1962) by the second definition \bar{W}_{C2} is expressed by Eq. (4), based on the second order approximation.

$$\begin{aligned} \bar{W}_{C2} = & \rho g h^2 \sqrt{g h} \left[\frac{L_1^2}{3} \left\{ \kappa^2 - 1 + 2(2 - \kappa^2) \left(\frac{E}{K} \right) - 3 \left(\frac{E}{K} \right)^2 \right\} + \frac{13}{3} L_1^2 L_3 \left\{ \kappa^2 - 1 + 4 \left(\frac{E}{K} \right) - 2 \kappa^2 \left(\frac{E}{K} \right) - 3 \left(\frac{E}{K} \right)^2 \right\} \right. \\ & \left. + \frac{L_1^3}{15} \left\{ 18\kappa^4 + 11\kappa^2 - 29 + (-36\kappa^4 + 6\kappa^2 + 124) \left(\frac{E}{K} \right) - 5(7\kappa^2 + 25) \left(\frac{E}{K} \right)^2 + 30 \left(\frac{E}{K} \right)^3 \right\} \right] + O(L_1^4 L_2^2) \dots (4) \end{aligned}$$

In Eq. (4), γ is the modulus of elliptic function, K and E are the complete elliptic integrals of the first and second kinds respectively and L_1 and L_3 the small expansion parameters given in Eq. (15).

Mean energy flux of waves obtained from cnoidal wave theory by the first definition \bar{W}_{c1} is calculated as the following equation.

$$\bar{W}_{c1} = \rho g h^2 \sqrt{g h} \left[\frac{L_1^2}{3} \left\{ \kappa^2 - 1 + 2(2 - \kappa^2) \left(\frac{E}{K} \right) - 3 \left(\frac{E}{K} \right)^2 \right\} + 5L_1^2 L_3 \left\{ \kappa^2 - 1 + 4 \left(\frac{E}{K} \right) - 2\kappa^2 \left(\frac{E}{K} \right) - 3 \left(\frac{E}{K} \right)^2 \right\} \right. \dots (5)$$

$$\left. + \frac{L_1^3}{15} \left\{ 23\kappa^4 + 6\kappa^2 - 29 + (-46\kappa^4 + 31\kappa^2 + 119) \left(\frac{E}{K} \right) - 15(4\kappa^2 + 7) \left(\frac{E}{K} \right)^2 + 15 \left(\frac{E}{K} \right)^3 \right\} + 0(L_1^m L_3^n) \right]$$

Substituting the relation between expansion parameters in Chappellear's first order approximate theory L_1 and L_3 given as

$$2L_3 + L_1 \left(\kappa^2 + \frac{E}{K} \right) = 0 \dots \dots \dots (6)$$

it is found that Eq. (5) coincides with Eq. (4) within the order of this approximation.

Based on Laitone's cnoidal wave theory expressed by the mean water depth, energy flux \bar{W}_{L2} is given as

$$\bar{W}_{L2} = \rho g h^2 \sqrt{g h} \left[\frac{1}{3\kappa^4} \left\{ \kappa^2 - 1 - 2(\kappa^2 - 2) \left(\frac{E}{K} \right) - 3 \left(\frac{E}{K} \right)^2 \right\} \left(\frac{H}{h} \right)^2 + \frac{1}{30\kappa^4} \left\{ 4(-\kappa^4 + 3\kappa^2 - 2) + (8\kappa^4 - 53\kappa^2 + 53) \left(\frac{E}{K} \right) \right\} \right. \dots (7)$$

$$\left. + 60(\kappa^2 - 2) \left(\frac{E}{K} \right) + 75 \left(\frac{E}{K} \right)^2 \right] \left(\frac{H}{h} \right)^3 + 0 \left(\left(\frac{H}{h} \right)^4 \right)$$

Eq. (7) agrees exactly with that obtained from the second order approximate solution by the first definition within this approximation, and moreover if the parameters L_1 and L_3 are expanded into power series of the ratio of water depth to wave height H/h , energy flux by Chappellear's theory, Eqs. (4) and (5) yields Eq. (7). This is a self-evident truth, because expanding the parameters L_1 and L_3 in Chappellear's theory into the power series of H/h , Laitone's theory coincides with Chappellear's theory to the second order of H/h , as the authors (1974) already proved.

WAVE SHOALING OF FINITE AMPLITUDE WAVES

In general, the calculation of wave shoaling using energy flux from a theory on a uniform depth is based on the two assumption that energy flux and wave period are invariable with change of water depth. Then, under the assumption that energy flux of waves in deep water may be given by the results from the Stokes wave theory of the fourth order, in case which wave theories by both the definitions coincide each other, equations to calculate wave shoaling by Stokes wave theory are formulated by the following ones.

$$\left(\frac{h}{L}\right)^4 \lambda_0^8 \left(1 + \frac{3}{4} \lambda_0^2\right) = \left(\frac{h}{L_0}\right)^4 \lambda^2 \left[\frac{A_{11}^2}{2} (2kh + \sinh 2kh) + \lambda^2 \left\{ 4kh \left(A_{02} + \frac{A_{11}A_{13}}{2} + A_{12} \right) + \frac{A_{11}^2 B_{22}}{2} \right. \right. \\ \left. \left. + 4A_{02}A_{11} \cosh kh + 2A_{11}A_{22} \cosh kh + A_{11}A_{13} \sinh 2kh + \frac{3}{4} A_{11}^2 \sinh 2kh + \frac{A_{11}^2 B_{22}}{2} \cosh 2kh \right. \right. \\ \left. \left. + 2A_{11}A_{22} \cosh 3kh + A_{12}^2 \sinh 4kh \right\} \right] \dots \dots (8)$$

$$2\pi(1 + \lambda_0^2) \left(\frac{h}{L_0}\right) = kh(1 + C_1 \lambda^2) \tanh kh \dots \dots \dots (9)$$

in which C_1 is the function of kh . The parameters λ and λ_0 are given in Eqs. (10) and (11) respectively.

$$\frac{\pi H_0}{L_0} = \frac{3}{8} \lambda_0^3 + \lambda_0 \dots \dots \dots (10)$$

$$\frac{\pi H}{L} = B_{33} \lambda^3 + \lambda \dots \dots \dots (11)$$

Under the similar assumption as the case of Stokes waves, equations to determine shoaling characteristics by the cnoidal wave theory are expressed as

$$\lambda_0^2 \left(1 + \frac{3}{4} \lambda_0^2\right) \left\{ \frac{1}{2\pi} (1 + \lambda_0^2) \left(\frac{h}{L_0}\right) \right\}^{3/2} = 8\pi \left(\frac{h}{L_0}\right)^4 \left(\frac{\bar{W}_0}{\rho g h^2 \sqrt{g h}}\right) \dots \dots \dots (12)$$

$$\frac{1}{2\pi} (1 + \lambda_0^2) \left(\frac{h}{L_0}\right) \left(\frac{L}{h}\right)^2 = \left(\frac{c}{\sqrt{g h}}\right)^2 \dots \dots \dots (13)$$

in which \bar{W} is the energy flux by each cnoidal wave theory mentioned above. Eqs. (14) and (15) are further added to calculate wave shoaling by Chappellear's theory.

$$\frac{H}{h} = \kappa^2 L_1 \left\{ 1 + \frac{1}{4} L_1 (7\kappa^2 + 10) + 6L_3 \right\} \dots \dots \dots (14)$$

$$2L_4 + L_1 \left(\kappa^2 + \frac{E}{K} \right) + L_2 \left\{ -\frac{1}{5} (-9\kappa^4 - 6\kappa^2 + 1) + 2(\kappa^2 + 1) \left(\frac{E}{K} \right) \right\} + 6L_1 L_3 \left(\kappa^2 + \frac{E}{K} \right) + L_5^2 = 0 \dots \dots (15)$$

Numerical computation was done by use of iterative technique composed of the combination with the Regula-Falsi method and the Newton method.

NUMERICAL RESULTS AND CONSIDERATIONS

Fig. 1 shows change of wave height calculated from Stokes wave theories by both the definitions, in which the breaking inception is obtained from the Stokes criterion that the wave celerity equals to the horizontal water particle velocity at the water surface. In addition to the well-known fact that change of wave height calculated from Stokes wave theory is more evident than that by Airy wave theory with increase in deep water wave steepness H/L , the wave height calculated from Stokes wave theory by the second definition⁰ is larger than that by the first definition by about 7 % at most. It is also noted that the ratio H/H_0 is greater than unity in the range of relatively large value of the ratio h/L_0 , in

case when the Stokes wave theory by the second definition is used.

Fig. 2 is the results based on Chappellear's cnoidal wave theory as well as the Stokes wave theories mentioned above. Wave height increases rapidly with decrease in h/L compared with the results by the Airy wave theory, as extended by Iwagaki and Sakai, using the hyperbolic wave theory. Results from cnoidal wave theories by both definitions do not differ from each other in relatively small ratio of h/L . This is expected from the fact that the cnoidal wave theories by both the definitions coincide each other in the case of a solitary wave.

The comparison between change of wave height computed from Chappellear's cnoidal wave theory by the second definition and that from Laitone's theory is given in Fig. 3, in which the ratio from Chappellear's theory becomes greater than that

Fig. 1 Change of wave height calculated from Stokes wave theories by both definitions

Fig. 2 Change of wave height calculated from Stokes and cnoidal wave theories by both definitions

from Laitone's theory with increase in deep water wave height H_0/L_0 . Since, moreover, the horizontal water particle velocity at phase of wave crest at the water surface by Laitone's theory greatly increases compared to that by other finite amplitude wave theories in the vicinity of breaking point, the ratio H/H_0 at breaking point calculated from the Stokes criterion by Laitone's theory becomes considerably smaller than that by Chappellear's theory.

Fig. 4 shows change of wave length computed from the Stokes wave and cnoidal wave theories by Chappellear. As shown in the figure, the wave length calculated from Stokes wave theory by the first definition as well as the cnoidal wave theories by both definitions increases with H/H_0 for the same ratio of h/L_0 , whereas the result from the Stokes wave theory by the second definition decreases with H/H_0 within a range of the ratio of h/L_0 .

The comparison between result for change of wave length L/L_0 computed from Chappellear's cnoidal wave theory by the second definition and that from Laitone's theory is shown in Fig. 5. There is little difference between them as well as the result for wave height shown previously except for a region near the breaking point and a range of relatively large values of h/L_0 and H_0/L_0 , where the applicability of cnoidal wave theory is questionable.

COMPARISON WITH EXPERIMENTAL RESULTS AND CONSIDERATIONS

A preliminary experiment of wave shoaling was conducted at Ujigawa Hydraulic Laboratory, Disaster Prevention Research Institute. The wave tank used in the experiment is 25 m long, 0.5 m wide and 0.65 m deep. Various devices were made by Tsuchiya and Yasuda in order to keep the uniformity of mass transport induced by waves. That is to say, the wave tank of which both the ends are opened was installed in the wide semi-circular basin of which diameter is 35 m. Next, attaching a big float to the usual piston-type wave generator, the generation of waves with opposing direction was suppressed, and a special wave absorber was set adjacent to the end of wave tank and at the sidewall of wave basin. These are owing to prevent the return flow in relation with the hydrostatic pressure gradient caused by mass transport of waves.

The experiment was carried out in the two cases. In the first case, a sloping model beach which gradient is 1/50 was installed in the wave tank so as

Fig. 3 Change of wave height calculated from Chappellear's theory and Laitone's one

Fig. 4 Change of wave length calculated from Stokes and cnoidal wave theories by both definitions

Fig. 5 Change of wave length calculated from Chappellear's theory and Laitone's one

to keep the water depth at the end of wave tank finite. This is corresponding to the experiment to realize the physical condition for the Stokes first definition to some extent. In the experiment, the care not to make the waves break on the sloping beach was taken, because wave breaking at the end of wave tank induces excess mass transport.

In the second case, the sloping beach model was installed under a situation that the outflow and inflow of water through the end of wave tank do not exist. Consequently, the dry bed on which waves are run up was ensured. This is corresponding to the experiment to realize the physical condition for the second definition.

Surface displacement was measured by six resistance-type wave gauges and wave celerity was estimated from propagation time between each gauge.

Since wave height and wave length in deep water are not uniquely determined from the given wave height and wave period at an arbitrary water depth when the wave theories by both the definitions are used, change of wave height and wave length starting from those at the most offshore wave gauge were treated for comparison.

The effect of wave damping due to bottom and sidewall friction on change of wave height with decrease in water depth was estimated by applying the following formula of wave damping step by step. The formula by Iwagaki et al. (1967) is expressed as

$$\left. \begin{aligned} \frac{H_x}{H_l} &= \exp\left(-\frac{\alpha \epsilon_{\beta+\omega} x}{L}\right), \\ \epsilon_{\beta+\omega} &= \left(\frac{4\pi^2}{\beta L}\right) \left(1 + \frac{1}{\psi}\right) \frac{1}{\sinh 2kh + 2kh}, \quad \psi = \frac{kB}{\sinh 2kh}, \\ \beta &= \left(\frac{\pi}{vT}\right)^{\frac{1}{2}} \end{aligned} \right\} \dots \dots \dots (16)$$

which was derived from laminar wave boundary layer theory on a uniform depth, in which x is the distance of wave propagation, B the width of wave tank and ν the kinematic viscosity. The value of α was adopted as 1.4 from comparison with their experiment on wave damping in order to take into account the effect of wave non-linearity and water surface contamination on wave damping. Consequently, it was found that the effect of wave damping on change of wave height is very important to be about 15% for 1/50 slope.

Fig. 6 is one of examples for change of wave height with decrease in water depth, in which h_1 and H_1 are the water depth and wave height measured at the most offshore site respectively. In spite of wide scatter of experimental results, it appears that the qualitative tendencies of experimental results may be explained by each theory.

Fig. 7 shows change of wave length estimated from the experimental results for wave celerity. Wave celerity measured was regarded as the one at the middle point of two wave gauges. The experimental results agree relatively well with the theoretical ones for each experiment.

Fig. 6 Comparison between theoretical results and experimental ones for change of wave height

Fig. 7 Comparison between theoretical results and experimental results for change of wave length

CONCLUSIONS

Wave shoaling was calculated, based on finite amplitude wave theories on a uniform depth which were extended by the authors using the Stokes second definition for wave celerity and difference in shoaling characteristics was considered in comparison with results obtained from the usual wave theories by the first definition. It was found that the difference is considerably significant for a region of applicability to Stokes waves.

From comparison with the experimental results made under the considerations to satisfy the physical condition corresponding to each definition for wave celerity as much as possible, the tendency of shoaling characteristics obtained from each wave theory was qualitatively confirmed.

ACKNOWLEDGEMENTS

Part of this investigation was accomplished with the support of the Science Research Fund of the Ministry of Education, for which the authors express their appreciation.

CHAPTER 29

Refraction of Finite-Height and Breaking Waves

by James R. Walker, Ph.D., P.E.*

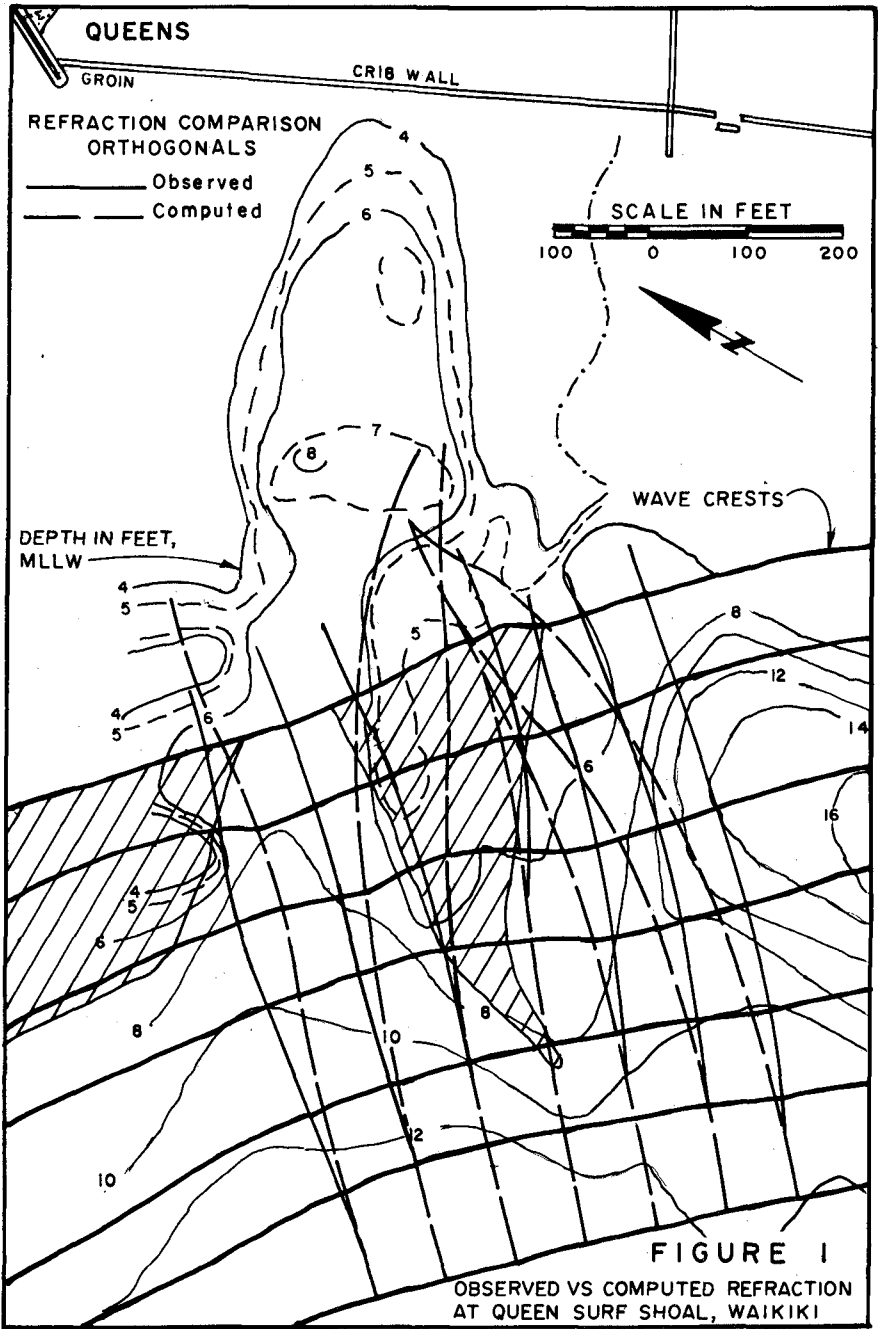

ABSTRACT

The primary objective of this study was to ascertain the influence of wave height and breaking on wave refraction over a three-dimensional shoal. The subject wave transformations were studied in an hydraulic model. Wave shoaling, decay in the breaker zone, and phase velocities were analyzed in a base test series over a bottom slope of 1:30. A second test series was conducted over a three-dimensional shoal. Wave patterns were photographed and wave heights and celerities were measured. The measurements were compared with wave refraction patterns and coefficients computed by analytical methods. Wave shoaling observed over the constant 1:30 slope was 25 percent greater than predicted by Airy theory at the breaking point for wave steepness $H_0/L_0 = .030$ and 50 percent greater than predicted for $H_0/L_0 = .002$. Shoaling measurements were compared with other empirical data sets, confirming the inadequacy of commonly used practice using linear wave theory near the breaker zone. The celerity measurements indicated that the non-breaking celerity was given by $C = (1 + .25 H/d)C_a$, where C_a is the Airy celerity. The discussion and results give a basic understanding of wave refraction near the breaker zone, supplementing analytical papers on refraction procedures using finite amplitude wave theories.

INTRODUCTION

The topic for this study evolved from field investigations of wave transformations over recreational surfing shoals in Hawaii. Walker, Palmer, and Kukea (1972) noted through observation of aerial photographs that, in some cases, breaking waves had a diverging pattern over the centerline of the shoal where linear refraction theory predicted a strong convergence. Figure 1 shows an observed wave at 5-second intervals propagating over Queens surf shoal in Waikiki. Orthogonals drawn from the wave crests are compared with those computed by linear refraction theory. The observed orthogonals tended to be considerably less affected by the bathymetry than were the theoretical orthogonals. This observation raised several questions concerning the applicability of extending refraction analysis into the breaker zone, especially over an irregular shoal. Whalin (1971) observed effects of finite height altering wave refraction patterns, but focused his attention on diffraction. Weigel and Arnold (1957) state that refraction theory is valid within two to three wave lengths seaward of the breaking position. Unfortunately, the coastal engineer often extends the limits of theory

*Moffatt & Nichol, Engineers, Long Beach, California.

into the surf to acquire the required design wave or frequency of occurrence of a given wave height.

The purpose of this study is to determine the influence of finite height and breaking on wave refraction over a three-dimensional shoal for application to surf shoal design and prediction of the influence of the shoal on adjacent beaches. The effects of diffraction, wave-induced currents, reflection, and energy dissipation other than breaker decay are assumed negligible in this study. This study was conducted in an hydraulic model of a shoal of specific shape; however, the results also have general application in understanding the nature of error and order-of-magnitude of error when conventional refraction techniques are employed near the breaking region.

THE MODEL

The primary objective of the model was to study the transformation of waves propagating from deep water into the surf zone over a three-dimensional shoal. Several compromises were made in design of the model basin and test shoal. Since wave propagation was to be followed through the surf zone, the scale should be as large as possible to reduce scale effects due to viscous dissipation and air entrainment. The bottom slope should be constant for a distance of at least a wave length seaward of the test shoal according to criteria developed by Camfield and Street (1966). The bottom slope should be representative of conditions typically found in nature. The wave generator should be located in water depth to wave length ratio $d/L > .1$ such that wave shoaling could be measured from relatively deep water and to ensure that secondary wave crests described by Galvin (1968) would not be generated.

Space limitations restricted the basin length to 50 feet and the wave generator established the basin width at 20.6 feet. Figure 2 shows the model basin dimensions. The basin side walls were 2 feet and the water depth was 1.8 feet. The test shoal was modeled after a general concept of a surf site discussed by Walker and Palmer (1971).

The bathymetry of the test shoal was required to:

- a. induce a theoretical wave orthogonal convergence by application of linear refraction theory;
- b. induce a wave to break in a form similar to that at a recreational surfing shoal;
- c. produce a spilling to plunging breaker-type;
- d. have minimum reflection effects and minimum effects from side walls or beach;
- e. have sufficient water depth to minimize scale effects induced by dissipation at the bottom boundary and in the turbulent breaking region; and,
- f. have the parameters under study be of a scale sufficient to deduce significant conclusions.

The selected shoal shape was a truncated cylinder inclined on a 1:20 slope relative to the horizontal. The cylinder was truncated on the bottom by the 1:30 basin slope and on the top by a 1:42.5 slope. The plan view of a truncated cylinder transcribes an ellipse. The semi-major axis of the 1:30 slope was 15 feet and was oriented parallel to the direction of wave approach. The semi-minor axis was 6.71 feet on a horizontal projection. The shoal and coordinate system are shown in Figure 2. The toe of the shoal starts at station $x=0$ feet, $y=15$ feet and intersects the shoreline at station $y=0$ feet, $x=\pm 5$ feet. The 1:42.5 slope starts at the shoreline to form a plane which also transcribes an ellipse. The 1:42.5 slope intersects the 1:20 slope at $z=0.222$ feet at station $y=9.44$ feet, $x=0$ feet. The bathymetry of the model and shoal for y less than 33 feet is give by three equations:

1. $z_1 = y/30$, for $y < 33$, $|x| \geq 5.0(1. - y^2/15^2)^{1/2}$
2. $z_2 = (y/20) - (15/20)(1. - x^2/45)^{1/2} + 0.5$, for $y < 15$, $|x| \leq 5.0(1. - y^2/15^2)^{1/2}$
3. $z_3 = y/42.5$, for $y \leq 9.44$, $|x| \leq 5.0(1. - y^2/9.44^2)^{1/2}$

The depth, z , is everywhere less than or equal to the z_1 plane and greater than or equal to the z_3 plane. The curved portion of the shoal is described by z_2 .

The model basin and shoal were constructed of reinforced, finished concrete. Measurements of the bathymetry after construction indicated that the 1:30 bottom slope was accurate to within ± 0.005 feet and that the test shoal was accurate to within ± 0.010 feet.

Waves were generated by a 20.5-foot-long plunger-type wave generator. The wave period was adjusted on a variable speed crank and the amplitude of the waves was changed by adjusting the stroke of the plunger. A wave filter was placed in front of the generator to reduce high frequency noise produced by the generator. A wave-absorbing beach was placed at the shoreline along $x=0$ to reduce the entry of reflections into the measurement area. The absorber comprised a 1:15 beach slope covered by two layers of 1/4-inch stone. The stones extended on the 1:30 slope to $y=1.8$ feet.

Wave heights were measured with double-wire resistance-type wave rods. Signals were displayed on a light beam oscillograph recorder. Wave crest patterns were photographed from a platform located 20 feet above the model.

Two series of tests were conducted using 15 test waves in each series. The base test series was conducted over the constant sloping bottom to calibrate the model and waves. The shoal test series was conducted using the same generator settings as the base tests to monitor the changes in wave response induced by the bathymetry.

The 15 test waves selected for study had periods of 1.16, 1.67, 2.00, and 2.33 seconds. Four wave generator settings were used with each wave period with the exception that the four-inch half-stroke was not used with the 1.16-second period. This latter wave overtopped the

basin walls. The tests covered a range of waves which broke approximately between station $y=2$ feet, depth $z=0.067$ feet, and station $y=12.5$ feet, $z=0.42$ feet on the constant slope. The breaker heights ranged from 0.08 feet to 0.38 feet.

Eighty-one gage locations were used for the base tests. Eighty gages were located on I-beams along $x=0, 2.5, 5.0,$ and 7.5 feet and at $y=2, 4, 6, \dots, 40$ feet. Figure 3 shows the locations of the gages during the base tests. In addition to the evenly spaced gages, a portable gage was used during a separate run of the group of test waves to measure breaker heights and locations.

Sixty-one gage locations were monitored in the shoal tests. The gages were located at stations $x=0, 1.25, 2.5, 3.75, 5.0$ feet, and $7.5,$ and at $y=2, 4, 6, \dots, 20$ feet. Figure 4 shows the location of the gages for the shoal series of tests. An additional group of test waves was run with a portable gage to measure the initial breaker height on the centerline of the shoal at $x=0$ feet.

Wave rod calibrations were taken prior to and after each group of test waves had been run. The gage calibrations were slightly non-linear over a large range of submergence. A second order polynomial was fit to seven calibration points by the method of least squares to describe the calibration curve. Calibration on gage 13, located at station $y=16$ feet on the wave test, was unstable and the results were assumed to be unreliable.

Test procedures consisted of running the wave generator for approximately one minute while the recording was made. The recording chart speed was $1/4$ inch per second for the series of gages from stations $y=22$ feet to $y=40$ feet, and one inch per second for the gages located from stations $y=2$ feet to $y=20$ feet.

Small variations in the generated wave height and tolerances in basin depths caused the wave to break non-uniformly across the basin. The variations in wave breaker position induced a current system which influenced the refraction and the breaking patterns. Even on the straight beach, the breaking pattern varied considerably when the generator was allowed to run for an extended period of time. For this reason, measurements were confined to the first five to ten waves, which were relatively unaffected by the induced currents. In most cases, little temporal variation in the wave height was evident. The greatest temporal wave height variations occurred when a gage was located close to the breaking point. The average wave celerity between successive gages was determined by measuring the time differential of crest passage between gages separated by 2-foot intervals.

The results of this investigation may be viewed in terms of dimensionless parameters. However, lengths and times may be scaled for application to coastal design. Scaling of the model was done through use of the Froude modeling relation. Viewed in terms of a model experiment of a prototype surf shoal, the length scale selected in the design of the model was 1:36 and the velocity and time scales were 1:6.

The laminar dissipation was calculated by the method of Keulegan (1950) to obtain an estimate of the dissipation in the model prior to wave breaking. Approximately five percent of the energy from non-breaking waves was dissipated by laminar dissipation by the time the wave reached station $y=2$ feet. Horikawa and Kou (1962) indicated that wave height decay in the breaking region was greater in the model than in the prototype. When applying these data to a prototype situation, these factors must be taken into account. Wave energy reflecting from the beach was computed by the Miche (1951) formula. The maximum calculated reflected wave height, H_r , was less than 14 percent of the incident wave.

The accuracy of the model procedures was estimated from a preliminary test series. The wave rods were spaced 2 inches apart and strung across the basin at $y=26$ and 27. Eight test waves were run to determine the variation in wave height. The measured wave heights were within a ± 10 percent deviation at two standard deviations. Wave height variation across the basin introduced an additional ± 5 percent error. Wave celerity was estimated to be within 10 percent error due to tolerance in positioning the wave gage and in reading the zero phase position on the wave.

RESULTS AND ANALYSIS

Wave Shoaling

The base test series was conducted to study transformations of waves propagating from intermediate water depths over a sloping bottom into the breaking region in shallow water. The primary topics investigated were wave height growth due to shoaling water depths and the influence of wave height and wave breaking on wave celerity. Measurements were compared with values predicted by application of linear wave theory commonly used in refraction analysis.

The characteristics of incident test waves and their breaking properties measured in the model are summarized in table 1. Figure 5 shows a typical wave height profile as a function of distance offshore. The figure indicates the typical scatter and accuracy of the data. The breaking position was measured by a single gage. An equivalent deep-water wave height was determined by application of the Airy shoaling coefficient to the wave measurements at gages located at Stations 26, 28, 30 and 32. Utilizing the calculated deep-water wave height and the Airy shoaling coefficient, the predicted wave height is shown by the dashed line in Figure 5. The wave shoaling measured in the model increases much more rapidly than the predicted wave shoaling. This increase is most noticeable just prior to the wave breaking position. The slope of the measured wave height profile appears to increase significantly when $H/d \geq .25$.

Wave shoaling from each of the tests was plotted in dimensionless form as a function of d/L_0 . The data were smoothed and shoaling curves are shown in Figure 6 as a function of H_0/L_0 . The data are compared with Airy shoaling theory. The rate of shoaling increases rapidly just prior to breaking. The low steepness waves, $H_0/L_0 = .002$, break at a

FIGURE 5 - WAVE SHOALING, TEST 7

height 50 percent greater than the Airy shoaling coefficient predicts. The higher initial steepness waves, $H_0/L_0 = .03$, break at a height 25 percent greater than Airy theory predicts.

Figure 6 represents an empirical set of wave shoaling curves for waves propagating over a 1:30 slope. The significance of these results is that the waves in shallow water shoal at a much greater rate than Airy theory predicts. Consequently, application of Airy theory in shallow water predicts a significantly lower wave height than observed in this model. These results are similar to those obtained by Iwagaki and Sakai (1972). The wave shoaling curves given in Figure 7 are compared with the shoaling curves based on cnoidal wave theory developed by Svendsen and Kjaer (1972) and stream function theory by Dean (1974). The comparison shows similar trends, height of shoaling as a function of H_0/L_0 . Cnoidal theory predicts a shoaling height less than unity for d/L_0 greater than .05. This is not confirmed by observation. Cnoidal theory also appears to predict a slightly greater rate of wave shoaling than measured for H_0/L_0 less than 0.01. However, the comparison is not strictly valid since H_0' rather than H_0 was measured. Stream function theory compares well with the expected set for $H_0/L_0 \geq .01$ with the exception that the published data uses the breaker index $H_b/d_b = .78$ compared to the observed index = 0.95. This may be attributable to the effect of bottom slope not accounted for in the theory. For $H_0/L_0 < .01$, the stream function shoaling is significantly greater than the observed. This is attributed in part to the estimate of H_0 made in the model at the low d/L_0 region. The wave had undergone more transformation than predicted by Airy theory. Consequently, the indicated $H_0/L_0 = .002$ curve may in fact be representative of some lower H_0/L_0 . Conversely, the shoaling curves are theoretical over a constant sloping bottom. The breaker index is equal to 1 for the measured data as drawn in Figure 6. Shoaling from deeper water $d/L_0 > .1$ through breaking for $H_0/L_0 < .01$ over different bottom slopes requires further research; however, the results of the studies indicate the magnitude of error when Airy theory is invoked. Figures 6 and 7 could be used in design, model, and field studies and in evaluating wave data.

Comparison of measured breaking height to deep-water height with values predicted by empirical data developed by Koh and Le Méhauté (1966) indicate that predicted values are 10 percent to 15 percent lower than measured. The difference between the observed and predicted values is attributed in part to the method of estimating the deep-water wave height. Rarely in the field or model is the deep-water wave measured and directly related to a shallow water breaking wave. Application of a linear shoaling coefficient to a measured wave height introduces a potential error which increases in magnitude with decreasing d/L_0 . The relative breaker height to breaker depth index, B , is also listed in Table 1. The average value of $B = .95$ for this data set. Application of methods developed by Galvin (1968) predicted an average value of $B = .85$.

Wave Celerity

The average phase velocity, \bar{c} , between two wave gages was determined by dividing the elapsed time for passage of the wave crest between gages by the distance between the gages. Figure 8 shows typical average

FIGURE 6 - WAVE SHOALING

FIGURE 7

COMPARISON BETWEEN MEASURED AND THEORETICAL WAVE SHOALING

celerities measured in the model in the base tests. The celerities increase as a function of wave height.

The measured celerities were compared with celerities commonly used in refraction analysis by defining a Froude number, $F_r = \bar{c}/\bar{c}_a$,

$$\text{where } \bar{c}_a = \frac{1}{y_1 - y_2} \int_{y_2}^{y_1} c \, dy = \frac{1}{y_1 - y_2} \int_{y_2}^{y_1} \frac{gT}{2\pi} \tanh(dk) \, dy,$$

where $k = \frac{2\pi}{L}$, and y_1 is gage 1 coordinate.

The Froude numbers are plotted in Figure 8 as a function of H/d . The results indicated a significant departure from Airy theory which would have had a $F_r = 1$ in all regions. Several theoretical expressions were plotted against the data; however, the simple expression below fits the data through the non-breaking region well:

$$F_r = 1 + 0.25 \frac{H}{d}$$

This expression gives a maximum Froude number of 1.25 at breaking where $H/d = 1$. The curve is applicable to the region prior to breaking. Airy theory predicts celerity approximately 6 percent too low at $H/d = .25$. This is also the region where the shoaling curve deviated noticeably from the Airy theory.

The Froude number increases with H/d until it exceeds 1.25 at breaking. The breaking and broken waves are shown in Figure 8 above $F_r = 1.25$. The maximum value was $F_r = 1.4$. The higher values appear to occur when the wave breaks. A discontinuity in wave phase appears to occur during the plunge of the breaker as the crest curls over the face of the wave. This is a short-duration occurrence, but accounts for observed apparent divergences in wave form in aerial photos and high Froude numbers in Figure 8. Data were insufficient to ascertain a reliable expression for wave celerity in the surf zone. Considering wave decay, scale effects, and the change of phase during breaking, $c = \sqrt{g(d+H)}$ when $H = .78d$ or $F_r = 1.33$ gives a reasonable approximation in the surf zone. An analysis was made using wave setup, η , in the surf zone. Setup was included in the velocity term where $c_b = \sqrt{g(d+\eta)}$; however, the analysis did not reduce the scatter of data significantly. After the wave breaks, however, the application of refraction loses some meaning. The wave crest patterns become the only meaningful relation unless wave decay can be modeled more accurately in the surf zone in regions of converging and diverging orthogonals.

Shoal Tests - Refraction

The shoal test series was conducted to study the influence of finite wave height and breaking on wave refraction. Comparison of wave crest patterns measured in the model and computed by linear refraction theory are shown in Figure 9. The comparison shows the wave pattern of a wave as it propagates over the shoal. The wave crests and initial surf line are traced over the shoal for test waves 3 and 14. Comparison of the theoretical with the measured refraction patterns shows that the low-height wave represented by test 3 tends to follow the conver-

FIGURE 8 - Fr . VS H/d

FIGURE 9 - OBSERVED VS COMPUTED WAVE CREST PATTERNS

gent patterns predicted by the theoretical analysis. With increase in wave height represented by test 14, the pattern tends to become divergent over the center of the shoal.

Computed refraction coefficients, K_r , range from 0.75 to 2.0. The waves approaching the shoal converge toward the centerline over the curved portion of the shoal. The conventional refraction analysis predicts wave concentration over the shoal centerline. The high refraction coefficients are located over the center of the shoal and the low coefficients along the side of the shoal. The observed wave patterns vary considerably as a function of wave height. The most noticeable feature of the observed patterns is the marked divergence in the vicinity of breaking as shown in the large wave in test 14.

The conclusion drawn from these observations is that finite height and wave breaking have a very significant influence on wave refraction over a shoal. The waves with small heights in Tests 1 through 5 converged toward the center of the shoal and conformed in general with linear refraction patterns up to a short distance seaward of breaking. The larger waves, however, tended to diverge. The combination of orthogonal divergence and diffraction, current, and reflection effects reduced the breaker height to less than that over the planar 1:30 slope for the larger waves. The application to design indicates that refraction over the shoal may not necessarily increase the wave height as would intuitively be expected.

MODIFIED REFRACTION TECHNIQUE

The influences of wave height and wave breaking were shown to affect wave refraction patterns in the hydraulic model. Linear refraction procedures were modified to account for the effects of wave height and wave breaking. The basic algorithm utilized the results of the base tests on celerity and shoaling to construct wave fronts at successive time intervals. Chu (1974) and Skovard and Petersen (1976) have developed computer programs utilizing the finite height theories to predict refraction of finite height, but not breaking waves.

The modified refraction theory is briefly described below using test 7 as an example. The incident wave parameters were $H_0 = 0.126$ feet and $L_0 = 14.22$ feet, resulting in $H_0/L_0 = 0.00885$. The wave height was determined as a function of depth from Figure 6, neglecting refraction effects by the equation

$$\frac{H}{d} = \left(\frac{H}{H_0}\right) \left(\frac{H_0}{L_0}\right) \left(\frac{L_0}{d}\right)$$

The wave celerity in the region prior to breaking was determined by the equation

$$c = c_a(1 + 0.25 H/d)$$

The wave in the breaking region was determined by $c = 1.33\sqrt{gd}$. Breaking was assumed to occur at $H/d = 1$. Refracted wave crests were drawn by the wave crest method and refraction coefficients were determined from or-

thogonals drawn through the crests. The method is tedious and not recommended for design practice. The wave front method was also employed using conventional refraction procedures for direct comparison of wave crest patterns and refraction coefficients shown in Figure 10.

The modified technique, which incorporates wave height and wave breaking, predicts a smaller degree of orthogonal convergence in the center of the shoal and a smaller degree of orthogonal divergence along the sides of the shoal. The refraction coefficients determined by using the conventional analysis predicts coefficients as high as 2, whereas the modified procedure yielded a maximum refraction coefficient of 1.25. Both procedures had coefficients = .75; however, a smaller area had values less than .75 in using the modified procedure.

The observed refraction patterns have an orthogonal divergence in the vicinity of the initial breaking region over the center of the shoal. During breaking, the wave crest slides down the front of the wave. This is manifested as a greater local wave celerity. This phenomenon was not modeled in the modified refraction procedure.

FINDINGS

The findings of this investigation illustrate the importance of considering the effects of finite height and wave breaking on wave transformation near and in the surf zone. The base test series studying the transformation of waves over a 1:30 slope indicated that the observed increase in wave height at the breaker point relative to the deep-water height was 25 percent greater than that predicted by application of Airy theory for $H_0/L_0 = 0.03$ and 50 percent greater at $H_0/L_0 = 0.002$. This result has a significant application when transforming a shallow-water wave to either a deep-water wave from a gage reading or transforming the wave to a breaker position. The result also suggests that model experiments should generate the waves in as deep water as possible, at least as deep as $H/d < .25$. Simple corrections to Airy theory have been deduced from the data to include the effects of finite height and breaking on wave celerity. In addition, during the breaking process, the lip transforms into a bore resulting in a considerably greater local celerity than the aforementioned correction. The conclusions above are more applicable to long-period wind-generated swell of regular form, as found in the Hawaiian Islands, as opposed to sea or locally generated waves found in the North Sea. Shorter period waves of greater steepness conform better to conventional analysis.

The model tests on the refraction of waves over a three-dimensional shoal illustrated the influence of finite height on wave refraction. The wave orthogonals tend to converge less over a shoal for increasing wave height due to the effects of finite height on wave celerity. This factor becomes important near the surf zone. The waves tend to diverge less over a trough. The influence of finite height and breaking are, therefore, to reduce the effects of refraction. Most existing computer programs using linear theory tend to strive for accuracy of bathymetry interpolation in refracting by the ray equation. Care should be exercised in the application and interpretation of such programs where H/d exceeds about .25 or when c is increased 6 percent over the Airy celerity.

FIGURE 10 - COMPARISON OF CONVENTIONAL U.S. FINITE HEIGHT REFRACTION PATTERNS

ty. The application of cnoidal theory presented by Skovgaard and Petersen, use of stream function shoaling curves, or a finite height scheme such as presented by Chu appears to be a step in the right direction. However, these schemes are for regular bathymetry. A wave front type method should be developed to more accurately predict finite height along a wave crest.

APPLICATION TO DESIGN PRACTICE

Application of a detailed refraction analysis using finite height procedures or corrections to linear analysis can be a time-consuming chore. Linear refraction and shoaling techniques appear valid for $H/d < .25$. The recommended procedure is to generally employ conventional refraction analysis using Airy theory and select a few critical cases to study in more detail starting at $H/d = .25$. The study results indicate that in design of a surf shoal similar to the one tested, wave refraction is of secondary importance relative to wave shoaling. The influence of finite height decreases the wave refraction effects considerably over a shoal. This is not a diffraction effect since the wave front pattern which is prescribed by refraction can be accounted for to a large extent by finite height considerations. Effects of wave-induced currents and diffraction are also of importance, but were not studied in this paper.

ACKNOWLEDGEMENT

Portions of this paper were extracted from a dissertation submitted to the University of Hawaii, Department of Ocean Engineering, in partial fulfillment of the requirement for the degree of Doctor of Philosophy in Ocean Engineering. The project was funded by the Surf Parameters project, a State of Hawaii funded research project. The author wishes to acknowledge Professors C. L. Bretschneider and F. Gerritsen for their guidance; Mr. J. F. O'Brien, Director of Look Lab; Mr. R. Q. Palmer who inspired the study; and Mr. H. Ho, technician who built the basin and associated appurtenances.

CHAPTER 30

THREE-DIMENSIONAL CONDITIONS OF SURF

ABSTRACT

Wave height variability along the crest of breaking waves is shown to be a significant factor in the assessment of surf zone dynamics. Variations in excess of 50 percent of the maximum wave height can occur along a single crest without significant variations in bathymetry. The horizontal scale of this longshore variability in crest height corresponds to the wave length of incident breaking waves. Four possible mechanisms for this variability are postulated and then evaluated individually on the basis of field observations. A major result of these evaluations is that two-dimensional shallow-water wave equations appear to be inappropriate for expressing natural surf zone wave transformations and water motions even under the condition of waves encroaching on a plane sloping bottom. Consequently, three-dimensional equations of surf should be used for describing most natural surf zone dynamics.

INTRODUCTION

Conventional techniques for estimating dynamic conditions in the surf utilize linear or weakly non-linear transformations of a set of deep water wave parameters to predict a set of shallow water wave parameters assumed to be incident at the outer limits of the surf zone. Once this set of shallow water wave parameters has been determined it is then used to establish initial and seaward boundary conditions for calculating two-dimensional wave transformations and water motions within the surf zone. To a first approximation two-dimensional irrotational motion of inviscid fluid on a shoaling beach satisfies nonlinear shallow-water equations (Meyer and Taylor, 1963; Ho, et al., 1963). However, most natural surf conditions are not two-dimensional thus, it is necessary to determine if longshore variations in the initial and seaward boundary conditions are of significant magnitude to invalidate the use of two-dimensional theory.

The three-dimensional time dependent shallow water equations of motion show that longshore variations in surf are caused primarily by longshore variations in the wave field approaching the coast and by longshore variations in bottom geometry within the surf zone (Stoker, 1957). Meyer and Turner (1967) have shown, for initial and seaward boundary

conditions independent of distance parallel to shore, that when the longshore bottom profile slope is gentler than the normal bottom profile slope "weakly three dimensional" surf can still be analyzed directly by two-dimensional theory. However the effect of longshore variations in the incident wave field at the outer surf zone has not yet been investigated.

Therefore, the primary purpose of this study was to measure three-dimensional variations in surf zone wave conditions and to relate them to incident wave conditions at the outer surf zone. An analysis of longshore variations in wave height at the outer surf zone was carried out in order to evaluate uniformity of the incident wave field. Wave height probability distributions were calculated from the observed data in order to show the distributional changes related to wave breaking and transformation through the surf.

THREE-DIMENSIONAL EQUATIONS OF SURF

Derivation of a shallow water wave theory from exact hydrodynamic equations utilizing a formal perturbation procedure, where all quantities are expanded in powers of $\sigma = kh$, (h is the depth and k is the maximum initial curvature of the free surface) has been carried out by Friedrichs (1948) and Stoker (1957). Defining the x, z plane as the undisturbed water surface with the y -axis positive upward, the free surface and bottom position are specified by $y = \eta(x, z, t)$ and $y = -h(x, z)$ respectively. The general three-dimensional problem is then formulated in terms of the equations of motion

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} = -\frac{1}{\rho} \frac{\partial p}{\partial x} \quad (1)$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} = -\frac{1}{\rho} \frac{\partial p}{\partial y} - g \quad (2)$$

$$\frac{\partial w}{\partial t} + u \frac{\partial w}{\partial x} + v \frac{\partial w}{\partial y} + w \frac{\partial w}{\partial z} = -\frac{1}{\rho} \frac{\partial p}{\partial z} \quad (3)$$

and continuity

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0. \quad (4)$$

It is assumed that the flow is irrotational with kinematic boundary conditions at the bottom and free surface given by

$$u \frac{\partial h}{\partial x} + v + w \frac{\partial h}{\partial z} = 0 \quad \text{at } y = -h \quad (5)$$

$$\frac{\partial \eta}{\partial t} + u \frac{\partial \eta}{\partial x} + w \frac{\partial \eta}{\partial z} = v \quad \text{at } y = \eta \quad (6)$$

respectively and a dynamic boundary condition at the free surface given by

$$p = 0 \quad \text{at } y = \eta. \quad (7)$$

Introduction of dimensionless variables through the use of a typical depth h and a typical horizontal length k into equations (1) through (7) and expanding u , v , w , η , and p in a power series of σ provides the opportunity to equate coefficients of like powers of σ . The first order approximation to u , w , and η are then given by the "three-dimensional shallow-water equations" (Stoker, 1957).

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + w \frac{\partial u}{\partial z} + \frac{\partial \eta}{\partial x} = 0 \quad (8)$$

$$\frac{\partial w}{\partial t} + u \frac{\partial w}{\partial x} + w \frac{\partial w}{\partial z} + \frac{\partial \eta}{\partial z} = 0 \quad (9)$$

$$\frac{\partial \eta}{\partial t} + \frac{\partial [u(\eta + h)]}{\partial x} + \frac{\partial [w(\eta + h)]}{\partial z} = 0. \quad (10)$$

TWO-DIMENSIONAL EQUATIONS OF SURF

It is easily seen that if w is assumed to be zero and all other quantities are assumed to be independent of z that equations (8) through (10) become the "two-dimensional shallow-water equations" [Stoker, 1947; Friedrichs, 1948; Stoker, 1957; Meyer and Taylor, 1963; and Meyer and Turner, 1967]

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + \frac{\partial \eta}{\partial x} = 0 \quad (11)$$

$$\frac{\partial \eta}{\partial t} + \frac{\partial [u(\eta + h)]}{\partial x} = 0. \quad (12)$$

Meyer and Turner (1967) also show these equations to be applicable to "weakly three-dimensional surf". Equations (11) and (12) are further simplified by assuming that u and η and their derivatives are small quantities whose squares and products are negligibly small compared to the linear terms. The resulting equations are the "linear shallow-water equations"

$$\frac{\partial u}{\partial t} + \frac{\partial \eta}{\partial x} = 0 \quad (13)$$

$$\frac{\partial \eta}{\partial t} + \frac{\partial (uh)}{\partial x} = 0 \quad (14)$$

The preceding derivation depends upon three important simplifying assumptions with respect to longshore water motions and bottom variability: that the longshore velocity component is zero; that the incident wave field at the seaward boundary of the surf zone is uniform in the longshore direction; and that the bottom slope in the longshore direction is zero. Meyer and Turner (1967) showed analytically that unless $\beta/\epsilon \rightarrow 1$, where ϵ is the beach slope normal to shore and β is the beach slope parallel to shore, the first and third assumptions above are valid approximations. However, they accepted the second assumption implicitly, asserting it was, in fact, valid whenever initial and seaward boundary conditions were primarily dependent upon beach slope ϵ . This assumption that uniform wave crests are a reasonable expectation for an incident wave field at the outer surf zone is one of the most important assumptions in formulating the two-dimensional equations of surf. A field evaluation of this assumption forms the primary context for this paper.

FIELD EXPERIMENT

In order to evaluate three-dimensional conditions of surf a three by three wave gauge array was positioned in the surf zone with its longshore axis parallel to the crests of incident breaking waves, Figure 1. Separation distance between individual wave monitoring positions was approximately one half the incident wave length. The three outer most stations were located seaward of the zone of active breaking. The six inner stations were located within the breaker zone and bracketed the region of most active breaking. Approximately eighty percent of initial breaking occurred within the monitoring array.

The bottom in the study area was characteristic of a sandy barred coastline with isobaths parallel or slowly varying in the longshore direction. Positioning of the monitoring array was such that ϵ was large (normal beach slope 1:20) and $\beta/\epsilon \rightarrow 0$ (to correspond to the conditions suggested by Meyer and Turner, 1967).

Wave monitoring was carried out continuously for fifteen minute periods separated by fifteen minute intervals. Wave breaking and transformation in the surf zone was monitored using a super 8 mm motion picture camera. The motion picture film records were taken in order to analyze the individual crests behavior as they passed through the monitoring grid. The only conditions monitored were those when waves broke within the monitoring grid. Conditions resulting in breaking or breaking and reforming seaward of the grid were not measured. Conditions during which waves appeared to be arriving from more than one direction, at the outer surf zone, were also excluded from the monitoring periods.

FIGURE 1. STATION CONFIGURATION FOR EXPERIMENT

EXPERIMENTAL RESULTS

Initially the movie film records were analyzed using the in situ grid, provided by the wave monitoring stations, as a reference base. Wave height along a single crest was observed to vary noticeably over short horizontal distances. Figure 2 shows successive wave crest height profiles for a single wave from approximately five meters seaward of the breaker zone to a position where fully developed breaking is occurring along the entire crest. The primary result from these film records is that significant variation in wave crest height is observed seaward of the breaker zone and prior to the development of major instability in the wave crest.

Nine free surface time histories from each monitoring period were evaluated directly and analyzed in two separate statistical contexts. First, wave height probability distributions were generated for each of the monitoring positions from the time history data and second, wave spectra were computed from each of the time series. The use of probability distributions was extremely convenient for understanding individual crest transformations in the surf zone.

Figures 3, 4 and 5 show five successive waves, measured at three positions along the crest, at the outer, middle and inner lines of the array (see Figure 1 for station locations). This series of waves is representative of the longer time histories and clearly shows the characteristic variation in wave height along the crest. Seaward of the surf zone, variations in excess of 50 percent of the maximum wave height occur along an individual wave crest, Figure 3. The regions of high crest height, stations 10 and 4, tend to maintain the same relative relationship to the region of low crest height, station 7, for successive wave passages. Many of the wave profiles at stations 10 and 4, appear to be near breaking waves. Film records verify, however, that no local breaking has occurred at or prior to reaching these stations. As this same group of waves pass into the breaker zone the crest height variability appears to be less clearly related, Figure 4. The low wave crests seaward of the breaker zone, station 7, have amplified and are steepening towards breaking limits, station 6. High wave crests seaward of the breaker zone, stations 10 and 4, have generally decreased in height due to breaking, stations 2 and 9. The result of these two inverse processes is to create a relatively uniform crest-wise wave height distribution. Near the shoreward limit of the breaker zone, these same waves again exhibit variations in excess of 50 percent of the maximum wave height along an individual wave crest, Figure 5. In contrast to the outer stations, Figure 3, the region of high crest height, station 5, is flanked by two regions of low crest height, stations 8 and 1. This result is, however, what would be anticipated due to wave height decay through breaking, at stations 8 and 1, and continued steepening or initial breaking at station 5. Thus differential breaking seems to be a reasonable explanation for the systematic changes along the crest as an individual wave passes through the surf zone. It is not, however, a satisfactory explanation for the initial conditions observed at the seaward boundary of the surf zone.

FIGURE 2. WAVE SURFACES FROM FILM RECORDS

FIGURE 3. FREE SURFACE TIME HISTORIES
AT OUTER LINE OF ARRAY

FIGURE 4. FREE SURFACE TIME HISTORIES
AT MIDDLE LINE OF ARRAY

FIGURE 5. FREE SURFACE TIME HISTORIES AT INNER LINE OF ARRAY

In order to verify that the wave crest height relationships, suggested by a limited sample of individual waves, Figures 3, 4 and 5, were characteristic of the entire time series, probability distributions were computed for the entire 15 minute monitoring period (approximately 200 waves). Comparisons of the probability distributions from the outer and inner lines of the array support the relative wave height variability suggested in the analysis of individual waves. Comparison of the probability distributions at the middle line of the array are inconclusive. Although the trend of the individual distributions is consistent with the inverse process argument posed earlier.

Analysis of variance was carried out for each of the three lines of the array. The results of this analysis supported the hypothesis that significant differences exist between individual probability distributions at the outer and inner lines of the array, $F(2,600) = 5.27$, $p < 0.01$ and $F(2,600) = 10.54$, $p < 0.01$ respectively. The results of the analysis failed to support the hypothesis that significant differences exist between individual probability distributions at the middle line of the array, $F(2,600) = 4.09$ rejected at $p < 0.01$.

Spectrum analysis of the nine stations individual time series indicated two major spectral peaks common to all of the series. A 6.0 second peak corresponded to the incident swell period and a 3.3 second peak corresponded to the breaker period. A long period component ($T > 50$ seconds) was present in all of the time series from the monitoring stations seaward of the breaker zone. This component also appears in all but one of the six breaker zone time series.

DISCUSSION

Longshore variation in wave crest height is neither an unexpected nor unrecognized physical occurrence in the surf zone. Bowen (1969) showed that periodic longshore variation in wave height caused by either bottom geometry or mean water level fluctuations was responsible for the generation and spacing of rip cells. Bowen and Inman (1969) suggested that edge waves could account for longshore variations in wave height on a planer beach. Inman, Tait, and Nordstorm (1971) assert that "the interaction of edge waves with incoming waves of the same frequency produces systematic fluctuations in breaker height along the beach." Guza and Davis (1974) showed that waves incident on a planer beach can in fact generate these edge waves, but of a mode different from that of Bowen and Inman (1969). Finally, Dalrymple (1975) has shown that longshore variation in wave height can be anticipated for conditions where two wave trains of the same frequency arrive at the outer surf zone from two distinct directions.

Subsequently there are four mechanisms which can be postulated for the causation of longshore variation in wave crest height: significant longshore variation in bottom geometry $\beta/\epsilon \rightarrow 1$; interaction of edge waves with the incident wave field; interaction of long-crested swell arriving from two distinct directions; and arrival of a "short-crested" wave field generated by local storm winds. Experimental conditions during the observations from this study tend to control for the first and third postulated causations. There were, of course, two distinct frequencies present in the wave spectrum at 6.0 and 3.3 seconds which clearly indicates the presence of two wave groups. However, the direction of arrival of these wave groups appeared to be coincident and their frequency separation was quite large for significant interaction to occur.

The possibility of edge wave interaction with the incident wave field is likely. Fluctuations in the total longshore velocity field with a periodicity close to that of the zero mode edge wave have been observed under similar field conditions (Wood and Meadows, 1975, Meadows, 1976). The wave length of the longshore wave height fluctuations, from this experiment, are equivalent to the incident wave length of the breaking waves. Thus the periodicity of these fluctuations would seem to be much shorter than those calculated from edge wave theory for the observed conditions. Likewise the observed wave height fluctuations are in excess of those anticipated by edge wave theory.

The final postulated mechanism, of an incident wave field arriving with a "short-crested" structure independent of the first three mechanisms, is theoretically possible but, within the limitations of this experiment difficult to substantiate. It has long been recognized that turbulence in a wind field can result in the generation of a short-crested wave field (Jefferies, 1924). Likewise McClenan and Harris (1975) analyzed 40,000 aerial photographs of waves in shallow-water and concluded that the dominant pattern is one of short-crested waves and randomness. Notably missing between these studies is the concurrent observation of wind and wave field structure in shallow-water. The crest height wave length correspondence to incident breaking wave length and the large fluctuations in wave height along the crest do, however, present intriguing possibilities for short-crested wave structure. Clearly, the question left to be answered is whether energy is being transmitted along the crests of these waves.

CONCLUSIONS

Significant variations in wave height occur along the crest of waves incident at the outer surf zone. These variations are independent of bathymetric control and persist through the surf zone due to differential effects of shoaling and breaking. The wave length of these variations is the same as that of the incident breaking waves.

Of the four postulated mechanisms which might cause these variations only bathymetric variability seems an unlikely mechanism under these

experimental conditions. Therefore, the assumption, accepted implicitly by Meyer and Turner (1967), that longshore variability in the incident wave field is negligible whenever $\beta/\epsilon \rightarrow 0$ and the normal beach slope is moderate to steep, is incorrect. Consequently, treatment of surf zone dynamics utilizing two-dimensional shallow-water equations seems to be generally inappropriate. In fact, the full three-dimensional equations of surf (8, 9, and 10) appear to be necessary to properly represent natural surf zone dynamics.

CHAPTER 31

ENERGY SPECTRA OF IRREGULAR SURF WAVES

by

Fritz BUSCHING¹⁾

ABSTRACT

The investigations under consideration are based on synchronous measurements of waterlevel deflections $\eta(t)$ at some positions in a beach profile with a slope of approximately 1:40.

Surf conditions are studied during a severe storm surge as well as during periods of attenuating wave action.

By the use of a FOURIER ANALYZER 40 energy spectra are calculated which are also presented in integrated form (co-cumulative spectra). Because of different site arrangements it is possible to analyze the deformation of the spectra due to tide dependent changes of the water depth as well as due to coastward decreasing water depth.

It happens that there are some phenomena associated with certain frequency bands.

With the water depth decreasing the energy densities in surf spectra are distributed over a wider frequency band.

In the present case unbroken waves are characterized by energy spectra in which at least 90 % of the energy is represented by FOURIER components in the frequency range $0 \lesssim f \lesssim 0.5$ Hz. Increasing distribution of the energy densities over a wider frequency band represents at first breaking and finally broken waves. Sometimes the amount of energy coastward of the surf zone is higher than seaward of the breakers. This phenomenon can be explained by refraction effects caused by local nearshore bathymetry. All of these investigations were sponsored by the DEUTSCHE FORSCHUNGSGEMEINSCHAFT (German Research Foundation).

1. INTRODUCTION

As it is well known that the energy dissipation processes taking place in the surf zone cannot completely be simulated in a model (FOHRBÖTER 1970 and 1971), since 1971 comprehensive field investigations have been performed on the west coast of the isle of SYLT/North Sea, see Fig. 1. FOHRBÖTER (1974) investigated the behaviour of waves in the nearshore zone and inside the surf, presented first results on the influence of a longshore bar and on the energy decay perpendicular to the coast. Additionally he proposed a β -number for a quantitative breaker classification.

DETTE (1974) reported on longshore currents in the range of high REYNOLDS-numbers and BÜSCHING (1974) investigated the orbital velocities of irregular surf waves. Subject of the investigations under consideration are the changes in surf energy spectra due to tidal dependent and coastward decreasing water depth.

The intended structural analysis is based for the one thing on synchronous measurements of the waterlevel deflections $\eta(t)$, which were carried out during a heavy storm surge and for another on two measurements during attenuating weather conditions.

2. MEASURING EQUIPMENT AND DATA ANALYSIS

For the purpose of wave height measurements (water level deflections $\eta(t)$) pressure type wave meters working on inductive principle were attached to steel supports driven into the seabed at positions 85 m, 100 m, 120 m and 128 m distant from the shoreline. Thus the deformation of the waves in a beach profile with a slope inclined 1:40 could be analyzed.

During the storm surge of December 13th to 14th 1973, only the devices at measuring positions 85 m and 100 m functioned satisfactorily, whereas during the later measurements also records from the two more offshore situated pressure devices at 120 m and 128 m could be received.

In order to analyze the data on a FOURIER ANALYZER all the measuring signals were fed to an analog magnetic tape recorder.

Fig. 1: Investigation area and underwater bathymetry west of the middle part of the isle of SYLT. Measured by surveying ships of DHI and WSA Kiel. After KÖSTER (1974)

The details of the measuring system are commented on by BOSCHING (1974) and FÜHRBÖTER and BOSCHING (1974).

Because of lack of space only a few things will be pointed out here:

1. For a wave analysis the maximum frequency

$$F_{\max} = F_N = \frac{1}{2 \Delta t} = 3.125 \text{ Hz}$$

is relatively high.

2. The frequency resolution is characterized by

$$\Delta f = \frac{F_{\max}}{N/2} = \frac{3.125}{256} = 0.012207 \text{ Hz and}$$

3. By averaging 10 successively calculated energy spectra, each representing $T'_R = 81.92 \text{ s}$ measuring time, the resulting time of measurement was:

$$T_R = 10 \times 81.92 = 819.2 \text{ s.}$$

Comparing spectra calculated in the same manner one can expect to recognize the fundamental changes involved. This is why it seemed not to be necessary to deal with the method of calculation itself.

3. ANALYZED MEASURING SERIES

3.1. Storm Surge of December 13th to 14th, 1973

The present storm surge data (water level deflections $\eta(t)$) had been previously analyzed by the author together with simultaneously recorded orbital velocity data.

Among others in that work an attachment of NORMALIZED ENERGY SPECTRA and surf phenomena could be established.

Contrary to that the present evaluations deal with ABSOLUTE SPECTRA taken simultaneously at measuring positions 100 m and 85 m.

During the storm surge period of about 30 hours at 16 measuring intervals samples were analyzed, see Fig. 2 and 3.

Each measuring interval is represented by 4 diagrams consisting of the energy spectra at positions 100 m and 85 m with the respective co-cumulative spectra beneath them.

In correspondence with wind and tidal dependant water level fluctuations peak energy densities (E_{fp}) occurred in the range of

$$0.87 \text{ m}^2/\text{Hz} \leq E_{fp} \leq 4.38 \text{ m}^2/\text{Hz}$$

3.2 Simultaneous measurements of January 20th and 23rd, 1974 respectively

During the period of attenuating wave activity another two measurements have been carried out, each, however, consisting of 4 spectra, as to be seen from Fig. 4 and 5.

At the farther offshore positions (at 128 m and 120 m) on January 20th a much wider peak due to higher wave activity at Bft. 6 can be seen than on January 23rd at Bft. 3 only.

On the other hand both measurements show similar values of maximum energy density:

$$E_{fp} \approx 1.1 \text{ m}^2/\text{Hz}$$

In order to attach also these spectra to the respective wave deformation the synchronously recorded wave traces of two neighbouring devices have been shifted in such a way that there exists nearly no phase difference between them and thus changes could be recognized very well, see Fig. 6 and 7.

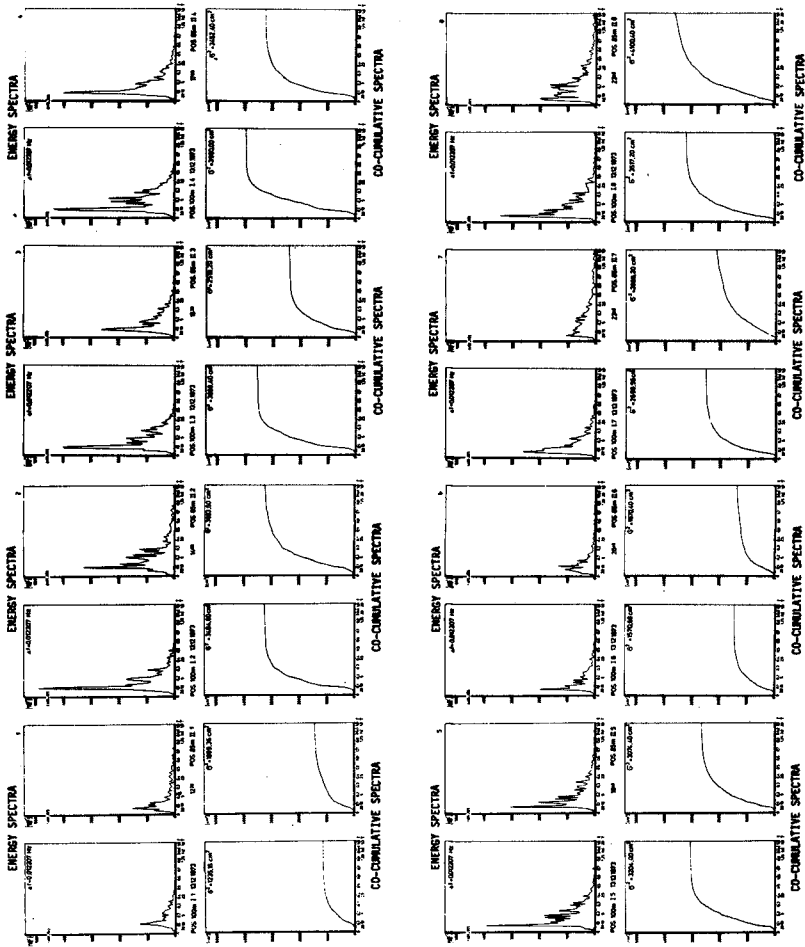

Fig. 2: Energy spectra and co-cumulative spectra at measuring positions

100 m and 85 m during the storm surge period on December 13th, 1973

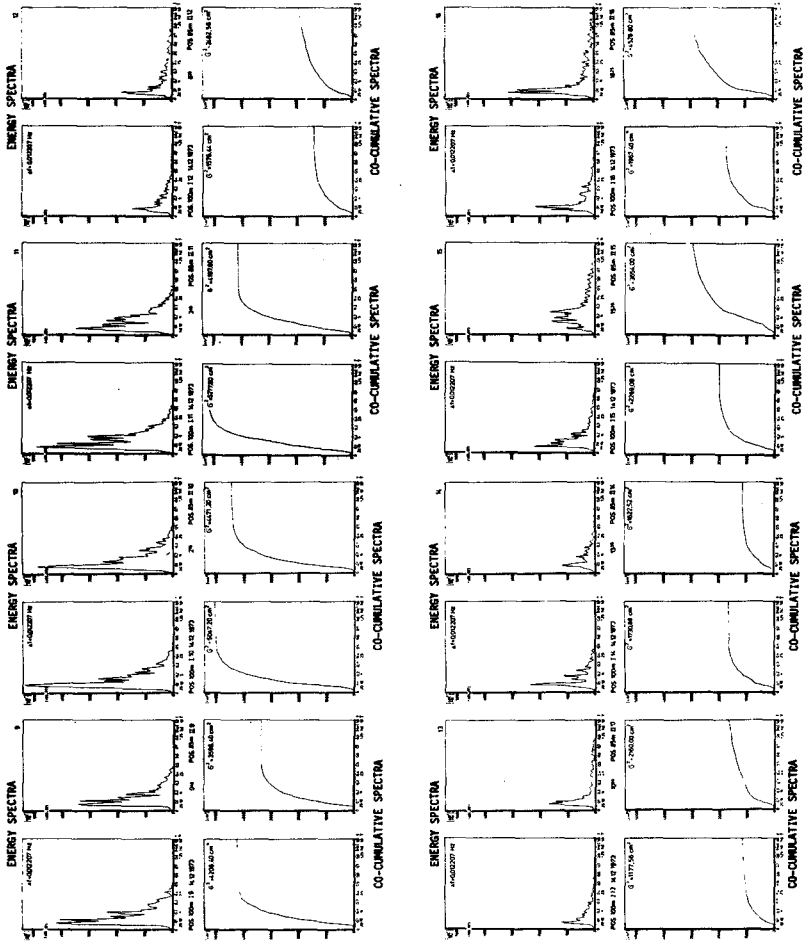

Fig. 3: Energy spectra and co-cumulative spectra at measuring positions 100 m and 85 m during the storm surge on December 14th, 1973

Fig. 4: Energy spectra and co-cumulative spectra on January 20th, 1974

Fig. 5: Energy spectra and co-cumulative spectra on January 23rd, 1974

Fig. 6: Synchronous water level deflections $\eta(t)$
on January 20th, 1974, 11.44 a. m.

Fig. 7: Synchronous water level deflections $\eta(t)$
on January 23rd. 1974, 00.55 a. m.

Comparing those two sets of strip charts the overall impression is that on January 20th

the magnitude of water level deflections is somewhat higher,
the waves at position 128 m are steeper and
the periods at position 85 m are much larger

As regards, however, the deformation and the stability of the waves in the measuring profile, a similar behaviour can be seen for both measurements:

particularly the traces at positions 128 m and 120 m are similar to a high degree; at Pos. 120 m they are only little steeper. At Position 100 m on an average nearly breaking waves are much steeper and at position 85 m less steepness indicates broken waves.

4. THE STRUCTURE OF SURF SPECTRA

The problem of energy dissipation in limited water depth (in the ELBE estuary) was studied by SIEFERT (1974) using energy spectra. With regard to the structure of the spectra he agrees with the results of WALDEN and RUBACH (1967) and HASSELMANN and COLLINS (1968):

With the energy dissipation increasing the energy density decreases and the peak of energy density shifts to shorter periods (higher frequencies). For the swash zone SONU, PETTIGREW and FREDERICKS (1974) found the contrary to be true:

Energy spectrum variation in the upbeach direction reveals a low-pass filter effect of the beach along with an enhancement of energy density in an infragravity frequency band.

Regarding the appearances in normalised energy spectra of breakers, breaking and broken waves, from the author's previous investigations the breaker zone turned out to be a transitional area:

With the water depth decreasing on the one hand the peaks of energy densities shift to lower frequency FOURIER components and at the same time some energy densities of a certain amount appear at higher frequencies.

In order to have a closer look into the processes taking place in the surf zone in the following the absolute spectra and co-cumulative spectra are analyzed, see Figures 2, 3, 4 and 5.

In the present study evaluations are carried out only to get a better interpretation of surf spectra; conclusions regarding the amount of energy dissipation are not drawn. In order to characterize the differences between the storm surge measurements and the remaining two measurements at attenuating wave action it shall only be mentioned here that the maximum peak energy density $\max E f_p$ as well as the maximum variance $\max \sigma^2$

$$\begin{aligned} \max E f_p &= 4.3817 \text{ m}^2/\text{Hz} \text{ and} \\ \max \sigma^2 &= 0.5278 \text{ m}^2 \end{aligned}$$

both are a multiple of the respective measurements on January 20th and 23rd, 1974.

Already from the graphs of the co-cumulative spectra (see Fig. 2 and 3) one can see that there is only a percentage of the total variance present in the frequency range in between 0 and 1 Hz.

In this connexion total variances are denoted as the numerical values σ^2 calculated for the total analyzed frequency band and plotted into the upper part of the graphs.

The following 4 figures are prepared for further illustration:

In Fig. 8. the development of the variances $\sigma^2 = \int_0^{f_1} G_{nn}(f) df$ at the measuring positions 100 m and 85 m respectively are shown along with the tide curve of the investigation area. The characterizing changes shall be discussed describing the curves ①, ③ and ⑥.

Fig. 8: Changes of the variance σ^2 during the storm surge measuring period of December 13th to 14th, 1973

- A. Frequency range $0 \leq f \leq 3.125$ Hz (Curve ①)
 Apparently the coherence between wave energy and tide level at position 85 m is less than at position 100 m:
 At 100 m distant from the shoreline high tide levels are in agreement with high wave energies whereas this is not true for the development of the variance at position 85 m where 5 maxima are to be recognized and the absolute maximum occurs at an extremely low water level at the end of the measuring period.
 Comparing curves ① at position 100 m and 85 m it is also obvious that sometimes the amount of energy nearer to the shore (i.e. at pos. 85 m) is higher.
- B. Curve ③ describes the variances of FOURIER components in between 0 and 0.3 Hz
 At position 100 m there is not a great difference to curve ① - but at position 85 m it is:
 From the areas between curves ① and ③ it can be stated that the increase of energy is predominantly due to high frequency FOURIER components at low water depth.
- C. Also the amount of energy belonging to the longperiodic Fourier components ($T > 8$ s, curve ⑥) shows good correlation to the water levels at position 100 m. This is also true for the position 85 m until 8.00 a.m. on December 14th 1973, but later on there are some changes to be recognized:
- C.1 There is a minimum of energy coincident with the third high tide level and
- C.2 just before and after this high tide level in this frequency range there are higher energies at position 85 m than at position 100 m.

In Fig. 9 some percentages of the total variances (calculated for the frequency band $0 \leq f \leq 3.125$ Hz) are shown up to 1.0 Hz. In order to illustrate the fundamental changes involved there are 3 areas limited by the 50- and 90 percentage variance isoline respectively.

Fig. 9: Percentage variance isolines of the storm surge measuring period of December 13th to 14th, 1973

At the measuring position 100 m from the coastline the relationship between tide level and certain percentage isolines is not quite clear:

The amount of 50 % of the total energy seems to be constantly present at frequencies lower than 0.2 Hz whereas there is a fluctuation in the 90 % isoline.

At position 85 m, however, those two isolines show significant correlations to the tide levels: Exclusively at very high tide levels at least 90 % of the total energy are present at frequencies between 0 and 0.5 Hz, and in correspondence with low tide levels 50 % of the total energy require a wider frequency band, i.e. frequencies up to 0.36 Hz maximum.

The evaluations of the synchronous measurements of 4 pressure devices on January 20th and 23rd have been carried out in a similar manner. Contrary, however, to the plots of the storm surge data in Figures 10 and 11 the changes are shown as functions of the shoreline distance.

During the measurements on January 20th at position 128 m nearly the total energy (more than 99 % of $\sigma^2 = 1097.64 \text{ cm}^2$) is present in the frequency range $0 \lesssim f \lesssim 0.5 \text{ Hz}$. With the waves approaching the shore the energy continuously decreases.

On January 23rd the energy at the farthest offshore position is only about half as much but similar to the above mentioned appearances there is an increase of energy nearer to the shore (at pos. 100 m).

5. CONCLUSIONS:

In consideration of the surf phenomena detected from strip chart records of the storm surge measurements (see BOSCHING 1974) in generell it can be stated that at low tide levels the energy present in surf spectra is distributed over a wider frequency band. This statement is in accordance with

- a) the results of a theoretical investigation on the deformation of sinusoidal waves increasingly deformed (steepened) by

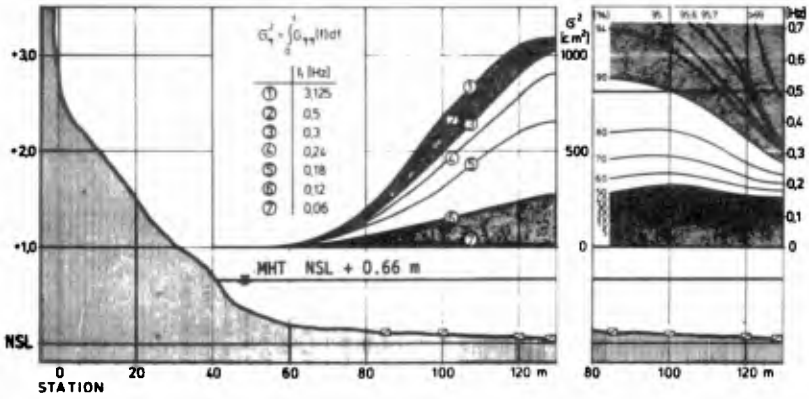

Fig. 10: Coast normal wave energy decrease on January 20th, 1974, 11.44 a.m.

Percentages of the energy present in the frequency range $0 \leq f \leq 0.78$ Hz

Fig. 11: Coast normal wave energy decrease on January 23rd, 1974, 00.55 a.m.

Percentages of the energy present in the frequency range $0 \leq f \leq 0.78$ Hz

decreasing water depth. SCHULEJKIN (1956) found out that the energy associated with higher harmonics increases at the expense of the fundamental oscillation.

- b) The decomposition of original waves into two or more waves (solitons) reported from wave tank investigations by GALVIN (1972).

Comparing surf energy spectra and respective strip chart records of the storm surge measurements for the present case it can be stated that unbroken waves are characterized by spectra in which at least 90 % of the energy is represented by FOURIER components in between 0 and 0.5 Hz. Increasing distribution of energy densities over a wider frequency band at first stands for breaking and finally signifies broken waves.

The statement is in accordance with the measurement on January 20th, 1974 (see Fig. 10) but for the measurement on January 23rd it demands for the instability of the waves to have occurred seaward of position 100 m (see Fig. 11). Thus it can be concluded that the interpretation of the wave deformation (see Fig. 7) has to be changed in such a way that the wave trace at position 100 m already represents breaking waves - probably spilling breakers.

As far as the energy increase in upbeach direction is concerned, it is obvious that this increase is due to Fourier components of frequencies higher than 0.3 Hz emerging at relatively low water levels. On the other hand at minimum water depth (before and after the last high tide of the storm surge measurement) there is another energy increase in the frequency range $0 \leq f \leq 0.12$ Hz (curve ⑥, Fig. 8).

Apparently this is in accordance with the shifting of peak energy densities to lower frequencies in line with coastward or tidal dependent water level decrease (see SONU et al 1974 and BÜSCHING 1974).

In the following an explanation of the temporary energy increase in the upbeach direction is presented. Fig. 1 shows the investigation area on the isle of Sylt with a bar located offshore perpendicular to the coast. Although this bar is relatively far away from the beach it can not be excluded that some phenomena result from it even on the beach:

The higher energies may be explained by refraction effects (interference) in such a manner that breaking waves are focussed on a special point in the measuring profile. The position of this point, i.e. the distance from the shoreline depends on the water depth present. This explanation is in agreement with visual observations. Frequently wave systems of little differing directions of propagation could be watched thus producing cross surf. Accordingly on January 23rd a focal point must have been near position 100 m whereas on January 20th at a higher tide level broken waves collided coastward of position 85 m and therefore could not be registered by the pressure devices.

As concerns the intensity of the interfering waves another conclusion can be drawn from the above mentioned previous study:

In Fig. 12 the resulting wave directions calculated from orbital velocity components (via transfer functions) are shown for the storm surge measurements on December 13th and 14th at position 85 m together with a levelling curve also describing the changes of the wind directions. In the study under consideration (BÜSCHING 1974) an explanation of the deviations from the mean line could not yet be given.

If, however, those deviations are compared with the fluctuation of wave energy present at position 85 m (see Fig. 8) a rather good correlation turns out until December 14th, 8.00 a.m.

As this agreement also would be significant after 8.00 a.m, if the amount of energy due to long periodic wave run up (just before and after the last high tide level) would not be considered, it might be concluded that the indicated variations of velocity directions result from the differing intensities of the contributing wave systems caused by refraction.

Fig. 12: Variations of horizontal orbital velocity directions during the storm surge of December 13th to 14th, 1973

ABSTRACT

A laboratory and theoretical study of the transition from strongly reflected surging to dissipative plunging breakers on a relatively steep plane beach (1:8) has revealed the following: (1) The run-up and offshore variation of sea surface elevation of surging waves are well predicted by linear theory. (2) The fluctuating part of the run-up (related to the amplitude of the reflected incident wave) reaches a maximum value; a further increase in incident progressive wave energy results in increased dissipation. (3) Subharmonic edge waves (the growing instabilities of surging waves) are driven primarily by the swash motion, which does not increase with increasing incident breaking wave height. However, the turbulence accompanying incident wave breaking, and the effective eddy viscosity, rapidly increases with increasing breaker height. As a result, subharmonic resonances do not occur with spilling or steep plunging waves; very strong viscous effects suppress the nonlinear instabilities. (4) Edge waves generated by a surging incident wave can be suppressed by superimposing an additional breaking wave of different frequency on the incident wave field. Thus, any excited edge waves are likely to have length scales at least the order of a surf zone width.

INTRODUCTION

The shoaling and breaking of a regular train of surface waves has been the subject of many extensive experimental investigations. However, the primary interest has been in waves which break by spilling or plunging and surprisingly little attention has been given to surging, or collapsing, waves. Surging occurs when the reflection from the beach is strong, and the interference between the incoming and reflected waves results in complex patterns of elevation and velocity markedly different from the essentially monotonic changes in wave height associated with spilling waves.

Surging waves, and the transition from surging to plunging, are of interest for several reasons. One is the suggestion that steady, wave-induced, bottom currents having convergences associated with either nodes or antinodes of a standing wave component, are responsible for the formation of offshore bars. However, except for the field work of Suhayda (1974) involving a complicated

spectrum of waves, there is little data to support the theoretical location of nodes and antinodes. A second motivation for a more detailed study of wave surging involves the resonant generation of edge waves. It has been shown theoretically that completely reflected, monochromatic, incident waves are unstable to edge wave perturbations (Guza and Davis, 1974; Guza and Bowen, 1975). Qualitative laboratory studies (Galvin, 1967; Guza and Inman, 1975) show that the edge waves excited by nonlinear interaction may have amplitudes at the shoreline more than twice as large as surging incident waves. However, as the incident wave amplitude is increased and the waves break by plunging, the resonance ceases and the edge waves disappear. In order to understand why the resonance ceases, it is clearly necessary to have a detailed understanding of the incident wave behavior.

Before considering the complexities which arise in three-dimensions due to edge waves, it is useful to first consider the two-dimensional case. In section II, a linear model is formulated for normally incident waves, partially reflected from a plane beach. This theoretical model is found to be in close agreement with laboratory measurements of sea surface elevation, seaward of the break point, when the coefficient of reflection, r , is greater than about 0.3. For lower reflections, that is steeper incident waves, nonlinear effects become significant.

In the experiments described in section III, the width of the wave basin is adjusted so that edge waves generation becomes possible. The two-dimensional, monochromatic, incident waves can now force edge waves at the subharmonic $\sigma/2$ of the incident wave frequency σ . Measurements show that these edge waves also have an offshore variation very close to that predicted by linear theory. The equilibrium amplitude of the edge waves was determined for various incident wave conditions, and the disappearance of the resonance with increasing incident wave amplitude was investigated in detail. Additional experiments superimposed a second wave train on a resonant situation so that the effects of a surf zone, not associated directly with the primary incident wave of the resonance, could be examined.

II. TWO-DIMENSIONAL WAVES

Linear Theory

When waves approaching the shore are reflected by a beach they propagate from water which is effectively infinitely deep, to zero depth and then back out into deep water. Although exact linear solutions for this problem are known, they are extremely cumbersome, especially for small beach slopes (Stoker, 1947). Simpler linear theories exist, but none provide a satisfactory description of the total motion even if frictional effects are neglected; different approximations apply for deep and shallow water.

Clearly, at the shoreline and for some distance offshore the appropriate approximation is provided by linear, shallow water theory. The solution for a wave, frequency σ , partially reflected from a plane beach of slope $\tan \beta$ is (Lamb, 1932; Suhayda, 1974)

$$\phi^S = \frac{a_S g}{\sigma} \left\{ J_0(x) \sin \sigma t + Y_0(x) \cos \sigma t + r \{ J_0(x) \sin(\sigma t - \theta) - Y_0(x) \cos(\sigma t - \theta) \} \right\} \quad (1)$$

where $\chi^2 = \frac{4\sigma^2 x}{g \tan^2 \beta}$, a_S is the amplitude of the incoming wave, r the reflection coefficient and θ a phase shift in the reflected wave, x is positive in the offshore direction with the shoreline at $x = 0$.

Offshore, in deeper water, the slowly varying Stokes solutions are valid, where in water depth h

$$\phi^d = \frac{a_d g \cosh k(z+h)}{\sigma \cosh kh} \left[\cos \left(\int_0^x k dx + \psi + \sigma t \right) + r \cos \left(\int_0^x k dx + \psi - \sigma t + \theta \right) \right] \quad (2)$$

provided $\sigma^2 = gk \tanh kh$, and $a_d = a_\infty (\tanh kh + kh \operatorname{sech}^2 kh)^{-1/2}$; where a_∞ is the amplitude of the incoming wave far offshore ($kh \rightarrow \infty$) and ψ is a constant.

Friedrichs (1948) showed that the shallow water limit of the Stokes solution and the offshore limit of the shallow water solution smoothly match together at intermediate depths if appropriate values of a_S and ψ are chosen. Then

$$\phi^{\lim} = \lim_{\chi \rightarrow \infty} \phi^S = \lim_{h_*^{-1} \rightarrow \infty} \phi^d = \frac{a_\infty g h_*^{-1/4}}{\sigma \sqrt{2}} \left(\cos \left(\chi - \frac{\pi}{4} + \sigma t \right) + r \cos \left(\chi - \frac{\pi}{4} - \sigma t + \theta \right) \right)$$

$$\text{where } h_* = \frac{\sigma^2 h}{g} = \frac{\sigma^2 x \tan \beta}{g} \quad (3)$$

if $a_S = a_\infty (\pi/2 \tan \beta)^{1/2}$ and $\psi = -\pi/4$. In the matching regions $\chi \gg 1$, $h_* \ll 1$, so that

$$\tan^2 \beta \ll h_* \ll 1 \quad (4)$$

For a wave totally reflected at the shore, a purely standing wave, the ratio of the wave amplitude at the shoreline to that in deep water, given by equation 3, is equivalent to the amplification factor known from the exact solution (Stoker, 1947) if the beach slope is small ($\beta \approx \tan \beta \approx \sin \beta$).

A general solution on a sloping beach, valid everywhere is given by

$$\phi = \phi^S + \phi^d - \phi^{\lim} \quad (5)$$

where if ϕ^S or ϕ^d are outside their range of validity they are cancelled by ϕ^{\lim} leaving the other as the only contribution in the relevant region. We note that the linear Stokes progressive wave solution (equation 2, $r = 0$) may be improved upon by adding a linear correction term of $O(\tan \beta)$ (Chu and Mei, 1970). This correction term smoothly matches to a higher order expansion of the shallow water Bessel function solutions (eq. 1), and it appears possible to produce a matched asymptotic solution which is an arbitrarily good approximation to the

exact linear solution. However, a comparison of the sea surface elevation given by the exact linear (Stoker, 1947) and smoothly matched solutions on a 6° slope shows insignificant differences between the two, and suggests that little is to be gained by linear improvements on equation 5. The marked profile asymmetry attributed to linear $O(\tan\beta)$ corrections by Biesel (1952) and Gaughan and Komar (1975) do not appear in the exact solution. The applicability of eq. 5 is limited because nonlinearities are neglected, and it is not likely to be a particularly good representation of the wave field right in to the break point unless r is large. The larger wave steepnesses which lead to smaller values of r produce plunging or spilling breakers whose size is generally underestimated by linear theory (Komar and Gaughan, 1972). However, the present experiments show that eqs. 1-5, are satisfactory up to breaking if $r > 0.3$, which does include part of the regime in which waves break by plunging. Figure 1 shows the normalized local sea surface displacement for a fully reflected wave ($r = 1, \theta = 0$) calculated from both the shallow water and Stokes solutions for three different beach slopes. Offshore the shallow water solution diverges from the correct solution, errors in amplitude $> 5\%$ occurring for $h_* > 0.25$. The phase of this solution diverges at even smaller values of h_* (phase errors tend to be cumulative) and on small slopes may become large where the amplitude is still well predicted. The parameter which limits the offshore validity of the shallow water solutions is $h_* = \sigma^2 h/g$, not the scale depth which actually appears in the solution $h_* \tan^2 \beta$. Consequently the shallow water solutions are valid much further seawards on beaches of gentle slope. As a rough rule, the shallow water solutions are valid for $h_* < 0.1$.

It is evident in Figure 1 that, regardless of beach slope, the linear Stokes solution will correspond very closely to the matched solution except in the immediate vicinity of the shoreline. Here, however, the discrepancy is serious; the solution has a singularity of order $h_*^{-1/2}$ and cannot provide a reasonable value for the amplitude at the shoreline in terms of deep water conditions. Higher order solutions (both linear and nonlinear) for the Stokes wave have even stronger singularities at the shoreline.

It is perhaps worth noting that although the linear shallow water and Stokes' solutions match smoothly together, their higher order, nonlinear terms do not. To provide a uniformly valid non-linear solution an additional intermediate zone governed by nonlinear equations of the Kortweg-De Vries type on a sloping beach is probably needed. Fortunately, waves which are strongly reflected are of low steepness and nonlinearities are negligible everywhere except on the beach face. Figure 2(a), discussed more fully later, shows the measured values of sea surface elevation for totally reflected waves of three different periods, which are in very good agreement with the theoretical estimation derived from the linear theory (eq. 5).

Partial Reflection

Carrier and Greenspan (1958) used the fully nonlinear, inviscid, shallow water equations to study the maximum possible size a standing wave can attain on an impermeable sloping beach. A review of their work, and of the general problem of waves on a sloping beach is given by Meyer and Taylor (1972). Carrier and Greenspan found that a standing wave solution is possible if

$$\epsilon = \frac{a_0 \sigma^2}{g \tan^2 \beta} \leq 1 \tag{6}$$

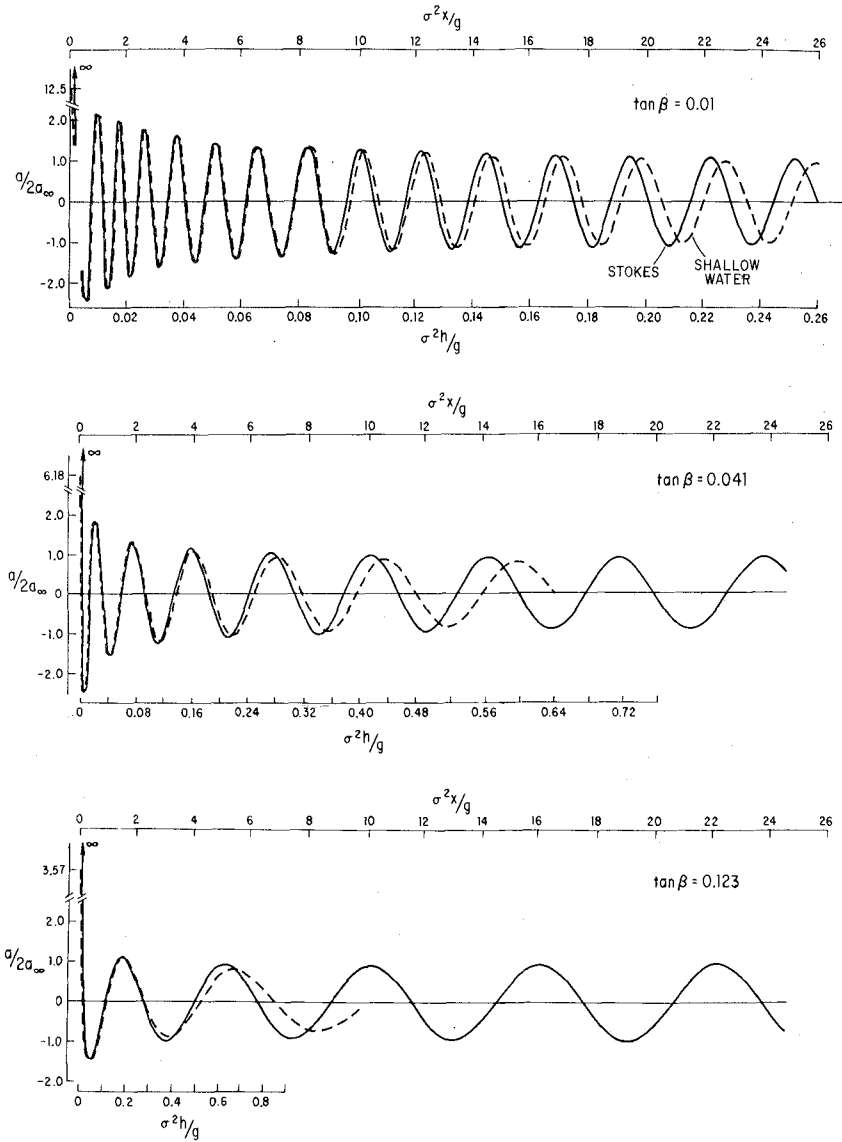

Figure 1. Theoretical local standing wave displacement (a) normalized by offshore amplitude ($2a_\infty$). Stokes solutions are valid offshore, while shallow water solutions properly describe the run-up.

where $2a_0/\tan\beta$ is the total horizontal excursion of the swash, and $a_0 = 2a_s$ (eq. 1; $r = 1.0$, $\theta = 0$) is the standing wave amplitude away from the immediate vicinity of the shoreline. Munk and Wimbush (1969), coincidentally, obtain the same limit condition (eq. 6) using linear theory. If $\epsilon = 1$, the standing wave is of maximum possible size, the nonlinearities producing considerable distortion of the wave profile; in the run-up the Fourier amplitude at frequency 2σ is theoretically about a quarter of the amplitude of the motion at σ . However, for nonbreaking waves the maximum horizontal displacement of the shoreline, $2a_0/\tan\beta$, is exactly the same as presented by the linear standing wave solution with amplitude a_0 . Thus, if the waves are nonbreaking and the effects of viscosity and percolation on the beach face are small, a measurement of the horizontal displacement of the shoreline provides an appropriate value of a_0 to compare to offshore measurements where the wave is essentially linear. Away from the immediate vicinity of the shoreline, the nonlinear shallow water standing wave does not differ appreciably from the linear solution and (3) provides the appropriate patching. The deep water condition for a standing wave which will not break at the shoreline is therefore that

$$\frac{2a_\infty \sigma^2}{g} \left(\frac{\pi}{2}\right)^{\frac{1}{2}} \tan^{-5/2} \beta \leq 1 \tag{7}$$

that is, incoming progressive waves amplitude a_∞ in deep water will be totally reflected provided (Meyer and Taylor, 1972).

$$\epsilon_i = \frac{a_\infty \sigma^2}{g} (2\pi)^{\frac{1}{2}} \tan^{-5/2} \beta \leq 1 \tag{8}$$

This result differs by a constant factor of about two from the formula of Miche (1951) which has been commonly used (Moraes, 1970; Suhayda, 1974; and others) to estimate the maximum amplitude of an incoming wave which will be totally reflected

$$\frac{a_\infty \sigma^2}{g} (2\pi)^{\frac{1}{2}} \beta^{-\frac{1}{2}} \sin^{-2} \beta \leq 2 \tag{9}$$

For small β , Miche's formula therefore implies that complete reflection may occur provided $\epsilon_i < 2$. For $\epsilon_i > 2$ Miche assumes the wave is partially reflected and that the reflection coefficient r decreases with increasing ϵ_i

$$r = \frac{2}{\epsilon_i}, \quad \epsilon_i > 2$$

Now the offshore amplitude of the wave reflected from the beach is ra_∞ so

$$\epsilon_r = \frac{2ra_\infty}{g} \left(\frac{\pi}{2}\right)^{\frac{1}{2}} \tan^{-5/2} \beta = r\epsilon_i \tag{10}$$

and the Miche hypothesis is

$$\epsilon_r = \frac{\epsilon_i}{2/\epsilon_i}; \quad \epsilon_i < 2. \tag{11}$$

Battjes (1974) has suggested a similar expression based on a shallow water parameter similar to ϵ (eq. 6). There is, however, no allowance for the $\tan^{-\frac{1}{2}}\beta$ (theoretical) amplification in shallow water (3), so Battjes deep water reflection parameter differs from (10, 11) by $\tan^{-\frac{1}{2}}\beta$

$$\epsilon_r = \frac{\epsilon_i}{0.787 \tan^{-\frac{1}{2}}\beta} ; \epsilon_i < 0.787 \tan^{-\frac{1}{2}}\beta \quad (12)$$

The formulas (11, 12) are numerically identical when $\beta = 8.8^\circ$, and both follow from the assumption that when wave breaking occurs, the wave field outside the breakpoint (or surge line) consists of an incoming progressive component plus a standing wave of the maximum possible amplitude which can occur without breaking.

Field Observations

The idea that the surf zone can be represented as the sum of a standing wave of some maximum amplitude, and an incoming progressive component which decays shoreward of the break point, suggests that the motion at the shoreline is determined primarily by the standing component and should be given by

$$\epsilon = \frac{a_0 \sigma^2}{g \tan^2 \beta} = \text{constant} = \epsilon_c$$

Therefore, if an incident wave field consists of several narrow banded components, the energy spectrum of the wave run-up (vertical)

$$E(\sigma) \approx a_0^2 = g^2 \tan^4 \beta \sigma^{-4} \epsilon_c^2 \quad (13)$$

provided the wave components behave, at lowest order, as independent (linear) waves. Although the assumption of independence seems a gross approximation with the breaking bores observed in real surf zones, field observations do seem to show a region in the run-up spectrum where the energy varies as σ^{-4} (Huntley, Guza, and Bowen, in press).

An immediate question is whether this agreement provides real support for the conceptual model of the surf zone and run-up as a simple sum of standing and progressive waves which is implicit in the formula for reflection coefficients. If so, then measurements of shoreline displacement should give the size of the standing wave component and hence the amplitude of the wave components reflected from the beach. The critical relation is then between the wave amplitude at the shoreline and the wave amplitude seen in the reflected wave outside the breakers. Clearly, a first look at this relationship will be most easily obtained in the laboratory.

Laboratory Experiments

To investigate the relevance of the various theoretical suggestions, detailed laboratory measurements were made to: (i) check the limits of applicability of the matched linear solutions (eq. 5) for fully and partially reflected waves; (ii) determine the criteria for the onset of breaking in terms of the parameters ϵ and ϵ_i ; and, (iii) to compare the behavior at the shoreline with the reflection coefficients determined from the observations offshore.

Experiments were conducted in the 15.2 m x 18.2 m wave basin at the Hydraulics Laboratory at SIO. The beach was a concrete sloping section ($\beta = 7^\circ$) extending from the shoreline end of the basin for 8.7 m, the depth being constant (65 cm) for the 5.1 m between the toe of the beach and the plunger type wavemaker. The width of the working area was adjusted so that no subharmonic edge waves could be excited by the incident waves. Incident periods of 2.39, 2.76 and 3.39 sec. were studied in detail.

Measurements of sea surface elevation were made with a sensitive resistance gauge from the beach toe to as shallow water (~ 10 cm) as the gauge design allowed. The records were either filtered to remove higher harmonics before the wave amplitude was measured or, equivalently, Fourier analyzed to obtain spectral coefficients. The offshore measurements, therefore, relate linear theory to that part of the wave field at the primary frequency. Ideally, it is possible to measure only the total wave height, and to allow for the harmonics with higher order Stokes theory (Goda and Abe, 1968; Moraes, 1970). However, in real laboratory experiments, a wavemaker producing the primary wave at σ , will in general, generate free waves at harmonics $2\sigma, 3\sigma, \dots$, even if the wavemaker motion is perfectly simple harmonic (Madsen, 1971). As the free harmonic waves and Stokes corrections are dynamically distinct, having different wavenumbers, they are affected differently by reflection and viscosity, and the total motion a 2σ may therefore be a complicated combination of standing and progressive waves of two different wavenumbers. Fortunately, the total Fourier amplitude of 2σ was generally small compared to σ , and the harmonic free waves probably had little effect on the overall wave dynamics. They may, however, provide some errors in the run-up and run-down measurements (done with a meter stick).

To eliminate as far as possible the effects of general boundary dissipation not associated with wave breaking, estimates of reflection are based on measurements of sea surface elevation made in shallow water on a rather steep beach ($\tan\beta = 0.123$). On very gentle beach slopes viscous effects will invalidate the amplification factors predicted by inviscid theory, and measurements in relatively deep water will always indicate less than complete reflection. Moraes (1970) clearly shows lower coefficients of reflection at small β for similar values of ϵ_j . We did some qualitative experiments with 1.5 sec waves on a 15 m long 2.3° beach and found (based on offshore measurements) relatively low coefficients of reflection no matter what the value of ϵ_j . This is to be expected since gentle beach slopes result in a large zone of shallow water waves with high shearing (short wavelengths, Figure 1) and dissipation.

Figure 2a shows some typical measured amplitudes of the primary frequency wave normalized by the amplitude at the shoreline, a_0 , where

$$2a_0 = R \tan\beta \tag{14}$$

and R is the horizontal displacement on the beach face. These very closely fit the theoretical profile for a completely reflected wave, as expected since $\epsilon \leq 1$. The values of a and hence ϵ_j , were computed by fitting the offshore points to eq. 5 (here $r = 1, \theta = 0$). The close correspondence between ϵ and ϵ_j shows that for completely reflected waves, the amplification at the shoreline relative to deep water, is correctly given by

$$a_0 = 2a_s = 2a_\infty \left(\frac{\pi}{2 + \tan\beta} \right)^{\frac{1}{2}} = 7.14 a_\infty \tag{15}$$

Figure 2a. Measured standing wave displacements (a) compared to linear theory (eqs. 1-5, $r = 1$, $\theta = 0$). Complete reflection occurs because $\epsilon < 1$. $\epsilon_i = 0.49, 0.99, 0.66$ for $T = 3.38, 2.76, 2.39$ sec.

This remains true and the waves are essentially completely reflected provided $\epsilon_i < 1$ as predicted by Carrier and Greenspan (1958). When $\epsilon_i > 1$ the incoming waves are partially reflected. Figure 2b shows data from several experiments where $r \approx 0.4$, the agreement between observations and linear theory is emphasized by the superposition which occurs when experiments of different wave heights and periods are properly scaled. There is some variation of ϵ_i with T for the same value of r . Figure 3 shows a series of experiments for wave period 2.39 sec. where the deep water wave amplitude is the only variable which is changing and provides the corresponding increase in ϵ_i . Generally, the results are well predicted by linear theory for $\epsilon_i < 6$. At larger values the amplitude variation with distance from the shore departs markedly from the theory both in the position and in the relative size of the antinodes outside the surf zone. It is clear that finite amplitude effects must eventually become important both directly in the solutions to the wave equations and indirectly through second order effects such as wave set-up. However, there is a suggestion in Figure 3 that the phase shift of the nodes and antinodes increases roughly as the width of the surf zone. Interactions between incident and reflected bores may also contribute to the discrepancy.

Figure 2b. Measured sea surface displacements (a) of partially reflected waves compared to theory (eqs. 1-5, $r = 0.4$, $\theta = 0$). The agreement is good right up to the break point, $X_B^2 = 10$.

Figure 3. Measured wave displacements (a) for $T = 2.39$ sec, and various a_0, ϵ_i .

	□	+	×	△	○	▲	●
ϵ_i	0.66	1.3	2.1	3.0	4.24	6.9	8.2
r	1.0	0.8	0.55	0.4	0.26	-	-
θ	0	0	0	0	0.25	-	-

The reflected wave amplitudes are shown in Figure 4 in terms of ϵ_r , see eqs. 11-12, with $r = \epsilon_r/\epsilon_i$. The Miche reflection prediction (11) is frequently reduced by an "intrinsic" reflection factor which varies according to roughness of the reflecting surface, ~ 0.8 for smooth surfaces, the maximum ϵ_r is then 1.6. It is emphasized that although Carrier and Greenspan (1958) provides sound theoretical insight into the maximum possible amplitude completely reflected wave, there is no basic theory which predicts the variation in the reflection coefficient with increasing ϵ_i (eqs. 11-12 are essentially empirical). The experimental data (Figure 4) suggests that the offshore standing wave amplitude continues to increase with increasing ϵ_i past the range of total reflection, $\epsilon_i \approx 1$, reaching a slight maximum when $\epsilon_i \approx 2.5$. It is clear from Figure 4 that Miche's concept of a standing wave of constant amplitude provides a reasonable approximation to the data in this range of ϵ_i . However, although the wave begins to break at $\epsilon_i \approx 1$, this does not impose an immediate upper limit on the amplitude of the reflected wave and the standing wave of constant amplitude with $2 < \epsilon_i < 6$ is not the amplitude of the maximum size standing wave which can occur without breaking, $\epsilon_r \sim 1$.

The horizontal displacement at the shoreline R gives a measure of a_0 (eq. 14) and ϵ (eq. 6) as a function of ϵ_i (Figure 5). For $\epsilon_i < 1$, $\epsilon = \epsilon_i = \epsilon_r$ (Figure 2a) and the motion at the shoreline is completely explained by the excursion of the standing wave at the shoreline; for $1 < \epsilon_i < 2.5$ the swash motion continues to be appropriate for the offshore standing wave associated with the partially reflected wave. However, for $\epsilon_i > 2.5$ the motion at the shoreline (ϵ) continues to slowly increase although the reflected wave (ϵ_r) estimated from wave conditions outside the surf zone tends to decrease slightly in amplitude (Figure 4). For very large values of ϵ_i , ϵ appears to reach a maximum value of about 4 (Fig. 5). The odd ϵ_i axis on Fig. 5 (linear when $\epsilon_i \leq 10$) emphasizes the detailed studies for $\epsilon_i \leq 10$ and is intended to show qualitative behavior for larger ϵ_i . Although the measurement of run-up and particularly run-down is somewhat

subjective, these results are substantially different from those reported by Battjes (1974) where $\epsilon \approx 1.26$ is suggested as a reasonable fit to data obtained on steep beaches. However, at the same time Battjes has proposed that reflection takes place as a standing wave where

$$\epsilon_r = 0.787 \tan^{-\frac{1}{2}} \beta$$

For very steep beaches this may be small but even when $\tan \beta = 0.123$ (1:8) this requires $\epsilon_r \approx 2.3$ (Figure 4). For gentler slopes, Battjes requires ϵ_r to become large, reaching 4.0 for the 2.3° slope used for some of the data in Figure 5.

Figure 4. Nondimensional reflected wave amplitude (ϵ_r) as a function of incident wave (ϵ_i), based on data seaward of breakpoint as in Figures 2a, b.

- - - - Battjes (eq. 12)
- — — Miche (eq. 11)

Figure 5. Swash parameter $\epsilon = a_0 \omega^2 / g \beta^2$ versus offshore incident wave parameter ϵ_i (eq. 8). Note the ϵ_i axis is linear for $\epsilon_i \leq 10$, and log for $\epsilon_i > 10$.

	▲	●	X	0	Δ	◇
T (sec)	3.06	2.48	3.38	2.76	2.39	1.00
tan β	0.04	0.04	0.123	0.123	0.123	0.123

In the present experiments ϵ and ϵ_r are very much the same size for $\epsilon_i < 3$, the run-up and down being primarily determined by a standing wave at the incoming wave frequency. For $\epsilon_i > 3$, ϵ tends to increase while ϵ_r remains steady, or slightly decreases. The ratio of the wave amplitude at the shoreline to the amplitude offshore will be effected by set-up, but other non-linear effects are probably more significant and ϵ may reflect the contributions of the various free and forced harmonic frequencies 2σ , 3σ , etc. to the swash on the beach.

III. EDGE WAVE EXCITATION

Normally incident waves strongly reflected at the shoreline are known to be unstable to perturbation by edge waves; edge waves can grow by extracting energy from the primary incident wave via a nonlinear interaction (Guza and Davis, 1974). The edge wave with the most rapid theoretical growth rate, and the experimentally observed wave, is a zero mode subharmonic having velocity potential

$$\phi^e = \frac{a_e g}{\sigma_e} e^{-k_e x} \cos k_e y \sin(\sigma_e t + \theta) \tag{16}$$

where $\sigma_e = \frac{\sigma}{2}$, and $\sigma_e^2 = g k_e \tan \beta$

Various experimenters (Galvin, 1965, 1967; Birchfield and Galvin, 1975; Guza and Inman, 1975) have qualitatively determined the final steady state edge wave amplitude as a function of incident wave parameters and beach slope. In all these experiments, the edge wave amplitude was determined through measurements of the swash. At an edge wave antinode, the run-up of the incident wave is alternately in and out of phase with the edge wave, so the difference between successive uprushes gives an approximation of the edge wave amplitude at the shoreline, a_e .

$$a_e = \frac{(R_2 - R_1) \tan \beta}{2}$$

where R_1, R_2 , are the maximum (horizontal) shoreward intrusions of successive incident wave uprushes. Thus, the existing edge wave amplitude estimates are based on measurements at the shoreline where nonlinear distortion and viscous effects may be significant. In the present experiments the edge wave amplitude is measured as a function of offshore distance and the exponential ($e^{-k_e x}$) decay verified. The offshore amplitude measurements qualitatively agree with the swash observations, especially at low amplitudes. However, when the incident waves break by plunging the swash measurements tend to give too low a value for the edge wave amplitude.

The incident wave amplitudes were also not well determined in the previous experiment; Guza and Inman (1975) measured the fluctuating part of the run-up, R , (with no edge waves present) and determined a_e as a function of ϵ . However, ϵ is not linearly related to ϵ_i , the incident wave parameter in deep water (Figure 5), so there is some ambiguity as to the amplitude of their incident waves. Galvin (1967) measured only "wave height at the toe of the beach". If reflection is significant, it matters whether the measurement is near a standing wave node or antinode. Birchfield and Galvin (1975) present

incident wave data as the "amplitude of the primary wave at the shore" but obtain values of $\epsilon \approx 9$, which is much larger than observed elsewhere; perhaps they refer to the incident wave amplitude at the break (surge) line. Here, we have taken the incident waves studied in detail in II, altered the basin width to allow edge wave excitation, regenerated the same incident waves, and measured the wave field with edge waves present.

The incident waves, periods 2.39, 2.76, and 3.39 sec. studied in II now generate subharmonic edge waves, periods 4.78, 5.52, and 6.78 sec. whose wave-numbers k_e satisfy the boundary conditions of no flow through the side walls separated by distance b ,

$$k_e = \frac{m\pi}{b}, \quad m \text{ integer} \quad (17)$$

for $m = 2, 3$, and 4 if $b = 8.8$ m. Measurements were made at various distances offshore at a longshore position corresponding to an elevation antinode of the edge wave. The wavemaker conditions were identically of those of II, so the form of the incident wave prior to edge wave growth, is known; theoretically, the incident wave may be substantially modified by the interaction with the edge wave.

The measurements of edge wave amplitude show the $e^{-k_e x}$ decay expected from (16), and hence provide a measurement of a_e , the edge wave amplitude at the shoreline. It is useful to also express a_e in a dimensionless form ϵ_e where

$$\epsilon_e = \frac{a_e \sigma_e^2}{g \tan^2 \beta} \quad (18)$$

Figure 6a shows the observed variation of ϵ_e as a function of the incident wave conditions defined by ϵ_i . The edge wave resonance disappears when $\epsilon_i > 8$ for wave period 2.39 secs. The paddle was not powerful enough to make incident waves of the longer periods large enough to suppress the resonance. The $T_i = 1.0$ sec point from Galvin (1967) is based on the amplitude at the beach tow, acceptable in this case of large ϵ_i , and minimal reflection.

Galvin's (1968) classification of breaker type is (Battjes, 1974, gives similar criterion)

$$\begin{aligned} \frac{H_o}{L_o \beta^2} < 0.09 & \quad \text{surging-collapsing} \\ 0.09 < \frac{H_o}{L_o \beta^2} < 4.8 & \quad \text{plunging} \\ 4.8 < \frac{H_o}{L_o \beta^2} & \quad \text{spilling} \end{aligned} \quad (19)$$

and when $\epsilon_i \approx 10$; $H_o/L_o \beta^2 \approx 0.44$ and the resonance ceases near the low steepness end of the plunging wave regime.

Figure 6b shows ϵ_e versus ϵ (the incident wave run-up parameter) and indicates that resonance ceased ($T_i = 2.39$) when $\epsilon \approx 3.2$. Guza and Inman (1975) present similar results for a range of periods and beach slopes, their edge wave

amplitudes are qualitative, being based on a swash measurement rather than detailed measurements offshore. Some maximum values of ϵ for which they observed resonance are shown (—a—, —b—) indicating that ϵ_{max} decreases with decreasing slope and period.

Figure 6a, b. Nondimensional edge wave amplitude ϵ_e (eq. 18) versus nondimensional incident wave offshore (ϵ_i) and swash (ϵ) parameters. Solid line is theory (eq. 21), independent of T_i for $C_v = 0$; $C_v = 3$ corresponds to $T = 2.7$ sec.

The theory of edge wave excitation by completely reflected incident waves is based on a weak nonlinear interaction formalism using the shallow water approximation for the incident wave (Guza and Davis, 1974; Guza and Bowen, 1976). The forcing of an initially small, zero mode, subharmonic edge wave by the incident wave results in an initial inviscid edge wave amplitude growth

$$a_e = a_e(t = 0) e^{\alpha \epsilon \sigma_i t}, \quad \alpha = \int_0^{\infty} f(x) dx = 0.0169 \quad (20)$$

where $f(x)$ is a complicated function which expresses the spatial coupling between incident and edge waves. Guza and Bowen (1976) have theoretically determined the equilibrium amplitude, based on the assumption that the incident wave is totally reflected ($\epsilon = \epsilon_i$). For a basin width and edge wave frequency satisfying (17)

$$\epsilon_e^2/\epsilon = 7.87 \left[-0.203 d^{1/2} + (2.9 \times 10^{-3} - 3.79 \times 10^{-2} d)^{1/2} \right] \quad (21)$$

where $d = \nu C_v^2 / \sigma_e a_0^2$

and viscous effects have been modeled with laminar boundary layers and an effective viscosity, ν' , where

$$\nu' = C_v^2 \nu \quad (22)$$

For clean water, smooth bottoms, etc., $C_v = 1.0$ and bottom boundary layers account for most of the damping. If ν' is some constant, independent of ϵ_e , viscous effects determine the minimum incident wave amplitude which will excite edge waves but do not limit edge wave growth if it occurs. The edge wave growth is finally curtailed by finite amplitude effects, radiation and finite amplitude detuning (Guza and Bowen, 1976). The condition that nonlinear forcing can overcome viscous damping and initiate resonant growth is

$$\epsilon > \frac{\sigma_i^2}{g\beta^2} \left(\frac{C_v^2 \nu}{\sigma_i} \right)^{\frac{1}{2}} 7.36 \quad (23)$$

Figure 6b shows a comparison between the laboratory measurements and theory (eq. 21) for $C_v = 0$ (inviscid) and $C_v = 3$; using the observed shoreline values for a_0 to calculate ϵ . The agreement is good for $\epsilon \leq 2.4$ (corresponding to $\epsilon_i \leq 5$, $H_0/L_0\beta^2 \leq 0.22$). Above $\epsilon = 2.4$ the edge waves are generally smaller than predicted, the resonance disappearing altogether at large values.

The existing theory is for totally reflected incident waves which do not break and it is not surprising that the observed edge wave amplitudes diverge from theory when the assumption of total reflection is violated. The presence of the progressive incident wave component, and the turbulence which dissipates its energy, have been neglected. We now consider these factors.

The forcing of the edge wave by the incident waves, whether standing or progressive, is expressed as an integral over the entire fluid (eq. 20). It can readily be shown, however, that most of the resonant forcing occurs quite close to shore where the edge wave is large. When only a standing wave is present, $\alpha(20)$ reaches 50% of its total value when $\chi^2 = 8.0$, and 70% when $\chi^2 = 12.8$. Now when $\epsilon_i \approx 3.5$, $r \approx 0.4$, $\epsilon \approx 1.8$, the surge line is about $\chi^2 = 10$ (Figure 2b). Therefore, when ϵ_i is so large that significant dissipation occurs, most of the edge wave forcing by the standing wave occurs inside the breakpoint, and is concentrated in the swash. Hence, ϵ determined by the value of a_0 measured at the shoreline will be assumed to give the edge wave forcing (eq. 20) by the standing component of a partially reflected incident wave. If the progressive incident wave component (whose amplitude after breaking is proportional to the depth) is superimposed on the standing wave the integral in (20) might be recalculated. This simple, surf zone model is clearly related to Miche's concept of reflection, but is probably a gross oversimplification of the actual conditions. However, because the resonant forcing tends to occur very close to the shoreline where the progressive wave vanishes the integral in (20) might be almost unaffected and it seems that the edge wave forcing is not greatly altered by the progressive wave component. The hypothesis that the edge wave forcing is determined primarily by the swash parameter (ϵ) implies that the forcing increases almost linearly with ϵ_i when $\epsilon_i \lesssim 2$, increases more slowly when $\epsilon_i > 2$, and eventually reaches a maximum corresponding to $\epsilon \approx 4$ (Figure 5).

The edge wave damping, however, might be expected to increase dramatically with increasing ϵ_i , when $\epsilon_i > 2$. Significant incident wave breaking is beginning to occur, and the associated turbulence results in an "eddy viscosity" much larger than molecular viscosity. If the edge wave dissipation increases much more rapidly than forcing, then it would be expected that there is some maximum ϵ_i for which resonance can occur; a simplistic model shows that this is indeed the case.

There is no generally accepted form for the eddy viscosity (A) in the surf zone, but the model of Battjes (1976) is certainly plausible;

$$A = Mh(D/\rho)^{1/3}$$

where D is the rate of energy dissipation of incident waves and M is a constant. For completely progressive waves

$$D_p = 0.31 \rho g^{3/2} h^{3/2} \beta \gamma^2 ; x < x_B$$

where the constant ratio between progressive wave height and water depth, $\gamma = H/h \approx 1.0$ on steep beaches. For partially reflected waves, the dissipation rate depends on the progressive component, and we take $D = D_p(1-r)^2$ where $r = 2/\epsilon_i$ (Miche's form, Figure 4). The average (across the surf zone) eddy viscosity is then

$$\bar{A} = 0.4M \left[0.31 \gamma^2 (1-r)^2 \right]^{1/3} \beta^{4/3} x_B^{1/2} (gh_b)^{1/2} \quad (24)$$

Assuming that the eddy viscosity is determined by the breaking incident waves (eq. 24), and that the edge wave damping can be modeled (albeit grossly) by replacing molecular with eddy viscosity, the average edge wave dissipation per unit longshore length is then

$$D_e = \frac{\rho a_e^2 \sigma_e^{5/2}}{2\sqrt{2} \beta^2} A^{-1/2} \int_0^{x_B} e^{-2kx} dx \quad (25)$$

The surf zone width, and hence average eddy viscosity (eq. 24) and edge wave dissipation (eq. 25), depend on ϵ_i . We take as an approximate fit to our data

$$x_B^2 = 0 \quad \epsilon_i < 2$$

$$x_B^2 = 4(\epsilon_i - 2) \quad \epsilon_i > 2$$

which results in

$$D_e = \rho a_e^2 g^2 (8\sigma_i)^{-1} (0.4M)^{1/2} (0.31\gamma^2)^{1/6} \beta^{2/3} \left(1 - \frac{2}{\epsilon_i}\right)^{1/3} (\epsilon_i - 2)^{3/4} \left[1 - e^{-(\epsilon_i - 2)/2}\right] \quad (26)$$

The condition for any subharmonic edge wave excitation is that the rate of energy input from the incident waves (eq. 20) exceed the rate of dissipation. Thus, the maximum ϵ_i which can generate edge wave occurs when (assuming $\gamma = 1$.)

$$\epsilon_i = 3.8\beta^{-1/3} (\epsilon_i - 2)^{3/4} \left[1 - e^{-(\epsilon_i - 2)/2}\right] \left(1 - \frac{2}{\epsilon_i}\right)^{1/3} M^{1/2} \quad (27)$$

Now the present observations (Figure 6) with $\beta = 0.123$ suggest the resonance ceases when $\epsilon_i \approx 3$, and $\epsilon_i \approx 10$, which implies that $M^{1/2} \approx 0.1$. Battjes (1976) has computed values of M from 20 longshore current experiments with fully

developed breakers on steep beaches and finds $0.55 < M^{\frac{1}{2}} < 1.34$. Since the edge wave dissipation rate (26) is proportional to $M^{\frac{1}{2}}$, $M^{\frac{1}{2}} \approx 0.1$ implies a dissipation rate an order of magnitude less than with fully developed surf zones, but an order of magnitude greater than laminar damping. It is possible to use the eddy viscosity model to predict ϵ as a function of ϵ_j (analogous to eq. 2, Fig. 6b) but this seems pointless in view of the unutterable crudeness of the model. The crux of the matter is that if edge wave forcing is approximately constant (or at least the same order) for breaking and non-breaking waves, then the orders of magnitude increase in viscous effects due to wave breaking effectively suppresses the resonance.

To look more closely at the idea that increased damping, rather than the changed form of the incident wave, is responsible for the absence of resonance, experiments were made in which an additional wave was superimposed on a resonant situation. Waves of period 2.76 sec of constant amplitude ($\epsilon_j = 2.16$, $\epsilon = 1.72$), strongly reflected from the beach ($r = 0.77$) generated a subharmonic resonance $\epsilon_e = 0.75$ in the absence of any further waves, in good agreement with theory (Figure 6). Waves of 1.0 sec period were then superimposed, the wave amplitude being measured in deeper water and a value of the breaker index, $H_0/L_0\beta^2$ obtained, the beach slope being 0.123. Table 1 shows the disappearance of the basic resonance, in terms of the edge wave amplitude, as the size of the 1.0 sec wave is increased. Other experiments show this to be a general result, the particular mix of incident wave frequencies and amplitude in Table 1 but one of a multitude of possibilities.

Table 1. Subharmonic edge wave amplitudes in the presence of high frequency waves of 1 sec period

$H_0/L_0\beta^2$ (T = 1 sec)	0	0.74	1.6	2.2	3.0	3.8
ϵ_e ($T_e = 5.56$ sec)	0.75	0.76	0.73	0.62	0.18	0

The question of how much incident wave breaking at other frequencies is needed to suppress a given surging wave resonance is unanswered, and presents great theoretical difficulties. However, it is clearly an important component in the problem of edge wave excitation by an incident wave spectrum. It seems likely that the most important factor will be the ratio between the width of the surf zone (regardless of which breaking waves introduce the turbulence) and the offshore length scale of the edge wave. The instabilities of relatively very long surging waves will be unaffected by very short breakers, where the surf zone, and hence band of increased viscosity associated with the chop is of small extent relative to the incident surging wave and excited edge wave wavelengths. Field situations with offshore breaker bars, and a shoreward zone of reformed potential waves present an even complex problem. Very short edge waves will not "feel" the offshore turbulence!

IV CONCLUSIONS

The model of a surf zone as a simple combination of a standing wave of fixed amplitude plus a progressive wave (decaying shorewards from the breakpoint) seems to provide an accurate representation of the sea surface elevations and run-up for large reflectivities ($r > 0.3$).

The nondimensional amplitude of the standing wave is not, however, determined completely by the condition of the onset of breaking, correctly

predicted by $\epsilon = 1$, but continues to increase to a value of about 1.6 (Figure 4). This agrees quite well with Miche's (1951) empirical suggestion. As the incoming wave height increases, finite amplitude effects seem to complicate the general picture and the relationship between the swash motion ϵ and ϵ_r the reflected wave becomes less clear.

The generation of subharmonic edge waves is known to be dependent on the breaker characteristics, the resonance disappearing when the incoming wave breaks cleanly (Galvin, 1965). Simple calculations suggest that the change is due to an increase in damping and not an alteration in the forcing itself, which seems primarily associated with the standing component of the incoming wave field. Experiments in which a surf zone is generated by a wave unconnected with the resonance, while the forcing remains constant, further supports the idea that the resonance is suppressed by the increase in the effective viscosity of the nearshore region.

This has substantial implications for the existence of any edge waves in surf. To exist at all they must be strongly forced and are most likely to survive if their offshore length scales are large in comparison to the width of the surf zone.

CHAPTER 33

Wave Spectrum of Breaking Wave

ABSTRACT

By wave breaking, an incident monochromatic wave is transformed to a wave composed of its harmonic frequency waves inside a surf zone.

Based on a dimensional consideration, the "-1 power law", the "-2 power law", the "-2/3 power law" and the "-1/2 power law" on the wave height spectrum, $H(f)$, are derived as sorts of equilibrium spectra.

These spectra except "-1/2 power law" are shown to agree with experimental data.

1. INTRODUCTION

The authors¹⁾ already revealed that 25% - 40% of total wave energy was dissipated due to a bottom shear friction and a horizontal roller formed by a plunging breaker in a surf zone.

Therefore, the turbulence with air entrainment will be thought to play an important role in the wave energy dissipation. It is necessary to measure an accurate time-history of water particle velocity in order to clarify the characteristics of turbulence, but, it will be impossible by lack of precise measuring instruments.

Since a wave profile is thought to be an expression of turbulence after breaking, it will be expected that some features of turbulence can be deduced by analysing wave surface profiles.

Inside the surf zone, as the authors already clarified¹⁾, an incident monochromatic wave is transformed to a complicated breaking wave composed of higher frequency component waves due to non-linearity of breaking phenomenon, and dissipates its excess energy which can not be kept for wave motion. Therefore, the wave will be considered to reach some critical state for maintaining the wave motion. In this critical state, there will exist some sorts of critical conditions for wave height distributions of component waves. With this situation, dimensional consideration is an efficient tool for deriving wave height spectral characteristics.

2. DIMENSIONAL ANALYSIS

The physical quantities to be considered in the dimensional analysis of

wave height spectrum, $H(f)$ are gravitational acceleration g , wave frequency f , still water depth h , density of water with air entrainment ρ^* , molecular viscosity of water with air entrainment μ^* , and surface tension K as shown in Eq.(1),

$$H(f) = f (g , f , h , \rho^* , \mu^* , K) . \quad \text{-----(1)}$$

As the significance of these parameters changes according to four kinds of frequency range such as one of shallow water waves, deep water waves, capillary ripple waves and the frequency range in which viscosity is predominant, important physical parameters must be selected to fit the physical situation.

Firstly, attention is paid to the wave frequency range associated with shallow gravity waves which satisfies the relation of $f < f_1$, in which f_1 is given by Eq.(2) deduced from Eq.(3),

$$f_1 = \sqrt{g / 4\pi h} \quad , \quad \text{-----(2)}$$

$$h/L_0 = 0.50 \quad , \quad \text{-----(3)}$$

where, L_0 is a wave length of deep water wave. In this case, the influence of surface tension K is unimportant. Furthermore, the direct effect of ρ^* and μ^* is manifest in wave damping, and under the condition with which we are concerned, these two factors may be the second order terms and may be included in the non-dimensional coefficient of wave height spectrum. Therefore, in this region, three quantities such as g , f , and h are predominant physical factors, and wave height spectrum $H(f)$ has a dimension $[L]$, so that the following wave height spectrum is considered:

$$\begin{aligned} H(f) &= f (g , f , h , \underbrace{\rho^*}_{\text{first order}} , \underbrace{\mu^*}_{\text{second order}}) , \\ &= G_1 (\sqrt{gh^3} / (\mu^* / \rho^*)) \cdot g^{1/2} \cdot h^{1/2} \cdot f^{-1} , \\ &\propto g^{1/2} \cdot h^{1/2} \cdot f^{-1} , \quad \text{-----(4)} \\ &\quad \text{for } f < f_1 (= \sqrt{g/4\pi h}) . \end{aligned}$$

(5)² Next, consider the frequency range of $f_1 < f < f_c$, where f_c is given by Eq.

$$f_c = \frac{1}{2\pi} \sqrt{\frac{\rho^* g}{K}} . \quad \text{-----(5)}$$

This frequency range corresponds to those of deep gravity waves and surface tension K is unimportant as the previous case. ρ^* and μ^* are treated by combining with h as the second order terms, then the predominant physical factors are g and f . Therefore, the following wave height spectrum is considered:

$$\begin{aligned}
 H(f) &= f(g , f , \{ \mu^* , \mathcal{S}^* , h \}) , \\
 &= G_2(\sqrt{gh^3} / (\mu^* / \mathcal{S}^*)) g \cdot f^{-2} \\
 &\propto g \cdot f^{-2} , \quad \text{-----(6)} \\
 &\quad \text{for } f_1 < f < f_c .
 \end{aligned}$$

In deep gravity waves, Michell³⁾ gave the critical wave steepness as a breaking condition as shown in Eq.(7):

$$(H/L)_b = 0.142 . \quad \text{-----(7)}$$

By using the relation of $L=(g/270)f^{-2}$, the critical wave height $H(f)$ is given as follow:

$$H(f) = 0.0226gf^{-2} . \quad \text{-----(8)}$$

Comparing Eq.(6) with Eq.(8), the physical meaning of the dimensional analysis is clear and it may be pointed out that the wave height distribution is limited so as to satisfy a sort of critical wave steepness.

As mentioned above, for a frequency range in which a restoring force is gravitational acceleration, the wave height spectrum $H(f)$ consists of Eq.(4) and Eq.(6). By combining Eq.(4) and Eq.(6), the following expression may be possible:

$$\begin{aligned}
 H(f) &= G^* (\sqrt{gh^3} / (\mu^* / \mathcal{S}^*)) gf^{-2} (\tanh(2\mathcal{X}hf^2/g))^{1/2} , \\
 &\propto gf^{-2} (\tanh(2\mathcal{Z}hf^2/g))^{1/2} , \quad \text{-----(9)} \\
 &\quad \text{for } f < f_c .
 \end{aligned}$$

For a frequency range of $f < f_1$, the relation of $(\tanh(2\mathcal{X}hf^2/g))^{1/2} \approx (2\mathcal{X}hf^2/g)^{1/2}$ is established, and then, $H(f) \propto \sqrt{gh}f^{-1}$ is easily deduced.

Secondly, aiming at the wave frequency ($f_c < f < f_k$) associated with capillary ripples, the influence of gravitational acceleration is ignored, where, f_c is given by Eq.(5), and f_k is the highest frequency for which the surface tension is predominant. In this case, three factors such as f , K , \mathcal{S}^* are very important physical factors and then the following wave height spectrum is considered:

$$\begin{aligned}
 H(f) &= f_3(f , \mathcal{S}^* , K) , \\
 &= G_3 k^{1/3} \mathcal{S}^{*1/3} f^{-2/3} , \\
 &\propto K^{1/3} \mathcal{S}^{*1/3} f^{-2/3} , \quad \text{-----(10)} \\
 &\quad \text{for } f_c < f < f_k ,
 \end{aligned}$$

where, G_3 is a non-dimensional coefficient.

Lastly, treat the very high frequency region ($f > f_k$) in which viscosity of water is only predominant. In this case, we can select only three factors such as f , \mathcal{S}^* and μ^* as predominant physical factors. Therefore, the wave height spectrum given by Eq.(11) is considered,

$$\begin{aligned}
 H(f) &= f_4 (f, \mathcal{S}^*, \mu^*), \\
 &= G_4 \cdot \mu^{*1/2} \mathcal{S}^{*-1/2} f^{-1/2} , \\
 &\propto (\mu^*/\mathcal{S}^*)^{1/2} \cdot f^{-1/2} , \text{----- (11)}
 \end{aligned}$$

for $f > f_k$.

By summarising the above-mentioned wave height spectra given by Eqs.(4), (6),(10) and(11), a wave height spectrum inside the surf zone may be expressed as shown in Fig.-1.

From Fig.-1, it is easily understood that "-1power law", "- 2 power law", "-2/3 power law" and "-1/2 power law" are established in turn as the frequency f increases in the wave height spectrum. The coefficients, G_1, G_2, G_3, G_4 express the levels of wave height spectrum and their features must be examined by various kinds of experiment.

Fig.-1. Schematic view of wave height spectrum.

3 EXPERIMENTAL STUDY

1. Equipment and Procedures

Experiments were conducted to examine the characteristics of wave height spectra predicted by the dimensional analysis. In the experiments, an out-door wave tank in 0.65 m width, 0.95 m height, and 50 m length was used. At one end of the wave tank was installed a plunger-type wave generator and waves were able to be generated in different periods and amplitudes. At the other end of the tank, four kinds of beach slopes such as 1/15, 1/25, 1/40 and a composite slope consisting of an approach ramp with 1/12 slope leading up to a horizontal surface, were installed. Experimental conditions are shown in Table-1.

Wave profiles measured by a resistance-type wave gauge were recorded on magnetic tapes with 60 sec. periods and the data were sampled at each 1/50 sec. interval. Fourier analysis was carried out by FFT method.

For each experimental run, by using a high speed cine-camera (100~200 frames/sec.), a breaking region was filmed through a grid on glass walls at the channel with the camera axis kept at a still water level. From these films, breaking points, breaking depths, domains of existence of horizontal rollers and the regions of air entrainment in breakers were decided.

2. Results and Discussion

Fig.-2 shows a change of wave height spectrum during wave propagation in the horizontal bed. In Fig.-2, the upper figure shows the characteristics of an incident wave, middle two figures are wave height spectra at a breaking point and at $X/L=1.07$ inside the surf zone, and the bottom figure shows the wave height spectrum of a reformed wave after passing through the surf zone. At the breaking point, the wave is composed of high frequency waves against the monocromatic frequency of an incident wave, and harmonic frequency component waves of an incident wave frequency are predominant. Inside the surf zone ($0 < X/L < 1.30$), wave heights of the harmonic frequency waves grow larger than those of the incident wave and the reformed wave after passing through the surf zone. The reformed wave has no higher frequency component wave differing from waves inside the surf zone.

The fact that an incident periodic wave is transformed to a wave composed of its harmonic high frequency waves, shows the remarkable feature of breaking waves. Since wave breaking is non-linear phenomenon, waves in high harmonic frequency will grow due to non-linear terms of the wave motion. But, the effect of non-linear interaction among component waves may be small, because predominant periods of the component waves after breaking are, as mentioned above, harmonic periods of an incident wave period.

Now, consider the relation between a measured height H_{ex} , and its Fourier component wave heights. The equivalent wave heights H_{eq} , calculated by Eq.(11) obtained with the Parceval theorem have good agreement with the measured wave height H_{ex} , as shown in Fig.-3. This shows that the measured wave can be treated as the sum of its Fourier component waves as follows:

$$H_{eq} = \left(\sum_{j=1}^{\infty} H_j^2 \right)^{1/2}, \quad \text{-----(11)}$$

where, $j=1 \sim \infty$ indicates Fourier component waves.

Fig.-2. Variation of wave height spectrum. (S = 0)

Fig.-4 and Fig.-5 show variation of wave height spectra plotted on log - log scale as waves propagate on a horizontal bed. Fig.-5 shows only predominant component waves. $f_1 = 3.3$ (c/s) and $f_c = 13.3$ (c/s) are obtained by Eqs. (2) and (5) for waves shown in Figs.-4 and -5, and the domain of air entrainment X_A/L is given to be $0 \leq X_A/L \leq 1.05$ for the wave shown in Fig.-4 and $0 \leq X_A/L \leq 1.30$ for the wave in Fig.-5 by the experiment.

Fig.-4 and Fig.-5 show that inside the surf zone with air entrainment, the slopes of wave height spectra are approximately proportional to " f^{-1} " for $f < f_1 = 3.3$ (c/s) and " f^{-2} " for $f_1 = 3.3$ (c/s) $< f < f_c = 13.3$ (c/s). In cases of waves before breaking and waves after passing through the surf zone, however, the higher frequency component waves more than 5(c/s) can not be observed, and then, the slopes of wave height spectra are not proportional to " f^{-1} " and " f^{-2} " (see Fig.-4 (a), (g) and (h), and points $X/L = 2.99$ and 3.04 in Fig.-5).

For the case of a spilling breaker, the slope of wave height spectrum at a breaking point is steeper than " f^{-2} " for 3.3 (c/s) $< f < 13.3$ (c/s) in Fig.-4(b) and, at the point $X/L = 0$ in Fig.-5(a). This may be due to the reason that the turbulence of breaking is not saturated⁵⁾ all over the wave as shown in Fig.-6 and that the characteristics before breaking still remain.

In the region such as $X/L = 0.322, 0.523$ and 0.775 in Fig.-4 where the turbulence of breaking is saturated, however, "-1 power law" and "-2 power law" are established as mentioned above.

Figs.-7 and -8 show variation of wave height spectra plotted on the log-log scale on a uniform slope of $1/40$ and $1/25$ respectively. Fig.-9 shows a change of wave height spectrum of predominant component waves piled up on the same graph, where h is a still water depth and h_b is a breaking depth. The characteristics of wave height spectra on uniform slopes are similar to those on the horizontal bed. As shown in Fig.-9, the slopes of wave height spectra are recognized to be nearly proportional to " f^{-2} " for the range of $f_1 < f < f_c$ independent of wave steepness, H_0/L_0 , and beach slope, S . On the other hand, the slopes of wave height spectra for $f < f_1$ is roughly proportional to " f^{-1} ".

In sloping beaches, the values of wave height spectra decrease as waves propagate into shallower water depth as shown in Fig.-10, and inside the surf zone, the pattern of wave height spectrum such that a spectral slope is proportional to " f^{-1} " for $f < f_1$, and " f^{-2} " for $f_1 < f < f_c$, is still maintained. In Fig.-10, the point of $h/h_b = 0.19$ is outside the surf zone.

Summarizing the above-mentioned experimental results, it can be concluded that the wave height spectrum $H(f)$ has the form of which slope is proportional to " f^{-1} " for $f < f_1 (= \sqrt{g/4\pi h})$ and to " f^{-2} " for $f_1 < f < f_c (= 1/2\sqrt{S^*g/K})$ as critical wave height spectrum inside the surf zone where the turbulence of breaking is saturated all over the wave.

On the other hand, since values of wave spectra are very small at the present experiment for $f_c < f < f_k$ in which the surface tension is a restoring force, the characteristics may not be discussed sufficiently. But, in many experimental cases, it is recognized that the slope of wave height spectrum is approximately proportional to " $f^{-2/3}$ " as shown in Fig.-11. Therefore, it may not be said too much that " $f^{-2/3}$ " can be established.

For the frequency range of $f > f_k$ in which water viscosity is predominant, the authors can not discuss about " $f^{-1/2}$ ", because wave profiles were measured by using a low pass filter of which sheltering frequency is more than 25(c/s), and values of spectra are considerably small. In future, the authors will carry out large scale experiments and discuss in detail.

Finally, variation of wave height of component waves will be discussed. The pattern of wave height decay of component waves is different between a spilling breaker and a plunging breaker.

As shown in Fig.-12(a), in case of the spilling breaker, high frequency wave heights grow larger once soon after breaking. On the other hand, in case of the plunging breaker, wave heights of high frequency waves decay uniformly after breaking as shown in Fig.-12(b). This difference may be due to the reason that the spilling breaker is not saturated by the turbulence of breaking at a breaking point, differing from the case of the plunging breaker.

The degree of wave height attenuation of component waves is generally larger as the frequency is higher, as shown in Fig.-12, where f_0 is the monochromatic frequency of an incident wave and f is the frequency of component waves. These mechanism may be due to the internal turbulent shear caused by breaking, and dissipating energy is proportional to νk^2 (k =wave number, ν =kinematic viscosity) as predicted by the classical turbulence theory.

4. CONCLUSION

In this paper, the characteristics of wave height spectrum $H(f)$ inside the surf zone of a monochromatic periodic wave are discussed.

Firstly, due to the dimensional analysis, it is predicted that there exist a critical wave height spectrum $H(f)$ of which slopes are proportional to " f^{-1} ", " f^{-2} ", " $f^{-2/3}$ " and " $f^{-1/2}$ " in turn as the frequency f becomes larger.

Secondly, experiments were carried out to examine the results of the dimensional analysis. It is made clear that inside the surf zone, an incident monochromatic wave is transformed to a wave composed of high frequency component waves and that the subranges of "-1 power law", "-2 power law" and "-2/3 power law" are established in the wave height spectrum as predicted by the dimensional analysis.

ABSTRACT

A bottom friction is an effective factor which will prove the deformation of progressive waves in shallow water, and many investigators have obtained the friction coefficients from field observations. However, they have not considered the effect of turbulent loss due to sand ripple at a sea bottom.

The authors, first of all, study on the friction coefficient for artificial fixed ripple by using the boundary layer theory of rough turbulence, and a new formula on the friction coefficient is proposed. The proposed friction coefficients are compared with Zhukovets' experimental results which were performed on a movable bed, and it is found that the theoretical friction coefficients for artificial fixed ripple have to be modified in order to apply for the natural beach. Lastly, the wave deformation due to the bottom friction on the movable bed is calculated by the modified friction coefficient and the effect of bottom friction on the wave deformation is discussed.

1. INTRODUCTION

It is very important to predict a wave height in shallow water for a design of coastal structure. A bottom friction is an effective factor which will prove the deformation of progressive waves in shallow water. Bretschneider¹⁾, Iwagaki and Kakinuma²⁾ and other many investigators have obtained the friction coefficient at the sea bottom from the measuring results of wave height in the field. However, the friction coefficient given by Iwagaki and Kakinuma is larger than 0.01 which was given Bretschneider. We don't know the reason even now. Many investigators have not considered the effect of turbulent loss due to a sand ripple at the sea bottom. But we know that a boundary layer at the sea bottom in shallow water is turbulent in rough state, and that the sand ripple develops at the sea bottom.

As a clue to elucidate the wave deformation due to the bottom friction, the authors, first of all, study on the coefficient for artificial fixed ripple by using the boundary layer theory on rough turbulence which was given by Kajiura³⁾, and a new formula on the friction coefficient is proposed.

Secondarily, the friction coefficient given by the new formula is verified by experimental results at a movable bed, and it is found that the friction coefficient by assuming fixed ripple have to be modified in order to apply for the natural beach.

Lastly, the deformation of shallow water waves on a constant beach slope is calculated by the modified friction coefficient, and the effect of bottom friction on the wave deformation is clarified.

2. FRICTION COEFFICIENT FOR ARTIFICIAL FIXED RIPPLE

The bottom friction under the ripple formation has been investigated by Bagnold⁴⁾, and Putnam and Johnson⁵⁾ have obtained $f = 0.01$ from the field investigation under the consideration of Bagnold's investigation results. This value of friction coefficient was verified by Bretschneider's field observation. However, these studies were not considered the effect of boundary layer.

According to Kajiura theory³⁾ on the boundary layer which expanded Bagnold's experimental results, the ranges of transition are given by the following equations.

$$\left. \begin{aligned} 0.4 \leq \delta^*/D \leq 5.0, \text{ for laminar-turbulent transition} \\ 0.4 \leq D/D_L \leq 5.0, \text{ for smooth-rough transition} \end{aligned} \right\} (1)$$

furthermore,

$$\left. \begin{aligned} D/D_L &= \hat{C}^{1/2} M/N, & \delta^*/D_L &= \hat{C}^{3/2} R^2 N \\ M &= 30 \hat{U}_b Z_0/\nu, & R &= \hat{U}_b / \sqrt{\sigma} \end{aligned} \right\} (2)$$

where, \hat{C} is an amplitude of friction coefficient, ν is a coefficient of kinematic viscosity, σ is an angular frequency of wave, \hat{U}_b is an amplitude of horizontal velocity at the sea bottom, Z_0 is a roughness length, D is Nikuradse's equivalent sand roughness, and $N=12$.

The authors assume the sand ripple to be fixed artificial ripple, and Nikuradse's equivalent sand roughness D equals $30Z_0$. Andmore, it is already revealed that D equals 4η by Motzfeld⁶⁾.

On the other hand, some equations about the sand ripple are given by Homma, Horikawa and Kashima⁷⁾ as follow,

for criterion of ripple formation : $\hat{U}_b / \sigma \lambda > 0.5$ (3)

for height of sand ripple : $\eta = 0.175 (2\hat{U}_b / \sigma)^{-0.915} \lambda^{1.19}$ (4)

for length of sand ripple : $\lambda = \alpha \tau (2\hat{U}_b / \sigma)^{1-2\gamma}$ (4)

where, α and γ are given by the function of sand grain size as shown in Fig. (1) and the authors approximate them by the following equations.

$$\left. \begin{aligned} \alpha &= -389.4 d_{50}^3 + 729.5 d_{50}^2 - 313.0 d_{50} + 40.7 \\ \gamma &= -82.7 d_{50}^3 + 87.2 d_{50}^2 - 28.6 d_{50} + 3.3 \end{aligned} \right\} (5)$$

where, d_{50} is a mean diameter of bed material, in centimeter.

Fig.1 Relation between α , γ and sand grain size.

From the above Eqs.(1) (5), it is known that the state of flow over the ripple due to wave shows almost rough turbulence. Furthermore, the relation between a bottom shear stress and a friction coefficient, C , is given by Eq.(6) due to Kajiura's theory.

$$\tau_b / \rho = C \cdot \hat{U}_b \cdot U_b, \quad C = \hat{C} e^{i\theta} \quad (6)$$

$$\left. \begin{aligned} \hat{C} &= 1.7 (30\lambda / 4\eta)^{-2/3}, \quad \text{for } 0.5 < \hat{U}_b / \sigma \lambda < 1.0 \\ \hat{C} &= A (U_b / \sigma Z_0)^{-B}, \quad \text{for } 1.0 < \hat{U}_b / \sigma \lambda \end{aligned} \right\} (7)$$

where, τ_b is a bottom shear stress, \hat{C} is an amplitude of friction coefficient as shown in Fig.2, θ is a phase of friction coefficient which is given by Kajiura as shown in Fig.3.

Fig.2 and Fig.3 are approximated by the dotted line. From the approximated line, A,B in Eq. (7) and θ in Eq. (6) are given by Table 1.

Fig. 2 Change of \hat{C} with $\hat{U}_b / (\sigma z_0)$

Fig. 3 Change of θ with $\hat{U}_b / (\sigma z_0)$

$\hat{U}/\sigma z_0$	$C=A(\hat{U}_b/\sigma z_0)^{-B}$	θ
~685	$1.7(\hat{U}/\sigma z_0)^{0.667}$	$\approx \frac{\pi}{4}$
$685 \sim 3 \times 10^3$	$0.711(\hat{U}/\sigma z_0)^{0.536}$	$1.558 - 0.266 \log_{10} \left(\frac{\hat{U}}{\sigma z_0} \right)$
$3 \times 10^3 \sim 8 \times 10^3$	$0.240(\hat{U}/\sigma z_0)^{0.4}$	$1.524 - 0.257 \log_{10} \left(\frac{\hat{U}}{\sigma z_0} \right)$
$8 \times 10^3 \sim 2 \times 10^4$	$0.068(\hat{U}/\sigma z_0)^{0.26}$	$1.287 - 0.196 \log_{10} \left(\frac{\hat{U}}{\sigma z_0} \right)$
$2 \times 10^4 \sim 10^5$	$0.068(\hat{U}/\sigma z_0)^{0.26}$	$1.092 - 0.150 \log_{10} \left(\frac{\hat{U}}{\sigma z_0} \right)$

Table 1. Approximated value of A, B and θ

In terms of friction coefficient \hat{C} , a mean energy dissipation $\langle E \rangle$ is given by Eq.(8).

$$\langle E \rangle = \rho/2 \hat{C} \hat{U}_b^3 \cos \theta \quad (8)$$

On the other hand, in the ordinary definition of friction coefficient, f , which is used by many investigators, the energy dissipation, $\langle E \rangle$ is given by Eq.(9).

$$\langle E \rangle = 4/3 \cdot \rho \cdot f \hat{U}_b^3 \quad (9)$$

So, the coefficient, f , is represented by Eq.(10) from the comparison of Eqs.(8) and (9).

$$f = 3/8 \hat{C} \cos \theta \quad (10)$$

Summarizing the above relation, the friction coefficient, f_{fix} , provided that the sand ripple is assumed to be fixed artificial one, is given by Eq.(11).

$$\begin{aligned}
 f_{\text{fix}} &= 0.116 \left(\frac{\nu}{a} \right)^{0.127} Re_T^{-0.127}, \quad \text{for } \left(\frac{1}{a} \right)^{\frac{1}{3}} < Re_T < \pi \left(\frac{2}{a} \right)^{\frac{1}{3}} \\
 f_{\text{fix}} &= 1.18 A \cos \theta \left\{ 0.0467 \left(\frac{\nu}{a} \right)^{1.19} \right\}^B \cdot Re_T^{-1.19B}, \\
 &\quad \text{for } Re_T > \pi \left(\frac{2}{a} \right)^{\frac{1}{3}} \\
 a &= \left(\frac{\nu}{\pi} \right)^{\delta} / \alpha, \quad Re_T = \hat{U}_b^2 T / \nu
 \end{aligned} \quad (11)$$

where, subscript "fix" shows that the sand ripple is assumed to be fixed artificial ripple. α and δ are given by Eq.(5) and A, B and θ are given by Table 1.

Using the above relations, the friction coefficient for an arbitrary

sand grain size is obtained. The relation between f_{fix} and Re_T of Eq.(II) for 4 kinds of sand grain size are shown by the full line in Fig.4.

In Fig.4 the friction coefficients in the field data obtained by many investigators are plotted, and they are scattered and indicate different values according to sand grain sizes. The field data contain the effect of wave directional dispersion, wave breaking, etc., so it is difficult to compare the theoretical coefficient with the field data.

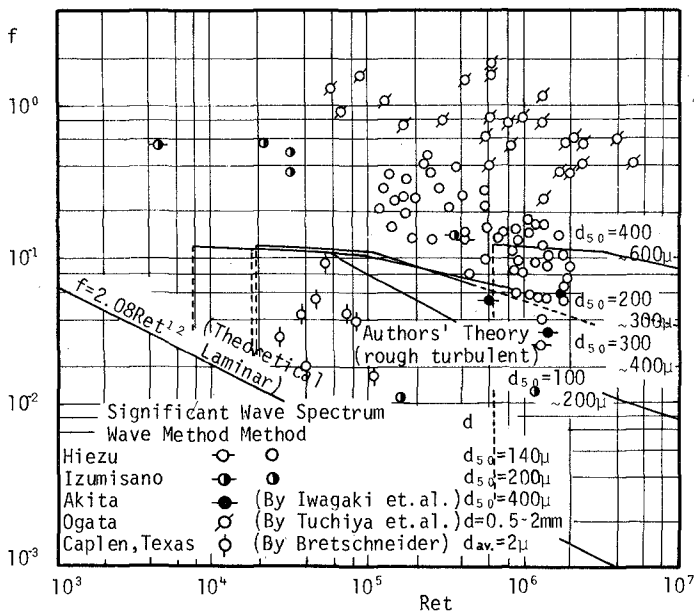

Fig. 4 Relations between f_{fix} and Re_T

3. VERIFICATION OF THE FRICTION COEFFICIENT BY THE EXPERIMENTAL ON THE MOVABLE BED

The friction coefficient of Eq.(II) is compared with the experimental values which were required by Zhukovets⁸⁾ from the wave deformation on horizontal movable bed in a laboratory. In this experiment, the wave height ranged from 3 to 18 cm, and the wave steepness varied from 0.1 to 0.04. As the bed material, the sand which the mean diameter of grain size is 0.25 mm was used.

The comparison of the experimental data within the range of rough turbulence with the theoretical coefficient is shown by Fig.5. In Fig.5, f_{exp} is the experimental friction coefficient and K_{sm} indicates the relative roughness of the bottom and is defined by Eq.(12). Re in this figure shows the Reynolds number which is given by Eq.(13).

Fig.5 Comparison of f_{fix} and f_{exp} .

$$K_{sm} = V_g^2 / \left\{ 2g d_{50} \sinh^4 \sqrt{1 + \eta / d_{50}} \right\} \quad (12)$$

$$Re = V_g H / \nu \sinh kh \quad (13)$$

where η is the height of sand ripple, and V_g is the velocity of water particle motion at bottom averaged over a quarter period of wave and is given by Eq.(14).

$$V_g = (\sigma H / \pi) \operatorname{cosech} kh + (3k\sigma H^2 / 8) \operatorname{cosech}^4 kh \quad (14)$$

where k is a wave number $k = 2\pi / L$, L is a wave length and H is a wave height.

Then, Re is transformed into Re_T by the following equation.

$$Re = \frac{V_g H}{\nu \sinh kh} \approx \frac{2}{\pi^2} \frac{U_b^2 T}{\nu} = 0.2 Re_T \quad (15)$$

From Fig.5, when K_{sm} is 0.75, f_{fix} has a fairly good agreement with f_{exp} , but when K_{sm} becomes larger, f_{fix} becomes larger than f_{exp} . The reason of this fact is not evident, but it is considered as follow; when K_{sm} becomes larger, V_g becomes large and the bed material seems to have a tendency of suspension. Generally, the friction in suspended state is less than the friction of non-suspended state, so the assumption of the fixed ripple model

for the theoretical friction coefficient is not able to apply for the case of large K_{sm} . Therefore, the theoretical friction coefficient f_{fix} has to be modified with regard to K_{sm} which indicates the characteristics of the movable bed. According to Fig.5, the ratio of f_{exp} to f_{fix} depends only on K_{sm} , and it is independent of the Reynolds number.

Now, the ratio is called a modification factor, F_c . The modification factor varies with K_{sm} as shown in Fig.6. Then, the theoretical friction coefficient for fixed ripple has to be modified into f_m by the modification factor F_c .

Fig.6 Change of the modification factor with K_{sm} .

The modified coefficient f_m is approximated by Eq.(16).

$$\left. \begin{aligned} K_{sm} &\leq 0.75 & f_m &= f_{fix} \\ K_{sm} &> 0.75 & f_m &= (0.75 / K_{sm}) f_{fix} \end{aligned} \right\} (16)$$

However, when K_{sm} becomes very large, f_m becomes smaller than the friction coefficient in case of laminar boundary layer, f_L , which is represented by Eq.(17).

$$f_L = 2.08 Re_T^{-1/2} \quad \text{for laminar boundary layer}^9) \quad (17)$$

In this case, f_m is assumed to be f_L for convenience.

4. EFFECT OF BOTTOM FRICTION TO WAVE DEFORMATION

The deformation of shallow water wave due to the bottom friction on a constant beach slope is calculated by the modified friction coefficient f_m .

In this calculation, Eq.(18) derived from the law of energy conservation is used.

$$H_{i+1} = \left(\frac{C_{g i}}{C_{g i+1}} H_i^2 - \frac{32 \Delta x}{3 \sqrt{g} C_{g i+1}} f_{mi} \sqrt{U_{bi}} \right) \quad (18)$$

where C_g is a group velocity of wave, the subscript "i" indicates the i-th step, and g is a gravity acceleration.

The calculation is started from the point where a relative water depth l and is stopped at the breaking point which was given by Kishi and Saeki as follows:

$$H_b / h_b = 5.68 S^{0.4} \quad (19)$$

where, S is a beach slope.

The calculation is carried out by the iterative method, that is, the authors evaluate the friction coefficient with the mean value of H_i and the assuming value of H_{i+1} . With the friction coefficient, the calculated value of H_{i+1} will be obtained by Eq.(18). The iteration is continued till the difference between the assuming value of H_{i+1} and the calculated value of H_{i+1} becomes small.

For the wave condition of wave period which equals to 4.0 sec, beach slope of 1/120 and 4 kinds of wave height at deep water, the deformation of wave height is obtained as shown in Fig.7.

Fig.7 Comparison of wave decay with various friction coefficient

In this figure, the full lines show the change of wave height by the authors' theory, the chain line is the result due to the laminar boundary layer theory and the dotted lines indicate the calculation results in case that the friction coefficient is 0.01. Furthermore, no friction curve, that is, the shoaling curve is drawn in this figure.

From these curves, it is found that the decay of wave height is considerably larger than the laminar case, and the decay curves indicate different tendency of the calculation results for $f=0.01$. According to the authors' theory, when the wave height becomes larger, the effect of bottom friction becomes smaller.

Fig. 8 shows the effect of wave period on the wave deformation due to the bottom friction under the condition that the wave height is 50 cm and the beach slope is $1/120$. From this figure, it is recognized that as the wave period becomes shorter, the wave decay becomes larger.

Fig. 9 shows the effect of beach slope upon the wave decay. From this figure, even if the wave condition at deep water is the same, as the beach slope is gentle, the degree of wave decay becomes larger.

Fig. 8 Effect of wave period for wave decay

Fig. 9 Effect of beach slope for wave decay

5. CONCLUSION

Considering the effect of sand ripple which is assumed to be fixed artificial ripple, the new formula on friction coefficient is proposed by using the boundary layer theory on turbulence. The proposed friction coefficients are compared with Zhukovets' experimental results which were performed on the movable bed in the laboratory. From the comparison, it is clarified that the proposed friction coefficient for sand ripple has to be modified by the modification factor for a movable bed, and the wave deformation due to the bottom friction on the movable bed is calculated by using the modified coefficient, f_m .

From the calculation, it is pointed out that the wave decay which is considered to be due to the effect of sand ripple under the turbulent condition, is considerably larger than one at laminar case and the wave decay curve indicates the different tendency from that in the friction coefficient $f=0.01$.

CHAPTER 35

PHYSICAL ASPECTS OF WAVE-INDUCED NEARSHORE CURRENT SYSTEM

By

Masaru Mizuguchi and Kiyoshi Horikawa

Coastal Engineering Laboratory
 Department of Civil Engineering
 University of Tokyo
 Bunkyo-ku, Tokyo
 JAPAN

INTRODUCTION

Since a theoretical approach on rip currents was made by Bowen (1969), our understandings on that system have progressed steadily.

It will be considered that the dynamics of current system are governed by the following equations which indicate the balance among the gradients of radiation stress and of mean water level, and the friction force induced by the current velocity:

$$\left. \begin{aligned} \frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{xy}}{\partial y} + \rho g(R+\zeta) \frac{\partial \zeta}{\partial x} + fU &= 0 \\ \frac{\partial S_{xy}}{\partial x} + \frac{\partial S_{yy}}{\partial y} + \rho g(R+\zeta) \frac{\partial \zeta}{\partial y} + fV &= 0 \end{aligned} \right\} (1)$$

Here radiation stresses such as S_{xx} are given by the local wave height H and wave ray direction θ . The terms ρ , g , ζ , h , and f denote fluid density, acceleration due to gravity, variation of mean water level above still water level, still water depth, and friction factor, respectively. U and V are components of current velocity which satisfy the following continuity equation:

$$\frac{\partial(Ud)}{\partial x} + \frac{\partial(Vd)}{\partial y} = 0 \quad (2)$$

where $d = h + \zeta$. To solve Eqs.(1) and (2), we need one more relation among the three terms stated above.

Hino (1974) treated this problem by the way of assuming that the wave height in a surf zone is proportional to the water depth as follows:

$$H = \sigma d \quad (3)$$

Iwata (1976) and Mizuguchi (1976) applied the following energy equation in order to close Eqs.(1) and (2):

$$\frac{\partial}{\partial x} \{ E(\bar{U} - c_g) \} + \frac{\partial}{\partial y} (E\bar{V}) + S_{xx} \frac{\partial \bar{U}}{\partial x} + S_{yy} \frac{\partial \bar{V}}{\partial y} = -D \quad (4)$$

where E , c_g , and D denote wave energy, group velocity, and dissipation, respectively. The axis of x is taken offshoreward, and the wave is assumed to come perpendicular to shoreline.

Another approach has been made to clarify the mechanics of rip current system. This is a way to give a wave height distribution or a radiation stress distribution by something came from the outside of the equation system.

Bowen and Inman (1969) and Harris (1967) suggested that generation of edge wave with the same period of incident waves could make a periodic longshore perturbation of wave height distribution. Sonu (1972) found the distinct correlation between the observed current system and bottom topography. While Noda (1974), Horikawa and Sasaki (1974), and others have tried to simulate the current field by using Eqs.(1) and (2) under the conditions of irregular wave height and ray angle field caused by refraction due to irregular bottom topography, and achieved success to calculate it at least in a qualitative sense. Recently Dalrymple (1975) tried to explain the current system from a view point of two intersecting synchronous waves.

These two kinds of approach to the rip current system suggest us the existence of the following two types of current system. The first one which corresponds to the former formulation can be called " the free type rip current system ", because there is no external force to generate the current system. Mathematically it would be formulated as an eigenvalue problem in spite of using either Eq.(3) or Eq.(4). The treatises by Hino, Iwata, and Mizuguchi are included in this category. But the wave height-depth assumption (Eq.(2)) is not verified well enough to go on forward along this assumption. While the energy coupling assumption (Eq.(4)) has also a deficiency of neglecting the first order dissipation term, which might be important on phenomena in a surf zone.

The second one which corresponds to the latter formulation can be called " the forced type rip current system ", because the external factor such as edge wave or irregular bottom topography plays a crucial part of generating the current system. This forced system is of a zero-th order current system caused by irregular radiation stress distribution in a wave breaking area and could be described enough by Eqs.(1) and (2) by using the radiation stress distribution which is externally given. Equation (4) would only contribute to modify the current system as treated by LeBlond and Tang (1974).

There are still some points which must be settled down in order to understand the dynamics of the rip current system. We have done some

laboratory experiments and observed a current system which is similar to that in the field [Sonu (1973)]. Analyzing and discussing the experimental results, we try to make some contribution to clarify the current system.

PRELIMINARY EXPERIMENTS

Experimental set-up and measuring technique are in the following:

- a. A fixed impermeable plane beach made of plywood was installed in a ripple wave tank, the size of which was 1.2m wide, 6m long and 0.15m deep. The selected slopes of beach were $1/20$, $1/10$, and $1/5$.
- b. The direction of incident waves was always perpendicular to the shoreline.
- c. The pattern of current system was observed by a video camera system in tracing the diffusion of dye which was poured into an uprush zone.
- d. Wave height distribution in the nearshore zone was obtained by using wave gages which were travelled parallel to the shoreline. Progressive pattern of wave crests was detected by viewing the video camera records.

We show in the following the experimental results in two cases which are the typical ones.

1. CASE 12 is the one where the wave steepness is not very large and the breaker zone is not very wide. In Fig.1 various curves cover the diffusion area by the current at the indicated time in second. Fine solid lines show a wave crest propagation pattern. Figures 1 and 2 give the following information:
 - 1) The wave crest pattern indicates that the wave propagation is delayed considerably in the region where offshoreward currents (hereafter written offshore currents) exist. We calculated roughly the distortion of the wave crest at the breaker line by using the measured velocity distribution in Fig.5. We get the values of 1.2cm for CASE 12 and 5.2cm for CASE 15 (which will be introduced in the following part) at the breaker line. These results agree well with the observed wave crest pattern.
 - 2) The results of wave height distribution measured in the nearshore area indicate that the wave reduces its height in the region of offshore currents. N

In addition to the above results, we observed that the breaking point in the the region of offshore currents had a tendency to approach the shoreline.

2. CASE 15 is the one where the width of breaker zone is relatively large. In this case the current system is divided into two parts; the first one is the circulation formed in the surf zone which we may call " a closed cell "; and the second one is the two branched feeder currents which join together and finally make an offshore current near the breaker line, thus we may call it " an open cell " (Fig.3). We will name this kind of the current system as a whole a double circulation system.

Another experimental result, which should be mentioned here, is that the beach slope is not important in the qualitative features of the current system except two points stated in the following, at least under the conditions of present experiments:

- 1) As the beach slope is gentler, the width of breaker zone becomes larger for the same condition of offshore waves.
- 2) In some cases for 1/5 beach slope, subharmonic resonant edge waves were clearly observed. The edge waves produced a dye diffusion pattern which is different from the others mentioned above as shown in Fig.4 [Horikawa and Mizuguchi (1975a)].

We calculate the offshore current velocity outside the breaker line by using the data of dye diffusion pattern. The results shown in Fig.5 tell us that the offshore current velocity has its maximum around the breaker line.

We measured the rip current spacing just outside the breaker line. In our experiments the spacings are mainly related to the period of incident waves. The results are plotted in Fig.6 where a solid line indicates the relation of $L_r = L_0$ (L_0 is deepwater wave length).

DISCUSSION: PART 1

As mentioned in Introduction, the senior author has developed a theory to treat the rip current system as an eigenvalue problem, where the wave-current interaction was taken into consideration in the equations of wave and energy conservation. The theory is also confined to the cases of relatively steep slope beach, because the long wave approximation is used all over the concerned area. When we neglect a relevant dissipation term in energy equation (Eq.(4)), an eigenvalue problem is formulated to determine the rip current spacing. This problem can be solved by assuming the bottom friction factor in the surf zone as a power of coordinate taking from the shoreline to offshore.

The theory predicts that the first order perturbation of wave energy has exactly the same alongshore phase as the offshore current perturbation. It means that the wave height in the region of offshore current is greater than that in the remained area. This prediction is completely opposite to our experimental result. From this fact we conclude that the observed current system cannot be explained by the theory in which the wave-current energy interaction is considered to be essential.

On the other hand we (1975) described that one possible explanation for the observed current system stated above is to attribute the origin of such current system to the incident wave itself. If we can assume that free oscillations in a uniform depth area of the wave basin would affect the wave height perturbation at the breaker line, the observed fact will be well explained. Horikawa and Maruyama (1976) found that in a rectangular wave basin resonant synchronous cross waves can occur, and pointed out that the

Fig. 3. Wave crest propagation and dye diffusion pattern.

Fig.4. Dye diffusion pattern by subharmonic edge wave.

Fig.5. Offshore current velocity profile of rip currents.

Fig.6. Measured spacings of rip currents.

cross waves generate a wave height perturbation around the breaker line. The wave basin used by them is the same as that we used.

In our experimental set-up with a sloping beach, wave records indicate simple harmonic and steady oscillations at every measuring point. Therefore we interpreted the "cross wave" as follows:

1. The wave maker might generate a little irregular wave component which does travel obliquely to the paddle of wave maker as denoted k_c in Fig.7.
2. Then the side walls select the component wave which satisfies the following boundary condition along the walls:

$$N\pi/R_y = \theta \quad (5)$$

where N is a mode number and not greater than kb/π .

3. The selected component travels across the wave basin, reflects at the side walls and finally makes a wave height distribution in the vicinity of the wave breaking area.

When the cross wave is superposed upon the incident waves, the following wave height distribution appears in the basin:

$$a \sim a_i + 2a_{cN} \cos\left(\frac{N\pi y}{B}\right) \cos\left(\int^x (k_r - k_x) dx'\right) \quad (6)$$

where a_i and a_{cN} are amplitudes of incident wave and of cross wave respectively. A noteworthy characteristic of the cross wave is that the alongshore wave number does not change with refraction.

Considering the fact that the offshore current is always located at the place of lower wave height, we have Fig.8 in which the possible rip current spacings in our experiments are shown. This figure is not in contradiction to the experimental results shown in Fig.6. Reminding the fact that almost every point in Fig.6 is scattering around the relation $L_r = L_0$, we are able to assume that the predominant cross wave is the one that has the largest number of mode in y -direction. Therefore, we can conclude that the phenomena in our experiments show one example of the forced current system, where the cross wave plays an important role to provide an externally given condition.

SECOND SERIES OF EXPERIMENTS (DETAILED OBSERVATIONS)

Based on the above discussions we conducted another series of experiments, paying much attention to the wave height distribution all over the wave basin. Experimental set-up and measuring technique are almost the same as the first series of experiments. We used, this time, static pressure tubes to measure the mean water level in a surf zone, and a wave gage to measure the run-up height distribution.

We selected the following three cases under the condition of the beach slope $1/10$ only as shown in Table 1. There d , T , H_i , H_0 , and X_B denote

Fig.7. Schematic illustration of " cross wave ".

Fig.8. Possible spacings of rip currents by " cross wave ".

Fig.9. Wave height distribution parallel and perpendicular to the wave maker in uniform depth area (CASE 22B).

water depth in a uniform depth area, period of wave maker, wave height in a uniform depth area, deep water wave height, and width of breaker zone, respectively.

Table 1 Experimental conditions.

CASE	d	T	H_i	H_0/L_0	X_B
22B	11.5cm	0.586sec	1.36cm	2.7%	13cm
26B(=27A)	12.0	0.726	1.70	2.3	12
27B	12.0	0.720	2.60	3.5	21

First we will check the existence of the cross wave in the following:

CASE 22B

Figure 9 shows the wave height distribution at the section of $x = 246\text{cm}$ in the uniform depth area. Resonant oscillations in y -direction exist as shown in Fig.9. Calculating the Fourier components, we get H_i ($i=0-4$) = 1.36, -0.10, 0.28, -0.07, 0.29 cm respectively. Although we can expect the existence of oscillations with mode number $N = 2$ and 4, we consider only $N = 4$. The reason is as follows. Figure 9, also, shows the wave height distribution along the section of $y = 107.0\text{cm}$, and Fig.10 shows that at the section of $y = 0$ for $N = 2$ and 4. These two figures indicate that $N = 2$ is not very important in our experiments.

From the above result shown in Fig.9 we will simulate the wave height distribution by the following equation, where $N = 2$ is neglected and the phase difference in front of wave maker is assumed to be 0 or π .

$$H = 1.36 - 0.30 \cos\left(\frac{4\pi y}{8}\right) \cos\left\{\frac{2\pi}{113}(x-417)\right\} \quad (7)$$

Solid lines in Fig.9 give the curves of the above equation.

CASE 26B AND 27B

Following almost the same procedure as in CASE 22B, we get the next equations to express the wave height distribution in a uniform depth area for CASE 26B and 27B respectively.

$$\left. \begin{aligned} H &= 1.70 + 0.60 \cos\left(\frac{2\pi y}{8}\right) \cos\left\{\frac{2\pi}{395}(x-295)\right\} \\ H &= 2.60 + 0.54 \cos\left(\frac{2\pi y}{8}\right) \cos\left\{\frac{2\pi}{401}(x-270)\right\} \\ &\quad + 0.48 \cos\left(\frac{3\pi y}{8}\right) \cos\left\{\frac{2\pi}{152}(x-270)\right\} \end{aligned} \right\} \quad (8)$$

In these cases a screen was inserted in a uniform depth area in order to diffract the incident waves and to get a stable state of the current system. As a result, phase relations between the incident wave and the cross wave are different from that in CASE 22B. Figures 11 and 12 show that these

Fig. 10. Calculated wave height undulation along sidewall (CASE 22B);
 with shoaling.

Fig. 11. Wave height distribution in uniform depth area (CASE 26B).

Fig. 12. Wave height distribution in uniform depth area (CASE 27B).

equations can explain well the measured wave height distribution.

From the foregoing figures we can conclude that there exist the cross waves and the assumption on the possible alongshore wave number is supported in CASE 22B and 27B, but not in CASE 26B. It is easy to calculate how the above wave height distribution gives its influences on the phenomena in the wave breaking zone. Snell's law tells us that the wave number of the cross wave in y -direction does not change with refraction. Each wave component makes its refraction process independently so far as the linear wave theory is valid.

One of the purposes of the present experiments is to find out the way how to describe the questioned current system which is now clearly classified into the forced type. We measured in detail the wave height distribution, current and wave crest patterns, and mean water level in a surf zone. In the following, three cases will be taken as representative ones.

CASE 22B

Figure 13 shows the current and wave crest pattern recorded by a video camera system. The area bounded by a hatched line shows the region where the poured dye is remained for a long time. Therefore it indicates the location of a closed cell. This pattern gives the same features as the double-circulation type mentioned previously. While Fig.14 shows the wave height distribution in the surf zone in a three dimensional space. The solid smooth line is the predicted curve of the wave height distribution at the section of $x = -1.5\text{cm}$ based on the offshore wave condition. It agrees well with the experimental result at least in a qualitative sense.

Here we will split the surf zone into two parts; the inner area and the outer area. They are divided by the line where the alongshore wave height perturbation disappears. In this case the line was located at $x = 4.0\text{cm}$. In the outer area offshore currents flow out through the region of lower wave height which is predicted by numerical calculations using the wave conditions in the uniform depth area. In the inner area offshore currents flow out also through the region of lower wave height. But the spacing between them is a half of the spacing in the outer area. Alongshore distribution of run-up measured by the wave gage as well as that given in video records show the same periodicity as the offshore current in the inner area. The region where the run-up height is relatively small corresponds to the place where the offshore current starts. Figure 15 shows the wave height distribution along the section of $y = \text{const.}$ in the surf zone. This result confirms also the above observation on the relationship between current and wave height distribution.

The measured static pressure distribution is shown in Fig.16. It is our regret to say that the data are not so accurate that anything decisive cannot be concluded. This is because the set-down and set-up are very small in our experiments, hence our hand-made apparatus was not very delicate to detect them.

CASE 26B (=27A)

In this case we made longer the period of wave maker, keeping the wave steepness almost the same as the former one (CASE 22B).

Fig.13. Wave crest propagation and dye diffusion pattern (CASE 22B).

Fig.14. Wave height distribution in surf zone (CASE 22B).

Fig.15. Wave height decreasing in surf zone (CASE 22B).

Fig.16. Mean water level variation in surf zone (CASE 22B).

Fig.18. Mean water level variation in surf zone (CASE 26B).

Fig.17. Wave height distribution in surf zone (CASE 26B).

Fig.19. Wave crest propagation and dye diffusion pattern (CASE 26B).

Fig.20. Wave crest propagation and dye diffusion pattern (CASE 27B).

Fig.21. Wave height distribution in surf zone (CASE 27B).

Fig.22. Mean water level variation in surf zone (CASE 27B).

The wave height distribution in this case is shown in Fig.17. Again the smooth solid line in this figure indicates the predicted curve. The measured wave height distribution is different from the predicted one especially near the side walls. The observed current pattern in Fig.19 corresponds well with the measured wave height distribution. The higher wave height region near the wall might be caused partially by the existence of side walls and partially by the wave-current interaction. Another features are the same as that in CASE 22B.

Again in Fig.18 are shown the measured static pressure distributions along the section of $x = \text{const.}$; one is in the inner area and the other in the outer area.

CASE 27B

In this case we made larger the amplitude of wave maker. Experimental results are seen in Figs.20, 21, and 22. New particular feature is that the diffusion pattern induced by the offshore current has a tendency to stay around the breaker line for a while. Therefore the outer area seems to disappear.

Now we have to draw a conclusion about the mean water level. We think that the alongshore variation of mean water level is not so large as that we expect from the measured wave height perturbation based on the wave height-depth assumption.

DISCUSSION: PART 2

Considering the results of the present experiments, we will discuss in the following how the current system can be generated and what kinds of equations can describe its phenomena.

We may say as follows:

- 1) In the surf zone the wave height distribution given externally would produce the radiation stress distribution, where the assumption $S_{xx} = 3/2E$ etc. and $E = 1/2\rho g a^2$ are considered to be still valid. At this stage, Bowen's formulation

$$H = \gamma d (1 + \epsilon \cos \lambda y) \quad (9)$$

would be a proper choice as a first step of approach. This expression is one of the simplest forms which gives an analytical solution and also seems to be a good approximation to the present problem if the wave-current interaction could be neglected as in CASE 12 of the first series of experiments. Outside the breaker line the offshore current velocity decreases monotonically. Therefore it might be reasonable to neglect the radiation stress in the outer area.

- 2) Continuity and momentum equations can be solved. The solution should give both the current field and the mean water level. Momentum equation

(Eq.(1)) may be rewritten as follows:

$$\frac{\partial \xi}{\partial x} \sim - \frac{fU}{fgR} - \frac{1}{fgR} \frac{\partial \delta \xi}{\partial x} \quad (10)$$

so that the currents have a tendency to reduce alongshore variation of mean water level in a surf zone. This fact does not disagree with the above experimental results.

- 3) Then the experimental results show that the wave-current interaction should be taken into consideration, especially in the case that the surf zone is wide enough to generate the double circulation pattern. The wave-current interaction has the following two aspects. One is the wave number interaction which distorts the wave crest line, and the other is the energy coupling which contributes to modify the wave height distribution.

In the outer area, the second one plays an important role to modify the wave height perturbation, as seen in the second series of experiments. The energy coupling contributes finally to weaken the offshore current velocity.

The first one holds a key to generate the double circulation system. The wave crest distortion in the inner area means the alongshore variation of the wave ray direction. As a result the wave in the inner area will refract and make a wave height distribution field as shown in Fig.23, where H and L denote a high and low wave region respectively. Thus the double circulation system could be generated.

Fig.23. Schematic illustration of a double circulation system.

It is a future problem to formulate the above processes mathematically and to solve and discuss the problem quantitatively

COMMENT ON FIELD OBSERVATIONS

Several papers on the field observations of nearshore current system have been published by Bowen and Inman (1969), Harris (1967), Sonu (1972), Sasaki and Horikawa (1975), Sunamura and Horikawa (1976), Sasaki, Horikawa and Hotta (1976), and others.

The field observations were usually done when the wave condition was not so severe that the change of bottom topography was not rapid even in the surf zone. Moreover wave conditions at the breaker line depend on the bottom topography outside the breaker line, where its change must be very slow and scarce. Therefore we can say that the observed current systems were mainly determined by the bottom topography at least temporarily. Sunamura and Horikawa (1976) reported a case where a distribution of exposed bed rocks near the shoreline determines a current system in that region. The current is very steady in spite of various wave conditions for a long period of time. On the other hand the current system is well simulated by using the refraction method, continuity equation and momentum equation. These facts assure the above idea.

When waves refract both inside and outside of the breaker line, they diverge at depressions and converge at shoals. The high wave region corresponds to the shoals. Applying Bowen's theory, we get outflows at depressions as usually observed.

There are several other explanations. Liu and Mei (1974) calculated radiation stress distribution caused by waves under refraction, and reflection and diffraction at a breakwater. They also calculate a nearshore current pattern as a result. Their idea is essentially the same as the synchronous intersecting wave of Dalrymple (1975). The observed current system in our experiments can be essentially the same kind of them. There is a limitation to apply their idea to the field problem, because monochromatic waves only can make a steady radiation stress distribution.

So far as edge wave is concerned, it creates a very weak current field both in our laboratory experiment (1975a) and that by Bowen and Inman (1969). The current field is completely different from the so-called rip current. Guza and Davis (1974) verified that subharmonic edge wave of Stokes mode is most easily excited under the condition of a standing incident wave. That kinds of edge waves have such a short characteristic length in offshoreward direction that their influence is confined to a region near shoreline.

Hino (1974) energetically approached to this rip current problem by treating it as a time-dependent self generating system on a movable beach. As we stated above, we think that any data obtained so far may not be relevant to compare with his treatment and that the wave height-depth assumption (Eq.(3)) seems to be incorrect.

Sasaki (1974) presented a hypothesis that " infragravity wave " is an essential factor to control the current system on a gently sloping beach through the bottom perturbation. As a result of the present discussion, it will be suggested to consider that the infragravity wave only modifies the current system which is temporarily controlled by bottom topography. For example the infragravity wave may be related to a pulsation of rip current. The bottom perturbation might be caused by the infragravity wave in a long term.

Finally, there must arise a question how an irregular bottom topography could be formed. We consider at present that the answer could be found in the free type rip current system. But it is still an open question what kinds of equations should be applied.

CONCLUSIONS

The wave-induced nearshore current system can be classified into two types; free type and forced type. In our laboratory experiment, we observed a kind of forced current system which is created by a periodic breaking wave height distribution caused by " cross wave ". Offshoreward currents always flow through the lower wave height region both inside and outside of a breaker line. When the surf zone was rather wide, we observed a double circulation pattern, where wave-current interaction might be important.

According to our experimental results, we propose to consider that the observed current system in fields should be interpreted as the forced type current system where irregular bottom topography plays a crucial part.

CHAPTER 36

NEARSHORE CURRENT ON A GENTLY SLOPING BEACH

By

Tamio Sasaki*, Kiyoshi Horikawa** and Shintaro Hotta***

ABSTRACT

The authors developed a new field observation system called STEREO-BACS by which simultaneous measurements of a spacial distribution on waves and currents in the nearshore environment can be obtained. This system was applied on Ajigaura Beach, Japan, and several analyzed results are presented. Also field observations of infragravity low mode edge waves to support the Infragravity Domain Hypothesis on nearshore currents concerning a gently sloping beach [Sasaki(1974,1975), Sasaki and Horikawa (1975)] are introduced.

INTRODUCTION

Extensive studies on nearshore currents have been made over the last several years. As a result, numerous theories on nearshore currents especially on rip current generation have been proposed by Bowen (1967), Bowen and Inman(1969), Sonu(1972), Noda(1972), Hino(1973), Hashimoto and Uda(1974), Noda et al.(1974), Sasaki(1974,1975), Sasaki and Horikawa(1975), Liu and Mei(1974,1976), Birkemeier and Dalrymple(1975), Dalrymple(1975), Iwata (1976), Mizuguchi (1976), Mizuguchi and Horikawa(1976), Horikawa and Maruyama(1976).

However, the validity of these theories have been not clarified in detail due to the lack of precise field data[Sasaki and Horikawa(1975)]. The major difficulties in observing nearshore currents are due to 1) the spatial distribution of their phenomena, 2) multiplicity of affecting factors involved, 3) rough waves and currents in the surf zone, and 4) time dependency. To overcome these difficulties, the authors have been making numerous efforts over the last 6 years.

The best solution conceivable for overcoming these obstacles is to apply the principle of photogrammetry by using a pair of helicopters and/or blimps to secure observation platforms in the air. The authors have once tried utilizing a pair of helicopters called SIHELs [Fig. 1,

Fig. 1 Schematic diagram of SIHELs. Fig. 2 Schematic diagram of BACS.
(Horikawa and Sasaki, 1972) (Horikawa and Sasaki, 1972)

Simultaneous HELicopter System, Horikawa and Sasaki(1972)], and realized that the obtained accuracy in mapping the wave height distribution was very satisfactory. However the cost was prohibitive, so that this system could only be utilized one time.

In place of the SIHELs, the authors developed a balloon borne camera system called BACS [Fig. 2, Horikawa and Sasaki(1972)]. By this system, the spatial flow field can be easily obtained by tracing floats in successive pictures [Sasaki(1974,1975), Sasaki and Horikawa(1975)]. This system is a very simple and convenient one, however, the wave height field cannot be obtained due to the fact that only a single balloon is used.

Last year, the authors further developed a new system, which consists of a pair of balloons called STEREO-BACS. The aim of this system is to achieve simultaneous measurements of spatial distributions of nearshore waves and currents over a relatively broad area.

In the present paper, the authors first introduce this new system, secondly present an outline of the results obtained from observations made in December, 1976 on Ajigaura Beach, Japan, and lastly show several results to support the Infragravity Domain Hypothesis on a gently sloping beach.

STEREO-BACS

An idea of STEREO-BACS appeared in 1893 by C. B. Adams for terrestrial mapping[Thompson(1966)]. For the application of this idea to unsteady phenomena in the surf zone, the development of a motor-driven camera is required.

Sonu(1969) utilized a Nikon motor-driven camera(35mm) for the study of nearshore current patterns and mixing [Sonu(1972a,1976)]. The Hasselblad 500EL motor-driven camera(70mm) was applied for the first time by Horikawa and Sasaki(1972) to obtain further accuracy in mapping the quantitative flow field in the surf zone.

Figure 3 shows a schematic representation of the STEREO-BACS. Two balloons are lifted about 150 m apart at an altitude of around 300 m. The volume of helium gas necessary to fill a balloon is 33 m³. The effective buoyancy is about 25 kg without tethers or a camera capsule. Two cameras are triggered simultaneously by a radio transmitter. A super-wide angle lens, Zeiss Distagon 40 mm, has been adopted to take wide coverage. About 30 to 50 floats are introduced around the surf zone by divers and from a pier. The floats are made of polyurethane foam coated by red or orange coloured polyvinyl-chloride sheet and equipped with a drogue.

Fig. 3 Schematic diagram of STEREO-BACS.

The pier was 100 m long (presently extended to 200 m), and was constructed by the Public Works Research Institute, Ministry of Construction for research use. Piers play an essential role in operating the STEREO-BACS. Most importantly, they act as a target for absolute orientation of the stereoscopic pairs in onshore-offshore direction. A second role is to secure a foothold for distributing many floats into the surf zone. And a third role is to give a stay for mooring balloons under onshore wind or windless conditions. Two tethers are employed, and the camera is suspended by a single rope from the balloon.

DESCRIPTION OF THE SITE OBSERVED

Field observations by this system were made on Ajigaura Beach. This beach is located 100 km northward from Tokyo and faces the Pacific Ocean (Fig. 4). About 1 km south of the pier, the beach is bounded by a headland. Figure 5 is an overview of the pier. Several rip currents can be seen in this picture.

Fig. 4 Location map of Ajigaura Beach.

Fig. 5 Overview of Ajigaura Beach.

The beach slope is $1/40$ to $1/70$, and classified as a gentle beach. Strictly speaking, this beach is in Infragravity Domain[Sasaki(1975)] under a relatively rough sea, while under a calm sea it is in Instability Domain.

FIELD OBSERVATION USING THE STEREO-BACS

Wave Climate

Simultaneous measurements of a spatial distribution on waves including infragravity waves, currents, and mean water surface using the STEREO-BACS were carried out in December, 1975.

Figure 6 is a mosaicked picture made from the stereoscopic pairs obtained on December 18, 1975. Because two cameras were used, the long-shore coverage of this picture became very wide compared to that using a single camera (BACS). It is estimated at about 400 m by comparing with the 100 m long pier.

The breaker height and period were around 1.2 m and 13 sec respectively. The wave direction was 2 degrees shifted leftward at the tip of the pier. It was almost windless, and the wave climate was classified as very calm for this coastal region.

Velocity Field

Figure 7 shows the velocity vector field obtained during a quarter

Fig. 6 An example of pictures taken by the STEREO-BACS (December, 1975).

Fig. 7 Velocity vector field (December, 1975).

hour observation. The thick dotted line indicates a significant breaker line, and the thick arrows indicate velocity vectors exceeding 30 cm/sec. The vectors were compiled from interpreting the position of each float in successive pictures taken every 15 sec. Alongshore coverage for the velocity distribution was somewhat limited about 300 m due to the small number of divers in the surf zone available for introducing floats.

On the lefthand side of the pier, a rip current flows out with a maximum velocity exceeding 70 cm/sec. Only one float could overcome the attack of the incoming waves and was able to leave from the surf zone. On the righthand side of the pier, an inflow of offshore water can be seen. This was the first time we were able to catch an entire circulation process of this kind. This is simply due to the combination of the higher altitude of the balloons lifted and the utilization of a pair of balloons. The longshore dimension of the cell was about 200 m.

Figure 8 shows a current speed contour map derived from Fig. 7. By tracing the 40 cm/sec contour line, the shape of the current can be seen vividly. On the shoal located on the righthand side, the inflow is separated into right and left directions. And on the lefthand side, two longshore currents from opposite directions meet to form the rip current at around one half of the surf zone width from the shoreline.

The maximum velocity of the longshore current across the surf zone takes place very close to the shoreline. This fact does not agree with the result based on the theory of Longuet-Higgins (1970) for a plane beach, in which the lateral mixing parameter, P , generally takes a value between 0.1 and 0.4, derived from laboratory data, as pointed out by Sasaki and Horikawa (1975).

Transport Stream Function

Figure 9 is the transport stream function [Arthur (1962)] derived from the longshore component of the observed velocities. The maximum discharge exceeds $20 \text{ m}^3/\text{sec}$.

Figure 10 is a simulated transport stream line using the numerical model originally developed by Noda (1972). However, the treatment of bottom friction was modified with Jonsson's (1966) wave friction factors in the present computation. The roughness length for the bottom was calibrated by the observed velocity field [Sasaki (1975)]. The general current pattern and velocity agree well with observations except near the rip current. The disagreement in the vicinity of the rip current may be the result of the neglect of a lateral mixing and a convective term.

Wave Height Field

Figure 11 shows the maximum wave crest height distribution corresponding to a wave height field. This was made from 5 different instantaneous stereoscopic pairs of water surface configurations. For this, the Hasselblad 500EL motor driven camera, instead of a photogrammetric one, was used, so that the expected accuracy in this mapping might not be so high. However, the characteristic features of the wave height distribution is considered to be significant.

Fig. 8 Current speed contour (December, 1975).

Fig. 9 Observed transport stream function (December, 1975).

Fig. 10 Simulated transport stream function.

On both sides of the rip current, the maximum wave height appears, and on the lee side of the rip current, wave breaking takes place very close to the shoreline. The main stream of the circulation selects its path where the wave height is lower in the surf zone. A similar phenomena was also observed in the laboratory at the University of Tokyo [Mizuguchi and Horikawa (1976)].

Mean Water Surface

Figure 12 shows a simulated mean water surface elevation of a wave set-up and set-down. The maximum set-up is about 20 cm on a shoal, and the maximum set-down is about 5 cm at the intersection between the breaker line and the rip current. The maximum water surface gradients are seen at a root of the rip current, and are estimated to be approximately $1/200$.

Figure 13 is the mean water surface observed by using the hydraulic filter originally designed by Sonu (1972a). The maximum difference of the water surface elevation is 40 cm, and the maximum water surface arises on a shoal. The longshore current flows from high to low zone like a river. The longshore gradient of the surface is about $1/350$ that is fairly larger than simulated value of $1/200$. Remarkable difference between observed and simulated in water surface distribution is the location where the maximum set-up appears. In the field data, maximum appears somewhat apart from the

Fig. 11 Observed maximum wave crest height distribution (December, 1975)

shoreline. One of the explanations for this is due to the effect of a percolation in the swash zone.

Estimate of a Convective Term

Noda(1972) and Noda et al.(1974) neglected convective terms in simulating the nearshore current. Based on the above field data, the authors tried to estimate the relative significance of a pressure term with a convective term in the equations of motion. The magnitude of each terms are estimated at every 10 m grid point. Figure 14 shows a comparison of longshore terms(y-axis). Upper diagram is the pressure term, and the lower is the convective term. Near the rip current, convective terms have the magnitudes of 1/3 to 1/5 of the pressure terms. Whereas in the other area, pressure terms have 20 to 30 times larger than convective terms. Therefore, it can be said that near the rip current convective terms may be effective in this case.

FIELD OBSERVATION OF INFRAGRAVITY LOW MODE EDGE WAVES

Infragravity Domain

As for the spacing of rip currents, two theories have been presented [Bowen and Inman(1969) and Hino(1973)]. However, there is some confusion concerning their applicability for the actual phenomena[Sonu(1972b)].

Sasaki(1974,1975) found the existence of three domains on nearshore currents by applying the Iribarren No., I_r , [surf similarity parameter, Battjes (1974)] and the concept of infragravity waves[Suhayda(1974)] and clarified that the previous two theories can only be applied to two of the

Fig. 12 Simulated mean water surface elevation.

three domains for steep and medium beaches, respectively. For the additional domain, an Infragravity Domain Hypothesis has been proposed for a gently sloping beach [Sasaki(1974, 1975) and, Sasaki and Horikawa(1975)].

Here, the authors review this Hypothesis briefly, and show several observational results to support this. Figure 15 illustrates the concept of the three domains on nearshore currents. The top shows the Infragravity Domain [Sasaki(1974,1975)], the middle is the Instability Domain [Hino (1973)], and the bottom is the Edge Wave Domain [Bowen and Inman(1969)]. These three domains correspond to gentle, medium, and steep beaches, respectively. As shown in Fig. 15, it is easy to understand the concept of

these domains using the number of waves in the surf zone [Battjes(1974)].

The Edge Wave Domain arises when the number of waves in the surf zone is less than 1, and has surging/collapsing or plunging breakers. This domain includes "the reflective system" [Guza and Inman(1975)]. The Instability Domain has 1 to 3 waves in the surf zone, and plunging or spilling breakers. On the contrary, the Infragravity Domain has more than 3 waves in the surf zone, and always has spilling breakers. This domain typically appears when relatively steep waves attack a gently sloping beach. For this domain, Sasaki (1974,1975) presented the next equation for the spacing of rip currents;

$$Y_r^* = 157 I_r^2 \quad (1)$$

where, Y_r^* is a nondimensional spacing of rip currents defined by Eq.(2);

$$Y_r^* = Y_r / X_b \quad (2)$$

I_r is the Iribarren No. [Battjes(1974)] defined by Eq.(3);

$$I_r = \tan\beta / (H/L)_o^{1/2} \quad (3)$$

In Eqs. (2) and (3), Y_r , X_b , $\tan\beta$, H , and L are spacing of rip currents, width of the surf zone, beach slope, wave height, and wave period, respectively. Subscript, o , denotes the value in deep water.

Figure 16 shows the relationship between Y_r^* and I_r for all three domains. The theory of Bowen and Inman corresponds for large values of I_r ($I_r > 1$), and Hino's theory can well be applied for medium values of I_r ($1 > I_r > 0.23$). In the Infragravity Domain ($0.23 > I_r$), Eq.(1) suggests the presence of low mode infragravity edge waves with significant amplitudes. Gravity waves having periods less than 20 sec have negligible reflection from the beach in this domain, while infragravity waves have fairly large reflectivity. So infragravity edge waves can be generated and are able to control nearshore circulation through bottom perturbation. Because the data on infragravity waves are very few, the authors have been trying to detect these waves on numerous occasions.

Fig. 15 Concept of three domains. (Sasaki, 1974)

Fig. 16 Y_r^* and I_r (Sasaki, 1974).

Infragravity Low Mode Edge Waves

Figure 17 shows an example of infragravity wave spectrum in the surf zone observed in March, 1976 on Ajigaura Beach. The breaker height at that time was around 3 m. As the width of the surf zone was very wide over 300 m, the 6 wave staffs which were used were all placed in the surf zone. The water surface fluctuations were measured by using 16 mm memomotion cine-cameras.

These three spectra show the results from offshore arrangement of sensors along a pier. There are two dominant peaks. The right peak shows an incident wave peak of 13 sec. The other one is an infragravity wave peak of around 50 sec. In the swash zone(C), the gravity wave peak disappears, and only the infragravity wave peak can be seen. The result of a cross-spectrum analysis by BMD-02T reveals the existence of a nodal line parallel to the shore between B and C sensors.

Figure 18 shows the results from a longshore arrangement of sensors at the same time. In this case, 4 alongshore sensors were located close to the shoreline, so the gravity wave peaks are lower than infragravity wave peaks. The energy levels are somewhat larger than those offshore, and a secondary low frequency peak is found at around 2 min wave period. In each of 6 spectra, the wave height of the infragravity waves is 40 cm to 60 cm.

Fig. 17 On-offshore infragravity wave spectrum (March, 1976).

Fig. 18 Longshore infragravity wave spectrum (March, 1976).

An offshore profile of a relative wave height is shown in Fig. 19. The thick solid curve indicates the infragravity low mode edge waves [Eckart (1951)] with an offshore modal number, $n = 1$. Similar result was obtained also on December 18, 1975 (Fig. 20) when the STEREO-BACS was carried out. The short length of the pier prevented us from detecting a perfect envelope of a wave height profile. The case in which a nodal line perpendicular to the shoreline was observed has been reported by Sasaki and Horikawa (1975).

It is very difficult to measure the perfect configuration of edge waves in the field, because numerous wave sensors or flow meters are required to detect it. However, most of our observations carried out on a gently sloping beach show an existence of low mode ($n = 1$ and/or 2) edge waves with infragravity wave frequencies.

Similar results have been shown by Inman and Guza (1976) on the Scripps Beach behind the La Jolla Canyon, and their periods were 70 to 80 sec. Guza and Bowen (1975) and Guza and Inman (1975) introduced Gallagher's (1971) work on surf beat generation; that is incident gravity wave frequency and directional spectra allow infragravity edge wave (30 to 150 sec) excitation through the interaction of different gravity wave components. As for the

Fig. 19 Infragravity low mode edge wave profile (March,1976).

Fig. 20 Infragravity low mode edge wave profile (Dec.,1975).

cause by nonlinear interactions through different wave frequencies, Yoshida (1950) also derived the generation of 1 to 3 min infragravity waves. As pointed out by Isaacs et al.(1951), surf beats might be, in fact, infragravity low mode edge waves, if some condition [Carrier and Greenspan (1958)] that can be also expressed by Iribarren No. I_r , is satisfied.

Regarding amplitudes of infragravity waves (surf beats), with those periods larger than 20 sec, Goda(1975) has shown several observational results in the surf zone, and revealed that the amplitude of infragravity waves may amount to 40 % of that of offshore waves. This value of 40 % is fairly large compared to that of Tucker(1950) obtained outside the surf zone. This difference may be due to the infragravity edge wave resonances in the surf zone.

The above mentioned several works on infragravity waves, though not fully organized, suggest the validity of the Infragravity Domain Hypothesis, however, further research is needed concerning precise coupling mechanism between nearshore currents, infragravity waves and nearshore topographies on a gently sloping beach.

SUMMARY AND CONCLUSION

1) The authors developed a new field observation system called STEREO-BACS based on a principle of stereophotogrammetry by which simultaneous measurements of a spatial distribution on waves and currents in the near-shore zone can be obtained. Also a broader coverage is achieved compared to the previous system [BACS, Horikawa and Sasaki(1972)].

2) The STEREO-BACS was applied on Ajigaura Beach, Japan, facing the

Pacific Ocean in December, 1975, and observations including infragravity waves and mean water surface elevations were carried out. In this observation, the authors succeeded in catching an entire process of one circulation for the first time.

3) The obtained wave height distribution in the surf zone shows that the rip current flows out at the location where the breaker height is minimum on the breaker line, and the main stream of nearshore currents selects its path where the wave height is lower in the surf zone.

4) Concerning a mean water surface elevation, it is observed that the maximum difference in water surface reached about 40 cm, and longshore currents flow like a river in the surf zone.

5) Based on the above observation, an estimate of a relative significance of a pressure term with a convective term could be made quantitatively, and it was found that the convective term has a magnitude of from 1/3 to 1/5 of the pressure term near the rip current.

6) Our numerous field observations, Goda's(1975) observation, and Gallagher's(1971) work on infragravity waves suggest the existence of infragravity low mode edge waves with significant amplitudes which can cause nearshore circulations through bottom perturbation, and thus support the Infragravity Domain Hypothesis on a gently sloping beach [Sasaki(1974,1975), Sasaki and Horikawa (1975)]. The typical periods of infragravity waves observed are around 1 min.

ACKNOWLEDGEMENTS

The field observations on Ajigaura Beach were financially supported in part by the Public Works Research Institute(PWRI), Ministry of Construction under contract with INA Civil Engineering Consulting Co., Ltd. and partly by the Science Research Fund of the Ministry of Education under the name of second author.

The authors acknowledge the permission given by the PWRI for reproduction of the data and figures concerning the observations on Ajigaura Beach. Without the efforts made by Mr. Hiroshi Hashimoto, Chief of the Coastal Engineering Laboratory at the PWRI to construct and to maintain the Ajigaura Pier, the present research could not have been achieved. The advice in mapping the wave height field kindly given by Dr. Sohtaro Tanaka at the Remote Sensing Technology Center is also acknowledged. The authors are indebted to Dr. Billy L. Edge, Associate Professor, Clemson University, and Dr. Yoshimi Goda, Chief of the Wave Dynamics Laboratory, the Port and Harbor Research Institute, Ministry of Transport, for their kind communications of the literature on edge waves [Edge(1975)] and surf beats [Goda (1975)]. Mr. Hiroshi Sakuramoto and Mr. Susumu Kubota, INA Civil Engineering Consulting Co., Ltd., carried out the essential work in operating the field work, computations and drawings.

CHAPTER 37

LATERAL AND BOTTOM FORCES ON LONGSHORE CURRENTS

David A. Huntley¹

ABSTRACT

A two-component electromagnetic flowmeter has been used on a natural beach of slope 0.01 to measure mean longshore currents and the horizontal fluctuating velocities in the frequency range 0-1 Hz. The measurements extend up to 120 m offshore and span about one third of a wide surf-zone. The cross product of the fluctuating horizontal velocities, assumed to contain the combined effects of radiation and Reynold's stresses, is plotted as a function of distance from the shoreline. The on/offshore gradient of the cross-product is then equated with a bottom friction term either in the form used by Bowen (1969a) or in a form similar to that used by Longuet-Higgins (1970). The apparent values of bottom friction coefficient obtained in this way are at least a factor of two smaller than expected for Reynolds numbers and bottom roughness appropriate to the beach. Attempts to separate the radiation stress and the Reynold's stress contributions to the total stress term using cospectra fail to show distinguishable Reynold's stress contributions. Although this may be construed as being consistent with Battjes' (1975) beach slope dependent form for horizontal eddy viscosity rather than Longuet-Higgins' (1970) form, it is argued that, in fact, the significant horizontal turbulence was not measured at all but was confined to a surface layer above the flowmeter. This leads to the hypothesis that lateral friction, as a surface boundary layer, and the bottom friction act on a less turbulent central layer, and that the small measured friction coefficient in the present experiment is the result of the combined effects of these layers.

INTRODUCTION

Wave-induced longshore currents, confined mainly to the surf-zone, are assumed to be the result of a balance between a gradient of incident wave radiation stress, a gradient of horizontal turbulent Reynold's stress and bottom friction acting on the longshore current (for a recent review see Longuet-Higgins 1972). Recent theories have parametrised these three balancing forces in terms of easily measured macroscopic properties of the flow. Radiation stress is generally calculated from incident wave height and angle of approach; the Reynold's stress acting in the longshore direction is assumed to be the product of the on/offshore gradient of the longshore current and a coefficient of eddy viscosity dependent in some way on distance from the shoreline and beach slope; bottom friction has been parametrised in a number of ways

¹Assistant Professor, Department of Oceanography, Dalhousie University, Halifax, Nova Scotia, Canada

involving a coefficient of friction, the value of the mean longshore current and possibly the wave orbital velocity (calculated in turn from the mean water depth).

Despite the success of these theories in predicting at least the order of magnitude of longshore currents there are a number of uncertainties, particularly in choosing the appropriate parametrization of Reynold's stress and bottom friction. These uncertainties arise primarily because the nature of turbulence within the surf zone is not well understood. Is the appropriate scaling length for the horizontal eddy viscosity coefficient a horizontal distance from the shoreline or a local water depth (Longuet-Higgins 1970; Battjes 1975)? Is a depth mean turbulence picture in fact appropriate or is the wave-breaking turbulence confined to a relatively thin surface layer? What are appropriate values of bottom friction coefficient if much of the turbulence is generated not by bottom roughness but by wave breaking?

The fast response and ruggedness of electromagnetic flowmeters provide an opportunity to begin answering these questions by direct measurement of the fluctuating components of the velocity field, both waves and turbulence, simultaneously with measurement of the mean longshore flow.

This paper discusses an experiment on a shallow beach (beach slope $\beta = 0.01$) in which a two-component flowmeter was used to measure on/offshore and longshore currents in a frequency range 0 - 1 Hz along a line normal to the shoreline. The data provided a direct measurement of the combined local radiation and Reynold's stress forces as well as an on/offshore profile of longshore current. The first part of the paper discusses the friction coefficient obtained from these data, and there follows some discussion of attempts to separate the radiation stress and Reynold's stress components in the data.

THEORY

We assume a co-ordinate system with the x - axis increasing seawards from zero at the shoreline, the y - axis alongshore and the z - axis increasing vertically upwards from the mean still water surface.

The longshore equation of motion for steady currents, assuming hydrostatic pressure and neglecting wave-current interaction, is the shallow water equation

$$\frac{u\partial v}{\partial x} + \frac{v\partial v}{\partial y} = - \frac{g\partial \bar{\eta}}{\partial y} + R_y + \tau_y \quad (1)$$

where u , v are the on/offshore and longshore depth mean currents (including wave-induced mass transport) respectively, $\bar{\eta}$ is the wave induced mean set-up of the water level, R_y is the bottom friction term and τ_y is usually written as the sum of radiation stress and Reynold's stress gradients in the on/offshore directions. If conditions are uniform in the longshore direction then terms in $\partial/\partial y$ disappear and the first term also becomes zero as a consequence of continuity, leaving only

$$R_y + \tau_y = 0 \quad (2)$$

The term τ_y is the on/offshore gradient of the flux towards the shoreline of parallel-to-the-shoreline momentum (Phillips 1969), and can be written

$$\tau_y = \frac{1}{\rho(\bar{\eta}+h)} \frac{\partial}{\partial x} S_{xy} \quad (3)$$

where

$$S_{xy} = \overline{\int_{-h}^{\eta} \rho u'v' dz} \quad (4)$$

Here h is the still water depth and u' , v' are the fluctuating velocity components, including both wave orbital velocities and turbulence. S_{xy} should also contain a term in the cross-product of the horizontal components of mass flux, but this term is proportional to the mean on/offshore flow. Its size can therefore be estimated from the measured mean on/offshore velocities. For the experiment under discussion it was much less than 10% of the term in eqn. 4 and has therefore been ignored.

If the assumption is made that wave and turbulent velocities are uncorrelated it is possible to separate the term on the right of eqn. 4 into a radiation stress part and a Reynold's stress part, and this is the usual way of proceeding. For the data from an electromagnetic flowmeter, however, it is not necessary to make this separation since the components u' and v' are measured directly. Nevertheless it is necessary to make two further simplifications of equation 4 before it relates directly to the measured quantities. These are

$$\begin{aligned} \overline{\int_{-h}^{\eta} \rho u'v' dz} &\approx \int_{-h}^{\bar{\eta}} \overline{\rho u'v' dz} \\ &\approx \overline{\rho u'v'} (\bar{\eta}+h) \end{aligned} \quad (5)$$

The first of these approximations is valid to the same order as

our neglect of the mass flux term in S_{xy} . The second approximation implies that $\overline{u\overline{v}}$ is independent of depth. This assumption must be made a priori since measurements were only made at a single position in the water column. However, the consistency of the results so obtained is later used to assess the validity of the assumption.

Although in principle the vertical and horizontal components of turbulent motion could be measured near the sea bed using the electromagnetic flowmeter, and these could be used to provide a direct measurement of bottom stress, in the present experiment only horizontal velocities were measured and hence the bottom friction must be approximated by empirical expressions involving horizontal components and bottom friction coefficients.

Three different forms of bottom friction have been considered, each involving a bottom friction coefficient. With these bottom friction terms, the equations of motion, eqn. 2, become

$$\begin{aligned} \frac{\partial}{\partial x} [\rho \overline{u\overline{v}} (\bar{\eta}+h)] &= \rho (\bar{\eta}+h) R_Y \\ &= \rho c_b V \quad (\text{Bowen 1969a}) \end{aligned} \quad (6)$$

$$= \rho c_f^1 |U_{\text{orb}}| V \quad (\text{Longuet-Higgins 1970}) \quad (7)$$

$$= \rho c_f^2 |U| V \quad (8)$$

c_b is a linear friction coefficient, with units m/s while c_f^1 and c_f^2 are dimensionless coefficients. In the Longuet-Higgins form U_{orb} is the maximum orbital velocity of the incident waves. In the third formulation $|U|$ is the modulus of the total current vector and differs from $|U_{\text{orb}}|$ mainly in including the steady longshore current V , which Longuet-Higgins assumed was much smaller than U_{orb} .

THE EXPERIMENT

The field experiment was carried out on Saunton Beach, N. Devon, England. This is an essentially straight beach approximately 4 km. long and a survey out to 300 m from the high water mark showed an approximately linear slope of 0.014; this slope is modified to 0.010 relative to the mean water level inside the surf-zone when set-up is taken into account. On the day of the experiments the surf-zone was 300-400 m wide with long-crested spilling breakers.

A single two-component electromagnetic flowmeter was mounted about 20 cms off the sea bed, oriented so as to measure the on/offshore and the longshore components of flow. The effective shoreline distance from this instrument varied as a result of tidal motion and allowed estimates of S_{xy} to be made in the region 0 - 120 m from the shoreline. The experimental technique was discussed in detail at the last Coastal Engineering Conference (Huntley and Bowen 1975a).

FRICTION COEFFICIENTS

Figure 1 shows the measured values of longshore current against distance offshore. The values shown are $8\frac{1}{2}$ minute averages of digital current measurements recorded every $\frac{1}{2}$ second. The measured currents compare well with independent measurements made using drifting floats at different distances offshore and the validity of the tidal excursion technique for measuring on/offshore variation of the velocity field is supported by the similarity of currents at the same offshore distance measured first on the rising and then on the falling tide (Huntley and Bowen 1975a). The current increases almost linearly with distance from the shoreline, as expected since the measurements were made within about $1/3$ of the surf-zone width from the shoreline.

Figure 2 shows the corresponding values of $\overline{u'v'}$ plotted against offshore distance. Here the fluctuating components are taken to be the velocities after removal of the $8\frac{1}{2}$ minute means only. High-pass filtering to remove energy at frequencies below the incident wave band would result in a reduction of about 20% in the values of $\overline{u'v'}$; the cause of this is discussed later. Apart from a single wild point at about 70 m offshore the values are encouragingly stable, the spread of points around 120 m suggesting that the estimates are stable to better than $\pm 40\%$.

Also shown on figure 2 are straight lines corresponding to different values of c_b , the linear friction coefficient. The fit of these straight lines is unconvincing and the values of c_b are lower than might have been expected. Bowen (1969a) estimates values of 0.002m/s for some laboratory data.

The values of c_f^1 and c_f^2 were estimated separately for each $8\frac{1}{2}$ minute section of record. A plot of $(\eta+h) \overline{u'v'}$ vs offshore distance was made and the data approximated by a smooth line increasing monotonically with distance from the shoreline. At the offshore distance corresponding to each $8\frac{1}{2}$ minute record the gradient of this line was measured and equated to the bottom friction terms (eqns. 7 & 8) to obtain values of c_f^1 and c_f^2 . Table 1 shows the results. It is seen that the estimates of c_f^1 and c_f^2 are generally stable, the standard deviations representing approximately $\pm 30\%$, and there is no obvious trend in the values with shoreline distance.

With the exception of the values nearest the shoreline, c_f^1 is consistently larger than c_f^2 . Thus the assumption that U_{orb} is much larger than V is invalid for this data. The ratio of mean values c_f^1/c_f^2 is about 1.4, implying that U_{orb} and V are of the same size. In fact it can be shown using the theory of Longuet-Higgins (1970) that, except for very small angles of approach of the incident waves (of order 1° at the breakpoint), V is generally of the same order as U_{orb} , and the Longuet-Higgins approximation, equation 7, is therefore usually invalid.

The coefficient c_f^1 deduced from longshore current data by various authors (Thornton 1970; Komar 1975) is therefore not a true bottom friction coefficient. The value of c_f^1 will generally be larger than the correct bottom friction coefficient, c_f^2 , but the amount by which it is larger will vary across the surf zone and will be strongly dependent on the angle of approach of the incident waves. This may explain the wide range of values of c_f^1 which have been deduced. [It is worth noting also that estimates of c_f^1 have often been made using the longshore current data of Galvin and Eagleson (1965), but the accuracy of these data is now questioned by Komar (1975) on the grounds of incompatibility with other data. Since the longshore currents of Galvin and Eagleson are larger than expected the estimates of c_f^1 will be low.]

The magnitude of the bottom friction coefficient c_f^2 is less than one half the magnitude expected on the basis of laboratory experiments of flow over rough plates. The experiments of Nikuradse (Prandtl 1952, Longuet-Higgins 1970) suggest that, for the bottom roughness appropriate to the beach and a Reynold's number determined by the incident waves, and friction coefficient should be around 5×10^{-3} (Note that the friction coefficient defined in equation 38 of Longuet-Higgins (1970) and equations 7 and 8 of the present paper is one half the value of c_f given by Prandtl (Longuet-Higgins - private communication)). Other direct estimates of wave friction coefficient have been made by Jonsson (1967) and Teleki and Anderson (1970), and estimates of a combined wave and longshore current friction factor have been made by Jonsson et al (1974), but in each case the values give a bottom friction term at least as large as Prandtl's estimate.

It seems probable that the apparently low value of friction coefficient c_f^2 is the result of the omission of a driving term in the equation of motion, equation 8. The two groups of terms which may have been omitted are the longshore variation terms included in equation 1, or the turbulent Reynold's stress term, which we assumed to be included in equation 5.

If the assumption of uniform conditions in the longshore direction were invalid, then the additional terms in equation 1 would have to be included and could result in a stronger (or weaker) longshore current than would be driven by τ_y alone. If it were nevertheless still assumed that the motion could be described by equations 2, and 6-8, this stronger (weaker) current could only be reconciled with these equations by an apparently smaller (larger) value of friction coefficient. Two mechanisms could be responsible for a longshore variability, edge wave generated circulation cells and refraction of incident waves. Edge wave generated circulation cells (Bowen 1969b, Bowen and Inman 1969) seem very unlikely to be generated on a beach as shallow as 0.01. Theory and experimental evidence suggest that circulation cells have an along-shore wavelength of the same order as the surf-zone width and edge waves of low mode number are most strongly generated; on Saunton beach synchronous edge waves giving circulation cells of the same size as the surf-zone would be of mode number greater than 200. The effect of wave refraction is less easy to dismiss since no

measurements were made alongshore. However offshore topography was relatively smooth and there were no indications of refraction on this long smooth beach. Additional evidence that wave refraction is not responsible for low values of friction coefficient comes from field measurements of longshore currents made by Ramkema (Battjes - private communication). He also found consistently low values of friction coefficient, although his measurements were made for a variety of directions of approach of the waves, and thus for a variety of wave refraction conditions.

The second possible explanation for the low values of bottom friction is that we are just not measuring the Reynold's stress at all. Since the data comes from the 1/3 of the surf-zone closest to the shoreline, a region where the effect of lateral mixing is to increase the longshore current above the unmixed value, we are again ignoring a driving term in the force balance and hence underestimating the friction coefficient.

This hypothesis clearly leads to an attempt to find Reynold's stress contributions to the measured stress term, and this is discussed in the following section.

SEPARATION OF REYNOLD'S AND RADIATION STRESSES

If we could separate the turbulent and wave contributions to the mean u, v product we could examine the hypothesis that turbulence is perhaps not being measured, or possibly test the various parametrisations of horizontal turbulent stresses which have been used in longshore current theories. There are three possible ways in which such a separation might be made. Most obviously we might try to measure elevation at the same time as the horizontal velocities and then remove the calculated elevation-related contributions to the velocities. Alternatively we might measure the variation of the $u\overline{v}$ product across and beyond a surf-zone and attempt to distinguish the two stress components by their different dependences on offshore distance: the Reynold's stress should fall to zero some distance outside the surf-zone and pass through zero at the position within the surf-zone where the longshore current is maximum; these two points and the shoreline limit should allow a reasonable estimate to be made of the radiation stress contribution throughout the nearshore zone. Finally it might be possible to separate the two stresses if they occur predominantly in separate frequency bands.

Unfortunately the data from the present experiment includes neither elevation measurements nor sufficient spread of measurements across the surf-zone to test the first two of these techniques. In fact the first technique would require a rather accurate directional spectrum of elevations, and this would be difficult to measure in the nearshore zone. However frequency separation is in principle possible with the current measurements alone.

The co-spectrum $\overline{u^{\prime}v^{\prime}}(f)$ separates the real part of the $u^{\prime}v^{\prime}$ product into contributions in separate frequency bands. Since the effect of the Reynold's stress gradient is to increase the longshore current within the first one third of the surf-zone we expect the Reynold's stress to contribute to $u^{\prime}v^{\prime}$ with the same sign as the radiation stress, but hopefully within a well defined band at a higher frequency than the incident wave band.

Figure 3 shows a typical example of the co-spectra calculated from the 8½ minute records. The peak just below 0.2 Hz represents the predominant incident wave frequency. The lower frequency contributions may be due to breaker interaction in the wide surf-zone (Huntley and Bowen 1975b) but in any case contribute only about 20% of the total area under the curve. There is no clear frequency band above 0.3 Hz containing a significant peak which may be attributed to Reynold's stress.

It is possible that the level of turbulence was too small to be significant in this co-spectrum. Longuet-Higgins (1970) estimates the total turbulent stress as

$$\overline{u^{\prime}v^{\prime}} = \frac{1}{\rho} N \rho x (gh)^{3/2} \frac{\partial V}{\partial x} \quad (9)$$

where h is local water depth

x is distance offshore

He assumes that the parameter N is a constant with a value ≈ 0.005 ; Bowen and Inman (1972) analyse surf-zone dye diffusion experiments and suggest that N should lie approximately in the range 0.01-0.06. In contrast Battjes (1975) suggests that N should not be constant but beach slope dependent in the form

$$N = \left(\frac{5}{16} \gamma^2 \right)^{1/3} (\tan\beta)^{4/3} M \quad (10)$$

where γ is the ratio of wave height to water depth.

M is a dimensionless parameter deduced by assuming that the N given by equation 10 for $\tan\beta = 0.1$ is similar to the constant N deduced by Bowen and Inman (1972); most experimental determinations of N were made on beaches of slope 0.1. The value of M calculated thus lies in the range 0.3-2.0. The effect of the beach slope dependence of equation 10 is then to give a considerably smaller estimate of turbulent Reynold's stress on a beach of the present slope of 0.01 than would be calculated using a constant N. We have calculated the Reynold's stress, equation 9, using both constant $N \approx 0.01-0.06$, and the beach slope dependent N,

equation 10, which for our slope of 0.01 gives $N \approx (3.5 - 21) \times 10^{-4}$. (we assume also that $\gamma \approx 1.2$ for $\tan\beta = 0.1$ and $\gamma = 0.78$ for $\tan\beta = 0.01$, following Bowen et al (1968), but the choice of γ does not significantly effect the result). Comparison of these predicted Reynold's stresses with the observed contribution to $u\bar{v}$ for frequencies greater than 0.3 Hz shows that the observed values are of a similar magnitude to predictions made using equation 10 but are at least an order of magnitude smaller than predictions made using a constant (independent of beach slope) N . Thus the observed cospectra are not inconsistent with Battjes model for horizontal turbulence but are definitely inconsistent with Longuet-Higgins' model.

It seems more likely however that the flowmeter was not in fact measuring the wave-induced turbulence at all. The mean values of u and v integrated over the complete frequency range can be completely accounted for by the expected values for surface wave breakers propagating in the observed water depths. The coherence between u and v is also around 0.3 in the frequency range 0 - 1Hz as might be expected for short-crested incident waves (Battjes 1975).

DISCUSSION

The conclusion from the present data is therefore that the turbulence is probably not being measured by our single flowmeter and that this omission is likely to be the cause of the low value of friction coefficient obtained.

The probable reason for the absence of turbulence in the flowmeter records is that the flowmeter was too far down in the water column. Laboratory experiments and field experience suggest that the turbulence of breaking is not distributed throughout the water column but is limited to the upper part, especially for spilling breakers. Thus the second approximation of equation 5 is invalid. Turbulence energy would also not be measured if it occurred predominantly at frequencies greater than the approximately 10Hz response frequency of the flowmeter, but this seems unlikely.

Thus the present results suggest a rather different model for longshore currents than has been used before. Rather than a turbulent intensity distributed throughout the water column, wave breaking turbulence is confined to an upper boundary layer which, with the bottom boundary layer, acts on a less turbulent central layer. If indeed the driving force of this upper layer is responsible for the low apparent value of c_f , then an upper limit of about one third the water depth can be put on the thickness of this upper layer, based on the fact that c_f remains small down to as little as 40 m. from the shoreline (table 1).

The hypothesis, then, is that the value of c_f measured here is not a bottom friction coefficient alone but is strongly modified by the

existence of a surface turbulent boundary layer formed by wave breaking. The formulation of the effect of lateral mixing as some kind of boundary layer rather than a depth independent eddy viscosity may explain why Jonsson et al (1974) and Komar (1975) find so little effect on the match of predicted and measured longshore currents when the parameter N (equation 9) is varied over a wide range.

The suggested three layer model may also provide the means to explain Komar's observation (Komar and Inman 1970, Komar 1975, 1976) that for a wide variety of field and laboratory measurements of longshore currents, the ratio of beach slope to the coefficient c_f^1

$$\frac{\tan\beta}{c_f^1} \approx \text{constant} \quad (11)$$

The constant in equation 11 is variously found to be $6.05 + 0.65$ for beach slopes in the range $0.05 - 0.15$ (Komar 1975), ≈ 6.7 (Longuet-Higgins 1972) and ≈ 7 for a beach slope of around 0.05 (Keeley 1975). The beach slope for the present experiment is considerably smaller than for these data, at 0.01 , but, as a consequence of the smaller value of c_f^1 , the ratio is found to be $3.9 +1.1$, in reasonable agreement with the other estimates. In fact, using the correct friction coefficient, c_f^2 , instead of c_f^1 also gives reasonable agreement, with the constant $\approx 5.2 +2.4$.

Komar (1971) assumes that c_f^1 is a friction coefficient and he has attempted to provide a physical explanation for the empirical result of equation 11 by assuming that bottom stress exerted on the beach is proportional to the radiation stress in the incident wave direction at the breakpoint. However, this and other unproven assumptions which he needs to make have been criticized by Longuet-Higgins (1972), also on physical grounds. More recently Komar (1976) has pointed out that, for the field data, a constant ratio $\tan\beta/c_f^1$ suggests an increase in c_f^1 with sand size, as we might expect for flow over a rough bed. However, this argument cannot explain the laboratory results, where most beaches are solid, with a constant, generally small, bottom roughness independent of beach slope.

The three layer model, however, suggests that the measured c_f^1 parameters are strongly influenced by the intensity of breaking turbulence. Increased beach slope will result in a narrower surf-zone over which turbulent breaking occurs, and hence a greater level of turbulence in unit surface area. This increased horizontal mixing will result in a decreased longshore current and hence a greater apparent c_f^1 parameter in our three layer model. This explanation is consistent with Longuet-Higgins' (1972) comments on equation 11.

Clearly what is needed is a new model for longshore currents, involving the correct parametrisation of the bottom friction term in terms of equation 8 rather than equation 7, and involving a new parametrisation of horizontal turbulent mixing as an upper boundary layer. Such a model may provide an explanation for equation 11.

There are several ways that the present three layer hypothesis may be tested experimentally. Direct estimation of bottom friction is possible through use of the electromagnetic flowmeter to measure vertical and horizontal velocities near the bed. Measurements of the distribution of horizontal turbulence in the vertical may also be possible, though measurement in the turbulent surface layer may only be possible by dye diffusion (see Inman et al 1971). Finally the value of c_f^2 deduced from horizontal velocities, as described in this paper, should be measured across and beyond the surf-zone. Since the effect of a surface turbulent layer should be to reduce the longshore current gradient, the maximum longshore current will be less than predicted in the absence of horizontal mixing, the horizontal mixing term will be a retarding force, and the value of c_f^2 should be larger than expected for bottom friction alone. Thus c_f^2 should be smaller near the shoreline increase beyond bottom friction values as the surf-zone is traversed seawards, and then drop again, possibly even becoming negative beyond the surf-zone.

CHAPTER 38

TIME DEPENDENT FLUCTUATIONS IN LONGSHORE CURRENTS

Guy A. Meadows

Department of Geosciences
Purdue University
West Lafayette, Indiana

ABSTRACT

During constant sea state conditions, longshore current velocities were monitored continuously for fifteen minute periods separated by fifteen minute periods separated by fifteen minute intervals. Three ducted impellor flowmeters were placed at equally spaced vertical positions through the water column. Sequential measurements were made with similar vertical current meter arrays at different locations across the surf zone. Simultaneous measurements of wave height, period and celerity were made at stations placed at equal intervals from the outer surf zone to the beach. The fifteen minute continuous records were subjected to spectral analysis. This analysis showed that the major power associated with fluctuations in the longshore current velocity field occurs in two major frequency bands. A significant spectral peak was coincident with the breaker period of the incident wave field, 4.2 seconds and, another dominant signature occurred at 78.8 seconds. Attenuation with depth of both the steady and fluctuating components of the longshore current flow field was relatively small. The maximum observed velocities for each station and each vertical current meter position varied from 90 to 150 percent above the observed mean longshore current velocity. However, at each station, variation of the means with depth was not appreciable and thus supports the results from time and space averaged theories of vertical uniformity in longshore currents, away from the boundary layer. Results from the field investigation of Wood and Meadows (1975) indicated that the steady state components are dominated by the fluctuating portions of the flow field. Therefore, time averaging of conservation equations in longshore current theory is a physically inappropriate procedure. In order to evaluate the magnitude of the unsteady components, a close examination of surf zone dynamics was made. The most obvious contribution to unsteadiness in longshore currents arises from the longshore component of the maximum horizontal particle velocity. However, the magnitude of observed current fluctuations is too large to be completely accounted for by this component. Spectral peaks at longer periods appear to be related to modes of edge wave phenomena. The long period spectral signature of 78.8 seconds is in direct agreement with the calculated period for a zero mode edge wave in shallow water. This agreement supports the contention that oscillatory components, other than the longshore component of the wave particle velocity,

are contributing to unsteadiness in longshore currents and are manifested throughout a wide range of frequencies.

INTRODUCTION

In the presence of an oscillatory wave field incident on a beach it is somewhat unrealistic to expect a steady or slowly varying longshore current. Unsteadiness of longshore currents has been noted for quite some time. However, the magnitude and dominance of the unsteadiness in the flow field has only recently been fully appreciated (Dette, 1974; Wood and Meadows, 1975).

Classically, field and laboratory investigations have relied on averaged results from Lagrangian measurements to establish longshore current velocities. Likewise, conservation equations have been time averaged in the formation of longshore current theories. As a result, design criteria for coastal engineering structures have only considered the periodicity of the incident wave field to be important and local longshore currents have been modeled as steady state and constant with depth. Results from this investigation indicate that these assumptions are inappropriate. Field observations show at a fixed point in the surf zone variations in excess of 150 percent of the mean longshore current velocity occur over time periods from three to eighty seconds (Figure 1). These unsteady motions in longshore currents persist horizontally across the surf zone and vertically from the surface to the bottom. The dominant period of these fluctuations correspond to that of the incident breaker period; however, significant longer period fluctuations are also evident. The magnitude of the time-dependent portions of the flow field as well as their persistence horizontally across the surf zone and vertically with depth suggests that they dominate the steady component. Consequently an analytical formulation for longshore current flow must be carried out in a time dependent framework.

Longshore currents result in a net translation of fluid particles parallel to the shoreline. This fluid flow is bounded by the beach on the nearshore side, by the somewhat arbitrary limit of the surf zone on the seaward side and by the bottom. The flow velocities are hence constrained to vanish at or near these boundaries. There can be no wave generated longshore current flow beyond the maximum wetted extent of the swash zone on the beach. The seaward extent of the longshore current is located where the effects of momentum and energy fluxes, associated with breaking waves, lie beyond the range of lateral mixing in the surf zone. The lower extent of the flow field is characterized by a shear dominated zone terminating in the loosely consolidated sediment comprising the under-water portion of the beach. The flow is constrained to vanish at a sufficient depth into this underlying beach sediment. This depth is not necessarily the top of the mobile sediment layer but a depth at which percolation through the beach material is non-existent. The last remaining boundary is that of the free surface. It is at this

FIGURE 1. THREE REPRESENTATIVE SIMULTANEOUS TIME HISTORIES OF FLUCTUATING LONGSHORE CURRENT VELOCITIES TAKEN AT THREE DEPTH LOCATIONS THROUGH THE SURF ZONE WATER COLUMN.

boundary that the flow velocity is anticipated to be a maximum. Since the shearing stress realized at the bottom must result from a loss of momentum at the bottom boundary, the maximum velocity must be achieved at the greatest possible distance from the bottom. The longshore current flow, outside the viscous boundary layer, appears to be a weak shear flow.

Classically, longshore current velocity has been modeled as a function of wave height, period, celerity and angle of approach at breaking as well as the local water depth (Galvin, 1967). The driving forces necessary to create and sustain the longshore current are most directly related to the breaking wave height, (Putnam, Munk, and Traylor, 1949). This observation led to the development of conservation of momentum and energy approaches to the treatment of the longshore current flow field. It was assumed that in shallow water the wave celerity at breaking can be adequately represented by

$$C_b = \sqrt{g(H_b + Z)}$$

which leads to an ambiguous conclusion. Accepting the premise that energy losses exist that are not accounted for by this approximation, the driving component associated with the horizontal component of the wave particle velocity must be of greater magnitude than the resulting longshore current velocity

$$C_b \sin \theta_b > V.$$

This result is not usually observed in nature, implying that other mechanisms, not accounted for by a simple time averaged momentum balance of the longshore component of the breaking wave horizontal particle velocity, must be associated with the generation of longshore currents.

Early conservation of momentum and energy approaches have led to the investigation of longshore currents based on continuity considerations (Bruun, 1963). The basic assumption in the conservation of mass approach is that a wave breaking at an angle to the beach contributes mass to the surf zone and raises the local mean water level. This creates a slope in the water surface which generates a longshore current. Variation of still water level at different locations along the beach imparts a longshore slope to the free water surface. The differential pressure head associated with this slope initiates flow from areas of high to low pressure. Hence, the velocity of the longshore current is controlled by the frictional pressure head loss within the current itself. The non-uniformity of these conditions implies variation of the longshore current flow field in the longshore direction and forms the basis for theoretical treatments of rip-cell generation (Bruun, 1963; Bowen, 1967). Rip-channels are formed at low areas of wave and slope water set-up and flow perpendicular to the beach. This is a necessary and sufficient condition to satisfy

conservation of mass in the surf zone since the continuity constraint cannot justifiably be met by imposing return flow with depth throughout the surf zone.

Perhaps the most sophisticated and least restrictive approach to longshore currents has been set forth in terms of conservation of energy considerations (Longuet-Higgins, 1970 (1) and (2)).

This approach utilizes the concept of radiation stress to relate the magnitude of the longshore current velocity to the incoming wave energy flux, given by

$$F_x = E c_g \sin \theta \quad (1)$$

outside the surf zone and

$$\frac{\partial F_x}{\partial x} = -D \quad (2)$$

inside the surf zone, where D is the rate of energy dissipation per unit time and horizontal area. The flux of y -momentum across a line $x = \text{constant}$, parallel to the shoreline is given by the radiation stress component

$$S_{xy} = F_x \left(\frac{\sin \theta}{c} \right) \quad (3)$$

and from balance of momentum flux considerations it can be shown that the waves exert a local stress

$$T_y = - \frac{\partial S_{xy}}{\partial x} \quad (4)$$

parallel to the shoreline. Substituting (3) and remembering that $\sin \theta/c$ is independent of x gives

$$T_y = - \frac{\partial F_x}{\partial x} \left(\frac{\sin \theta}{c} \right) \quad (5)$$

or from (2)

$$T_y = D \left(\frac{\sin \theta}{c} \right) \quad (6)$$

A simple momentum balance for steady state conditions on a straight coastline can be expressed as

$$T_y - B = 0 \quad (7)$$

where B is bottom friction and lateral friction is neglected. Applying linear theory of waves in shallow water to (1) under the assumption

that in the breaker zone θ is small enough that $\cos \theta$ can be approximated by unity gives

$$F_x = \frac{1}{2} \rho g a^2 \sqrt{gz} = \frac{1}{2} \alpha^2 \rho g^{3/2} z^{5/2} \quad (8)$$

where ρ is density, g acceleration of gravity, a wave amplitude, z water depth, and $\alpha = a/z$. Longuet-Higgins (1970 1, 2) assumed the Chezy Law

$$B = C\rho |\bar{u}|\bar{u} \quad (9)$$

where \bar{u} is the horizontal velocity, having both a steady and oscillatory component, and C is a constant. Combining equations (5), (8), and the time averaged expression of (9) and substituting into (7) gives a longshore velocity

$$\bar{v} = \frac{5\pi}{8} \frac{\alpha s}{C} gz \frac{\sin \theta}{c} \quad (10)$$

The extension of shallow-water theory out to the breaker line and the inclusion of lateral mixing across the breaker line result in

$$V_o = \frac{5\pi}{8} \frac{\alpha}{C} \sqrt{gz} b (s \sin \theta_b) \quad (11)$$

and

$$V_b = \frac{5\pi}{8} \frac{\alpha \beta}{C} \sqrt{gz} b (s \sin \theta_b) \quad (12)$$

respectively (Longuet-Higgins, 1970 1, 2).

Longshore current velocities predicted from this approach only agree with experimental results under the conditions of a monochromatic sea surface incident at a straight planar beach of constant slope. The assumptions employed in these solutions still remain far too restrictive to produce physically realistic prediction under natural conditions. For an excellent discussion of recent developments in the predictions of steady longshore currents see Longuet-Higgins (1972).

The existence of second order effects across the surf zone with a wide range of incident periods, can add significant contributions to unsteadiness in the longshore current velocity. Wave set-up and set-down (Eagleson, 1965) across the surf zone can add slope water effects to the driving sources. The effect of short crested waves (Fuchs, 1952) and edge waves (Ursell, 1952) can also supply driving forces not accounted for by classic temporal and spatial averaged momentum theory.

Therefore, formulation of longshore current theories based on temporally or spatially averaged quantities appears to be physically inappropriate. It is unrealistic to expect a steady or slowly varying longshore current in the presence of an irregular oscillatory wave

field. Although the oscillatory nature of the longshore current, due to the presence of breaking waves in the surf zone should be expected, the resulting total longshore current velocity field is a far more complex oscillatory field.

FIELD INVESTIGATION

A field investigation was carried out along a section of eastern Lake Michigan shoreline, characterized by a multiple barred configuration and nearly parallel bathymetry. Only conditions of wave breaking on the inner bar were considered for this investigation. This restriction was imposed to avoid the added complication of waves reforming and breaking at multiple locations.

Three ducted impeller flow meters oriented parallel to the shoreline were placed at equally-spaced vertical positions at each monitoring station. The upper meter was placed below the level of the lowest wave trough so that it was continuously submerged. The lower meter was placed adjacent to the bottom and the middle meter half way between the upper and lower meters (Figure 2). Sequential measurements were made with three similar vertical current meter arrays at different locations across the surf zone. The outermost current monitoring station (Station I), was located within the zone of active breaking. The inner stations (Station II and III), were located five and ten meters, respectively, shoreward of Station I. Maximum wave breaking occurred at Station II, hence, the breaker zone was bracketed by the station locations. The total surf zone width was approximately thirty meters.

Simultaneous measurements of wave height, period and celerity were made perpendicular to the shoreline at stations spaced at equal intervals from the outer surf zone to the shore. The spacing of these stations was approximately 5 meters. The incident wave angle at breaking was determined to be 21 ± 5 degrees.

During constant sea state conditions, longshore current velocities and wave characteristics were simultaneously monitored continuously for fifteen minute periods separated by fifteen minute intervals. Constant sea state was determined by requiring that the probability distributions of wave height and period at the outer most wave monitoring station remain stationary. Hydrographic surveys were conducted, at close spatial intervals, offshore to a position outside the surf zone and alongshore to a distance of one surf zone width, which is the theoretical limit of rip cell width. The average nearshore beach slope was found to be 1:40.

ANALYSIS

The most appropriate representation of the longshore current and its associated wave field should be expressed in a statistical context.

FIGURE 2. BATHYMETRIC PROFILE SHOWING CURRENT METER LOCATIONS AND WAVE MONITORING STATIONS.

Application of this approach to nearshore circulation has been the subject of recent work (Dette, 1974; Earl, 1974; Collins, 1972; and others). Consideration of probability distributions of wave characteristics across the surf zone anticipate a variation in wave height, incidence angle and celerity. Under a monochromatic assumption, all waves are expected to break at the same location in the surf zone. However, with a random distribution of the sea surface, the breaker line becomes a breaker zone and the region over which energy dissipation is active also becomes a broad zone.

Data obtained from the ducted impeller flow meter array were analyzed for their periodic and steady state components. The time intervals between discrete on-off signals of the meter were converted to instantaneous velocities. These velocities were then interpolated on equal time intervals between adjacent points. This data was then subjected to spectral analysis to determine its periodic components. Inherent to the monitoring system are aliasing problems. Data from the flow meter was only available at discrete instants of time, therefore, frequency information was lost from the signal. Frequencies greater than twice the interval between meter signals (averaged approximately 1.0 seconds) can not be resolved. Filtering of the input signal and smoothing of the power spectrum was therefore employed.

The analytical treatment of the longshore current flow field should be developed within the framework of an incompressible, inviscid fluid. The problem also must be formulated in a time dependent context with shallow water wave parameters as inputs. It is therefore necessary to evaluate the initial state of the wave field incident at the outer surf zone (Figure 3).

To evaluate wave induced unsteadiness of the longshore current flow field it is advantageous to remove from the experiment all secondary variations in the velocity field not directly related to the incident breaking waves. For this reason, only wave and current data collected during constant sea state conditions was acceptable for this investigation. The wave field was, therefore, required to be statistically steady in its mean, $\partial\bar{\eta}/\partial t = 0$. This restriction eliminates the existence of significant long period fluctuations in the longshore current velocity field induced by either growth or decay in the wave field incident at the outer surf zone. This restriction, however, does not preclude wave transformations within the surf zone, hence, $\partial\eta/\partial x \neq 0$.

It is not necessary for the incident wave field to be non-uniform in the alongshore direction for periodic unsteadiness in longshore current velocity to exist. Significant unsteadiness in the velocity field should be expected both from direct velocity contributions from breaking waves and from interactive phenomena associated with the entire wave group (Meadows and Wood, 1975).

Incident Wave Field Conditions	
Wave Field Steady in Mean Wave Field Uniform in Y-Direction (Alongshore)	Wave Field Steady in Mean Wave Field Non-Uniform in Y-Direction (Alongshore)
$\frac{\partial \eta}{\partial t} = 0$	$\frac{\partial \eta}{\partial t} = 0$
$\frac{\partial \eta}{\partial x} \neq 0$	$\frac{\partial \eta}{\partial x} \neq 0$
$\frac{\partial \eta}{\partial y} = 0$	$\frac{\partial \eta}{\partial y} \neq 0$
Longshore Current	
Uniform in Y-Direction (Alongshore)	Non-Uniform in Y-Direction (Alongshore)
<u>Steady</u>	<u>Steady</u>
$\frac{\partial u_i}{\partial t} = 0$	$\frac{\partial u_i}{\partial t} = 0$
$\frac{\partial u_i}{\partial x} \neq 0$	$\frac{\partial u_i}{\partial x} \neq 0$
$\frac{\partial u_i}{\partial y} = 0$	$\frac{\partial u_i}{\partial y} = 0$
<u>Unsteady</u>	<u>Unsteady</u>
$\frac{\partial u_i}{\partial t} \neq 0$	$\frac{\partial u_i}{\partial t} \neq 0$
$\frac{\partial u_i}{\partial x} \neq 0$	$\frac{\partial u_i}{\partial x} \neq 0$
$\frac{\partial u_i}{\partial y} \neq 0$	$\frac{\partial u_i}{\partial y} \neq 0$

FIGURE 3. INITIAL CONDITIONS DEFINING POSSIBLE ANALYTICAL CONSIDERATIONS FOR THE DEVELOPMENT OF LONGSHORE CURRENT THEORIES BASED ON THE INCIDENT WAVE FIELD.

The approximation $\partial\eta/\partial y = 0$, requires the incident waves remain long crested and two dimensional as they move through the surf zone. Hence, the initial conditions for a steady, uniform incident wave field have been established.

Another representation of the near shore wave field is that of a non-uniform sea surface in the alongshore direction, $\partial\eta/\partial y \neq 0$. Under this condition, additional driving forces for periodic variations in the longshore current velocity field may be expected. This condition may be a manifestation of either a short-crested sea surface or longer period edge waves. Both of these types of alongshore wave motion result in additional release of energy to the longshore current. However, at a fixed point in the surf zone, the direct cause of these secondary velocity fluctuations can not be established. Their magnitude will at best appear as a residual when all other primary fluctuations are accounted for.

Once the initial conditions describing the incident wave field have been established, the nature of the longshore current flow may be defined. As with the case of the incident wave field, the resulting longshore current flow field may be either uniform or non-uniform in its longshore extent. Classical treatments of longshore current have generally been restricted to a two dimensional long crested incident sea surface encroaching on a bottom with straight and parallel contours. Therefore, with the exception of rip cell formation, the longshore current is treated as uniform in the y -direction.

Figure 3 shows the various analytic assumptions which can be applied to the incident wave field and related longshore current. Existing longshore current theory is formulated on the assumption that only one of the eight possible combinations shown is observed in the surf zone (wave field steady and uniform, longshore current uniform and steady). The major restriction of these classical longshore current theories is that the motion has been confined to steady state, $\partial u_i/\partial t = 0$. The field investigation of Wood and Meadows (1975) has shown that at a fixed point in the surf zone variations in excess of 150 percent of the mean longshore current velocity occur over time periods from three to eighty seconds. These unsteady motions persist horizontally across the surf zone and vertically from the surface to the bottom. The persistence and magnitude of the observed velocity fluctuations imply that time dependent analytical treatments of conservation equations are necessary in order to properly predict longshore current velocity.

It is reasonable to assume that the total longshore current velocity field is composed of a steady and a fluctuating component which result from the incident wave field.

$$v = \bar{v} + v' \quad (13)$$

Recent field measurements (Wood and Meadows, 1975) suggest that the steady flow component and the fluctuating flow component are of comparable magnitude. Similarly, there exists in the surf zone driving components that can be expected to contribute only to the steady portion of the flow field and others that contribute only to the unsteady portions. Therefore, the governing differential equations for longshore current flow (Collins, 1972) should have been retained in their original time dependent form.

Consider the momentum and continuity equations for a two dimensional, incompressible, constant density fluid in the x and y direction (perpendicular and parallel to the beach respectively

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = -g \frac{\partial \eta}{\partial x} + T_x - B_x \quad (14)$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} = -g \frac{\partial \eta}{\partial y} + T_y - B_y \quad (15)$$

$$\frac{\partial \eta}{\partial t} + \frac{\partial (uh)}{\partial x} + \frac{\partial (vh)}{\partial y} = 0 \quad (16)$$

where T_x and T_y are the radiation stress components in the x and y direction respectively and B_x and B_y represent corresponding components of bottom friction.

Now let the velocity components u and v be composed of both a steady and a time dependent component of comparable magnitude, in the following form

$$u = \bar{u} + u' \quad v = \bar{v} + v'$$

and the free surface elevation, η , be similarly decomposed into a steady and a fluctuating surface component

$$\eta = \bar{\eta} + \eta'$$

The governing equations now become:

$$\begin{aligned} \frac{\partial u'}{\partial t} + \bar{u} \frac{\partial \bar{u}}{\partial x} + u' \frac{\partial \bar{u}}{\partial x} + \bar{u} \frac{\partial u'}{\partial x} + u' \frac{\partial u'}{\partial x} + \bar{v} \frac{\partial \bar{u}}{\partial y} + \bar{v} \frac{\partial u'}{\partial y} + \\ v' \frac{\partial \bar{u}}{\partial y} + v' \frac{\partial u'}{\partial y} = -g \frac{\partial \bar{\eta}}{\partial x} - g \frac{\partial \eta'}{\partial x} + T_x - B_x \end{aligned} \quad (17)$$

$$\frac{\partial v'}{\partial t} + \bar{u} \frac{\partial \bar{v}}{\partial x} + u' \frac{\partial \bar{v}}{\partial x} + \bar{u} \frac{\partial v'}{\partial x} + u' \frac{\partial v'}{\partial x} + \bar{v} \frac{\partial \bar{v}}{\partial y} + \bar{v} \frac{\partial v'}{\partial y} +$$

$$v' \frac{\partial \bar{v}}{\partial y} + v' \frac{\partial v'}{\partial y} = -g \frac{\partial \bar{\eta}}{\partial y} - g \frac{\partial \eta'}{\partial y} + T_y - B_y \quad (18)$$

$$\frac{\partial \eta'}{\partial t} + \frac{\partial [(\bar{u} + u')h]}{\partial x} + \frac{\partial [(\bar{v} + v')h]}{\partial y} = 0 \quad (19)$$

(Note: previous field observations have shown that $\partial \bar{u}/\partial t$ and $\partial \bar{v}/\partial t$ are non-zero terms due to slight variations in the main flow, however their magnitude is negligibly small).

Spectral analysis of the longshore current velocity series (Figure 4) indicated that significant energy was associated with the incident breaking wave period, 4.2 seconds. However, other dominant signatures occur at longer periods, with the maximum being 78.8 seconds. The observed longshore current velocity fluctuations seem to fall into three period ranges of interest. These periods are: 3 to 10 seconds, order of the incident breaking wave period, 25 to 200 seconds, range of the anticipated long period edge wave modes; and greater than 200 seconds, for the quasi steady state component.

The most obvious contribution to unsteadiness of longshore current velocity arises from the longshore component of the breaking wave horizontal particle velocity. Theory suggests that the longshore current velocity is most directly related to the magnitude of the longshore component of the breaking wave horizontal particle velocity at the surface, $c_b \sin \theta_b$. When time averaged, this oscillatory component was assumed to generate a mean longshore current, $\bar{v} = f(c_b \sin \theta_b)$. In order to evaluate the magnitude and the distribution of this component of the velocity field, only the periodic component of the velocity series is of interest. Hence, the steady state component was removed from the series. The magnitude of the horizontal particle velocity was evaluated throughout the water column. Experimentally derived profiles of maximum horizontal particle velocities and their variation with depth from the tank studies of Morison and Crooke (1953), and Divoky, Le'Mahaute' and Lin (1970), and the field studies of Miller and Zeigler (1964) and Wood (1970) were used for this evaluation. The calculated longshore component of these breaking wave maximum horizontal particle velocity profiles, $U_h' \sin \theta_b$, is plotted for each of the above studies on Figure 5. The velocity range for the three current meter depth locations through the water column of the observed periodic component of the longshore current from this investigation is also plotted on Figure 5.

The observed magnitudes of the fluctuating longshore current velocity compare favorably with the expected magnitudes of the longshore component of the breaking wave horizontal particle velocity. However,

FIGURE 4. POWER SPECTRA FOR UPPER CURRENT METER COMPUTED FROM FIFTEEN MINUTE LONGSHORE CURRENT VELOCITY SERIES.

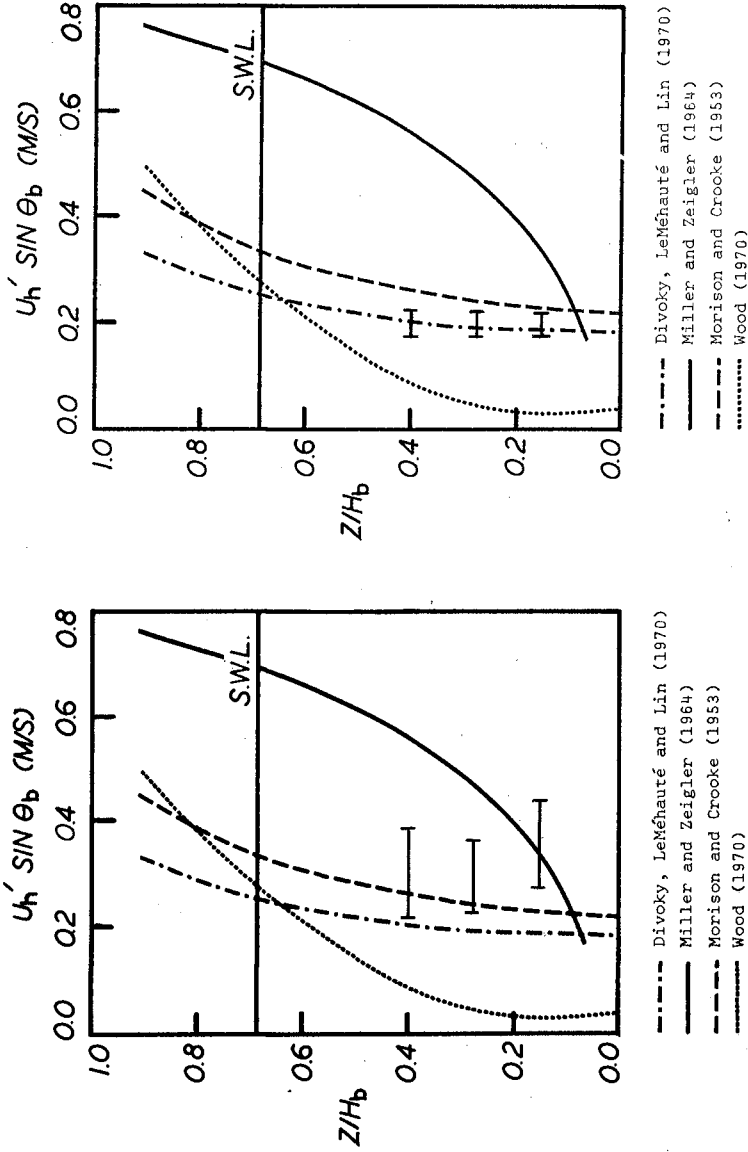

FIGURE 5. COMPUTED LONGSHORE COMPONENT OF BREAKING WAVE MAXIMUM HORIZONTAL PARTICLE VELOCITY COMPARED WITH OBSERVED DE-MEANED LONGSHORE CURRENT VELOCITY FLUCTUATIONS FROM THIS INVESTIGATION.

FIGURE 6. COMPUTED LONGSHORE COMPONENT OF BREAKING WAVE MAXIMUM HORIZONTAL PARTICLE VELOCITY COMPARED WITH OBSERVED DE-MEANED AND FILTERED WAVE PERIOD (3-10 SECONDS) LONGSHORE CURRENT VELOCITY FLUCTUATIONS FROM THIS INVESTIGATION.

the magnitude of the velocity fluctuations from this investigation are generally, with the exception of Miller and Zeigler (1964), 50 to 100 percent larger than would be predicted from these studies. Re-examination of the longshore current velocity series provides an explanation for this discrepancy.

The demeaned longshore current velocity records with which the horizontal particle velocity profiles were compared, contain additional frequencies of longshore current velocity fluctuations. To isolate only that component of unsteadiness associated with the longshore component of the wave horizontal particle velocity, all frequencies other than the breaker zone wave frequencies were removed from the record. Band pass filtering was performed on the fifteen minute longshore velocity records to remove the effect of any long period waves from the observed fluctuations. The filtered series only contained fluctuations whose periods were between 3 and 10 seconds, Figure 6. This filtered series is then the observed longshore current velocity component resulting from the breaking wave horizontal particle velocity, $U_h' \sin \theta_b$. This filtered series of longshore current velocity fluctuations exhibit several characteristics that would be anticipated to be associated with breaking wave induced motions. First, the velocity fluctuations are nearly symmetrical about the abscissas, thus, suggesting that these motions are truly the result of the oscillatory wave particle velocity. Second, the magnitudes of the observed fluctuations are nearly uniform with depth. Near uniformity with depth is suggested by shallow water wave theory as well as by the observed maximum horizontal particle velocity profiles of Morison and Croke (1953) and DiVoky, LeMehaute' and Lin (1970). The observed magnitudes of this filtered series of longshore current velocity fluctuations are in excellent agreement with the results of both previously mentioned tank experiments and are bracketed by the profiles obtained from the field investigations of Wood (1970), on the low side and by Miller and Zeigler (1964), at the upper end. This agreement suggests that the contribution of the breaking wave horizontal particle velocity to fluctuations in longshore current velocity has been isolated from the observed time series.

Results of spectral analysis of the fifteen minute longshore current velocity series has shown significant energy at a period of approximately 80 seconds. Examination of the band pass filtered (3-10 seconds), demeaned longshore current velocity series also shows repeated occurrences of groups of high velocity pulses in the longshore current. The regular occurrence of these pulses at approximately 80 second intervals suggest a correlation with the spectral signature at that same period.

The distinction must be made that the individual high velocity pulses still retain their identity of approximately 5 second period and that groups of these large pulses arrive as a beat phenomenon at

approximately 80 second intervals. However, for the spectral signature at an 80 second period to exist a wave phenomenon at that frequency must be present. Since, periodic amplitude modulation alone of the wave period fluctuating velocity series would not produce a spectral response at that period. It appears that this long period longshore current velocity fluctuation may be driven by the surf beat. Thus the fluctuating portion of the longshore current flow is composed of at least two distinct components. A component of period coincident with the breaking wave period and a long period component of approximately 80 seconds, Figure 7.

The original longshore current velocity series was then low band passed filtered to only allow periods between 200 seconds and 25 seconds to remain. This filtered, demeaned series (Figure 7) shows the existence of the anticipated long period wave phenomena of approximately 80 second period. The maximum magnitude of this velocity component was approximately $\pm .3$ m/sec. The phase of this long period fluctuating component corresponds to the arrival of groups of high velocity pulses of the wave period fluctuation series. If we return to the conservation of mass theory of Bruun (1963) the suggestion was made that the longshore current flow is a response of the surf zone to an influx of mass associated with transitory breaking waves. Since the arrival of the group of high velocity pulses in the longshore current velocity field, is in phase with the long period velocity fluctuation, then perhaps this oscillation is a response of the surf zone to an increased mass flux. As was suggested by Bowen (1967), a corresponding set-up, set-down phenomenon could be expected in the longshore direction. However, since this correlation does appear to exist between the long period and wave period portions of the fluctuating flow, the generation of a low mode edge wave may be a reasonable expectation. The calculated maximum period for a zero mode edge wave for the conditions of this field investigation was 77.8 seconds (Guza and Inman, 1975). The nearshore beach face slope of 5.7° approaches the 6° beach slope for which these calculations were made. This is in agreement with the observed 78.8 second period fluctuation in the longshore current velocity. However, the effect of the well developed barred beach configuration, present during this study, on maximum edge wave periods is not clear, the choice of an "effective" beach slope over this region greatly alters the anticipated edge wave periods. Edge wave period calculations for the area immediately adjacent to the steep beach face suggests a period of 27.7 seconds. Examination of the power spectra for the current meter array at this location in the surf zone does show a weak signal at this frequency.

The major portion of the observed time dependent fluctuations in the longshore current velocity can be accounted for by the two components previously discussed. However, the linear addition of the breaking wave period fluctuating component, V'_w , and the long period component, V'_L does not produce the original longshore current velocity series. The steady state component contributing to the longshore current velocity is absent from the series. The magnitude of the

REPRESENTATIVE FLUCTUATING LONGSHORE CURRENT VELOCITY SERIES FROM UPPER CURRENT METER: A) TOTAL OBSERVED LONGSHORE CURRENT VELOCITY SERIES; B) Demeaned LONGSHORE CURRENT VELOCITY SERIES; C) Demeaned, BAND PASS FILTERED (3-10 SECONDS) LONGSHORE CURRENT VELOCITY SERIES; AND D) Demeaned, BAND PASS FILTERED (25-200 SECONDS) LONGSHORE CURRENT VELOCITY SERIES.

steady longshore current velocity component \bar{V} , for this set of observations, was approximately 0.65 m/sec. For the purpose of this analysis, the steady state component is defined as the velocity component whose period of variation in magnitude is greater than 200 seconds. Therefore, there must exist a net stress on the fluid within the surf zone of sufficient magnitude to produce the observed steady component of the flow.

The radiation stress concept as applied to the generation of longshore currents by Longuet-Higgins (1970, 1 & 2) states that the presence of waves exerts a net stress on the water of the surf zone. This excess flow of momentum is a result of the flux, toward the shoreline of momentum parallel to the coast

$$S_{xy} = \int_{-h}^{\delta\eta} \rho u V dz. \quad (20)$$

This formulation, employing the radiation stress concept, for the prediction of steady longshore currents has been criticized (S.P.M., 1973) for predicting the magnitude of longshore currents too low. However, for the results of this investigation, the formulation of Longuet-Higgins predicts the magnitude of the steady component, that which it was intended to predict, very well. The calculated value for the steady longshore current component using this formulation was 0.61 m/sec. While the observed steady component ranged from 0.60 to 0.66 m/sec (Wood and Meadows, 1975).

CONCLUSION

Three distinct longshore current velocity components have been isolated which contribute to the total observed longshore current velocity

$$V = \bar{V} + V_w^i + V_L^i \quad (21)$$

where \bar{V} is the steady longshore current velocity component and V_w^i and V_L^i are respectively the wave period and long period fluctuating longshore current velocity components. The mean longshore current velocity component, \bar{V} , was found to be dominated by the combination of the fluctuating components V_w^i , the incident breaking wave period fluctuations, and V_L^i , the long period fluctuations. Variations in the longshore current velocity of 90 to 150 percent of the mean current velocity have been shown to occur over periods from 3 to 80 seconds and these fluctuations have also been shown to persist horizontally across the surf zone as well as vertically from the surface to the bottom. In addition an interactive mechanism appears to be in operation within the surf zone by which short period

velocity fluctuations, order of the incident wave period, appear to interact with long period fluctuations in the longshore current velocity. This interaction seems to be excited by 80 seconds periodic variations in the magnitude of the short period longshore current velocity fluctuations. Decomposition of the longshore current velocity record has shown that a steady state component also contributes to the observed velocity field. The formulation of longshore current theories based on temporally or spatially averaged quantities is a physically inappropriate procedure. In view of the results of the field investigation of Wood and Meadows (1975) it is unrealistic to expect a steady or slowly varying longshore current velocity field in the presence of an irregular oscillatory wave field. Consequently, a reevaluation of the reasonability of the steady state approach to the prediction of longshore current velocity is clearly needed. The success of solutions to problems associated with the coastal environment depends on an appropriate and complete understanding of physical processes active in the environment. The steady state approach to the longshore current velocity field cannot provide this understanding.

ACKNOWLEDGEMENTS

This study was supported by the Geography Programs, Office of Naval Research, through the Great Lakes Coastal Research Laboratory, Purdue University.

I wish to express my sincere appreciation to Dr. William L. Wood, Department of Geosciences, Purdue University, for his helpful comments and discussion during the preparation of this report as well as his untiring assistance in the field. I also wish to extend my appreciation to the staff of the Great Lakes Coastal Research Laboratory for their assistance in the field portion of this investigation.

CHAPTER 39

TERRESTRIAL PHOTOGRAMMETRIC MEASUREMENTS OF BREAKING WAVES AND LONGSHORE CURRENTS IN THE NEARSHORE ZONE¹

Joseph W. Maresca, Jr.² and Erwin Seibel³

I. INTRODUCTION

We conducted a study to determine the feasibility of shore-based, oblique photographic monitoring of breaking waves, water levels, and currents within the surf zone. The purpose of this paper is to describe a new method of oblique single-image and stereoscopic-image analysis, the potential errors, and the types of measurements that can be made in the surf zone. Examples of application are presented to demonstrate the technique. Sophisticated photographic equipment is not required to collect, analyze, and interpret the data. The analysis and error discussions are directed toward the problems encountered using common equipment.

Vertical images from aircraft, helicopters, and balloons have been used in the past to study shoreline changes,¹ directional ocean-wave spectra,² and longshore currents.³ Oblique images taken from the bridge of a ship have been successfully used to measure whitecap coverage under different wind speeds.⁴ Terrestrial oblique images have been used to study longshore currents,⁵ ice-ridge formation and breakup,^{6,7} and beach changes.⁸

Oblique images, taken with a 35-mm single-lens reflex camera from an elevated point such as a bluff, are particularly suitable for the measurement of breaking waves, water level, beach run-up, and current in the surf zone under storm conditions. In contrast to other techniques of monitoring the surf zone, the photographic technique described in this paper is simple to install, reliable, accurate, and inexpensive. It can be used in all weather conditions, and the analysis of the images is simple. Both stereoscopic and single oblique images can be analyzed, depending on the specific needs and existing environmental conditions. Since the scale of an oblique photograph changes with increasing distance from the camera, the technique is limited in range to about 250 m for a cliff approximately 8 m above the mean water level. Accuracies to within 1% in the horizontal plane and better than 10% in the vertical plane are achievable at this distance.

-
1. Contribution No. 209 of The Great Lakes Research Division, The University of Michigan, Ann Arbor, Michigan 48104.
 2. Stanford Research Institute, Menlo Park, California 94025.
 3. University of Michigan, Ann Arbor, Michigan 48104.

Higher accuracies are obtained as distance from cliff to camera decreases. The unique feature of the oblique image is that it provides a method of delineating changes in space and time without the need for an expensive array of instruments.

II. EXPERIMENTAL METHOD

No special equipment is required for taking the oblique images. If stereoscopic oblique images are required, two 35-mm single-lens reflex cameras can be used. The cameras should be tripod-mounted and separated by a known distance. Polarizing filters are useful to decrease the glare from the water surface. In this study, stereoscopic measurements were taken along the California coast by two cameras placed 8 m apart and 8 m above the mean water level. The focal lengths of the cameras' lenses were 50 mm. The nominal focal length is sufficient for analysis. Although the simultaneous camera exposures could be taken using a long shutter release, we took the exposure by voice command. The two exposures were found to be visually identical, so no more elaborate method was pursued. Kodachrome II color slide film (ASA 25) was used. The color film is necessary for easy identification of points on the image. Slides are necessary, since they can be projected on a screen and enlarged sufficiently until points can be easily identified.

Single and stereoscopic oblique images can be taken along any region, providing the cameras are above the mean water level and the horizon is clearly visible and horizontal in the viewfinder (Figure 1). If the tilt of the horizon is less than 1° , no correction for tilt is required. This is well within the visual judgment of the photographer. The available topography usually dictates the camera elevation. The authors have taken measurements at three camera elevations ranging from 8 to 24 m (depression angles ranging from 2° to 10°) and identified objects at over 600 m from the camera. Generally, for camera elevations of 10 m, measurements offshore are limited to about 250 m. The principal point of the image should be centered on the region of most interest.

For single oblique image analysis, no reference stakes are required if the horizon, the focal length of the camera lens, and the datum elevation are known. However, reference stakes are required for stereoscopic image analysis. The stereoscopic analysis requires that the principal axes of the two cameras are parallel ($\beta = 0^{\circ}$ in Figure 2). The reference stakes should be placed between the cameras. A minimum of three reference stakes are required to mathematically rotate the principal axis of one camera relative to the other camera such that $\beta = 0^{\circ}$. It is not necessary to relate the beach stakes to the camera.

If water level fluctuations are required at known points, it is suggested that plastic buoys supported by polyethylene floating rope be stretched offshore. Theoretically, this is unnecessary, but the floats provide identifiable points. This is unnecessary for the wave measurements.

III. ANALYSIS

The numerous methods of analysis of an oblique image are described in the Manual of Photogrammetry.⁹ The Equivalent Vertical Photographic Method of rectifying points in the oblique image to real ground distances is well suited for surf-zone analysis. Consider an oblique image (color slide) of a plunging breaker taken along the Northern California coastline (Figure 3). The field setup is shown in Figure 1 along with several of the important points of interest such as the plunging breaker, the buoys, and the beach reference stakes. The oblique slide was enlarged using a slide projector (and photographic enlarger), and these points were digitized (Figure 4) with respect to a rectangular coordinate system with the origin at the principal point of the projected image. Fundamental relationships of an oblique image required for the analysis of this digitized image can be derived from the principal-plane diagram (Figure 5) for a slide. The plane of the positive taken by a camera lens of focal length f is defined by the points T, P, I, and N, where T is the intersection of the horizon with the principal plane, P is the principal point of the image, I is the isocenter of the image, and N is the nadir point. The depression angle, θ , is the vertical angle from the horizon plane to the optical axis. The tilt of the photograph is defined as $t = 90 - \theta$. The equivalent vertical photograph is the imaginary photograph that would be obtained if $t = 0$. The equivalent vertical photograph intersects the oblique image at the isocenter. The isoline, the line created by the intersection of the equivalent vertical photograph and the oblique image, is common to both images.

The equations required to calculate real ground distances with the origin at the camera from an oblique slide are given below. The analysis includes the effects of magnification of the slides. The magnification of the slide C is the ratio of the height of a slide, d_1 , to the height of the slide on the screen, d_2 , or

$$C = \frac{d_1}{d_2} . \quad (1)$$

The locations of the points P, T, I, N along the principal plane can be calculated if the positions of any two points are known. Points T and P can be measured directly from the image, and points I and N can be calcu-

lated. Then the coordinates of any point in the equivalent vertical photograph can be determined. The principal point of the enlarged oblique image is the center of the image. The distance from the principal point, P, to the apparent horizon point, T, on the slide, \overline{PT} , can be measured directly. The apparent depression angle, θ' , is

$$\theta' = \arctan (C \overline{PT}/f) \quad (2)$$

The apparent horizon is slightly lower than the true horizon, and a correction angle, $\delta\theta$, can be added to θ' to obtain the true horizon:

$$\delta\theta = 0.98(H)^{\frac{1}{2}} \quad (3)$$

where H is in feet and $\delta\theta$ is in minutes.

Thus,

$$\theta = \theta' + \delta\theta \quad (4)$$

and

$$\overline{PT} = f \tan \theta \quad (5)$$

The following distances in the oblique image are given without derivation:

$$\overline{PI} = f \tan \frac{\theta}{2} \quad (6)$$

$$\overline{PN} = f \tan \theta \quad (7)$$

$$\overline{TI} = \overline{PT} + \overline{PI} \quad (8)$$

$$\overline{TN} = \overline{PT} + \overline{PN} \quad (9)$$

Using Eqs. (1) through (9), we obtain the coordinates of any point in the equivalent vertical photograph (X_{evp} , Y_{evp}), with the origin at the camera (i.e., the principal point of the equivalent vertical photograph, and not the isocenter):

$$X_{\text{evp}} = X_{\text{ob}} C \left(\frac{\overline{TI}}{\overline{TI}-K} \right) \quad (10)$$

$$Y_{evp} = K \left(\frac{\overline{TI}}{\overline{TI}-K} \right) + \overline{NI} \quad (11)$$

where $K = Y_{ob} C + \overline{PI}$, $\overline{NI} = \overline{PI}$, and (X_{ob}, Y_{ob}) are the coordinates of any point on the enlarged oblique image with the origin at the principal point of the oblique image. The real ground coordinates (X_{gr}, Y_{gr}) of any point on the equivalent vertical photograph with respect to the camera are given by

$$X_{gr} = \left(\frac{H X_{evp}}{f} \right) \quad (12)$$

$$Y_{gr} = \left(\frac{H Y_{evp}}{f} \right) \quad (13)$$

where H is the difference in elevation between the camera and the point on the ground. If single images are being analyzed, H is the datum. Usually H is the difference between the elevation of the mean water level and the camera. Thus, horizontal distances can be calculated using Eqs. (12) and (13). The height of an object in a single oblique image can be calculated if the object is vertical. For vertical objects in which the bottom and top points are visible, the height, h , is given by

$$h = \frac{H(K_{top} - K_{bot}) \overline{TN}}{[(TN - TI) + K_{top}] (TI - K_{bot})} \quad (14)$$

where Y_{ob} in K_{top} is the "Y" coordinate of the top point of the vertical object and Y_{ob} in K_{bot} is the "Y" coordinate of the bottom point of the object.

If the datum fluctuates in time and space and the actual elevation of each point is of interest, then stereoscopic images are required. If two cameras with their optical axes approximately parallel are used to simultaneously take overlapping pairs of slides, then the real ground height below the camera of each point in the oblique image can be determined from parallax measurements.

The algebraic difference in the "X" coordinates of the same point in each slide of the stereo-pairs is the parallax, P , and is given by

$$P = X_{\text{evp}} - X'_{\text{evp}} \quad (15)$$

where X_{evp} and X'_{evp} are the left and right "X" coordinates on the equivalent vertical photograph. The difference in elevation between the camera and the point is given by

$$d = \frac{f B}{P} \quad (16)$$

where B is the baseline distance between cameras. Thus the real ground distance of any point in the oblique image is given by Eqs. (12), (13) and (16) if $H = d$.

IV. SINGLE-IMAGE ANALYSIS

Single oblique images can be used to measure horizontal distances such as the location of the breaker zone, nearshore wavelength, run-up on a flat beach, and ice-ridge location, using Eqs. (12) and (13) with the mean water level as the datum. For example, this method was applied to the comparison of the location of the breaker zone to the location of nearshore ice ridges found during the winter on Lake Michigan (Figure 6). These measurements are sometimes difficult to obtain by any other technique. Fluorescein dye and floats are often used to monitor the mean longshore current velocity in the nearshore zone. Consider a sequence of time-interval photographs of a dye patch at times 0, 30, and 60 s [Figures 7(a), (b), and (c), respectively]. Elaborate systems have been used to obtain vertical photographs.³ Single oblique images can be used to make the measurements from shore. The real ground positions of the dye patch are shown in Figure 8. The mean longshore current can be calculated from the displacement of the centroid of the dye patch over time. Plunging-breaker heights can be estimated using Eq. (14). Consider the oblique image of a plunging breaker shown in Figures 3 and 9. The crest of the breaker (point A) and the intersection of the plunging breaker with the mean water level (point C) are points that can be identified on the oblique image. If the crest and the point directly below the crest (point B) could be identified, then Eq. (14) could be used directly to measure the vertical height of the wave. Although the height A-B is not a true measure of breaker height (usually defined as the difference in elevation between the crest and the trough), it does provide a good estimate. In general, point B cannot be precisely identified on images of this type. However, it is possible to estimate point B. Then, using points A and B, Eq. (14) can be applied directly. Since our estimated location of point B may not be directly below point A, an error can be expected. If the oblique image is taken when points B and C are visible along the wavefront, we can estimate the maximum possible error in the selection of point B. This possibility is considered in Figure 9. To

quantify the possible error, assume that the breaker is circular. Therefore, the maximum horizontal displacement is $\frac{1}{2}H_b$. This results in an estimate of the wave height too large by \overline{DE} shown in Figure 9. If a more realistic plunging-breaker shape were chosen, then a better estimate of the true plunging-breaker height would result. The above technique has been used in the field (Figure 10) and gives accurate estimates of the breaker heights.

To determine the accuracy of this simple estimate of the plunging-breaker height, a laboratory study was conducted. Circular waves 4.1, 7.7, 10.8, and 16.8 cm in diameter were constructed out of white paper. Oblique images of the paper waves similar in perspective to those found in nature were taken. The camera was kept at the same elevation but was moved farther away from the paper waves. This also changed the depression angles. The results of the experiment are shown in Figure 11. Errors of less than 5% were found. The greatest fluctuation around the mean occurred at the greatest distance from the camera because the points on the wave, such as the crest, could not be positively identified. We expect that accuracies of better than 10% can be expected routinely in the field. Further tests comparing the photographic method with wave-gauge measurements are planned.

V. STEREOSCOPIC OBLIQUE IMAGE ANALYSIS

More comprehensive measurements can be made if stereo-pairs are taken, since the vertical coordinate can be calculated directly. Thus wave height, water level fluctuations, and beach profiles can be obtained. While the single-oblique-image method can be applied at any location, providing the camera elevation above the datum is known, the stereoscopic oblique-image method requires reference stakes located between the cameras. Using the reference stakes, the angular rotation (Figure 2) of the left camera relative to the right camera can be computed. Any deviation greater than 0.1° , such that the optical axis of the left camera is not parallel to that of the right camera, will induce large errors in the analysis of the vertical coordinate using parallax. From experience, we have found that a minimum of three stakes and preferably five stakes are required. The relative elevation and distances between stakes can be surveyed simply with the stake and horizon method of Emery,¹⁰ using standard surveying instruments. If the cameras are not parallel, the rotation error can be determined and a mathematical correction to the horizontal coordinates (X_{evp}, Y_{evp}) of an equivalent vertical photograph can be made. Assume that the left camera is oriented correctly and rotate the right camera until the absolute values of the "X" coordinates in the left and right oblique image of each reference stake add to the baseline separation difference between cameras - - i.e.,

$$B = |X_{\text{left stake}}| + |X_{\text{right stake}}| \quad (17)$$

Due to measurement error, an average of the rotation error can be determined from three or more reference stakes. The accuracy of the correction can be determined by calculating the relative elevation and separation differences between stakes. Any rotation will result in increasing elevation errors with increasing offshore distance. The corrected equivalent vertical photograph coordinates are given by

$$X_{cevp} = X_{evp} \cos\beta + Y_{evp} \sin\beta \quad (18)$$

$$Y_{cevp} = -X_{evp} \sin\beta + Y_{evp} \cos\beta \quad (19)$$

where X_{evp} and Y_{evp} are given by Eqs. (10) and (11), and β is the rotation angle.

The analysis proceeds as for the single-image analysis except that identical points must be selected in each slide (Figure 12). Identical points can be selected along the wave crest without much difficulty. However, it is not as easy to select points in the wave trough. If repeated measurements are to be made at one site, a string of buoys will provide profile lines to identify the water level at about the same point over time. An example of the water level fluctuation at two buoys separated by 8 m is given in the time series in Figure 13. If identical points are not selected in each photograph, it is usually immediately obvious, because unrealistic fluctuations occur.

VI. ERROR ANALYSIS

There are three primary sources of error in the analysis. These are:

- Measurement error
- Datum error
- Rotation error.

The measurement error is common to both the single and stereoscopic-oblique-image analyses, while the datum error affects only the single-oblique-image analysis and the rotation error affects only the stereoscopic-oblique-image analysis. There are other sources of error - - for example, due to horizontal tilt; uncertainty in the absolute focal length of the camera, uncertainty in the simultaneous exposure of the stereo-pairs, and surveying error. However, these effects are apparently negligible in the analysis.

A. Datum Error

Other than measurement error, the largest error in single-oblique-image analysis is due to the uncertainty in the datum elevation. In single-oblique-image analysis, it is assumed that all points lie on the datum. The datum in our analysis is the mean water level. Since the water surface fluctuates around the mean water level, the horizontal coordinates will have some error (Figure 14). For example, if a dye patch is determined to be 150 m from the camera at an elevation of 8 m, and the water level fluctuates ± 10 cm around the mean, then the error is approximately 1 m in the offshore (Y) direction. The longshore (X) direction error is not reported, since it is not significantly affected by a datum error, and most horizontal measurements in the nearshore zone such as breaker zone, wavelength, and run-up are Y-dependent. The error in the location of a breaking wave is more critically dependent on the datum. If the amplitude of a breaking wave (crest to mean water level) located 150 m offshore is 50 cm, then an error of 7 m in the offshore distance results. However, an estimate of the amplitude of the breaker height can be made and subtracted from H to give a more realistic offshore coordinate. Therefore, a datum error of 10 cm or less can be expected for most measurements.

B. Rotation Error

Rotation primarily affects the calculation of elevation since the parallax is dependent on the "X" coordinates of an object in two oblique images. The angular rotation of one camera relative to the second required to make the line of sight of both cameras parallel is defined as β (Figure 2). If β is greater than zero degrees, an error will result. The effects of rotation error (Figure 15) increase significantly with increasing distance offshore. A relief error of over 5 m is expected at 150 m from shore if the angular rotation is 0.8° . Fortunately, the angle β can be calculated to within $\pm 0.01^\circ$. Therefore, these large errors are not found in the analysis. However, Figure 15 indicates how critically dependent the stereoscopic analysis is on rotation, and emphasizes the need for reference stakes on the beach.

C. Measurement Error

Measurement error is the primary source of error in our oblique-image analysis, because the analysis is done by hand and does not utilize the sophisticated equipment commonly used in aerial surveys. The measurement error includes the effects of outlining the enlarged slide frame, locating the principal point, drawing the (X_{ob} , Y_{ob}) axes through the principal point, drawing and digitizing the horizon, selecting the image point from the slide, and measuring its coordinates with a caliper. All measurements were made with a caliper accurate to ± 0.001 inch. Repeated measurements indicated that an error of ± 0.003 inch can be expected from

any one measurement. The expected measurement error due to all the above sources was found to be about 0.015 inch. The (X_{ob} , Y_{ob}) coordinates of two different reference stakes located about 35 m from the camera were measured from 50 different oblique exposures. The standard deviation of the measurement was 0.016 and 0.015 inch, for the left and right cameras, respectively.

The effects of a possible measurement error in the X direction (ΔX) and in the Y direction (ΔY) of 0.005, 0.010, 0.015, 0.020 and 0.025 inch on the ground coordinates were calculated for three locations. The error analysis was applied at the reference stakes (35 m), the offshore buoys used to calculate mean water (50 m), and the breaking wave (150 m) in Figure 1. Corrected datum levels were used in the calculation. The results are shown in Figures 16 through 20.

The error in estimating a plunging-breaker height by single-oblique-image analysis 150 m from the camera is shown in Figure 16. A total measurement error of 0.015 inch in determining the Y_{ob} coordinate would result in a 15-cm error. This error includes the effects of selecting the points from the image, including the uncertainty of selecting the trough. Since the computation depends on the difference between two " Y_{ob} " coordinates, and the major portion of the 0.015-inch error is a constant bias and not a random error for this calculation, better accuracies are possible.

The possible measurement errors in the longshore (X) and offshore (Y) directions for single oblique images are shown in Figures 17 and 18. Measurement error is linear in the X direction and negligible over the range of offshore distances assumed in the analysis. Although the error in the offshore distance is larger than the error in the longshore direction, it too is small. For example, a measurement error of 0.015 inch in a wave 150 m from shore results in an error of about 3 m. This is about 2%, which is sufficiently accurate for most measurements.

The range of possible relief errors for stereoscopic oblique image analysis due to measurement errors in X_{ob} and Y_{ob} is shown in Figures 19 and 20. Since the calculation of X_{evp} in Eq. (10) is dependent on the calculation of Y_{evp} , the measurement errors in the Y_{ob} direction will effect the parallax. In fact, for increasing offshore distances the effect of ΔY measurement errors increases until it affects the parallax more rapidly than do ΔX measurement errors.

For offshore distances greater than 150 m, the relief errors are more dependent on ΔY measurement errors than on ΔX measurement errors. The family of curves in Figure 19 would be linear if the same datum were assumed for all calculations.

VII. CONCLUSION

Single- and stereoscopic-oblique-image analysis can be used to monitor waves, water level, and longshore currents in the nearshore zone using a 35-mm camera, a tripod, and a slide projector. Accuracies of 10% or better can be attained for these measurements. This technique should find application in coastal monitoring programs.

Acknowledgments. The authors would like to express their appreciation to Messrs. C. Carlson, J. Maresca, Sr., G. Springer, C. Vogelsang, and W. Zavoli for their assistance in the field experiments. We express appreciation for Mr. C. T. Carlson's efforts in assisting in developing and refining this technique for application to nearshore ice studies on Lake Michigan. We would also like to thank Dr. C. Olson for his encouragement and helpful discussions on analysis of oblique images.

CHAPTER 40

NON-UNIFORM ALONGSHORE CURRENTS

Michael R. Gourlay *

Abstract

Alongshore gradients of breaker height have been shown to significantly influence the velocities and circulation patterns of nearshore current systems. Experimental data from an idealized laboratory experiment shows that the form of the nonuniform wave generated current system resulting from diffraction behind an offshore breakwater is essentially determined by the beach-breakwater geometry while its magnitude depends upon the wave height. Furthermore the current may produce significant increases in the magnitude of the wave set-up within the three dimensional system. For the case investigated, where the alongshore gradient of breaker height is comparatively large, the maximum mean alongshore current velocity is not greatly affected by bottom resistance and may be computed for plunging breakers from a relation of the following form;

$$\frac{v}{\sqrt{gH_b^3}} = f\left(\frac{H_b}{d_b}, \frac{x_p}{H_b}, \tan \alpha\right)$$

derived from a simple momentum analysis including "radiation stress" terms. The influence of bottom resistance can be included if necessary.

1. Introduction

The phenomenon of the uniform alongshore current caused by waves breaking at an angle to a straight beach has received a considerable amount of study (1,2). The simple case with waves of uniform height seldom occurs in nature and in practice there is often an alongshore gradient of breaker height which influences the velocity and form of the alongshore current (3). Indeed it is now generally accepted that rip currents are produced by regular alongshore variations in the breaker height (4,5). Moreover it is possible, when the approaching wave crests are parallel to the coast, that the current velocity and circulation pattern are almost completely determined by alongshore breaker height gradients (6).

In the vicinity of coastal structures and coastal features such as reefs and headlands it has been found that wave generated current systems are very much influenced by variations both in the breaker height in the alongshore direction and in the location of the break point relative to those structures and/or features which determine the local coastal geometry (7). In general, any nearshore wave generated current system where breaker height and/or breaker angle varies along the shore may be described as a non-uniform alongshore current.

The author's investigation involved a laboratory study of a non-uniform alongshore current system generated by an alongshore gradient of breaker height with the wave crests parallel to the beach. A previous paper (6) described the experimental arrangements and techniques; presented the general results of a typical test; and treated some aspects involving the calculation of the wave set-up. This paper presents experimental results for various deep water wave heights, H_0 , and two wave periods, T , and describes a simple method for calculating the wave generated current for the situation where the driving force causing the current is created solely by the alongshore gradient of breaker height.

2. Laboratory Experimental Arrangements

The layout of the 12.5 m by 6.6 m outdoor test basin and the measurement methods used were described in a previous paper (6) to which the reader is referred for a more complete description. The experimental arrangement involved the generation of a non-uniform alongshore current by wave diffraction behind an offshore breakwater in a three dimensional fixed bed laboratory model (Figure 1). Waves approached with crests parallel both to the breakwater and the exposed portion of the 1 in 10 concrete beach while the beach in the sheltered area was curved so that it was parallel to the crests of the diffracted waves. Waves thus broke at all times parallel to the beach. The breakwater itself was located at a distance of 3.05 m from the still water line in the exposed area, while the constant offshore water depth at the head of the breakwater was 0.2 m.

Wave heights were recorded using capacitative wave probes and a twin channel pen recorder; wave set-up was measured using piezometer tappings in the beach and a multitube manometer; and current velocities and circulation patterns were obtained from the analysis of movie film records of the paths of small almost neutrally buoyant floats together with some direct measurements with a modified total head tube device (see section 3.1).

3. Results of Laboratory Investigation

3.1 Basic Characteristics of Non-uniform Alongshore Current System

The characteristics of the current system generated in the test basin were described in a previous paper (6). In that description the results of one test only for a specific H_0 and T were considered. To assist in the understanding of the results presented in this paper a brief description of the current system will be given first. Referring to figure 2 it can be seen that as a consequence of the diffraction of the waves by the offshore breakwater, the surf zone is wide in the exposed area where the waves are large while it is narrow within the sheltered area where the waves are of necessity very much smaller. An alongshore gradient of breaker height is thus present and this results in an alongshore gradient of wave set-up since the latter is generally proportional to the breaker height in shallow water.

Now the wave set-up itself is maintained by the onshore thrust created by the change in momentum as the breaking waves are dissipated within the surf zone. However there is no such opposing thrust in the longitudinal direction to balance the alongshore gradient in the mean water level resulting from the alongshore variation in wave set-up. The result is that an alongshore current flows from the surf zone of the exposed area into the sheltered area. Since the geometry of the system is a closed one the alongshore current becomes a circulatory eddy. Referring to figure 2 it is seen that the entire circulation is contained inside the point where the exposed area breaker height is a maximum, i.e. inside of the first interference maximum of the diffraction pattern.* Moreover the seaward limit of the current is initially defined by the location of the plunge point in the exposed area since this represents the point in the onshore-offshore direction where wave set-up commences. Between the point of maximum breaker height and the geometric shadow of the breakwater there is a zone of spatially varied flow where the alongshore current discharge increases as it travels towards the sheltered area since water flows inshore through the breakers from further

* A series of secondary circulation systems is set up in the exposed area where the alternating interference maxima and minima provide the necessary alongshore gradients in energy levels to produce rip currents. The first such rip current occurred within the test basin but as it was affected by the presence of the model sidewall (especially for 1.5 second waves) it was not studied in detail.

offshore. The current discharge itself attains a maximum value at the geometric shadow of the breakwater.

Within the sheltered area the current becomes too large to remain within the rapidly narrowing surf zone and so flows increasingly outside the breaker line until it is eventually completely removed from the surf zone. It is deflected by the stagnation eddy at the corner where the breakwater intersects the curved beach. The return circuit is then completed as the current flows along the shoreward face of the breakwater before turning shoreward at the head of the breakwater to flow back into the surf zone in the inflow region. Inside the primary wave generated current the initially motionless fluid is set in motion by the current and moves as a slow induced eddy within the main current system.

The driving force for the current system appears to be essentially the increase in head created by the breaking waves in the inflow region. Indeed the current system can be visualized as being powered by a "pump" located in the inflow region drawing water in from the offshore zone and discharging it as a high velocity "jet" parallel to the beach. The "jet" is then deflected by the curved beach and breakwater so that it flows back into the "pump" inlet, offshore of the inflow region. Diffusion of momentum offshore creates the induced eddy inside the primary current circulation.

Observations of horizontal velocity profiles of the current, made from photographs of surface floats, indicate that the surface velocity profile is approximately parabolic in shape with a rather well defined offshore boundary between the primary alongshore wave generated current and the induced eddy inside it (figure 3). Measurement of the vertical velocity profile of the alongshore current is much more difficult on account of the very shallow depths in the surf zone and the unsteady nature of the wave orbital motion superimposed at right angles to it. Figure 4 shows one such profile measured along the line of the geometric shadow of the breakwater using a small pitot tube device with two total head tubes, one pointing upstream and the other downstream. Figure 4 includes surface float data from figure 3 which are found to be consistent with the sub-surface measurements resulting in the velocity contours as shown. The maximum velocity occurs within the surf zone, just below the wave trough elevation. Integration of the velocity with respect to depth indicated that the actual current discharge (or mean velocity) is in fact about 50% greater than that calculated from surface float velocities alone. Consideration of the isovel pattern, together with visual observation of the uprush-backwash cycle in the test basin shows that there is spiral secondary flow superimposed upon the primary alongshore current similar to the helicoidal flow observed in the field by Eliot (8) for alongshore currents.

3.2 Influence of Variations in Wave Height and Period upon the Current System

The effect of variations in input wave conditions, upon the wave generated current system was obtained from the results of two series of tests, one made with a wave period of 1.0 seconds, the other with a period of 1.5 seconds. Each test series consisted of four tests with different deepwater wave heights. Two parallel series of tests were also made in which the sheltered area of the test basin was blocked off so as to give two dimensional conditions in the exposed area.

The experimental results indicate that there is a general overall similarity of the current circulation system for all H_0 and T . Variations in detail do occur but the geometrical form of the beach and breakwater determine the overall form of the current system. For instance when breaker height H_b and wave set-up at the still water line $\bar{\eta}_s$ are made nondimensional in terms of H_b^* and $\bar{\eta}_s^*$, their equivalent two dimensional values for the same H_0 and T , general similarity is found for each period (figure 5). Different wave periods which correspond to different

deep water wave lengths, L_0 , cause some differences in the alongshore gradients of breaker height and wave set-up. Specifically, in the region between the maximum wave height in the exposed area and the geometric shadow of the breakwater, the alongshore gradient of dimensionless wave set-up is greater for 1.0 second period waves than for 1.5 second waves. This difference is in agreement with diffraction theory. The alongshore dimensionless breaker height also varies locally in two regions with the deep water wave height. This effect, which occurs in the sheltered area in the vicinity of the stagnation eddy and in the exposed area outside the primary current circulation system, is caused by interaction between the waves and the wave generated currents.

Similarity of the alongshore velocity profiles may be considered from two points of view. The first is to express the velocity profiles in nondimensional parameters based upon the breaking wave conditions which should relate the velocities to those quantities which most directly influence them. Alternatively the alongshore current velocities can be related to the incident or deepwater wave conditions and geometric factors which determine the overall characteristics of the nearshore current system.

Consideration of theoretical investigations for uniform alongshore currents such as that of James (9) suggests that an appropriate set of dimensionless parameters to represent this data would be the following:

$$\frac{v}{\sqrt{gd_b^*}} ; \frac{x}{d_b^*} ; T\sqrt{\frac{g}{d_b^*}}$$

where v is the alongshore velocity at distance x from the still water line;

$$d = \bar{\eta} + h \text{ is the mean water depth;}$$

$$h \text{ is the still water depth.}$$

These parameters are used to plot dimensionless velocity profiles along the geometric shadow for wave periods of 1.0 and 1.5 seconds as shown on figure 6. There is considerable scatter in the data points but it does appear that the dimensionless velocity and distance parameters are satisfactory. However it is evident that the 1.0 second period tests do not show the same consistent variation with the third parameter as shown by the 1.5 second tests. Moreover the magnitudes of this latter parameter are inconsistent for the two wave periods. Analogy between James' theory and theory for non-uniform alongshore currents (e.g. Komar (3)) shows that the velocity profiles could also be affected by the following dimensionless quantities:

$$\frac{dH_b}{dy} ; \gamma = \frac{H_b}{d_b} ; N ; C_f ; \tan \alpha$$

Of these, the bottom slope $\tan \alpha$ was constant in these tests. The bottom friction coefficient C_f is a complex function of the wave orbital velocity and the alongshore velocity. As indicated in section 4.3, bottom friction effects are relatively small in this situation. The factors upon which the lateral mixing coefficient N depends are not yet clear and its exact magnitude remains uncertain. The alongshore gradient in breaker height will only affect the alongshore velocity significantly if bottom friction is important. Otherwise it is the dimensionless difference in alongshore breaker height $\Delta H_b/H_b^*$ which is important and this is the same for both wave periods. This leaves only the breaker index γ as an alternative relevant third parameter. However, while there is some evidence of better agreement between the two series of tests when the equivalent two dimensional breaker index γ^* is considered as the third parameter on figure 6, complete consistency is impossible since γ^* varies in opposite senses for the two wave periods.

Figure 7 shows the dimensionless maximum alongshore velocity as a function of the alongshore distance y for each wave period. This clearly indicates that the magnitude of the velocity is influenced by quantities other than $\sqrt{gd_1^3}$ but as before it is not possible to deduce a simple dependence upon any one of the parameters previously considered which applies to both wave periods.

Considering the alternative of relating the current velocity to the deep water wave conditions it is quite evident that the alongshore current velocity increases with wave height. Consequently the maximum velocity v_m was plotted as a function of H_0 for each location along the shoreline. A simple picture emerged in which $v_m = B(t)H_0$ where $B(t)$ varied consistently along the shoreline. Figure 8a shows the plot of v_m versus H_0 for the profile at the geometric shadow. Similar plots were obtained at the other locations with relatively few discordant points. The magnitude of $B(t)$ has been plotted as a function of the alongshore distance in figure 8b. This figure suggests that, apart from the slight variation with wave period of the location of the point where the current commences, which is a result of the effect of the wave length upon the diffraction process, the wave period does not enter the current velocity similarity parameter. Thus the alongshore current velocity is apparently determined by the deepwater incident wave height H_0 and the geometric characteristics of the system. As the latter were not varied in these tests the relevant variables can only be inferred at this stage. The relevant parameters could be the following:

$$\frac{v_m}{\sqrt{gd_1}} = B\left(\frac{H_0}{X}\right)$$

$$\text{where } B = f\left(\frac{y}{X}, \frac{d_1}{X}, \tan \alpha\right);$$

d_1 is the incident water depth at the breakwater ;

and X is the distance between breakwater and still water line.

3.3 Interaction between Alongshore Current and Wave Set-up

As previously mentioned the alongshore current modifies the breaker heights in certain regions. The wave set-up is also modified by changes in the mean water level created by the current system. In figure 9 the wave set-up at still water level, $\bar{\eta}_s$, is plotted as a function of the corresponding breaker height measured in the three dimensional basin, for each of the four tests with 1.0 second wave period. For comparison the equivalent relation between $\bar{\eta}_s$ and H_b derived from the two dimensional tests is shown on each plot. It can be clearly seen that in the three dimensional case the wave set-up $\bar{\eta}_s$ is relatively greater than its two dimensional value for the corresponding breaker height and that this discrepancy increases with increasing deep water wave height H_0 . Since the current velocity also increases with H_0 (figure 8) it would appear that $\bar{\eta}_s$ increases as the current velocity increases. The tests with 1.5 second period waves indicate a similar result. In figure 10, $\bar{\eta}_s$ is plotted on a very much magnified scale as a function of the distance along the still water line for one of the tests. Also shown on figure 10 is the equivalent two dimensional wave set-up $\bar{\eta}_s^*$ corresponding to the observed alongshore variation in breaker height. $\bar{\eta}_s^*$ is plotted downwards from the corresponding three dimensional value of $\bar{\eta}_s$ and, except at two points, the two dimensional value is generally about 10 to 15% smaller than the three dimensional value.

The following specific characteristics of the alongshore variation of wave set-up may be discerned from figures 9 and 10:

- (i) The wave set-up has its maximum value in the region within the exposed area outside the primary alongshore current system where it is essentially independent of the breaker height (see also figure 5). This represents the effect of the alongshore feeder currents to the rip current, which produce a stagnation condition on the shore at the point where the rip current flows seaward through the breaker zone.
- (ii) The two dimensional wave set-up is greater than the three dimensional set-up at points where there is inflow into the surf zone and alongshore outflow in both directions with a consequent reduction in the magnitude of the backwash.
- (iii) The maximum discrepancy between the three and two dimensional wave set-up generally occurs at or near the geometric shadow line defining the boundary between exposed and sheltered areas. This corresponds to the region where the alongshore velocity attains its maximum value.
- (iv) The minimum value of wave set-up occurs within the sheltered area but not right at the corner on account of refraction of the waves by the current which increases breaker heights within the stagnation eddy but reduces them further upstream.

The explanation for the difference between the three and two dimensional wave set-ups is found in three separate factors. These are breakpoint set-up, $\bar{\eta}_b$; superelevation caused by normal acceleration, $\bar{\eta}_c$; and alongshore translation of the uprush-backwash cycle, $\bar{\eta}_d$. Hence the wave set-up at the still water line at position y within the region influenced by the primary alongshore current is given as follows:

$$\bar{\eta}_s = \bar{\eta}_s^* + \bar{\eta}_b + \bar{\eta}_c + \bar{\eta}_d$$

Breakpoint set-up $\bar{\eta}_b$

In the three dimensional case expansion of the diffracted wave crests behind the breakwater causes a reduction in radiation stress and a consequent increase in mean water level. This results in a breakpoint set-up $\bar{\eta}_b$ in the sheltered area of the order of 1 mm for the particular test shown on figure 10. This factor accounts for about half the observed discrepancy in the stagnation region. In the exposed area there is a breakpoint set-down of similar order of magnitude.

Superelevation caused by normal acceleration $\bar{\eta}_c$

The alongshore current is deflected by the beach and the resulting normal acceleration results in a superelevation of the water surface on the beach. This has been calculated using the relationship

$$\bar{\eta}_c = \sum \frac{v^2}{gr} \Delta r$$

where r is the radius of curvature of the flow streamlines.

The value of $\bar{\eta}_c$ has been plotted on figure 12 upwards from the breakpoint set-up level. It is found that all the three dimensional wave set-up is now accounted for within the stagnation eddy region. With regard to the rip current in the exposed area, calculation of the stagnation velocity of the alongshore feeder currents confirms the previously quoted explanation for the increased wave set-up in this region.

Alongshore translation of uprush-backwash cycle $\bar{\eta}_d$

Visual observation in the test basin suggested that the process referred to earlier in which a helicoidal secondary motion is superimposed upon the primary alongshore current also provides the explanation for the remaining component of the three dimensional wave set-up in the vicinity of the geometric shadow of the breakwater where the alongshore current has its maximum value. Referring to

figure 11 it can be seen that the wave set-up at a point on the beach is in fact determined by waves breaking further upstream along the beach since the alongshore current translates the wave uprush-backwash cycle along the beach. Thus the magnitude of the wave set-up at a point C within the alongshore current depends upon the height of the breaking waves between points A and B upstream of it; and not upon the breaker height at point D on the same profile as point C.

The actual magnitude of the increase in $\bar{\eta}_s$ at point C will depend upon both the velocity of the alongshore current between points A and C and the alongshore gradient of breaker height between points A and B. A simple estimate of this effect was calculated using the observed variation of mean alongshore velocity V and the alongshore variation of the gradient of $\bar{\eta}_s^*$ calculated from the observed breaker heights. Assuming that the mean alongshore displacement distance Δy is equal to the distance travelled by the mean alongshore current during one wave period T , the increase in wave set-up, $\bar{\eta}_d$, at a certain point is given by the following expression:

$$\bar{\eta}_d = VT \frac{d(\bar{\eta}_s^*)}{dy}$$

where the magnitudes of $\frac{d(\bar{\eta}_s^*)}{dy}$ and V are those at a point located a distance equal to $\Delta y = VT$ upstream of the point under consideration.

The results of this calculation are found to give values of $\bar{\eta}_d$ which agree to within 0.3 to 0.5 mm of the observed values. The agreement is particularly good in the inflow zone in the exposed area but not so good in the sheltered area where the current leaves the surf zone. It is however considered adequate for confirmation of this explanation for the influence of the current upon the magnitude of $\bar{\eta}_s$ in the three dimensional case. The remaining small discrepancy may be explicable by the fact that the diffracted wave crests are not exact circular arcs. Consequently the breaker angle may not be exactly zero everywhere along the beach.

4. Computation of Alongshore Current

4.1 General Scheme of Computation

The calculation of the alongshore current from the alongshore gradient of wave set-up has not been found to be easy for a number of reasons. For instance, apart from the nonlinear interaction effects between the current and the wave set-up, there are the problems of defining the seaward extent of the current; the extent of the inflow region where water is being fed into the surf zone from offshore; the point where the current leaves the surf zone and the magnitude of the bottom friction and lateral mixing effects.

The computation process may be considered in four basic stages. These are as follows:

- (i) Determination of the alongshore gradient of breaker height and the location of the break point;
- (ii) Determination of the wave set-up resulting from the alongshore gradient of breaker height;
- (iii) Determination of the wave generated current from the previously determined alongshore gradient of wave set-up;
- (iv) Adjustment of the first estimate of the wave generated current for the effects of interaction between the current and the surf zone conditions.

In a previous paper (6) the author has described how it is possible to determine the location of the breakpoint and the alongshore breaker height gradient

using a graphical combination of 1st order diffraction and shoaling theory together with empirical wave breaking data correlated by Goda (10). The results of this computation were generally promising. However to simplify the treatment of the subsequent stages of the computation process the work described in this paper takes the observed break point and alongshore variation of breaker heights as its starting point.

4.2 Wave Set-up

With regard to the determination of the wave set-up this can be approached from two viewpoints. Firstly a purely empirical approach can be adopted. For instance, the parallel series of two dimensional tests yielded the empirical relationships;

$$\bar{\eta}_s = 0.303 H_b \left[\frac{H_o}{L_o} \right]^{0.12} \quad 1.$$

$$\bar{\eta}_m = 0.288 H_b \quad 2.$$

where $\bar{\eta}_s$ is the wave set-up at the still water line
and $\bar{\eta}_m$ is the maximum wave set-up.

Such empirical relationships derived from this study have the drawback that they allow, neither for the influence of the geometry of the particular two dimensional system in which the measurements were made, nor for scale effects. An alternative approach is to compute the wave set-up using the radiation stress theory of Longuet-Higgins and Stewart as applied by Bowen et al (11), assuming that conditions at the breakpoint and within the surf zone can be represented by the shallow water approximations. On this basis Bowen et al have shown that the mean water level gradient normal to the shore is given by the following expression:

$$\frac{d\bar{\eta}}{dx} = - \frac{1}{1 + 8/3\gamma^2} \cdot \frac{dh}{dx} \quad 3.$$

where $\frac{dh}{dx} = \tan \alpha$ is the bottom slope.

Wave set-down at the breakpoint, assuming the same approximations, is given by:

$$\bar{\eta}_b = - \frac{1}{16} \gamma H_b \quad 4.$$

Simple geometry then permits the derivation of relationships for $\bar{\eta}_s$ and $\bar{\eta}_m$ as functions of γ and H_b in the manner presented by several authors (12, 13 and 14). All these authors assume spilling breakers. Plunging breakers have been treated in a similar manner by Swart (15) and Gourlay (6). In this case an additional parameter is involved, either an energy dissipation factor as in Swart's treatment or the breaker plunge distance x_p in Gourlay's treatment.

For the present study it has been found expedient to adopt slightly modified forms of these empirical relationships in which the wave set-up is referred to the mean water level at the breakpoint rather than the deep water mean water level. This involves neglect of the break point set-down (equation 4) which in the case under consideration varies in the alongshore direction becoming positive in the sheltered area (see section 3.3). In passing it should also be noted that equation 4 generally overestimates the observed wave set-down by a factor of 2 to 3. As the set-down is at least an order of magnitude smaller than the wave set-up, its inclusion at this stage in the calculation of the latter is questionable.

Taking account of the above points the relevant equations for the computation of wave set-up assuming shallow water conditions within the surf zone may be summarized as follows:

$$\bar{\eta}_s^1 = \frac{3}{8} \gamma \frac{(1 - C \gamma \tan \alpha)}{1 + 3\gamma^2/8} H_b \quad 5.$$

$$\bar{\eta}_m^1 = \frac{3}{8} \gamma (1 - C \gamma \tan \alpha) H_b \quad 6.$$

where $C = \frac{x_p}{H_b} = 0$ for spilling breakers
 $= 2$ to 4 for plunging breakers

and $\bar{\eta}_s^1$ and $\bar{\eta}_m^1$ represent wave set-ups measured relative to mean water level at the breakpoint.

The author has previously shown (figure 13 of reference 6) that equation 5. gives reasonable estimates of $\bar{\eta}_s^1$ as measured in the two dimensional tests of this investigation, having regard to the general uncertainty as to what factors determine the magnitude of the dimensionless plunge distance C . Equation 6 has been found to behave similarly with respect to $\bar{\eta}_m^1$.

When plunging breakers are considered it is necessary to be able to determine the depth h_p at the plunge point. Simple geometry gives the following result compatible with equations 5 and 6.

$$h_p = \frac{(1 - C \gamma \tan \alpha)}{\gamma} H_b \quad 7.$$

The analogous directly derived experimental result compatible with equations 1 and 2 is:

$$h_p = 2.55\bar{\eta}_s = 0.773H_b \left[\frac{H_0}{L_0} \right]^{0.12} \quad 8.$$

4.3 Mean Velocity of the Alongshore Current

The following observations of the characteristics of the non-uniform alongshore current have been used in formulating a simple analytical expression for computing the maximum mean velocity of the current.

- (i) Inflow into the alongshore current ceases at the geometric shadow line. Hence discharge Q and mean velocity V are assumed to have attained their maximum values at this point.
- (ii) The seaward limit of the current at this point corresponds to the distance x_{c1} from the still water line to the plunge point of the largest breakers in the exposed area.
- (iii) The landward limit of the current occurs at the point where the onshore-offshore gradient of mean water level intersects the beach, i.e. at the point where the wave set-up equals $\bar{\eta}_m$ located at a distance x_s from the still water line.

The differential equation of motion in the alongshore direction is written as follows:

$$\frac{dS_{yy}}{dy} + \rho g (\bar{\eta} + h) \frac{d\bar{\eta}}{dy} + \rho \frac{d}{dy} [v^2 (\bar{\eta} + h)] + \tau_b + \tau_l = 0 \quad 9.$$

where S_{yy} is the alongshore component of the "radiation stress";

τ_b and τ_l are the shear stresses due to bottom friction and lateral mixing respectively.

For a simple engineering solution we will adopt a control volume type of analysis initially neglecting the effects of bottom friction and lateral mixing,

$$\tau_b \text{ and } \tau_l \rightarrow 0$$

In the alongshore direction (y) the control volume is assumed to be bounded in the upstream direction at the point where the alongshore current velocity V is zero and H_b has its maximum value. The downstream end of the control volume is at the geometric shadow where both velocity and discharge have attained their maximum values. The offshore limit of the control volume in the x direction is assumed to be equal to x_{c1} as noted above. The form of the water surface at either end of the control volume is as indicated in figure 12.

Application of the momentum principle, i.e., the integral form of equation 9, to the flow of the alongshore current into and out of this control volume in the y direction gives the following expression:

$$\rho A_2 V_2^2 = P_1 + S_1 - (P_2 + S_2) \quad 10.$$

where A is the cross sectional area of flow;
 P is the integrated thrust due to hydrostatic pressure
 S is the integrated thrust due to radiation stress;
 V is the mean velocity of flow through a given cross section;
 ρ is the fluid density
 and subscripts 1 and 2 refer to upstream and downstream locations respectively.

Using the shallow water approximation for S_{yy} ,

$$S_{yy} = \frac{1}{16} \rho g \gamma^2 (\bar{\eta} + h)^2 \quad 11.$$

together with equation 3, simple geometry and integration lead to the following relations:

$$P_1 + S_1 = \frac{\rho g}{6 \tan \alpha} \left(1 + \frac{\gamma^2}{8}\right) (h_{p1} + \bar{\eta}_{m1}) h_{p1}^2 \quad 12.$$

$$P_2 + S_2 = \frac{\rho g}{6 \tan \alpha} \left(1 + \frac{\gamma^2}{8}\right) \left(h_{p1}^3 + \frac{64\bar{\eta}_{m1}^3}{9\gamma^4}\right) \quad 13.$$

$$A_2 = \frac{1}{2 \tan \alpha} \left(h_{p1}^2 + \frac{8\bar{\eta}_{m1}^2}{3\gamma^2}\right) \quad 14.$$

In obtaining equation 13 for $P_2 + S_2$ it has been assumed that the ratio between wave height and water depth, γ , is the same outside of the plunge point as inside of it. While this assumption is of course not valid, the simplification of the form of the resulting expression for $P_2 + S_2$ is considered to more than offset the resulting relatively small underestimation of the final value of V.

Substitution into equation 10 yields the result

$$V_2 = \sqrt{\frac{g}{3} \left(1 + \frac{\gamma^2}{8}\right) \frac{h_{p1}^2 \bar{\eta}_{m1} - \frac{64\bar{\eta}_{m1}^3}{9\gamma^4}}{h_{p1}^2 + \frac{8\bar{\eta}_{m1}^2}{3\gamma^2}}} \quad 15.$$

Further simplification is dependent upon the following decisions:

- (i) The choice between equations 8 and 2 or equations 7 and 6 for expressing h_p and $\bar{\eta}_m$ in terms of the incident wave conditions.
- (ii) The specification of the alongshore gradient of $\bar{\eta}_m$ or as a consequence of the substitutions for $\bar{\eta}_m$ referred to in (i) above, the specification of the alongshore gradient of breaker height.

With regard to (i) equations 8 and 2 express h_p and $\bar{\eta}_m$ in terms of H_b and H_0/L_0 with the bottom slope $\tan \alpha$ implicit in the constants while equations 7 and 6 express them in terms of H_b , γ , C and $\tan \alpha$. In the latter case γ is known to be a function of H_0/L_0 and $\tan \alpha$ (10). Since equation 15 already includes the breaker index γ , the substitution of the theoretical equations 7 and 6 will be adopted as most likely to produce a simple consistent result.

As to (ii) this is determined by the system geometry and is of course the result of the combined diffraction - shoaling process behind the breakwater. Consideration of figure 5 suggests that it will be reasonable in the first instance to assume the following relationship for the alongshore change in breaker height.

$$H_{b1} = 2 H_{b2} = H_b^* \quad 16.$$

When the relevant substitutions based upon the above considerations are made in equation 15 the latter becomes

$$\frac{v}{\sqrt{gH_b^*}} = \sqrt{\frac{7}{64} \gamma (1 + \frac{\gamma^2}{8}) \frac{(1 - C \gamma \tan \alpha)}{1 + 3 \gamma^2 / 32}} \quad 17.$$

Equation 17 is compared with experimental values on figure 13.

The general result is similar to that for the two dimensional wave set-up (6) in that most of the experimental values lie within the scatter resulting from the possible variation of the parameter C .

A similar substitution in equation 14 yields

$$\frac{A}{H_b^{*2}} = \frac{(1 + 3\gamma^2/32) (1 - C \gamma \tan \alpha)^2}{2 \gamma^2 \tan \alpha} \quad 18.$$

and combination of equations 17 and 18 leads to an expression for the discharge of the alongshore current of the following form:

$$\frac{Q}{g^{1/2} H_b^{*3/2}} = f(\gamma, C, \tan \alpha) \quad 19.$$

$$\text{where } \gamma = f\left(\frac{H_0}{L_0}, \tan \alpha\right)$$

$$C = f(\tan \alpha, ?)$$

- see Galvin (16).

The comparatively good agreement of equation 17 with experimental observations indicates that the assumption of negligible bottom friction is reasonable. It is however desirable to check this assumption more positively by incorporating the bottom friction force T into the original momentum analysis. Equation 10 now becomes

$$\rho A_2 V_2^2 = P_1 + S_1 - (P_2 + S_2) - T \quad 20.$$

T can be most conveniently evaluated using the non-linear expression for bed shear stress proposed by Jonsson et al (17),

$$\tau_b = f_s \frac{1}{2} \rho V^2$$

where $f_s = f(f_c, f_w \text{ and } \frac{u_{bm}}{V})$

f_c is the current friction factor which is estimated by the usual rough boundary logarithmic formula;

f_w is the wave friction factor which is estimated using the equations of either Jonsson (18) or Kamphuis (19);

u_{bm} is the maximum value of the wave orbital velocity within the surf zone.

Assuming a constant value of f_s determined by average values of f_c , f_w and u_{bm}/V together with a linear variation of mean velocity V with alongshore distance y , within the inflow region, the friction force is given by

$$T = \frac{\rho f_s Y}{6 \tan \alpha} [h_{p1} + \frac{1}{2} (\bar{v}_{m1} + \bar{v}_{m2})] V^2 \quad 21.$$

where Y is the alongshore length of the control volume.

Using the same substitutions as were used to obtain equation 17 from equation 15 the following expression including the effect of bottom friction is obtained:

$$\frac{V}{\sqrt{gH_b^*}} = \sqrt{\frac{7 \gamma (1 + \frac{\gamma^2}{8}) (1 - C\gamma \tan \alpha)}{64 \left(1 + \frac{3\gamma^2}{32} + \frac{f_s \gamma (1 + 9\gamma^2/32)}{3(1 - C\gamma \tan \alpha)} \right) \cdot \frac{Y}{H_b^*}} \quad 22.$$

It is doubtful whether the use of an equation of the complexity of equation 22 is warranted. For instance taking a specific test and substituting actual observed wave conditions and surf zone geometry into equation 20 using equations 12, 13, 14 and 21 enables the effect of bottom friction upon the magnitude of V to be estimated.

For example, for the test with the following conditions

$$\begin{aligned} T &= 1.0 \text{ s} ; & H_o &= 69 \text{ mm} ; & H_b^* &= 77 \text{ mm} ; \\ h_{p1} &= 44 \text{ mm} ; & \bar{v}_{m1} &= 22 \text{ mm} ; & \bar{v}_{m2} &= 11 \text{ mm} ; \\ Y &= 1.2 \text{ m} ; & \gamma &= 1.0 ; & \tan \alpha &= 0.1 ; \\ & & f_s &= 0.025. \end{aligned}$$

the observed value of V was 0.25 m/s.

Neglecting the friction force, V was 0.23 m/s.

and allowing for the friction force, V was 0.21 m/s.

4.4 Further Aspects of Non-uniform Alongshore Current Computations

The planning of the author's experimental work was directed to obtaining a situation where the driving force for the alongshore current resulted solely from an alongshore gradient in breaker height. This represents one limiting case for alongshore currents, the completely non-uniform alongshore current. At the

opposite end of the spectrum lies the uniform alongshore current whose driving force results solely from waves of uniform height breaking at an angle to an infinitely long plane beach. The author's situation represents a current system which is very definitely limited in size and which in fact results in a closed circulation system. The uniform alongshore current on the other hand is ideally of infinite length and open ended in nature.

Once the above contrasts are appreciated it is clear that there may be significant differences in the formulation of theoretical models to allow for the effects of alongshore gradients of breaker height upon the velocity of the alongshore current. In the situation studied by the author the alongshore current is only related to surf zone characteristics within the inflow region where the flow is highly non-uniform and the current discharge is increasing in the alongshore direction. Thus the consideration of the convective acceleration term and variable surf zone width is essential but bottom friction is relatively insignificant. On the other hand if the problem is approached as one where the alongshore gradient of breaker height is modifying the alongshore current produced by waves breaking at an angle to the shoreline, then the bottom friction term is almost certainly more important than the convective acceleration term and the variation in surf zone width with breaker height can be neglected. This latter situation is the one envisaged by Bakker (20) and Komar (3) in their approaches to non-uniform alongshore currents. The differences between the two approaches arise essentially from the assumption of either a large or a small alongshore gradient of breaker height.

The simple methods for computation of non-uniform alongshore currents presented in this paper are subject to the following limitations:

- (i) The breaker angle has been assumed to be negligible.
- (ii) Both the offshore boundary of the current and the alongshore gradient of breaker height have been determined from experimental observations for the particular system considered.
- (iii) The downstream component of the thrust on the control volume due to radiation stress has been overestimated. This results in an underestimation of the alongshore current velocity. However as the magnitude of this error is of the same order but less than the magnitude of the bottom friction force, its overall effect is negligible.
- (iv) The following factors have been ignored or assumed to be negligible:
 - wave set-down or set-up at breakpoint;
 - lateral mixing and the resulting shear stress at the offshore boundary of the control volume as well as the effect of non-uniform velocity distribution upon the momentum thrust;
 - interaction between the alongshore current and the wave surf zone parameters.
- (v) Both the breaker index γ and the dimensionless plunge distance C are based upon laboratory experimental data without any adequate supporting theory to relate them to the offshore wave conditions.

5. Conclusion

For an alongshore current system resulting solely from an alongshore gradient of breaker height produced by diffraction behind an offshore breakwater,

it has been found that the basic current pattern is imposed by the system geometry and that there is a general similarity of alongshore breaker height and wave set-up gradients in terms of their equivalent two dimensional values.

For a given geometry the alongshore current velocity is primarily determined by the deepwater wave height. The wave period appears to have only a secondary effect upon the alongshore current system. The relationship between the current velocity and surf zone parameters has not been clearly established.

The alongshore variation of wave set-up may be considerably influenced by the alongshore current and may be increased above its two dimensional value by the effects of break point set-up, superelevation caused by normal acceleration and alongshore translation of the uprush-backwash cycle.

A simple theoretical analysis has shown that the alongshore current velocity at the point where maximum discharge is attained can be calculated as a function of the equivalent two dimensional breaker height, the breaker constants γ and C and the bottom slope. Bottom friction can be allowed for but has a comparatively small effect in the situation considered.

CHAPTER 41

CURRENT DEPTH REFRACTION USING FINITE ELEMENTS

Ove Skovgaard¹ and Ivar G. Jonsson²

ABSTRACT

A computational model is presented for the steady state prediction of currents, waves, and sea surface elevations in a coastal region outside the surf zone. Irrotational flow of surface gravity waves on large-scale steady currents over a gently sloping sea bed is considered. A second order Stokian approach is used, and all dynamic quantities are integrated over depth and averaged over time, in that order. The flow equations and the boundary conditions are presented. A method is developed for the solution of the non-linear steady model by introducing a sequence of two-level calculations, viz. a 'wave level' and a 'current level'. The variables are split on the two levels. The wave field is found, using that the flux of wave action is constant between adjacent wave rays. The current field and the mean sea surface elevation are determined using a Galerkin finite element method. The current field is approximated by triangular elements with linear interpolation functions, and the mean sea surface elevation is approximated by a triangular element with quadratic (parabolic) interpolation functions. A quasi-two-dimensional test solution is tabulated.

1. INTRODUCTION

The purpose of the present computational model is to make a steady state prediction of currents, waves, and elevations of the mean sea surface in a coastal or offshore region outside the surf zone, when the topography of the gently sloping sea bed is given, see Fig. 1.

The computation of depth refraction of regular surface gravity waves presents no fundamental difficulties, see e.g. Skovgaard et al. (1975, 1976) and Skovgaard and Petersen (1976). When the wave height H is small, the combined effect of diffraction and depth refraction can also be calculated in the shallow water region, see Berkhoff (1973, 1975), Chen and Mei (1974, 1976), and Zienkiewicz and Bettess (1975, 1976). On greater water depths, where the intermediate depth wave theory must be applied, combined diffraction and refraction has only been determined for a very simple geometry of the sea bed, see Jonsson et al. (1976b). In the presence of a current the problem becomes much more complex on account of current-wave interaction and anisotropy. Therefore we exclude reflection and diffraction and consider only combined current

depth refraction, i.e. the approach is within the framework of geometrical optics.

Subcritical, irrotational flow of large-scale, horizontally non-uniform and vertically uniform, steady currents over an arbitrary gently sloping sea bed is considered. This means that variations in current velocity and depth are slow, in the sense that changes are appreciable only over many wave lengths. Surface and bottom shear are disregarded, and so is dissipation. The waves are periodic and progressive with the constant absolute wave period T_a ($= 2\pi/\omega_a$), ω_a being the absolute angular frequency. Stokes' second order wave theory is used, and the wave fronts are long-crested. Fluxes of mass, momentum, and energy are integrated over depth and averaged over T_a , in that order. The two-dimensional flow region Ω is simply connected with waves in the whole domain. The fluid is incompressible and homogeneous with density ρ . The Coriolis force and the spherical form of our planet are neglected. The non-linear steady model will be solved by a sequence of two-level calculations, viz. a 'wave level' and a 'current level'.

Another model for current wave interaction in two horizontal dimensions, but with bed shear, is reported by Noda et al. (1974) and Noda (1976). This model is like the present one solved by a sequence of two level iterations; however, the approaches on both calculation levels are completely different from our.

The governing equations for irrotational current depth refraction were introduced by Jonsson (1971b), see also Jonsson and Wang (1976). These equations were solved in one horizontal dimension (no refraction) by Jonsson et al. (1971). Plane flow with vorticity is being reported, see Brink-Kjær (1976), Jonsson et al. (1976a), and Jonsson (1977).

The effect of a combined current wave field is in principle that, when the current has a positive component in the direction of wave propagation, the waves are 'lengthened' and so 'feel bottom' at a greater depth than without the current. So in this case the bending of the wave orthogonal in the combined field is stronger than for pure waves. Conversely, a negative current component will 'shorten' the waves, and the bending of the wave orthogonal is less than for no current (see later).

2. THE GOVERNING EQUATIONS

The arbitrary bottom topography is known (measured from a horizontal datum) in a fixed horizontal Cartesian coordinate system (x,y) . It was

Fig. 1

Horizontal sketch of a coastal region

proved by Jonsson et al. (1971) that for a periodic, irrotational free surface flow a constant horizontal level exists, which is inherently connected with the flow. The level was called the mean energy level (MEL). It is also denoted the mean irrotational stagnation level (MISL), see Jonsson (1977), since it stems from the time mean version of the Bernoulli equation. The distance D between the sea bed and MISL is denoted the geometrical depth. The distance h between the sea bed and the time mean water surface (MWS) is for obvious reasons called the physical depth. The distance η between MWS and MISL is the current wave set-down, see Fig. 2. Notice that our definition of the set-down is opposite in sign to the conventional, see Bowen et al. (1968).

Fig. 2 Vertical definition sketch. Geometrical depth D , physical depth h , and current wave set-down η

The problem has 7 primary dependent variables, which are (see Figs. 2 and 3): (1) and (2) radian wave number vector $\vec{k} = (k \cos A, k \sin A)$, or wave number $k (= |\vec{k}|)$ and wave orthogonal direction characterized by the angle A from the x -axis to the wave orthogonal, (3) wave energy density $E (\equiv 1/8 \rho g H^2)$, where g is the acceleration of gravity, (4) and (5) current vector $\vec{U} = (u, v) = (U \cos \delta, U \sin \delta)$, or current speed $U (= |\vec{U}|)$ and direction characterized by the angle δ from the x -axis to \vec{U} , (6) physical water depth h , and (7) current wave set-down η . Observe that U is an average-over-depth current speed, defined such that the mean volume flux q (per unit width) through a vertical section at right angles to \vec{U} is hU , see Jonsson (1976). The *wave orthogonal* should not be confused with the *wave ray*, see Fig. 3.

The 7 primary governing equations are: (1) conservation of mass, (2) and (3) conservation of momentum, (4) conservation of wave action E/ω_r (ω_r being the intrinsic (i.e. relative) angular frequency, see

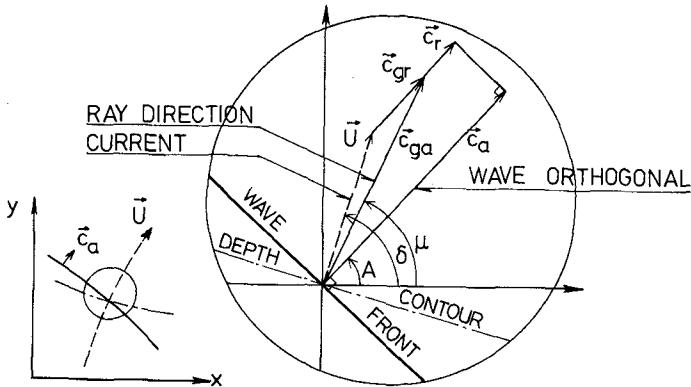

Fig. 3 Horizontal definition sketch for angles and velocities

later), (5) conservation of zero vorticity, (6) conservation of wave crests, and (7) conservation of bottom topography. The conservation equations given by Jonsson (1971b) become in the above mentioned order

$$\frac{\partial}{\partial x}(h u) + \frac{\partial}{\partial y}(h v) = 0 \quad (1)$$

$$\begin{aligned} \frac{\partial}{\partial x} \left[\frac{E}{2} (G + (1+G) \cos^2 A) + \rho h u^2 \right] - \rho g h \frac{\partial \eta}{\partial x} \\ + \frac{\partial}{\partial y} \left[\frac{E}{2} (1+G) \cos A \sin A + \rho h u v \right] = 0 \end{aligned} \quad (2)$$

$$\begin{aligned} \frac{\partial}{\partial x} \left[\frac{E}{2} (1+G) \cos A \sin A + \rho h u v \right] - \rho g h \frac{\partial \eta}{\partial y} \\ + \frac{\partial}{\partial y} \left[\frac{E}{2} (G + (1+G) \sin^2 A) + \rho h v^2 \right] = 0 \end{aligned} \quad (3)$$

$$\frac{\partial}{\partial x} \left[\frac{E}{\omega_r} (u + c_{gr} \cos A) \right] + \frac{\partial}{\partial y} \left[\frac{E}{\omega_r} (v + c_{gr} \sin A) \right] = 0 \quad (4)$$

$$\frac{\partial}{\partial x} \left[v - \frac{E \sin A}{\rho h c_r} \right] - \frac{\partial}{\partial y} \left[u - \frac{E \cos A}{\rho h c_r} \right] = 0 \quad (5)$$

$$c_a = c_r + u \cos A + v \sin A \quad \text{or} \quad \omega_a = \omega_r + k(u \cos A + v \sin A) \quad (6a,b)$$

$$D = h + \eta \quad (7)$$

where we have introduced 5 new (secondary) unknowns: The absolute phase speed (see Fig. 3)

$$c_a = L/T_a \quad (\equiv \omega_a/k) \quad (8)$$

L being the wave length, the relative phase and group speeds

$$c_r = \sqrt{\frac{g}{k} \tanh kh} \quad (9) \quad c_{gr} = \frac{1}{2} c_r (1+G) \quad (10)$$

the relative angular frequency ω_r and the parameter G

$$\omega_r = c_r k \quad (11) \quad G = 2kh / \sinh 2kh \quad (12)$$

In the shallow water limit we have $G = 1$ and $c_r = c_{gr} = \sqrt{gh}$. If we insert these limiting values in eqs. 1-7, we get the shallow water version of the conservation equations, see Skovgaard and Jonsson (1976b).

As shown by Skovgaard and Jonsson (1976a) it is possible to replace any of the conservation equations with the differential equation for the wave orthogonal or with the algebraic equation for the set-down (see later), or to replace any two of the conservation equations with these two equations.

The differential equation for the wave orthogonal reads, see e.g. Skovgaard and Jonsson (1976a)

$$\frac{DA}{Ds} = \frac{1}{c_a} \left(\sin A \frac{\partial c_a}{\partial x} - \cos A \frac{\partial c_a}{\partial y} \right) \quad (13)$$

where s is a coordinate along the wave orthogonal (positive in the direction of the wave propagation). Together with eq. 13 we have the two parametric differential equations

$$Dx/Ds = \cos A \quad (14) \quad Dy/Ds = \sin A \quad (15)$$

The equation for the current wave set-down reads, see Jonsson (1971a, 1976)

$$\eta = \frac{1}{2g}(u^2 + v^2) + \frac{E}{\rho gh} \left(\frac{G}{2} - (u \cos A + v \sin A) / c_r \right) \quad (16)$$

The direction of the wave ray is given by the direction of the absolute group velocity vector $\vec{c}_{ga} (= \vec{U} + \vec{c}_{gr})$, and so is determined by

$$\tan \mu = \frac{v + c_{gr} \sin A}{u + c_{gr} \cos A} \quad (17)$$

where μ is the angle from the x-axis to \vec{c}_{ga} , see Fig. 3. When eq. 17 is differentiated with respect to a coordinate r along the wave ray, the differential equation for the wave ray is obtained

$$\frac{D\mu}{Dr} = \cos^2 \mu \frac{D}{Dr} \left(\frac{v + c_{gr} \sin A}{u + c_{gr} \cos A} \right) \quad (18)$$

Together with the wave ray equation we have two parametric equations

$$Dx/Dr = \cos \mu \quad (19) \quad Dy/Dr = \sin \mu \quad (20)$$

Remark that the wave ray equation presented by Jonsson (1971b), eq. 30, is not correct.

3. BOUNDARY CONDITIONS

The current vector \vec{U} must be given everywhere on the boundary Γ which surrounds Ω , see Fig. 4. The boundary is divided in two parts, Γ_1 and Γ_2 . Γ_1 is that part of Γ where all rays are running in (or out) of Ω , see Fig. 4, and along it the wave field must be known. (Along Γ_2 the wave field is determined by the calculations.)

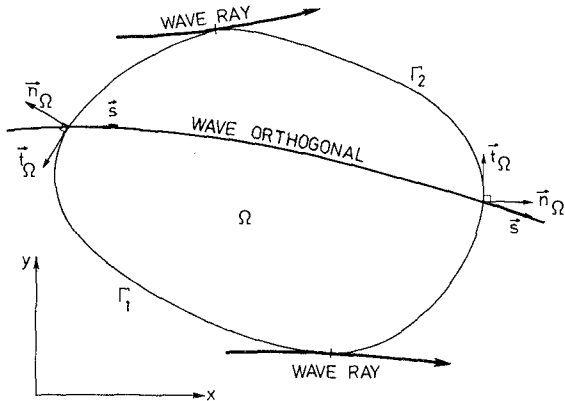

Fig. 4
Definition sketch
of flow domain Ω
with the boundary
 $\Gamma = \Gamma_1 + \Gamma_2$

The wave field is in principle defined by T_a , A , E , L , and h ; however, in an irrotational model it is not necessary to prescribe h in more than one point of Γ_1 for the following reason. For given \vec{U} , T_a , A , E , and h in one point of Γ_1 , we can calculate η in that point by

iteration in eqs. 6, 8, 9, 12, and 16, and then D using eq. 7. Thereby the MISL is determined, which is horizontal in Ω . Combining eqs. 6, 7, 8, 9, 12, and 16 we then can calculate h for all other points of Γ_1 .

We shall later show that it is more convenient if the (incoming) waves are prescribed by the curvature of the ray front κ_e and by A (or μ) in some selected points along Γ_1 rather than by the continuous variation of A along Γ_1 . The angles A and μ are connected by eq. 17 in any point where \vec{U} and h are known, i.e. if A is given we can determine μ , and vice versa. The curvature of the wave action front κ_e is determined by a pure geometrical consideration

$$\kappa_e \equiv D\mu/De = -\sin\mu \partial\mu/\partial x + \cos\mu \partial\mu/\partial y = (D(De)/Dr)/De \quad (21)$$

where De is the infinitesimal distance between two rays, see Fig. 6. Since r is not constant along e-lines, and vice versa, lengths r and e do not form a set of curvilinear coordinates. This is the reason for using the formalism D/Dr instead of $\partial/\partial r$, etc.

In summary we have

$$\vec{U} = \vec{U}_{\Gamma_1} \quad \text{along } \Gamma_1 \quad (22a)$$

$$\kappa_e = \kappa_{e,\Gamma_1} \quad E = E_{\Gamma_1} \quad A = A_{\Gamma_1} \quad \text{or} \quad \mu = \mu_{\Gamma_1} \quad (22b)$$

in some selected points of Γ_1

$$h = h_1 \quad \text{in one point of } \Gamma_1 \quad (22c)$$

$$\vec{U} = \vec{U}_{\Gamma_2} \quad \text{along } \Gamma_2 \quad (22d)$$

For the present irrotational steady state model we can make two integral checks of volume fluxes and velocities. The normal component of \vec{q} ($= h\vec{U}$) along Γ ($= \Gamma_1 + \Gamma_2$) is controlled by mass conservation

$$\int_{\Gamma} \vec{q} \cdot \vec{n}_{\Omega} d\Gamma = 0 \quad (23)$$

where \vec{n}_{Ω} is a unit vector normal to the boundary of and going outward from Ω , and we have assumed that Ω is without sources or sinks. As h is not known along Γ_2 (η is a function also of the unknown wave field) we cannot check in advance that eq. 23 is exactly fulfilled. However, we can calculate h along Γ corresponding to a pure current, and it is expected that for a 'realistic' problem the error introduced in eq. 23 by neglecting the wave contribution to h is small, since it is a second order term. The wave field could also be estimated along Γ_2 before using eq. 23. One could formulate the above as: Eq. 23 must be roughly fulfilled in advance for a realistic problem.

The tangential component of the mean velocity is controlled by the condition of zero vorticity. Introducing the Eulerian mean velocity vector \vec{U}_t ($\equiv \vec{U} - E/(\rho hc_r) \vec{s}$) below wave trough level (\vec{s} being a unit vector in the direction of wave travel), Stokes' theorem gives

$$\int_{\Omega} \text{rot } \vec{U}_t d\Omega = \int_{\Gamma} \vec{U}_t \cdot \vec{t}_{\Omega} d\Gamma \quad (24)$$

where \vec{t}_{Ω} is a unit vector tangential to Γ going counterclockwise around Ω . Using eq. 5 we therefore get

$$\int_{\Gamma} \left(\vec{U} - \frac{E}{\rho hc_r} \vec{s} \right) \cdot \vec{t}_{\Omega} d\Gamma = 0 \quad (25)$$

The wave contribution to the integrand in eq. 25 is a second order term which furthermore has not the same sign along Γ . Thus it can be inferred that the advance neglect of the wave term in eq. 25 will correspond to a realistic problem. Also here we can say: Eq. 25 must be roughly fulfilled in advance for a realistic problem.

4. THE TWO-LEVEL APPROACH

The current depth refraction model is solved by a two-level iterative scheme. In this way we so to speak 'split' the unknowns in two groups, and we do not have to solve all equations simultaneously. The two levels will be named the wave level and the current level.

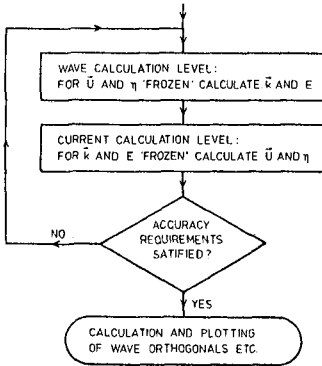

Fig. 5 The two-level splitting of the calculations

two consecutive levels of the same type are lower than a chosen limit for both the wave and the current level, i.e. the number of iterations is determined by accuracy requirements.

After the completion of the two-level iterations the paths of some wave orthogonals are calculated by numerical integration of the three ordinary differential equations 13 - 15, and the wave field is plotted with the wave heights and the current components written at discrete points along these orthogonals. Also the phase field, i.e. the wave fronts is calculated and plotted after the completion of the two-level iterations. Eqs. 13 - 15 cannot be used in the given form to calculate the phase field. Time t must be used as independent variable in this case

$$dA/dt = \sin A \partial c_a / \partial x - \cos A \partial c_a / \partial y \quad (13a)$$

$$dx/dt = c_a \cos A \quad (14a)$$

$$dy/dt = c_a \sin A \quad (15a)$$

5. THE WAVE LEVEL

The approach on this level is a generalization of the method which is used in depth refraction calculations, see e.g. Skovgaard et al. (1975).

In the wave level calculations the 'propagation medium' is held fixed ('frozen'), i.e. \vec{U} , h , and η are known in Ω on this level, and \vec{k} and E are the primary unknowns, see Fig. 5.

In the current level calculations the wave field is frozen, i.e. \vec{k} and E are known in Ω on this level, and \vec{U} , h , and η are the primary unknowns. The governing equations on this level are non-linear, which implies that we have to iterate during the calculations.

The calculations are initiated on a wave level, where we assume $\vec{U} = 0$ and $\eta = 0$ in Ω . The two-level iteration scheme is continued until the differences between

The wave field is determined from one-point conditions (initial conditions) by integration along characteristic lines. By a suitable placing of the boundary points (initial points) along Γ_1 , Ω is covered by a set of characteristic lines. The method is attractive, because we only have to solve a set of four ordinary differential equations along each of the lines.

In depth refraction the characteristic lines are the wave orthogonals, and in current depth refraction the characteristic lines are the wave rays which, of course, for $U = 0$ coincide with the wave orthogonals. The path of the wave ray is determined by eqs. 18 - 20. Bretherton and Garrett (1968) have shown generally that there is no flux of wave action E/ω_r across a wave ray, i.e. between two rays we have a constant flux of wave action, see eq. 4. For water waves, Jonsson (1971a, 1976) found the same result, using quite a different approach. For $U = 0$ the wave action is, of course, proportional with wave energy density, the flux of which is constant between two orthogonals.

$$De_{st} \left(\frac{E}{\omega_r} c_{ga} \right)_{st} = De \frac{E}{\omega_r} c_{ga}$$

Fig. 6 Two adjacent wave rays and two 'wave action fronts'

Munk and Arthur (1952) derived a differential equation for the wave *orthogonal* separation factor β for $U = 0$. In almost the same manner it is possible to derive a differential equation for the wave *ray* separation factor β_r with distance r along the ray as the independent variable. The factor β_r is defined by

$$\beta_r \equiv De/De_{st} \quad \beta_r > 0 \tag{26}$$

in which suffix 'st' denotes a value at the starting or initial point along Γ_1 , see Fig. 6. The separation factor is found in the following way. Introducing eq. 26 in eq. 21 we get

$$D\mu/De = \beta_r^{-1} D\beta_r/Dr \tag{27}$$

Using the operators

$$\frac{D}{Dr} = \cos \mu \frac{\partial}{\partial x} + \sin \mu \frac{\partial}{\partial y} \tag{28}$$

$$\frac{D}{De} = - \sin \mu \frac{\partial}{\partial x} + \cos \mu \frac{\partial}{\partial y} \tag{29}$$

we have

$$\frac{D}{De} \left(\frac{D\mu}{Dr} \right) - \frac{D}{Dr} \left(\frac{D\mu}{De} \right) = \left(\frac{D\mu}{Dr} \right)^2 + \left(\frac{D\mu}{De} \right)^2 \tag{30}$$

(or $D\kappa_r/Ds - D\kappa_e/Dr = \kappa_r^2 + \kappa_e^2$, κ_r being the curvature of the wave ray). Inserting eq. 27 and using eqs. 28-29 once more, we get an ordinary second-order homogeneous differential equation for β_r

$$\frac{D^2 \beta_r}{Dr^2} + q_s \beta_r = 0 \quad (31)$$

$$q_s = \left(\left(\frac{\partial \mu}{\partial x} \right)^2 - \left(\frac{\partial \mu}{\partial y} \right)^2 - \frac{\partial^2 \mu}{\partial x \partial y} \right) \cos 2\mu + \left(\frac{1}{2} \left(\frac{\partial^2 \mu}{\partial x^2} - \frac{\partial^2 \mu}{\partial y^2} \right) + 2 \frac{\partial \mu}{\partial x} \frac{\partial \mu}{\partial y} \right) \sin 2\mu \quad (32)$$

The coefficient q_s depends on some explicitly known quantities (u , v , h , and η , and their partial derivatives up to the second order) and on some implicitly known quantities (A and E , etc., and their partial derivatives up to second order). The implicit quantities are calculated from some of the conservation equations and the wave orthogonal equation 13.

The condition of constant flux of wave action between two adjacent rays determines in principle E (and so the wave height)

$$E = \frac{E_{st}}{\beta_r} \frac{\omega_r}{\omega_{r,st}} \frac{c_{ga,st}}{c_{ga}} \quad (33)$$

where we have used eq. 26, and c_{ga} ($\equiv |\vec{c}_{ga}|$) is the absolute group speed.

The associated one-point boundary conditions at $r = r_{st}$ for the four ordinary differential equations 18-20 and 31 are

$$\mu = \mu_{st} \quad x = x_{st} \quad y = y_{st} \quad \beta_r = \beta_{r,st} \quad \frac{D\beta_r}{Dr} = \beta_{r,st} \kappa_{e,st} \quad (34)$$

where x_{st} and y_{st} are chosen on Γ_1 , μ_{st} is calculated from eq. 17, $\beta_{r,st}$ is arbitrarily chosen as 1, and $\kappa_{e,st}$ is the curvature of the wave action front in the considered point of Γ_1 . When the differential equation for β_r (eq. 31) is written as a system of two simultaneous first-order equations, eqs. 18-20 and 31 constitute a system of five simultaneous first-order ordinary differential equations, where the five requisite 'initial' conditions at $r = r_{st}$ are given by eq. 34. The system is integrated step-by-step along one ray at a time. A standard variable order code with automatic local control of the error level and corresponding adjustable step length is used.

The calculation along a wave ray stops when one of the following conditions is fulfilled: (1) The boundary of the region of analysis is reached, (2) the orthogonals converge too much, (3) the Stokes parameter is too high (thereby we in practice exclude wave breaking), (4) the bottom slope is too high, (5) the water depth is too small, or (6) the rays converge too much.

The first five conditions equal those for depth refraction, see Skovgaard et al. (1975). Here condition (2) was formulated $D\beta/Ds < -\beta/(1L)$, where l probably is about one. However, since $\beta^{-1} D\beta/Ds = DA/Df = -\sin A \partial A/\partial x + \cos A \partial A/\partial y$, we need not solve the differential equation for β to test condition (2), (Df is the infinitesimal distance between two orthogonals). Nor do we have to determine the wave orthogonal paths. Condition (6) is of the same type as condition (2). Condition (3) reads $HL^2/h^3 > 20$ (say), thus excluding non-Stokian waves.

The solution (i.e. \vec{k} , E etc. and the associate position (x,y) of the ray) is recorded in the computer at a set of prescribed values of distance r along the path of the wave ray. Note that the paths of the rays are new on each level, since the propagation properties of the medium changes on the current level.

6. THE CURRENT LEVEL

On this level the wave field (i.e. \vec{k} and E) is frozen in Ω , and \vec{U} , h and η are the primary unknowns. Using eq. 7, and remembering that D is also known in Ω , we immediately can eliminate h, which implies that we have only three scalar unknowns u, v and η on this level. These three variables are determined by three conservation equations, viz. conservation of mass, eq. 1, and conservation of momentum in the two horizontal directions, eqs. 2-3. We solve the partial differential equations by a direct finite element method, the so-called Galerkin weighted residual process (i.e. a weak formulation). The region Ω is approximated with a domain $\bar{\Omega}$ (with boundary $\bar{\Gamma}$) consisting of a finite number N of triangular subdomains ω . The only difference between Ω and $\bar{\Omega}$ is along the boundary. The triangular subdomains are constructed by connecting the prescribed points along the wave rays with straight lines, see Fig. 7. As the rays are new on each wave level, the triangular subdomains are also new on each current level.

It is well known that we cannot freely select the polynomial order of the shape functions (interpolation functions), see e.g. Hood and Taylor (1974) and Olson and Tuann (1976). We choose to apply the most simple shape functions, which for the present differential equations 1-3 are a linear shape function for u and v, and a quadratic shape function for η . Remark the simple connection in eq. 16 between u, v and η .

It should be explained why we choose to eliminate the physical depth h and not the set-down η . If η was eliminated, and a shape function for h chosen, the indirectly assumed form of the MWS would be influenced by the local form of the sea bed (see eq. 7 and Fig. 2).

We select the most simple placing of the nodal points, i.e. we use for the linear interpolation functions the three vertices as nodal points (see Fig. 8(a)), and for the quadratic interpolation functions the three vertices plus the three mid-side points as nodal points, see Fig. 8(b). Implicit in the preceding discussion is the fact that the same triangular subdomains are used for set-down and velocity fields. Details of these standard elements can be found in e.g. Zienkiewicz (1971), chapter 7. With these two elements the u, v and η solutions become continuous but not differentiable along the sides of the triangular domains. In a typical domain ω we have the following approximations

Fig. 7 Placing of triangular elements

$$u = \psi_j(x,y) \bar{u}_j \quad v = \psi_j(x,y) \bar{v}_j \quad n = \phi_1(x,y) \bar{n}_1 \quad (35a,b,c)$$

where the bar indicates a nodal value, and ψ_j , $j = 1,2,3$, and ϕ_1 , $l = 1,2,\dots,6$ are the shape functions. Here and henceforward the repeated nodal indices j , l , etc. are summed over the range of the index.

o NODAL POINT

Fig. 8 Placing of nodal points in isoparametric triangular elements
(a) linear three-node element, (b) quadratic six-node element

For the conservation equation of mass (where h is eliminated) we form the residual $r_e(x,y)$ at point $(x,y) \in \omega$ by inserting eqs. 35 a-c in the left hand side of eq. 1

$$r_e(x,y) = \bar{u}_j \frac{\partial}{\partial x}(D\psi_j) - \bar{n}_1 \bar{u}_j \frac{\partial}{\partial x}(\phi_1 \psi_j) + \bar{v}_j \frac{\partial}{\partial y}(D\psi_j) - \bar{n}_1 \bar{v}_j \frac{\partial}{\partial y}(\phi_1 \psi_j) \quad (36)$$

The residual r_e is multiplied with weight functions which for this residual are the shape functions for the set-down ϕ_m ($m = 1,2,\dots,6$). Support for the appropriate selection of the weight function is given by e.g. Chung and Chion (1976). The functions $(r_e \phi_m)$, $m = 1,2,\dots,6$ are integrated over ω , and each of the results is equated with zero. Oden and Wellford (1972) p. 1592 have given the reason for this approach, 'We can guarantee that the residual vanishes in an average sense over the element by requiring that it be orthogonal with respect to the inner product $\langle f,g \rangle \equiv \int_{\omega} fgd\omega$ to the subspace spanned by the functions $\phi_m(x,y)$, $m = 1,2,\dots,6$. Then $\langle r_e, \phi_m \rangle = \int_{\omega} r_e \phi_m d\omega = 0$, and we obtain the finite element model of the mass conservation equation.'

Using $\int_{\omega} r_e \phi_m d\omega = 0$, we get

$$\bar{u}_j A_{mj} - \bar{n}_1 \bar{u}_j B_{mlj} + \bar{v}_j C_{mj} - \bar{n}_1 \bar{v}_j D_{mlj} = 0 \quad m = 1,2,\dots,6 \quad (37)$$

and A_{mj} , B_{mlj} , C_{mj} , and D_{mlj} denote the four local arrays

$$\left. \begin{aligned} A_{mj} &\equiv \int_{\omega} \phi_m \frac{\partial}{\partial x}(D\psi_j) d\omega & B_{mlj} &\equiv \int_{\omega} \phi_m \frac{\partial}{\partial x}(\phi_1 \psi_j) d\omega \\ C_{mj} &\equiv \int_{\omega} \phi_m \frac{\partial}{\partial y}(D\psi_j) d\omega & D_{mlj} &\equiv \int_{\omega} \phi_m \frac{\partial}{\partial y}(\phi_1 \psi_j) d\omega \end{aligned} \right\} \quad (38)$$

In the same manner we obtain the finite element model of the two momentum conservation equations, the only difference being that the weight functions are ψ_m , $m = 1,2,3$ for both equations. For eq. 2 we get

$$\begin{aligned}
 & \rho \bar{u}_j \bar{u}_p E_{mjpp} - \rho \bar{\eta}_1 \bar{u}_j \bar{u}_p F_{mljpp} - \rho g \bar{\eta}_1 G_{m1} + \rho g \bar{\eta}_1 \bar{\eta}_n H_{m1n} \\
 & + \rho \bar{u}_j \bar{v}_p I_{mjpp} - \rho \bar{\eta}_1 \bar{u}_j \bar{v}_p J_{mljpp} \\
 & = - \int_{\omega} \psi_m \left[\frac{\partial}{\partial x} \left(\frac{E}{2} (G + (1+G) \cos^2 A) \right) + \frac{\partial}{\partial y} \left(\frac{E}{2} (1+G) \cos A \sin A \right) \right] d\omega \quad (39)
 \end{aligned}$$

$m = 1, 2, 3$; where E_{mjpp} , F_{mljpp} , G_{m1} , H_{m1n} , I_{mjpp} , and J_{mljpp} denote 6 local arrays, which are not presented. Nor are the similar equations for eq. 3.

Off-node function values and derivatives of u , v , h , and η , which are used in the wave level calculations, are not formed directly from the finite element method (FEM) solution, using the FEM interpolation functions etc. We follow, however, the guidance given by Carl de Borr (1974), see Roache (1975), p. 235, 'The acknowledged best procedure is to ignore the basis function and evaluate off-node function values and derivatives by standard interpolation formulas.'

Eqs. 37 and 39, and the similar one for eq. 3 represent a set of 12 (= 6 + 3 + 3) non-linear algebraic equations in 12 unknowns, which are $\bar{\eta}_1$, $l = 1, 2, \dots, 6$, \bar{u}_j , $j = 1, 2, 3$, and \bar{v}_j , $j = 1, 2, 3$. Upon assembling the elements, the global stiffness matrix form is sparse, but the system of algebraic equations is non-linear. Along the boundary $\bar{\Gamma}$, the specified current components \bar{u} and \bar{v} are inserted directly in the global matrix form. Using these specified values of \bar{u} and \bar{v} we can calculate $\bar{\eta}$ along $\bar{\Gamma}$ from eq. 16 by iteration, using that E , A , c_r , and G are known from the calculations on the wave level. These values of $\bar{\eta}$ are then inserted directly into the global matrix form.

The global non-linear system of algebraic equations is solved using the Newton Raphson iteration scheme, see e.g. Dahlquist and Björck (1974), p. 250. The iteration is started by interpolation in the current level solution used on the preceding wave level. The number of iterations is determined by accuracy requirements.

Combined diffraction refraction FEM models for short waves are rather expensive in use, as the minimum number of elements is a function of the wave length. The present model for current depth refraction does not have this restriction. The number of elements in our model is a function of the depth variations and the associated variations of the current field. Only the variation of the wave height (amplitude envelope) is modelled. In contrast a diffraction refraction FEM model describes simultaneous amplitudes, i.e. rapid oscillations in horizontal space.

It should be explained why we choose to use both momentum equations, and do not substitute one of them with eq. 16. If we had done this, our model would have been 'tailored' to irrotational flow only, and a later inclusion of bottom friction would be less straightforward. With the present approach we can instead use eq. 16 as a check equation in the nodal points.

7. TEST SOLUTION

For straight and parallel (but arbitrarily spaced) sea bed contours, with the current \bar{u} everywhere parallel with these, a test solution is

calculated numerically (assuming plane incidence in deep water). With these constraints we have a quasi two-dimensional problem in that no phase-independent parameters vary with distance along-shore. Therefore we can calculate the solution (except the ray and orthogonal paths) with D as the only independent variable, without integrating the differential equations for the rays and the orthogonals. In order to simplify the presentation we place the x-axis at right angles to the contours, $\vec{U} = (0, v)$, or $U = v$, and $\delta = \pm 90^\circ$.

For the present problem we can directly integrate the conservation equations (4 and 5) for wave action and zero vorticity

$$\frac{\omega_a}{\omega_r} E c_{gr} \cos A = \text{const}_1 \quad (40)$$

$$v - \frac{E \sin A}{\rho h c_r} = \text{const}_2 \quad (41)$$

When the y-component of the conservation (3) for momentum is integrated and combined with eqs. 8, 10, 11, and 40 we get Snell's law (see Jonsson, 1971a, 1976)

$$c_a / \sin A = \text{const}_3 \quad (42)$$

Further we can easily derive algebraic formulas for the ray and orthogonal separation factors β_r and β ($= Df/Df_{st}$)

$$\beta_r = \cos \mu / \cos \mu_{st} \quad (43)$$

$$\beta = \cos A / \cos A_{st} \quad (44)$$

Note that by combining eqs. 40 and 43 we get eq. 33.

The solution, i.e. the 12 unknowns ($k, A, E, v, h, \eta, c_r, c_a, \omega_r, c_{gr}, G$, and μ) as a function of D, is found by numerical iteration in 12 non-linear algebraic equations (Nos. 6, 7, 8, 9, 10, 11, 12, 16, 17, 40, 41, and 42). After the completion of the iteration, β_r and β are found from eqs. 43 and 44. The ray path is deter-

TABLE 1 Test solution, plane sloping sea bed, slope 1:50

Fig. 9 Paths of wave orthogonals and rays, and variation of wave height. The effect of a 'positive' and a 'negative' current. At $D_{st} = 20 \text{ m}$ the angle A_{st} is 60° . Plane sloping sea bed, slope 1:50

mined by simultaneous integration of the two parametric differential equations for the ray, eqs. 19 and 20 (independent variable r). Similarly the orthogonal path is found by another simultaneous integration of eqs. 14-15 (independent variable s).

The wave level part of the general program can be separately checked using the given test solution.

For a plane sloping sea bed (slope 1:50), $T_a = 8$ sec, $H_{st} = 1$ m, $A_{st} = 60^\circ$, $v_{h \rightarrow \infty} = \pm 1$ m/sec, i.e. $v_{st} = +1.0046$ m/sec, and $v_{st} = -0.99497$ m/sec (both values are rounded with 5 significant digits, 5S), and $D_{st} = 20$ m, the paths of the rays and the orthogonals, and the variation of the wave height are given in Fig. 9. Note that in both cases shown, the rays turn with the current, in contrast to the orthogonals. This phenomenon is explained in the introduction. The figure gives also the path of the orthogonal for $v_{st} = 0$ (and $E_{st} = 0$, i.e. the current $O(H^2)$ is also vanishing, so $v = 0$). It can be shown that if we are in shallow water, the influence of the current on the orthogonal and on the wave height is exceedingly small in this case.

In Table 1 one of the test solutions in Fig. 9 is tabulated for some points along the wave ray. Integers in parentheses indicate powers of 10 by which the following numbers are to be multiplied.

8. CONCLUSION

The irrotational flow equations and the boundary conditions for current depth refraction of surface gravity waves on large-scale steady currents are presented for second-order Stokes waves. An iterative solution algorithm is formulated using a two-level splitting of the calculations, viz. a wave calculation level and a current calculation level. On the wave level, the wave rays are determined in a 'frozen' medium, and wave heights are found using that the flux of wave action is constant between neighbouring rays. On the current level, the waves are 'frozen', and the current field and elevation of the mean surface are determined from the conservation equations for mass and momentum using that the mean irrotational stagnation level (MISL) is horizontal. These conservation equations are solved by a direct finite element method, using triangular linear finite elements for the current and triangular quadratic finite elements for the elevation of the mean sea surface. A test solution is presented, and tabulated for one set of the parameters. The described model is currently being implemented in a general current depth refraction program.

9. ACKNOWLEDGMENT

This study is supported by the Danish Council for Scientific and Technical Research, contract No. 516-5116.B-452.

The authors also wish to thank the Danish Hydraulic Institute, Danish Academy of Technical Sciences, Copenhagen for their financial support to this basic research project.

APPENDIX A: Programming

The numerical methods described are programmed in the IBM OS 360/370 implementation of PL/I. All the floating point calculations are made with 14 hexadecimal digits, i.e. with about 15 decimal digits. The presented results are calculated with about 10S, and the numbers in the test solution in Table 1 are rounded to 5S.

CHAPTER 42

SET-UP AND RUN-UP IN SHOALING BREAKERS

William G. Van Dorn
Research Oceanographer
Scripps Institution of Oceanography, University of California
La Jolla, California 92093

ABSTRACT

This paper reports the results of a series of laboratory experiments with periodic waves breaking on uniformly sloping impermeable beaches with the object of distinguishing set-up from dynamic shoreline motions due to partial reflection, the combination of which is normally referred to as 'run-up'. The principal findings are:

1. The mean set-up across the breaker zone was observed to be linear with mean slope proportional to the square of the bottom slope. The mean slope was independent of frequency over slopes of 0.04 or less, and increased with wave period over steeper slopes.
2. The dynamic run-up range was found to be proportional to the square of wave period times beach slope, in agreement with the equation of motion for a nearly frictionless block sliding on corresponding slopes under gravity.
3. The total run-up was poorly correlated with Hunt's empirical formula, nor could any reasonable deterministic justification of this formula be deduced from the present results.
4. Transient run-up was observed to considerably exceed steady-state values in most cases, suggesting that time-dependent momentum flux should be considered in the run-up of variable (natural) waves.

INTRODUCTION

Although commonly lumped together under the ubiquitous headings of run-up and run-down, it is now generally recognized that the shoreline fluctuations in water level observable in the presence of steady, periodic waves breaking on a sloping beach comprise an equilibrium that is the result of at least two different physical effects: (1) periodic oscillations at wave frequency which are the result of partial reflection from the shore slope of that portion of the initial energy of each incident wave not expended through breaking; and, (2) a super-elevation of the mean level against the shore caused by the gradient of momentum flux associated with wave decay in the surf zone.

The transition from a lowering of mean level under the breaker line (set-down) to a positive maximum (set-up) somewhere within the range of periodic shoreline excursions was predicted in principle by Longuet-Higgins and Stewart (1964) as a particular application of their more general theory for momentum flux in non-breaking waves. It was examined in some detail during a series of experiments by Bowen, et al (1968), in which waves of several frequencies and amplitudes were breaking on a uniform beach slope ($S = dD/dx = 0.082$). It was

found that the mean surface gradient $-d\bar{\eta}/dx$ was nearly linear, varied inversely with frequency, and was nearly independent of breaker height. Assuming, as roughly observed, a constant empirical proportionality factor γ between breaker height H and total water depth $(\bar{\eta} + D)$ within the surf zone, they were able to integrate the momentum flux equation of Longuet-Higgins and Stewart to obtain a linear ratio

$$-(d\bar{\eta}/dx)/S = (1 + 8/3\gamma^2)^{-1} \quad (1)$$

The authors note that, although the shoreline set-up $\bar{\eta}_S$ comprised the majority of the observed total run-up R , the latter was still in reasonable agreement with the empirical formula of Hunt (1969)

$$R = HS(H/L_0)^{-\frac{1}{2}} \quad (2)$$

where H is a wave height ordinarily taken as the corresponding deep water wave height H_0 , but, in fact, is most commonly obtained by linear transformation from heights measured in a uniform channel ahead of the slope. Lastly, Bowen, et al suggest that the ratio of beach-to deep water wave-steepness $S/(H_0/L_0)^{\frac{1}{2}}$ may have particular relevance to conditions in the surf zone, since it also appears in the breaking criterion of Iribarren and Nogales (1949). In an attempt to better estimate the quantitative predictions of their slope theory, they present a plot of $\bar{\gamma}$, the average of many determinations of γ across the surf zone, versus $S/(H_0/L_0)^{\frac{1}{2}}$, which includes data for two other beach slopes reported by Putnam (1945), but without drawing any further conclusions.

A more deterministic attempt to predict surf zone set-up is that of Hwang and Divoky (1970), who numerically integrated the momentum flux equation, assuming that (spilling) breakers can be represented by cnoidal waves, whose energy is dissipated at a rate equivalent to a constant fraction of that for a bore of equal local height. Although the many assumptions of this theory are difficult to defend, it provides a means of calculating the set-up and wave height decay simultaneously, and the latter, at least, appears to be in much better agreement with observations than the linear decay assumed by Bowen et al (1968). However, their computed set-up profiles are convex upwards, while the bulk of experimental results suggest that they are linear, or even concave upwards. Even so, the differences are small, and the method deserves further study.

Meanwhile, Battjes (1974a, b) has attempted by dimensional arguments to show that the steepness ratio

$$\xi \equiv S/(H/L_0)^{\frac{1}{2}} \quad (3)$$

is a similarity parameter that, depending upon the interpretation of H , can be used to categorize a wide variety of surf zone phenomena; such as, breaking, breaker type, breaker depth, energy reflectance, and the number of waves simultaneously present between the breaker point and the shoreline. Additionally, Battjes and Roos (1976, in press) present some results of experiments with water velocities and elevations within the swash zone, and try to fit them

into the same mold. But it is difficult to judge the accuracy of these results or conclusions for lack of adequate descriptions of equipment, methodology, or measurement error.

The present paper presents a portion of the results of a two year series of laboratory studies of the dynamics of periodic waves breaking on uniform impermeable beach slopes, in which the time histories of surface elevation, crest velocity, and horizontal fluid velocity, were measured at a plurality of observation stations before and after breaking, as function of slope and wave period. Particular attention was paid to the mean, and periodic, water level excursions across the breaker zone in an attempt to distinguish set-up from the dynamic shoreline excursions caused by reflections. Those experiments dealing with breaking kinematics are described elsewhere (Van Dorn, 1977), and this paper is restricted to shoreline effects, except as regards some pertinent new results from the above paper.

INSTRUMENTATION AND PROCEDURES

All experiments were conducted in a 0.5 m wide by 24 m long glass-sided wave channel with a constant still water depth of 36 cm. Twelve combinations of three plate-glass beach slopes ($S = 0.022, 0.040, \text{ and } 0.083$) and four wave periods ($T = 1.65, 2.37, 3.43, \text{ and } 4.80$ sec) covered the ordinary range of prototype wave conditions for length and time scales of 16:1 and 4:1, respectively. Waves were generated by a planar paddle, hinged 55 cm beneath the channel floor, and driven sinusoidally at the top by a crank shaper. All data runs commenced after at least 5 minutes of generator operation, found by experiment to be about the minimum for low-frequency start-up transients to decay and stable equilibrium to be achieved. Measurements involved the following types of instrumentation.

Surface elevation η versus time, referred to still water, was monitored simultaneously by a plurality of digital (shorting-contact) wave staffs and analog subsurface pressure gages. They were supplemented at specific locations by stroboscopic and flash photography through the channel walls. Comparison of data from these three sources soon established that elevations computed hydrostatically from subsurface pressure were substantially lower than the staff and photo elevations, which generally agreed within 1 cm. The discrepancy was greatest under the wave crests, where it sometimes amounted to 50 percent, diminishing to zero at the shoreline; trough elevations by all three methods agreed within 0.2 cm (Figure 1). This result may substantially affect the assumption of mean hydrostatic equilibrium basic to the theory of time-averaged momentum flux. It may also affect the interpretation of mean elevation given below. Overall elevation accuracy was poorest in vicinity of the plunge and rebound regions of intense breaking, especially on the 0.083 slope, where, in fact, the admixture of air and water made any definition of free surface elevation questionable.

Figure 1. Hodographs of maximum and minimum waves elevations as an individual wave moves toward shore. Pressure and staff elevations agree under troughs, but peak pressure is clearly a poor indication of crest elevation.

Mean elevation $\bar{\eta}$ was observed at fifteen stations evenly distributed between the respective slope toes and the still water shoreline. The sensors comprised 1.0 mm diameter glass tubes taped to channel wall, with their lower ends 1.6 mm above the glass slope. These tubes were connected by plastic tubing via a glass capillary restriction to 2.5 cm diameter, open-ended thistle tubes mounted vertically outside the channel. The time constant of these 'hydraulic hi-pass filters' was adjusted to one minute by varying the capillary lengths. The free surface elevations within the thistle tubes could be rapidly determined by an electric-contact prick probe mounted on a micrometer depth gage. It was found possible to replicate elevations within 0.002 cm after the channel had stabilized, and that annulment of channel seiche fluctuations within these tubes provided the best evidence for stability. While the glass beaches were sealed to the channel walls with rubber gasketing, the slope toes were unsealed, since it was found that sealing them resulted in slow mean elevation drift due to minute seepage between the ground, but unsealed, abutting ends of the glass sections.

Shoreline elevation was monitored versus time by a digital comb-type, shorting contact, wave staff suspended over each beach so that the comb tips cleared the glass surface by about 1 mm, found experimentally to be the minimum elevation required to reduce spurious signals produced by meniscus puddling of water between contacts. Contact spacing was 2 cm on the 0.083 and 0.040 slopes, and 4 cm on the 0.022 slope. The corresponding relative vertical (run-up) resolution of these staffs was always less than 0.2 mm, although the absolute dynamic run-up range may have been slightly larger than reported, owing to elevation of the contacts above the beach. A more-serious problem is the possibility of underestimating the run-up range by virtue of spurious contact shorting in the thin retreating film from a previous wave as a new

bore advanced over the slope. The only ready answer to this question seems to be the nearness of the observations to the limiting possible range, equivalent to the sliding of a frictionless block under gravity only (see Figure 8 and relevant discussion).

Data acquisition of all electric signals was accomplished on a Statos Mark III digital strip chart recorder. This instrument has a 2 khz response, 100 data increments per channel, and prints at a rate of 100 samples per second.

BREAKER CLASSIFICATION

All waves in the present experiments were breaking, and it is appropriate to place them in proper context before discussing results. All relevant breaking point variables are listed in Table 1. Here, phase velocity C_b was obtained from the slope of arrival time curves (accurate to 2%), but later found (Van Dorn, 1977) to be closely approximated by

$$C_b = (2g\eta_b)^{\frac{1}{2}} = (1.54 gH_b)^{\frac{1}{2}} \quad (4)$$

which is substantially slower than the commonly accepted shallow water velocity: $\{g(\eta_b + D_b)\}^{\frac{1}{2}}$. Breaking wavelength is taken as $L_b = C_b T$.

With this preamble, Figure 2 compares breaking steepness H_b/L_b versus beach slope S for the present data on a field of similar data subjectively classified by Galvin (1968) according to breaker type*. The two solid lines $\xi_b = 0.4$ and $\xi_b = 2.0$ represent Battjes (1974a) reinterpretation of Galvin's 'inshore' criteria separating spilling, plunging, and surging or collapsing (non-breaking) waves, where $(\xi_b \equiv S/(H_b/L_b)^{\frac{1}{2}} = 0.32S/(H_b/L_b)^{\frac{1}{2}}$; but the dashed line $\xi_b = 0.6$ appears to be more consistent with the stroboscopic sequences taken during the present study. By either criterion, about half the present waves were spilling and half plunging; but most students of this complicated subject would agree that there is a continuous apparent increase of breaking intensity as either slope or period increases toward the point where no breaking occurs.

* This representation omits Galvin's "plunging altered by reflection", since it has no statistical correlation with any other breaker type.

Figure 2. Classification of present breaker types according to Battjes' reinterpretation of Galvin's observations.

RESULTS

As a basic perspective of the results obtained in these experiments, Figures 3, 4, and 5 show, for the three respective beach slopes, comparisons of surf zone variables, ordered downward with increasing wave period. From left to right in each of the twelve period-slope combinations, mean surface elevation (black dots) is increasingly depressed below still water level as the break point (arrows) is approached, reaches a minimum in the vicinity of breaking, and then rises linearly toward the shoreline, although the data do not extend beyond the still water intersection with the beach. The open bars along the beach face give the dynamical range ΔY of steady state water motion, measured vertically from still water level, and whose upper limit represents the engineer's interpretation of run-up. The tic marks on the beach face labeled Y_t give the maximum recorded transient water level excursion associated with the initial surge at the start of each data run. Relevant numerical values of all data are included in Table 1.

Pre-Breaking Set-Down

The depression of mean elevation (set-down) in shoaling water predicted by Longuet-Higgins and Stewart (1964) has been shown by Bowen, et al (1968) to be in good accord with observation where wave growth is governed by linear conservation of energy flux, and to become too small as wave steepness increases beyond the linear range. Near breaking, this trend was reversed: predicted set-down continues to increase, whereas the experimental values were found to reach a flat maximum depression in the vicinity of the break point.

Figure 3. Set-down, set-up, and run-up range for the 0.022 slope.

Figure 4. Set-down, set-up, and run-up range for the 0.040 slope.

Figure 5. Set-down, set-up, and run-up range for the 0.083 slope.

Much the same results were obtained over the three present slopes, the steepest of which ($S = 0.083$) was the same as that used by Bowen, et al whose experiments were also conducted in the same wave channel. However, in an attempt to find a better approximation to the set-down under steep waves, the dashed curves shown in Figures 3-5 were calculated from the expression

$$\bar{\eta} = -\frac{H^2 k}{8 \sinh 2kD} \quad (5)$$

using observed values of H and D , and taking $k = 2\pi/CT$, where C was observed phase speed. It was hoped that the intersections of these curves with corresponding set-up lines within the surf zone might lead to a means of estimating maximum shoreline set-up, provided that these intersections could somehow be linked to breaker characteristics, and hence to deep water properties (Van Dorn, 1977). As can be seen the computed curves fit the data quite well over most of the growth range, except for those where $T = 1.65$ sec on the 0.022 and 0.040 slopes, where the observed set-down is unexpectedly large in deep water. The reason for this is not known: the experiments were repeated three times with always the same result.

Set-Up

In common with Bowen, et al (1968), set-up within the surf zone was found to be approximately linear, and, on the 0.083 slope, the mean surface slope also appears to increase with wave period, although the definition is doubtful for $T = 3.43$ sec, and completely uncertain for $T = 4.80$ sec, for both of which photographs indicate extremely violent turbulence extending clear to the bottom over most of the very-limited "surf zone". Seemingly, no simple meaning can be attached to 'mean elevation' under such conditions, where there is only one wave or less present simultaneously.

By contrast, the slopes of the set-up lines over the 0.022 and 0.040 slopes appear to be constant and independent of frequency within experimental error. Figure 6 is a plot of set-up slope $m = d\bar{\eta}/dx$ versus beach slope S which includes all present data together with others reported by Bowen, et al and Putnam (1945), where any possible variation due to frequency is represented by error bars. If the line

$$m = 3.4S^2 \quad (6)$$

can be assumed a reasonable fit to the distribution shown, then (1) requires that

$$3\gamma^2/8 = 3.4S/(1 - 3.4S) \quad (7)$$

From the geometry of Figures 3-5, it is evident that, to the extent that the set-down curves and set-up lines intersect at the breaking point (where the wave properties are reasonably predictable), then (1) can be integrated from this intersection ($\bar{\eta} = \bar{\eta}_b$) to obtain the maximum shoreline set-up $\bar{\eta}_s$:

$$\bar{\eta}_s = \bar{\eta}_b + \{3.4S/(1 - 3.4S)\} (\bar{\eta}_b + D_b) \quad (8)$$

Values of $\bar{\eta}_s$ computed from (8) by inserting breaking data into (5) to obtain $\bar{\eta}_b$ are given in Table 1. Comparing these with corresponding values obtained by extrapolating the observed mean slopes to intersection with the beaches shows too great a disparity for (8) to be regarded as a satisfactory prediction method. The principal sources of error are the neglect of the influence of frequency on the 0.083 slope, and the fact that the breaking points do not necessarily coincide with the intersections of the set-down and set-up intersections. Even so, (8) gives set-up values much closer to observations than the shallow water approximation, $\bar{\eta}_s = 0.3H_b$ suggested by Battjes (1974, p 58).

One of the assumptions basic to the set-up theory of Bowen, et al (1968) is the proportionality between breaker height and total water depth across the surf zone. Figure 7 shows plots of observed wave height versus total water depth and horizontal distance, all normalized to their respective breaking values. While the data for the 0.083 slope are scattered, they conceivably could be represented by straight lines, but over both smaller slopes wave height drops rather abruptly from the breaking point, and tends smoothly to some finite value at the still water shoreline. There appears to be relatively little systematic correlation with frequency. This behavior is qualitatively very similar to that predicted by the numerical set-up model of Hwang and Divoky (1970), although their appropriate bottom slopes are numerically too small. This difference might be resolved by a better energy loss coefficient.

Run-Up

Evidence of periodic shoreline oscillations at wave frequency is the most sensitive test that energy is being reflected from a sloping beach. Le Mehaute, et al (1966) and Putnam (1945) observed no perturbation of the mean level over a slope of 1:100, but the run-up range ΔY in these experiments was readily measurable on all three slopes, and increased regularly with slope and wave period, as shown by the open bars along the slopes in Figures 3-5.

Figure 6. Observed variation of linear mean set-up slope versus beach slope.

In analyzing the motion of bores on slopes, Shen and Meyer (1963) remark that the majority of the motion in $x-t$ space above the still water level should be expected to obey the parabolic law

$$x = u_0 t - \frac{1}{2} gSt^2 \quad (9)$$

where u_0 is the characteristic bore speed at $t = 0$. Equation (9), of course, also describes the motion of a frictionless block projected with velocity u_0 up a slope S . For the periodic shoreline oscillations considered here, the intuitively reasonable picture is that each breaker runs up or the backwash from its predecessor at intervals of a wave period; the whole motion being somehow superimposed on the mean shoreline set-up. Differentiating (9), and noting that $dx/dt = C = 0$ and $x = x_m = \Delta Y/S$ (say) when $t = T/2$, it is easily shown that

$$\Delta Y = gT^2 S^2 / 8 \quad (10)$$

Thus, to the extent that the waves can be considered frictionless bores, and that $S = \tan \alpha = \sin \alpha$, where α is the beach slope angle to the horizontal, (10) should be descriptive of the run-up range. The test of this estimate is: Figure 8, where ΔY is plotted versus $L_0 S^2 = gT^2 S^2 / 2\pi$ for all present data

as well as for that reported by Bowen, et al (1968) and Battjes and Roos (1977, in press)*.

Figure 7. Wave height versus total water depth and surf zone width, all normalized to breaking values.

The straight line labeled frictionless reflection represents (10) in these coordinates, and parallels the data very well. The present experiments, being conducted over plate glass slopes gives results much closer to the frictionless limit than those of Bowen, et al over a plywood slope, and that of Battjes is not described. The conclusion is that run-up range is independent of breaker height, and depends significantly on bottom friction. Indeed, such experiments might provide a sensitive test of frictional losses.

* For Bowen, et al, ΔY was taken as twice run-up, minus mean set-up; for Battjes and Roos, it was taken as ΔX_{cscx} , where ΔX was the observed water excursion along the slope.

Figure 8. Run-up range versus beach slope and wave period.

Total Run-Up

Nothing said so far provides a clue as to how set-up and run-up range combine to produce the observed maximum run-up, and the above results shed little light on this interesting problem. While no reliable means for predicting set-up has been discovered, Figures 3-5 show clearly that it always amounts to a substantial fraction of the run-up range, since the run-down seldom (if ever) goes below still water level. Second, run-up range, normalized to deep water wave height, is nearly the square of Hunt's (1969) relative run-up:

$$R/H_0 = (L_0/H_0)^{\frac{1}{2}} S \quad (11)$$

which is generally quoted as a reliable run-up index. At least, the comparisons given in Table 1 show that (11) is not a good approximation for small slopes. The values of H_0 used in the calculations were obtained from Van Dorn (1977), and are believed accurate to 10 percent.

Transient Run-Up

Figures 3-5 and the last column in Table 1 give observed values of transient run-up Y_t resulting from the initial surge associated with generator start up. The transient is manifested on the run-up records as a single intumescence, having a duration equal to 3-5 wave periods, that reflect back-and-forth between the wave paddle and beach slope, slowing decaying after several minutes. These transient surges are of interest because their amplitudes substantially exceed the steady-state run-up in many cases, and because they can be expected to occur whenever the momentum flux is varied rapidly, as for example, when waves come in groups. Because their characteristics clearly depend upon the shape of the advancing energy front, no attempt was made here to relate them to other fixed parameters.

CHAPTER 43

WAVE RUN-UP ON A SIMULATED BEACH

A.J. Sutherland¹, J.N. Sharma², O.H. Shemdin³

ABSTRACT

A set of experiments concerning wave run-up in the presence of an offshore bar is described. Results pertaining to the direct relationship between incident waves and run-up heights are presented. It is clear that in the majority of cases the offshore bar does reduce run-up heights. The experiments showed that under certain conditions very large run-up and run-down heights are produced. This is ascribed to a resonance effect between either the basin, formed between the bar and the beach, or the beach face and the incident waves.

INTRODUCTION

The run-up resulting from the arrival of a train of waves at a beach slope is an important design consideration in many coastal engineering problems. Wave run-up is the maximum vertical height, above the local mean water level, reached by a wave at the end of its travel across the beach.

In reaching the beach, waves pass through the breaking zone and the surf zone in each of which they experience highly non-linear transformations and undergo energy dissipation. Studies of the run-up produced by a bore (Meyer and Taylor, 1972) indicate the importance of frictional dissipation in determining run-up. Other important effects include the interactions between successive waves (by collisions) on the beach slope and the presence of an offshore bar which can cause breaking. The former is important when irregular wave trains are considered while the latter applies to periodic waves as well as to irregular waves. Both effects increase energy dissipation to an unknown extent.

Laboratory measurements of run-up made by van Oorschot and d'Angremond (1968), with mechanically generated waves, and by Webber and Bullock (1968), with wind generated waves, have provided data for conditions in which interactions between waves on the beach slope are an important factor. Battjes (1971) has presented an analytical model of this process but no comparison with data was attempted. Field measurements of run-up by

³ Professor of Coastal and Oceanographic Engineering on leave to Jet Propulsion Laboratory and Scripps Institute of Oceanography, California

Waddell (1973) and Sonu *et al* (1974) must reflect, in addition to the above interactions, the influence of many other factors including the offshore profile, the beach profile, the beach roughness and permeability and the characteristics of the incident waves.

The present study is primarily concerned with the effect of a beach profile which includes a bar. Such profiles are typical of the east coast of Florida. Tests were conducted in the laboratory using a profile modelled on that at Jupiter Island, Florida. Effects of the pronounced offshore bar were determined by measuring wave run-up with a variety of incident wave and water depth conditions.

EXPERIMENTAL APPARATUS AND PROCEDURE

The experiments were performed at the University of Florida in the Coastal and Oceanographic Engineering Laboratory air-sea facility, shown in Figure 1, which has been described by Shemdin (1969). Waves are generated by a plate hinged at the bottom and driven by a hydraulic piston. Sinusoidal waves with frequencies in the range 0.2 to 4.0 Hz can be produced with amplitudes up to 10 cm. By using prepared analogue tapes as input the wave generator can be driven so as to produce irregular waves of known spectral shape. There is provision for blowing air over the waves. This was not used in the present experiment.

A model (approximate scale 1:20) of the Jupiter Island beach profile as measured in November-December 1974 was placed at the beach end of the facility. Figures 2 and 3 show the beach profile and the model as constructed. For water depths over the bar of less than 30 cm (68 cm total depth) it was not possible with the wave generator hinged at the base, to generate waves of height comparable to the water depth over the bar. For subsequent tests with reduced water depths at the bar the profile was raised 23 cm and the forward slope of the offshore bar extended at the same slope until it again met the floor of the channel. At the minimum bar depth tested, 5 cm, the water depth in the channel was 66 cm in which waves of sufficient height could be easily generated. For tests with a plane beach slope the horizontal section and the bar were removed from the channel.

Capacitance wave height gauges made from Nyclad insulated wire were placed at the mid-point of the horizontal section 6.10 m "seaward" of the bar at station 2 and 18.29 m "seaward" of the bar at station 4. Most calibration curves were linear with the occasional one consisting of two straight lines meeting near the zero point. Hewlett Packard 7700B recorder bridge circuits conditioned the signals from the gauges. The bridge output, an analogue voltage signal, was taken directly to a Kinematics DDS 1103 (16 channel) Data Acquisition System set to digitize the signal at 10 samples/sec.

A 1.88 cm diameter spiral wound resistance wire wave-staff manufactured by Oceanographic Services was installed parallel to and 6.3 mm from the beach face (see Figure 4). The associated electronics gave an analogue voltage output which was sampled by the data acquisition system at 10 samples/sec, essentially simultaneously with the wave height records. The gauge was calibrated by filling the facility above the level of the

Fig.2:- TYPICAL BEACH PROFILE AT JUPITER ISLAND

-Dimensions in metres-

Fig.3: BEACH PROFILE MODEL

highest expected run-up and then lowering the water level slowly. At selected points the water surface elevation and the resultant output voltage were noted. The calibration curves were closely approximated by two straight lines of similar slope and in a few instances were exactly linear.

Fig. 4:—SPIRAL WOUND WAVE GAUGE USED FOR MEASURING RUN-UP

A prepared analogue tape was used to provide an input signal for the wave generator. This produced waves having a Bretschneider spectrum and was used for all tests with irregular waves.

At each of eight water depths at the bar a series of tests was performed. Firstly irregular waves having a Bretschneider spectrum were generated and the run-up recorded. Five such runs with different significant wave heights were carried out. Then sinusoidal waves with a frequency of 0.7 Hz, corresponding to the frequency of the peak of the spectrum of the irregular waves, and various wave heights were examined. Sinusoidal waves of 0.3 Hz were also investigated as the peak of the run-up spectrum occurred at 0.3 Hz.

With the bar removed the same series of tests was performed on a plane beach with a water depth of 41 cm in the channel.

The data recorded during each run was the water depth at the bar, the output from the run-up gauge and the three wave height gauges and the RMS voltage supplied to the wave generator. The last being a measure of input wave energy. The digitised records as recorded on tape were processed at the NERDC computing center.

In all, 109 runs were performed. The output from the computer for all these runs is available in the Coastal Engineering Department. The calibrated records have been recorded on a master tape deposited at the NERDC.

RESULTS AND ANALYSIS

Some general observations and impressions are given first. These are followed by the numerical results.

General Observations

Irregular waves cause run-up patterns on a plane slope which differ markedly from those created by regular waves. In these experiments the dominant frequency of run-up (approximately 0.3 Hz) was noticeably less than that of the incident waves (0.7 Hz) and the run-up distribution appeared wider than the wave height distribution. Spectral widths of the run-up ranged from 0.6 to 0.7 compared to 0.42 to 0.49 for the incident waves. Both effects (lower dominant frequency and wider spectrum) result from collision and overtaking on the beach slope. These mechanisms are the significant ones in determining the run-up distribution.

Webber and Bullock (1968) noted that it is often impossible to attribute a particular run-up crest to any individual wave. This was certainly true in the present experiments being most noticeable in the presence of a bar on which a significant number of the incident waves broke.

Most experiments showed a significant rundown which may be defined as the vertical distance below still water level to which the water's edge retreats. There were also negative run-up heights, maxima in the run-up record, which were as much as 2.0 cm below still water level. This would seem to be a result of seiching in the basin lowering the mean water level at the beach as a small wave reached the beach. Such seiching would be excited if the incoming wave has frequency components corresponding to the natural frequency of the basin. With sinusoidal waves of 0.7 Hz both the run-up and the run-down were less than for sinusoidal waves of 0.3 Hz at much smaller incident wave heights. An example is given in Table 1. The high run-up shown for 0.3 Hz could result from the beach having a natural swash frequency of 0.3 Hz, but it is hard to see this producing the observed run-down. Present results do not allow seiching effects to be separated from resonance effects on the beach.

TABLE 1
 RUN-UP AND RUN-DOWN FOR SINUSOIDAL WAVES

Bar Depth (cm)	Wave Frequency (Hz)	Incident Wave Height (cm)	Run-up (cm)	Run-down (cm)
15	0.7	11.0	6.1	-
15	0.3	4.8	11.4	4.9

Having more wave gauges in the basin would possibly allow these effects to be separated. Using the same beach slope with a basin of different geometry may shed light on relative importance of the seiching and the beach resonance.

For a given water depth over the bar the percentage of waves breaking on the bar increased with incident wave height. With sinusoidal waves, spilling from the top occurred when the incident wave height was approximately 60% of the bar water depth. On reaching 70% of the bar water depth all the waves were breaking at the bar crest. For further increase in wave height the break point moved "seaward" down the slope leading to the bar. Observations typical of those made with irregular waves are given in Table 2.

TABLE 2
 BREAKING PERCENTAGE FOR IRREGULAR WAVES

Bar Depth (cm)	Significant Incident Wave Height (cm)	Percentage of Wave Breaking
25	10.4	0
	13.1	5
	16.2	20
	20.4	70
15	7.6	5
	11.5	20
	16.4	70
	20.4	>90

For a water depth at the bar of 5.0 cm the incident wave height seemed almost irrelevant for the run-up. Waves all broke on the seaward slope of the bar and spilled over into the basin. This created waves in the basin which in turn resulted in run-up. The waves were much more regular and much smaller than the incident waves; their properties were probably governed by a combination of the basin geometry and the impulse given to the water in the basin. This represents one end of the spectrum of possible effects caused by the presence of a bar. The other end is when the bar is absent or ineffective.

Fig. 6:-- SPECTRA OF RUN-UP, WAVES BETWEEN BAR AND BEACH (St.2) AND INCIDENT WAVES (St.4)

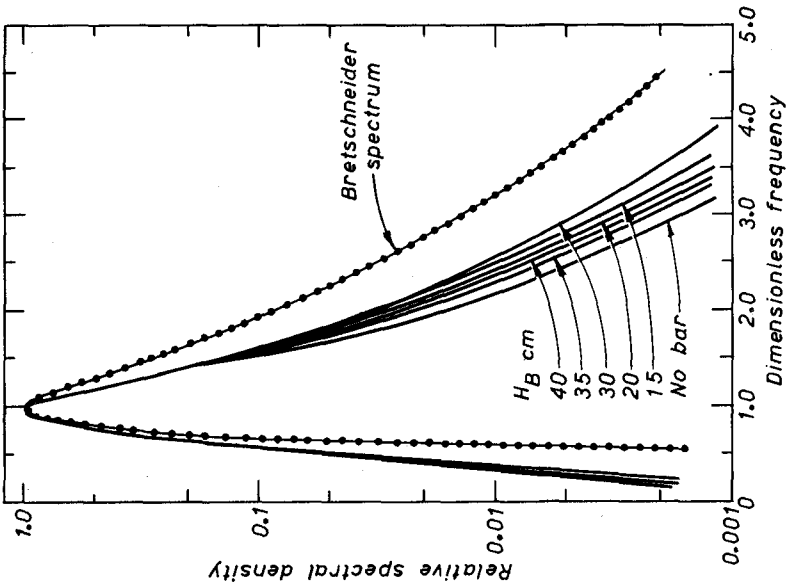

Fig. 5:-- INCIDENT WAVE SPECTRA AND BRETSCHNEIDER SPECTRUM

Numerical Results

Incident Wave Spectra: Smoothed incident wave spectra from all runs at a given bar water depth H_B were plotted in dimensionless form and averaged. Figure 5 shows there is little difference between the spectra at different water depths. However, the generated spectra contain more power at low frequencies and less power at higher frequencies than does the Bretschneider spectrum. The spectral width parameter, ϵ , as defined by Coorschot and d'Angremond (1968) ranged from 0.42 to 0.49 for the generated spectra.

Run-up Measurements: The run-up gauge was designed as a wave staff to be used in a vertical position. When placed on a 1:8 slope and being 1.88 cm in diameter a horizontal water surface intersected the staff over 15.0 cm of its length, see Figure 4a. By calibrating as described above it was assumed that the gauge would be shorted from the last wetted coil down to its lower end, i.e. from coil A in Figure 4a. Then during operating conditions, see Figure 4b, the level recorded would be that of coil B and as such a good measure of the run-up height. However, it appears that simply wetting the coils along the underside of the staff is not sufficient to short them out. The value recorded actually lay somewhere between B and C of Figure 4b where the water surrounds the staff in a way equivalent to that during calibration. The effect is worst when the run-up is highest. Such run-up has a very long thin tongue that extends up the slope and only the underside of the gauge is wet for perhaps 60.0 cm corresponding to a vertical height of 7.5 cm. The error in reading these highest run-ups may thus be 3 or 4 cm in 15 or 20 cm. For the majority of the run-ups, those without very long tongues, the error is of course much less.

This effect was first noticed when values of run-up height on a plane beach divided by incident wave height less than published values were being obtained. A check on the gauge was made in a number of experiments. The run-up height was measured by marking the maximum excursion on the beach face and later measuring its position relative to still water level. These values were later compared with those measured by the run-up gauge. For sinusoidal wave input this is a viable technique because the run-up does not vary significantly between waves. For irregular waves only the maximum could be recorded and an estimate made of the mean.

Such observations confirmed that high run-up values were being under estimated. In some cases this amounted to 25%. One cannot however reliably estimate the error introduced into the results because, particularly for the irregular waves, the shape of the run-up tongue will vary from run-up to run-up. The effect on the run-up spectrum may not be as serious since each run-up event would be recorded and the record would reach a peak at virtually the same time as the run-up peak. The effect is not simply to clip the top off each peak and thus introduce spurious frequency components.

Clearly a different type of gauge must be designed and built for any further tests. It must be such that it responds to point wetting. A step gauge made from a series of electrical contacts each of which records the presence or absence of water is recommended.

In spite of run-up measurement limitations as discussed above, it has been possible to obtain valuable results on run-up dynamics in the

presence of a bar. Spectra of run-up, incident waves (at St. 2) and waves behind the bar (at St. 4) are shown in Figure 6. The spectrum behind the bar is lower than the incident wave spectrum as a result of bottom friction between the two gauges and of dissipation over the bar. The peak frequency of waves remains unchanged before and after the bar. The run-up spectrum, however, shows a distinct shift in the peak frequency to a lower value. Significant dissipation in the higher frequencies and amplification of the lower frequencies in the run-up records is evident. The coherency between the incident waves and run-up height is generally small.

Interesting results on run-up dynamics are also deduced from the equilibrium slope of the spectrum. The incident wave spectrum is shown in Figure 7 and has the (-5) slope expected for gravity waves. The corresponding run-up spectrum exhibits a (-4) slope in the equilibrium range as shown in Figure 8. Dimensional analysis based on the assumption that the dominant spectrum parameters are turbulence intensity, (cm^2/sec^2) and frequency, (Hz) yields a slope of (-4) in the equilibrium range. In contrast gravity and frequency yield a (-5) slope for gravity waves. The result of Figure 8 coupled with the fact that normally significant breaking occurs on the bar suggests that the dynamics of run-up are dominated by turbulence rather than by gravity.

The statistics of the run-up height also differ from those associated with the narrow band gravity wave spectrum. Figure 9 shows the run-up height distribution on probability paper and suggests that run-up can be reasonably described by a Gaussian distribution. This is in accord with the results of Webber and Bullock (1968). It is clear that despite the highly non-linear process affecting run-up, as deduced above, run-up remains a random process but with a different signature. The Gaussian run-up distribution is consistent with the broader band spectrum of Figure 8 compared to that of Figure 7.

Reduction of Run-up Due to Bar:

The direct effect of the bar is to reduce the energy in the wave train. A measure of this energy is the area under the power spectral density curve. The percentage reduction in this value as a function of water depth at the bar H_B is given in Figure 10. The reduction refers to that occurring between a wave gauge 18.29 m from the bar and the gauge in the basin. Some of the reduction is therefore due to viscous action as the waves move along the channel. It appears as though this may be about 25% because at H_B/H_G greater than 3.5, the effect of the bar can be expected to be small.

The effect of this reduction in energy can be seen in Figure 11. Here run-up height has been plotted as a function of incident wave height. The points were derived from the observations made with sinusoidal waves. The number beside each point is the ratio H_B/H_G . As the ratio reduces the points tend to fall further below the standard Beach Erosion Board curve.

Run-up divided by incident wave height as a function of incident wave steepness is shown in Figure 12, in which the points of Figure 11 have been replotted. The number beside each point is again the ratio H_B/H_G . Ignoring those points corresponding to a bar depth H_B of 5 cm (for reasons discussed under General Observations above) there is a tendency for high values of H_B/H_G to be towards the upper left and low

values to be low and to the right. Although these points are barely sufficient to define contours of H_B/H_S , best contour lines are inserted to emphasize trends. The contours suggest that run-up heights can be either smaller or greater than the values predicted by the Beach Erosion Board formula depending on the ratio of water depth over the bar to the incident wave height. An examination of dominant wave height, period and beach conditions during a storm suggests that H_B/H_S is approximately 1.0 and the expected run-up is significantly below the value predicted by the BEB formula.

CONCLUSION

This study has revealed a number of important and interesting aspects of the run-up process occurring in the presence of an offshore bar. The following specific conclusions are derived:

1. The run-up is the product of a highly non-linear process acting on waves approaching a beach. The run-up process is dominated by turbulence generated by breaking waves and friction.
2. The offshore bar has a significant reducing effect on the run-up height. Resonance and seicheing in the region between the bar and the slope can produce significant amplification in run-up and in some cases produce run-down.
3. Continued research is recommended on this problem to investigate the effects induced by movable beds and variable geometry on run-up. Run-up measurements should be made by implanting electronic contact elements in the surface along the beach slope. Field and laboratory studies will be necessary to arrive at adequate modeling relationships for proper prediction of the run-up height.

CHAPTER 44

WAVE RUN-UP IN FIELD MEASUREMENTS WITH NEWLY DEVELOPED INSTRUMENT

Heie F. Erchinger

Coastal Protection Department
D 2980 Norden/Ostfriesland, West-Germany
P.O.-Box 102

ABSTRACT

The height of dikes and other coastal structures can only be calculated after determination of the wave run-up. Several formulas for the calculation of wave run-up are developed after model tests as a rule. But the influences of scale effects and natural wind conditions are practically unknown. To clear these questions further investigations and especially field measurements should be carried out.

By measuring the markerline of floating trash on the slope of the seadikes the maximum wave run-up could be found out after four storm surges in 1967 and 1973. In two graphs it will be shown that on the tidal flats the run-up depends on the waterdepth. The run-up was higher than it could be expected after model tests of 1954.

With a newly developed special echo sounder the run-up could be measured in January 1976. The waves and the run-up could be registered synchronously during two severe storm surges. As shown in Fig. 9 it was found a logarithmic distribution of the wave height, wave period and the higher part of the wave run-up. The found wave run-up is considerably higher than estimated before. The measured 98 % run-up is found about twice the computed value. That is an interesting and important result of the first synchronous recording of wave run-up on sea dikes.

INTRODUCTION

For the design of dikes and other coastal structures and especially for the calculation of their height it is fundamental to determine the wave run-up. The run-up can be calculated with several formulas for different conditions relating to the wave characteristics, the steepness and the roughness of the slope and the position of the structure to the wave propagation direction. As a rule the equations are developed after model tests. But nature and magnitude of scale effects are practically unknown. Also the natural wind conditions are not accurately simulated.

As Professor Führböter has found that model tests with breaking waves do not provide quantitative transferable results, when they are carried out with usual model scales, further investigations are to be done. One way is to carry out field measurements.

THE MARKERLINE OF FLOATING TRASH

Two methods of measuring wave run-up data in the field are usual and carried out at several places:

1. measurement of the markerline of floating trash and
2. visual measuring the run-up of the waves during the storm surge by men on the dike.

Field measurements of the markerline are carried out along the Eastfrisian coast of the German Bight, the south-eastern part of the North Sea. In front of the sea dikes the 5 to 8 km wide tidal flats and the range of sand islands are situated.

After four storm surges in 1967 and 1973 the markerline of the floating trash was measured on the sea dikes in 37 positions. The maximum wave run-up of each position during each storm surge followed from the difference between the storm tide water level and the markerline of floating trash, measured in a

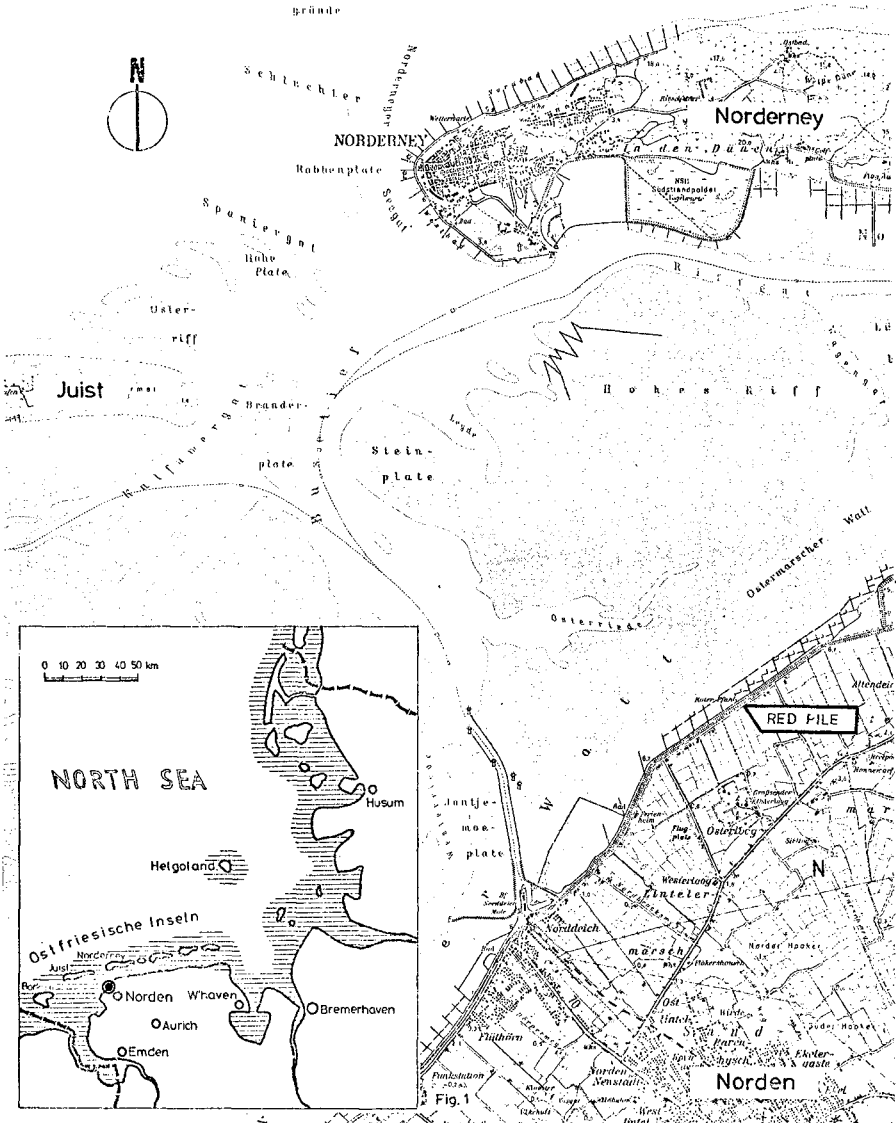

Fig. 1 LAY-OUT PLAN: POSITION "RED FILE" WITH THE TIDAL FLATS AND THE INLET BETWEEN THE ISLES OF JUIST AND NORDERNEY

perpendicular line. Fig. 2 shows the height of the markerline, the highest storm tide level in several locations and the height of the foreland or the tidal flat in front of the dike. It shows further that the markerline is similar to the reflected image of the section through the ground in front of the dike. In three different positions the values of wave run-up during the highest storm tide of this period on Nov. 19th 1973 are specially marked:

	waterdepth near the dike	wave run-up
1. dike without foreland position: "Red Pile"	3.60 m	2.95 m
2. dike with 250 m wide foreland	1.87 m	0.97 m
3. dike with 250 m wide foreland with a summer- dike, 0.57 m waterdepth on its crest	1.87 m	0.11 m

markerline of floating trash	max storm tide water level	storm surges on:

—————	—————	Nov. 19th 1973
—————	—————	Dec. 6th 1973

foreland
 summerdyke

Wave Run-up by Measurement of the Markerline of Floating Trash

Fig. 2

These data show the influence of the waterdepth near the dike and mark out the importance of the foreland and the summerdike in reducing the wave run-up and the wave-wash on the dike. The summerdike is a dike on the foreland with a height of approximately 1.5 m, which prevents the inundation of the land behind during lower summer surges.

As wave characteristics on the tidal flats depend on the waterdepth the run-up data were related to the waterdepth in front of the dike. They could not be related to wave data as no wave measurements are carried out on the Eastfrisian tidal flats during these storm surges in 1967 and 1973.

Fig. 3

The graph Fig. 3 shows the "wave run-up" dependent on the "waterdepth". Three groups of data are to be distinguished:

- 1) on dikes without foreland,
- 2) with foreland and
- 3) behind a summerdike on the foreland.

After researching the relation of the values of one place in the four storm-surges the bordering lines with most of the data between them were drawn. We found that wave run-up on the dikes behind a tidal flat with shallow waterdepth and the protection by a range of islands was higher than we could expect after model tests of 1954.

But this measuring of the markerline of floating trash only shows the maximum wave run-up and not the scattering of the values. But the variability is important to know for the determination of the 50 %, 98 % and other values. It is unfavourable, too, that in severe storm surges the trash will be thrown onto the crest or even onto the inside slope of the dike in some places. Sometimes the trash will be scattered by high wind velocities.

Therefore, further study of wave run-up by field measurements was necessary. It would be desirable to get wave and wave run-up data for several positions with different conditions during storm surges and to record synchronously the waves and the wave run-up in these positions.

THE WAVE RUN-UP RECORDER

In December 1975 a special echo sounder record was mounted on the dike near the position "Red Pile". The Red Pile is situated on a dike without foreland, with a low tidal flat in front of it and comparatively high wave action during storm surges as the position lies in a distance of 8 km from the inlet between the isles of Juist and Norderney in south-eastern direction. The normal on the slope of the dike has a direction of approximately North-West, exactly 324 degrees to North.

Fig. 4 Slope of a Seadyke with Instruments for Wave Measurement

The dike is covered with a revetment at the outer toe up to NN + 3.0 m that means 1.8 m above MHW, then a slope of smooth asphaltic concrete with an inclination 1 on 6 up to NN + 4.5 m and the upper part with grass covered clay up to NN + 8.0 m also 1 on 6.

Fig. 5 THE STEEL BOX WITH THE TRANSCIEVER
AND THE TUBE WITH THE HOLES

The instrument consists of a waterproof steel box with the transceiver, a small stainless steel tube with a bore of 1 inch and 4 to 8 mm wide holes with a distance of 2 m between each other, and a recorder in a shed at the inside toe of the dike. The tube is fastened on the slope of the dike. Its length is limited at 12 m and, therefore, on the 30 m long slope the system was needed three times. Each second the echo sounder sends 3 pulses into the tube. The pulses are reflected at the non covered holes and each hole is registered in a separate line by the recorder. When the hole is covered by water of the wave uprush the registration is interrupted. The highest interruption shows the maximum run-up of the wave.

Fig. 6 STEEL BOXES AND TUBES FASTENED
ON THE SLOPE OF THE DIKE

The echo sounder for wave run-up is combined with a supersonic echo sounder for wave measurement. Its receiver is mounted on a frame of steel and placed on the ground of the tidal flat in front of the dike with a distance of 50 m. The time interval between the generation of the sounding signal and the return of its echo after striking the bed is automatically recorded by the instrument and shows the water depth in that moment. The values of both instruments are transmitted by cable to the recorder in the shed inside the dike.

Fig. 7 THE "RED PILE" AND THE SHED FOR THE RECORDER

In the foreground the Red Pile, which formally has signed the border of two sections for the maintainance of the dike.

This wave run-up recorder and the wave recorder are developed by Dr. Fahrentholz in Kiel / West-Germany.

Another type of wave run-up recorder is developed by the Bundesanstalt für Wasserbau in Hamburg. At the lower side of the quadratic steel tube inductive approximity switches are mounted. When they are touched by the wave uprush they give an impulse to

the recorder. As the instrument was mounted this year in springtime no results could be registered by this recorder to date.

REGISTRATION IN JANUARY 1976

Therefore, only the before explained instrument was able to registrate wave run-up in the severe storm surges on January 3rd and 21st 1976. In these storm surges the water level increased 3 m higher than MHW due to wind set up. The following interesting values could be recorded during the hour of the highest water level at station "Red Pile".

Fig. 8 RECORDING PAPER WITH REGISTERED VALUES

Fig. 8 shows the registration. Three pulses each second are reflected at the holes in the tube. After receiving the pulses they are recorded in a line. Three recording systems with the transceiver and the tubes with holes can be distinguished. As the tubes are open at the low end the water level in the lower tube gives echos, which are recorded too. The single wave uprushes on the slope cover the holes and hence

follows an interruption of the line. The upper interruption gives the highest hole covered by that wave. Hence follows that the run-up reaches the following interval. The plotted black point marks the highest hole covered by water.

During both storm tides the wave run-up data were registered continually but we did not succeed in recording the waves during the high storm tide level without interruption following from two reasons:

1. By the strong movement of the water much silt and fine sand of the ground was kept in suspension and gave an echo which was recorded so that no clear echo of the waves could be distinguished. This trouble will be repaired by varying the transceiver.
2. Near Red Pile the radio station Radio Norddeich for ships broadcast is situated. By a strong radio long-wave transmitter the echos of the wave recorder are influenced and as during stormsthis transmitter is in action very often this second trouble is to be repaired by varying the transceiver.

From these teething troubles follows that only 40 % of the record of waves on January 21st could be analysed and we hope that this part gives a representative section. The wave run-up data have been registered without interruption.

Fig. 9 FIELD MEASUREMENTS OF WAVES AND WAVE RUN-UP AT STATION "RED PILE"

- ▽ Wave height (m)
- Wave run-up (m)
- Wave period (s)

FIRST RESULTS

Fig. 9 shows the analysis of the wave run-up and wave recording during the hour of highest water level. The data of the run-up are prepared after the method of WEIBULL. The curves are plotted with abscissa representing the logarithm of the data of wave height, wave run-up and wave period and with ordinates representing the integral of normal distribution. As the curve of wave height and period approximately follows a straight line we find a logarithmic distribution. The higher part of the run-up data follows a straight line too; only the lower part follows a curve becoming flatter to the low end.

Local conditions at station Red Pile:

Slope of the dike : smooth asphaltic concrete
up to NN + 4.5 m;
the upper part: grass
covered clay;
inclination 1 on 6

	<u>Jan. 3rd</u>	<u>Jan. 21st</u>
Storm tide mean high water level during measurement	: NN + 4.07 m	NN + 4.07 m
Waterdepth in front of the dike	: ~ 4.0 m	~ 4.0 m
Angle of incidence of waves	: ~30 degrees	~30 degrees
Wind conditions (Beaufort force)	: W 10 - 11	W 9 - 10

The main data are:

Wave run-up (m)

	angle of incidence			
	30 degrees		reduced to rightangled (115 %)	
	Jan. 76,	3rd 21st	3rd 21st	
max: wave run-up	3.80	3.50	4.35	4.05
98 % " " "	3.20	2.95	3.70	3.40
<u>sign. wave height</u>	Jan. 21st:	$H_s = 1.44$ m ($H_m = 1.07$ m)		
<u>sign. wave period</u>	Jan. 21st:	$T_{Hs} = 4.9$ s ($T_m = 3.9$ s)		

The found wave run-up is considerably higher than estimated before, even with the probable maximum water level, which is 1.3 m higher than the storm tide level during the measurements.

And at the end an example, controlling some of the numerous formulas for wave run-up:

HUNT VINJE:

$$Z = 1.56 \cdot \sqrt[4]{H_s} \cdot T_{Hs} \cdot \frac{1}{n} = \underline{1.53 \text{ m}}$$

BATTJES:

$$Z_{0.98} = 2.3 \sqrt[4]{H_s} \cdot T_m \cdot \frac{1}{n} = \underline{1.79 \text{ m}}$$

DELFT:

$$Z = 8 H_s \cdot \frac{1}{n} = \underline{1.92 \text{ m}}$$

In fact we measured a 98 % run-up, reduced to rightangled incidence of

$$Z_{0.98} = \underline{3.4 \text{ m}},$$

that is wellrounded about twice the computed value.

That is an interesting and important result of the first synchronous recording of wave run-up on sea dikes. Further investigations will be necessary in several positions with different wave conditions on dikes with foreland and without foreland.

CHAPTER 45

CHARACTERISTICS OF FLOW IN RUN-UP OF PERIODIC WAVES

By Ary Roos¹ and Jurjen A. Battjes²

ABSTRACT

An experimental study is presented of some characteristic parameters of the flow in the up-rush and down-rush of periodic waves breaking on a plane, smooth slope. The water layer thickness has been measured as a function of time at four locations above still water level. Discharges and particle velocities have been calculated. The results have been made non-dimensional on the basis of Hunt's formula for the run-up height. They appear to be either independent of the wave steepness H/L_0 and slope gradient $\tan \alpha$ or to be a function of a single similarity parameter $\xi = \tan \alpha / \sqrt{H/L_0}$ only. An hypothesis is stated concerning a relation between the mean rate of overtopping of a dike by waves, and the run-up which would occur under the same circumstances on an uninterrupted slope. On the basis of this hypothesis the overtopping volume per wave can be normalized so as to make it independent of slope angle and wave steepness. A comparison of the result with measurements from other sources indicates a rough agreement.

1. INTRODUCTION

The run-up of waves is an important factor in the design of shore structures. It has been investigated in many studies, both theoretical and experimental. The experimental studies have mostly been confined to the run-up heights (the greatest heights above still water level, reached by the individual waves on the slope). A simple and reliable formula for the run-up height is given by Hunt (4), based on measurements with periodic waves breaking on smooth plane slopes. However, virtually no data are available regarding the characteristics of the flow in the up-rush and the down-rush on a smooth slope, such as layer thickness, particle velocity, wave front velocity, and so on. Such information can be of use in developing or adjusting schemes for numerical calculation of run-up and overtopping, as well as in problems of stability of cover layer material or of seepage of water into the core material of a dike. The purpose of this paper is to present empirical results concerning the above-mentioned flow parameters, obtained from experiments with periodic waves breaking on smooth plane slopes. In the analysis of the data considerable attention is given to similarities in the run-up process; the existence of such similarities had previously been inferred from Hunt's formula for the run-up height.

2. RUN-UP PARAMETERS

In this study periodic waves of perpendicular incidence are considered, breaking on smooth plane slopes. Only the motion of the relatively thin water layer on the slope above the still water level is dealt with.

The independent parameters considered are (see fig. 1) the height of the incident waves H , the wave period T , the water depth d , the acceleration of gravity g , the slope angle α (a smooth plane slope is considered) and the mass density ρ and the dynamic viscosity μ of the water. A coordinate system is chosen as shown in fig. 1. The origin O is situated at the still water line. The x -axis is directed upwards along the slope. The dependent variables are the layer thickness h , the particle velocity v (averaged over the layer thickness) and the velocity of the run-up wave front c . The variables h and v are functions of the independent variables x and t , in which t is the time; c is a function of x or t .

1. Research Engineer, Directorate for Watermanagement and Hydraulic Research, Rijkswaterstaat, The Hague, The Netherlands.
2. Associate Professor of Fluid Mechanics, Department of Civil Engineering, Delft University of Technology, Delft, The Netherlands.

Fig. 1. Definition sketch.

Altogether the following parameter equations are obtained:

$$\begin{aligned}
 h &= F(x, t, H, T, d, g, \rho, \mu, \alpha) \dots\dots\dots (1) \\
 v &= F(x, t, H, T, d, g, \rho, \mu, \alpha) \dots\dots\dots (2) \\
 c &= F(t, H, T, d, g, \rho, \mu, \alpha) \dots\dots\dots (3)
 \end{aligned}$$

Dimensionless combinations can be formed from the variables of Eq. 1 to 3. It may be possible to reduce the number of relevant independent dimensionless parameters by choosing proper scaling quantities. In this way the variables are not merely made dimensionless; they are normalized. Hunt's formula (3), supplemented by an interpretation given by Battjes (1), provides a clue as to the choice of the appropriate scaling quantities.

Hunt's formula is based on measurements of the run-up of periodic waves breaking on smooth plane slopes. It can be written as:

$$R = \sqrt{HL_0} \tan \alpha \dots\dots\dots (4)$$

in which R is the run-up height and L_0 is defined by:

$$L_0 = \frac{gT^2}{2\pi} \dots\dots\dots (5)$$

By substituting Eq. (5) in Eq.(4) this can be written as:

$$R = 0.4 T \sqrt{gH} \tan \alpha \dots\dots\dots (6)$$

From the Eqs. (4) and (6) it appears that the horizontal distance between the still water line and the point of maximum wave run-up is $\sqrt{HL_0}$ or $0.4 T \sqrt{gH}$, independent of the slope angle and the wave steepness. This suggests the use of T , \sqrt{gH} and $\sqrt{HL_0}$ as scaling parameters for the time and the horizontal velocities and lengths of the run-up process. No information is available regarding the scale for the layer thicknesses. Tentatively the same quantity will be chosen as for the horizontal lengths, i.e. $\sqrt{HL_0}$. The following relations are obtained in this way:

$$\frac{h}{\sqrt{HL_0}} = F\left(\frac{x}{\sqrt{HL_0}}, \frac{t}{T}, \frac{d}{L_0}, \frac{\rho H^2}{\mu T}, \frac{H}{L_0}, \alpha\right) \dots\dots\dots (7)$$

$$\frac{v}{\sqrt{gH}} = F\left(\frac{x}{\sqrt{HL_0}}, \frac{t}{T}, \frac{d}{L_0}, \frac{\rho H^2}{\mu T}, \frac{H}{L_0}, \alpha\right) \dots\dots\dots (8)$$

$$\frac{c}{\sqrt{gH}} = F\left(\frac{t}{T}, \frac{d}{L_0}, \frac{\rho H^2}{\mu T}, \frac{H}{L_0}, \alpha\right) \dots\dots\dots (9)$$

The parameter $\rho H^2 / \mu T$ is a Reynolds number for the incident waves. It is assumed that this does not affect the dimensionless dependent variables of Eqs. 7, 8 and 9. The dimensionless variable d/L_0 gives the effect of the water depth. From experiments, such as those reported by Saville (6), it appears that the depth does not affect the run-up heights for periodic waves that break on the slope. Since we are restricting ourselves to breaking waves it is assumed that d/L_0 has no influence on the water movement on the slope. In this way the dependent dimensionless variables appear to be determined only by the location on the slope $x/\sqrt{HL_0}$, the phase t/T , the factor H/L_0 (which for brevity is called the wave steepness) and the slope angle α . Based on the arguments which led to the choice of the

scaling quantities given above, it may be expected that at least some of the dependent normalized variables given in Eqs. 7, 8 and 9 will in fact turn out to be independent of slope angle and wave steepness.

3. RUN-UP EXPERIMENTS

In order to find the effect of the wave steepness and the slope angle on the water movement on the slope, model experiments have been performed.

3.1. Experimental Set-Up

The wave run-up experiments have been performed in a wave flume of the Civil Engineering Department of the Delft University of Technology. This flume is 30 m long, 0.80 m wide and 0.60 m deep. At one end of the flume the waves were generated by a wave board, at the opposite end a plane plywood slope had been installed (see fig. 2).

Fig. 2. Slope with gauges for the measurement of layer thicknesses.

On this slope layer thicknesses were measured by means of four wire resistance gauges perpendicular to the slope at equal distances above still water level. They were placed in 6 cm deep trays, which were filled with water and closed by covers flush with the slope facing, in order to maintain the minimum submergence necessary for a linear response. In the constant depth portion of the flume a wire resistance gauge had been placed to measure the incident waves.

3.2. Experimental Procedure

In the experiments the slope angle and the wave characteristics were varied. During each run the incident waves and the layer thicknesses on the slope were registered on recording paper. The measurements on the slope started when the waves reflected from the slope and re-reflected from the wave board arrived at the slope again. The smallest number of waves per run so obtained was thirteen.

The instrumental measurements in each run were supplemented with visual observations of the average run-up length l_u (i.e. the average distance from the still water line to the point of maximum run-up per wave) and the average run-down length l_d (i.e. the average distance from the still water line to the highest point on the slope which appeared to be submerged at all times. During the run-down process the water

tongue becomes relatively thin. For this reason the visually determined values of l_d are not as accurate as those of l_u . However, they turned out to be consistent with the instrumental measurements of the water level variations on the slope.

3.3. Experimental Program

Only waves breaking on the slope are considered. The slope gradients which have been chosen are 1:3, 1:5 and 1:7 (vertical : horizontal); they are typical of dikes. The wave steepness (H/L_0) ranged from 0.02 to 0.07 approximately. Reference is made to table 1. The depth in the constant portion of the flume was 0.45 m in all the runs.

Run number	Slope Gradient	Wave Height H, in meters	Wave period T, in seconds	Wave steepness H/L_0	$\sqrt{HL_0}$, in meters	l_u , in meters	l_d , in meters	$\sqrt{HL_0} \tan \alpha$ in meters	$R = l_u \sin \alpha$, in meters

a) not recorded

Table 1. Experimental data.

The gauges which measure the layer thickness should cover a constant, fairly large part of the maximum length of the water tongue on the slope in all the runs. Furthermore it was expedient to move the gauges only when the slope angle was changed. For this reason the incident wave characteristics were chosen in such a manner that the run-up length l_u ($\approx \sqrt{HL_0}$ according to Hunt's formula) is about constant per slope angle; see table 1. The value of $\sqrt{HL_0}$ for each slope angle is chosen as large as possible (limited by the flume dimensions) to get the best accuracy of the measurements and the least possible scale effects.

The four gauges on the slope were placed at equal distances, which were constant for each slope angle : 0.125 m for slope 1:3, 0.200 m for slope 1:5 and 0.225 m for slope 1:7. The length covered by the gauges was about $0.9 \sqrt{HL_0}$ for all the runs.

3.4. Experimental Data

A summary of experimental data is given in table 1. For run 7 (which is used as an example throughout the following in this paper) the recorded signals are shown in fig. 3. The index of h in this figure denotes the

gauge number (given in fig. 2).

Fig. 3. Recorded waves and layer thicknesses (Run 7).

4. ELABORATION OF THE EXPERIMENTAL DATA

The data available such as those shown in fig. 3 have been elaborated for all the runs presented in table 1. An extensive presentation of the results has been given in ref. (3). In this paper only the results of run 7 are given as an example.

4.1. Phase-Averaging of the Records

From fig. 3 it appears that the records of the layer thicknesses are not quite periodic. To eliminate the irregularities the records have been phase-averaged over ten successive waves at 0.05 sec - intervals. As an example the averaged $h(t)$ -curves of run 7 are presented in fig. 4.

Fig. 4. Phase-averaged $h(t)$ -curves (Run 7).

4.2. Time-History of the Run-Up Front

In the further elaboration the averaged $h(t)$ -curves have been used. The sharp bend in these curves followed by a very quick rise of the water

level (see fig. 4) corresponds with the moment of upward front passage. These passage moments have been used to construct an x-t-diagram of the run-up front (see fig. 5, circled points). Through these points a curve has been drawn, which determines the slope of the curve in S. For the completion of the x-t-curve of the wave front the run-up length (l_u) and the run-down length (l_d) are available. The latter of these determines point Q. These data together determine the shape of the dashed curve in fig. 5 reasonably well.

4.3. Determination of the Particle Velocities

To determine the particle velocities (averaged over the layer thickness) on the slope, the profiles of the water tongues were constructed for successive phases of the wave period with an interval of 0.1 sec. The construction of the profile of the water tongue on the slope for an arbitrary instant $t = t_1$ is illustrated in fig. 6. The layer thicknesses h_1 , h_2 , h_3 and h_4 were read at $t = t_1$ from the $h(t)$ -curves (see fig. 6a, which schematically represents the results given in fig. 4) and were plotted in fig. 6b. This determines the points A, B, C and D.

Fig. 5. Construction of the x-t-curve of the wave front on the slope.

Fig. 6. Construction of the water tongue profile on the slope.

Then the x-coordinates of the run-up wave front (x_p) and the run-down wave front (x_R) were taken at $t = t_1$ from fig. 5 and plotted in fig. 6b. The known points of the profile have been connected by straight lines, except in the area where the run-up wave front is between gauges. In this area the water level of the upper part (between the gauges 3 and 4 in the example of fig. 6) has been extrapolated to x_p ; this gives point E. From this point to point B a straight line has been drawn. An alternative would have been to extrapolate the water level between the gauges 1 and 2 also to x_p , so that a discontinuity in the water level would occur at that location. However, from the $h(t)$ -curves and also from visual observations in the flume it appeared that the run-up front is outlined as a bend in the water tongue profile.

From the constructed water tongue profiles the quantities of water stored above each of the four gauges have been calculated as functions of the time. The curves obtained for these quantities for run 7 are presented in fig. 7a. In this figure B_1 denotes the volume per unit width stored above gauge 1, etc. The particle velocities averaged over the layer thickness have been calculated from these curves according to:

$$v_i(t) = \frac{1}{h_i(t)} \frac{B_i(t + \frac{1}{2}\Delta t) - B_i(t - \frac{1}{2}\Delta t)}{\Delta t} \dots \dots \dots (10)$$

in which i denotes the number of the gauge. The time step Δt is equal to the interval between the successive constructed water tongues, i.e. 0.1 sec. Fig. 7b presents the calculated particle velocities for run 7.

The calculated particle velocities v are less accurate than the water layer thicknesses h because of the procedure used in the elaboration.

Fig. 7. Calculated volumes of water stored per unit width (a) and particle velocities (b) on the slope (Run 7).

5. EXPERIMENTAL RESULTS

In this section the results of the elaboration as presented in the figs. 4, 5 and 7 are analysed.

5.1. Run-Up Heights

Run-up heights are presented in table 1, column 9 and 10. $\sqrt{HL_0} \tan \alpha$ is the run-up height according to Hunt's formula, while R is the run-up

height calculated from the measured l_u -values and the slope angles. Inspection of the data shows that the measured run-up values are in very good agreement with Hunt's formula.

5.2. Water Layer Thicknesses

Eq. 7 gives the parameter equation for the layer thicknesses. With the elaborated data a relation between $h/\sqrt{HL_0}$ and the independent parameters will be sought. To this end it is useful to characterize the h -values by a single value, for which the maximum layer thickness h_{max} has been chosen. Plots of h/h_{max} versus t/T delivered shape functions (not shown here) which were more or less independent of the wave steepness and the slope angle, for which reason h_{max} can be accepted as the only scale parameter characterizing the h -values. The parameter equation for h_{max} can be obtained as a reduced version of Eq. 7:

$$\frac{h_{max}}{\sqrt{HL_0}} = F\left(\frac{x}{\sqrt{HL_0}}, \frac{H}{L_0}, \alpha\right) \dots \dots \dots (11)$$

In fig. 8a the dimensionless layer thickness $h_{max}/\sqrt{HL_0}$ has been plotted versus the wave steepness H/L_0 . The layer thickness parameter shows virtually no dependence on the wave steepness. Fig. 8b presents a plot of the layer thickness parameter versus the slope gradient. The dependence on the slope gradient is weak. In fig. 8c the dimensionless layer thickness has been plotted versus the location on the slope. In this figure the point $x/\sqrt{HL_0} = 1.0$ is the location of maximum run-up on the slope according to Hunt's formula (apart from a factor $\cos \alpha$).

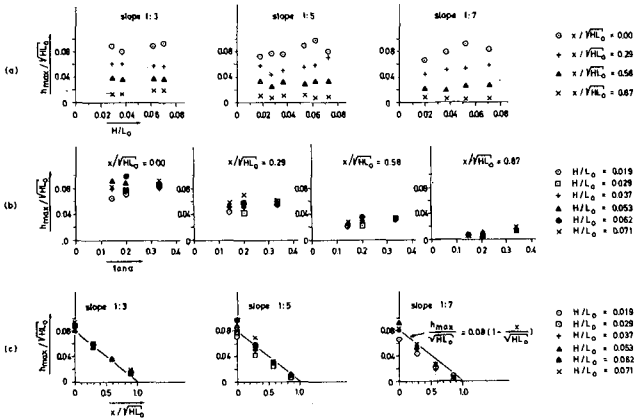

Fig. 8. Normalized layer thickness versus H/L_0 (a), $\tan \alpha$ (b) and $x/\sqrt{HL_0}$ (c).

It is concluded from fig. 8 that $h_{max}/\sqrt{HL_0}$ is roughly independent of H/L_0 and $\tan \alpha$, and that it is related to the location on the slope approximately as follows:

$$\frac{h_{max}}{\sqrt{HL_0}} = 0.08 \left(1 - \frac{x}{\sqrt{HL_0}}\right) \dots \dots \dots (12)$$

This formula is represented in fig. 8c by the straight lines.

5.3. Particle Velocities

Eq. 8 gives the parameter equation for the particle velocities in the water tongue on the slope. The $v(t)$ -curves (see fig 7b) can be characterized by v_{max} (extreme upward velocity) and v_{min} (extreme downward velocity). The shape functions of the $v(t)$ -curves were found to be even more similar than those of the $h(t)$ -curves. In this way the two following parameter equations are obtained from Eq. 8:

$$\frac{v_{max}}{\sqrt{gH}} = F\left(\frac{x}{\sqrt{HL_0}}, \frac{H}{L_0}, \alpha\right) \dots \dots \dots (13)$$

$$\frac{v_{min}}{\sqrt{gH}} = F\left(\frac{x}{\sqrt{HL_0}}, \frac{H}{L_0}, \alpha\right) \dots \dots \dots (14)$$

Various cross-plottings of these parameters were made. In each of the three lowermost gauge locations v_{max}/\sqrt{gH} was found to be approximately inversely proportional to $\sqrt{H/L_0}$ and directly proportional to $\tan \alpha$. This means that in those locations v_{max}/\sqrt{gH} is in fact proportional to the similarity parameter ξ (2) defined by:

$$\xi = \frac{\tan \alpha}{\sqrt{H/L_0}} \dots \dots \dots (15)$$

This is illustrated in fig. 9. The linear dependence of v_{max}/\sqrt{gH} with ξ implies that v_{max} is in fact proportional to $g^T \tan \alpha$, independent of the wave height H . This is a rather surprising result, which obviously can be true in a restricted range of the independent variables only. The coefficient of proportionality of v_{max}/\sqrt{gH} with ξ is the same for the three lowermost gauge locations ($x/\sqrt{HL_0} \approx 0.00, 0.29$ and 0.58). It is only in the upper 1/3 of the run-up length that the particle velocities appear to diminish.

Conclusions such as those stated above for v_{max} also hold for v_{min} (see fig 10).

5.4. Front Velocity

The parameter equation for the dimensionless front velocity is given by Eq. 9. In this equation c is the instantaneous derivative of the x - t -curve of the run-up wave front. A characteristic value for c is its average during run-up, defined by $\bar{c} = l_u/t_u$, in which l_u is the run-up length and t_u is the run-up time (see fig. 11). By dealing with the average front velocity \bar{c} Eq. 9 becomes:

$$\frac{\bar{c}}{\sqrt{gH}} = F\left(\frac{H}{L_0}, \alpha\right) \dots \dots \dots (16)$$

From the analysis of the \bar{c} - data it appeared that \bar{c}/\sqrt{gH} is proportional to $\sqrt{\tan \alpha}$ and inversely proportional to $\sqrt{H/L_0}$. In fig. 12a the parameter \bar{c}/\sqrt{gH} has been plotted versus ξ . From this figure it appears that the following relation holds:

$$\frac{\bar{c}}{\sqrt{gH}} \approx 0.6 \sqrt{\xi} \dots \dots \dots (17)$$

Eq. 17 can also be written as $\bar{c} \approx 0.6 \sqrt{\tan \alpha} \sqrt{g \sqrt{HL_0}}$. The term $\sqrt{g \sqrt{HL_0}}$ in this formula can be interpreted as the velocity of a low shock wave in water with a depth $\sqrt{HL_0}$. It has already been pointed out (see Eq. 12)

Fig. 9. Normalized upward particle velocity versus ξ .

Fig. 10. Normalized downward particle velocity versus ξ .

Fig. 11. Definition sketch for the run-up time t_u and the average front velocity \bar{c} .

Fig. 12. Normalized average front velocity (a) and run-up time (b) versus ξ .

that the water layer thicknesses on the slope are proportional to $\sqrt{HL_0}$ (although an order of magnitude smaller).

5.5. Run-Up Time

Another characteristic quantity of the x - t -curve of the run-up wave front is the dimensionless run-up time t_u/T . It depends on the wave steepness and the slope angle, expressed by the following parameter equation:

$$\frac{t_u}{T} = F\left(\frac{H}{L_0}, \alpha\right) \dots \dots \dots (18)$$

It appears from the analysis that t_u/T is proportional to $\sqrt[4]{H/L_0}$ and inversely proportional to $\sqrt{\tan \alpha}$. In fig. 12b the dimensionless run-up time t_u/T has been plotted versus ξ . From this figure it can be seen that the following relation is obtained:

$$\frac{t_u}{T} \approx 0.7 \frac{1}{\sqrt{\xi}} \dots \dots \dots (19)$$

5.6. Synthesis to Hunt's Formula

From the expressions for the average front velocity and the run-up time, which have been found independently, Hunt's formula can be reconstructed. From Eqs. 17 and 19 one obtains $\bar{c}t_u/T \sqrt{gH} \approx 0.42$, which can be

written as:

$$l_u \approx 1.05 \sqrt{HL_0} \dots \dots \dots (20)$$

According to Hunt's formula l_u equals $\sqrt{HL_0}/\cos \alpha$, which varies from $1.01\sqrt{HL_0}$ to $1.05\sqrt{HL_0}$ for the three slopes 1:3, 1:5 and 1:7. This agrees well with Eq. 20.

6. WAVE OVERTOPPING

It was deemed worthwhile to investigate to which extent the run-up data obtained could be used in relation to wave overtopping, although no such measurements have been performed in the present study. To this end the following hypothesis is introduced: The maximum quantity of water stored above a certain location on the uninterrupted slope (B_{max}) as measured in the run-up experiments, is equated to the volume of overtopping per wave (V) which would occur if the crest of the dike would be situated at that location (see fig. 13). B_{max} and V are taken per unit width.

Fig. 13. Definition sketch for the hypothesis on wave overtopping.

It is expected that according to this hypothesis the actual quantity of overtopping is underestimated due to the fact that in the case of overtopping a certain amount of water passes the crest. This implies that the up-rush of the next wave is slowed down less than it would be in the absence of overtopping.

Values for B_{max} are available from the elaboration of the experimental results (see fig. 7a). The variable B_{max} is scaled with HL_0 , because the maximum length of the water tongue is about equal to $\sqrt{HL_0}$ and the layer thicknesses are proportional to $\sqrt{HL_0}$. The dimensionless variable B_{max}/HL_0 depends on the location on the slope, the wave steepness and the slope angle, expressed by the following parameter equation:

$$\frac{B_{max}}{HL_0} = F\left(\frac{x}{\sqrt{HL_0}}, \frac{H}{L_0}, \alpha\right) \dots \dots \dots (21)$$

From the analysis of the B_{max} - data it appeared that B_{max}/HL_0 is independent of H/L_0 and proportional to $\sqrt{\tan \alpha}$. The slope influence is ascribed to phase differences between $h(t)$ at various points along the slope, which increase with decreasing α ; on the 1:3 slope the maximum values of $h(t)$ at the four gauge locations were attained practically simultaneously. So the normalized volume $B_{max} \sqrt{\cot \alpha}/HL_0$ is independent of H/L_0 and $\tan \alpha$ and depends on the location $x/\sqrt{HL_0}$ only. This is shown in fig. 14. A smooth curve has been drawn through the points.

For the case of a dike crest at a finite elevation, a parameter x_c is defined as the x - coordinate of the upper termination of the slope

(see fig. 13b). The ratio $x_c/\sqrt{HL_0}$ is about equal to the ratio of crest height h_c (see fig. 13b) and run-up height according to Hunt's formula $\sqrt{HL_0} \tan \alpha$ (apart from a $\cos \alpha$ -term).

Fig. 14. Normalized maximum volume of water stored on the slope versus $x/\sqrt{HL_0}$

Defining for brevity:

$$R_H \equiv \sqrt{HL_0} \tan \alpha \dots \dots \dots (22)$$

then $x_c/\sqrt{HL_0} \approx h_c/R_H$.

The curve of fig. 14 has been plotted in fig. 15 on double logarithmic paper (drawn line). Along the horizontal axis $(1-h_c/R_H)$ is given, which represents the relative excess of run-up height (R_H) over crest height (h_c).

An alternative definition of a maximum volume stored above a location $x = x_c$ on the slope is given in fig. 13a as B_{max}^I . The behaviour of B_{max}^I is similar to that of B_{max} . The smooth curve through the data points of B_{max}^I has been plotted in fig. 15 as the dashed line.

To check the hypothesis stated above, overtopping data given by Saville (5) have been used. They were obtained with waves breaking on smooth plane slopes of 1:3 and 1:6; the wave steepness H/L_0 varied from 0.026 to 0.066. The data given by Saville have been converted to $V\sqrt{\cot \alpha}/HL_0$ -values and plotted versus $(1-h_c/R_H)$ in fig. 15. The scatter is a known fact in results on wave overtopping and can at least partly be ascribed to the inaccuracy in the measurements, particularly for the relatively small rates of overtopping.

The drawn line in fig. 15, representing $B_{max} \sqrt{\cot \alpha}/HL_0$, is a reasonable lower limit for the overtopping results for the relatively large values of $(1-h_c/R_H)$ (low crest elevations). The dashed line for $B_{max}^I \sqrt{\cot \alpha}/HL_0$ seems to be more nearly a mean value.

Quite apart from the fit of the curves to the data points in fig. 15, it can be seen that the normalization which has been adopted, does serve to bring the data for the 1:3 and 1:6 slopes in a common range for all the wave steepnesses which were used. This means that the rate of overtopping of waves breaking on smooth plane slopes, normalized as $V\sqrt{\cot \alpha}/HL_0$, appears to be a function of the relative crest height h_c/R_H only.

7. DISCUSSION

The variables have been normalized with scaling factors which were chosen on the basis of Hunt's formula. The expectation was that the

Fig. 15. Normalized maximum volume of water stored on the slope versus $(1-h_c/R_H)$ with plotted data from overtopping measurements.

dimensionless variables so obtained should be independent of the wave steepness H/L_0 and the slope angle α , or nearly so. This turned out to be the case for $h_{max}/\sqrt{HL_0}$, but not for v_{max}/\sqrt{gH} , v_{min}/\sqrt{gH} , \bar{c}/\sqrt{gH} and t_u/T , all of which were found to vary with ξ . It therefore appears that the detailed relationships of the flow in the run-up of breaking waves are somewhat more complex than previously had been inferred from Hunt's formula (1).

The importance of the parameter ξ has been noted before for other characteristics of waves breaking on slopes, such as Iribarren and Nogales' breaking criterion, the breaker type, the reflection coefficient, and the relative importance of (periodic) run-up and (steady) set-up, and to a smaller extent also for the height-depth ratio at breaking. Furthermore, the normalized run-up height itself, if normalized with the incident wave height H , is a function of ξ only, as long as the waves break. This can be seen by writing Hunt's equation in the form $R/H = \xi$. A more detailed discussion of the role of ξ as a similarity parameter for the waves breaking on slopes has been given elsewhere (2).

LIST OF SYMBOLS

- B = volume of water stored above a certain location on the slope (per unit width);
- B_{max} = maximum volume of water stored above a certain location on the slope (per unit width);
- B'_{max} = maximum volume of water stored above a certain level on the slope (per unit width);
- \bar{c} = velocity of the run-up wave front;
- \bar{c} = average velocity of the run-up wave front = l_u/t_u ;
- d = constant waterdepth in the flume;
- g = acceleration due to gravity;
- H = height of the incident waves;
- h = layer thickness of the water tongue on the slope;
- h_{max} = maximum layer thickness at a fixed point;
- h^c = crest height of dike above still water level;
- L^c = wave length in deep water = $gT^2/2\pi$;
- l^c_d = run-down length, average distance from the still water line to the highest point on the slope which appeared to be submerged at all times;
- l_u = run-up length, average distance from the still water line to the point of maximum run-up per wave;
- V = volume of overtopping water per wave (per unit width);
- R = run-up height, or greatest height above still water level reached by an individual wave on the slope;
- R_H = run-up height according to Hunt's formula = $\sqrt{HL^c_0} \tan \alpha$;
- T_H = wave period;
- t = time;
- t_u = run-up time, time used by the wave front to run up from $x = 0$ to $x = l_u$;
- v = particle velocity in the water tongue on the slope, averaged over h;
- v_{max} = extreme upward particle velocity at a fixed point;
- v_{min} = extreme downward particle velocity at a fixed point;
- x = coordinate along the slope, positive upwards; origin at still water line;
- x^c = x-coordinate of the crest;
- α^c = slope angle with respect to the horizontal;
- μ = dynamic viscosity of water;
- ξ = similarity parameter = $\tan \alpha / \sqrt{H/L^c_0}$;
- ρ = mass density of water.

CHAPTER 46

MACH-REFLECTION AS A DIFFRACTION PROBLEM

by
Udo BERGER ¹⁾
and
Sören KOHLHASE ²⁾

ABSTRACT

As under oblique wave approach water waves are reflected by a vertical wall, a wave branching effect (stem) develops normal to the reflecting wall. The waves progressing along the wall will steep up. The wave heights increase up to more than twice the incident wave height.

The study has pointed out that this effect, which is usually called MACH-REFLECTION, is not to be taken as an analogy to gasdynamics, but should be interpreted as a diffraction problem.

1. INTRODUCTION

Observations made at vertical walls in prototype as well as in experiments have shown that under certain assumptions gravity waves are apparently not reflected according to the laws of regular reflection. With small angles of wave approach ($\theta_0 < 45^\circ$; angle between wave crest and axis of incidence) the reflected wave will not leave the wall totally; a wave-stem normal to the wall will be developed (Fig. 1a,b). The height of the stem-wave will increase progressively along the length of the wall and will reach a value of more than double the height of the incoming wave (Fig. 1b).

Fig. 1

Explanation of MACH-Reflection

PERROUD (7) and WIEGEL (13) explaining their investigations with solitary waves in analogy to the incoming flow of a compression shock against a re-entrant angle in gasdynamics named this effect MACH-reflection. Fig.1a shows the wave field in front of the wall using wave vectors. The wave strikes the structure with a small angle θ_0 ; a stem-wave and a reflected wave are developed. The point T of intersection between the wave crests of the stem-wave and the incident wave moves on a straight line, cutting the wall with angle α .

Due to the fact that the physical problem is rather unclear and, moreover, the knowledge of the stem-height may be of considerable importance dimensioning structures against wave attack (see SFB 79 (9)) the aim of this investigation was to complete the experiments of NIELSEN and HAGER as follows:

by measurements of both stem-height and stem-width, as a function of the incoming wave-parameters and to give a theoretical explanation of this so-called MACH-effect.

The measurements were carried out at the FRANZIUS-INSTITUTE FOR HYDRAULICS AND COASTAL ENGINEERING, TECHNICAL UNIVERSITY OF HANNOVER using a three-dimensional wave basin from the SONDERFORSCHUNGSBEREICH 79 (Water research in Coastal Regions).

2. REVIEW OF PREVIOUS INVESTIGATIONS

Investigations concerning MACH-reflection of gravity waves have been conducted in the sea and in hydraulic models and with walls of different shape and slopes.

PERROUD (7), CHEN (1) and SIGURDSSON, WIEGEL (8) have studied the MACH-Effect with solitary waves at a vertical as well as at inclined walls. Bended forms also have been investigated. The measurements of NIELSEN (5) and HAGER (4) have been carried out using monochromatic waves and are restricted to straight and vertical walls.

Using a two-dimensional model, NIELSEN established the increase of the stem-height at the reflecting wall, the stem-width as a function of the angle of incidence and of the wave length. However, the number of data is too small to show the results in a functional form. For larger angles of incidence ($> 15^{\circ}$), NIELSEN assumed that the experimental results were influenced by the rather small distance to the boundary of the model at the end of the wall.

In addition to that the reflecting wall is in contact with a lateral boundary at one end which is not in accordance with the conception of a free-standing breakwater. Finally no theoretical explanation of the MACH-reflection is given by NIELSEN.

Contrarily to the investigations of NIELSEN with rather small wave heights and small wave lengths, HAGER's experiments have been carried out under prototype conditions.

HAGER also investigated the increase of the stem-height within an extensive programme at the jetty of the Eckernförde harbour/Germany. However, the limited number of measurements and the scattering of the data only allow qualitative conclusions.

The fundamental results of the investigations of PERROUD,

Fig. 2.1

NIELSEN and HAGER are summarized in Fig. 2.1. The stem-height increases with the increasing angle of incidence for solitary waves as well as for regular (monochromatic) waves. The stem-height and the stem-width increase in the direction of wave propagation. The stem-width decreases with the increasing angle of incidence. The decrease of the stem-angle is not mentioned very much by NIELSEN, but is readily understood from the decrease of the stem-width with the increasing angle of incidence and is similar to PERROUD's results. The observation of a second MACH-stem for periodical deep-water waves is remarkable.

Theoretical investigations about MACH-reflection of gravity waves have been conducted by PERROUD and HAGER. The analytical solution of PERROUD is connected to the problem of a solitary wave and may not be used in connection with periodical waves. The four unknown parameters - height of the stem-wave, height of the reflected wave, angle of reflection and angle of the stem - are determined by a four-equation-system, which can only be solved implicitly. Two equations of the system are found from geometrical considerations and the other two equations are deduced from the mass and energy-conversion conditions. The theoretical statement of HAGER is similar to PERROUD's and leads to the calculation of the stem-height only. This statement doesn't agree with the experimental results.

3. DIFFRACTION THEORY

From the previous chapter it may be seen that for monochromatic waves there is no theory to calculate the wave pattern, i.e. stem-height and stem-width, with sufficient accuracy. If we suppose that the MACH-reflection has to be interpreted as a diffraction-problem in the area of reflection as opposed to how it was formerly investigated, a new theoretical concept must be examined.

From the linear partial differential equation

$$\Delta \phi = 0$$

and using a polar coordinate system and the well-known boundary conditions of the linear wave theory, we get the scalar wave equation.

$$\Delta F + k^2 \cdot F = 0 \quad ; \quad \Delta \text{ in polar coordinates}$$

$$k = \frac{2 \pi}{L}$$

As shown in (6) after some transformations it can be seen that the modulus of $F(r, \theta)$ is equal to the diffraction coefficient

$$K = \frac{\text{height of diffracted wave}}{\text{incoming wave height}} = |F(r, \theta)|$$

The solutions of the scalar wave equation aren't uniquely determined in infinity through specified sources as opposed to potential equations. The wave equation allows standing waves as a solution, which would physically mean that waves coming from infinity superimpose waves coming from the finiteness. To avoid this, the radiation condition (11) must be determined. This prevents all energy from infinity. Analytically it is enough to say that the solutions of the scalar wave equations have the following condition in infinity

$$F \rightarrow \frac{e^{-ikr}}{\sqrt{r}}$$

SOMMERFELD (12) gives a comprehensive definition of the radiation condition

$$\lim_{r \rightarrow \infty} r \left(\frac{\delta F}{\delta r} - ikF \right) = 0$$

and shows that the solution of the scalar wave-equation is uniquely determined.

For the special case of the half-infinite breakwater, SOMMERFELD has found a solution which allows the computing of the diffraction for all wave-lengths.

SOMMERFELD's solution

Fig. 3.1

Without mentioning the derivation of the solution function which had been handled in (12), the solution of the searched function is given with the period 4π .

$$F = f(r, \theta - \theta_0) \pm f(r, \theta + \theta_0) \quad (3.1)$$

$$f(r, \theta - \theta_0) = F(r, \theta, \theta_0) \cdot \frac{1+i}{2} \int_{-\infty}^{\sigma} e^{-i \frac{\pi}{2} t^2} dt$$

$$\sigma = 2 \sqrt{\frac{kr}{\pi}} \sin \frac{1}{2} (\theta - \theta_0)$$

Putting the result in equation (3.1) we get the solution of the diffraction problem:

$$F(r, \theta) = e^{-ikr \cos(\theta - \theta_0)} \cdot \underbrace{\left(\frac{1+i}{2} \int_{-\infty}^{\sigma} e^{-i \frac{\pi}{2} t^2} dt \right)}_{\Psi(\sigma)} \pm e^{-ikr \cos(\theta + \theta_0)} \cdot \underbrace{\left(\frac{1+i}{2} \int_{-\infty}^{\sigma'} e^{-i \frac{\pi}{2} t^2} dt \right)}_{\Psi(\sigma')} \quad (3.2)$$

$$\sigma' = -2 \sqrt{\frac{kr}{\pi}} \sin \frac{1}{2} (\theta + \theta_0)$$

In this case the integral $\Psi(\sigma)$ can be written in a similar way

$$\Psi(\sigma) = \frac{1+i}{2} \left(\int_{-\infty}^0 e^{-i \frac{\pi}{2} t^2} dt + \int_0^{\sigma} e^{-i \frac{\pi}{2} t^2} dt \right)$$

Using the LAPLACE-integral after the first integral

$$\int_0^{\infty} -e^{-\alpha \tau^2} d\tau = \frac{1}{2} \sqrt{\frac{\pi}{\alpha}}$$

and splitting up the second integral into a real and an imaginary part, we get:

$$\psi(\sigma) = \frac{1+i}{2} \left(\left(\frac{1-i}{2} \right) + \int_0^{\sigma} \cos \frac{\pi}{2} t^2 dt - i \int_0^{\sigma} \sin \frac{\pi}{2} t^2 dt \right)$$

$$\psi(\sigma) = \frac{1+i}{2} \left(\frac{1-i}{2} + M - i N \right),$$

by which

$$M = \int_0^{\sigma} \cos \frac{\pi}{2} t^2 dt$$

$$N = \int_0^{\sigma} \sin \frac{\pi}{2} t^2 dt$$

M and N are the FRESNEL-integrals.

To discuss the physical problems, in fig.3.1 the lines OS' and OR' are marked as are the shadow borders that are generated through the incoming and reflected wave.

We get three regions S, Q, R. σ and σ' possess a special sign in each of these parts.

That is, for e.g., in the area S:

$$\sigma^{(\pm)} = (-) 2 \sqrt{\frac{k \cdot r}{\pi}} \sin \left(\frac{1}{2} (\theta^{(\pm)} \theta_0) \right)$$

$$\theta - \theta_0 < 0 \Rightarrow \sigma < 0$$

$$\theta + \theta_0 > 0 \Rightarrow \sigma' < 0$$

That is why the regions (fig.3.1) have the following arrangements of signs

$$S - \text{region} \quad (\sigma, \sigma') = (-, -)$$

$$Q - \text{region} \quad (\sigma, \sigma') = (+, -)$$

$$R - \text{region} \quad (\sigma, \sigma') = (+, +)$$

The wave-heights in the three regions finally result in the following solutions:

a) In the region of the geometrical shadow $\sigma < 0, \sigma' < 0$

$$F(r, \theta) = \psi(-\sigma) e^{-ikr \cos(\theta - \theta_0)} + \psi(-\sigma') e^{-ikr \cos(\theta + \theta_0)}$$

b) in the unshadowed region $\sigma > 0, \sigma' < 0$

$$F(r, \theta) = e^{-ikr \cos(\theta - \theta_0)} - \left\{ \begin{array}{l} \psi(\sigma) e^{-ikr \cos(\theta - \theta_0)} + \\ + \psi(-\sigma') e^{-ikr \cos(\theta + \theta_0)} \end{array} \right\}$$

c) in the reflecting region $\sigma > 0, \sigma' > 0$

$$F(r, \theta) = \begin{array}{l} \text{incident wave} \\ e^{-ikr \cos(\theta - \theta_0)} \end{array} + \begin{array}{l} \text{reflected wave} \\ e^{-ikr \cos(\theta + \theta_0)} \end{array} \quad (3.3)$$

$$- \left(\psi(-\sigma) e^{-ikr \cos(\theta - \theta_0)} + \psi(-\sigma') e^{-ikr \cos(\theta + \theta_0)} \right)$$

diffracted wave

This solution in the reflecting region describes the MACH-reflection of gravity waves. Computing the wave-height in front of the wall (stem-height) it is

$$\frac{H_S}{H} = F(r, \theta)$$

The equation (3.3) was computed in Fortran IV.

4. HYDRAULIC MODEL AND TEST CONDITIONS

The wave₂ basin mentioned before has the dimensions 18.3 x 45.0 m², the test area was 11.0 x 45 m². The lateral limitations (guide vanes) in the direction of the wave orthogonals have been installed to control the energy entry of the waves. The length of the reflecting wall has been 7,32 m or 9.80 m respectively. Opposite to the wavemakers, a wave absorber has been installed in the basin consisting of a 7.6°-slope and specially-designed wave absorbing elements which have been tested in some pilot tests (2) before.

The basin is covered by an electrical driven measuring bridge movable with constant speeds of 5 m/min or 20 m/min for measuring the wave field. Resistance-type wave gauges (FÜHR-BÖTER (3)) were used for all tests. The wave heights were registered on a thermosensitive recording instrument.

Mechanical and electrically controlled wavemakers were used for the tests. The movement of the wave paddles was adjustable corresponding to the chosen wave parameters. The combined motion components (translatory + rotary) have been optimized using special tests for these machines at the FRANZIUS-INSTITUT.

Despite this, some model-caused inaccuracies in the experiments should be noted. The reflection-coefficient of the wave-absorber was in the order of 9%, but the error in reproducibility of single tests (measuring time 30 min.) was in the order of 2% only. In addition to the reflection at the wave absorber and re-reflection at the wavemaker-paddle, transverse oscillations in the wave field could be seen leading, to some extent, to disturbances in the wave field. But model-caused reflections have not been investigated in more detail within this programme and the test results reported in this paper show the original (unfiltered) data.

5. RESULTS OF MEASUREMENTS AND COMPARISON WITH DIFFRACTION

THEORY

The stem-height has been measured for different wave heights and wave lengths as a function of the direction of the incident wave as shown in fig. 5.1. The water depth was constant in all tests.

For example, the stem-heights for a wave length of $L = 100$ cm are plotted in fig. 5.1 to 5.4. The full lines show the theoretical development of the stem according to the diffraction theory. The stem-height increases with an increasing angle θ_0 of the incoming wave, as demonstrated by NIELSEN and HAGER (see fig.2.1). Because the theoretical and experimental results were in good agreement, the theoretical development of the stem as a function of the wall-length has been summarized for different angles θ_0 in fig. 5.5.

The oscillating data in fig. 5.1 to 5.4 may be explained by model-caused disturbances (see chapter 4). After about 2/3 of the wall length, the differences between the measured results and the theoretical curve are somewhat greater than at the beginning of the wall. These deviations may be explained by the fact that in addition, a diffraction wave is caused by the end of the wall which is superimposed with the wave field.

For the test conditions given in Tab.1 the stem-widths in front of the wall have also been measured (x/L spaced equidistantly). As an example fig. 5.6 shows the experimental and corresponding theoretical results for an angle of incidence $\theta_0 = 20^\circ$.

The agreement between theory and measurement can be seen rather well. The trough bounding the stem-width becomes steeper and narrower in proportion to the stem-wave's propagation along the wall.

The scattering of the data may be explained by model-caused disturbances (see chapter 4) as mentioned before.

Test conditions

H_I (cm)	L (cm)	θ_0 ($^\circ$)	d (cm)
2,2 3,6	100	10 15	25
4,3	150	20	
	200	25	

Tab. 1

The examples of fig. 5.1 to 5.6 have shown that the diffraction theory describes totally the development of the stem-height at the reflecting wall as well as the wave pattern in front of the wall (stem-width). A comparison with the measurements of NIELSEN and HAGER (see fig. 2.1) although qualitative, confirms both theoretical and experimental results.

The development of a second stem-wave as observed by NIELSEN with larger angles θ_0 of incidence and with a height also greater than double θ_0 the incident-wave height is approved by the diffraction theory, too. Fig.5.7 shows as an example, the water level normal to the wall at a distance of 5 wave lengths from the wall edge for wave-approach angles $\theta_0 = 20^\circ, 25^\circ$ and 30° . A second stem can be seen clearly.

6. CONCLUSION

Investigations with regular waves in connection with the so-called MACH-effect have only been carried out by NIELSEN and HAGER.

From supplementary measurements and by comparing the results with the diffraction theory, it has been proved that the MACH-reflection, i.e. the increase of a wave up to more than double the height of the incoming wave striking a wall with an acute angle, should not to be seen as an analogy to gas-dynamics.

On the contrary, the increase of the wave and the wave pattern before the wall is to be interpreted as a diffraction problem within a region of reflection.

CHAPTER 47

ACTION OF NON-LINEAR WAVES AT A SOLID WALL

by

Mohamed S. Nasser¹, M.ASCE and John A. McCorquodale², AM.ASCE

ABSTRACT

A one-dimensional finite difference model is developed to simulate the action of long non-linear shallow water waves at a solid barrier. A damping parameter is introduced to account for the centrifugal effects in the incident wave. A stability criterion for $\Delta t/\Delta x$ is suggested. The numerical predictions of reflection and run-up compare satisfactorily with experimental results.

INTRODUCTION

The phenomenon of run-up and reflection resulting from water waves impinging on breakwaters is an important problem in coastal engineering. Breakwaters are designed to avoid excessive overtopping. On the other hand, reflection causes local disturbances that persist for some distance outside of the breakwater.

This paper presents a one-dimensional, finite difference model simulating wave motion in front of a vertical, solid breakwater. The discretization of the solution domain is constrained

¹Assistant Professor, Department of Civil Engineering, Concordia University, SGW Campus, Montreal, Quebec, Canada.

²Professor, Department of Civil Engineering, University of Windsor, Windsor, Ontario, Canada.

Fig. 1. Definition of Problem

by the characteristic directions to improve numerical convergence and stability. The model predicts wave run-up and rush-down on the breakwater as well as the reflection coefficient. Long, shallow, non-breaking waves are considered in the analysis, and the model is capable of treating both symmetric and asymmetric waves. The model should aid in designing vertical solid breakwaters and is being modified to accommodate sloping sections.

DEVELOPMENT OF MODEL

Figure 1 defines some of the variables of the study. Assuming long, shallow water waves, i.e., approximately hydrostatic pressure distribution, it can be shown that the governing equations of motion and continuity are, respectively (1, 4):

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + g \frac{\partial \eta}{\partial x} = -gS_f \quad (1)$$

$$\frac{\partial \eta}{\partial t} + u \frac{\partial \eta}{\partial x} + (h_o + \eta) \frac{\partial u}{\partial x} = 0 \quad (2)$$

where u = horizontal velocity; η = perturbation height with respect to the still water level, h_o ; g = acceleration of gravity; S_f = friction slope = $\frac{u|u|}{C_f(h_o + \eta)}$; C_f = Chezy friction factor; the bed is assumed horizontal.

Eq. 1 describes fairly accurately the motion of long linear waves. For non-linear, i.e., asymmetric waves, hydrodynamic pressure may become appreciable. However, in this study, Eqs. 1 and 2 are applied to asymmetric waves with an allowance for additional damping due to centrifugal effects. Assuming a sinusoidal wave (Fig. 2), the total head loss, h_t , between sections 1 and 2 may be expressed as

$$h_t = h_f + \epsilon h_c \quad (3)$$

Fig. 2. Approximation of Centrifugal Effect

in which h_f = frictional head loss between sections 1 and 2; h_c = difference in centrifugal pressure head between the two sections; ϵ = empirical constant.

Applying Newton's second law to compute the approximate centrifugal pressure, it can be shown that h_c is given by (3)

$$h_c = \frac{2h_o}{gr} v^2 \quad (4)$$

where r = radius of curvature of water surface;
 v = mean velocity in the vertical.

The frictional head loss, h_f , can be represented by

$$h_f = \frac{v^2 L}{2C_f^2 h_o} \quad (5)$$

in which L is the incident wave length.

Also, the total head loss, h_t , may be assumed as

$$h_t = \frac{v^2 L}{2C_t^2 h_o} \quad (6)$$

where C_t is the equivalent Chezy factor accounting for both frictional and centrifugal effects.

Substituting Eqs. 4 through 6 into 3 and rearranging, gives

$$C_t = \sqrt{\frac{gLrC_f^2}{gLr + 4\epsilon h_o^2 C_f^2}} \quad (7)$$

From Fig. 2, the value of r may be approximated as follows:

$$r \approx [(H_i/2)^2 + (L/4)^2]/H_i \quad (8)$$

Based on a correlation with laboratory experiments, Eq. 7 takes the form

$$c_t = \sqrt{\frac{gLrC_f^2}{gLr+1.2h_o^2C_f^2}} \quad (9)$$

Since r varies inversely with wave steepness, S , Eq. 9 indicates the energy dissipation due to centrifugal action increases with wave steepness.

In order to proceed to the finite difference formulation, η is made dimensionally identical to u through the transformation

$$c = \sqrt{g(h_o + \eta)} \quad (10)$$

which represents a local wave celerity utilized as a measure of η .

The equations of motion and continuity, in terms of c , along with the total differentials of u and c constitute the hyperbolic system of equations governing the phenomenon as given by the matrix form (1):

$$\begin{bmatrix} 1 & u & 0 & 2c \\ 0 & c & 2 & 2u \\ dt & dx & 0 & 0 \\ 0 & 0 & dt & dx \end{bmatrix} \begin{Bmatrix} \frac{\partial u}{\partial t} \\ \frac{\partial u}{\partial x} \\ \frac{\partial c}{\partial t} \\ \frac{\partial c}{\partial x} \end{Bmatrix} = \begin{Bmatrix} -gS_f \\ 0 \\ du \\ dc \end{Bmatrix} \quad (11)$$

The above system yields the following positive and negative characteristic directions:

Fig. 3. Boundary Conditions and Discretization of the $x-t$ Plane

$$\alpha = \frac{dx}{dt} \Big|_+ = u + c \quad (12)$$

$$\beta = \frac{dx}{dt} \Big|_- = u - c \quad (13)$$

Based on these directions, the condition,

$$\frac{\Delta t}{\Delta x} \leq \frac{1}{2} (u+c)^{-1} \quad (14)$$

is obtained and used, initially, to control the finite difference, x-t plane (Fig. 3) for stability and convergence (5). The equations of motion and continuity, from Eq. 11, are discretized using central differences in space and forward differences in time, viz.

$$u(i,j+1) = u(i,j) - \frac{\Delta t}{\Delta x} \{u(i,j)[u(i+1,j)-u(i-1,j)] + 2c(i,j)[c(i+1,j)-c(i-1,j)] + g\Delta x S_f(i,j)\} \quad (15)$$

$$c(i,j+1) = c(i,j) - \frac{\Delta t}{\Delta x} \{u(i,j)[c(i+1,j)-c(i-1,j)] + [c(i,j)/2][u(i+1,j)-u(i-1,j)]\} \quad (16)$$

Eqs. 15 and 16 were used to advance the solution from initially still water conditions, i.e., $u = 0$ and $c = \sqrt{gh_0}$.

The boundary condition at the right end of the solution domain, is zero normal velocity at all times. The incident wave is originated in the model at one wave length away from the breakwater; this is the minimum distance required to ensure the generation of at least one loop and one node in the standing wave pattern. The boundary condition simulates the vertical displacement of the incident wave which is represented by a composite as shown in Fig. 4. The amplitudes, A_1 and A_2 , and the periods, T_1 and T_2 , are proportioned so that volume continuity is satisfied which leads to

Fig. 4. Composite Input Wave

Fig. 5. Comparison of Observed and Predicted Values

$$A_1/A_2 = T_2/T_1 \quad (17)$$

In order to calculate the unknown dependent variable at each boundary, the value of the dependent variable specified by the boundary condition at time (j+1) was included in the calculation. This was achieved by combining the equations of motion and continuity, and discretizing the augmented equation by forward differences in space and time. Assuming that the boundary is located at the ith column, the unknown celerity at the breakwater is calculated by the α -characteristic difference equation,

$$c(i, j+1) = c(i, j) + 2 \frac{\Delta t}{\Delta x} \{c(i, j)u(i-1, j)/2 - c(i, j)[c(i, j)-c(i-1, j)]\} \quad (18)$$

Likewise, a β -characteristic difference equation is used to find the unknown velocity at the left boundary, i.e.,

$$u(i, j+1) = u(i, j) + 2[c(i, j+1)-c(i, j)] + \frac{2\Delta t}{\Delta x} \{2[u(i, j)-c(i, j)][c(i+1, j)-c(i, j)] - [u(i, j)-c(i, j)][u(i+1, j)-u(i, j)] - \Delta x g S_f(i, j)u(i, j)/2\} \quad (19)$$

Throughout the solution, the values of velocity, celerity and the non-linear friction term were improved, within each time increment, by an iterative procedure.

VERIFICATION OF MODEL

A laboratory investigation was conducted to evaluate the proposed mathematical model. The Test flume was 45.8 cm wide and 11 m long with plexiglass walls and aluminum bed. The slider-crank, wave machine used has adjustable stroke and speed that were selected to produce shallow water waves. The breakwater

was simulated by a vertical plexiglass barrier, located at 9.2 m away from the intermediate position of the wave paddle. Wave experiments were performed within the following range of variables:

h_o (cm)	22 - 38
H_i (cm)	4 - 24
Wave Period, T (sec)	2 - 5.8

In the experimental procedure, the stroke and speed were set so as to minimize surface disturbances and secondary waves. The incident wave celerity, c , was determined, prior to the interference of reflection, using a stop watch to time the movement of a wave peak over different distances. The wave period, T , was taken as the average of the rotation time of a point marked on the flywheel of the wave machine. The product of the values of c and T yielded the wave length, L . After a few wave traverses, an asymmetric standing wave pattern was observed to develop and stabilize with nodes and loops forming, alternately, at almost every quarter wave length. The measured loop height, h_p , and node height, h_n , were used to find the "apparent" incident wave height, H_i , and the "apparent" reflected wave height, H_r , according to the linear wave theory, i.e.,

$$H_i = \frac{1}{2} (h_p + h_n) \quad (20)$$

$$H_r = \frac{1}{2} (h_p - h_n) \quad (21)$$

The "apparent" reflection coefficient, C_R , was defined as:

$$C_R = H_r/H_i \quad (22)$$

The maximum limits of run-up, R_u , and rush-down, R_d , bounding the impact wave height, H_T , at the breakwater were recorded. The experimental measurements are estimated to have been within an accuracy of about ± 2 cm.

When the mathematical model was operated, using the equality condition in Eq. 14 with $u \approx c \approx \sqrt{gh_0}$, the procedure was numerically unstable. This instability is thought to originate from the boundary conditions, especially the incident wave boundary condition. The development of Eq. 14 does not consider this type of boundary condition. In order to obtain stability, it was necessary to reduce the time step to between 1/5 and 1/10 of limiting value in Eq. 14.

The stable model was run for the equivalent of 5 wave periods and the third, fourth and fifth periods were used to obtain average values for h_p , h_n , R_u , R_d and H_I . The apparent values of H_I and H_T were calculated from Eqs. 20 and 21, respectively. It is noted that the non-linear values of C_R are much less than for linear waves.

An attempt to make a third order Stokes correction to both experimental and numerical reflection coefficients was unsuccessful because most of the waves had high H_I/h_0 and low h_0/L . Similarly, second or third order Stokes waves were not suitable to describe the observed incident waves. Fifth or higher order Stokes waves or cnoidal waves can be used with the model but more computation time would be required. The crests and troughs of the composite incident waves can be established using information presented by Bretschneider (2).

In Fig. 5 some experimental values of R_u , H_I and C_R are compared with those predicted by the model.

CONCLUSIONS

The simplified numerical model gives representation values for wave reflection and run-up at a solid barrier under attack by long non-linear shallow water waves. Numerical stability was achieved by reducing the method of characteristic time step to about 1/10 of its limiting value. An empirical damping parameter is introduced to account for centrifugal effects in the non-linear waves.

CHAPTER 48

ESTIMATION OF INCIDENT AND REFLECTED WAVES IN RANDOM WAVE EXPERIMENTS

by

Yoshimi Goda and Yasumasa Suzuki

Marine Hydrodynamics Division

Port and Harbour Research Institute, Ministry of Transport

Nagase, Yokosuka, Japan

ABSTRACT

A technique to resolve the incident and reflected waves from the records of composite waves is presented. It is applicable to both regular and irregular trains of waves. Two simultaneous wave records are taken at adjacent locations, and all the amplitudes of Fourier components are analyzed by the FFT technique. The amplitudes of incident and reflected wave components are estimated from the Fourier components, and the incident and reflected wave spectra are constructed by smoothing the estimated periodograms. The wave resolution is effective in the range outside the condition of the gauge spacing being even integer of half wavelength. The ratio of incident and reflected wave energies in the effective resolution range is employed in estimating the overall reflection coefficient. The incident and reflected wave heights are estimated from the composite wave heights by energy consideration.

INTRODUCTION

The importance of wave irregularity concept in coastal engineering study and application is now rightly recognized by many researchers and engineers. A rapid increase in the number of random wave generators in hydraulic laboratories in the world testifies it. With this situation, many researchers are keenly feeling the necessity of developing various experimental techniques inherent to irregular waves. Resolution of incident and reflected waves in a continuous, irregular wave system is one of the most needed techniques. If the resolution becomes feasible, then we can make tests of reflective coastal structures in continuous runs without worrying about the multi-reflection of irregular waves between a wave paddle and a reflective structure. Otherwise, we have to employ a tedious

procedure of repeating a number of short runs of different wave sequences, each of which must be stopped before the return of re-reflected waves by the wave paddle to the structure. Not only the procedure is laborious, but also the test waves are deficient in the spectral component of high frequency band due to the wave dispersion unless a special wave generation technique is employed.

The authors present a resolution technique, which involves a simultaneous recordings of wave profiles at two adjacent stations in a wave flume. The technique is similar to the one employed by Kajima [1] and by Thornton and Calhoun [2], but the use of the Fast Fourier Transform technique in yielding the Fourier components of all the frequency resolutions makes the calculation simple and versatile. For example, the technique is applicable to regular waves too, which has provided a means of calibration of resolution. The paper describes the principle of resolution technique and its accuracy with supporting data. Examples of application in the authors' experiments are also discussed.

PRINCIPLE OF RESOLUTION TECHNIQUE

Suppose we have a multi-wave-reflection system of regular waves in a wave flume. Waves generated by a wave paddle propagate forward in the flume and are reflected by a test structure. The reflected waves propagate back to the wave paddle and are re-reflected. The re-reflected waves propagate forward again and the process is repeated until the multi-reflected waves are fully attenuated. Thus the wave system can be regarded as a superposition of a number of waves propagating in the positive and negative directions of the coordinate, x (see Fig. 1). The waves propagating in each direction form a single train of progressive waves as a whole, because of the constancy of wave frequency (see Appendix). The wave train in the positive direction is called the incident waves and that in the negative direction is called the reflected waves. Let the amplitude of superposed incident waves be a_I and that of reflected waves be a_R . Then these waves are described to have the general form of

$$\left. \begin{aligned} \eta_I &= a_I \cos(kx - \sigma t + \epsilon_I), \\ \eta_R &= a_R \cos(kx + \sigma t + \epsilon_R), \end{aligned} \right\} \quad (1)$$

where η_I and η_R are the surface elevations of incident and reflected waves, k is the wave number of $2\pi/L$ with L being the wavelength, σ is the angular frequency of $2\pi/T$ with T being the wave period, and ϵ_I and ϵ_R are the phase angles of incident and reflected waves.

Fig. 1 Definition Sketch

Further, we suppose that the surface elevations are recorded at two adjacent stations of x_1 and $x_2 = x_1 + \Delta l$. The observed profiles of composite waves will be

$$\left. \begin{aligned} \eta_1 &= (\eta_I + \eta_R)_{x=x_1} = A_1 \cos \sigma t + B_1 \sin \sigma t, \\ \eta_2 &= (\eta_I + \eta_R)_{x=x_2} = A_2 \cos \sigma t + B_2 \sin \sigma t, \end{aligned} \right\} \quad (2)$$

where,

$$\left. \begin{aligned} A_1 &= a_I \cos \phi_I + a_R \cos \phi_R, \\ B_1 &= a_I \sin \phi_I - a_R \sin \phi_R, \\ A_2 &= a_I \cos(k\Delta l + \phi_I) + a_R \cos(k\Delta l + \phi_R), \\ B_2 &= a_I \sin(k\Delta l + \phi_I) - a_R \sin(k\Delta l + \phi_R), \end{aligned} \right\} \quad (3)$$

$$\left. \begin{aligned} \phi_I &= kx_1 + \varepsilon_I, \\ \phi_R &= kx_1 + \varepsilon_R. \end{aligned} \right\} \quad (4)$$

Equation 3 can be solved to yield the estimate of

$$\left. \begin{aligned} a_I &= \frac{1}{2|\sin k\Delta l|} \sqrt{(A_2 - A_1 \cos k\Delta l - B_1 \sin k\Delta l)^2 + (B_2 + A_1 \sin k\Delta l - B_1 \cos k\Delta l)^2}, \\ a_R &= \frac{1}{2|\sin k\Delta l|} \sqrt{(A_2 - A_1 \cos k\Delta l + B_1 \sin k\Delta l)^2 + (B_2 - A_1 \sin k\Delta l - B_1 \cos k\Delta l)^2}. \end{aligned} \right\} \quad (5)$$

In the calculation, the dispersion relation of the following is presumed to hold:

$$\sigma^2 = gk \tanh kh. \quad (6)$$

Actual wave profiles usually contain some higher harmonics. Use of the Fourier analysis enables to estimate the amplitudes of A_1 , B_1 , A_2 , and B_2 for the fundamental frequency as well as for higher harmonics. The amplitudes of incident and reflected waves, a_I and a_R , are then estimated by Eq. 5. This is the procedure to be taken for regular wave tests.

The principle of resolution is the same for irregular waves with that for regular waves, because irregular waves can be treated as the superposition of a large number of component waves with the constant amplitudes and frequencies. The number of component waves which can be analyzed in irregular wave records is one half of the number of data sampling. By means of the Fast Fourier Transform technique, the amplitudes of A_1 to B_2 can be calculated for all the component waves and the corresponding amplitudes of a_I and a_R are estimated by Eq. 5. The spectra of incident and reflected waves can be obtained by smoothing the periodograms based on the estimates of a_I and a_R .

ESTIMATE OF INCIDENT AND REFLECTED WAVE HEIGHTS

Calibration of Resolution Technique with Regular Waves

The resolution technique was first applied to regular waves for the purpose of calibration. Trains of waves were generated in a wave flume temporarily built with a partition wall in a wave basin. At the generator side the partition wall was terminated with a gap of about 60 cm and a part of reflected waves could be dispersed into the wave basin. The wave absorber in the flume was built with crushed stone in the slope of 10 to 1. Two wave periods of 1.088 and 1.410 sec were employed. The mean wave heights were 8.98 and 9.23 cm, respectively, at the water depth of 43 cm. The spacing between two wave gauges was varied from $\Delta\ell = 10$ to 250 cm, and continuous wave records of 102.4 sec long were taken at the sampling period of $\Delta t = 1/15$ sec. The records were analyzed for the Fourier components of $f = 0$ to $f = 7.5$ Hz with the frequency resolution of $\Delta f = 0.0084$ Hz. Then, Eq. 5 was applied to estimate a_I and a_R for all the frequencies.

As expected, the resultant estimates showed clear peaks around the frequencies of $f = 0.92$ and 0.70 Hz and their harmonics. The peaks were not confined to one frequency resolution band because of wave fluctuations and signal noises; they were spread in a few neighbouring bands. Thus, the sum of the estimated amplitudes of three to four continuous frequency bands around the peaks was employed as the representative amplitudes of incident and reflected waves. These amplitudes are plotted in Fig. 2 against the ratio of gauge spacing $\Delta\ell$ to the wavelength L . The reference amplitude, a_0 , is the mean of estimated incident wave amplitudes in the range of $\Delta\ell/L < 0.4$ and $0.6 < \Delta\ell/L < 0.9$. The estimated amplitudes of a_I and a_R are seen to diverge around the relative spacing of $\Delta\ell/L = n/2$ with $n = 0, 1, 2, \dots$, at which the divisor of Eq. 5, $\sin k\Delta\ell$, becomes null.

Figure 3 is a similar result of analysis for the case of perfect reflection with the same waves. Divergence of estimated amplitudes around $\Delta\ell/L = n/2$ is observed. The decrease of the reference amplitude a_0 is considered due to the selection of test wave periods which corresponded to the antiresonance condition of the wave flume setup. (The reflective wall was located at the distance of 15 m from the wave paddle.) The divergence of estimated amplitudes is due to the amplification of noises and errors as the divisor of $\sin k\Delta\ell$ approaches 0. For the purpose of application, the zone of inaccuracy (or the effective range of resolution from the other viewpoint) needs to be specified. This will be discussed in the next section.

It is indicated in Fig. 2 that the estimates of a_I and a_R are quite stable except for the diverging zone. The estimates of a_R are several per cent of a_0 , being in agreement with the characteristics of wave absorber. The estimates of a_R for the case of perfect reflection in Fig. 3 are almost equal to a_0 , indicating the reflection coefficient being nearly 1.0. Additional test for a submerged, upright breakwater with the crest submergence of 6 cm yielded the estimate of reflection coefficient of 0.44 to 0.55 (refer to Fig. 6). The conventional method of the measurement of reflection coefficient by means of nodal and antinodal wave heights yielded the reflection coefficient of 0.51 to 0.59 for this case. These estimates of a_R as a whole indicate their consistency with respect to reflecting conditions tested.

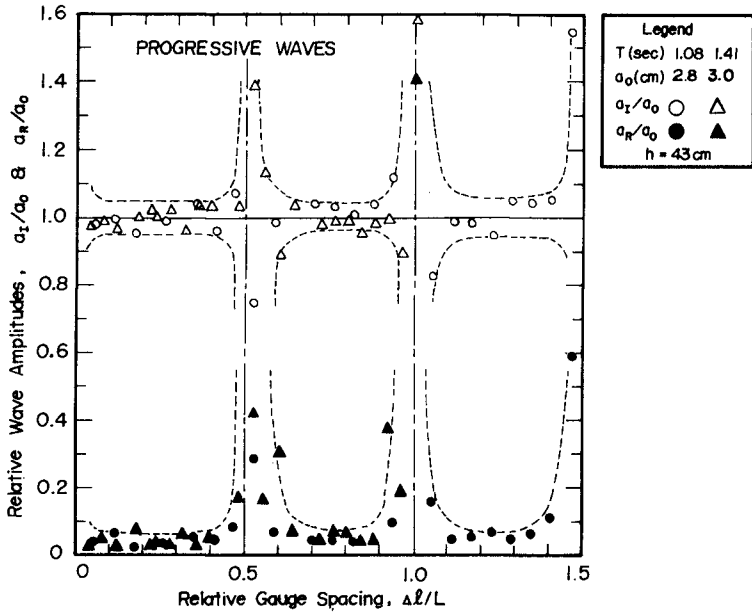

Fig. 2 Variations of Resolved Amplitudes with Wave Gauge Spacing (1)

Fig. 3 Variations of Resolved Amplitudes with Wave Gauge Spacing (2)

Application for Irregular Waves

Figure 4 is an example of spectral resolution of irregular waves. A submerged, upright breakwater with its crest at the depth of 6 cm from the mean water level was set at the distance of 15.0 m from the wave paddle. The wave gauges were located at the distance of 4.80 and 5.00 m from the breakwater face. The observed waves at the gauge locations had the significant height of $H_{1/3} = 8.2$ cm and period of $T_{1/3} = 1.44$ sec. The spectra shown in Fig. 4 are the average of three runs with the same source spectrum but with different wave sequences. The duration of a record was 68.3 sec and the data were sampled at the interval of 1/15 sec. The resolved spectra of incident and reflected waves in Fig. 4 indicate the divergence of spectral density near $f = 0$ and $f = 1.97$ Hz; the latter frequency corresponds to the wavelength of $L = 40$ cm or $\Delta\lambda/L = 0.5$. The result is a natural consequence of Figs. 2 and 3. Therefore, the resolution is effective only in some range of wave frequency. The situation is illustrated in Fig. 5.

There may be several methods to estimate the incident and reflected wave heights on the basis of spectral resolution such as shown in Fig. 4. The authors propose the following procedure. First, the effective range of resolution is set for a given gauge spacing; in practise, the latter is to be selected for a given wave condition. The lower and upper limits of frequency, f_{\min} and f_{\max} , are better chosen by a preliminary test for progressive waves. As a reference, the following guideline may be consulted:

$$\left. \begin{aligned} f_{\min} : \Delta\lambda/L_{\max} &= 0.05, \\ f_{\max} : \Delta\lambda/L_{\min} &= 0.45, \end{aligned} \right\} \quad (7)$$

where L_{\max} and L_{\min} are the wavelengths corresponding to f_{\min} and f_{\max} , respectively. Equation 7 is based on the calibration with regular waves such as shown in Figs. 2 and 3 as well as the frequency-wise examination of resolution results of irregular waves. There is a possibility that the effective range may be taken slightly wider than that given by Eq. 7; e.g., f_{\min} may be chosen so that $\Delta\lambda/L_{\max} = 0.03$.

The second step is to evaluate the energies of resolved incident and reflected waves, E_I and E_R , contained between f_{\min} and f_{\max} , i.e.,

$$\left. \begin{aligned} E_I &= \int_{f_{\min}}^{f_{\max}} S_I(f) df, \\ E_R &= \int_{f_{\min}}^{f_{\max}} S_R(f) df. \end{aligned} \right\} \quad (8)$$

The integrations are to be performed on the raw spectra of periodograms without any smoothing to avoid the effect of divergence of resolved amplitudes near $\Delta\lambda/L = n/2$.

The third step is to estimate the overall coefficient of reflection by

$$K_R = \sqrt{E_R/E_I}. \quad (9)$$

Fig. 4 Example of Spectral Resolution for a Submerged, Upright Breakwater

Fig. 5 Illustration of Spectral Resolution

This equation is based on the relation of irregular wave heights being proportional to the square root of wave energy. Then the incident and reflected wave heights, H_I and H_R , are calculated as

$$\left. \begin{aligned} H_I &= \frac{1}{\sqrt{1 + K_R^2}} H_S, \\ H_R &= \frac{K_R}{\sqrt{1 + K_R^2}} H_S, \end{aligned} \right\} \quad (10)$$

where H_S denotes the significant or other representative wave height of composite waves observed by the two wave gauges; the mean of two gauges are employed.

Equation 10 is based on the two presumptions. The first is that the energy of composite waves appearing as the result of superposition of multiple trains of irregular waves is the sum of the energies of individual wave trains. The second is that the proportionality of representative wave heights to the square root of wave energy holds for such composite waves too, regardless of the directions of individual wave trains. The first one may be taken as an axiom for the analysis of irregular waves. The second one can be proved by a numerical simulation of irregular waves. The proof of it by the field data is almost impossible. But the applicability of the Rayleigh distribution of wave heights to ocean waves with multi-peaked spectra or the existence of the relation of $H_{1/3} \approx 4.0 \eta_{rms}$ for such waves [3,4] provides a supporting evidence for the presumption, because a multi-peaked spectrum usually indicates a coexistence of wind waves and swell propagating in the different directions.

Selection of Wave Gauge Stations in a Wave Flume

The present technique of wave resolution can be employed in the vicinity of reflective structure if the magnitude of reflection coefficients only is of concern. Figure 6 shows the variation of resolved, incident and reflected wave amplitudes against the distance of wave gauge from the face of submerged breakwater. The test was done with regular waves at the conditions same with those shown in Figs. 2 and 3. The test result indicates that the wave gauge may be set as near as $0.1 L$ to the reflective face. The dashed line for closed triangles and the dash-dot line for closed circles show the average values of a_R/a_S for the range of $x_1/L > 0.2$. The test was also carried out with irregular waves by shifting the wave gauge position from $x_1 = 1$ to 480 cm, while the wave gauge spacing was fixed at $\Delta x = 20$ cm. The wave spectra shown in Fig.4 were taken from the data of this test. The reflection coefficient defined by Eq. 9 is found to vary little except at $x_1 = 1$ cm, as shown in Fig. 7.

For the estimation of incident and reflected wave heights, on the other hand, wave gauges are required to be away from both the test structure and wave paddle. This is because the composite wave height H_S used in Eq. 10 fluctuates in the neighbourhood of a reflective boundary. The fluctuation of wave heights of irregular standing waves can be calculated with spectral information as demonstrated by Ishida [5]. For a component wave with the angular frequency of σ and wave number of k , the surface elevation of standing waves at the distance of x_1 from the reflective boundary is given as:

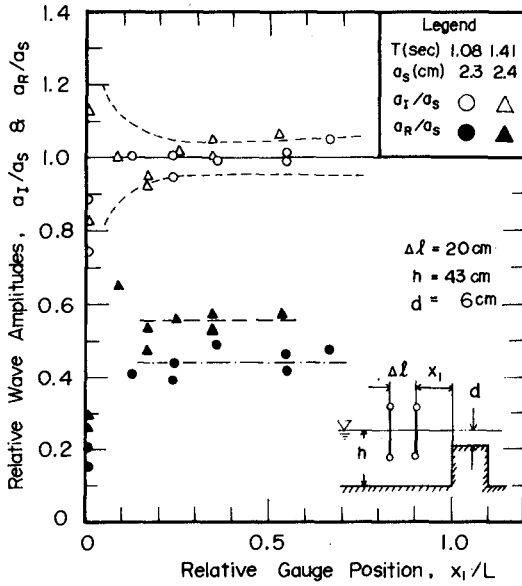

Fig. 6 Variations of Incident and Reflected Wave Amplitudes with Wave Gauge Position

Fig. 7 Variation of Reflection Coefficient of Irregular Waves with Wave Gauge Position

$$\begin{aligned}
 \eta &= a_I \cos(kx_1 - \sigma t) + K_R a_I \cos(kx_1 + \sigma t) \\
 &= (1 + K_R) a_I \cos kx_1 \cos \sigma t + (1 - K_R) a_I \sin kx_1 \sin \sigma t \\
 &= \sqrt{1 + 2K_R \cos 2kx_1 + K_R^2} \cos(\sigma t - \varepsilon_1),
 \end{aligned} \tag{11}$$

where,

$$\varepsilon_1 = \tan^{-1} \frac{(1 - K_R) \sin kx_1}{(1 + K_R) \cos kx_1}. \tag{12}$$

The root-mean-square value of surface elevation of standing waves, $(\eta_S)_{\text{rms}}$, is calculated with the relation of Eq. 11 and the information of incident wave spectrum, $S_I(f)$, as

$$(\eta_S)_{\text{rms}}^2 = \int_0^{\infty} (1 + 2K_R \cos 2kx_1 + K_R^2) S_I(f) df. \tag{13}$$

The significant or any other representative height of irregular standing waves is then obtained as

$$H_S = \frac{(\eta_S)_{\text{rms}}}{(\eta_I)_{\text{rms}}} H_I. \tag{14}$$

Figure 8 is an example of the fluctuation of irregular standing wave heights; the test condition is the same with those of Figs. 4 and 7. The curves represent the result of calculation by Eq. 13 and 14. The incident wave spectrum was obtained from the measurement of progressive waves without a reflective structure. The reflection coefficient of 1.0 and 0.55 were used for the case of a high vertical wall and that of submerged, upright breakwater, respectively. The observed heights of significant waves are represented with the open and closed circles. Though the observed heights are somewhat larger than the calculation possibly because of the multi-reflection and nonlinearity effects, the magnitude of fluctuation is quite in agreement with the calculation. Such the fluctuation of standing wave heights directly affects the estimate of incident and reflected wave heights as the consequence of Eq. 10. The fluctuation becomes negligibly small, however, at the distance of more than one wavelength. A similar phenomenon will take place in front of a wave paddle with the high reflectivity. Therefore, the wave gauges for wave resolution are recommended to be located at the distance of more than one wavelength from both the test structure and wave paddle.

ACCURACY OF THE ESTIMATES OF INCIDENT AND REFLECTED WAVE HEIGHTS

Possible Sources of Inaccuracy

There are several sources of inaccuracy in the present resolution technique. They are:

- 1) Deviation from the dispersion relation of Eq. 6 due to nonlinear effect and others,
- 2) Existence of nonlinear harmonic terms in progressive waves,

Fig. 8 Undulation of Significant Wave Heights in front of Reflective Wall

Fig. 9 Frequency-wise Resolution of Reflection Coefficient of Seawalls

- 3) Generation of nonlinear interaction terms in standing waves,
- 4) Appearance of transversal waves and other disturbances in a wave flume,
- 5) Signal noises.

The dispersion relation of Eq. 6 is for the small amplitude waves. The regular waves of finite amplitudes are known to deviate from that relation. The wave number decreases for progressive waves [6,7], while it increases for standing waves in relatively shallow water [8,9]. The existence of the deviation for wind waves has also been reported [10], though not examined yet for mechanically generated irregular waves. Any deviation from Eq. 6 leads to the inaccuracy in the estimates of a_I and a_R in Eq. 5 because the resolution is based on the relative phase difference of $k\Delta\lambda$. The inaccuracy is greatest at the condition of $k\Delta\lambda = n\pi$ where $\sin k\Delta\lambda = 0$ and smallest at $k\Delta\lambda = (n+1/2)\pi$ where $\sin k\Delta\lambda = 1$. The divergence of a_I and a_R in Figs. 2 and 3 or $S_I(f)$ and $S_R(f)$ in Fig. 4 is due to the deviation of wave number from Eq. 6 to a large extent.

The second source of inaccuracy affects not the spectral peak of irregular waves nor the fundamental component of regular waves but the estimates of harmonic components. The regular waves of finite amplitudes are accompanied by the harmonics which propagate with the same celerity with the fundamental one to keep the wave profile permanent despite of their high frequencies. For such harmonic components Eq. 6 does not apply and errors may be evoked. The situation in a wave flume is more complicated, however. There are free waves with the frequencies of harmonics and nonlinear interacting waves, both of which contribute to the generation of travelling, secondary waves in a wave flume [11, 12, 13]. Similar situation exists in case of irregular wave experiments, though the analysis of nonlinear harmonics and their behaviour is difficult. At present, we should content ourselves by taking caution in the interpretation of the resolution results in the range of harmonic components.

When two trains of finite amplitude waves interact such as in the case of wave reflection, there appear nonlinear interaction terms the frequencies of which are the sums and differences of fundamental and harmonic components. Calculation of the third order solution of partial standing waves [9] has shown the generation of the terms of $\cos[(\bar{k} + 2\Delta k)x \pm 3\sigma t]$ and $\cos[(3\bar{k} \pm 2\Delta k)x \mp \sigma t]$ in which \bar{k} and Δk are the mean and difference of the wave numbers of incident and reflected waves in the standing wave system for the angular frequency of σ . The phase velocities of these nonlinear interaction terms are different from those of free waves having the angular frequency of σ or 3σ , and therefore they become a source of inaccuracy in wave resolution. Similar phenomenon occurs in irregular waves having frequency spectra, though detailed analysis will be complicated.

An indication of such nonlinear effects can be seen in Fig. 9, which shows the frequency-wise representation of reflection coefficient of a seawall with vertical face (type V) and a seawall with a mound of artificial concrete blocks (type B) on the bottom slope of 1 in 10 and 1 in 30. Thin dash-dot lines indicate the overall reflection coefficient estimated by Eq. 9 for the effective range of resolution. Humps of $K_R(f)$ around twice the spectral peak frequency for the type V seawall may be due to the nonlinear effects. When the reflection coefficient is low such as for the type B seawall or the case of no seawall, the humps become insignificant. Experiments with waves of longer periods have exhibited another

humps around thrice the spectral peak frequencies. Therefore, the frequency-wise representation of reflection coefficient should be treated with due regard for the nonlinear effects. The employment of the overall reflection coefficient by Eq. 9 is based on this consideration.

Estimation of Accuracy of the Resolution Technique

Indication of the accuracy of the present technique is seen in Figs. 2, 3, and 6 as the dispersions of resolved amplitudes. In case of progressive waves and partial standing waves, the dispersion is of the order of $\pm 5\%$ except for the diverging zone, while it becomes about two times in the case of standing waves. These dispersions are partly due to the variability of waves in a laboratory flume, and the error involved in the resolution technique is considered less than those indicated in these figures.

The effect of nonlinear terms of finite amplitude waves upon the wave resolution is difficult to quantitate. It should be mentioned here that the conventional method of estimating the reflection coefficient with the observed heights of maxima and minima of partial standing wave systems is much susceptible to the nonlinear effects. For example, the conventional method tends to yield an apparent reflection coefficient of low value for a highly reflective structure and a correction is required [9]. The conventional method is essentially for the fundamental frequency component of small amplitude waves. It cannot detect other associated components such as the harmonics, but it is influenced by them instead.

The overall accuracy of wave height estimation is considered rather small for incident waves. Suppose that the significant height of $H_G = 20$ cm was measured for an irregular standing wave system and the reflection coefficient of the structure in test is 0.6. The true incident wave height is $H_I = 17.1$ cm by Eq. 10. If the wave resolution have produced the estimate of $K_R = 0.7$ by some reason, the estimate of H_I would be 16.4 cm, which is smaller than the true value by 4%. When the reflection coefficient is small, the error in the estimate of incident wave height becomes negligible.

EXAMPLES OF APPLICATIONS

The resolution technique has been employed in the authors' laboratory for irregular wave experiments since 1973. A series of wave overtopping tests have been carried out for seawalls with vertical faces and other types of seawalls [14]. Trains of irregular waves of about 200 waves long were generated and exerted upon model seawalls. The total amount of overtopped water was measured for each wave train, which yielded the rate of wave overtopping per second per unit length of seawall. At the same time, wave records of composite waves were taken by the two gauges in the offshore, and the incident and reflected wave heights were estimated from those records by the present technique. Figure 9 for the frequency-wise reflection coefficient is an example of the results of wave overtopping tests. Without the use of the resolution technique, the tests would have been much laborious since a number of short wave trains would have had to be employed to avoid the multi-wave-reflection problem. The tests have produced a set of twelve diagrams for the estimation of wave overtopping rate of seawalls under irregular wave actions, covering the full range of water depth from the offshore to the foreshore.

Fig. 10 Transmission and Reflection Coefficients of a Composite Breakwater

Fig. 11 Change of Wave Periods by Wave Transmission over a Composite Breakwater

Another example of wave tests for continuous wave actions is the wave transmission characteristics of a composite-type breakwater, which consists of a caisson rested upon a rubble mound. When the crest of breakwater is not high enough, some waves overtop it and new waves are generated behind it. The characteristics of transmitted waves by irregular wave actions can be revealed by experiments with continuous runs only. Figure 10 is a result of such experiments [15]. The ratio of significant height of transmitted waves to the incident significant wave height, $(H_{1/3})_T / (H_{1/3})_I$, as well as the reflection coefficient are plotted against the ratio of crest height to incident wave height, $h_c / (H_{1/3})_I$. The curves are those of regular waves previously formulated by the senior author [16]. The transmitted waves have two distinct properties. The one is the distribution of wave heights being broader than the Rayleighian. The second is the wave period being shorter than the incident waves. Figure 11 shows the latter characteristic. Both the mean and significant wave periods decrease to 50 to 80% of the incident wave periods.

The present resolution technique is also effective to detect the enhancement of harmonic components of waves through the interaction with structures. Figure 12 is one of such examples. A slit caisson with the opening ratio of 20% was tested for wave absorbing characteristics. As listed in the figure, the reflected wave height was estimated as 4.9 cm for the incident waves of $(H_{1/3})_I = 10.3$ cm and $T_{1/3} = 2.65$ sec, and the overall reflection coefficient was 48%. An interesting feature of the slit caisson is that it enhances the third harmonic component when it reflects waves. The feature has been predicted by Mei, Liu, and Ippen [17] in general form and is demonstrated in Fig. 12 as a hump of reflected wave spectrum around $3f_0 = 1.05$ Hz, where $f_0 = 0.35$ Hz corresponds to the spectral peak of incident waves. Though a caution should be taken in the interpretation of resolved harmonic components as discussed earlier, the result of Fig. 12 is judged to represent actual generation of the third harmonics because it is not observed in the spectrum of incident waves and the overall reflection coefficient is relatively low.

The enhancement of odd harmonic components by wave reflection was more conspicuous when the slit caisson was tested for regular waves. The undulation of wave heights by formation of partial standing wave system was obscured by the presence of odd harmonics and the conventional method for the measurement of reflection coefficient had difficulty to obtain the correct value of reflection coefficient.

The application of the present technique of wave resolution is not confined to the above examples. It is applicable to any wave test with regular or irregular trains of waves. Though the question of wave nonlinearity effects remains to be clarified, it will provide the most needed means to measure the coefficient of reflection of irregular waves.

CONCLUSIONS

A technique to resolve the incident and reflected waves from the records of composite waves has been proposed. Examination of the technique with wave tests has shown the followings:

- 1) The wave resolution is not possible around the condition of $\Delta\ell/L = n/2$ where $n = 0, 1, 2, \dots$. As a guideline, the wave resolution may be performed in the range of $0.05 < \Delta\ell/L < 0.45$.

Fig. 12 Example of Spectral Resolution of a Slit Caisson

- 2) The wave gauges are recommended to be located at the distance of more than one wavelength from the test structure and wave paddle in the irregular wave test. In the regular wave test, the wave gauges may be set as near to the structure as at the distance of 0.2 L.
- 3) There remains the problem of nonlinear wave interaction which may affect the accuracy of the wave resolution technique.
- 4) The technique is effective in detecting the enhancement of odd harmonics in the wave reflection by a structure such as a slit caisson.

The authors sincerely express their thanks to Messrs. Yasuharu Kishira and Osamu Kikuchi, members of the authors' laboratory, for their earnest cooperation in carrying out the experimental verification.

APPENDIX: MULTI-REFLECTED WAVES IN A LABORATORY FLUME

As described in the text, waves in a closed, laboratory flume may travel many times between a reflective model structure and the wave paddle as the result of wave reflections at the both boundaries. This composes a multi-wave-reflection system. Let the amplitude of initially generated waves be denoted by a_0 , the reflection coefficients of the test structure and wave paddle by r and R , respectively, and the distance between them by ℓ . Then the wave profile of multi-wave-reflection system can be expressed as an infinite series of

$$\begin{aligned} \frac{\eta}{a_0} = & \cos(\sigma t - kx) + R \cos(\sigma t + kx - 2k\ell) \\ & + r R \cos(\sigma t - kx - 2k\ell) + r R^2 \cos(\sigma t + kx - 4k\ell) \\ & + r^2 R^2 \cos(\sigma t - kx - 4k\ell) + r^2 R^3 \cos(\sigma t + kx - 6k\ell) \\ & + \dots \end{aligned} \quad (A.1)$$

where η is the surface elevation of waves, σ is the angular frequency of $2\pi f$, and k is the wave number of $2\pi/L$. The infinite series can be summarized after a few manipulations as a closed form of

$$\eta = \frac{a_0}{\sqrt{1 - 2rR \cos 2k\ell + r^2 R^2}} \{ \cos(\sigma t - kx + \theta) + R \cos(\sigma t + kx - 2k\ell + \theta) \} \quad (A.2)$$

where,

$$\theta = \tan^{-1} \left\{ \frac{r R \sin 2k\ell}{1 - r R \cos 2k\ell} \right\} \quad (A.3)$$

This proves the formation of two trains of waves propagating in the opposite directions as the result of multi-wave-reflections.

CHAPTER 49

DECOMPOSITION OF CO-EXISTING RANDOM WAVE ENERGY

Dennis B. Morden¹, Eugene P. Richey² and Derald R. Christensen³

INTRODUCTION

Of the several transformations that water waves may undergo, the phenomenon of reflection has received relatively little quantitative attention, although the analyst is sensitized to reflection in a qualitative way. Commonly the investigator is interested in progressive or transmitted waves and the characteristics of reflected waves and the energy dissipated during the reflection process are of little consequence. There are, however, certain structures, such as piers, floating bridges, bulkheads, etc., where waves reflecting from the structure can be of concern if they should impinge on a site or shoreline sensitive to a new, or changed, wave climate. Quantitative assessment of the energy dissipated during reflection is essential to the evaluation of devices which are intended to reduce site interaction problems and/or reduce the loading on structures and anchor systems.

This paper examines the analysis of sea states where wind-generated waves and their reflection co-exist. Using the results of a field test the characteristics of co-existing sea states are discussed. The decomposition of these waves to obtain separate incident and reflected wave spectra requires two applications of spectral analysis. First, spectral estimates are computed from co-existing wave data acquired simultaneously at multiple, fixed sensor locations. These spectra are then divided into frequency increments and the amplitude associated with each increment used as an independent input into a technique to decompose the co-existing waves into appropriate incident and reflected wave spectra. Because the incremental amplitudes of the original spectral estimates are used as independent inputs, the shape and accuracy of these original estimates naturally have a profound influence on the final separated wave spectra. Various spectral estimating techniques were used on the field data and the accuracy of the results were compared to three validation criteria.

Because the findings and discussion are validated primarily by the analysis of specific data it seems appropriate to first describe the relevant features of the field test. Though the present study involves deep water waves and zero transmission, the principles apply equally well to any situation where wave reflections are of interest.

TEST DESCRIPTION

Test Site - Sea states composed of wind-generated deep water waves and their reflections were examined in Lake Washington which adjoins Seattle.

 2. Professor of Civil Engineering, Department of Civil Engineering, University of Washington, Seattle, Washington, U.S.A.
 3. Research Engineer, Department of Civil Engineering, University of Washington, Seattle, Washington, U.S.A.

Washington, U.S.A. A sixty-foot wide floating bridge with a seven-foot draft traverses the lake in a generally east-west direction and is exposed to waves generated over a 2.8 mile effective fetch by the prevailing southerly winds of the region. Near the center of the span a test site was established to evaluate the waves reflected from the solid vertical walls of the bridge pontoons (which extended 11 feet above SWL) and those reflected from a perforated wall breakwater appended to the pontoon. For the waves occurring at the site the bridge forms an excellent barrier, completely eliminating transmitted waves. The 200-foot depth of the lake is sufficient to classify all waves as deep water waves. During storms reflected wave trains are apparent as far as 4,000 feet south of the bridge.

Figure 1 depicts an aerial close-up of the test site. Co-existing incident and reflected waves were monitored using pressure transducers located five feet below stillwater level (SWL). Analog data were recorded simultaneously at four locations: two in front of a breakwater and two more 150 feet away in front of the solid vertical wall of the bridge. Viatran Model PTB 101 transducers were rigidly mounted 7'9" and 12'9" away from each barrier, as shown in the figure. Morden (1975) shows details of the apparatus and test procedure.

Perforated Wall Breakwater - To produce reflected waves with amplitudes substantially different from those at the solid vertical bridge wall, a perforated vertical wall and solid (but removable) bottom were appended to the bridge, as shown in Figure 2. This "L"-shaped structure and resulting chamber form a perforated wall breakwater of the type originated by Jarlan (1961). The test breakwater section was long enough to avoid diffraction effects on the outer wave sensors, and terminated by solid vertical end plates to maximize the two-dimensional response of the chamber.

Several authors have tested and analyzed the behavior of this type of breakwater; their results have been reviewed by Morden (1975). Richey and Sollitt (1970) successfully model the behavior of the breakwater in monochromatic waves as a linear damped oscillator. As such the amplitude and phase angle of a wave are altered during the reflection process, but its frequency is not changed.

The reflection coefficient for the breakwater in monochromatic waves (Fig.3) is defined as the ratio of reflected to incident wave heights, and has a minimum value at a particular frequency, which depends primarily upon breakwater geometry. This definition must be modified for the random wave case, and becomes the square root of the ratio of the reflected to incident energy over a specified frequency band width, i.e.,

$$R = \sqrt{\frac{\sigma_r^2}{\sigma_i^2}} \quad (1)$$

CHARACTERISTICS OF CO-EXISTING* SEA STATES

Ippen (1966, p. 58) points out that the average potential energy density (i.e., potential energy per unit surface area) is a function of distance from

* Sea states composed of the superposition of wind-generated waves and their reflections. Superposition of unrelated waves are not considered.

FIGURE 1: AERIAL SCHEMATIC OF TEST SITE SHOWING WAVE SENSOR LOCATIONS

FIGURE 2: CROSS SECTION OF PERFORATED WALL BREAKWATER

FIGURE 3: TYPICAL PERFORMANCE OF PERFORATED WALL BREAKWATERS

the reflecting barrier. For a single linear wave component the time averaged potential energy at a fixed location, x , obtained from the application of linear wave theory is

$$PE(x) = \frac{\gamma}{4} (a_i^2 + a_r^2 - 2 a_i a_r \cos(\theta_r + \frac{4\pi x}{L})) \quad (2)$$

where a_i , a_r , L , and θ_r are the incident and reflected wave amplitudes, wave length, and relative phase angle, respectively. Since the wave sensors monitor the potential energy, the time averaged energy density at a fixed location in a co-existing sea state is not the same as the sum of the time averaged energy densities (taken independently) of the incident and reflected progressive waves that combine to form the co-existing waves. The measured amplitude is modulated by the last term of Eq. 2.

Inherent in the computation of average energy density for a progressive wave is the assumption that the time average of the wave amplitude at a fixed location is the same as the spatial average of the wave amplitude at a fixed time. For random progressive waves this requirement is met statistically by assuming that the random process is ergodic; i.e., that the ensemble average equals the time average for any location and time. Random waves progressing in a given direction are represented as the superposition of a number of components each with its own characteristic amplitude, frequency, speed, length, and phase angle. The phase angles for random progressive waves are taken to be independent, random, and uniformly distributed between 0 and 2π . When a random progressive wave and its reflection co-exist there is a deterministic relationship between each incident and reflected wave component. The relationship is a function of the speed of the wave component, the distance between the sensor and the location of reflection, and the phase change occurring during the reflection process, if any. The speed associated with each component is linearly related to the frequency such that product of the frequency and speed is a constant.

Any two components of a progressive wave move into and out of phase with each other as time progresses, causing a beat effect. If energy density for progressive waves is averaged over a beat period, the average energy density is not a function of location and the average value equals the sum of the energy densities for each component.

On the other hand, the time series obtained at a fixed location in a co-existing incident-reflected sea state not only contains the beat effect for each wave system but also the amplitude modulation which is a consequence of being, in effect, at different locations on a partial standing wave envelope for each frequency component. For each frequency component the amplitude modulation has a different value (due to the space and frequency dependence of the last term in Eq. 2). The net result is a time series with a beat effect and an amplitude modulation causing the peak measured amplitude values to be strongly dependent on sensor location. The effects are evident in the typical time series shown in Figure 4 for data acquired simultaneously at two fixed locations in front of a solid vertical wall. The effect of position in a standing wave envelope is evidenced by the maximum values recorded. Signals obtained in front of the breakwater are similar in appearance.

Spectra obtained from these time series are shown in Figure 5. The

FIGURE 4: TYPICAL TIME SERIES AT TWO LOCATIONS IN FRONT OF A SOLID VERTICAL WALL.

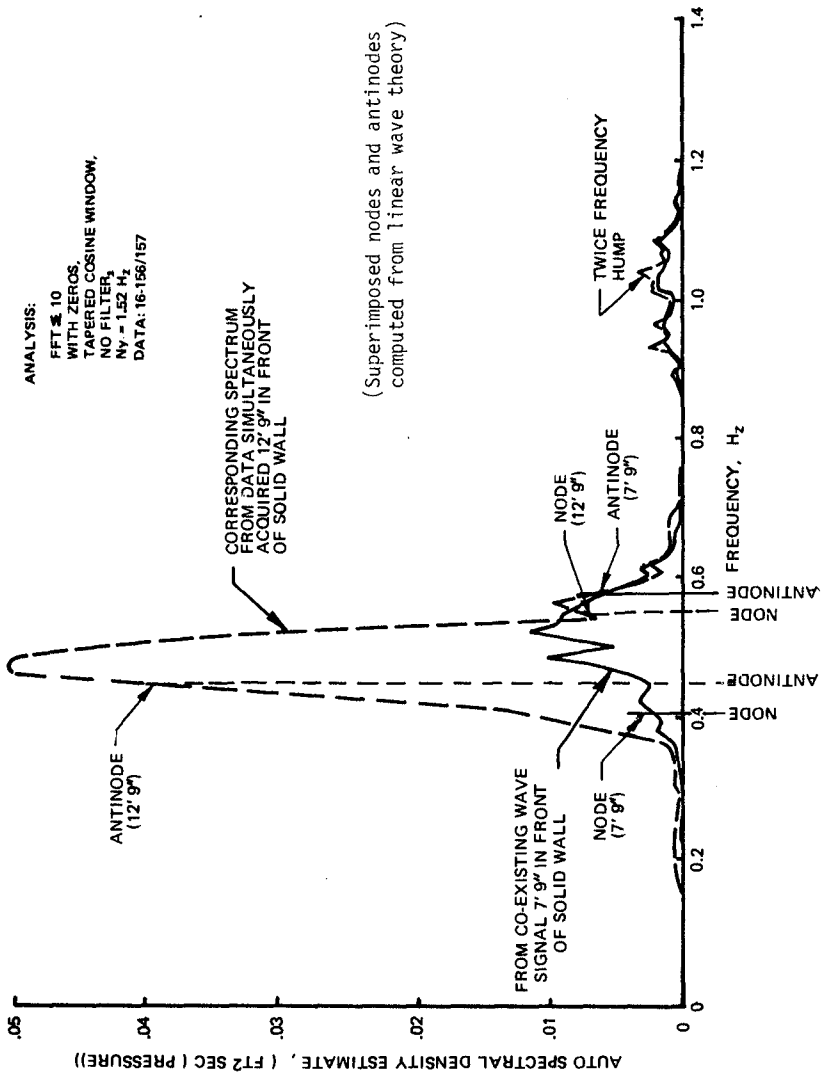

FIGURE 5: CO-EXISTING WAVE SPECTRA FROM PRESSURE DATA IN FRONT OF SOLID VERTICAL WALL.

variances computed at the two distances in front of the solid wall display a strong dependence on sensor location. The twice frequency hump is due to using subsurface pressure sensors. Longuet-Higgins (1950) and Silvester (1974) established that in co-existing sea states a second order pressure variation of the form $\frac{\gamma \pi a_1 a_r}{L} \cos(4\pi ft)$ exists in addition to the usual. The

term is not attenuated with depth and ultimately dominates over the first order term (with its $e^{2\pi z/L}$ pressure response factor) as depth increases. The second order term can be attributed to the movement of the center of gravity in the water column as above the sensors, the fluctuations, occurring at twice the frequency of the surface wave components, are not "real" in the sense of contributing to the surface energy density and therefore must be filtered from spectra obtained using pressure sensors in co-existing sea states.* In the present study the filtering was not a problem, but in co-existing sea states where the spectrum is relatively broad band (the twice-frequency hump might be buried in the spectrum) surface piercing gauges should be used.

The characteristics of the remaining spectra may be better understood by considering a single frequency component of both the incident and reflected wave system. Conceptually, the resulting sea surface at a fixed location due to these two components can be thought of as the sum of a progressive wave and a standing wave. The progressive component eliminates the possibility of true nodes, while the standing wave component produces maxima and minima in the wave envelope which are functions of location. Since these locations are determined by the standing wave component, the phase angle and distance relationships producing the amplitude extremes can be obtained by examining the nodes and antinodes for a perfect reflection. The frequencies associated with node and antinode locations for perfect reflection were computed from linear theory and superimposed on Figure 5. The nodes and antinodes suggest frequencies at which the spectra for each fixed location should contain minimum and maximum (respectively) amounts of information about the wave process. When simultaneously acquired co-existing wave data are examined at two fixed locations, the effects of spatial dependence of the information contained in the spectra can be seen. No location exists where the computed spectrum contains the appropriate ordinate values for the process at all frequencies. Instead, the location where the largest variance (and spectral area) will be calculated is at the position where the frequency for an antinode most nearly matches the peak frequency of the incident wave (assuming that the band width of the process is on the order of, or less than, the frequency difference between nodes). For the wind condition represented by Figure 5, the majority of the incident wave energy occurs at frequencies (.4 - .5 HZ) near a node at the inner (7'9") station and near an antinode for the outer (12'9") station. The opposite occurs in the high frequency tail of the curves where the spectral ordinate value associated with the outer station is less at a frequency corresponding to a node. Since the energy in the incident wave was concentrated

* Alternative one could analyse only the twice frequency spectrum because it is not attenuated with depth, provided the size of the $\frac{\gamma \pi a_1 a_r}{L}$ terms are sufficient to analyse. Due to the considerable reduction in a_r caused by the breakwater the twice frequency hump was exceedingly small for spectra obtained from data taken in front of the breakwater.

in a frequency range near the antinode for the outer station, its calculated variance is much larger than that for the inner one (in this case 4.6 times as large). For all wave conditions tested, the peak incident wave frequency was nearer the antinode frequency for the outer station. Thus, the variance calculated at that station was always larger than the variance at the inner one. The ratio of the variance at the two stations (outer/inner) ranged from 1.4 to 8.1 for the wave conditions of record.

When a linear reflection process occurs at barriers other than solid vertical walls, the location of the node and antinode associated with each frequency increment is altered due to the phase change occurring during the reflection process. As a result of the phase change during reflection altering the frequencies associated with nodes and antinodes, a fixed location in front of the breakwater is not monitoring the same portion of the partial standing wave envelope as that being monitored at the same physical distance in front of a solid vertical wall. Thus, direct comparison of spectral ordinate values obtained from co-existing wave data taken at the same physical distance in front of two types of barriers is a comparison of "apples and oranges."

Having discussed the behavior of co-existing sea states and demonstrated that the variance obtained from any fixed sensor data does not represent the true average energy density, a technique is now discussed to circumvent the problems and decompose multiple co-existing wave spectra into separate incident and reflected spectra.

DECOMPOSITION TECHNIQUE

Thornton and Calhoun (1972) initially presented a theory for separating incident and reflected wave spectra using co-existing wave data acquired simultaneously at two fixed locations in line along the wave ray. The sea state is presumed to result from the superposition of random waves progressing in opposite directions. Each wave is assumed to pass over both sensors. As commonly done in spectral analysis, the random waves progressing in a given direction are represented as the superposition of a number of components each with its own characteristic amplitude, frequency, speed, length, and phase angle. The phase angles for random progressive waves are taken to be independent, random, and uniformly distributed between 0 and 2π . Spectral analysis is used to compute mean square spectra (as well as cross spectra) for the co-existing waves at each sensor location.

The theory was developed by applying linear wave theory to mono-chromatic waves. For a single wave component frequency, the incident and reflected component wave amplitudes are related to the co-existing wave amplitude at two stations. The resulting equations are:

$$\theta_r = \tan^{-1} \left[\frac{A_1 \cos kx_2 - A_2 \cos \theta}{A_1 \sin kx_2 - A_2 \sin \theta} \right] \quad (3)$$

$$\theta_i = \tan^{-1} \left[\frac{a_r \sin \theta_r}{A_1 - a_r \cos \theta_r} \right]$$

$$\theta_i = \tan^{-1} \left[\frac{A_1 \cos kx_2 - A_2 \cos \theta}{A_1 \sin kx_2 + A_2 \sin \theta} \right] \quad (4)$$

$$a_r = \frac{-A_2 \cos \theta + A_1 \cos kx_2}{2 \sin kx_2 \sin \theta_r} \quad (5)$$

$$a_i = \frac{a_r \sin \theta_r}{\sin \theta_i} = \frac{A_1 \cos kx_2 - A_2 \cos \theta}{2 \sin kx_2 \sin \theta_i} \quad (6)$$

The quantities A_1 and A_2 are the amplitudes of the particular frequency component under consideration as calculated from spectral analysis of the signals at 1 and 2. x_2 is the measured distance between gauges; k is calculated from linear wave theory to be $k = 2\pi/L = (4\pi^2/g)f^2$ (in deep water). The phase relationship θ can be obtained directly from the data through cross-spectral analysis of simultaneously acquired records at the two in-line sensor locations. The cross-spectrum is obtained from the Fourier transform of the cross-covariance function in the same manner that the energy spectrum is obtained from the Fourier transform of the auto-covariance function. The inverse tangent of the odd contribution to the cross-spectrum (quadrature spectrum, $Q_{12}(f)$) divided by the even contribution (co-spectrum, $C_{12}(f)$) can be used to calculate the average phase shift, θ , within each frequency band; i.e.,

$$\theta(f) = \tan^{-1} \left[\frac{Q_{12}(f)}{C_{12}(f)} \right] \quad (7)$$

These quantities are sufficient to solve for θ_r and θ_i using Equations 3 and 4. The values of a_r and a_i are then available as a function of these phase angles for the given frequency.

Thus, by evaluating each frequency bandwidth using Equations 3 - 7 the component incident and reflected wave amplitudes can be calculated and the corresponding separate incident and reflected wave spectra computed. In random waves, A_1 and A_2 are obtained by applying spectral analysis to the measured co-existing wave data. The resulting co-existing wave spectra are necessarily only estimates of the distribution of amplitudes (squared) with frequency (i.e., each co-existing wave spectrum is divided into frequency increments and the amplitude representative of that frequency band used as an independent input to equations 3 - 7.). Incident and reflected spectra are then created by plotting the solution to the equations (at each frequency increment) over the range of frequencies. Thus, the accuracy of the resulting spectra is strongly dependent on the shape as well as the variance of the co-existing wave spectra. The process is reviewed schematically in Figure 6. The assumptions inherent in the application of the technique include:

1. Linear wave theory applies. This requirement, which is a reasonable engineering approximation for most non-breaking sea states, is due to the linear wave theory applied to solve the equations.

2. The reflection process does not alter the frequency. Since each

SPECTRAL ESTIMATES OF CO-EXISTING WAVE SIGNALS:

DECOMPOSITION:

- Divide co-existing spectrum into frequency increments
- Apply linear wave theory to each frequency increment independently
- 4 equations $f(A_1, A_2, x_2, \text{relative phase})$
- Solve for incident and reflected wave amplitude and phase

OUTPUT:

- If accurately computed, σ_i^2 and σ_r^2 are independent estimates and can be used directly to evaluate reflection coefficients and energy dissipation

FIGURE 6: OUTLINE OF DECOMPOSITION TECHNIQUE

frequency increment is treated independently there is no analytical mechanism to account for frequency alterations.

3. Wave crests are sufficiently long and parallel to the reflecting barrier that the incident wave passes both sensors, is reflected and passes both sensors again.

4. The surface at each sensor location is the linear superposition of progressive incident and reflected waves.

5. The process is statistically stationary. Typically this requirement is met by comparing calculations based on different portions of an analogue data record.

The distance between sensors must be known, but it is not necessary to know the distance to the reflecting barrier nor the characteristics of the reflection process (except for requirement #2 above).

To evaluate the accuracy of various spectral analysis techniques three performance criteria were specified for the test data. Before the particular techniques are compared, some general characteristics of the spectra resulting from decomposing the co-existing waves are presented.

The required inputs for the decomposition technique are the incremental amplitude and phase information obtained from spectral estimates of two simultaneously acquired co-existing wave signals taken at two different distances in front of a reflecting barrier. The incident waves must have crests nearly parallel to the reflection barrier and the sensors sufficiently in-line with the wave advance that any given incident wave component can be assumed to pass both gages, be reflected, and again pass both gages. Linear wave theory is then used to separate the incident and reflected components from the co-existing wave components at the two fixed locations on the partial standing wave envelope. Because each frequency increment is treated independently, it is necessary to know or assume that the reflection process does not appreciably alter the frequency of the incident wave component. It is not necessary to know anything else about the location or characteristics of the reflection process.

The technique produces the phase and amplitude for both the incident and reflected spectra at each frequency increment. These are presented in Eqs. 2 - 6 and are functions only of the physical distance between sensors and the characteristics of the co-existing wave signals.

Surface or subsurface wave sensors can be used to obtain the co-existing wave information. If subsurface transducers are used the twice frequency components must be filtered from the spectra before they are input to the decomposition technique.

Eqs. 3 - 6 are consistent if the outer gage is designated 1 and inner gage 2. The two signals can be interchanged if the sign on the phase angle, θ , is changed. Usually, an auto spectrum can be calculated without regard to the sign of the amplitude. Due to the use of information from two auto spectra in calculating the incident and/or reflected spectra using this technique, the

signs must be consistent with the physical signal (or both opposite from reality).

Figure 7 shows the reflected wave spectrum in front of a solid vertical wall (from the co-existing wave spectra shown in Figure 5). From Figure 5 it can be seen that the amplitude values at frequencies below .2 Hz are extremely small. Terms involving the difference of these small values are used in the denominator of the equation for amplitude (Eq. 5). Thus, the values of the reflected spectra calculated where the amplitudes of both co-existing spectra are nearly zero ($f < .2$) is erroneous and should be set to zero.

The denominator of Eq. 5 goes to zero when the wave length equals twice the spacing between the sensors. For the distance between the sensors in the present investigation of five feet the amplitude should go to infinity at $f = .716$ Hz. This is clearly evident on Figure 7. For any application of the technique the distance, x_2 , between the sensors should be chosen so that $\sqrt{x_2}/2.56$ is greater than any frequency containing surface wave data of interest.*

The remaining spectral information, which for the figure shown is concentrated between $f = .35$ and $.65$ Hz., is the actual spectral estimate associated with the reflected wave that contributed to the co-existing sea state of Figure 5. Due to the equation similarity, the incident spectrum has identical characteristics.

Eqs. 4 and 6 are written in two forms which are trigonometrically identical. The numerical problems discussed relative to frequencies below .2 Hz produce different spectral calculations for the different identities below $f = .2$ Hz and above $f = .75$ Hz (because the input amplitudes were nearly zero). Over the range of interest, i.e., the range of frequencies when the co-existing wave spectra indicated wave activity, the identities produced identical answers.

For any application of this technique, the range of frequencies containing surface wave information should be established from the co-existing wave spectra and/or knowledge of the specific test conditions. Outside the desired range the extraneous incident and reflected spectral amplitude should be filtered off. The variances of the resulting incident and reflected spectra can then be obtained.

These variances now represent the average energy densities in the incident and reflected wave process and are independent. Since they are separate from each other and independent of spatial location, they can now be used directly to calculate the reflection coefficient of a barrier and/or the dissipation occurring during reflection. The dissipation is easily expressed as the decrease in average incident energy (\sim incident variance, σ_i^2 , and reflected variance, σ_r^2).

$$\text{Percent dissipation during reflection} = \left(1 - \frac{\sigma_r^2}{\sigma_i^2}\right) \cdot 100 \quad (8)$$

* From linear deepwater wave theory, $f = \sqrt{\frac{5.12}{L}}$. The decomposition is valid for wave lengths greater than $2x_2$. decomposition is valid for $f < \sqrt{x_2}/2.56$.

FIGURE 7 : AUTO-SPECTRUM FOR REFLECTED WAVE IN FRONT OF SOLID WALL; COMPUTED BY DECOMPOSITION OF CO-EXISTING WAVES.

Either the reflection coefficients or the dissipation can be calculated equally well from the surface or sub-surface sensor data once the desired frequency range has been defined (and provided the pressure response factor does not reduce the signal strength to an unacceptable level within the range of interest).

A technique has thus been shown to circumvent the problems associated with co-existing random wave data, and produces separate incident and reflected spectra from which the desired reflection characteristics of a barrier can be obtained. The only requirements to using the technique are (1) that the reflection process be known or assumed to occur without altering the wave component frequency, (2) that the distance between two in-line sensors be known, and (3) that the co-existing wave spectra from the two sensors be used as inputs to the decomposition technique where each frequency increment of the spectra is operated on independently. The effect of the last requirement on the numerical computation of incident and reflected spectra is now considered.

COMPARISON OF LAG PRODUCT AND FAST FOURIER TRANSFORM METHODS APPLIED TO THE DECOMPOSITION TECHNIQUE

The decomposition technique requires, as input information, the auto and cross spectra from data acquired simultaneously at two "in-line" locations in a sea state where random incident waves and their reflections co-exist. Increments of the auto spectra become the inputs to Eqs. 3 - 6 and increments of the cross spectra are used to evaluate the phase, Eq. 7. The technique operates on each frequency increment of the spectra independently. Thus the shape and accuracy of the co-existing wave spectral estimates could profoundly influence the computed incident and reflected spectra.

Two methods are commonly used to obtain spectra from random signals; namely, lag product and fast Fourier transform techniques. The lag product method follows the procedure given by Jenkins and Watts (1968). A fast Fourier transform program is described by Paniker (1971). Programmed versions of both methods are widely available. The lag product method involves computing the autocovariance function, which is the correlation of the random signal with itself for the desired number of lags (time increments). The zero lag product of the process is the variance, or mean square value of the signal about the mean. The mean is always zero for the present investigation and the variance is directly proportional to the average energy in the wave signal, and the Fourier transform of the autocovariance function is the spectrum.

Parseval's Theorem (Brigham, 1974) establishes that the spectrum also results from the direct Fourier transform of the continuous time series. For digital computation the Discrete Fourier Transform, DFT, provides a Fourier transform pair made up of the digital time series and a discrete approximation of the continuous spectrum. The fast Fourier transform, FFT, is just an algorithm for efficiently computing the DFT (Bergland, 1969).*

* For 1024 data points used for most of the present analysis the FFT produces a 2DD to 1 reduction in computation relative to the DFT.

The transformations above are defined for infinite time. For the finite length records actually used the transformation can be thought of as an infinite time series multiplied by a window with length equal to the data record. Since multiplication in the time domain is convolution in the frequency domain, the transform of the data (or autocovariance function) is automatically convolved with the transform of the window function. When no window shape is specified it automatically becomes a function which equals zero for all time except the time of the data record and equals one (i.e., has no effect on the time series) during the time of the record (referred to as a rectangular window). The transform of the rectangular window has substantial side loops, which when convolved with the transform of the data produces undesirable positive and negative contributions to the spectral value at each frequency. To minimize this effect several window functions are in common usage which, when transformed, have smaller or better behaved side loops and produce more desirable or less noticeable contributions to the spectral estimate. Though the effect of convolving the data with a window can be reduced through the choice of window functions, the resulting spectrum is always an estimate of the true spectrum for the process.

The spectrum resulting from the transformation of the finite digitized data is referred to as a raw periodogram. Since the periodogram is the direct transform of the finite data from the time to the frequency domain, it is the least squares representation of the raw data (convolved with a window), and it contains the raw coefficients of the Fourier line spectrum. For random signals, the individual component amplitudes do not converge to the true spectrum as the data record length increases. To estimate the true spectrum for the process, adjacent values of the line spectrum are summed together. If too many points are summed together the spectrum becomes oversmoothed (biased). The appropriate number of points to sum to best approximate the true spectrum is more of an art than a science. The window most commonly applied to the data for the FFT technique is the tapered cosine window where the first and last 10 percent of the time series is smoothed using a quarter period segment of the cosine function. The effect of varying the number of line spectral components summed together will be considered further.

The lag product method involves transforming a number of lags of the autocovariance function. The resulting spectral estimate is a function of the number of lags transformed and the window used to multiply the autocovariance function (lag window). When the number of lags transformed is too few the spectrum is oversmoothed (biased). As the number of lags increases, the spectrum approaches the true spectrum of the autocovariance function, then becomes very jagged and unstable. The jagged spectrum produced by the lag product method does not converge to the raw line spectrum produced by the FFT technique. The number of lags necessary to produce the best estimate is unknown and will be considered further. Several window functions are commonly used to smooth the spectral estimate and minimize the effects of side loops (Jenkins and Watts, 1968).

A decision must be made about which combination of windows and transform techniques should be used to produce the best estimate of spectra for co-existing waves which can then be broken into frequency components and used as inputs into the decomposition technique. Experimental data were acquired at four stations simultaneously; two in front of a solid wall (7'9" and 12'9")

and two at the same distances in front of a perforated wall breakwater, 150 feet away (Figure 1). The co-existing waves at the two stations should be different because of the different reflecting processes, but the energy density of the incident waves averaged over the 5.6 minutes of the record should be the same at two stations, only 150 feet apart. Decomposition can be used to compute the incident spectra and average energy density (proportional to the variance) at the two locations. A perfect estimate of the actual incident wave process would require that the incident variance at the two locations be identical. Defining this desired condition as C,

$$C = \sqrt{\frac{\sigma_{I\infty}^2}{\sigma_{I\infty}^2}} \rightarrow 1 \quad (9)$$

where a perfect decomposition requires $C = 1$.

Reflections from a solid vertical wall are nearly perfect below a critical wave camber (Morden, 1975, Section IIC). Over most of the wave conditions encountered in the present investigation, the reflection coefficient in front of the solid wall, R_{∞} , should equal .99-1.0. Co-existing wave data in front of the wall can be decomposed and the resulting variances for the incident and reflected components used to obtain R.

$$R_{\infty} = \sqrt{\frac{\sigma_{R\infty}^2}{\sigma_{I\infty}^2}} \rightarrow .99-1.0 \quad (10)$$

A perfect decomposition requires $R_{\infty} = .99-1.0$.

Perforated walled breakwaters reduce co-existing wave action enough that several observers qualitatively claim that the devices work well. A reduction in co-existing waves substantial enough to be clearly seen in a random sea state would require a considerable dissipation during the reflection process. Therefore, properly decomposed spectra should show a reflection coefficient significantly less than 1. Model-scale predictions (Richey and Sollitt, 1970) suggest overall reflection coefficient (R_{BW}) values in the range of 0.4 to 0.7.

$$R_{BW} = \sqrt{\frac{\sigma_{R_{BW}}^2}{\sigma_{I_{BW}}^2}} \rightarrow .4 \text{ to } .7 \quad (11)$$

These criteria can now be applied to the data for various combinations of lags and windows for the lag product techniques and various sums of spectral line components for the FFT technique. The variations are applied to the co-existing wave data, the resulting spectra can then be incremented and used as inputs into the decomposition technique. The computed incident and reflected variances and spectra can then be judged by the natural criteria.

Stationarity was established for each set of data by analysing the different portions of long analog data records and using only those without changes in computed spectra. Following analysis of many combinations the data was digitized and sampled with a sampling rate of .328 second/sample. (Nyquist frequency 1.52 Hz) 1024 data points represent 5.6 minutes of analog data.

Jenkins' and Watts' (1968) window closing technique was initially used to examine 20, 40, 60, 80 and 95 lags of the co-existing wave data. The lag product method produces very smooth unbiased input spectra when the number of lags equals 50, approximately 5 percent of the record length. Progressive wave spectra often become unstable with lag numbers approaching twice this number. Since the co-existing wave record is expected to be much less smooth because of the effects of partial nodes and antinodes, a high number of lags, say 95, were also tried. The window which produces the least stable spectra is the rectangular window (with its large negative side loops). Tukey and Parzens windows were also applied to smooth the spectra (with the Parzens window presenting the advantage of no negative side loops). The effect of the extremes of these conditions on the shape of the co-existing wave data is shown in Morden (1975). The resulting incident and reflected spectra can be grouped to display the spectral shapes corresponding to the natural criteria. Even transforming 95 lags of the autocovariance of a co-existing sea state produces a spectrum (convolved with appropriate window) which is too smooth to be broken into increments which can be treated independently.

The FFT technique provides the advantage of transforming the data directly. The number of raw periodogram coefficients to be summed together to produce co-existing wave spectra can be varied to show their effect on the computed incident and reflected spectra. Sums of 3, 10, and 15 points (denoted $\sum 3$, $\sum 10$, $\sum 15$) were considered. To increase the number of line spectral components computed, zeroes can be added also to the record. The effect of adding the same number of zeroes as original data points was also considered. The tapered cosine window is an accepted window for use with FFT and is used in all the following comparisons (Bergland 1969). The FFT spectra appear less smooth than those computed from the lag product method, and they do satisfy all three criteria.

Table I summarizes the results of applying the various conditions above to the arbitrarily chosen data set. In all cases the reflection co-efficients are defined over the range of frequencies containing measurable data, .25 to .65 Hz. Application of FFT $\sum 3$ to fourteen sets of field data records produced root mean square error from the criteria for perfect estimation of 4.0 percent for the reflection coefficient (Eq. 10) and 12.7 percent for C (Eq. 9). FFT $\sum 10$ with zeroes added produced r.m.s. values of 3.9 percent for all R_{∞} and 10.7 percent for all C.

It is concluded that the decomposition technique is indeed sensitive to the shape of the input co-existing wave spectra. The lag product method, with its intermediate computation and transformation of the autocovariance function, produces too much smoothing to allow independent treatment of frequency increments. While not perfect, the decomposition technique incorporating the FFT produced input spectra is capable of reducing co-existing wave spectra differing by almost an order of magnitude and produce spectra which satisfy the established criteria within 10 percent.

Based on the examination of the available data, the FFT technique incorporating the summation of 10 spectral line components of co-existing wave data with zeroes added is recommended. Finally, it is suggested that any desired smoothing be done on the output incident and reflected spectra after decomposition. One effective smoothing technique is the moving average.

TABLE I. SUMMARY OF TECHNIQUES APPLIED TO AN ARBITRARY DATA SET
(DATA 16-156/157)

CO-EXISTING WAVE DATA - INPUT

LP = Lag Product Method

FFT = Fast Fourier Technique

(w/z) = with zeroes added

σ^2 outer = Variance at outer gage

σ^2 inner = Variance at inner gage

σ_r^2 = Calculated variance for reflected wave system

σ_i^2 = Calculated variance for incident wave system

fq = Frequency of peak spectral ordinate

Since the variance is not affected, the application of smoothing to the final computed incident and reflected spectra would primarily be for visual effect. (This was not done on any spectra shown.) Comparison of smoothed spectra could affect the incremental reflection coefficients, but not the overall reflection coefficient.

CONCLUSIONS AND RECOMMENDATIONS

Sea states where wind-generated waves and their reflections co-exist cannot be analyzed using the techniques commonly applied to progressive random waves. The co-existing sea surface consists of modulated waves contained in a complicated standing wave envelope. As a consequence, the time-averaged energy density varies continuously with position along wave rays. The average energy in a co-existing wave at any fixed location was shown to be a function of a phase relationship as well as the incident and reflected wave amplitudes.

By combining the appropriate spectral analysis with a theory based on linear waves relationships, the stochastic process of wind generated waves and their reflection are amenable to analysis in spite of their deterministic phase relationships. The decomposition technique provides a means of separating incident and reflected wave spectra using spectral estimates computed from data obtained simultaneously at two fixed, in-line sensor locations in wave fields where incident and reflected waves co-exist. Data from either surface or sub-surface sensors can be used, provided the wave energy is sufficiently narrow banded to allow filtering of the "twice frequency hump." The distance, x_2 , between sensors affects the maximum frequency component obtainable in the decomposed spectra. ($f_{\max} = \sqrt{x_2/2.56}$ for deep water waves). Though it is necessary to know or assume that the frequency of a wave component is unaltered during the reflection process, no other knowledge is needed of either the location or fluid dynamics of the reflection.

The accuracy of the technique depends on the spectral analysis method applied to estimate the co-existing wave spectrum. The fast Fourier transform method, which produces a spectrum by directly transforming the digitized data, provides a more accurate assessment of reflection characteristics than the lag product or autocovariance method. Based on the application of validation criteria to field test data obtained in wind generated deep water waves, it is recommended that a number of zeroes equal to the length of the digital data record be added to the co-existing wave data before analysis, that the tapered cosine window be applied, and that ten components of raw periodogram be summed together to produce the best input spectra for the decomposition technique.

As a result of accurate decomposition, the characteristics of waves reflected from, and the dissipation of wave energy occurring at, a barrier can be quantitatively evaluated for any reflected wave process where the wave frequency is not significantly altered during reflection.

CHAPTER 50

Resonant Refraction by Round Islands

Richard E. Meyer
Mathematics Department, University of Wisconsin
Madison, WI 53706

Wave trapping by refraction can give rise to resonance of a kind unfamiliar in oceanography. Trapping over realistic seabed topographies is incomplete, but conversely, possesses a mechanism for direct, harmonic excitation from the open sea that is unknown in classical resonance. These phenomena have been studied for the simplest example of an axisymmetric island of typical shape with small seabed slope. Asymptotic analysis has led to simple formulae for resonant frequencies, energy leakage rates and resonant response coefficients. Resonances of extraordinarily large but narrow response have been found.

I. Introduction

Localized natural surface wave modes in the open sea had long been known to be impossible, because their energy could propagate away freely. Edge waves, however, are just such modes, and their practical significance has come to be appreciated rapidly since their mathematical discovery [Ursell 1952] . Meanwhile, much more unfamiliar resonances have been studied, which are also caused by refraction. The key example of a round island exhibits these novel phenomena in their simplest form, and the following summarizes some recent results.

The mechanism of trapping by refraction is simple. The propagation velocity of surface gravity waves on water increases with depth. Therefore, if parts of a wave crests lie over deeper water, those parts travel faster and in brief, all wave crests over water of uneven depth always turn towards the shallows, during propagation. The possibility thus arises that waves coming from shore might be turned back shoreward, by and by, before they can reach the open sea: such waves are trapped. (The invisible barrier beyond which they do not travel seaward is called a caustic by analogy with optics.) If the phase relationships are just right, moreover, then resonance becomes a plausible possibility.

Such a direct approach, however, proves inadequate because realistic trapping turns out to be much less straightforward. Over an axisymmetric seabed topography, for instance, the depth level lines themselves are circles and to be trapped, the crests must therefore be turned faster than the local level circle. That is impossible [Longuet-Higgins 1967, Shen, et al. 1968] at sufficiently large distances from the

center. The far field is therefore always a field of progressive waves radiating energy from and to the open sea. This stands in striking contrast to edge waves which decay exponentially with distance from shore (a behavior now recognized as rather special and exceptional).

Figure 1 shows the most typical pattern of wave crests for a trapped wave mode around an island. An inner wave ring around the island is separated from the far field of radiation by a quiescent zone, in which the motion is damped exponentially rapidly with distance from the zone edges. All the same, since the damping zone has finite width, the two wave motions separated by it cannot be independent. For instance, if such a wave mode be set up and left to develop freely, without further energy supply, then a non-zero amount of wave energy will pass through the damping zone to the outer wave field, whence it will ultimately be radiated to infinity. Such "leakage" makes complete trapping impossible. There can be no resonance in the clear-cut classical sense. Rather, any resonance must be a matter of degree, depending on the leakage rate.

II. Natural Frequencies

A first question is what trapped wave modes are possible and at what frequencies? Shen, Meyer and Keller [1968] obtained estimates for round islands of quite realistic seabed topography by an approximation based on smallness of the seabed slope ϵ . If horizontal distances are measured in units of the island radius L and vertical distances, in units of ϵL , then the standard equations [e.g. Stoker 1957] of the classical, linear theory of surface waves for the velocity potential $\phi = \phi(x, y, z) \exp(-i\omega t)$ read

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} + \epsilon^{-2} \frac{\partial^2 \phi}{\partial z^2} = 0 \quad \text{for } 0 > z > -h(x, y)$$

$$\partial \phi / \partial z = \epsilon \omega^2 \phi \quad \text{at } z = 0 \quad (1)$$

$$\epsilon^{-2} \frac{\partial \phi}{\partial z} + \frac{\partial \phi}{\partial x} \frac{\partial h}{\partial x} + \frac{\partial \phi}{\partial y} \frac{\partial h}{\partial y} = 0 \quad \text{at } z = -h(x, y)$$

The first is Laplace's equation, the second combines the linearized, kinematical and dynamical surface conditions, the last expresses impermeability of the seabed; viscosity and surface tension are ignored. In the form (1), for $\epsilon \ll 1$, they lead to a refraction approximation for gentle water depth variation, but not to any short- or long-wave approximation in a usual oceanographical sense.

Figure 1

The manner in which ϵ appears in (1) suggests application of Keller's [1958] Geometrical Optics Approximation, a sophisticated and very powerful form of familiar ray methods. The fuss with rays and orthogonals, etc., is cut out by the simple idea that a natural mode must accommodate precisely an integer number of wave lengths both (i) around the island and (ii) between shore and the inner caustic circle bounding the trapped wave ring (Fig. 1. Only patterns with a single trapped wave ring will be considered here; more complicated patterns and spectra are possible, but rare for round islands [Shen et al. 1968]). Condition (i) is easy to apply at a caustic circle because the crests must be perpendicular to this refraction boundary. The wave length along the inner caustic $r = r_1$ is therefore $\lambda_1 = 2\pi/[\omega^2 k(r_1)]$, if $\omega^2 k(r)$ denotes the wave number magnitude (this notation reflects convenience of scaling for $\epsilon \ll 1$), and (i) says simply

$$2\pi r_1 / \lambda_1 = r_1 k(r_1) = n \quad n = 1, 2, 3, \dots \quad (2)$$

For (ii), it will be seen in Section V below that $\omega^2 \xi(r) / 2\pi$ with

$$\xi(r) = \int_1^r |k^2 - n^2 / (\omega^4 r'^2)|^{1/2} dr' \quad (3)$$

counts radial distance in units of local wave length (which varies greatly with the radius r), if the wave number function $k(r)$ is determined from the full dispersion relation [e.g. Stoker 1957].

$$k \tanh(kh) = 1. \quad (4)$$

Condition (ii), actually, is not quite correct as first stated. A full propagation loop goes, say, from shore through refraction at the caustic back to shore (Fig. 1), and the radial distance

$\omega^2 \xi(r_1) / 2\pi$ from shore to inner caustic in wave length units must therefore be a half-integer,

$$\frac{\omega^2}{\pi} \int_1^{r_1} |k^2 - n^2 / (\omega^4 r'^2)|^{1/2} dr = m - \frac{1}{2}, \quad m = 1, 2, \dots \quad (5)$$

The extra $-\frac{1}{2}$ stems from the phase shifts of shore reflection and caustic refraction [Shen and Keller 1975, Shen et al. 1968] and may serve as a reminder that the simplicity of the present account represents, of course, use of hindsight for shameless corner-cutting; for slightly longer, more tenable derivations see [Shen et al. 1968, Meyer 1971].

Given n and m , (2) and (5) are two equations for the frequency ω and caustic radius r_1 , which turn out [Shen et al. 1968] to have at most one solution for realistic topography $h(r)$. Those are the discrete eigenfrequencies and it is clear from (i), (ii) that n counts the number

of crests around the island at fixed radius, while m counts (twice) the number of crests radially outward from shore to caustic and back. Of course, $r_1 < \infty$ for a pattern as in Fig. 1 and a closer look at (2)-(5) [Shen et al. 1968] shows this to set an upper bound to the values of m (and hence, also of ω) for which (2), (5) do have a solution, given n . That bound, moreover, usually rules out the lowest pairs (n, m) , which general experience would have suggested to furnish the most prominent and important modes... For a conical island, for instance, there is no natural mode for any pair (n, m) with $n < 3$ [Shen et al. 1968].

For each n , on the other hand, (2) and (4) can be satisfied with $r_1 = \infty$ (which makes condition (ii) irrelevant) for any frequency ω exceeding a "cut-off" value, and those are the continuous spectra. In sum, there is a countably infinite discrete spectrum embedded in a continuous spectrum of countably infinite multiplicity. That is, as the frequency increases, the continuous spectrum gains more and more progressive wave modes coexisting at the same frequency; but always, further discrete frequencies are encountered at which trapped modes also exist. It is remarkable that so complicated a physical situation can be described by as simple and practical a set of formulae as (2), (4) and (5); Keller's Geometrical Optics Approximation can therefore cope with more complicated circumstances and holds promise of a practical approach to real topographies.

The simple version [Keller 1958, Shen et al. 1968] of this theory actually fails at shore and caustics, but Shen and Keller [1975] have constructed a uniform approximation which now offers a practical approach to the estimation of wave amplitudes at just those places where they are maximal and of most direct interest.

III. Leakage and Response

The theory so far outlined ignores, however, that every natural wave mode must involve leakage of energy from the trapped wave ring through the damping zone to the far field whence that energy is radiated away to the ocean. All eigenvalues are therefore complex. (The real part will continue to be called frequency and the imaginary part will be called "leakage rate.") The flaw in the use of this form of refraction theory for the present purpose is not only that it is logically based on reality of the eigenvalues, which its own results on natural modes show to be impossible. A more weighty objection is that resonance is now a matter of degree, and we need actual estimates of the leakage rate before we can distinguish effectively resonant eigenvalues from harmlessly damped ones.

Indeed, the organic connection between the waves trapped near shore and the associated waves in the far field implies an equal possibility of energy leakage outward and inward across the damping zone. It thereby creates a mechanism for direct excitation of resonant modes by plane waves of the same frequency incident from the ocean. This is a new mechanism, entirely absent in classical water wave resonance.

Classical edge waves [Ursell 1952], for instance, have no far field and, therefore, linear theory has no mechanism by which they could possibly be excited (short of an earthquake, which Ursell [1952] had to use for his experiments). Accordingly, they remained academic until Galvin [1965] showed how to excite them subharmonically, a process dependent on small effects of the second order. That is typical of classical resonance. "Leaky modes," by contrast, possess an inherent, first-order, and therefore potentially highly effective, mechanism of direct harmonic excitation by the natural wave environment, which is new in oceanography although not unfamiliar in some other fields.

This first-order mechanism also implies an opportunity of calculating, from the classical linear theory, the amplitude response of the water surface around an island to a given wave input from the ocean. It turns out to depend greatly on the energy spectrum of the input which, in turn, depends a good deal on the circumstances. The extreme cases are a single, plane wave pulse and a steady monochromatic plane wave input. In the absence of fairly definite specification of the input spectrum, the latter, standing-wave extreme may be the most practical estimate, conservative in that it overestimates the response to be expected in a real situation. For that extreme, the "response coefficient," that is, the standing trapped wave amplitude for unit incident wave amplitude, turns out, plausibly enough, to be just the reciprocal of the leakage rate [Longuet-Higgins 1967, Lozano and Meyer 1976].

This reciprocal relation, on the other hand, creates the paradoxical situation that an estimate of the imaginary part of the eigenvalues is the more important, the smaller this imaginary part. The main engineering interest is precisely in the most negligibly small needles in the haystack, and this imposes a severe demand for precision on any approximate analysis.

These notions of leakage and response were first set out by Longuet-Higgins [1967] and Summerfield [1972] in their long wave approximation for wave trapping by a "hedge," that is, a steep slope terminating a pronounced shelf around an island. (They also offer helpful estimates and comments on the relation between input spectrum and trapping response in their approximation.) That somewhat exceptional topography lends itself, in the long wave limit, to idealization by a topography of piecewise constant depth, for which the natural modes can be represented classically in terms of Hankel functions. Detailed computation of many complex eigenvalues was made possible thereby, and among many others, also quite a number of modes of very large response were found. Their frequency band width of response is so narrow [Longuet-Higgins, 1967], however, that they are virtually inaccessible to a more directly numerical approach. Indeed, some brilliant computational efforts [Lautenbacher 1970] have been defeated by this feature of the response.

IV. Generalized Refraction Theory

The Geometrical Optics Approximation, on the other hand, is defeated by the complex eigenvalues, which are incompatible with its basic formulation [Keller 1958] as an asymptotic expansion in powers of the small parameter ϵ . Leakage introduces factors exponential in ϵ^{-1} , which transcend approximation to any order in powers of ϵ . Such inherent contradictions are, of course, less obvious in more vaguely based ray methods. In short, the better known refraction methods are designed for self-adjoint problems and fail decisively, like many well-known mathematical methods, for non-self-adjoint problems such as trapping.

A more general refraction approximation to (1) is therefore needed. Preferably, it should not be a long wave approximation because we have already seen in Section II that the usual, longest modes are absent, whence the longest actually present are doubtful candidates for strong resonance. For application to the most common topographies, it should be based on the gentleness of seabed variation expressed by the parameter ϵ , that is, on the assumption that the seabed topography varies only on a scale large compared with the local wave length. Such an approximation has been proposed independently by a number of authors who arrived by diverse reasoning at the hypothesis that, over such "gentle" topographies, the vertical velocity profile depends to the first approximation only on the local water depth, but not also on the horizontal derivatives of the water depth.

To express this, write the exact potential

$$\Phi(x, y, z, t) = \phi_s(x, y; \epsilon) F(z; x, y, \epsilon) \exp(-i\omega t)$$

with $F(0; x, y, \epsilon) \equiv 1$ so that ϕ_s is the surface value of the potential. Then F expresses the vertical structure and its dependence on z must, to first approximation, be that predicted by the classical linear theory for waves over water of uniform depth equal to the local value of $h(x, y)$. But that is well known [Stoker, 1957] and implies that $\alpha(h)F$ is to be approximated by

$$F_0 = e^{-kh} \cosh [k(z+h)], \quad k \tanh(kh) = \alpha^2 \quad (6)$$

(The convenience factor $\alpha = \frac{1}{2} [1 + \exp(-2kh)]$ is used to avoid formal degeneracy as $h \rightarrow \infty$.) Vertical averaging of (1) [Lozano and Meyer 1976] then shows $\Psi = \alpha^{-1} \phi_s$ to be governed by the short-scale Helmholtz equation

$$G^{-1} \nabla(G\Psi) + \epsilon^{-2} k^2 \Psi = 0, \quad (7)$$

with

$$G = \int_{-h}^0 F_0^2 dz = [\sinh(2kh) + 2kh] / [4k \exp(2kh)].$$

Equations of the form (7) have been proposed by Battjes [1968] and derived by Berkhoff [1973] from an assumed asymptotic expansion of the potential which, however, is known [Shen and Keller 1975] to be incorrect, especially in the present context. To avoid such pitfalls, Lozano has given a vertical averaging argument [Lozano and Meyer 1976] supporting (6), (7), but a mathematical proof is not claimed. On the other hand, (6), (7) are there shown to include as special cases all known exact solutions of (1), and all the best known approximations (including Geometrical Optics and other ray approximations).

From an oceanographers viewpoint, it is noteworthy that the generalized refraction equations (6), (7) encompass long and short waves impartially: the full, exact dispersion relation $k \tanh(kh) = \varepsilon \omega^2$ is used.

V. Leakage Rates

The Generalized Refraction Equations (6), (7) have been applied to trapping by axisymmetric islands, since those are the simplest topographies exhibiting the new physical effects. Apart from that symmetry, a general, realistic topography is envisaged: the water depth $sh(r)$ increases monotonically and (analytically) smoothly from shore to ocean. To restrict attention to the simplest and most common trapping pattern (Fig. 1), exceptionally pronounced shelves are excluded (which makes the study complementary to Longuet-Higgins' [1967] and Summerfield's [1972], who specialized on the effect of such shelves). Attention has also been restricted to natural modes harmonic in the angular variable because the geometrical optics approach [Shen et al. 1968] has not revealed any others and the new study does not, in any case, aim at an exhaustive calculation of all possible such modes. The surface potential can then be written as

$$\phi_s = e^{in\theta} [\alpha(h)/g(r)] w(r), \quad n = 1, 2, \dots \quad (8)$$

in polar coordinates r, θ based on the island center, with factor

$$g(r) = (rG)^{1/2} = \frac{1}{2} e^{-kh} [2rh + (r/k) \sinh(2kh)]^{1/2}$$

introduced to simplify the differential equation for the unknown function $w(r)$.

Substitution in (7) shows that equation to be

$$\frac{d^2 w}{dr^2} = \left(\frac{f(r)}{\varepsilon^2} + \frac{g''}{g} \right) w, \quad (9)$$

$$f(r) = (n\varepsilon/r)^2 - k^2, \quad (10)$$

$$k \tanh(kh) = \varepsilon \omega^2. \quad (11)$$

It is formidable, not only because of the complexity of the coefficient g''/g , but because even the main coefficient, $f(r)/\varepsilon^2$, can be defined only implicitly through the dispersion relation (11) for $k(r)$. The general form of $f(r)$ is determined by the assumption of a simple trapping pattern (Fig. 1), which implies [Shen et al. 1968] that $f(r)$ has precisely one maximum for $1 < r < \infty$. With $n\varepsilon$ chosen to exceed a certain cut-off value--which implies $n = O(\varepsilon^{-1})$, i.e., a rather large number of wave crests around the island-- $f(r)$ then has precisely two roots, r_1 and $r_2 > r_1$ (Fig. 2). They mark the caustic radii because the basic form of (9) is

$$\varepsilon^2 w'' - f w = 0(\varepsilon^2) \quad (12)$$

so that the solution are oscillatory for $f < 0$, i.e., in the trapped wave ring $1 < r < r_1$ (Fig. 2) and the far field $r > r_2$. For $r_1 < r < r_2$, $f > 0$ and the solutions are non-oscillatory; this is the damping ring.

Since $f(r)$ varies so much (Fig. 2), comparison of (12) with the standard equation $y'' + y = 0$ is assisted by the variable

$$\xi(r) = \int^r | -f(r') |^{1/2} dr'$$

which brings (11) into the form

$$\varepsilon^2 \frac{d^2 w}{d\xi^2} + v(\xi) \frac{dw}{d\xi} + w = 0$$

This shows $\xi/(2\pi\varepsilon)$ to measure radial distance in local wave lengths and explains (3) (with the normalization $\varepsilon\omega^2 = 1$).

Actually, all this holds only for real ω , which has been seen to be impossible for natural modes! With leakage, $k(r)$ is complex for real r , by (11), and so are $f(r)$ and its caustic roots r_1, r_2 , which Fig. 3 shows in the complex plane of the radius r .

That figure also shows the Stokes lines of the differential equation (9) with each of which is associated an abstract pair of exact solutions of (9) of progressive wave character. The pair of L_0 (Fig. 3) represents the fundamental, incoming and outgoing, wave solutions near shore, the pair of L_∞ represents those in the open sea. The main object of the analysis is to calculate the matrix T which relates these pairs of fundamental solutions of (9), or at least, to estimate T adequately. The difficulty is that adequacy, in view of the importance of modes of the very smallest leakage rate, implies a precision unprecedented for differential equations of the generality and inexplicitness of (9) - (11). Adequate precision, however, has now been achieved [Lozano and Meyer 1976] in respect of the leakage rate.

Figure 2

Figure 3

The exact wave solution pairs of the Stokes lines L_0 and L_∞ are of interest because physical boundary conditions are most naturally phrased in their terms. To-date, the radiation condition adopted for natural modes has been that no energy be supplied by radiation from infinity; we envisage a trapped wave mode to be set up, and watch it decay slowly in time by radiation damping. The shore boundary condition adopted to-date has been boundedness of the water velocity at the shore. The reason for it is two-fold, despite its implication of perfect reflection. First, it is successful in edge wave theory [Ursell 1952] and secondly, while a better shore condition could be incorporated into the analysis just as readily, none appears to be known...

The matrix T , which depends on ω , connects these boundary conditions into a characteristic equation [Lozano and Meyer 1976] which can be solved abstractly to deduce rigorous estimates for the eigenvalues. The result is that the frequencies ω_{mn} of Shen, Meyer and Keller [1968] (cf. Section II) are confirmed, with a correction factor of only $1 + O(\omega_{mn}^{-4}) = 1 + O(\epsilon^2)$. In addition, the imaginary part of the eigenvalues is found to be

$$\text{im}(\omega^2) \sim -(2q)^{-1} \exp(-4\pi d) \quad \text{as } \omega_{mn} = \epsilon^{-1/2} \rightarrow \infty \quad (13)$$

where

$$d = (2\pi)^{-1} \omega_{mn}^2 \int_{r_1}^{r_2} |k^2 - n^2 / (\omega_{mn}^4 r^2)|^{1/2} dr \quad (14)$$

would be the width of the damping zone in local "wave lengths," if there were waves in the damping zone... The leakage rate (13) is therefore seen to be exponentially small in ϵ and reciprocally, the response coefficient is exponentially large! In (14), ω_{mn} is found from (2), (5), with $k(r)$ found from the dispersion relation (4). Similarly,

$$q = \int_1^{r_1} |k^2 - n^2 / (\omega_{mn}^4 r^2)|^{-1/2} \frac{k^2 dr}{1 + (k^2 - 1)h}$$

is readily computed by the help of (4).

VI. Quasiresonance

One of the immediate applications of this result is to the standing waves around an island, i.e. monochromatic waves of real frequency ω and surface potential (8). For real frequency, (1) exhibits energy conservation in fixed space-domains [Stoker 1957] and (6), (7) preserve this property. A ratio of respective energy flux levels in the trapped wave ring and in the far field in the open sea is therefore definable [Lozano and Meyer 1976] and its square root represents an amplitude ratio $\rho(\omega)$ characteristic of wave amplification by trapping. This amplification may be computed from the matrix T , given the shore condition of bounded velocity, and is found extremely frequency-dependent. It varies from an exponentially small minimum

$$\min \rho = \frac{1}{2} \exp(-2\pi d) [1 + O(\epsilon)]$$

at a frequency midway between successive eigenfrequencies to an exponentially large maximum

$$\max \rho = \exp(2\pi d) [1 + O(\epsilon)] \quad (15)$$

close to an eigenfrequency [Lozano and Meyer 1976]. The occurrence of such large standing wave amplifications is called quasiresonance in quantum mechanics.

An advantage of the analytical approach is that it promotes an understanding of cause-and-effect relations. The amplification (15) is expressed directly in terms of the intrinsic width (14) of the damping zone that separates the trapped waves from the far field of progressive waves extending to the open sea. This confirms the plausible idea that the wider (in an appropriate sense) the zone of damping, the more it inhibits leakage and promotes amplification. Closer scrutiny permits us to distinguish two effects which promote amplification. First, natural

modes with a large number m of half-wavelengths counted radially across the trapped wave ring have usually a correspondingly wide damping zone. (There are exceptions when n/ω_{mn}^2 is close to the cut-off value so that the maximum of $f(r)$ in Fig. 2 is small and the interval (r_1, r_2) of positive f -values is narrow.)

Secondly, natural modes with $n \gg m$, i.e., with many more crests around the island than radially across the trapped wave ring can occur, and such crests have local character akin to edge waves on a straight coast, which have no leakage. Indeed, as $n \rightarrow \infty$, the analysis can be shown to cover the modes with m not large, even $m = 1$, and the trapped wave ring then becomes narrow by comparison with the island radius. For the spectral conditions (i), (ii) of Section II, however, the relevant scale is the width of the trapped wave ring, and on that scale, the island radius tends to ∞ , the shore appears straight, the waves approach ordinary edge waves, the leakage almost disappears. An indication of this second effect is numerically apparent in Longuet-Higgins' [1967] and Summerfield's [1972] results for long wave trapping by idealized "hedges." Both effects can combine to produce exceptional amplifications due to leakage rates as tiny as [Lozano and Meyer 1976]

$$\text{im } \omega^2 \sim -\pi^{-1} \varepsilon^{2n-1}, \quad n \rightarrow \infty$$

where ε denotes the small beach angle.

The asymptotic estimates for the eigenvalues also permit estimation of the half widths of the resonant peaks of the $\rho(\omega)$ curve of amplification vs. frequency as

$$(4q\omega_{mn}^2 \sqrt{3})^{-1} \exp(-4\pi d)$$

[Lozano and Meyer 1976]. The frequency band width of resonance is therefore seen to be exponentially narrow!

This feature balances the large amplification to some extent, but the resonant modes should still be prominent under many circumstances [Longuet-Higgins 1967] --much in contrast to oceanographical experience and intuition (based on the classical prominence of the lowest modes). Of course, a balanced judgment of such unfamiliar phenomena is not easy at this early stage of their study.

The narrow band width of resonance also suggests experimental and observational difficulties. Scale effects, however, dominated the first experiments [Pite 1973], which indicated the resonant modes to be suppressed by viscous damping in a table-top tank. Laboratory tests on a larger-scale [Barnard and Pritchard 1976] have now detected some of the resonant modes of a sill [Longuet-Higgins 1967].

CHAPTER 51

PHYSICS AND MATHEMATICS OF WAVES IN COASTAL ZONES

H. Lundgren*

ABSTRACT

This paper presents a discussion of four methods available for the computation of small amplitude periodic waves in coastal zones of arbitrary topography. With no reflections (or reflection from a single structure) the methods that proceed in space (Refraction and Propagation) or time (Timestep) seem the natural ones from a physical point of view. With repeated reflections, recourse must be taken to the solution of an Elliptic boundary value problem. - It is suggested that a P-method based on (energy) flux lines and energy fronts be developed for cases where the R-methods give crossing orthogonals.

1. WAVE EQUATION

In 1949 Lowell (Ref. 9) derived, for shallow water waves, the wave equation

$$(c^2 \eta_x)_x + (c^2 \eta_y)_y = \eta_{tt} \quad (1)$$

where $c = \sqrt{gh}$ is the local phase velocity, $\eta(x,y;t)$ the surface elevation, and $h(x,y)$ the local depth, while indices x,y,t denote differentiation. For shorter waves c is a function not only of h but also of the period T , and the (reduced) wave equation must be confined to a fixed T , for which $\eta_{tt} = -\omega^2 \eta$, where $\omega = 2\pi/T$. In 1951 Pierson (Ref. 11) asked whether (1) could be derived for an arbitrary period. Indeed, this was easily done from simplified considerations of continuity and equilibrium (Ref. 10).

In 1952 Biéssel (Ref. 4) published the potential theory solution for the two-dimensional case correct to terms of order h_x (slope of bed). On this basis, Svendsen (Ref. 14) in 1967 derived a two-dimensional form of the wave equation that later (Ref. 8) was shown to agree with the three-dimensional form

$$(c c_g \eta_x)_x + (c c_g \eta_y)_y + \frac{c_g}{c} \omega^2 \eta = \nabla \cdot (c c_g \nabla \eta) + \frac{c_g}{c} \omega^2 \eta = 0 \quad (2)$$

where $\nabla = (\partial/\partial x, \partial/\partial y)$. In 1972 Berkhoff (Ref. 2) derived (2) using a surface potential ϕ_0 instead of η (and Schönfeld had obtained it in a different form). c_g is the group velocity.

With the local wave number $k = 2\pi/L = \omega/c$ it is easily seen that the classical shoaling formula for a progressive wave

*Professor of Marine Civil Engineering, Institute of Hydrodynamics and Hydraulic Engineering, Technical University of Denmark, DK-2800 Lyngby. Consultant, Danish Hydraulic Institute.

$$\eta = \frac{1}{2} H_0 \sqrt{c_{g,0}/c_g} \sin \left[\omega t - \int_{x_0}^x k \, dx \right] \quad (3)$$

satisfies the mild-slope equation (2), including terms of the order c_x and $(c_g)_x$, both corresponding to the order h_x , but excluding terms of the order $(h_x)^2$ and h_{xx} . Assuming that (3) holds good also for steeper and curved slopes

$$\nabla \cdot (c c_g \nabla \eta) + \left[\sqrt{c_g} \nabla \cdot (c \nabla \sqrt{c_g}) + \frac{c_g}{c} \omega^2 \right] \eta = 0 \quad (4)$$

(which includes terms $(h_x)^2$ and h_{xx}) should be slightly better than (2). However, Eq. 4 (or the correct formula!) would have to be derived from potential theory and, the improvement is of limited value for most waves, which are not sinusoidal in small depths.

The important *conclusion* of (2) and (3) is that a mild slope does not reflect any energy of the order h_x but, at most, of the order h_x^2 (and hardly of the order h_{xx}). It should be noted that derivatives of η are normally an order of magnitude larger than derivatives of c .

2. R-METHODS (REFRACTION METHODS)

The development of R-methods can be said to have been completed with the establishment of fast, inexpensive computer programs that plot not only the orthogonals but also the wave heights along the orthogonals, taking account of bottom friction (Refs. 12-13). The R-methods will continue to be useful tools in most applications where it is not justified to mobilize better and more expensive methods. In principle, R-methods may be applied to an arbitrary directional spectrum.

The main deficiencies of the R-methods are due to converging and, particularly, crossing orthogonals, in which cases the solutions are unreliable or unusable.

3. E-METHODS (ELLIPTIC METHODS)

An elliptic equation pertains to a problem the solution of which is defined when the boundary conditions along a closed curve are given. (2) is an elliptic equation in (x,y) , corresponding to the fact that wave energy might enter the region bounded by a closed curve from all sides. Particularly, if there are many successive reflections, such as inside harbours, E-methods are the natural tool.

The most common elliptic problem is Laplace equation for which various computational methods are available. The wave equation, however, is distinctly different from Laplace equation because of the last term in (2), giving rise to solutions with wavelengths that are small compared to the region considered. This circumstance eliminates several computational methods.

Finite elements were used by Berkhoff (Ref. 2-3) for the wave motions around an island, over a shoal, and in a harbour basin. Chen and Mei (Ref. 6) also used finite elements, correcting Berkhoff's functional. According to Ref. 3, 5 and 10 elements per wavelength give errors of 10% and 4%, respectively.

In their very nature, E-methods are confined to regions outside the breaker zone.

4. T-METHODS (TIMESTEP METHODS)

By a T-method is understood a method by which the development of the water surface and velocity field is followed over the entire coastal zone, one timestep after the other. Because of the large number of grid points and timesteps, the requirements to storage and machine time are heavy. Despite these difficulties a T-method is, in principle, the only one that - probably in a rather distant future - would be able to handle the general situation of irregular waves in a coastal zone, including breaking, surf and wave-induced currents.

Ito and Tanimoto (Ref. 7) presented examples of T-method calculations, applying an approximate version of the wave equation.

5. P-METHODS (PROPAGATION METHODS)

According to the conclusion in Sec. 1, the reflection from a gently sloping bottom of waves approaching the coast is definitely negligible. (Some swell-exposed beaches are so steep though that they reflect an essential part of the energy.)

In the case of shoals the R-methods give orthogonals that meet at a point (focus) or are tangential to certain curves (caustics), cf. Fig. 1. No reflection can be expected from foci or caustics because, by means of diffraction theory, it has been shown that the rays from a lens pass through the focus without reflection.

It is thus concluded that waves from the sea normally propagate without essential reflection onto the beach where their energy is dissipated. Hence, for periodic waves the elliptic character of the wave equation is rather a mathematical than an important physical property and, therefore, it is highly natural to look for methods where the propagation is followed from deep water into shallower areas, without consideration of the 'future' of the wave motion nearer the beach.

For small waves P-methods should also be applicable if there is a single reflecting structure such as a breakwater. With repeated reflections inside a harbour they are not fit.

Fig. 1
Refraction orthogonals (thin lines)
and actual fronts (heavy lines)
for waves passing over a clock glass
(from Ref. 11)

The R-methods represent the simplest type of P-methods. A proper P-method should be able to account for the conditions around foci, caustics and crossing orthogonals (Fig. 1).

In principle, the deformation of waves over a gently sloping bottom may also be treated as a P-problem. Hence, in the future computations by P-methods might be continued through breaker and surf zones, though the interaction with wave-induced currents would require iteration.

6. HUYGENS' PRINCIPLE

Historically, Huygens' principle was the first P-method proposed, dealing with the progressive construction of wave fronts. However, because of the smoothing of the wave fronts, it could never produce the crossing orthogonals known to occur in nature (Ref. 11). An attempt at computing refraction with 'moderate diffraction' was made in Ref. 5, with the result that the interference behind the shoal was expressed by wavy orthogonals rather than crossing ones.

Mathematically, any solution to (2) may be written $\eta(x,y;t) = A(x,y) \exp i\omega t$, where A is the complex amplitude satisfying

$$(c c_g A_x)_x + (c c_g A_y)_y + (c_g/c) \omega^2 A = 0 \quad (5)$$

For constant depth (5) simplifies to $A_{xx} + A_{yy} + k^2 A = 0$, valid for all waves in a homogeneous medium. For this special case it has been derived from Green's formula, in 3 dimensions by Helmholtz and in 2 dimensions by Weber (Ref. 1), that A at a point Q_2 inside a closed surface (or curve), S , can be expressed as an integral over S . Weber's formula is

$$A(Q_2) = \frac{1}{4} \iint_S \left[Y_0(kr) \frac{\partial A}{\partial n_1} - A(Q_1) \frac{\partial Y_0}{\partial n_1} \right] ds \quad (6)$$

where Y_0 is the Bessel function of the second kind, $\partial/\partial n_1$ denotes differentiation along the inward normal at the point Q_1 on S , and r is the distance $Q_2 Q_1$, cf. Fig. 2, where line l is only a part of S .

Though (6) has been called the 'mathematical theory of Huygens' Principle' in commemoration of this genius (who advocated the wave nature of light in opposition to Newton), it hardly represents what has been on his mind physically, for the following reason: (6) gives the solution A inside S in the general case where wave energy passes S both inwards and outwards. Since the elliptic wave equation is of the second order, the complete solution A inside S is defined if the values $A(Q_1)$ are given along S . In (6) it seems that $\partial A/\partial n_1$ must also be known on S ; however, in principle, these derivatives can be found by solving a large number of equations established by applying (6) to points inside of and close to S . Thus (6) is the mathematical solution to an elliptic problem with one boundary condition at each point of the closed curve S . In contrast to this, Huygens' physical intuition said that the field of progressive waves would be defined if, along one open curve (a wave front) two boundary conditions were given, viz. elevation + phase (i.e. A) and phase velocity (i.e. $\partial A/\partial n_1$).

7. APPLICATIONS OF HUYGENS' PRINCIPLE

Since the author felt that the physical possibilities of Huygens' principle had not been fully explored, he made - in cooperation with

Dr. Uri Kroszynski - an attempt at calculating the wave motion at Q_2 (Fig. 2) from a knowledge of the wave conditions along line 1.

It was found that the basic formula should be

$$A(Q_2) = \frac{1}{2} \iint \left[Y_0(k_2 r) \frac{\partial A}{\partial n_1} - k_2 A(Q_1) Y_1(k_2 r) \cos q_1 \right] ds_1 \quad (7)$$

where k_2 is the wave number at Q_2 and Y_1 the negative derivative of Y_0 . The factor $1/2$ in (7) indicates that, for constant depth, the integral along the infinite line 1 contributes one half to $A(Q_2)$ in (6), while the other half originates from the integral over an infinitely large semicircle.

It is assumed that the computation of the propagating wave has reached line 1, which is straight or curved. Normally, lines 1 and 2 will not be wave fronts but be chosen in a convenient manner in relation to the topography of the sea bed. According to (7), all points along line 1 have an influence on the wave motion at any point Q_2 on line 2.

The influence coefficients, Y_0 and $k_2 Y_1 = -dY_0/dr$, appearing in (7) correspond to the effects at Q_1 of a wave that spreads from Q_2 uniformly in all directions. These Bessel functions define the diverging wave exactly only when the depth is constant. When r is large, an essential depth variation may be expected between Q_2 and Q_1 , introducing an error by the application of the Bessel functions. The error is reduced, however, partly by the oscillatory character of these functions (corresponding to the varying phase difference from Q_1 to Q_2) partly because the influence from Q_1 diminishes as $1/\sqrt{r}$ when r approaches infinity. Still, the assumption underlying (7) is that the distance between lines 1 and 2 is not too large.

Eq. 7 has been applied to the case of simple shoaling over a plane slope with a depth reduction of 10% in one wavelength. For a distance of $L/8$ from line 1 to line 2, $A(Q_2)$ was found to deviate 0.5% from the correct value, while the error was 2% for a distance of $L/4$.

Thus there is hope that Huygens' principle will eventually materialize in a numerical method applicable to general situations with a reasonably large space propagation step. With the accumulation of errors in a purely explicit method, it is believed that (7) should be somewhat modified. Because of the step size, asymptotic expressions requiring little computation may be used for the Bessel functions Y_0 , Y_1 and Y_2 , of which Y_2 occurs in the expression for the derivative $\partial A/\partial n_2$ (Fig. 2).

It is probable that (7) can also be applied to the combined diffraction and refraction around a breakwater, including reflection from it.

8. FLUX LINE METHOD

In analogy to the R-methods it seems possible to construct diagrams of energy flux lines, transcribing (5) into orthogonal, curvilinear coordinates consisting of flux lines and energy fronts. The computation

Fig. 2 Influence at Q_2 of wave motion at Q_1

progresses simultaneously along all flux lines. The crucial point of the method is, in analogy to (3), to utilize the energy velocity c_e for direct integration along the flux lines, thus reducing the difficulty of the spatial phase variation, which requires much machine time for E- and T-methods.

The variation of A along the energy fronts influences c_e , as can be seen from the interference of two similar wave trains propagating at right angles to each other. The phase velocity is then $c\sqrt{2}$ with maximum flux along the lines where the 'double crests' propagate.

CHAPTER 52

HURRICANE TIDE FREQUENCIES ON THE ATLANTIC COAST

FRANCIS P. HO¹

I. INTRODUCTION

HISTORICAL BACKGROUND

Hurricane surge is a serious and not uncommon event along the Gulf of Mexico and Atlantic coasts of the United States. The most disastrous display of hurricane forces in recent decades was by Camille, which struck the Mississippi coast in 1969. The storm tide reached 24.6 ft MSL. Reported storm tides on the Atlantic coast have reached elevations of 15 to 20 ft in Florida, Georgia, the Carolinas and New England.

One of the latest coordinated efforts to alleviate losses from hurricanes -- supplementing warning services, community preparedness, and evacuation plans-- is the Flood Insurance Program.

NATIONAL FLOOD INSURANCE PROGRAM

The National Flood Insurance Act of 1968 provides for a cooperative program between the United States Government and private industry for insuring residences and small businesses against floods. The program is administered by the Federal Insurance Administration (FIA). Other federal agencies assist by making technical studies.

Essential to establishing flood insurance rates in any community, whether on the coast or an inland valley, is a flood frequency analysis. Flood frequencies are also used as guides in formulating local zoning and flood plain occupancy ordinances. The 100-yr level (1% chance of being exceeded in any year) is the main criterion for this. The 10-, 50-, and 500-yr levels are also required by FIA regulations.

II. JOINT PROBABILITY METHOD OF THE TIDE FREQUENCY ANALYSIS

Hurricane tide frequency analyses have been made by the National Oceanic and Atmospheric Administration (NOAA) for the open coasts of the states of Florida, Georgia, the Carolinas, Virginia, Maryland, and Delaware, and also Puerto Rico (Fig. 1). The method that NOAA has developed for coastal tide frequency analysis, has come to be known as the joint probability method, and was first applied to Atlantic City, N.J. (13). Refinements of this method have been made over several years and the method extended to other sections of the Atlantic coast (e.g., 1, 14).

¹Meteorologist, Office of Hydrology, National Weather Service, National Oceanic and Atmospheric Administration, Silver Spring, Md.

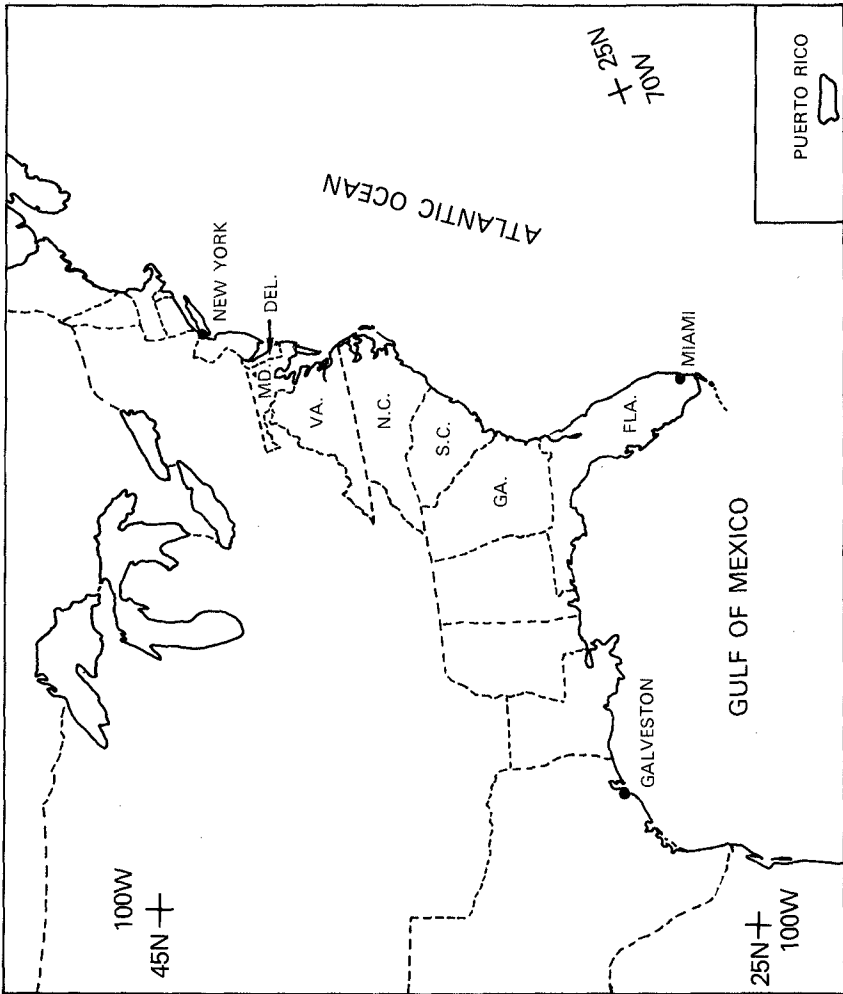

Figure 1.--Location map.

With geophysical data of all kinds, models are used to convert available information to other forms needed but not directly available. The application here is to derive storm tide data from hurricane atmospheric parameters. The first step is to assess from past records the magnitude and frequency distribution of hurricane parameters that are related to surge generation along the coast. The second step is to calculate the coastal surge levels that each of a number of combinations of the hurricane parameters would produce. For this, a dynamic calculation method is used that has been demonstrated to reproduce hurricane surges within an acceptable tolerance. Enough combinations are used to represent the entire range of possibilities. Third, the computed hurricane surges are each combined with the astronomical tide with various time displacements between surge peak and high and low tide. The range of the astronomical tide is also varied.

The frequency of each computed storm tide is worked out from the hurricane parameter and astronomical tide probabilities in a manner briefly described later. Winter coastal storm tide frequencies are estimated at tide gage sites by a statistical analysis. Finally, the hurricane and winter storm tide frequencies are summed to yield the total tide frequencies from all storms.

HURRICANE PARAMETERS

There are four parameters used to compute the surge associated with a hurricane. The first of these is the central pressure, a universally used index of hurricane intensity. The radial profile of sea-level pressure vs. distance from storm center (panel A of Fig. 2) shows a sharp increase within the first few miles with the curve flattening out at greater distances. The distance from the storm center to the area of maximum winds is symbolized by R (schematically shown on B of Fig. 2). R is used as the index of the lateral extent of the storm and referred to as radius of maximum winds. The third and fourth parameters are the forward speed of the storm and the direction of the storm motion. These parameters can be scaled from a hurricane track as illustrated in panel C of figure 2. The lower righthand panel (D) illustrates the dimensions of a hurricane tide. This is a profile of hurricane Hazel's tide observed along the coast. The coastal distance is measured from the point of landfall of the storm center near the North Carolina - South Carolina border.

PROBABILITY DISTRIBUTION OF HURRICANE PARAMETERS

Figure 3 illustrates the climatological analysis of these hurricane parameters. The data sample is collected from all hurricanes exceeding a certain intensity and striking or passing close to the coast within a prescribed span of years. The data are plotted on accumulated probability diagrams as shown in the figure for coastal segments approximately 400 n.mi. in length, for each of the four hurricane parameters. Similar graphs are obtained for the entire coast, for about 60 overlapping zones centered at 50-n.mi. intervals.

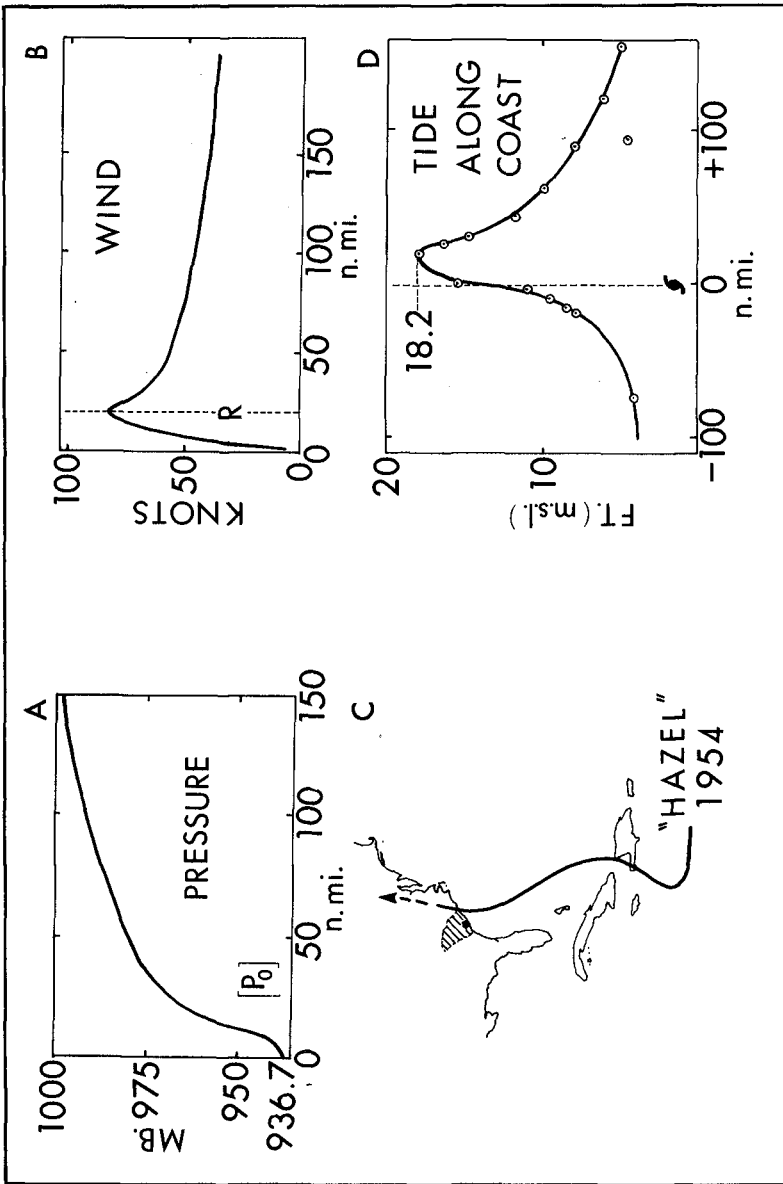

Figure 2.--Examples of basic characteristics of hurricanes from Hurricane Hazel.

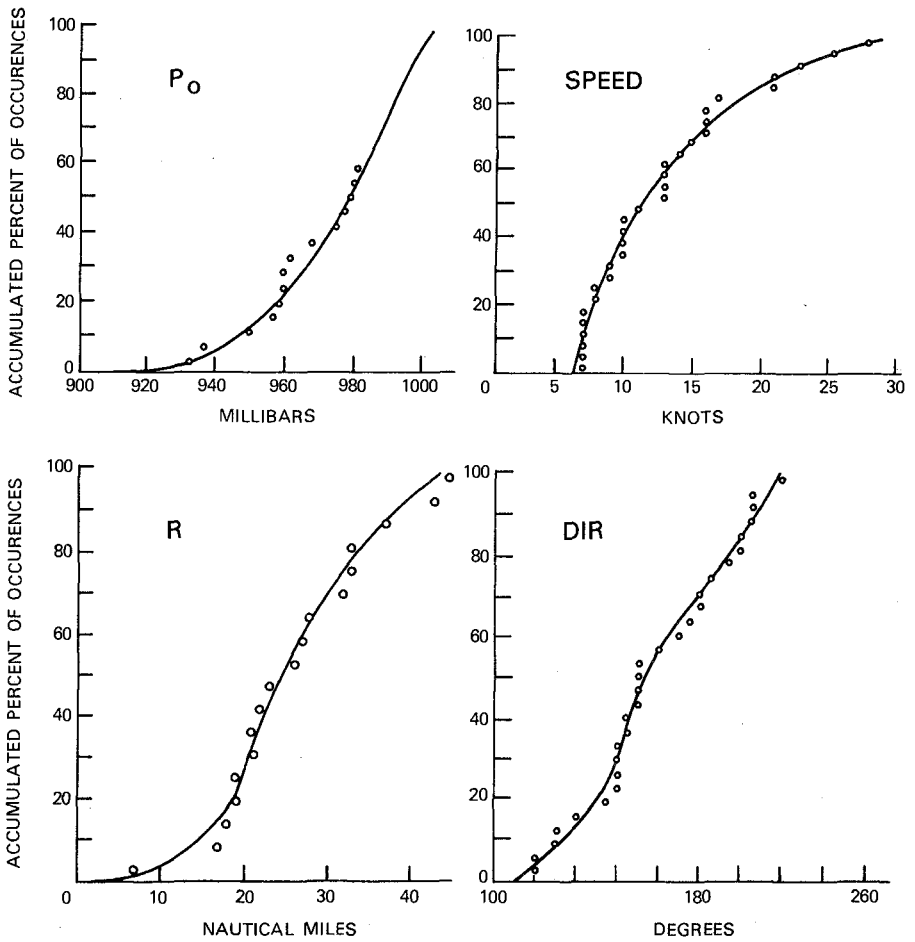

Figure 3.--Hurricane parameters -- data and probability distribution curves for a coastal zone.

Next, values at certain probability levels are read from each of these graphs and smoothed along the coast by applying a weighting function. The resultant coastal profiles for the central pressure are shown in figure 4 (reproduced from Fig. 11 of ref. 4), depicted as lines joining values at the percentiles indicated inside the right margin. The distance scale for the abscissa is measured along a smoothed coastline running from Texas to Maine. The diagram indicates that the minimum central pressures are expected in the Florida Keys, where the most intense hurricane in the western hemisphere, with central pressure of 892 mb, was reported. The trends in the curves reflect the fact that hurricanes tend to become less intense with increasing latitude.

The R in hurricanes affecting the United States coast since 1900 was subjected to a frequency analysis in overlapping zones in the same manner as central pressure. Forward speeds were scaled from track charts and a probability analysis made as with the other parameters, except that hurricanes landfalling on the coast and those bypassing the coast (alongshore hurricanes) were analyzed separately. The direction of forward motion analysis was restricted to landfalling storms. For this, all tracks of tropical cyclones since 1871 were used. For numerical calculations of surges, alongshore hurricanes are treated as if they were moving exactly parallel to the coast.

HURRICANE FREQUENCY

In addition to the distributions of these hurricane characteristics, the overall frequency of hurricane occurrences is basic to calculating hurricane tide frequencies. The frequency of occurrences is assessed by counting tracks (separately for landfalling and alongshore) and smoothing the counts along the coast, similar to the other parameters.

Figure 5 shows the frequency of landfalling hurricanes (from ref. 4). The frequency varies from a minimum of 0.1 storms per 10 n.mi. of smoothed coastline per 100 years near Boston, to maxima of 2.2 in the middle of the Gulf coast and in the Florida Keys.

Similar analyses were made for alongshore hurricanes, and for hurricanes that exited the coast after an earlier entry of the coast elsewhere. Because of hydrodynamic factors, exiting hurricanes give half or less the surge heights as landfalling hurricanes of the same intensity. Exiting hurricanes also tend to have weakened while passing over land and contribute little to the frequency of high storm tides.

WINTER COASTAL STORMS

From time to time, winter coastal storms originating in mid-latitudes also cause millions of dollars of damage along the northern part of the Atlantic coast. At the 100-yr return period storm tide magnitude the activating storms are hurricanes and the additional contribution by winter coastal storms is generally small. The contribution to storm tide frequency of the latter may be evaluated with sufficient precision by direct analysis of long period tide gage records, and interpolation along the coast. These storms are taken into account in coastal storm tide frequency analysis north of Cape Hatteras, but their frequency of occurrence and characteristics are not discussed further in this paper.

Figure 4.--Hurricane parameter probability profiles along coast -- central pressure. Based on 1900-74. Plotted points (Δ) are taken from frequency analyses at 50-n.mi. intervals for the 5th percentile.

Figure 5.--Frequency of landfalling hurricanes and tropical storms based on 1871-1974.

HYDRODYNAMIC SYNTHESIS

Having defined the hurricane climatology, the next step in the tide frequency analysis is the simulation of hurricane surges. A hydrodynamic-numerical model, called SPLASH, has been developed by Jelesnianski (9, 10) for calculating the surge produced by a hurricane moving over the continental shelf. The model simulates the moving wind and pressure fields over the sea from the basic parameters described above, then computes the surge produced by these fields. This model was developed to predict storm tides when a hurricane approaches, as part of the public warning service of the National Weather Service. The operational application of this model is described in separate reports (11, 12). The same model is used here to compute storm surges from climatological possibilities for frequency analysis.

SHOALING FACTOR

Because of dynamic effects, the surge height that a given hurricane will produce at the coast varies with the shape of the continental shelf. The bathymetry effect on storm surges is handled by the use of a shoaling factor². The shoaling factor is the ratio of the peak surge height that a standard hurricane would produce in a given locale compared to the maximum surge height the same storm would produce over a "standard basin." Figure 6 shows the coastal profiles of the shoaling factor for two different radii of maximum winds. The application of this will be described later.

ASTRONOMICAL TIDE

Another feature of hurricane tides, shown in figure 7, is illustrated by observed tides at Charleston, S.C. in Hurricane Gracie. This diagram includes curves depicting three different water levels. The normal astronomical tide is shown by the solid curve. The dashed curve is the tide level actually observed during the storm. The difference between these is by definition the "surge." That is, the surge is the storm effect, and the graph of this is shown in the lower panel. The surge reached a magnitude of 8.3 ft MSL but, since this was coincident with low astronomical tide, the observed tide peaked at only 5.6 feet. If the same storm had coincided with the normal high astronomical tide, the hurricane tide would have reached 11.2 ft; if the storm were coincident with spring tide, the water level would have been 12 ft. This illustrates the fact that in a synthetic calculation of storm tide frequencies, the relative phasing of storm surge and astronomical tide should be taken into account.

FREQUENCY DISTRIBUTION OF HIGH AND LOW TIDES

Most of the combinations of forces producing the astronomical tides are experienced during a 19-yr cycle. There is also a seasonal variation in the mean water level with the maximum in September-October in most of the study

²The same topic is also discussed by Barrientos and Jelesnianski: "A Numerical Model for Forecasting Hurricane Storm Surges," in the storm surge section of these proceedings.

Figure 6.--Shoaling factor curves for Gulf of Mexico and east coasts. R in statute miles.

"GRACIE"

area. The months July, August, September, and the first half of October are taken to represent the hurricane season. Astronomical high and low tides for these representative months are recomputed for a 19-yr period with the standard tide computation program written by Pore and Cummings (18). The accumulated frequencies of the high and low tides are calculated separately by months, then weighted in proportion to hurricane occurrences in each month at a particular location. Each distribution is divided into four range class interval values. The representative astronomical tide marigrams needed to combine with each hurricane surge marigram are then approximated as cosine waves with a period of 12.42 hours oscillating between corresponding high tide and low class interval values. This assumes that the highest high tides occur with the lowest low tides, etc. The foregoing calculations are carried out at tide stations and then interpolated along the coast as needed.

COMBINATION OF ASTRONOMICAL TIDE AND HURRICANE SURGE

To combine calculated storm surges with the astronomical tide in search of the maximum height of the combination, the time variation of both is needed. The SPLASH program computes the surge height at grid points every 2.5 minutes. For combining surge profiles and the astronomical tides for the indicated purpose of finding the statistical distribution of maximum total, the asymmetry of the rise and fall of the surge and the non-simultaneity along the coast of the time of maximum surge height in a particular case make no difference. The only requirement is to know how long the surge remains above each height. A saving in computation time is made by precomputing the time variation from a number of representative SPLASH surge computations, then normalizing these by fitting to two parameters. The time variation of the coastal surge is then approximated by a Gaussian curve defined by the maximum surge height, S_x , (in feet) and the time that the surge exceeds 2/3 of S_x , $t_{2/3}$ (in hours). The time variation is then described by:

$$s = S_x e^{-.40547(2t/t_{2/3})^2} \quad (1)$$

where t is the time (in hours) after the occurrence of the maximum surge and $t_{2/3}$ is the time duration indicated above. For the justification for this, the reader is referred to a previously cited report (13).

Each surge is combined with astronomical tide in 84 different ways. These are 21 phasing displacements from low-tide coincidence to high-tide coincidence and four amplitudes of the astronomical tide, ranging from neap tide to spring tide.

III. HURRICANE TIDE FREQUENCY

Hurricanes striking a point of interest are represented by all possible combinations of selected values of the hurricane parameters. This could be, for example, six different central pressures, three R's, three directions of motion, and six speeds, a total of 324 hurricanes. Surges are computed for the 324 storms, with both time and space variation defined. (A SPLASH computation yields surge heights at 8-mi intervals on the coast for specified time increments).

Allowing the same set of hurricanes to strike various points up and down the coast gives a multiple of 324 hurricanes. The surge height produced by each of these hurricanes can be approximated by shifting the surge envelope from a SPLASH computation and applying the shoaling factor adjustment mentioned earlier. Each surge is combined with astronomical tides in the ways described.

The frequency of each of these hurricane tides is the product of the storm parameter probabilities, the landfalling frequency, and the astronomical tide probability. The accumulative frequencies of all these hurricane tide events are plotted as a tide frequency curve for the landfalling hurricanes. Alongshore storms are treated in a similar manner and the two frequency curves summed.

Statistical interdependence of hurricane parameters is handled by assigning conditional probabilities. For example, the speed of storm motion is defined separately for landfalling and alongshore hurricanes. Similarly, a different central pressure distribution is used for small R storms than for medium and large R storms. Details are given in cited reports.

Figure 8 illustrates a typical tide frequency diagram -- a plot of storm tide level against return period, for Rehoboth Beach, Del. The landfalling hurricane tide frequency curve and the alongshore hurricane tide frequency curve are computed separately by the procedure just described. The tide frequency curve from winter coastal storms is obtained by direct statistical analysis of tide gage data.

Summing the frequencies (reciprocal of return periods) of these three classes of storms at each tide level gives the frequency that level of tide is equaled or exceeded, from all storm classes. The figure indicates the contributions made by the different classes of storms. The winter coastal storm is the major factor contributing to the lower end of the frequency curve. The alongshore hurricanes contribute significantly to the recurrence intervals of 100 - 200 years; the landfalling hurricanes contribute most to the more rare return periods. This is typical in the study area north of the entrance of Chesapeake Bay (8). For coastal areas to the south, the tide level produced by landfalling hurricanes is the prime factor in the total storm tide frequencies (e.g., 6, 7).

COMPARISON OF FREQUENCY CURVE WITH HISTORICAL HURRICANE TIDE DATA

Repeating the same process at another point on the coast, we obtain a tide frequency curve, as shown in figure 9 for Savannah Beach, Ga. (1). The 100-yr tide level reaches 14-1/2 ft MSL. It should be noted here that the computed tide frequencies are of still-water levels on the open coast that would be measured in a tide gage house or other enclosure, excluding wave action. The plotted points are the five highest observed high-water marks at Savannah Beach since 1854. This is to verify the correspondence of the computed frequency curve to the local historical record. Other localities with a long period of observed high-water mark records also indicate similar good fit to the computed tide frequency curves, but there are exceptions in some places. The indirect method described, of course, gives hurricane tide frequencies where there are no or few historical storm tide data.

Figure 8.--Tide frequency curves to illustrate significant contribution of alongshore hurricanes, landfalling hurricanes and winter coastal storms.

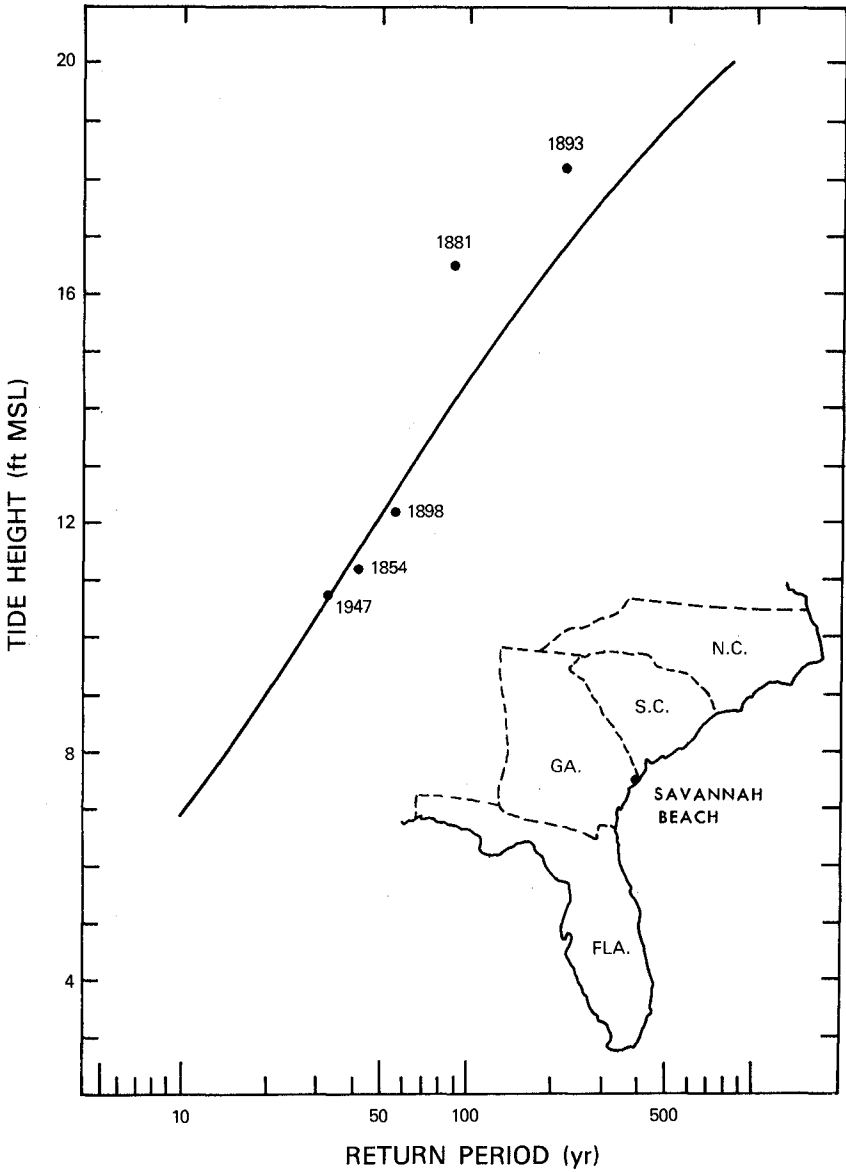

Figure 9.--Comparison of computed tide frequency curve at Savannah Beach, Ga., and high-water marks.

COASTAL PROFILES OF TOTAL TIDE FREQUENCY

Interpolating from results of tide frequency analyses at many points, we have coastal profiles of tide frequencies. Figure 10 shows such profiles for a portion of the Atlantic coast for the 10-yr, 100-yr, and 500-yr recurrence intervals. The 100-yr tide frequencies vary from about 16 ft MSL south of Savannah, Ga., and 14 ft near Miami, Fla., to a low of about 8 ft along the northern portion of the Florida peninsula.

In summary, these coastal variations are associated with the variations of hurricane parameters and the shoaling factor along the coast, illustrated schematically in figure 11. The 100-yr tide frequency profile in the figure is copied from figure 10 (heavy line). Effects of bathymetry are reflected in both the 100-yr tide profile and the shoaling factor curve. The rapid northward decrease of the 100-yr tide level on the Florida coast is related to both the decreasing frequency of hurricane occurrence northward, and weaker hurricane intensities as indicated by the decreasing ΔP curves, ΔP being the depression of the central pressure of a hurricane below its peripheral pressure.

North of Cape Hatteras both the ΔP and the hurricane frequency curve (which pertains to landfalling storms) decrease. The 100-yr flood level remains about the same because of increased frequency (not shown on the diagram) of by-passing hurricanes. Higher storm speeds and larger R 's are also compensating factors which tend to increase the storm tide levels in this region.

IV. OTHER STUDIES

Hurricane tide frequency profiles along the Gulf coast of Florida have been obtained in the same manner as for the southern Atlantic coast (5). Other sections of the Gulf coast are not covered in this series of studies. Hurricane tide frequencies on the coast of Puerto Rico have also been developed from a set of climatologically representative hurricanes, using the NWS numerical dynamic surge model adapted to local conditions (2).

NOAA has also extended the joint probability method of tide frequencies in bays and estuaries as part of the Flood Insurance Program (3, 15). Apalachicola Bay in Florida and the Cape Fear River estuary in North Carolina were selected for pilot projects. Hydrodynamic models had to be developed for routing hurricane tides into the bay and the estuary respectively (16, 17). Again, without going into details, this development leads to hurricane tide frequency estimates in the selected bay and estuary by storm tide simulation.

V. CONCLUSION

The tide frequency analysis technique developed by NOAA has been extended along the Atlantic coast. The simulation method has the advantages of giving results that are consistent from one stretch of coast to another, and for giving a result where there is little local data available. Tide frequencies estimated in this way form the technical basis for flood hazard boundary maps prepared for the Flood Insurance Program for communities subject to inundation from the sea.

CHAPTER 53

AUTOMATED FORECASTING OF EXTRATROPICAL STORM SURGES

N. Arthur Pore*

ABSTRACT

The Atlantic coast of the United States is affected by extratropical storm surges several times each winter. The most devastating storm of this type on record is that of March 1962. This storm caused damage estimated at over \$200 million. The National Weather Service has developed an automated technique for forecasting such storm surges. Statistical forecast equations have been derived for 11 locations from Portland, Me., to Charleston, S.C. Input data to these equations are values of sea-level pressure as forecast by an atmospheric prediction model of the National Meteorological Center. A sample forecast equation is shown.

The method was put into operation in 1971. Forecasts are transmitted via teletypewriter and extend to 48 hours at 6-hour intervals. A sample teletype message is shown. Forecasts of the devastating storm surge of Feb. 19, 1972, are discussed. These forecasts agreed reasonably well with observations of the storm surge. Experience with the method indicates it to be useful and therefore it will be expanded to include additional forecast locations.

INTRODUCTION

The extratropical storm of March 5-8, 1962, affected much of the east coast of the United States and caused record breaking high tides at locations between Long Island and Cape Hatteras. This storm was the most devastating on record, as it caused damage estimated to be over \$200 million. Figures 1 and 2 show some of the damage at Virginia Beach, Va., and Rehoboth Beach, Del. It is fortunate that storms causing this much damage are rare. However, storms of lesser damage potential occur several times each winter. Accurate and timely forecasts of flooding caused by these storms are important. The crucial times to

*Techniques Development Laboratory, National Weather Service, NOAA, Silver Spring, Md.

forecast these conditions are also the times when forecasters already have burdens brought on by poor weather conditions associated with coastal storms. Therefore, the National Weather Service has developed an objective forecast technique for forecasting extratropical storm surges. This technique has been automated and operates with meteorological input data from an atmospheric prediction model.

SURGE CHARACTERISTICS

Storm surge is defined as the meteorological effect on sea-level and is computed as the algebraic difference between observed tide and the normal astronomical tide. Figure 3 illustrates this definition with a 2-day length of tide record. Here the observed tide is shown by the upper solid curve, the normal (or predicted) astronomical tide by the dashed line, and the storm surge by the lower curve.

The principal factors involved in the generation and modification of the extratropical storm surge are as follows:

1. The rise of water caused by the action of the wind stress on the water surface. It can be thought of as consisting of two components. One component is the set-up of water by the onshore wind in which the slope of the water surface is directly proportional to the wind stress and inversely proportional to the water depth. The other component is the effect of the alongshore wind that generates a current parallel to shore. The effect of the earth's rotation is to have water piled up along the shore if the shore is to the right of the current.

2. The reduction of atmospheric pressure, generally called the inverted barometer effect that causes an increase in sea level in areas of low pressure.

3. The transport of water by waves and swell in the shallow water area near shore.

4. The modifying effects of coastline configuration and the bathymetry, such as convergence or divergence in bays.

The effect of the time of occurrence of the storm surge with respect to the stage of the normal astronomical tide is shown in Figure 4. Here, two identical storm surges are combined with different phases of the normal tide, one occurring at normal high tide and the other at normal low tide, with the one at high tide resulting in a higher actual tide. The time of occurrence of the storm surge with respect to the normal tide can mean the difference between serious and minor flooding.

The recurrence intervals in cases per year for storm surges of 2 ft or greater, 3 ft or greater, and 4 ft or greater for Portland, Boston, Newport, New York, Atlantic City, Breakwater Harbor, Baltimore, and Norfolk are shown in Figure 5. For example, New York City experiences a 2-ft or greater storm surge about six times a year. A 4-ft or greater surge would be expected to occur only once every 2 years.

DEVELOPMENT OF FORECAST EQUATIONS

The forecast technique is a statistical method based on actual storm surge data during the months of November through April from 1956 through 1969. Storm surge values were determined by subtracting hourly values of the astronomic tide from hourly values of observed tide as shown in Figure 3. Data were selected on the basis of storm surge occurrence. Those storms that produced surges of 2 ft or more at four or more of the stations considered were used. Sixty eight storms were selected in this manner.

Earlier studies related surface wind conditions at coastal weather stations to the storm surge Pore (1964, 1965). In the operations of the National Meteorological Center (NMC), meteorological information at computational grid points is more readily available than at weather stations. For that reason, sea-level pressure forecasts at specific grid points were used to represent the generating winds off the east coast in the storm surge generation process. Every 12 hours the NMC runs their numerical atmospheric model (primitive equation model) that produces forecasts for most of the northern hemisphere. Figure 6 shows the grid points where sea-level pressure was considered in this study. Sea-level pressure at these grid points was obtained at 6-hour intervals from analyzed weather charts for the 68 storm cases. These pressure values, with appropriate lag times, were considered as possible predictors of storm surge.

Forecast regression equations were derived by the statistical screening procedure that has been described by Klein (1965) as follows:

"The object of the screening procedure is to select from a large set of possible predictors only those few which contribute significantly and independently to the forecast of a predictand. This is accomplished by a forward method of multiple regression in which significant predictors are picked in a stepwise fashion, one by one. As a result, a small number of predictors can be selected which contain practically all the linear predictive information of the entire set with respect to a specific predictand. The importance

of using a small set of predictors to prevent redundancy and instability of the multiple regression equation and to insure good results when applying it to new data has been emphasized by Lorenz (1956, 1959), Grant (1956), Panofsky and Brier (1958), and others."

A detailed description of the selection of predictors by screening is given by Miller (1958). The manner in which predictors of storm surge are screened is shown below:

$$SS = A_1 + B_1X_1 \dots \dots \dots (1)$$

$$SS = A_2 + B_2X_1 + C_1X_2 \dots \dots \dots (2)$$

$$SS = A_3 + B_3X_1 + C_2X_2 + D_1X_3 \dots \dots \dots (3)$$

·
·

$$SS = A_n + B_nX_1 + C_{n-1}X_2 + \dots + N X_n \dots \dots \dots (n)$$

where SS is storm surge; A_1, A_2, A_3, \dots , are constants; X_1, X_2, X_3, \dots , are predictors; and B_1, B_2, C_2, \dots , are regression coefficients.

The procedure is to first select the best single predictor (X_1) for regression Eq. 1. The second regression equation contains the first predictor (X_1) and the predictor (X_2) that contributes most to reducing the residual after the first predictor is considered. This screening procedure is carried out until the desired number of predictors is included.

A separate forecast equation was derived for each of the locations shown in Figure 7, so that local effects at each location are considered. The locations extend from Portland, Me., on the north to Charleston, S.C. on the south. These locations were chosen because they are in densely populated areas that are frequently threatened by extratropical storm surges. Also, accurate tide observations, necessary for verification of forecasts, are available from the National Ocean Survey and U.S. Army Corps of Engineers for these locations.

Figure 8 shows, as an example, the forecast equation derived for storm surge at New York. Predictors are the sea-level pressure expressed in millibars at the indicated grid points. The subscripts on these terms indicate the time lags in hours. In this case, nearly all the predictors have time lags of 6 hours. Similar equations were derived for the other 10 locations.

APPLICATION TO THE MARCH 1962 STORM

The waves and storm tides generated by the storm of March 5-8, 1962, caused unprecedented damage to coastal areas from southern New England to Florida. The very persistent strong northeast winds blowing over an extremely long fetch were responsible. Another important factor is that the storm occurred at a time of very high astronomical tide. Articles by Stewart (1962) and Cooperman and Rosendal (1962) give details of the storm.

At 7 a.m. EST on March 5th there was an ill-defined low pressure area with a frontal wave northeast of the Bahamas. Low pressure also extended northwestward through the Carolinas and Virginia. By 7 a.m. EST on the 6th, the entire low pressure area had deepened, resulting in a long easterly fetch over the western Atlantic north of Cape Hatteras. The storm continued to intensify and resulted in an elongated low with strong northeast wind over a very long fetch. Four pressure analyses for the storm are shown in Figure 9.

Since the automated method described in this paper did not become operational until Oct. 8, 1971, automated forecasts were not made for the 1962 storm. However, we have made calculations of the storm surge for this storm based upon actual sea-level pressure analyses.

Curves of observed storm surge and calculated storm surge are shown in Figure 10 for the eight locations, for which we have data, for the period March 5-8, 1962. The heavy solid curves show the observed storm surges based on hourly values. The dashed lines connect the computed values of the storm surge made at 6-hour intervals.

We feel there is considerable skill in the calculation of surge for this storm, even though it was a very intense, record-breaking storm.

OPERATIONAL FORECASTING

In operational use, sea-level pressure forecasts at the appropriate grid points are used as input to the storm surge equations. The pressure forecasts are available twice daily from the numerical weather model of the NMC. Pressure forecasts to 48 hours at 6-hour intervals are used.

A sample teletype bulletin of storm surge height forecasts for the 11 locations is shown in Figure 11. The forecasts are expressed in feet at time intervals of 6 hours for the 48-hour forecast period. Such messages are transmitted on a Weather Service teletype circuit to

forecast offices along the east coast where they are used as guidance in preparing the official storm tide bulletins.

AN ACTUAL FORECAST CASE

A very severe coastal storm, to which the automated storm surge method was applied during its first year of operation, was the storm of Feb. 18-20, 1972 (Pore, 1973). The northern portion of the U.S. Atlantic Coast suffered extensive damage and beach erosion. Conditions were very bad as the time of maximum storm surge was near the time of astronomical high tide.

A low pressure system centered over the Great Lakes at 7 a.m. EST on Feb. 18th had a frontal system extending southward over eastern Tennessee, Georgia, Alabama, and into the Gulf of Mexico. Subsequent developments, as depicted on the Northern Hemisphere surface charts of NMC, are shown in Figure 12. By 1 p.m. EST, a closed low had developed over Georgia. Further development occurred and the storm moved rapidly toward the north-northeast, to a position just north of Cape Cod at 1 a.m. EST on the 20th.

Some of the numerical weather model forecasts of storm position and central pressure are shown in Figure 13. The storm center positions and central pressures, taken from the NMC Northern Hemisphere surface charts can be compared to these 12-hour, 24-hour, and 36-hour forecasts. The shorter-range numerical forecasts of the track were very consistent with the longer-range forecasts and are considered to be quite good.

The numerical weather sea-level pressure forecasts, valid about the time of maximum storm surge, can be compared to the NMC pressure analysis in Figure 14. Here it is seen that the longer-range forecasts, such as the +30-hour forecast, did not have the storm intense enough. The shorter-range forecasts, such as the +6-hour forecast, look quite good, both for storm intensity and position.

Calculations of the storm surge based on sea-level pressure analyses and forecasts are shown in Figures 15 through 18. Storm surge calculations, based on sea-level pressure analyses of the NMC Northern Hemisphere surface charts, are shown in Figure 15. Here the observed storm surges, based on hourly values, are shown by the solid curves. Maximum values of observed surge are printed near the peak of each curve. Calculations of storm surge, based on pressure analyses, are shown by dots at 6-hour intervals. It is felt that these storm surge calculations agree fairly well with the observations. Figures 16 through 18 show, in the same manner, actual forecasts of surge based on the sea-level

pressure forecasts. Figure 16 shows 6- and 12-hour forecasts of the surge. Two forecast intervals are combined on one chart so that there is a forecast value every 6 hours rather than every 12.

The actual forecasts of storm surge, of course, are not as accurate as the calculations based on the pressure analyses. The underforecasting of storm intensity of the numerical weather model in the longer-range forecasts was discussed earlier and is reflected in the longer-range forecasts of storm surge, as shown in Figure 18. The 6- and 12-hour surge forecasts were closer to the observed surge than the longer-range 30- and 36-hour forecasts. It is felt that the automated storm surge forecasts provided useful guidance material, especially on the timing of the surge.

CONCLUSION

The statistically derived extratropical storm surge forecast method uses the meteorological forecasts of the NMC as input to provide guidance material for Weather Service coastal forecast offices. The accuracy of the surge forecasts depends greatly upon the accuracy of the meteorological forecasts. Experience, so far, has shown the method to be useful and for that reason it is being expanded to include more locations.

ACKNOWLEDGMENTS

Appreciation is expressed to the National Ocean Survey and the U.S. Army Corps of Engineers for the observed tide data. Appreciation is also expressed to W. S. Richardson and H. P. Perrotti of the Techniques Development Laboratory of the National Weather Service for their assistance and to Mercedes Bakon for the typing of the manuscript.

CHAPTER 54

Generalized Model for Storm Surges

Gour-Tsyh Yeh¹, M. ASCE

and

Fei-Fan Yeh², M. ASCE

Abstract. A two-dimensional numerical simulation model of storm surges based on the vertically integrated hydrodynamic equations of continuity and momentum is adopted. The model embodies the inundation over the low-lying land surface with moving water-land interfaces. Wind stress coefficient is considered not only function of wind speed but also dependent on the temperature differential between air and water. Bottom stress is treated by an evaluation of convolution integrals over the surface slope pressure depression and wind shear. The contribution of momentum by river inflows is taken into account. Particular attention is directed to the treatment of nonlinear terms in the governing equations to insure the improvement of numerical stability and accuracy. The model is applied to the New Jersey Coastal area and reproduces the historical storm surges quite well both at Atlanta City and Sandy Neck.

INTRODUCTION

Reliable estimates of water-level changes under storm conditions are essential for the planning and design of coastal engineering works. Determination of design water elevations during storms is a complex problem involving interaction among the bathymetry and geometry of the water body, the forces of the wind field and atmospheric depression, the resistance of the bottom, the momentum generated in the water body, and the effects caused by other mechanisms unrelated to the storms, such as astronomical tides, earth rotation, etc.

The development of numerical models for predicting storm surges has been advanced rapidly during the past decade, from simple one-dimensional bathystropic theory (Bretschneider and Collins, 1963) to more complex two-dimensional simulation of arbitrary water bodies (Reid and Bodine, 1968; Pearce, 1972; Tsai and Chang, 1974; Pearce and Pagenkopf, 1975; Wanstrath, 1975; Damsgaard and Dinsmore, 1975). Most of the models are found to be useful only for specific localities to where one must approximate its underlying assumptions. In view of the various deficiencies in the existing storm surge models, additional considerations to improve the accuracy of the results and the generalization of the applications are listed as follows:

1. Inundation boundary conditions over the low-lying land surface are incorporated automatically with the rationale of both mathematical and physical justification rather than based on the empirical or a weir-type formula.
2. Bottom stress is time varying and may be obtained by an evaluation of convolution integrals over the surface slope, pressure depression, and wind stress. Only with this wind dependent bottom stress, it seems possible to facilitate the computational scheme over the low-lying land surface.
3. Wind stress coefficient is not a unique function of wind speed but also a function of temperature differential between the air and water. This inclusion of temperature effects is highly significant for the estimation of wind stress coefficients in the Northern United States, and should greatly enhance the predictability of storm surges in the Great Lake of Northern America where the temperature has significant change during storms.
4. The surge elevations at the lateral open boundaries perpendicular to the coastline are obtained by assuming zero gradient of total water depth. This would allow the selection of the locations of lateral boundaries with less restriction.

5. The stream inflows in estuarine areas are included in the momentum equations. Conventional assumption by neglecting the stream momentum but adding only the stream mass flux into the continuity equation is not totally true for many estuarine conditions.
6. All nonlinear terms such as advections are not linearized in order to account for the bathymetries involving irregular coastlines and bay complexes.

The numerical techniques used for computing long wave equations generally fall into one of the three schemes: (i) Explicit Finite Difference Method, (Reid and Bodine, 1968; Pearce, 1972; Wanstrath, 1975), (ii) Implicit Finite Difference Method (Leendertse, 1967; Tsai and Chang, 1974), and (iii) Finite Element Method (Pearce and Pagenkopf, 1975; Gallagher, etc., 1973; Gallagher and Chan, 1973). Engineering practice has indicated that the explicit scheme having to satisfy the Courant stability condition is too strenuous. Although the finite element method offers smooth treatment on irregular boundaries, it has serious drawback in the requirements of computing time and computer storages. Furthermore, the lack of provability on the stability of the method often leads to obscure trial and error. The alternate direction (ADI) implicit scheme has gained the popularity. It is unconditionally stable to the long wave equations without nonlinear advection terms (Leendertse, 1967). The authors have been unable to make practical use of this advantage for the cases when the nonlinear terms are included in the long wave equations. It is surmised that this may be due to the way these nonlinear terms are approximated as part implicit and part explicit. A modified ADI scheme, which considers all terms implicit, is therefore adopted.

MODEL FORMULATION

Basic Equations and Assumptions

The mathematical equations describing storm driven surges can be obtained by integrating vertically the Navier-Stokes equations for fluid motions. In this development, it is assumed that density over the depth is constant, pressure variation with the vertical coordinate is hydrostatic, and the variation of momentum transport with vertical coordinate dominates those with horizontal coordinates. The vertically integrated forms of the conservation equations in a Cartesian Coordinate system with x and y on the horizontal plan can be written as

$$\frac{\partial H}{\partial t} + \frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} = qH \quad (1)$$

$$\frac{\partial U}{\partial t} + \frac{\partial}{\partial x} \left(\frac{U^2}{H} \right) + \frac{\partial}{\partial y} \left(\frac{UV}{H} \right) - 2qU - fV = - \frac{g}{2} \frac{\partial H^2}{\partial x} + gH \left(\frac{\partial h}{\partial x} - \frac{1}{\rho g} \frac{\partial p_s}{\partial x} \right) + \frac{\tau_x^w - \tau_x^b}{\rho} \quad (2)$$

$$\frac{\partial V}{\partial t} + \frac{\partial}{\partial x} \left(\frac{UV}{H} \right) + \frac{\partial}{\partial y} \left(\frac{V^2}{H} \right) - 2qV + fU = - \frac{g}{2} \frac{\partial H^2}{\partial y} + gH \left(\frac{\partial h}{\partial y} - \frac{1}{\rho g} \frac{\partial p_s}{\partial y} \right) + \frac{\tau_y^w - \tau_y^b}{\rho} \quad (3)$$

The symbols used in Equations (1), (2), and (3) are defined as follows:

- H = total water depth
- h = undisturbed water depth
- U, V = flux density in x- and y-directions, respectively
- g = gravitational acceleration
- f = coriolis coefficient
- τ_x^w, τ_y^w = wind stress components in x- and y-directions, respectively
- τ_x^b, τ_y^b = bottom stress components in x- and y-directions, respectively
- p_s = atmospheric pressure
- x, y = horizontal orthogonal coordinates
- t = time
- ρ = water density

The terms included in the momentum equations are from the left to the right representing inertia term; nonlinear longitudinal and lateral advection momentum terms; the momentum attributed to the artificial discharges or river inflows and outflows; coriolis acceleration; nonlinear gravity terms; forces due to bottom slope and atmospheric pressure gradient; and wind and bottom stresses. It is interesting to note that the atmospheric depression column and the water depth column are equivalent. Therefore, the accurate reading of the undisturbed water depth is more important than the consideration of atmospheric pressure depression.

Variables in Equations (1), (2), and (3) are H, U, V, h, q, p_s , τ_x^w , τ_y^w , τ_x^b , and τ_y^b . Among these variables, p_s , τ_x^w , and τ_y^w are the forcing functions

depending on the atmospheric pressure and wind field distributions of the storms; h and q are given functions of x and y . Thus, if bottom stress components, τ_x^b and τ_y^b , are related to H , U and V , Equations (1), (2) and (3) will constitute three simultaneous partial differential equations for three unknowns, H , U , and V .

Wind and Bottom and Stresses

The most important and sensitive parameter in storm surge modeling is the wind shear stress since it is the primary driving force. In general, the wind shear stress is related to the wind speed, w , through the following expression

$$\tau^w = \rho_a K w^2 \quad (4)$$

where ρ_a is the density of air and K is the wind stress coefficient. The values of K should be a function of other parameters involving wind speed, surface roughness, and stability and turbulence of the atmosphere. A model treating K as function of wind speed has been presented elsewhere (Van Dorn, 1953; Reid and Bodine, 1968),

$$K = K_1 \quad \text{for} \quad W \leq W_c \quad (5a)$$

$$K = K_1 + K_2 (1 - W_c/W)^2 \quad \text{for} \quad W > W_c \quad (5b)$$

in which the constants, K_1 , K_2 and the critical wind speed have been taken as

	K_1	K_2	W_c
Van Dorn (1953)	$1.2 \cdot 10^{-6}$	$1.8 \cdot 10^{-6}$	6.7 m/sec
Reid & Bodine (1968)	$1.1 \cdot 10^{-6}$	$2.5 \cdot 10^{-6}$	7.2 m/sec

A slightly different formula for describing K has been proposed (Tsai and Chang, 1974) as follows:

$$K = \begin{cases} 1.25 \cdot 10^{-6} & \text{for } W \leq W_1 \\ 1.25 \cdot 10^{-6} + 1.75 \cdot 10^{-6} \sin\left(\frac{\pi}{2} \frac{W-W_1}{W_2-W_1}\right) & \text{for } W_1 < W < W_2 \\ 3.0 \cdot 10^{-6} & \text{for } W \geq W_2 \end{cases} \quad (6)$$

In which $W_1 = 5.1$ m/sec and $W_2 = 15.4$ m/sec. Most of the investigators has not included the atmospheric stability in the formulation of K . However, it has been demonstrated that the temperature differential between the water and air has a significant effect on the value of K (Gillies and Punhani, 1971). It is, therefore, proposed in this paper that K be given by the following equation:

$$K = \begin{cases} K_1 + K_3 \Delta T & \text{for } W \leq W_c \\ K_1 + K_2 (1 - W_c/W)^2 + K_3 \Delta T & \text{for } W > W_c \end{cases} \quad (7)$$

The values of K_1 , K_2 and K_3 will have to be determined from further numerical experiments on storm surges.

The relationships describing the bottom stress have been taken for granted by many authors (Reid and Bodine, 1968; Dansgaard and Dinsmore, 1975) as simply given by the following formula:

$$\tau_x^b = \frac{\rho g \sqrt{U^2 + V^2} U}{C^2 H^2} \quad (8a)$$

and

$$\tau_y^b = \frac{\rho g \sqrt{U^2 + V^2} V}{C^2 H^2} \quad (8b)$$

where C is the Chezy coefficient. Bottom stress formulation based on this line of approach may sometimes yield large error, since there are possible flows in which the transport is small but there still may be a significant bottom shear layer. This problem can be avoided by calculating the drag from the flow profile calculations based on linear theory of long wave equations, as done by Jelesnianski (1970) and Forristall (1974). Accordingly, the bottom stress is given by

$$\vec{\tau}^b = \frac{2u}{H^2} \int_0^t \left(\frac{\vec{t}}{\rho} - \frac{1}{\rho} \vec{v}_p^s \right) K_F(t-\tau) d\tau - \frac{2u}{H^2} \int_0^t g \vec{v}_\eta^s K_Q(t-\tau) d\tau \quad (9)$$

in which ν is the eddy viscosity, $\eta = H - h$, and K_P , K_Q , ∇_p^{\rightarrow} , $\nabla\eta^{\rightarrow}$, $\tau^{\rightarrow w}$, and $\tau^{\rightarrow b}$ denote

$$K_P = \sum_{n=0}^{\infty} (-1)^n (n + 1/2)\pi \text{Exp}\{-\nu(n + 1/2)^2 \pi^2 t/H^2 - (if - 2q)t\} \quad (10a)$$

$$K_Q = \sum_{n=0}^{\infty} \text{Exp}\{-\nu(n + 1/2)^2 \pi^2 t/H^2 - (if - 2q)t\} \quad (10b)$$

$$\nabla_p^{\rightarrow} = \frac{\partial p_s}{\partial x} + i \frac{\partial p_s}{\partial y}; \quad \nabla\eta^{\rightarrow} = \frac{\partial \eta}{\partial z} + i \frac{\partial \eta}{\partial y}; \quad \tau^{\rightarrow b} = \tau_x^b + i \tau_x^b; \quad \tau^{\rightarrow w} = \tau_x^w + i \tau_y^w \quad (10c)$$

respectively. The adoption of Equation (9) is more physically appealing and consistent with the overall method than Equation (8). The derivation of Equation (8) involves more assumptions than that of Equation (9).

Finite Difference Equations

A space-staggered scheme is used to approximate the differential equations with finite difference equations (Leendertse, 1967). The scheme describes the flux density, total water depth, and undisturbed water depth at different grid points as shown in Figure 1.

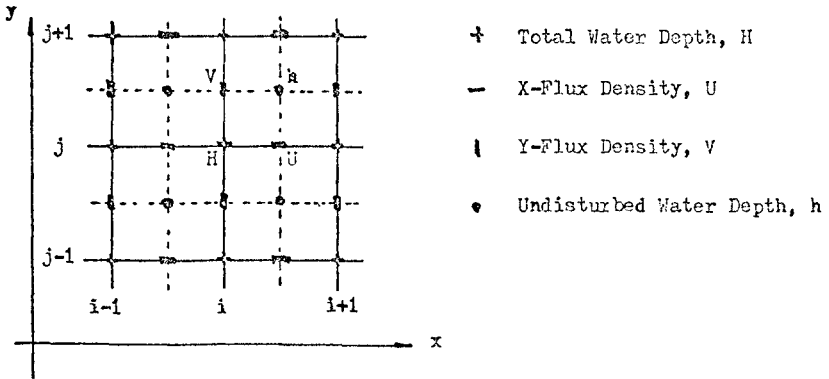

Figure 1

To simplify the discussion on the formulation of finite difference equations, Equations (1), (2), and (3) can be written as

$$\frac{\partial \vec{V}}{\partial t} + \frac{\partial \vec{F}}{\partial x} + \frac{\partial \vec{G}}{\partial y} - I = 0 \tag{11}$$

where

$$\vec{V} = \begin{bmatrix} H \\ U \\ V \end{bmatrix}; \quad \vec{F} = \begin{bmatrix} U \\ \frac{U^2}{H} + \frac{gH^2}{2} \\ \frac{UV}{H} \end{bmatrix}; \quad \vec{G} = \begin{bmatrix} V \\ \frac{UV}{H} \\ \frac{V^2}{H} + \frac{gH^2}{2} \end{bmatrix} \tag{12}$$

and

$$I = \begin{bmatrix} qH \\ gH\left(\frac{\partial h}{\partial x} - \frac{1}{\rho g} \frac{\partial p_s}{\partial x}\right) + fV + 2qU + \frac{\tau_x^w}{\rho} - \frac{\tau_x^b}{\rho} \\ gH\left(\frac{\partial h}{\partial y} - \frac{1}{\rho g} \frac{\partial p_s}{\partial y}\right) - fU + 2qV + \frac{\tau_y^w}{\rho} - \frac{\tau_y^b}{\rho} \end{bmatrix} \tag{13}$$

Let

$$\vec{V}_{i,j}^{(n+1)} = \begin{bmatrix} H(i\Delta x, j\Delta y, (n+1)\Delta t) \\ U(i\Delta x, j\Delta y, p\Delta t) \\ V(i\Delta x, j\Delta y, q\Delta t) \end{bmatrix}$$

where p and q will be replaced by (n+1) or (n) as demanded by the ADI algorithm, then the finite difference approximation of Equation (11) is

$$\frac{\vec{V}_{i,j}^{(n+1)} - \vec{V}_{i,j}^{(n)}}{\Delta t} + \frac{1}{2\Delta x} \left[\vec{F}_{i+1,j} - \vec{F}_{i-1,j} \right] + (1-\theta) \left[\vec{F}_{i+1,j} - \vec{F}_{i-1,j} \right] + \dots = O(\Delta t, \Delta x^2) \tag{14}$$

where θ is a weighting factor ranging from 0 to 1, and $\tilde{F}_{i,j}^n$ is given by

$$\tilde{F}_{i,j}^n = \frac{F_{i+1,j}^+ + F_{i,j}^+ + F_{i-1,j}^+}{4} \tag{15}$$

Expansion of Equation (14) in Taylor series, it becomes,

$$\frac{\partial V}{\partial t} + \frac{\partial F}{\partial x} + \frac{\Delta x^2}{4}(1-\theta) \frac{\partial^3 F}{\partial x^3} + \dots = 0 \tag{16}$$

The third term which has the magnitude of the order of Δx^2 is the numerical filter term to screen the short wave number. For complete implicit scheme, $\theta = 1$, and therefore, no filter term is encountered. This would probably explain the frustration experienced by many model practitioners when Equation (14) with $\theta = 1$ is applied to the solution of circulation problems. Under such circumstances, the noise caused by the short wave would amplify very fast and blow out the computations. Instead of $\tilde{F}^{(n)}$, if $\bar{F}^{(n)}$ is used in Equation (14), similar problems will also arise since no filter term is involved to dampen the short wave noise.

Since \bar{F} , \bar{C} and \bar{I} are nonlinear functions of H , U , and V , Equation (14) is a system of nonlinear algebraic equations. These equations can be solved directly by iterative method. However, iterative solution to a large number of simultaneous equations at each time step is not only time consuming but also causes convergent problems in many areas. Hence, linearization techniques must be used to render these equations to a system of linear algebraic equations that direct solution can be obtained. In general, Taylor series expansion is adopted, i.e.,

$$\bar{F}^{(n+1)} = \bar{F}^{(n)} + \frac{\partial \bar{F}}{\partial H}(H^{(n+1)} - H^{(n)}) + \frac{\partial \bar{F}}{\partial U}(U^{(n+1)} - U^{(n)}) + \dots$$

For example, the term U^2 in the second component of \bar{F} in Equation (12) can be expanded as

$$U^2(n+1) = U^{(n)}(U^{(n+1)} + U^{(n+1)} - U^{(n)}) + \dots \tag{18}$$

Most of the numerical modelers would linearize this term by treating it as part explicit and part implicit (Leendertse, 1967; Tsai and Chang, 1974), i.e.,

$$U^2(n+1) = U^{(n)}U^{(n+1)} \tag{19}$$

It is seen from Equations (18) and (19) that the former will render the latter as its special case if $U^{(n+1)} \rightarrow U^{(n)}$. The implicit scheme, Equation (14), has been proved unconditionally stable when it is applied to linear partial differential equations (Leendertse, 1967). However, frustrations have been experienced more than often when it is applied to nonlinear equations in along with Equation (19), unless the time step is smaller than that given by Courant stability criteria. This fact may be explained by comparing Equations (8) and (19). The comparison indicates that the time step has to be small for the two to agree.

Boundary Conditions

There are two types of boundaries in the numerical simulation of storm surges. One is the water-land interface while the other is the fictitious open boundaries which are artificial termination of the flow field. During a storm, the wind generated surge close to shoreline is most prominent. For locations further seaward, the magnitude of the wind setup (or setdown) becomes progressively insignificant for several reasons. The first effect occurs due to decreased hindrance of the boundary. The increase in water depth accounts for the second reason as the water mass would be more difficult to set in motion at a location of greater depth by the water surface shear forces.

For locations beyond the Continental Shelf, the water elevation due to wind shear would be insignificant. Thus, at seaward boundary the setup (setdown) could be reasonably assumed equal to the barometric and astronomical tides. The treatment of lateral open boundaries is still very controversial. Reid and Bodine (1968) proposed radiative boundary conditions. Pearse and Pagenkopf (1975) assumed zero onshore transport. Zero gradient of water surface slope has been used with the requirements that the lateral boundaries be chosen roughly perpendicular to the bottom contours lines (Stone & Webster, 1976). In this paper, this requirement will be removed by specifying the gradient of total water depth equal to zero at lateral boundaries.

Most of the existing storm surge models does not consider the moving boundaries at the water-land interfaces. General practice is to assume vertical wall interface that the normal flow is zero (Pearse and Pagenkopf, 1975). A few investigators model the inundation of low-lying land with weir type approach (Reid and Bodine, 1968; Dansgaard and Dinsmore, 1975). In the present model, the moving boundaries are accomplished by progressively advancing (retreating) the land-water interface as surges increase (decrease). Both continuity and momentum equations are actually utilized in tallying these moving inundation boundary grids.

MODEL APPLICATION

The storm surge model is applied to the New Jersey coastal area for 1944, hurricane, whose track parallels the east coast and lies well within the confines of the Continental Shelf. The track of the pressure center in the storm is taken from the report by Graham and Hudson (1960). The hurricane characteristics were given both near Hatteras, North Carolina, and Point Judith, Rhode Island (Graham and Hudson) as follows.

	<u>Hatteras, NC</u>	<u>Point Judith, RI</u>
Radiative of maximum winds, R	49 N. Mi	36 N. Mi
Center pressure index, p_o	27.88 in.	28.31 in.
Peripheral pressure, p_n	30.66 in.	29.39 in.
Maximum gradient wind, V_{gx}	113 mph	71 mph

Based on these hurricane parameters and the track, wind and pressure fields are constructed using the method suggested by Graham and Nunn (1959).

The New Jersey coastal area is constructed on a rectangular grid of 22 by 31 with grid size of 33,333 ft. It included the Continental Shelf to a depth of approximately 600 ft and is extended far north and south of the area of interest that the lateral boundary conditions are applicable.

Surge histories for 1944 hurricane are available at both Atlanta and Sandy Hook tidal gage stations in the southern and northern New Jersey coast, respectively (Harris, 1963). Both recorded and computed surges with the model at Atlanta City are shown in Figure 2. Figure 3 shows comparisons between the tidal gage measurements and the simulated results at Sandy Hook. The agreements at both Atlanta City and Sandy Hook are considered favorably. The peak surge as computed at Sandy Hook is higher than the measured.

CHAPTER 55

SIMULATION MODEL FOR STORM SURGE PROBABILITIES

by

M. H. Fallah¹, J. N. Sharma², C. Y. Yang³

I. INTRODUCTION

Storm surge and its impact on the coastal regions have been of interest to many researchers and engineers for a long time. Deterministic models based on classical hydrodynamics can be used for reliable predictions only for short terms, e.g. up to 24 hours for which the characteristics of the storm can be projected accurately. Long-term predictions, on the other hand, is a statistical problem due to the random nature of the storms. Such long-term prediction is becoming increasingly important as the coastal regions are rapidly developed into residential, recreational and industrial areas.

One of the first statistical studies on coastal storm surge predictions was published in 1961 by Wemelsfelder who used a Poisson probability law to fit the observed high tide data at Hook of Holland. From this fitted law, risk curves for long-term in years can be constructed for design purposes. In 1970 Yang et al applied the extreme value model to fit storm surge data for Atlantic City, New Jersey and Breakwater Harbor, Delaware. This so-called "purely" statistical method is sound in concept and simple to use. It has some serious limitations, however. First, it requires a collection of long term data (say 100 years for reliable design predictions) which is difficult to obtain in general. Secondly, the prediction for one location is not valid in general for other locations even when they are not far apart. To overcome the first limitation on the unavailability of long-term data at least partially, it is recognized that although storm tide data is limited, the general meteorological data is relatively abundant, so that more data on storm tide can be derived from meteorological data (wind field) via a hydrodynamic analysis. The analysis, of course, involves a general coastal area and consequently, the spatial variation of the storm tide can be predicted and the limitation on the location can be removed also. These observations lead to the concept of a combined statistical and hydrodynamic model which takes into account both the randomness of the long-term meteorological data and the physics of the storm surge.

³ Professor, Civil Engineering and College of Marine Studies, University of Delaware, Newark, DE

The first study known to the authors by this combined statistical and hydrodynamic approach was conducted by Bretschneider (1959) for Delaware Bay and Chesapeake Bay. In this study, the 1944 hurricane which was the most severe storm recorded along the Atlantic Coast at that time was selected as the so-called standard project hurricane. The track of this hurricane was then varied in position and orientation relative to the location in question. For each position and orientation of the hurricane, maximum storm surge height was calculated using a simplified hydrodynamic model. Following Bretschneider's study, a severe winter storm hit the Atlantic City area in 1962 and caused loss of lives and disastrous damage of properties. The following year, through an act of the Congress, the Corps of Engineers did a study for hurricane surge along the Atlantic Coast. A report was published in 1963 in which maximum surge heights were predicted for several locations based on the same standard project hurricane concept as used by Bretschneider (1959). In particular a 500 year return period was estimated for the standard project hurricane, unfortunately with little technical details. Subsequent to the 1963 study, under a contract with the Federal Insurance Administration, the Corps of Engineers in 1972 conducted a study of storm surge for the city of Rehoboth Beach, Delaware. Design surge heights of 500-year and 100-year return periods were predicted based on tide observations at Atlantic City, New Jersey and the 1963 prediction through the standard project hurricane with the estimated 500-year return period. Parallel to the studies by the Corps of Engineers (1963, 1972), Myers (1970) of the National Oceanic and Atmospheric Administration developed a refined method which he called the joint probability method to study the frequency of high tides at Atlantic City, New Jersey. It is refined in two respects. First, a thorough frequency analysis was made for the parameters of all hurricanes so that for a selected set of severe hurricanes, a frequency of occurrence can be calculated under the assumptions of independent hurricane parameters. Secondly, a refined hydrodynamic model due to Jelesnianski (1967) was used in the surge calculations from hurricane wind field. The same method was used to predict storm surge for the South Carolina coast by Myers in 1975 and for the Atlantic Coast by Ho in 1976, using a revised hydrodynamic model from Jelesnianski (1974).

The purpose of this paper is to present a simulation model which includes the generation of random artificial hurricanes and the hydrodynamic model of Jelesnianski (1974) for the long-term prediction of design storm surge. The model is then applied to the Delaware coast. Finally a comparison with other predictions and suggestions for further work are made.

II. SIMULATION MODEL

A Monte Carlo simulation model (see for example, p. 124, Benjamin and Cornell, 1970) is developed to predict storm surge probabilities. This model consists of six essential parts: (1) estimating the statistical distribution of historical hurricanes and hurricane parameters, (2) generating artificial hurricanes associated with the set of random hurricane parameters, (3) computing the surge heights in each artificial hurricane by a suitable hydrodynamic model, (4) combining the hurricane surge with astronomical tide, (5) generating random winter total tide (storm plus astronomical) and (6) constructing extreme value distribution based on yearly maxima.

A flow chart is shown in Figure 1 for the simulation and combination of the hurricane storm surge, astronomical tide and winter tide in a year. This chart is explained in the following steps.

- (1) Generate a uniformly distributed random number, U , between 0 and 1.
- (2) If $U < P$ (the probability of occurrence of a hurricane in the area during one year), a hurricane occurs; otherwise it does not.
- (3) If a hurricane occurs, then generate a set of hurricane parameters, center pressure drop ΔP , radius R , forward speed V and direction θ , consistent with their distributions.
- (4) Generate another uniformly distributed random number, U , to compare with P_L (the probability of a landfalling hurricane) and decide whether it is a landfalling hurricane or one moving parallel to the coast.
- (5) Calculate temporal surge profile due to the artificial hurricane.
- (6) Generate random amplitude and phase for astronomical tide.
- (7) Calculate the combined maximum tide S_H (hurricane surge plus astronomical tide). If a hurricane does not occur, set $S_H = 0$.
- (8) Generate a total winter tide S_W (storm plus astronomical) based on the distribution of observed total winter tide.
- (9) Take the larger of the two values, S_H and S_W , and set it as the extreme event of the year.
- (10) Plot the extreme events on extreme value probability paper.

III. APPLICATION TO DELAWARE

For Delaware coast, data source and input data to the simulation model consists of (1) hurricane occurrence frequency and hurricane parameters for 70 years from Bretschneider (1972), (2) amplitudes of astronomical tide in September from Myers (1970) and (3) total winter tide (1953-1974 storm plus astronomical) from U. S. Geological Survey. These raw data were first analyzed to obtain statistical distributions for use in the model as explained in the previous section. It should be pointed out, however, that due to the inefficiency of the computer available, the cost in running the hydrodynamic model of Jeleznianski (known as SPLASH II) was found to be prohibitive when hundreds of runs are needed in the simulation process. Accordingly, only four runs of the SPLASH II were made to furnish the needed information (the shoaling factor) in the simplified analysis based on Jeleznianski's monographs. This known crudeness and other major assumptions such as the independence of random parameters of a hurricane indicates the approximate nature of the final result.

A total of 792 sample years were used in the final simulation analysis from which key values of the total tide (either hurricane surge plus astronomical tide or winter storm surge plus astronomical tide) together with their frequency of occurrences are sorted out. To facilitate design application, these values are plotted on extreme value probability paper as shown in Figure 2, where the abscissa on the bottom of the figure is the probability distribution function, i.e. the probability that the yearly extreme is equal or less than the indicated tide; and that on the top of the figure is the so-called return period in years. The return period in years means that on the average, the indicated tide level will be exceeded at least once in these many years.

IV. COMPARISON AND DISCUSSION OF RESULTS

In Figure 2, a comparison is presented among the predictions by Yang et al (1970) for Breakwater Harbor, Delaware, by Myers (1970) for Atlantic City, New Jersey, by Corps of Engineers (1972) for Rehoboth Beach, Delaware and by the present simulation model for Breakwater Harbor, Delaware (1976). Although the present analysis is admittedly crude in many aspects, the large discrepancies among these four sources indicate that the prediction by the Corps of Engineers in 1972 based on the concept of a standard project hurricane of 500 year return period and by Myers in 1970 for Atlantic City, New Jersey are probably overly conservative for the Delaware coast. This comment is based on the seemingly lack of technical basis for the assessment of the 500 year return period for the Corps study and the result by Ho (1976) which indicates a higher tide at Atlantic City, New Jersey than at Delaware. To be more specific than this requires further improvement of the simulation analysis on at least the following aspects: (1) a more complete hydrodynamic model taking into account the effect of the Delaware Bay should be used in place of Jelesnianski's (1974) SPLASH model which considers a straight coastline only; (2) the correlation among the hurricane parameters should be taken into account; (3) amplitudes of astronomical tide should be analyzed for all the hurricane season rather than the month of September only; (4) all of the raw data used should be constantly updated and examined for accuracy; (5) a hydrodynamic model for winter storm needs to be developed to improve the prediction reliability particularly for locations like Delaware where winter storms are perhaps more important in the sense of severity than hurricane storms.

V. ACKNOWLEDGMENT

The authors wish to acknowledge their appreciation to Dr. Jelesnianski for providing the SPLASH II computer program and technical advice in its use, and to NOAA and the State of Delaware for financial support of this study.

CHAPTER 56

SPLASH - A MODEL FOR FORECASTING TROPICAL STORM SURGES

Celso S. Barrientos
Chester P. Jelesnianski

Techniques Development Laboratory
National Weather Service, NOAA
Silver Spring, Maryland

ABSTRACT

A significant portion of the damage by hurricanes is the storm surges. The National Weather Service has developed a dynamical-numerical model to forecast hurricane storm surges. The model is used operationally for prediction, warning, and planning purposes.

The model requires fixed oceanographic and real time meteorological input data. The oceanographic data were prepared for the Gulf and East coasts of the U.S. and are stored as an essential part of the program. Meteorological data for any tropical storm are supplied by the forecasters or planners using the model.

The model was applied to hurricane Camille 1969. Comparison between the observed and computed surges for Camille was satisfactory for prediction purposes.

INTRODUCTION

Coastal high waters (commonly called surge) generated by tropical storms can cause a significant fraction of the total storm damage. Because the potential for destruction can be enormous, it is useful to have at hand an estimate of the height of the potential surge and the extent of the coastal areas that can be affected by the flooding. Such an estimate can be given by a numerical model such as SPLASH.

What is SPLASH? SPLASH is an acronym for "Special Program to List Amplitudes of Surges from Hurricanes." It is the name of a computer program for a dynamical surge model to predict hurricane storm surges. The program is used operationally at the National Weather Service (NWS).

SPLASH is a numerical-dynamical model to predict storm surges generated by tropical storms (Jelesnianski 1972, 1974, 1976). The model solves the linearized transport equations of motion with storm driving forces on the

surface and bottom stress. The model uses an input basin truncated from the ocean which contains coastal areas of interest. We use a truncated basin of proper size so that numerical computations can be performed at reasonable cost and yet not compromise on the dynamics of the open coast surge.

A very useful adjunct of the SPLASH model is a shoaling curve. (The meaning of shoaling correction will become clear in later parts of the paper.) The shoaling curve indicates the relative increase (or decrease) of the surges if a storm's landfall position changes along the coast. This is important because the surge varies as bathymetry varies along the basin, and bathymetry relative to the storm will vary as landfall is varied. For application purposes, the shoaling curve serves as a powerful tool to determine how surges change if the landfall point is varied. Also, with the aid of the shoaling curve, dangerous and ill-conditioned situations can be anticipated without resorting to extensive computer runs. For planning purposes, a shoaling curve is most effective to obtain added information with a minimum number of computer runs.

SPLASH is used operationally at the National Hurricane Center of NWS in Miami. In this paper, we will discuss the model, the basin, input data, a shoaling correction, and applications of the model. The program is applicable for the Gulf and East coasts of the U.S., from Brownsville, Texas, to Shinnecock Inlet, Long Island, N.Y. This stretch of coast is approximately 300 miles long. Recently, we extended the application of SPLASH to the New England area up to the U.S.-Canadian border.

The SPLASH product is also used to estimate flooding potentials in the coastal areas of the U.S. and Puerto Rico (Jelesnianski and Barrientos 1973). This work is being done by the National Oceanic and Atmospheric Administration (NOAA) as a reimbursable project for the Federal Insurance Administration of the Department of Housing and Urban Development to fix flood insurance rates. A discussion of the NOAA procedure to compute storm tide frequencies is in Myers (1975).

SPLASH MODEL

The SPLASH model has been partially documented in three publications, the mathematical technique in Jelesnianski (1967), and three operational techniques to run and interpret the results for forecasting purposes, Jelesnianski (1972, 1974, 1976). The mathematical techniques are adapted from Platzman (1963). The tropical storm model used to generate surges is discussed in Jelesnianski and Taylor (1973).

SPLASH is a dynamic model which numerically solves the linearized transport equations of motion in a basin bounded by a curvilinear parallel surface;

the curved coastline is a vertical wall and the remaining three boundaries are open to the sea. Initially, the sea in the basin is assumed at rest. Driving forces from the storm are applied on the water's surface; also, a time-history formulation of the bottom stress is utilized.

Initially, the storm is set at zero strength and then allowed to grow to maturity in a continuous but rapid manner. Initial positioning of the storm is unimportant, if on reaching maturity the storm lies in deep water beyond the continental shelf. For storms traveling more or less parallel to the coast and along the continental shelf, initial placement must be at least sufficiently distant from the area of interest so that the surge has time to form; this can be determined by empirical tests through variation of initial storm placement, growth time of storm to maturity, etc.

The grid distance used in our numerical computations must be fine enough to portray not only the storm surge but also the driving forces of the storm. The grid length may be determined by empirical tests.

On the two lateral, open boundaries, the boundary condition used is $\partial V/\partial y=0$; where V is the component of transport along the coastal y -coordinate. This boundary condition is arbitrary and used purely for convenience. In any case, reflections from these boundaries eventually corrupt the interior of the basin. However, if the boundaries are placed sufficiently far from an area of interest along the coast, there will be a time interval before the area is corrupted by reflections from the boundaries. The placement of these side boundaries are determined by empirical tests.

The deep water open boundary is placed somewhat arbitrarily, near the juncture of continental shelf and slope. In deep water away from coastal influences, the dynamic surge is small and corresponds very closely to the inverted barometer effect. The boundary condition used is $h=h_0$; where h_0 is the static height of the surface.

BASIN AND STORM DATA

The dynamic model, SPLASH, computes storm surges via numerical computations for particular storms in particular basins. A basin is described by two-dimensional depth fields, coastal boundaries, local and geographical references, and geographical orientation. To acquire basin data, we used the National Ocean Survey marine charts with scale 1:500,000. The chart delineates coastlines, the continental shelf, depth contours in shallow water, and spot depths in deep water. Detailed descriptions of preparing basin data are presented in our two reports to the Federal Insurance Administration (Barrientos and Jelesnianski, 1973; Barrientos and Chen, 1974).

For orientation purposes regarding the basin, the observer is at sea and facing the coast. The coast to his right will be considered relative north, to his left relative south. Crossing angles of the storm's path to this oriented coast will be described as follows: A storm moving from relative north has a crossing angle of 0° , moving normal to the coast from sea, a crossing angle of 90° , exiting (moving from land to sea), a crossing angle of 270° , etc.

Figure 1 positions pre-selected stations on the East and Gulf coasts of the U.S. used by the SPLASH operational model to indicate approximate positions of basin centers. Some of the location names are abbreviated. The abbreviations are exactly as used in the model for routine operations at NOAA's National Hurricane Center. The stations are 100 miles apart (more or less) and are situated at (or near) the center of the various basins.

To refine the technique for planning and flood insurance study, we find it necessary to add additional basins between the stations (Figure 1); i.e., basins are now overlapped every 50 miles instead of every 100 miles. Geographical locations of the basin centers are included in the basin data. We have not identified the additional basins with any new cities because we want to keep these reference cities to a minimum.

Due to computer core limitations and economics of machine operations, it is impossible to consider an entire ocean as a basin. Open boundaries are therefore used as an artifice in the model. (The basin used is 600×72 statute miles in size and grid length is 4 miles. Thus, total grid points are $1/2(151 \times 20) = 1510$ for each basin.) A more detailed description of basin preparations is in the report of Barrientos and Jelesnianski (1973).

Two versions of the dynamical model are in use. SPLASH I to compute storm surges for landfalling (or exiting) storms only, and SPLASH II for storms moving along the coast. SPLASH requires input meteorological parameters that have to be supplied by weather forecasters. The data for a computer run are shown schematically in Figure 2. In SPLASH I, these are: (a) the pressure drop, $\Delta p = p_\infty - p_0$, where p_∞ is the ambient pressure outside the influence of the storm and p_0 is the central pressure of the hurricane; (b) the radius of maximum wind R ; (c) the vector storm motion, U_s/θ , where U_s is the storm speed of translation θ is the compass (meteorological) storm direction of motion; and (d) landfall point referenced to stations or cities (Figure 1).

The landfall point is important, for it determines which basin will be used in the model. SPLASH I deals with a steady state storm, of constant size and intensity, and constant, linear, vector storm motion. This idealization in SPLASH I has been proved useful in actual operations and climatological studies.

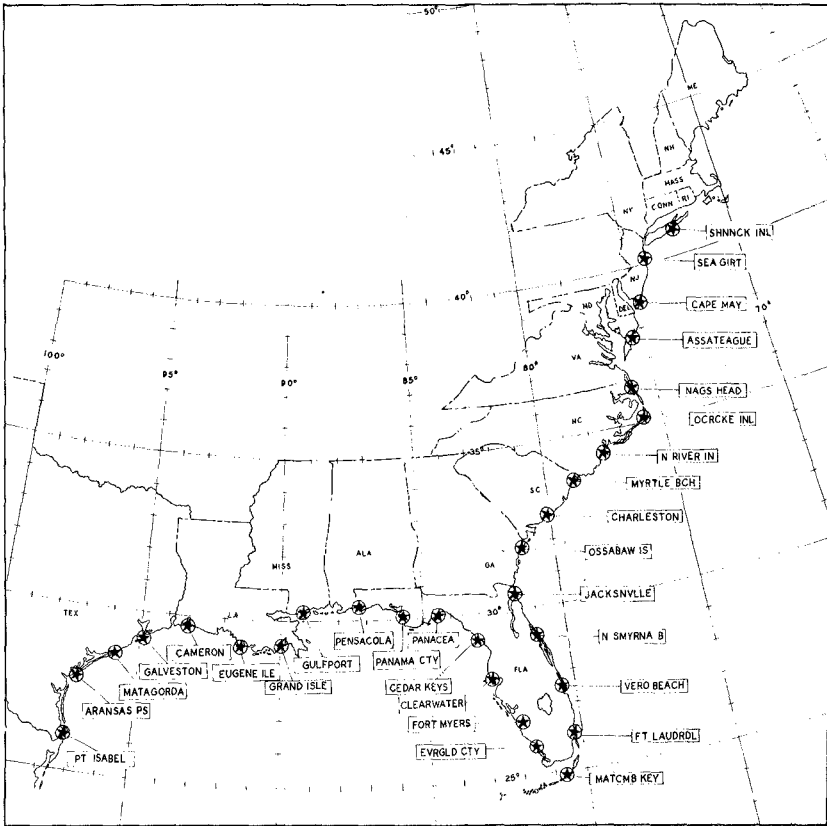

Fig. 1. Selected stations on the East and Gulf coasts of the U.S., used by the SPLASH operational model to indicate positions of basin.

Fig. 2. A schematic representation of the use of the SPLASH programs and input meteorological data.

In contrast, SPLASH II deals with variant conditions of the storm and its track; i.e., a nonsteady state storm. The storm track is quite general; it can landfall (or exit--moving from land to sea) at any angle with the coastline, move parallel to the coast, be bow-shaped, etc. The speed of the storm can be variable along the storm track and even remain stationary. Note that SPLASH I is a special case of SPLASH II. For this program, the weather forecaster supplies a 24-hour track segment (Figure 2). The track is defined by latitude, ϕ , and longitude, λ , for five points on the track staggered six hours apart for a 24-hour period. These input latitudes and longitudes define the track, and the speed of propagation of the storm, i.e., vector storm motion. Other input data are the size of the storm, that is the radius of maximum wind, at initial and final time of the 24-hour period; also, the intensity or pressure drop at initial and final time of the 24-hour period. Both the size and the pressure drop can vary with time. The storm track is very important in the surge computations. A slight shift of the track either toward the coast, or toward the sea, can make a significant difference in coastal surges (Jelesnianski and Barrientos, 1975). Several dynamic phenomena, such as resonance and wave transients, can be generated by storms with generalized motions (Jelesnianski, 1974).

With the basin data and input meteorological parameters, peak surges, profiles, and envelopes of high water along the coast are computed by the SPLASH model.

SHOALING CORRECTIONS

A very important property derived by SPLASH is a normalized shoaling correction. It is a powerful tool to correct surge computations along the coast if the landfall point is shifted.

A shoaling curve for both the East and Gulf coasts is derived from the ratio of the peak surge computed in a local basin to that of the peak surge computed in a standard basin. A shoaling correction curve in a particular basin indicates the change in the coastal surge envelope* as it is displaced by a change in landfall point. The change of the surge envelope is due to changes in the bathymetry of the continental shelf with respect to landfall point. We used a standard storm and standard vector motion in the computations. (A standard storm has a maximum wind speed of 100 mph.) Peak surges computed by the SPLASH model with a standard storm in local basins are normalized with the peak surge computed in a standard basin. A standard basin has a continental shelf sloping linearly at 3 feet per mile, with a depth of 15 feet at the coast; its coast is a straight line, and the depths

*Envelope means the plot of the coastal high water heights during passage of a storm. Highest surges at various points along the coast don't occur simultaneously.

vary in one dimension only. This standard basin may be considered as the mean depth field averaged throughout the continental shelf of the Gulf and East coasts.

We define the standard vector motion to be perpendicular to the coast with a speed of 15 mph from sea to land. Hurricanes, of course, ordinarily do not landfall precisely normal to the coast, but for the purpose of computing shoaling curves our approach is the most convenient. Another alternative is to compute shoaling curves for various track angles to the coast. This kind of approach however would require voluminous amounts of data and staggering computer expense.

Storm surges are related to storm size (radius of maximum wind). For the same maximum wind, the larger storm will give larger surges, up to a critical size. Storm size is even more important for storms moving along the coast (Jelesnianski, 1974; Jelesnianski and Barrientos, 1975).

For convenience in our derivation of shoaling curves, we form the storm's pressure drop so that maximum winds are 100 mph; this wind is maintained for any storm size and also for latitude of real basins on the coast. We can follow this procedure because the storm model accommodates these parametric values (Jelesnianski and Taylor, 1973). In previous work, we found that peak surges along the coast depend only mildly on latitude, but to some extent on radius of maximum wind (storm size). Thus, we computed two reference peak surges in the standard basin with a standard storm for two storm sizes, or radii of maximum winds, of 15 and 30 miles. These two peak surges are used to scale maximum surges computed with the same storms in real basins.

To produce peak surges for standard storms along the Gulf and East coasts, we made SPLASH runs on all 50 basins for two storm sizes: 15 and 30 miles radii of maximum wind. We then plotted the resulting peak surges on the coast. For each basin, we chose a minimum of three landfall points: at the center of the basin baseline, and 16 miles on either side of the center. In complicated locations, e.g., Mississippi Delta, Cape Fear, and Sandy Hook, we made more runs to get better resolution for the shoaling curve. For landfall on either side of the basin center, the track was made normal to the true coastline.

In addition to the location of peak surges for each storm size, we successively plot a portion of the computed envelope on either side of the peak surge. Figure 3 is an example of the process. We plot only a portion of each envelope that is within about one storm radius on both sides of the peaks. We now hand draw an envelope of peak surges, that is, an envelope of surge envelopes. This is done separately for the two storm sizes. The final envelope of peak surges is an unscaled shoaling curve.

Fig. 3. Analysis of the envelope of surge envelopes to arrive at shoaling curves. The upper envelope is for storm size of 30 miles, the lower for storm size of 15 miles.

In Figure 3, some peak surges are not on the shoaling curve because subjective adjustments of the envelope were made considering the bathymetry of the continental shelf. If more runs of the SPLASH program were made at closer spacings along the coast, then peak surges would have been computed to fit the shoaling curve. The shoaling curve was based on all individual envelopes as shown in Figure 3.

We don't want to be constrained to peak surge values generated by standard storms only. Hence, the shoaling curve must be scaled locally for each basin if it is to be useful in the SPLASH model. The procedure for scaling is now discussed.

The peak surge computed for a standard storm along the coast is a function of the slope of the continental shelf. Hence if we scale the final envelope of Figure 3 according to the peak surge generated by a standard storm in a standard basin, then we reduce the final envelope to a common denominator. We call such a scaled, final envelope a shoaling curve. The shoaling curves for the Gulf and East coasts are shown in Figures 4a and 4b for both 15- and 30-mile storm sizes. The curved coasts are extended linearly for convenient display. The ordinate is the shoaling factor or surge potential (the ratio of peak surge on any point of the coast to that of peak surge on a standard basin).

Also included in Figures 4a and 4b are depth contours on the continental shelf. There is close correlation between the shoaling curve and depth contour, i.e., the shallower the shelf the higher the potential. This is illustrated in Eugene Isle in the Gulf and Ossabaw Island in the East coast. The surge potential is small between Pensacola and Panama City in the Gulf and on the east coast of Florida due to the narrow shelves in these areas.

The shoaling curve varies by a factor of about four on both coasts. The highest surge potential on the Gulf coast is higher than on the East coast for both storm sizes. We can conclude that for the same storm, the Gulf coast has higher storm surge potential than the East coast. However, we point out that storms are not necessarily the same on the Gulf and Atlantic shelves.

To correct a computed surge envelope for alternate landfall points, we have designed an individual shoaling correction curve for each basin. The basin shoaling correction curve is composed as follows: (1) Read from Figure 4a the shoaling value at the center of each basin. (2) Along the shoaling curve of Figure 4a for a given basin, divide the shoaling factors by the shoaling value from (1), for a shoaling correction curve. The value of the correction is unity at basin center. Because the coastal distances

Fig. 4a. Shoaling correction curves along the Gulf coast.

Fig. 4b. Shoaling correction curves along the East coast.

represented by abscissa distances on Figure 4a are curvilinear lengths, whereas the SPLASH model calculations are for equidistant coastal points on a tangent to the coast (a baseline), then the correction curve must be compressed to the linear lengths along the baseline.

After local shoaling corrections are computed, they are stored in the SPLASH program for instant use. The basin shoaling corrections are part of the basin data. The corrections operate on a computed surge envelope; if landfall point is hypothetically shifted on the coast, then the computed envelope is also shifted and operated on by the shoaling curve to correct for changing bathymetry.

The basin shoaling corrections are included in the SPLASH program for each of the 58 basins in the Gulf and East coasts. The program is used operationally at the National Hurricane Center, NWS and by the Office of Hydrology, NWS, NOAA, to compute outer coast surges with climatological input data for flood insurance projects.

APPLICATION TO HURRICANE CAMILLE 1969

To run the SPLASH program in NOAA, users will feed the computer with necessary meteorologic data as shown in Figure 2. For users without access to NOAA computers, we have an earlier version of the program available at the National Technical Information Service. The program includes the file of basin data.

To illustrate the SPLASH program we show a verification run for hurricane Camille 1969. Camille was probably the most devastating hurricane to hit the coast of the U.S. The important result of SPLASH is shown in Figure 5 for Camille.

On the top of Figure 5, the input data that the forecaster supplied are repeated for a visual check. The next group of data are the correction factors for the pressure drop. This is useful to correct the computed surges without rerunning the program. We gave corrections for ± 10 mbs deviation of pressure drop.

We also predict the astronomical tides, above MSL, for various stations near the Landfall point. In operational use, the forecaster's may modify the computed surges accordingly. We don't add the astronomical tide to the storm surges because it is very hard to phase the two waves together.

The main output of the SPLASH program is the surge envelope indicated by asterisks in Figure 5. The symbol \sim^* represents the landfall point of

Fig. 5. A verification run of the SPLASH program for hurricane Camille 1969.

the hurricane. The peak surge generally occurs at a distance equal to the radius of maximum wind, R to the right of landfall. Below the graph, we print the values of the computed surge envelope. Note these values are the highest surges on the coast but not necessarily occurring at the same time. For Camille, the computed peak surge is 25.0 ft. We also print the stations along the coast for reference and the distances along the coast from landfall point.

The second row of numbers, from the bottom of Figure 5, is the surge envelope if the landfall is shifted 100 miles to the right; the first row is when landfall is shifted 100 miles to the left. It is possible to compute these surge values because of the shoaling correction factors.

The inset in Figure 5 shows a comparison of the observed surges and computed surges by SPLASH for Camille. Considering that the observations are taken at various distances from the coastline, we believe the comparison here is quite good. Also errors in measurements are very difficult to account for.

SUMMARY AND CONCLUSIONS

Rising coastal waters are generated by hurricane driving forces. These forces are low atmospheric pressure (inverted barometer effect) and wind force. Thus a rotating mound of water forms under a storm in deep water. If the variable momentum in the sea (i.e. rotating mound of water or vorticity) is transformed into divergence, then storm surges are further generated. The bathymetry or sloping depths of continental shelf and the coastal boundary are effective mechanisms to transform vorticity to divergence.

NOAA has an existing dynamical-numerical model to compute surges, called SPLASH. To compute surges with this model, basin data are stored for all basins of the Gulf and East coasts of the United States. Basin data consist of depth values at grid points, orientation of the basin with respect to north, local and geographical references, and shoaling corrections.

We have numerically computed surge envelopes at equally spaced landfall intervals of 16 miles, along the 3000-mile stretch of the Gulf and East coasts. At each landfall point, we made computer runs for two storm sizes, 15- and 30-mile storm radius. We then derived envelopes of peak surge to obtain shoaling curves. When the storm size is not 15 or 30 miles, then whichever of the two sizes is nearest to R is used, e.g., $R = 25$ the shoaling curve for $R = 30$ is used.

Finally, shoaling corrections were prepared for each basin in the SPLASH model.

The shoaling curves are used: (a) for comparing the peak surge potential at one location to another, along the Gulf and East coasts, provided the storm characteristics are the same; (b) for pointing out critical coastal areas to planners and developers; (c) for guiding climatologists in collecting and processing hurricane data; and (d) for giving meteorologists information on the isobathic effects on surge along coastal areas.

The shoaling correction curves, localized for each basin, are used even more extensively. In NOAA's work for flood insurance projects, a shoaling correction curve is used to redefine the surge envelope for variable landfall points along the coast, without additional computer runs. Shoaling correction is very convenient for the frequency method of NOAA for estimating flood potentials on the outer coast. In studies for a coastal county, the outer coast tide frequency curve is based on many hypothetical hurricanes determined from hurricane climatology. Because of shoaling corrections, it is not necessary to run the SPLASH program with these storms at successive landfall points on the coast; it is only necessary to run storms for one landfall point.

In operational use of SPLASH, we provide the forecasters with two additional surge envelopes based on landfall point left or right of the forecast landfall. Additionally, the peak surges for the 600-mile long basin are included in the output for any conceivable landfall point in the basin. We are able to provide this extra information because of shoaling correction curves.

We showed the SPLASH run for hurricane Camille 1969. The comparison between the observed and computed surges is quite good; although it is not perfect. Similar runs have been performed for many other historical storms.

Since there are many storm parameters which can be adjusted, as well as coefficients in the equations of motion, a model comparison against a single event does not constitute verification. Our model was verified against 43 actual recorded storms along the Atlantic and Gulf coasts and has been field tested for six hurricane seasons. The calibration for our model is in a global (not local) sense, and no attempt was made to force agreement between computed and observed results for particular storms in local regions. This is one reason why our verification for hurricane Camille is not perfect.

Simple versions of SPLASH are being used in the Philippines, India, and Hong Kong. SPLASH was modified for application to these countries because they don't have similar big computers as the U.S. They told us that satisfactory results were obtained in the SPLASH applications for their areas of the world.

ACKNOWLEDGMENTS

We are grateful to Jye Chen and Mark Flaherty for their help in preparing the basins and shoaling corrections and to Mercedes Bakon for the typing of the manuscript.

CHAPTER 57

CURRENTS IN TIDAL FLATS DURING STORM SURGES

by Harald Göhren *)

Wind action in the viewpoint of coastal engineering is mainly a topic for discussions or investigations of waves, breakers, storm surges, sand transport on beaches and so on. Offshore currents, generated by wind shear stress concern more the scientific field of oceanographers.

But in shallow coastal water windinduced drift currents indeed may be important for coastal engineering problems, as sediment transport, sewage spreading, salinity and so on. For example, along the German North Sea Coast (Fig. 1) we have a rim of extended tidal flats, built up by sand and mud and covered only by a water layer of 1 to 2 m at high tide. At low tide sands and mud flats fall dry. Fig. 2, an aerial view, gives an impression of a typical tidal flat, the "Neuwerker Watt" at the south side of the Elbe Estuary. The distance between main land and the sea side border of the flat is here about 20 km. A lot of investigations have been carried out here - initiated by a harbour planning task - giving some interesting results about currents in the tidal flat area during strong winds and storm surges.

For the current measurements a recording current meter (Fig. 3) has been used, fixed at a tripod aluminum frame in 40 cm above bottom. The propeller meter starts at velocities of 5 cm/s. Tests in a flume proved that orbital currents give no disturbance if unidirectional currents of a certain magnitude are superimposed.

*) Strom- und Hafengebäude Hamburg, W. Germany

Fig. 1 Tidal Flats in front of the German North Sea Coast

Fig. 2 Aerial View of the "Neuwerk" Tidal Flat

The diagram in Fig. 4 presents a typical example of one measurement of 17 days duration, including a severe storm surge (2.11.1965). Velocities are comparatively small at normal tides, in maximum 30 to 40 cm/s. Directions are adverse in flood and ebb tide. Towards the end of the observation period wind increases to 8 and 9 Bft, blowing from west, that means coastwards. Water level raises and a storm surge occurs on 2. November. The currents increase with wind speed and exceed about 1 m/s in the storm surge. Current directions obviously are influenced - the adverse ebb and flood current is substituted by a more unidirectional movement towards northeast, that means in the direction of the acting wind shear stress.

The wind influence can still better be seen at another graph (Fig. 5) of the same measurement - it is a plot in form of a vectorial track, adding the consecutive data of velocity and direction. The zero point is at tide Nr. 564. The residual flow of the first 15 tides - to Nr. 580 - is comparatively small. The wind induced water motion starts with a significant turning of the vectorial track towards north-east. The residual current velocity increases up to 20 km/tide and more in the storm tides Nr. 590 and 591.

This is a single but typical result. A lot of data of that kind have been collected, suitable for some statistical evaluations. Fig. 6 presents the data of 50 storm surges, stemming from different stations.

In the upper diagram frequency curves of maximum velocities at normal tides and storm tides are compared. At normal tides there is a peak at 30 cm/s, that is the average maximum velocity in tidal flats. The storm surge frequency curve covers the range from 40 to 120 cm/s.

In the lower diagram a frequency curve for the relationship storm tide velocities over normal tide velocities is plot-

Fig. 5

Currents plotted as Vectorial Track Containing a Storm Surge (s. Fig. 4)

Fig. 6

Frequency of Maximum Velocities in Tidal Flats

ted. Here again a significant peak exists indicating that during storm surges the maximum velocities in tidal flats in average increase about 100%.

Fig. 7 presents curves of residual current velocities over wind speed, again evaluated from some hundred measurements at different stations. The scale in the upper plot is km/tide and the increase of residual current with wind speed - about 1 km at normal tides and about 12 km/tide at storms of 8 Bft and more - is remarkable. But this curve includes the longer duration of water cover in the tidal flat due to the raising water level. This effect is eliminated in the lower diagram with a scale of cm/s for the magnitude of the residual current. In the same range of wind velocities the residual current increases from 5 to 30 cm/s. Especially these statistical results may be helpful for example for estimations of sewage spreading under different wind conditions.

Of special interest is the dependency of current direction. Flume tests and simple mathematical models show that in a rectangular basin we have a flow in the direction of the wind shear stress in the upper layer and an adverse flow beneath that layer, the boundary being $2/3$ over bottom. The current meter used in the field program measures 40 cm above bottom, so that the records present mainly the bottom layer. There is no motion adverse to wind direction in the tidal flats in this layer. This was already shown in Fig. 4 and 5 and is proven by the Fig. 8, presenting residual currents from a simultaneous measurement at 5 different stations over 17 days plotted as vectorial tracks. At the beginning - tides Nr. 600 to 610 - there is no wind stronger than 4 Bft. This part of the track presents normal tidal currents. After that a wind period begins, the wind velocity increasing up to 10 Bft and turning from south-west over west, north-west and north to south-west again. The track of the residuals

Fig. 7 Residual Current over Wind Speed

Fig. 8 Residual Currents influenced by Wind

follows that changing of wind direction. Fig. 10 gives another statistical evaluation. At one station inmidst of the Neuwerker tidal flat continuous measurements over two years have been carried out. The collected data of current directions in a 5 minute sequence were classified in groups of wind direction and wind velocity and plotted in the form of direction frequency schemes. With increasing wind velocity the normal tide direction pattern changes and currents in wind direction prevail.

It is to expect that the adverse flow in the bottom layer, which must be present to counterbalance the water transport in the upper layer in wind direction, occurs in the gullies and channels of the shallow water areas. This is proven by Fig. 11. From all measurements with considerable wind influence drift current vectors were computed by a vectorial subtraction of wind induced residual currents and normal tidal residual currents. This vector presents the pure wind influenced current under the assumption that there exist a simple superimposition of tidal and wind induced currents. This is of course a rough approximation. Then the angles between wind direction and drift current directions were computed and plotted as frequency curves. These data include measurements from the bottom layer in the channels and gullies. The left curve presents the frequency of difference angles for the tidal flat, the right curve for the channels. There is a very clear tendency that in the shallow water drift currents prevail in wind direction while in the deeper layer of the channels (superimposed to the much stronger tidal currents) a flow adverse to the wind sheer stress exists.

The question of vertical distribution of the described current pattern is of great interest, but difficult to investigate as waves prevent accurate measurements in the surface layer and tidal currents are superimposed. Flume tests and theoretical considerations show that there is a

strong decrease of velocity in the surface layer (Fig. 12). To get some field data a special station with 3 current meters was set up in levels of 0.4, 1.4 and 2.4 m above bottom. The upper instrument was only to work at higher water levels i.e. at storm surges.

Good observations during a storm surge in December 1966 were obtained. Fig. 13 presents the most interesting part of the record. The three current meter levels a), b) and c) are marked. Neglecting some parts during raising and falling water where the upper meter may be disturbed by waves, a significant but comparatively small decrease of velocities over depth can be seen. There is no indication of a strong velocity gradient as shown in Fig. 12.

Using the data from the two lower instruments it was tried to evaluate a relationship between velocity gradient and wind speed (Fig. 14). Though there is a considerable scattering, the plot indicates that the velocity gradient decreases with increasing wind velocity up to a wind speed of 10 m/s. From this point the gradient increases with further increasing wind velocity. This result can be explained as follows: At calm weather currents at that measuring point are very small - 10 to 20 cm in average. This is a more laminar motion which indeed should have a higher gradient. Increasing wind speed leads to waves and higher turbulence with the effect of a decreasing gradient. But from a certain point - here at a wind velocity of 10 m/s - the gradient increase due to the laws of wind generated flow becomes predominant.

CHAPTER 58

TSUNAMI PROPAGATION IN THE PACIFIC OCEAN

by

Manfred Engel⁺ and Wilfried Zahel⁺⁺

ABSTRACT

The Alaska tsunami of March 28, 1964, caused by a tectonic uplift, propagated across the Pacific Ocean and was even recorded at the shores of New Zealand and the Antarctica. The large distance propagation of this tsunami is investigated by a numerical model based on the shallow water equations. The model includes bottom friction, eddy viscosity and Coriolis acceleration and yields the water elevation and the vertically integrated current velocity. The generation mechanism is given by a simplified initial condition, that is derived from the observed average uplift of 1.8 m for an area of 110000 km² on the Continental Shelf. The computed tsunami propagation is presented by means of the first wave travel time and height on Pacific Ocean maps and by giving sea surface time series for selected stations. These computed results are compared with observations, especially considering the limitations of the model due to the coarse grid net having been used.

INTRODUCTION

Research of tsunami hydrodynamics until now seems to be split up into three parts: generation mechanisms, propagation of tsunamis in open ocean, amplification and run up at coasts. A great variety of methods is used for these investigations, such as model building on the basis of analytical or numerical solutions to the hydrodynamic equations and carrying out experiments with hydraulic models of the prototypes.

The present contribution shall be understood as an attempt to simulate the open ocean propagation of an actual tsunami by hydrodynamic-numerical modelling considering as many physical properties as possible. Use was made of a 1°-World-Ocean-model, that yielded realistic results when it was applied to the computation of oceanic tides by ZAHEL, 1975. Because of the far smaller characteristic wave lengths of tsunamis, some preinvestigations had to be performed in order to throw light upon the question, whether the grid net resolution suffices to comprehend the main features of tsunami propagation and initiation. Reference will be made to these considerations in the Chapter PREINVESTIGATIONS.

The 1964 Alaska tsunami was characterized by an extended uplifted area with an average sea surface elevation of 1.8 m and by

⁺ Institut für Meereskunde, Universität Hamburg

⁺⁺ do.

a period of about 1.3 hours of the radiated wave (BERG et al., 1972). Because of these relatively proper conditions for the application of the available model we decided to simulate this actual tsunami. A description of the model is given in the Chapter THE HYDRODYNAMIC MODEL, the grid net arrangement and the numerical treatment of the differential equations are outlined there.

The Chapter COMPUTATIONAL RESULTS contains a discussion of the computational results in view of observations. The distributions of propagation times and heights of the first crest are presented on Pacific Ocean maps, time series of the surface elevation are given for selected positions being as near as possible to gauge positions and originating from all over the Pacific Ocean.

PREINVESTIGATIONS

In order to get an insight into the problems of a large scale numerical tsunami propagation model, we first ran some one-dimensional models. Especially the usefulness of a 110km-grid-resolution with respect to the propagation of the main wave train had to be investigated. As already can be seen from the dispersion relation yielded by the explicit difference equation scheme, the phase velocity for waves with periods longer than 1.3 hours, a value which was observed in connection with the Alaska tsunami, is only insignificantly falsified by the applied numerical treatment in deep ocean areas. Also the decay time due to eddy viscosity remains proportional to the square of the wavelength and to the inverse eddy coefficient for such long period waves in the numerical procedure, so they are insignificantly affected by eddy viscosity while propagating across the Pacific Ocean. Because of the exclusion of small scale processes in the model the convective terms were neglected. A simple shelf radiation model, allowing no reflection to take place at the right hand side open boundary, gave a good impression of the continuous energy radiation from the shelf area for a given initial water elevation distribution (Fig.1). This distribution was well resolved by the used grid net with a spatial grid point distance of 7.4 km. Against that the global model is far from being able to take care of a realistic generation mechanism, only the estimated potential energy of the realistic uplift in the generation region could be considered.

In a $1^{\circ} \times 2^{\circ}$ -testing-model two different schematic distributions of the uplift with the same potential energy content were prescribed, one with different uplifts, the other with a uniform uplift at the eight marked grid points. Fig.2 shows the travel times of the first wave crest for both tsunamis thus having been initiated, that means there is no difference appearing within the accuracy of the plot. Because of this conformity in travel times we finally ran the global model for the Alaska tsunami with the simplest generation mechanism, a uniform initial surface elevation of 2 m at these grid points, the initial potential energy amounting to 2.0×10^{22} erg by this way.

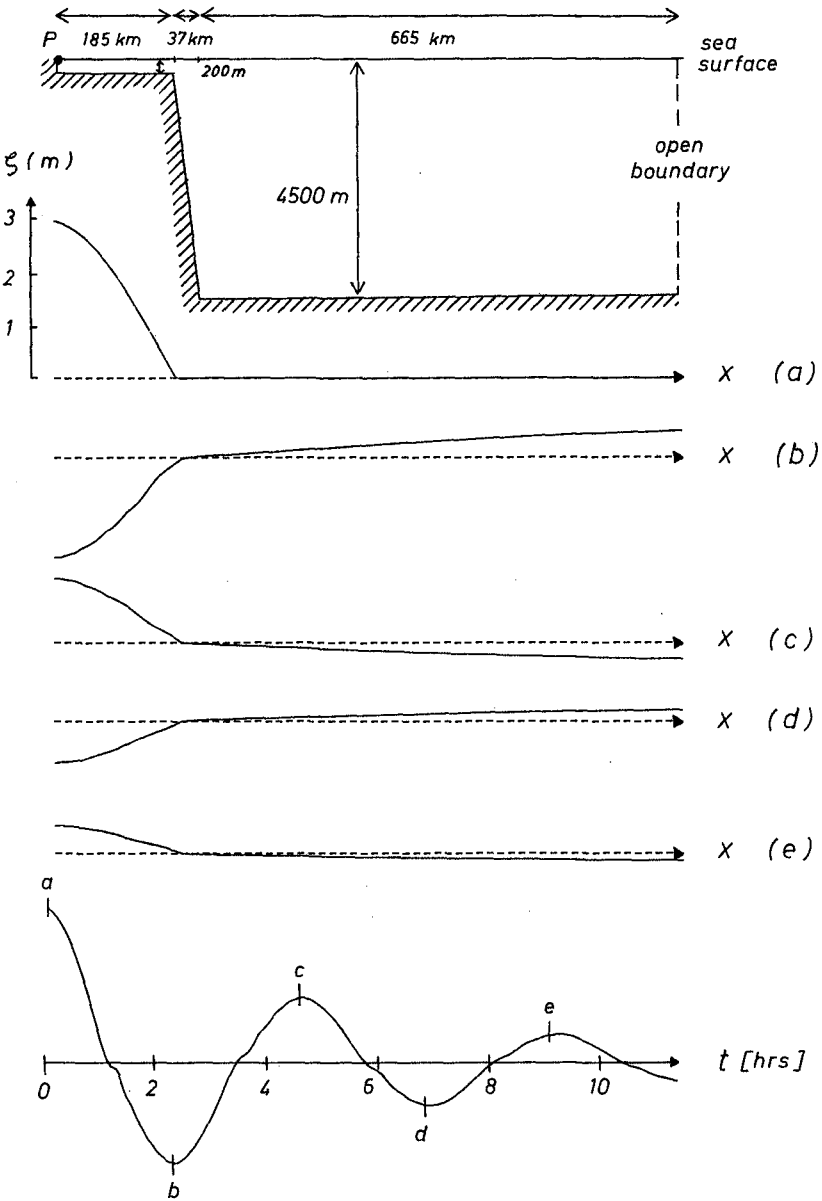

Figure 1. Distribution of sea surface elevations in space and time(at Point P) for computed wave radiation from an idealized shelf.

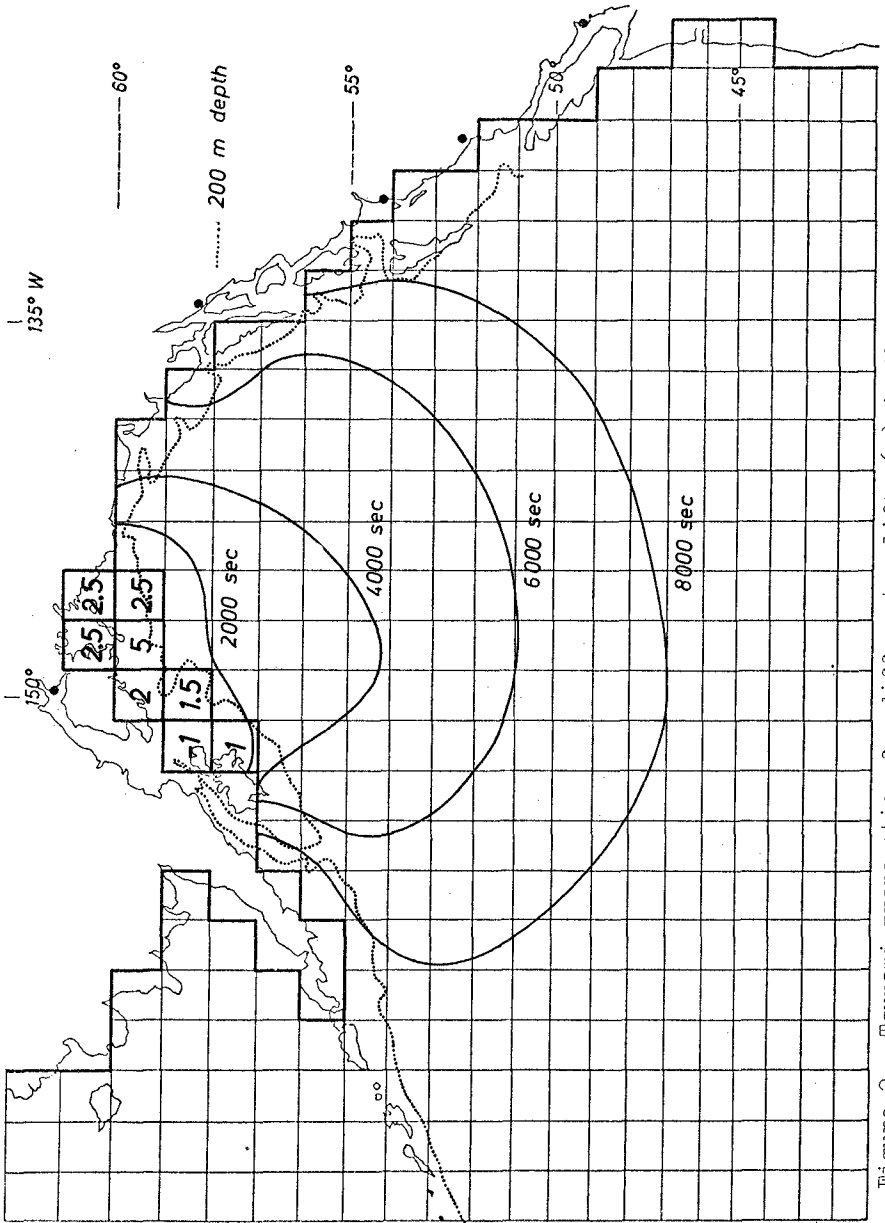

Figure 2. Tsunami propagation for different uplifts (m) in the source area.

THE HYDRODYNAMIC MODEL

The model has already been used for ocean tide investigations by ZAHLE, 1975 and it was developed from that one presented by ZAHLE, 1970 in detail. The equations of motion for long waves and the equation of continuity are taken as a basis for the model. With t =time, λ =geographic longitude, φ =geographic latitude they are given by:

$$\frac{\partial u}{\partial t} - 2\omega \sin\varphi v + \frac{r(u^2+v^2)^{1/2}}{D} u + R\lambda + \frac{g}{R \cos\varphi} \frac{\partial \zeta}{\partial \lambda} = 0$$

$$\frac{\partial v}{\partial t} + 2\omega \sin\varphi u + \frac{r(u^2+v^2)^{1/2}}{D} v + R\varphi + \frac{g}{R} \frac{\partial \zeta}{\partial \varphi} = 0$$

$$\frac{\partial \zeta}{\partial t} + \frac{1}{R \cos\varphi} \left(\frac{\partial (Du)}{\partial \lambda} + \frac{\partial (Dv \cos\varphi)}{\partial \varphi} \right) = 0$$

$u=u(\lambda, \varphi)$, $v=v(\lambda, \varphi)$ denote the vertically integrated current velocity components, eastward and westward respectively, $D = d + \zeta$ the actual depth and $\zeta = \zeta(\lambda, \varphi)$ the surface displacement. The lateral eddy viscosity terms

$$R\lambda = A_h \Delta u + A_h R^{-2} (-u(1 + tg^2\varphi) - 2 \frac{tg\varphi}{\cos\varphi} \frac{\partial v}{\partial \lambda})$$

$$R\varphi = A_h \Delta v + A_h R^{-2} (-v(1 + tg^2\varphi) + 2 \frac{tg\varphi}{\cos\varphi} \frac{\partial u}{\partial \lambda})$$

roughly take account of turbulence effects on the mean flow. A_h is a constant coefficient, $A_h = 10^5 \text{ m}^2/\text{sec}$ is assumed in this case.

As the model is a global one, the domain of integration of the differential equations is only bounded by coasts, which are defined to be impermeable. Therefore the normal component of the current velocity is assumed to be zero at the boundary. Provided that proper initial conditions are prescribed, this condition uniquely determines the solution of the first order equation system. The inclusion of the second order term requires the further homogeneous boundary condition of zero current velocity. The initial conditions defining the tsunami generation mechanism, in strong simplification are given by an uplift distribution of the sea level and zero current velocity at $t = 0$.

Although in the present problem the polar regions are unimportant, the numerical procedure shall for completeness briefly be described as it is applied to the world ocean as a whole. In order to avoid a strong reduction of the grid-point-distance due to the convergence of meridians, poleward doubling of the zonal angular grid-point-distance is performed at five parallels, namely at 55°N, 55°S, 72°N, 72°S, 81°N. Hence the grid net covering the globe is characterized by a mesh size of 1°x1° between 55°N and 55°S, of 1°x2° between 55°N and 72°N as well as between 55°S and 72°S, of 1°x4° southward of 72°S as well as between 72°N and 81°N. Finally, northward of 81°N adjacent grid points are 1° distant on a meridian and 8° distant on a parallel, respectively. The parallels defining the mentioned transitions are marked on Fig.3, which shows the approximated coastlines and the bottom topography that is used in the model.

The numerical scheme has been used in the following form :

$$D_+^t u_{i,j}^n - 2\omega \sin\varphi_i \bar{v}_{i,j}^n + \frac{r\sqrt{(u_{i,j}^n)^2 + (\bar{v}_{i,j}^n)^2}}{D_{i,j}^n} u_{i,j}^n + (R\lambda)_{i,j}^n +$$

$$+ \frac{g}{R \cos\varphi_i} (D_0^\lambda \zeta_{i,j}^n a(\varphi_i) + D_0^\lambda \zeta_{i,j}^{n+1} b(\varphi_i)) = 0$$

$$i=1,3,5,7,\dots ; j=1,3,5,7,\dots$$

$$D_+^t v_{i,j}^n + 2\omega \sin\varphi_i \bar{u}_{i,j}^n + \frac{r\sqrt{(\bar{u}_{i,j}^n)^2 + (v_{i,j}^n)^2}}{D_{i,j}^n} v_{i,j}^n + (R\varphi)_{i,j}^n +$$

$$+ \frac{g}{R} (D_0^\varphi \zeta_{i,j}^n) = 0 \quad i=0,2,4,6,\dots ; j=0,2,4,6,\dots$$

$$D_+^t \zeta_{i,j}^n + \frac{1}{R \cos\varphi_i} (D_0^\lambda (D_{i,j}^n u_{i,j}^{n+1}) + D_0^\varphi (D_{i,j}^n v_{i,j}^{n+1} \cos\varphi_i)) = 0$$

$$i=1,3,5,7,\dots ; j=0,2,4,6,\dots$$

$$D_+^t w := \frac{w(t+\Delta t) - w(t)}{\Delta t} ; \quad D_0^\psi w := \frac{w(\psi+\Delta\psi/2) - w(\psi-\Delta\psi/2)}{\Delta\psi} \quad \psi = \lambda, \varphi;$$

$$w_{i,j}^n := w(i\Delta\varphi/2, j\Delta\lambda/2, n\Delta t) \quad w = \zeta, u, v ; \quad a(\varphi_i) + b(\varphi_i) = 1$$

$0 \leq a \leq 1$, $0 \leq b \leq 1$. Except from a small neighbourhood of the North Pole $a=1$, $b=0$ is taken. Thus the applied time stepping scheme is explicit in the area of tsunami propagation in question. The only transition from one uniform grid net to another in this area takes place at 55°N . Because of technical reasons arrival times and surface elevations of the first maximum were only stored for the $1^\circ \times 1^\circ$ area and for the Gulf of Alaska separately, so that this information was lost for the Bering Sea north of 55°N , as can be seen on Fig.5 and Fig.10.

To give an impression what global results gained by this 1° -model look like, amplitudes and phases of the rather well reproduced M_2 -tide are presented on Fig.4, which is taken from ZAHTEL, 1975. When computing tsunami propagation, calculations are, of course, not performed for areas where the tsunami will not get in the time of interest.

The same hydrodynamic method was applied by ENGEL, 1974 to tsunami simulation in the Black Sea.

COMPUTATIONAL RESULTS

To give an idea of computed tsunami propagation properties we at first refer to the propagation time of the first maximum. The isolines of this time, that can better be defined than the arrival time of the first disturbance, are displayed on Fig.5. Due to the applied simple generation mechanism even the tsunami propagating in the open ocean will differ from the real one when being computed by the η^0 -model. This fact gets obvious when considering e.g. the slow ascent of the computed water level compared with the real one at certain oceanic islands. Nevertheless, it is expected from the computations, having been carried out on the basis of a hydrodynamic model, that the characteristic features of the radiated long wave are yielded concerning its propagation in the open ocean. In order to give an impression of the effects of depth distribution on the wave propagation, the lines of equal depth have been entered into the presentation. There are obvious features as to the deformation of travel time isolines due to the bottom topography as e.g. the high speed propagation in the central South Pacific and the comparatively delayed propagation through the shallower parts of the south-eastern Pacific. Refraction effects gathered from Fig.5 at the transition zone from the open ocean to the American coast are evidently not realistic in all cases because of the poor resolution of the narrow shelf there. An improvement of the results, concerning phenomena that arise on small scale areas, could be obtained by including nested grids into the global one. A very distinct effect due to reflection can be recognized at the Japan Trench as well as at the Kuril Trench. While the reflected wave contributes to the formation of the first maximum, superposition with the arriving second wave takes place before the first one has reached its maximum, and in this way the particular propagation pattern comes about. Other effects of reflection cannot be detected from the presentation of the first maximum, although, of course, being fully inherent in this model.

Before comparing computed arrival times with gauge observations, some limitations of the model shall be summarized. As the wave generation was performed rather schematically, the computed wave train only reflects the gross features of the shelf source area and the initial condition in sea level variation and current velocity and therefore it cannot be considered to be directly comparable with the real one. The phase velocity in any numerical model is subject to discretization errors depending on the difference scheme, on the grid resolution and on the wave length governing the physical process being modelled. The described η^0 -model admits long waves with at least thousand kilometers wavelength to propagate in the deep ocean with a phase velocity deviating less than 1 per cent in magnitude from the real phase velocity. A somehow generated wave train containing a broad spectrum of wave lengths will at all events be dispersed numerically. The leading wave of the investigated Alaska tsunami, characterized by a period of 1.3 hours, thus proves to be long enough in deep water to be subject to an appropriate approximation concerning the phase velocity. On extended shelf areas, like that of the Yellow Sea, the computed wave properties are unreliable because of numerical dispersion effects.

Moreover the poor resolution of shelf areas extending in front of coasts leads to insufficient approximation of the wave arriving at the coast, since gauge records coming from such coasts are characterized by the response behaviour to the local topography. As the most available gauge records refer to such positions, computed and observed values can also for this reason not directly be compared.

The positions for which the water elevations have been printed out for every time step are marked on Fig.6, they are close to places where gauge data were gained. Fig.7 and Fig.8 show the computed water elevations at these locations, with the arrival time of a significant disturbance, defined by a water level rise of 2 mm and indicated by the beginning of the curves. The longer vertical lines represent observed arrival times, taken from the gauge records published by SPAETH and BERKMAN, 1967 and others. The above remarks are applicable to the comparison at the mentioned positions, showing itself by the fact that opposite to the observations the computed water elevations yield similar curves for all stations. There is an almost constant time difference between the computed first disturbance and the first wave crest, it amounts to about 65 minutes. Hence, taking this first disturbance instead of the first wave maximum when representing tsunami propagation, a picture of high similarity to that one given on Fig.5 would result. In all cases the observed arrival time is later than the computed one, the difference running up to about 10 minutes except for Galapagos and Lyttelton, where it is nearly 3 times larger. The relatively large time difference at Galapagos may result from the fact that the gauge position at San Cristobal is located farther from the source area than the nearest grid point, which moreover lies on the other side of the island. Because of its backward position in a bight there are similar difficulties in adjoining a grid point to Lyttelton. Finally, it proves to be difficult to recognize a 2 mm disturbance on a gauge record in any case.

Three N-S-surface profiles are plotted on Fig.9, beginning in the source area and extending southward as far as the wave has propagated. As can be seen also from this picture, the form of the leading wave is preserved, although its energy decreases successively. To get an idea of the spatial energy supply, reference to at least the surface elevations shall be made. Fig. 10 shows the computed surface elevation of the first wave maximum in mm. Effects of bottom topography can easily be recognized, e.g. regarding the increased magnitude of elevations at the Hawaiian Ridge, at the north-east coast of Australia and at the American coast. Obviously these surface elevations are not suitable for being compared with the observed ones, they at best can be hoped to be a first approximation for the wave entering coastal areas.

Thus applying the global hydrodynamic model to the 1964 Alaska tsunami is understood as a first step in trying to bridge the gap between investigations concerned with generation mechanisms and those studying run up processes. No model can explicitly include all physical processes governing tsunamis, and therefore besides the application of nesting techniques parameterizations

of significant processes will have to be introduced, in order to achieve an overlapping modelling of generation, propagation and run up of tsunamis that will be of use for practical purposes.

CHAPTER 59

TRANSFORMATION OF TSUNAMIS IN A COASTAL ZONE

Shigehisa NAKAMURA¹⁾

Haruo HIGUCHI²⁾

and

Yoshito TSUCHIYA³⁾

ABSTRACT

In order to obtain fundamental informations to establish warning practices and effective countermeasures against the tsunamis on the coast, the authors have studied on refraction of the tsunamis propagating into Osaka Bay and on tsunami spectra. The refraction of the tsunami is studied by a numerical computation for a program of refraction and shoaling of small amplitude wave. An example is shown for Chilean Tsunami in 1960 to reveal that the refraction is an important factor to study on the tsunami wave height distribution along the coast of Kii Peninsula and Shikoku Island. The mareograms of the tsunamis are analyzed to obtain power spectra to study on transformation of the tsunamis from the Pacific Ocean to the head of Osaka Bay. The result suggests that it is necessary to be careful to study on transformation of the tsunamis with use of the refraction diagram because the tsunami is not a simple monochromatic and small amplitude plane wave. A brief remark is given for the analysis of the tsunami as non-stationary process.

1. INTRODUCTION

There are various kinds of the external forces acting on the coast. The occurrence of tsunami is one of the remarkable phenomenon in relation to the destructive suffers on the coast. And it is not yet solved the protection of the tsunami at present even though many efforts have been concentrated to the tsunami. On the other hand, in these years, reclamative land use for the industrial zones and the higher utilizations of the coastal zone have become triggers to increase and spread the destructive suffers. Now, it is necessary to study and solve the problems of the tsunami in order to give any effective countermeasure for it. In this paper, at first, a reviewal remark is given. And then, refraction characteristics of tsunami is studied through a numerical computation for Chilean Tsunami in 1960 as a small amplitude wave. And the actual existing tsunamis are not necessarily similar to the exact small amplitude wave but the finite amplitude wave in the coastal zone. Tsunami spectra are studied as a linear transform of the mareogram of the tsunami as a stationary stochastic process, and after that, a remark is given to be studied it as a non-stationary process.

2. REVIEWAL REMARKS

As for Kwanto district and Tokyo Bay, the surveys and researches have been concentrated to solve the problem (for example, since Meiji Era (Omori, 1918)). In the recent years, a countermeasure is introduced as a political practice referring to the results of the researches (for example, Kawasumi, 1969). And as for Ise Bay, a similar countermeasure is offered in a report by Iida (1975). By the way, there have been no researches and surveys for Osaka Bay systematically. It might be a fresh report by Tsuchiya and Nakamura (1974) that is related to a filing of the data and an analysis of the tsunamis propagated into Osaka Bay. They have focused to the mareograms of the recent tsunamis which gave any significant influences to the water level in Osaka Bay from the reports published in the past and the filed mareograms in Osaka District Meteorological Observatory in order to analyze and clarify the mechanisms of the propagation and transformation of the tsunamis. They have traced the historical procedures for the tsunamis, for example, the geographical distributions of the tsunami heights, the travel time of the tsunami fronts, refraction diagrams of the tsunamis etc. The authors have also studied on the tsunami spectra (Nakamura et al., 1976).

The studies on the tsunamis in the past, for example, the geographical distributions of the tsunami wave heights, had been studied with a little consideration on dependency of the refraction of the tsunamis. It might be caused by the difficulty of the surveys of the tsunami refractions in the past. The authors would like to introduce a refraction diagram with use of high speed electronic computer to study the propagation of the wave front, the wave ray, the shoaling effect caused by the water depth, the transformation of the wave caused by refraction etc. They have focused to study on the transformation of the wave by refraction and shoaling.

Adding to that, a method of ocean wave spectrum is introduced into the study on the transitional phenomena of the tsunamis to treat the tsunamis as a stationary Gaussian processes to obtain the tsunami spectra. The transformation of the tsunami spectra is also the authors' interest in this paper. Spacial and time dependent transformation of the waves are considered for the tsunami spectra. And a remark will be given for the tsunami spectral analysis as non-stationary process.

3. REFRACTION DIAGRAM

Judging from the results of the surveys, the researches (for example, by Iida, 1956) and the tabulated catalogues (Imamura, 1942; Iida et al., 1967; Soloviev and Gao, 1974) concerning the tsunamis on the coast of Japan, it might be statistical expect that the one third of the earthquake exceeded Richter's magnitude $M = 6$ those of which had occurred around Japan Islands has the epicenter under the sea, and the one third of the earthquakes which had occurred under the sea accompanied the tsunamis to attack the coastal zone of Japan. In Japan, the records concerning the tsunamis can be found since the seventh century.

The tsunamis which have propagated into Osaka Bay are included not only in the tabulated records introduced above but in the records of the tsunamis occurred off the Aleutian arc, off Alaska and off South America propagated across the Pacific Ocean to attack the coast of Japan Islands. One of the examples is

Chilean Tsunami in 1960 which is surveyed and observed along the coast of Japan Islands exactly and in the detail as far as possible by the organized group in Japan. The refraction diagrams are drawn from the wave source in the neighbour of the coast of Japan by Meteorological Agency of Japan, University of Tokyo and the other related organizations(1961).

In this section, Chilean Tsunami in 1960 is taken as an example in the tsunamis propagated into Osaka Bay, because the details and the accuracy of the data and the records of Chilean Tsunami in 1960 are reliable and abundant in comparison to the other tsunamis.

In order to find the process of the propagation of Chilean Tsunami in 1960, a schedule is arranged to draw a refraction diagram from the Pacific Ocean to Osaka Bay by a numerical computation and a manual drawing. For a convenience of practice, the authors referred to the refraction diagram of Chilean Tsunami in 1960 by Meteorological Agency of Japan, in which the location of the tsunami front just arrived at the south of Shionomisaki is taken as a boundary to start the computation and to draw the refraction diagram of the tsunami propagating into Osaka Bay. A schematical topography from the Pacific Ocean to Osaka Bay is shown in Fig.1. And for a convenience of analysis, the wave heights are assumed to be same along the line which is introduced above as the boundary for the in-put data.

The manual drawing of the refraction diagram is obtained under the assumption of the tsunami as a long wave and with the considerations of the effects of the water depth and of refraction. This manual method has been widely utilized for studying on the propagation of the tsunami fronts and for estimation of the source areas of the tsunamis. As the first step to construct a refraction diagram the wave fronts are drawn time to time successively at a given time step, after that the wave rays are drawn as the orthogonals to the wave fronts. And the wave transformation in height may be estimated to apply Green's formula to the water depth and the width of the neighbouring two wave rays for a linear theory.

On the other hand, a method to use a high speed electronic computer is introduced to obtain the refraction diagram of the tsunami. In this case, the tsunami is assumed to be a small amplitude wave to apply the computer program for refraction of wave, which is developed by Worthington and Herbich(1970) in Texas A and M University.

In order to practice the computation, the areas are taken as shown in Fig.2. Initially the wave front is assumed to be located on the line stretching toward southwest from off Kushimoto. The line forms a part of the large square(about 160 km square). And the wave front is assumed initially to propagate perpendicular to the initial line, which is taken to approximate to a line corresponding to a wave front of Chilean Tsunami in 1960 off Nankaido at a certain time.

For the first step of the computation, the large square is divided to form a mesh with the points of 15×16 , in which the water depth is given by an interpolation from the nautical charts published by Hydrographic Office, Maritime Safety Agency of Japan.

The results of the computations are shown in Figs.3 and 4. In the computa-

tions, the period of the wave is taken to be 30 min. In Fig.3, the wave rays and the wave fronts at every one minute are shown by the solid lines and the dot lines respectively. The refraction coefficient and the shoaling factor are obtained at the same time at the each step of the computations. Relative wave height is also obtained by a product of the refraction coefficient and the shoaling factor. The result is shown by curves in Fig.4, which are characterized by a parameter to indicate the relative wave height referring to the initial wave height.

After the computation in the first area, the twenty two small areas of square (about 15 km square) with the mesh points 25×25 are considered to practice the successive computations from the open ocean to Osaka Bay under the consideration of the availability of the computer at the Data Processing Center of Kyoto University. The wave directions of the last steps in each area are the next initial data of the wave directions as the in-put data. For the practical computation, one of the authors, Tsuchiya, has insisted not to fail the generality of the small amplitude wave in the application of the computing program to the tsunami so that no approximation and no simplification of the equations are considered except the numerical truncations even if the cpu time in the computation is elongated.

As the result of the computation in the first area, it is easily found that the wave front needs more than twelve minutes to travel from off Kushimoto to the entrance of Kii Channel, if the given wave front behaves similar to the tsunami. And, only two or three rays initiated not far from the coast in Fig.3 are passing Kii Channel. The wave rays far from the coast attack the coast of Shikoku Island, on the way to which the wave rays are strongly refracted by the effect of the water depth in the area of the large square. The wave rays in Fig.3 are quite similar to those in the refraction diagram obtained by Nakamura(1974) manually.

In these computations, the wave height and direction are assumed to be uniform along the initial line. Through the successive computations, the wave heights are obtained on the wave rays at each step of one minute. The estimated wave height distribution along the coast of Kii Peninsula from Kushimoto to Osaka is shown by the curve A in Fig.5. The abscissa is a convenient distance from Kushimoto and the wave height referred to that at Kushimoto is the ordinate. The curve B is the estimated wave height distribution obtained by the computations along Awaji Island. And the curve C is the wave height distribution estimated along the axis of Osaka Bay from Tomogashima Passage to Osaka. The dots and circles are the observed heights of the first and the second wave respectively. The simple dots and circles are the data along the coast of Shikoku, Awaji Island and Kobe. The crossed dots and circles are the data along the coast of Kii Peninsula. For the region from the open ocean to Tomogashima Passage ($0 \leq x < 110$ km), the observed wave heights are much smaller than the computed ones and the second wave heights are fairly good correspondence to the computations. In Osaka Bay, the observed wave height is a few but seems to be good agreement to the computed wave height distribution along Awaji Island (curve B). Although, the computed wave height along the axis of Osaka Bay (curve C) cannot be expected as an actual phenomenon. The curve C is anomalous as an actual trend, which might be caused by the given conditions and the matching conditions in the computer program through the successive computations. The authors have been aware of that it is necessary to effort to avoid the unstable results appearing in the computation of the long period waves in the very shallow water. At the cross point of the wave

rays, the computed wave height is anomalously large as far as the computation is referred to the linear theory of wave refraction. In the successive computation, the initiative of the wave direction is essential. And this might be a cause of an undesirable result. Adding to that, it is necessary to remark that no reflection is considered through the computation.

Judging from these refraction diagrams and the analysis, the wave height of Chilean Tsunami might be not so large as the computed results along the axis of Osaka Bay and not so small as the expected results from the hand written refraction diagram. It is necessary to consider not only a simple travel time of the tsunami for a glance but the wave rays or the effect of refraction when the arrival time of the tsunami at the coast is discussed.

There have been obtained and collected the records of the tsunamis caused by the earthquake off Tonankai in 1944, off Nankaido in 1946, off Alaska in 1964, off Aleutian arc in 1965, Hiuganada in 1968 and the others. Even when these records are only reliable ones, the authors may expect that the wave height at the head of Osaka Bay cannot be larger but much smaller than the wave height at Kushimoto.

It is necessary to remark that the initial wave front is different from the exact location of the wave source. And the essential remarks are that the tsunamis are the phenomena of transitional rather than a linear long wave or a small amplitude wave, so that the discrepancy is more or less inevitable between the computed results and the observed wave heights. The tsunamis are not necessarily periodical, so that frequency analysis or spectrum analysis should be also introduced to study on the mechanism and the characteristics of the tsunamis.

4. TSUNAMI SPECTRA

The concept of the tsunami spectrum might be originated and introduced to detect what component of frequency is dominant in the mareogram including a tsunami. When the water level as a time series is assumed to be a stationary Gaussian process, the method of the spectrum analysis might be useful in studying the frequency characteristics of the tsunami.

The introduction of the spectrum analysis in the problem of the tsunamis might be carried out at first by Takahashi(1961a,t). And recently, the records of the tsunamis in the world have been compiled at International Tsunami Information Center(for example, ITIC,1975) to offer the records as well as the informations and contributions of the latest tsunami spectra analyzed with use of Fast Fourier Transform(or FFT). As mentioned by Kajiura, it is essential to study what length of the data is necessary in obtaining the tsunami spectrum. On the other hand, one of the authors, Higuchi had ever analyzed the mareograms of Chilean Tsunami in 1960 by the use of periodogram(Higuchi,1963) and he had been desired to have a chance to cooperate in a study on tsunami spectra.

In this paper, the records are selected so as to study on tsunami spectra for the significant four examples, i.e., the tsunamis caused by the earthquakes off Tonankai in 1944, off Chile in 1960, off Alaska in 1964 and off Aleutian arc in 1965. In this section, the focus is to study on the transformations of the tsunami spectra through the propagations of the tsunamis from the open ocean to Osaka Bay. Before start of analysis, the elevation of the water surface is

read from the mareograms of the tsunamis at a certain constant step or a constant time interval. The discrete values of the elevations in a tsunami are assumed to be a time series of a stationary Gaussian process and treated to analyze by Blackman-Tukey's method which has been widely utilized for the spectrum analysis of ocean waves.

5. TIME DEPENDENCY OF TSUNAMI SPECTRA

When the assumed stationary process is sure, the length of the data for the analysis might not affect the form of the tsunami spectrum. The freedom of the data should be also considered statistically through the analysis. The time dependency of the data length in the analysis might show that the assumption is not suitable. In this section, the two tsunamis in 1944 at Osaka and in 1960 at Kushimoto are taken up for the analysis. The mareograms are read at the step of every three minutes to give a time series of the water level (cf. Table 1). The analysis is followed as that for ocean waves so that the number of the data is taken to be six hundred or much more under the consideration of freedom by the successive folding of the original data (see the sixth column in Table 1).

As for the tsunami caused by the earthquake off Nankaido at Osaka, the spectrum analysis is carried out for the data length of 2.5, 5 and 10 hours of the tsunami record to show the spectra in Fig. 6. In this figure, it is easily found that the principal peak of the spectrum is at the period of near 70 min ($f = 2.2 \times 10^{-4}$ cps) for the initial stage of 2.5 hours, and the other peaks are smaller than one hundredth of the principal peak. For the longer data of 5 hours and 10 hours, the second and the third harmonics of the principal peak become significant which might be caused by shoaling effect or the other effects. And the wave might be transformed into a nonlinear wave in the shallow water. The longest data (10 hours) gives the power spectrum which have the less significant higher harmonics to show that the energy of the wave is decreasing with the time elapse. The principal peaks of the three are quite similar and a little variation to give the similar form of the power spectra except the details of the forms for the significant higher harmonics.

And for Chilean Tsunami in 1960 at Kushimoto, the three kinds of the data lengths are considered, i.e., 3, 6 and 12 hours for the data originated at the time three hours before the arrival of the tsunami. The spectra are shown in Fig. 7. The power of the spectra after the arrival of the tsunami are ten times at least comparing to that before the arrival of the tsunami as a whole of the frequency. The spectra after the arrival of the tsunami have the two peaks at the periods of 40 min and 23 min (that is, $f = 4.4 \times 10^{-4}$ cps and 7.4×10^{-4} cps) respectively. In these two peaks, the one for the period of 23 min is fairly sharp and significant in the three spectra. This peak might be formed by the local resonant oscillation excited by the energy supply from the incident wave. The tsunami might be characterized by the peak at the period of 40 min in Fig. 7. After the arrival of the tsunami, the form of the spectra show the dependency of the analyzed data lengths to give significant higher harmonics. The existence of these higher harmonics suggests that the waves are transformed into the nonlinear waves or affected by the water depth to appear so called shoaling effect.

In the mareogram, the tsunami and tides are recorded in a superposed form.

When the focus is at the problem of the tsunami, the components except the tsunami should be treated as a background noise. In the spectrum, the components except the tsunami are taken to be the background spectrum as is considered by Munk, Snodgrass and Miller(1962). In Fig.7, the power spectrum before the arrival of the tsunami may correspond to the background spectrum mentioned above. When the principal peak and the pattern of the power spectrum are referred to discuss the frequency characteristics, and when the principal peak is sharp with a narrow band width, the assumption might be acceptable that the tsunami is similar to the monochromatic waves as is considered in the refraction diagram. Judging from Figs.6 and 7, the above assumption should be a fairly rough assumption. This assumption might be sufficient for only the initial part of the tsunami as considered in the refraction diagram.

6. TSUNAMI SPECTRA FROM OPEN OCEAN TO OSAKA BAY

In this section, the transformation of the forms of the tsunami spectra is considered from the Pacific Ocean to Osaka Bay for the significant tsunamis listed up in Table 2 except the tsunami caused by Hiuganada Earthquake in 1968. In order to obtain the tsunami spectra of each station, the data are treated and processed in similar manner as done for Figs.6 and 7. For the convenience of a glance to detect the transformation of the tsunami spectra, the distance from Kushimoto is taken as the ordinate and the abscissa is taken as frequency to form a diagram with a parameter of power density for each tsunami respectively. The obtained results are shown in Figs.8, 9, 10 and 11 for each tsunami respectively.

One of the example is Fig.8 which is for Tonankai Earthquake in 1944, the mareograms are obtained only at Shimotsu and Osaka so that the detail cannot be detected. The increase of the power density with the distance is easily found in the lower frequency region in Fig.8. -- And the principal peak(at $f = 9 \times 10^{-4}$ cps) in Kii Channel decreases in Osaka Bay down to less than one tenth and the incidence of the wave induces the local other oscillations.

As for Chilean Tsunami in 1960, as is shown in Fig.9, the frequency at the principal peak of the spectra is almost uniform from Kii Channel to Osaka Bay except Kushimoto. The local effect in the spectra might be characterized by the higher harmonics. The peak of $f = 8 \times 10^{-4}$ cps at Kushimoto may be caused by the effect of the local topography as mentioned for Fig.6. In case of the propagation, the reflection and refraction might cause the significant transformation of the tsunami for the tail part. The peak of $f = 3 \times 10^{-4}$ cps suggests that a oscillation is induced and formed to locate the node at Tomogashima Passage and the loops at the head of Osaka Bay and the mid Kii Channel. This oscillation is easily found by a glance of the diagram as shown in Fig.9. And the trend shows that the power density for the higher frequency region decreases gradually with the distance.

The other examples similar to Chilean Tsunami in 1960 are the tsunamis in 1964 and 1965, which are analyzed and shown in Figs.10 and 11. The wave sources are in each cases far from Japan and the waves come to Japan across the ocean. And the analyses of these tsunamis suggest that the tsunami wave heights and the power density of the tsunami spectra depend on the locations of the wave sources and the paths of the wave rays as well as the magnitude of the waves at the source areas.

The above results are obtained from the tsunami spectra obtained by Blackman-Tukey's method which has been widely utilized in the spectrum analysis of the ocean waves. Exactly speaking, it is necessary to remark that all phenomena of the tsunamis are transitional and to consider to treat the tsunamis as nonstationary processes. The appreciation of the tsunami in the scope of the nonstationary stochastic process might be an important and interesting problem to be solved as remarked by Nakamura(1975).

7. CONCLUSIONS

The authors have analyzed the tsunamis propagating into Osaka Bay in order to study the transformation of the tsunamis through the propagation. (1) At first, Chilean Tsunami in 1960 is taken to study on the wave height distribution along the coast from Kushimoto to Osaka(from the Pacific Ocean to the head of Osaka Bay) in a fairly good correspondency between the refraction diagrams which are obtained by the numerical computations and the manual drawings. The observed wave height along the coast seems to fit well to the computed ones for the initial part of the tsunami, especially for the second wave, except along the axis of Osaka Bay. (2) The tsunamis are analyzed to study the tsunami spectra as a tool to reveal what are the peak frequencies of the tsunamis and what are the induced local oscillations with the consideration of the above refraction diagrams. An oscillation is found by the spectrum analyses of the tsunamis on the frequency-distance diagram with a parameter of the power density to form an oscillation with a node at Tomogashima Passage and two loops at the head of Osaka Bay and at the mid Kii Channel. (3) Adding to the above, it might be necessary to develop a study of tsunami spectrum as a nonstationary stochastic process in relation to the generating processes of the tsunamis.

ACKNOWLEDGEMENT

In this study, the authors have owed to refer to the records and data which are systematically filed by Messers. K.Onishi and H.Sato of Osaka District Meteorological Observatory. And Prof. K.Kajiura and Drs. T.Hatori and I.Aida in University of Tokyo stimulated the authors to construct the refraction diagrams by a numerical computation. The computations are carried out by the computer FACOM 230-75 in the Data Processing Center of Kyoto University and the tsunami spectra are obtained by the use of the computer FACOM 230-25 in Information Processing Center of Disaster Prevention Research Institute, Kyoto University.

CHAPTER 60

TSUNAMI INUNDATION PREDICTION

Charles L. Bretschneider¹ and Pieter G. Wybro²

ABSTRACT

This paper concerns the run-up and inundation characteristics of tsunami surges. The forces and moments produced by the waves are not discussed, however, the proposed technique does provide the necessary information for their determination. The method relies on the knowledge of the wave elevation at the coast (as determined from historical data or other means) and an estimation of the bed roughness. The considerations and calculations involved in determining these parameters are discussed in detail. Twenty-four observed run-ups on the island of Hawaii in the case of the 1946 Aleutian tsunami, and 18 run-ups on the island of Maui for the Chilean 1960 tsunami are used to illustrate the technique. Methods are also presented to predict the shoreline heights and extent of inundation of tsunami surges where historical data is not available.

INTRODUCTION

This paper presents the theory and technique for determining the extent and profile of flooding due to tsunamis as affecting the coastal zone, especially the State of Hawaii. An earlier paper by Bretschneider and Wybro (1973) gave results for tsunami flooding over a flat, dry bed as in Hilo, Hawaii. These results are extended for the case of sloping land profiles and also for composite slopes consisting of a flat foreshore and sloping backshore.

To determine the wave height at the coastline, it is necessary to select an appropriate value of a roughness parameter, namely Manning's n , to account for the frictional effect of the bed on the inland advance of the surge. From this, then, flooding under existing or improved conditions can be determined. For improved conditions, it should be expected that the extent of flooding will be greater than that which occurred during past conditions.

The distribution of coastline elevations obtained from historical data provide an extrapolation base for which coastline elevation at intermediate locations can be determined.

BASIC EQUATIONS

The frictional shear stress opposing the flow of water is given by the Darcy-Weisbach (1858) relationship

$$\tau = \frac{f \rho u^2}{2} \quad (1)$$

¹Chairman and Professor, Dept. of Ocean Engineering, University of Hawaii

²Graduate Student, Dept. of Ocean Engineering, University of Hawaii

where τ is the bottom shear stress, ρ is the fluid density, u is the mean velocity, and f is a non-dimensional friction coefficient. Because the frictional coefficient is dependent not only on the bed roughness, but also on the depth of fluid, various laws have been formulated to attempt to separate these effects.

The most common formulation that attempts to correct this defect is Manning's formula

$$u = \frac{1.486}{n} R^{2/3} S^{1/2} \quad (2)$$

where R is the hydraulic radius (feet), S is the slope of the water surface, and n is Manning's n which is a measure of the roughness of the boundary and has dimensions ($\text{ft}^{-1/3} \text{ sec}$). The hydraulic radius is defined by

$$R = A/P \quad (3)$$

where A is the cross-sectional area of flow and P is the wetted perimeter. R is equal to the depth of water, h , in the case of very wide channels.

The Chezy-Kutter formula is given by

$$u = C_h \sqrt{RS} \quad (4)$$

where C_h is the Chezy coefficient ($\text{ft}^{1/2} \text{ sec}$) and is related to Manning's n by

$$C_h = \frac{1.486}{n} R^{1/6} \quad (5)$$

Manning's n is related to the Darcy-Weisbach f as follows:

$$f = 0.9 g n^2 h^{-1/3} \quad (6)$$

Hence, if Manning's n is only a function of bed roughness, then the friction factor f varies inversely to the 1/3 power of the water height. Bretschneider and Wybro (1973) showed that Manning's n for any particular roughness remains essentially constant with water depth. This is particularly so for values of n less than 0.04 and water heights between 5 and 50 feet.

Values of Manning's n can be found in numerous references such as Creager and Justin (1950) or Parsons (1965) in the case of effects of vegetation.

The classical long wave equations consist of the momentum and continuity equations which are, respectively:

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} = -g \frac{\partial h}{\partial x} - gm \frac{-g u |u|}{C_h^2 (d_0 + h)} \quad (7)$$

$$B \frac{\partial h}{\partial t} + \frac{\partial}{\partial x} (Au) = 0 \quad (8)$$

where: A is the cross sectional area of flow
 B is the surface width of flow
 d_0 is the natural water depth
 h is the depth of water above d_0
 m is the bottom slope

and differentiation with respect to x and t denote flow direction and time, respectively.

The last term in equation (7) accounts for frictional dissipation and can be rewritten in terms of Manning's n as

$$\frac{g u |u|}{C_h^2 (d_0+h)} = \frac{n^2 g |u| u (d_0+h)^{-4/3}}{(1.486)^2} \quad (9)$$

SOLUTIONS TO EQUATIONS

We will first consider the special case of a tsunami surge propagating inland over an open coast and a flat dry bed. This case was examined earlier by Bretschneider and Wybro (1973).

The momentum equation becomes (for $m = 0$, and $u = F\sqrt{gh}$ where $F = \text{constant}$ and assuming negligible local accelerations in comparison to the convective terms)

$$\frac{\partial h}{\partial x} = - \frac{n^2 u^2 h^{-4/3}}{(F^2/2+1)(1.486)^2} \quad (10)$$

for which it is found:

$$\frac{h}{h_0} = \left[1 - \left(\frac{x}{x_R} \right) \right]^{3/4} \quad (11)$$

and

$$x_R = \frac{3}{4} \frac{h_0^{4/3}}{F^2 n^2} \cdot \frac{(1.486)^2}{g} \left(\frac{F^2}{2} + 1 \right) \quad (12)$$

where h_0 is the initial surge depth, h is the surge depth after travelling x feet inland, and x_R is the distance to complete dissipation (see Fig. 1). Note that equation (12) differs from that of Bretschneider and Wybro (1973) in the constant term 6.5. However, the earlier report fitted inundation profiles to the observed data, whence Manning's n was determined. To convert the Manning's n so determined to the correct value in equation (12) involves multiplying by the factor $\sqrt{3} = 1.73$. The resultant inundation curves are hence identical, except the Manning's n obtained in the earlier work are to be corrected.

Solutions to equations (11) and (12) are depicted graphically in Figures 2 through 5. Each figure, for a particular roughness value, describes the envelope curve of the surge height as it propagates inland for various initial heights and for Froude numbers $F = 1$ and $F = 2$.

In the theoretical dam break problem, considering frictionless flow, Keulegan (1949) arrives at $F = 2$. Experiments by Fukui, et al., (1963) found that $F = 1.73$ for a bore propagating over a dry bed with $n = 0.013$. More recent experiments by Cross (1966) for tsunami surges finds $F = 1.41$ for a bed roughness of $n = 0.02$.

Miller's (1968) experiments indicated that the characteristic Froude numbers are functions not only of the roughness, n , but also of the ratio of surge depth to depth of water prior to sloping bottom. The relationships $F = f(n, h/d)$ was not determined, however. It appears from Figures 2 through 5 that $F = 2$ causes greater frictional dissipation than $F = 1$ because of higher fluid velocities. It is, hence, conservative to use $F = 2$ to predict shoreline elevations from run-up data and for conservative purposes, until more exact information is known, it appears desirable to use $F = 2$ (as, for instance, if forces are calculated).

In the case of surges advancing over a sloping bottom, equation (7) becomes (neglecting local acceleration and friction)

$$u \frac{\partial n}{\partial x} = -g \tan \alpha - g \frac{\partial h}{\partial x} \quad (13)$$

where α is the bottom slope. For the case of $u = F \sqrt{gh}$ then

$$\frac{\partial h}{\partial x'} = - \frac{\sin \alpha}{(F^2/2+1)} \quad (14)$$

where x' is the coordinate along the flow length. Upon integrating, the expression for the vertical runup, R'' , becomes

$$R'' = h_c + h_t + \frac{u_t^2}{2g} \quad (15)$$

where h_c is the vertical rise of the berm or beach (Fig. 1) and h_t and u_t are the surge height and surge velocity, respectively, at the toe of the slope.

Equation (15) can be compared to the value $u_t^2/2g$ arrived at by Freeman and LeMehaute (1964) where $h_c = 0$ and also $h_t = 0$ as a result of the first-order, non-linear long wave analysis. In this analysis, the surge collapses at the shoreline to a thin sheet of water with a velocity u_t .

Note that for $h_c = 0$ and $F = 2$, $R'' = 3$ or the vertical rise in water will triple.

It appears that for tsunami surges, the inclusion of h_t in equation (12) is justified as it is well known that the surge height does not collapse at the shoreline. This was experimentally justified by Miller (1968).

Cross (1966) found experimentally that the rise of water on a vertical wall is approximately $1.33 u_t^2/2g$ for a dry bed. In equation (15) with $F = 1.41$ and $h_c = 0$ yields $R^u = 1.9 u_t^2/2g$ which is conservative.

In the case of a roughened slope, equation (7) becomes the governing equation, and equation (14) becomes (neglecting the local acceleration)

$$\frac{\partial h}{\partial x'} = -\left\{\sin\alpha + \frac{n^2 g F^2 h^{-1/3}}{(1.486)^2} \cos\alpha\right\} [F^2/2 + 1]^{-1} \quad (16)$$

and the runup, R , is found by numerical integration. This has been done for various slopes (2.5° and 5°), various roughness ($n = 0.025, 0.035, 0.045,$ and 0.055) and a range of surge depths, h_t . The results are depicted in Figures 6 and 7, wherein R is plotted versus h_t for various Manning's n values.

For composite profiles (horizontal foreshore and sloping backshore), Figures 2 through 5 can be used to determine h_t , and this value is entered in Figures 6 or 7 with the corresponding Manning's n value to determine the run-up, R . Note that for the composite slopes, the roughness of the sloping portion need not be the same as the flat portion.

APPLICATION TO HISTORICAL DATA

Bretschneider and Wybro (1973) investigated the results of the tsunamis of 1946 and 1960 for the case of Hilo, Hawaii using the flat bottom equations. It was found that the land profiles were ideally suited due to the very gentle grade and an excellent comparison was obtained between the computed and observed inundation profiles. In this section, the analysis is extended to include composite land profiles whence equations (10) and (11) are used along with Figures 6 and 7. The areas of interest are the north coast of the island of Hawaii as experienced by the 1946 Aleutian tsunami and the southwest coast of the island of Maui for the case of the 1960 Chilean tsunami.

Island of Hawaii

Figure 8 shows the wave advancement of the 1946 tsunami as affecting the north coast of the island of Hawaii. The solid lines represent the wave fronts, the light dashed lines represent orthogonals and the heavy dashed lines represent orthogonal intersections, as was computed by Shepard, et al. (1950). The region of interest extends from Upolu Point in the west to Kumukahi Point in the east, a coastal distance of roughly 100 miles. The reported run-ups, also shown, were obtained from the Tsunami Research Center, University of Hawaii as documented on 1:24,000 scale USCGS quadrangle charts. The land profiles were obtained from these charts and the coastal terrain and roughness conditions were estimated from a field survey coupled with infrared aerial photographs taken from U-2 flights in 1974 and 1975.

It is found that the land profiles for a majority of the locations can be very adequately described by the composite slope method, using backshore slopes of 0.5° up to 10° with an average of about 2° to 3° . The steep,

nearly vertical cliffs that are common to this coastline were not used as these regions are inaccessible, hence, no run-ups were reported.

The reported run-ups are plotted in Figure 9 (solid circles) versus coastal distance measured west to east. These run-ups are projected back to the coast by means of Figures 2 through 7 using the iteration method described in the previous section and where the values of Manning's n are determined from Table I. The coastal elevations are indicated by open circles in Figure 9. Table II lists the run-ups, inundations, coastal elevation and Manning's n determined at each location.

A somewhat smooth curve can be passed through the coastline distribution, and on the basis of this curve, an equivalent, uniform wave of height z_r in open ocean is

$$z_r = \sqrt{\frac{1}{\lambda} \int_0^L z_0^2 ds} \quad (17)$$

where λ = projected distance of coast along the wavefront, ds is the increment of length along the shoreline, and L is the length of the coast. Note that z_r is a fictitious height in that shoaling has already been taken into account. In this case, projecting to the 6:30 a.m. wavefront (Fig. 8) gives $\lambda = 80$ miles, $L = 100$ miles, and $z_r = 46$ feet. On this basis the refraction coefficient is

$$K_R = \frac{z_0}{z_r} \quad (18)$$

The distribution of K_R as obtained by equation (18) is compared to the values obtained from the refraction diagram, Figure 8. The results are shown in Figure 10. The agreement is good, and both curves exhibit the same trends. The discrepancies can be attributed to the basic assumptions involved in arriving at the frictional effect (equation (16)) and the neglect of reflection and diffraction effects.

The determination of the appropriate friction factor involves some subjectivity, especially in the case where the flow length is composed of various roughnesses. The values in Table I were, however, determined not only from a literature review, but also from the fitting of envelope curves to the known inundation profiles (such as Hilo) and hence determining Manning's n . For example, Kolekole Beach Park is situated somewhat midway along the northern coast (see Fig. 11). Field observations made after the 1946 tsunami show that the wave overtopped and destroyed the existing railroad bridge and overtopped the Nanahoa highway bridge by three feet. A fitting of the inundation profile using Figures 2 through 7 determined Manning's n to be 0.04 which is as expected from Table I.

Suppose that the terrain was cleared to an open area with finely cut grass, etc., whence $n = 0.025$. If the same tsunami surge advanced inland under the new conditions, then it would have overtopped the highway bridge by 11 feet and the vertical run-up would be 30 feet instead of 17 feet. This exemplifies the changes in inundation characteristics corresponding to terrain changes as, for instance, when development occurs.

TABLE I
SUGGESTED VALUES OF MANNING'S n FOR VARIOUS COASTAL TERRAIN CONDITIONS

n	Conditions
0.015 - 0.025	Very smooth (mud flats, ice, well maintained concrete paved ways, beaches of fine sand)
0.025 - 0.030	Smooth (dried earth, coarse sand beaches, badly maintained concrete paved ways, very thin lawn grass up to 1 cm high)
0.030 - 0.035	Average for developed areas (lawn grass up to 5 cm high, gravel, presence of some buildings, houses, and other obstructions)
0.035 - 0.045	Open coast, relatively smooth and open area (grass up to 10 cm, sparse population of trees*, sparse bush, even bottom)
0.045 - 0.055	Moderately rough open coastal areas (thick grass, uneven bottom consisting of large rocks, coral, etc., presence of trees with low foliage, brush, lava rock, etc.)
0.055 - 0.070	Unusually rough coastal areas (dense brush, dense tree population with exposed roots, coarse lava rock formations)

* Trees with high foliage such that only trunks are exposed to flow

Island of Maui

A second coastline is examined in detail, that being the southwest coast of the island of Maui, a coastal distance of roughly 35 miles (see Fig. 12). In this case the 1960 tsunami, which originated from Chile, is examined in much the same manner as the previous case. The reported run-ups were substantially lower due to the sheltering effect of the island of Kahoolawe, however, there is a preponderance of data. This coastline is also ideally suited for the composite slope model.

The results of this analysis are depicted in Figures 13 and 14 and Table III where generally good agreement is obtained between the expected and calculated refraction effects. The discrepancy in the southeast region (right hand side, Fig. 14) can be attributed to diffraction effects due to Kahoolawe.

The method of fitting curves to the distribution of coastline elevations allows for the determination of heights at intermediate locations having no historical data. This is a common occurrence, especially for newly developed areas.

SUMMARY AND CONCLUSIONS

The prediction of the height and extent of flooding due to tsunamis should take into account the initial height, Green's law, convergences or divergences, and friction effects. The equations developed in this report take all of the above into account except convergences and divergences, i.e. they are valid only for the open coastline.

It appears from an analysis of historical run-up data that frictional effects can account for the generally wide data scatter, and on this basis coastline elevations can be determined at locations other than where data is present. When these values have been determined for existing conditions, it is then possible to predict flooding contours under existing conditions and also for extreme conditions. If the existing conditions are changed because of development, then it will be important to select the appropriate value of Manning's n in order to predict the extent of normal and extreme flooding under the improved conditions.

Although the technique has been tested and verified by field conditions, it appears that experimental justification is necessary, especially in regards to the following:

1. The Froude number relationship in regards to bore height and roughnesses.
2. The constancy of the Froude number over the flow length, especially in the case of composite slope.
3. The quantitative criteria for bore formation.

ACKNOWLEDGEMENTS

Appreciation is given to the Sea Grant College Program; the Pacific Urban Studies and Planning Program, University of Hawaii; and the Structural Engineers Association of Hawaii for partial support of this paper.

CHAPTER 61

NUMERICAL SIMULATION OF TSUNAMIS ORIGINATING IN THE PERU-CHILE TRENCH

BY

A. W. Garcia¹ and H. L. Butler²

I. Introduction

1. The U. S. Army Corps of Engineers has as an objective of its research and development program the determination of better harbor design criteria for tsunami protection. A previous report (Houston, et. al., 1975b) addressed the subject of tsunami vulnerability of the Pacific Coast of the continental United States to tsunamis originating in the Aleutian Trench. That report determined the variation in tsunami amplitude as a function of coastal distance due to a standard uplift source at different locations in the Aleutian Trench. The present report is a continuation of that study and addresses the subject of tsunami vulnerability along the same stretch of coast to tsunamis originating in the Peru-Chile Trench. In addition, modifications to the numerical code used in the previous report allowed the simulation of the Chile tsunami of May 22, 1960.

II. Historical Narrative

2. There have been four well documented major tsunamis to strike the Pacific Coast of the United States in recent times; the Great Aleutian tsunami of 1946, the Alaska tsunami of 1957, the Chile tsunami of 1960 and the Alaska tsunami of 1964. The 1964 Alaska tsunami claimed 107 lives in Alaska, 4 in Oregon and 11 in Crescent City, California. In addition to 330 lives in Chile, the 1960 Chile tsunami claimed 61 in Hawaii and 199 in Japan. Table 1 (Symons, et al., 1960) shows a comparison of maximum wave heights for the tsunamis of 1946, 1952, 1957, and 1960. The comparative intensity of the 1960 tsunami is evident. Indeed, the generating earthquake was of magnitude 8.6, one of the largest ever recorded.

3. The association of large submarine earthquakes with island arcs and deep submarine trenches is well documented (Kelleher, et. al., 1974; Kelleher, 1972; Sykes, 1971). The Japan-Kurile-Kamchatka, the Aleutian and the Peru-Chile Trench regions have long recorded histories of tsunamigenic activity. Of these, however, only tsunamis originating in the Aleutian and Peru-Chile Trenches have a history of causing significant runup along the Pacific Coast of the United States. Because tsunamis originating in the Aleutian Trench is the subject of a previous report, (Houston, et. al., 1975b) it will not be recounted here.

San Diego, Calif.	1.2	2.3	1.5	4.6

*Measured rise or fall. No extrapolation made for height beyond gage limit.

4. There is some evidence, however, to indicate that Richter scale magnitudes tend to underestimate the source parameters (fault length, width and uplift) and thus the tsunamigenic potential of very large earthquakes. Cumulative frequency vs. surface wave magnitude (M_s) plots show a linear trend for earthquakes with M_s values less than about 7.0 but for higher values of M_s the locus becomes increasingly steep tending toward vertical at M_s approximately equal 8.6. Therefore, it has been commonly assumed earthquakes with M_s greater than about 8.6 do not occur which may indeed be true. This, however, does not necessarily imply there is an upper limit on earthquake source parameters. Conventional analyses of earthquake energy spectra to determine M_s are frequency dependent. Chinnery and North (1975) hypothesize that because very large earthquakes produce spectra that have significant proportions of energy at frequencies below the band where M_s is normally measured and have dislocations which propagate for times significantly greater than 20 seconds that an upper limit to M_s will be observed no matter how large the true earthquake size.

III: Peru-Chile Trench As A Tsunamigenic Region

5. In terms of plate tectonics, the shallow seismic zone of western South America is a continuous boundary along which one plate (the Nazca plate) underthrusts the adjacent plate (the Americas plate). Kelleher (1974) cites numerous studies that indicate this plate motion is accomplished by large magnitude earthquakes, consequently any segment of the boundary that has not ruptured for many decades should be considered a zone of high risk. Moreover, Kelleher (1972) has observed that about once each century the entire fault segment near the Central Valley province

of central and southern Chile (approx. 32° -- 46° S) has fractured in a general north-south direction by a progression of large earthquakes and hypothesizes that a new series of quakes might start about the end of this century near Valparaiso (33° S) and progress southward.

6. Hayes (1966) states that crustal thinning beneath the trench is evidence the major tectonic forces involved are not laterally compressive and the absence of these compressive forces can be produced by a combination of faulting and flexure in the transition region of an ocean-continent margin. He also observes that almost all quake epicenters in the area lie shoreward of the axis of the trench.

7. Plafker and Savage (1970) report that records kept by the Japanese suggest that the subsea tectonic displacement of the 1960 Chile earthquake is probably greater than those associated with any of the earlier earthquakes during a period of nearly 500 years. Indeed, vertical movements of a larger regional scale appear to be characteristic of that portion of the trench extending from Columbia to southern Chile.

IV. Tsunami Source Characteristics

8. Figure 1 shows the contours of elevation of the initial sea surface deformation used as input to the simulation of the Chile tsunami of May 22, 1960. The shape of the deformation is inferred from the works of Plafker and Savage (1970) and Hwang, et. al., (1970). Plafker and Savage show the maximum upward vertical displacement of their preferred interpretation of the fault model to be about 10 m although the maximum observed upward vertical displacement was about 6 m. To avoid distorting the large scale features, the available data were smoothed, that is the maximum vertical uplift of 24 ft was chosen to compromise between the maximum predicted uplift of 10 m and maximum observed uplift of 6 m. Because the data indicate there was little downthrow (less than 2 m) associated with the tectonic deformation this feature was neglected in the model. The length of the deformation was determined from the spatial distribution of the epicenters of the initial quake and aftershocks as shown in Plafker and Savage (1970) and both its meridional and latitudinal extent are consistent with the area of the rupture zone as shown in Figure 2 (from Kelleher et. al., 1974).

9. There is little question that the deformation used for the simulation of the 1960 Chile tsunami is not known with the confidence of that used to simulate the Alaska tsunami of March 28, 1964. Nonetheless, there are enough data available to credibly reconstruct the bottom deformation which generated the tsunami.

10. Figure 3 shows the idealized axis of the Peru-Chile Trench as divided into 12 segments. A hypothetical sea surface deformation which generates a tsunami of approximately four intensity is centered in and aligned with segments one, eight and twelve. In order to facilitate comparison with results of a previous study (Houston, et. al., 1975b), the present hypothetical uplift is identical to that of the previous study.

Figure 1. Contours of elevation of uplift used to simulate 1960 Chile earthquake.

Figure 2. Rupture zones for large shallow earthquakes of this century and existing seismic gaps (after Kelleher, et. al., 1972).

V. Computational Model

11. The numerical code used to simulate the 1960 Chile tsunami and the idealized hypothetical disturbances is based upon the linearized longwave equations obtained by vertically integrating the Navier-Stokes equations and equation of continuity. The equations used in the code are formulated in a spherical system as follow:

$$\frac{\partial U}{\partial t} = - \frac{g}{R_e} \frac{\partial \eta}{\partial \theta} \quad (1)$$

$$\frac{\partial V}{\partial t} = - \frac{g}{R_e \sin \phi} \frac{\partial \eta}{\partial \phi} \quad (2)$$

$$\frac{\partial \eta}{\partial t} = - \frac{1}{R_e \sin \phi} \left\{ \frac{\partial}{\partial \theta} (\eta+d) U \sin \theta + \frac{\partial}{\partial \phi} (\eta+d) V \right\} \quad (3)$$

where

U = depth-averaged wave velocity component in the θ direction

V = depth-averaged wave velocity component in the ϕ direction

g = acceleration due to gravity

R_e = radius of earth

η = wave elevation from reference water level

θ = latitude measured positive from north pole

ϕ = longitude measured positive eastward from Greenwich

d = local water depth

The validity of using linearized equations and the conditions under which they hold are discussed in Houston, et. al., (1975b).

12. In order to facilitate simulation of the tsunami of May 22, 1960, modifications were made to the code used for previous reports (Houston and Garcia, 1974; Garcia and Houston, 1975, Houston et. al., 1975b) to permit larger grids and faster execution. In the above mentioned reports the finite difference forms of Equations 1, 2, and 3 were solved by an alternating direction multistep technique whereby during the first half-time step, η and U were computed implicitly along lines of constant longitude and V explicitly along lines of constant latitude; in the second half-time step η and V are computed implicitly along line of constant latitude and U explicitly along lines of constant longitude. In the present report, Equations 4-6 are the finite difference forms of Equations 1-3.

$$U_{i,j}^{n+1/2} = U_{i,j}^{n-1/2} - \frac{g \Delta t}{R_e \Delta \theta} (\eta_{i+1,j} - \eta_{i,j})^n \quad (4)$$

$$V_{i,j}^{n+1/2} = V_{i,j}^{n-1/2} - \frac{g \Delta t}{R_e \Delta \phi \sin \theta} (\eta_{i,j+1} - \eta_{i,j})^n \quad (5)$$

$$\eta_{i,j}^{n+1} = \eta_{i,j}^n - \frac{1}{R_e \sin \theta} \left\{ \frac{\Delta t}{\Delta \theta} \left[(U d \sin \theta)_{i,j} - (U d \sin \theta)_{i-1,j} \right] + \frac{\Delta t}{\Delta \phi} \left[(V d)_{i,j} - (V d)_{i,j-1} \right] \right\}^{n+1/2} \quad (6)$$

(where it is assumed $n \ll d$)

Figure 4 shows the grid scheme used. The depth, d , is considered the averaged depth over the grid square j to $j+1$, i to $i+1$. Equations 4 and 5 are solved explicitly at the same halftime step along lines of constant longitude and latitude respectively. Equation 6 is then solved for η onehalf time step later. The boundary conditions, reflective at land boundaries and transmissive at the open ocean grid boundaries, are treated in the same manner as in the previous report (Houston, et. al., 1975b).

13. The explicit code was verified by comparing the results of hindcasting the Alaska tsunami of March 28, 1964 with results of hindcasting the same tsunami using the earlier implicit-explicit code. There was almost exact agreement of the results.

14. To further reduce the computational time required and to allow a greater area to be covered, a one-third by one-third degree grid was used instead of the onethird by one-fifth degree grid used in the previous report (Houston, et. al., 1975b). The validity of using the coarser grid to propagate tsunamis over the open ocean has been demonstrated by Houston, et. al., (1975a). Use of the latest bathymetric information for the Pacific Coast of the United States allows significant improvement in the detailing of the coastline and continental shelf area.

15. Depths for the open ocean portion of the numerical grid were interpolated from data of ocean depths averaged over areas of one-degree squares of latitude and longitude (Smith, et. al., 1966) available from the National Oceanographic Data Center. Normally, the numerical code interpolates depth data from one point per square degree to nine points per square degree. However, for the continental shelf area, the interpolation process was not used; instead data taken directly from bathymetric charts in a form compatible with the numerical code were inserted.

16. By the modifications made to the finite difference form of the equations used in the numerical code and the use of coarser depth grid, the computational time for similar problems is reduced by a factor of approximately three relative to the previous code.

VI. Procedure

17. To locate the hypothetical uplifts, the Peru-Chile Trench was divided in twelve equal segments as shown in Figure 3. An uplift of the same configuration used in the previous report (Houston, et. al., 1975b) was centered in segments 1, 8 and 12. Segment 1, although closest to the Pacific Coast of the continental United States, is least favorably oriented for producing large waves which propagate in that direction. Segment 8, although more favorably oriented for production of large waves, would be the segment most influenced by the "shadowing" effect of the reach of coast immediately northward of the perimeter of the uplift area. In principle, an uplift centered in segment 7 would experience more shadowing effect, but the uplift placed there would have had a significant proportion on land and therefore produce a smaller tsunami. The orientation of segment 12 is very similar to that of segment 8, that is, more favorably oriented than segment 1 for production of large waves in the direction of the United States, but without the "shadowing" effect experienced by segment 8. One therefore would expect the overall amplitudes of the tsunamis arriving at the Pacific Coast of the United States to be least for those produced by the uplift centered in segment 8 (excluding segment 7) with tsunamis originating in the remaining eight segments producing values between those of segments 1 and 12.

18. To compare the amplitude of the leading wave of the tsunami generated by the three hypothetical ground motions as a function of distance along the Pacific coast of the United States, the amplitudes were normalized to a depth of 600 ft. This is done by analytically solving a one-dimensional standing wave equation (Lamb, 1932). This is done in detail in (Houston et. al., 1975b) but will be recounted briefly here.

19. Combining the one-dimensional long-wave equation of motion and the continuity equation (in rectangular coordinates) yields the wave equation

$$\frac{\partial^2 \eta(x)}{\partial t^2} = g \frac{\partial}{\partial x} d \frac{\partial \eta(x)}{\partial x} \quad (7)$$

Under the assumption of simple harmonic motion,

$$\eta \propto \cos(\omega t + \epsilon) \quad (8)$$

and Equation 7 becomes

$$g \frac{\partial}{\partial x} \frac{\partial \eta(x)}{\partial x} + \omega^2 \eta(x) = 0 \quad (9)$$

If we now substitute $d(x) = d_a x/a$ and $K = \omega^2 a/g d_a$ where d_a is the water depth at the gage location some distance $x = a$ from the shoreline in Equation 9 we get,

$$\frac{\partial}{\partial x} \left[x \frac{\partial \eta(x)}{\partial x} \right] + K \eta(x) = 0 \quad (10)$$

The solution to Equation 10 is

$$\eta(x) = AJ_0(2k^{1/2} x^{1/2}) \quad (11)$$

or with the time dependence restored

$$\eta(x,t) = AJ_0(2k^{1/2} x^{1/2}) \cos(\omega t + \epsilon). \quad (12)$$

Because a tsunami has a very long wave length, we can assume the entire local water surface oscillates in the vicinity of some local depth, d , where $x \geq a$, thus

$$\eta(x) = C \cos(\omega t + \epsilon) \quad (13)$$

for $x \geq a$. Equating equations 12 and 13 yields

$$A = \frac{C}{J_0(2k^{1/2} a^{1/2})} \quad (14)$$

Therefore

$$\eta(x) = C \frac{J_0(2k^{1/2} x^{1/2})}{J_0(2k^{1/2} a^{1/2})} \cos(\omega t + \epsilon) \quad (15)$$

Solving for C at $x = a$

$$C = \frac{\eta(a)}{\cos(\omega t + \epsilon)} \quad (16)$$

From Equation 15,

$$\eta(b) = C \frac{J_0(2k^{1/2} b^{1/2})}{J_0(2k^{1/2} a^{1/2})} \cos(\omega t + \epsilon) \quad (17)$$

and substituting Equation 16

$$\eta(b) = \frac{J_0(2k^{1/2} b^{1/2})}{J_0(2k^{1/2} a^{1/2})} \eta(a) \quad (18)$$

Since $\eta(a)$ is known from the numerical simulation, η at $x = b$ can be determined. The values of a , b and d_a are determined from U. S. Coast and Geodetic Survey charts.

20. Because the method described above is one dimensional, it accounts for the effects of shoaling and reflection but not refraction or diffraction. However, since a tsunami wavelength is so great in waters deeper than 600 ft, few bathymetric features are large enough to significantly refract or diffract the waves over the relatively short distance from the nearest gage location to the 600 ft contour.

VII. Results

21. Table 2 shows a comparison of amplitudes of the leading wave of the 1960 Chili tsunami as recorded by tide gages at selected exposed locations with results of the numerical simulation at locations nearest the tide gages. To avoid the false appearance of exact agreement at locations such as Port Hueneme, the results of the numerical simulation are rounded to the nearest hundredth foot rather than the nearest tenth.

Table 2
Comparison of Elevations of Maximum Rise of Initial Wave
of 1960 Peru-Chile Tsunami to Numerical Simulation

<u>Gage Location</u>	<u>1960 Peru-Chile Tsunami (feet)</u>	<u>Numerical Simulation (feet)</u>
La Jolla, Calif.	1.4	1.05
San Clemente Island, Calif.	0.9	0.89
Port Hueneme, Calif.	1.9	1.86
Presidio (San Francisco), Calif.	1.3	1.46
Crescent City, Calif.	1.3	1.02
Neah Bay, Wash.	0.9	0.73

22. Ideally, the amplitudes resulting from the simulation should be slightly less than those recorded at corresponding tide gages because of shoaling of the wave into shallower gage locations. With the exception of the Presidio gage, this is indeed the case. Two factors which could account for the anomaly at Presidio are frictional dissipation of the actual tsunami over the shallow shelf seaward of Presidio (frictional effects are neglected in the governing equations of motion), and the inadequacy of the averaged depths used in the finite difference code to represent the small detail of the shelf accurately.

23. Figure 5 shows contours of sea surface elevation of the leading tsunami waves 15 hours after generation by simulation of the 1960 Chile quake. The reason for the extensive damage caused by the 1960 Chile tsunami in the Hawaiian Islands and Japan is evident as the highest section of the wave front is directed toward these locations. The preferential radiational patterns of non-circular uplifts are well documented (Takahashi et. al., 1962; Hatori, 1963).

24. Figure 6 shows the locations of the 64 gages used to determine the leading wave amplitude as a function of distance along the Pacific coast of the United States. Figures 7-9 are plots of the amplitude of the leading wave of tsunamis generated by hypothetical uplifts located in segments 1, 8 and 12 respectively. While tsunamis generated in segments 1 and 12 generally produce similar responses along the Pacific coast, the response to the tsunami generated in segment 8 is markedly less. This

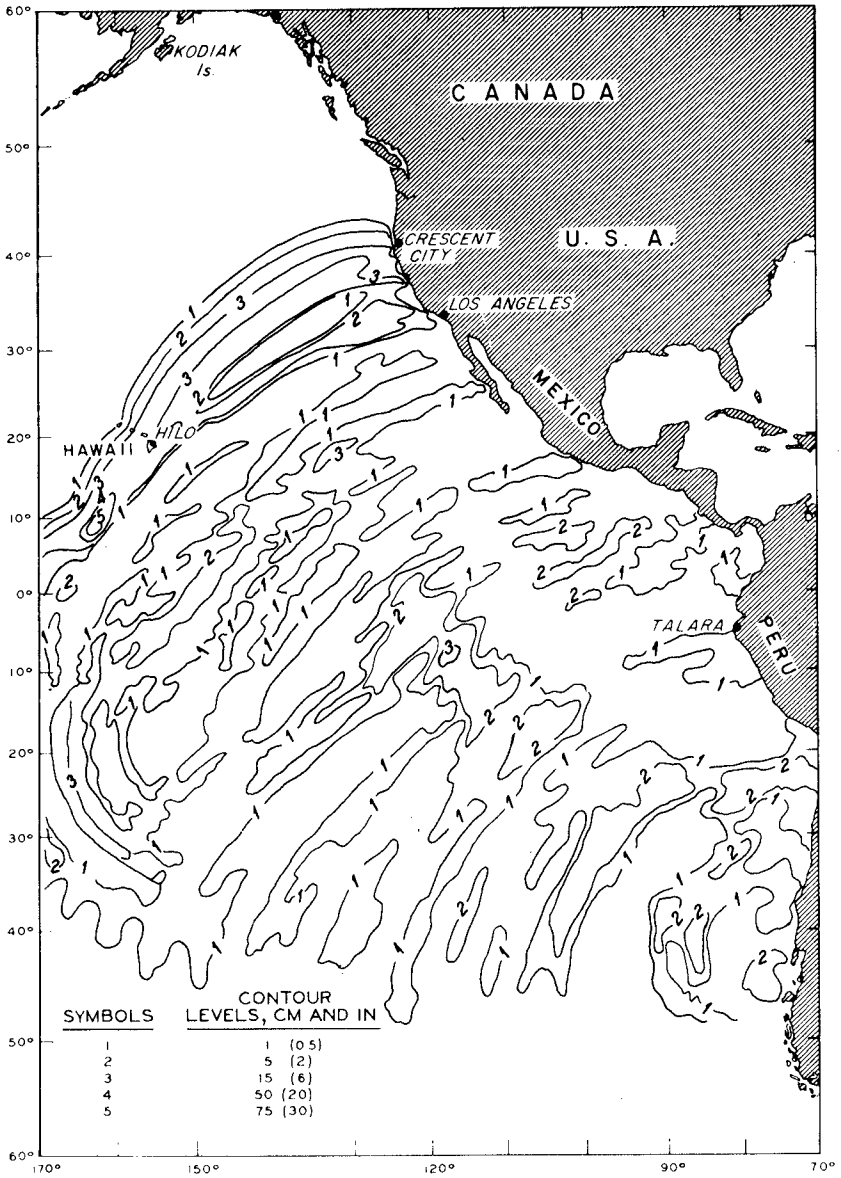

Figure 5. Contours of water-surface elevation for the leading tsunami waves 15 hrs after simulation of the 1960 Chile earthquake.

FIGURE 6. GAGE LOCATIONS ALONG THE WEST COAST

Figure 7. Wave amplitude of leading tsunami wave generated in Segment 1 versus distance of the recording gage from the U. S. - Mexico border.

Figure 8. Wave Amplitude of leading tsunami wave generated in Segment 8 versus distance of the recording gage from the U. S. - Mexico border.

Figure 9. Wave Amplitude of leading tsunami wave generated in Segment I2 versus distance of the recording gage from the U. S. - Mexico border.

is probably due to the "shadowing" by the northwestward to southeastward oriented stretch of South American coast between 15 and 20 degrees south latitude. The generally low response exhibited along the coast from about San Diego to Los Angeles due to tsunamis generated in the three segments is probably the result of sheltering by the Channel Islands. The peaks shown in the vicinity of Port Hueneme (1.4 to 3.3 ft) agree fairly well with heights recorded there during past tsunamis, e.g., 1960 Chile, 2 ft; 1957 Aleutian, <3.5 ft. The validity of the large peaks shown in Figures 7 and 9 just south of Pt. Sur is unknown. There are no gage records existant near that location with which to compare results and it is alsb a relatively uninhabited stretch of coastline. The response of the remainder of coastline is relatively uniform with a maximum amplitude variation of about 1.5 feet. This is not unexpected due to the gradual eastward turning of the coastline as one proceeds northward.

VIII. Summary

25. The Peru-Chile Trench has a long recorded history as an area of generation of tsunamis which cause significant runup along the Pacific coast of the continental United States. An explicit numerical code has been developed and is demonstrated to adequately hindcast the Chile tsunami of 22 May 1960. The code is used to simulate the generation and propagation of tsunamis of approximately four intensity which originate in the Peru-Chile Trench. The amplitudes of the tsunamis are normalized to 600-ft depth and are plotted as a function of distance along the U. S. west coast from the Mexican to the Canadian Borders, thus allowing a relative comparison of the vulnerability of various locations along the U. S. west coast to tsunamis originating in the Peru-Chile Trench.

a	Distance along x-axis, ft
A	Amplitude constant
C	Amplitude constant
d	Depth of Water
d_a	Water depth a distance "a" from shore
e	Base of natural logarithms
g	Acceleration of gravity
J_0	$J_0()$ Zeroth order Bessel function of the first kind
k	Variable, ft^{-1}
L	Characteristics length of the wave in its direction of propagation
n	Refers to a time, $n\Delta t$
R_e	Radius of the earth
t	Time
U	Depth-averaged wave velocity component in the θ direction
V	Depth-averaged wave velocity component in the ϕ direction
x	Distance, ft
Δt	Length of a half-time step
ϵ	Phase factor
η	Wave elevation from reference water level
θ	Latitude measured from the north pole
ϕ	Longitude measured from Greenwich
ω	Wave frequency, sec^{-1}
∂	Partial differential

CHAPTER 62

NUMERICAL MODELS OF HUGE TSUNAMIS OFF THE SANRIKU COAST

Toshio Iwasaki
Professor of Tohoku University

Abstract

Although numerical computations of the generation and propagation of tsunamis are successfully achieved in recent years, modeling of their wave sources is still a big problem. Three kinds of wave source model, that is statistical, oceanographic and fault model, are studied in this paper.

It is found that the first model gives reasonable wave heights as shown in the previous paper, the second one presents roughly one half of those for the first model and the last one produces too small wave heights.

Based on the analysis of computed results, nature of undulations off from the shore boundary, directivity of wave propagation and the spindle-shaped leading part are discussed.

Comparing magnitude of various wave parameters for the leading wave along the minor axis of the wave source, it is shown that the long wave approximation modified by the slope effect illustrates the tsunamis in deep region of the sea and the slope effect is most dominant in shallow region.

INTRODUCTION

For the numerical computation of the generation and propagation of tsunamis, one of the most important problem is the knowledge of the wave sources, such as their location, their dimensions and the motion of the sea beds. A set of empirical equations were proposed by the author in 1974 which gave dimensions of source ellipse assuming the earthquake magnitude M or the tsunami magnitude m^1 (Iwasaki, 1974, hereafter referred to as the previous paper). A wave source derived from these equations is called a statistical model in this paper since these equations are obtained from data collected statistically.

However concerning on the motion of the sea bed, uniform distribution with a rumped function is assumed in this model. This seems to much simple to be realistic.

Dr. I. Aida tried to extract information on the crustal deformation from available data for the Tokachi-oki Tsunami in 1968²). Performing numerical experiments for several models with various distributions of sea bed deformation in the wave source area and comparing amplitudes of water surface oscillations thus calculated with actual tide gauge records, he selected a model. Since bay oscillations were not taken into account in his analysis which should be included in actual records, his method of

selection was somewhat immature. Nevertheless this is one of more developed model. Since it is derived by comparison with actual marigrams, this model is called an oceanographic model.

The Alaskan 1964 Earthquake was an epoch-making which investigation started the study of huge earthquakes along submarine ditches since survey on the bed deformation due to the earthquake was successfully achieved which made possible the interpretation of source mechanism³⁾. Until today there were three other examples for which survey on the bed deformation were accomplished, that is the Kanto 1923 Earthquake, the Nankaido 1946 Earthquake and the Chilean 1960 Earthquake. Owing to these experiences such huge earthquakes are explained as accompanied by the rupture of lithospheres. Thus although huge earthquakes off the Sanriku Coast have their sources in quite deep areas which make bottom survey impossible, estimation of source mechanism was presented by Dr. Kanamori⁴⁾⁵⁾⁶⁾. He urged that the most reliable and quantitative data concerning the deformation of the lithosphere could be obtained by his method. Distributions of sea bed deformations thus derived are called fault models.

It is intended in this paper to obtain the most creditable information of tsunami waves by comparing results of numerical computations for three kinds of source models mentioned above with each other and with observed values. Then a number of special characteristics inherent to tsunami waves are discussed.

SOURCE MODELS FOR THREE TSUNAMIS

The Sanriku Coast is the name of the coast which situates in northern part of the main island of Japan facing the Pacific Ocean stretching from 38° N to 41.5° N. Although a lot of tsunamis have attacked there in the past, there were only three cases for which scientific records were obtained among those which originated off this coast and caused severe damage. They are the Sanriku Tsunami in 1896, the Sanriku Tsunami in 1933 and the Tokachi-Oki Tsunami in 1968.

Fig. 1 shows the region of computation where the Japan Sea Trench lies almost parallel with the Japan Island arcs.

Numerical Computation scheme and the boundary conditions are mostly similar with those in the previous paper in which inertia terms and friction terms are included. Alteration is that Corioli's terms are added and the time and space steps are changed from 10 seconds to 6 seconds and from 20 km to 10 km respectively on account of resolution of networks. Depth at the shore boundary is assumed as 20 meters so that the sea bed is not exposed by negative waves.

Fig 2 shows the wave sources of the statistical models for three tsunamis mentioned above which locations are estimated from inverse-refraction diagrams. Dimensions are computed by the equations proposed by the previous paper such that,

Fig. 2 Wave Sources of the Statistical Models for Three Tsunamis.

Fig. 1 Japan Islands and the Japan Sea Trench.

$$\ell = 10 \exp [(M - 6.27) / 0.76] \tag{1}$$

$$\epsilon = \tanh [1.5 \tanh ((\frac{\pi}{2012})^{1/2} \cdot \ell^{2/3})] \tag{2}$$

$$2a = \ell / \epsilon \tag{3}$$

$$2b = \ell (1 - \epsilon^2)^{1/2} / \epsilon \tag{4}$$

$$S = \pi ab \tag{5}$$

$$m = 2.61 M - 18.44 \tag{6}$$

$$E_t = 10 \exp [0.6 m + 11.4 - \log_{10} 9.8] \tag{7}$$

$$\eta_{\max} = (2E_t / w_o S)^{1/2} \tag{8}$$

, in which m and M are the magnitudes of tsunami and earthquake respectively. ϵ , ℓ , a, b, S are the eccentricity, the distance between foci in km, the half length of the major axis in km, that of the minor axis in km and the area of the source in square km respectively. And E_t is the tsunami energy in ton-meter units. Table 1 shows the dimensions of wave sources for these three tsunamis.

Table 1. Dimensions of the Wave Sources for Statistical Models

Tsunami		M	2a(km)	2b(km)	η_{\max} (m)	T(sec)
Sanriku	1896	7.6	307	272	8.15	96
Sanriku	1933	8.3	420	190	7.54	60
Tokachi-oki	1968	7.9	168	94	9.18	60

Although the earthquake magnitude of Sanriku 1896 was very small if compared with that of Sanriku 1933, the source area derived from the inverse refraction method was comparable with the latter. Dr. Kanamori illustrated this was due to the abnormal slow deformation with the time constant of about 100 secs of the former which was out of the instrument response at that time⁶). So, from eqs. (1) to (7), M is estimated so as to produce the dimensions of such source areas, which is $M = 8.12$. η_{\max} in table 1. is derived by eq. (8) using this value. T is the duration time of earth movement and is selected to be approximately equal to the time constant proposed by Dr. Kanamori.

For another two tsunamis, source dimensions are derived using values of M in table 1 and T are given as illustrated in the previous paper.

Fig. 3 shows the oceanographic model for the Tokachi-oki 1968 presented by Dr. Aida²). It is noted that there is a region of subsidence in northwest part which is separated by the longitude of 143°E from a region of upheaval where the maximum dislocation is roughly 5 m.

For another two tsunamis, such model is not obtained.

Fig. 4 shows fault parameters defining a faulting plane and its motions, which are a breadth W , a length L , a dislocation D , a dip direction ϕ , a dip angle δ and a slip angle λ with a duration time T and a rupture velocity ν . Displacements of the sea bottom can be computed from such fault parameters. Dr. Maruyama⁷⁾ and also Dr. Mansinha and Smylie⁸⁾ presented theories for them. Fig. 5 shows an example in which abscissa is in unit of breadth of the fault plane. In lower figure, the adverse dip slip planes with the dip angles are shown. In the upper figure, the vertical displacements of the surface of the earth are shown in unit of dip slip component. The length of horizontal bars show the horizontal displacements.

Fig. 6 shows the sea bed displacements for the Sanriku 1933 drawn from fig. 5 taking rupture velocity ν 3.5 km/sec, dip angle δ 45°, dip direction ϕ 90° and the time duration T 10 sec which were presented by Kanamori⁴⁾. As shown in this figure, a zone of upheaval is recognized in the east half and a zone of subsidence in the west half. The motion is the normal faulting without the strike component. There is some ambiguity on the wave source motion. Thus we assume the displacement started at the fault line and propagated to east- and westward.

Fig. 7 shows for the 1969 Tsunami presented by Dr. K. Abe⁹⁾. It was said this earthquake was caused by the low angle thrust faulting with a considerable strike-slip component, in which the ocean side underthrust beneath the continent.

Wave sources thus obtained are summarized in table 2.

Table 2 Wave sources

Tsunamis	Statistical models	Oceanographic models	Fault models
1896	x	-	-
1933	x	-	x
1968	x	x	x

MAXIMUM WAVE ELEVATIONS ABOVE STILL WATER LEVEL

A lot of data on the inundation levels were reported by many sources. Fig. 8, 9 and 10 show such data collected. Northern to Hachinohe, the coastline is monotonous with sloping beach. Since these area was still undeveloped, reliable informations were not available except few places. Remaining area is composed of a large number of bays with various size, shape and topography. Five bays which are Kuji, Miyako, Kamaishi, Hirota and Kesenuma and Onagawa are shown in more detail with dotted contour lines at bay entrances. It is noted that remarkable discrepancy is

 dislocation 4 m
 rupture velocity 3.5 km/sec
 T = 48 sec

Fig. 7 The Fault Model for the Tokachi-oki Tsunami in 1968 by Abe.

recognized between maximum wave heights even in a same bay. So it is extremely difficult to examine justifiability of source models by comparison of numerical results with observed values.

One procedure tried in this paper is to calculate wave heights at 5m deep for sloping beach areas or those at bay mouths for remaining areas from those at output points which are 20 kms off the shore boundaries by the Green's law. These are shown in frames also in figs 8, 9 and 10.

It is noticed that computed wave heights by the statistical model give reasonable values at Kuji, Miyako, Kamaishi, Hirota and Kesennuma for the Sanriku 1896 Tsunami, but too large at Hachinohe and Onagawa. Also those derived for the Sanriku 1933 by the statistical model which are denoted by S in frames give acceptable values except Onagawa. However the statistical model for the Tokachi-oki 1968 produces too large wave heights.

The computed wave heights by the oceanographic model are probably too small and it seems that they should be doubled.

Results by the fault models are mostly very much small and those for the 1933 tsunami should be multiplied by 18 times in order to give comparable values with results by the statistical model. Similarly those for the 1968 tsunami are to be multiplied by 8 times.

However it should be noted that such estimation is reduced simply by comparison of numerals shown in figures without detailed inspection on hydrodynamic effects due to locality.

SURFACE OSCILLATIONS AT OUTPUT POINTS IN NEAR-COAST OFFSHORE REGION

In spite of the difference of the wave heights with each other, it is possible to examine oscillation pattern at output points in nearcoast offshore region since water depths of these points are deep enough such that effects of non-linear terms in equations of motion can be neglected and surface oscillations thus computed are linearly proportional to the amount of sea bed deformation which make possible relative comparison of wave pattern with each other by adjusting vertical scales.

Fig. 11 shows surface oscillations of the Sanriku 1933 Tsunami, in which full lines are results by the statistical model and dotted lines are plotted of values multiplied by 20 times of results by the fault model. It is noticed that oscillation patterns are not so different except Obuchi and Hachinohe where free oscillations may be invoked in the water body bounded by the Hokkaido and the Honshu which are superposed on the oscillations over the continental shelf. Since the wave source is roughly parallel with the meridian line, the tsunami waves proceed to the coast as if one dimensional waves. So such indifferent pattern of undulations with the distributions of the sea bed movement lead an expectation such that one depressed and one elevated wave may be appeared forcedly at first which are not be effected remarkably by higher order components of the bed movement and following oscillations may be free oscillations over the

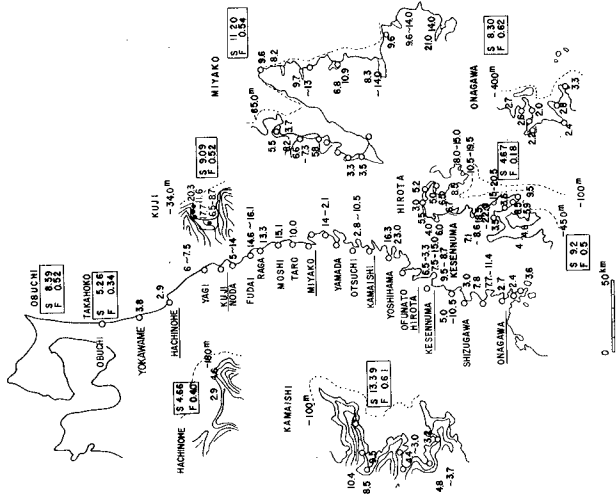

Fig. 9 Maximum Water Levels above MSL in meters for the Sanriku Tsunami in 1933. (Figures in Frames are computed Values. S for the Statistical Model. F for the Fault Model.)

continental shelf.

Oscillations of the 1968 tsunami are somewhat more complicated as shown in fig. 12. Full lines show waves by the statistical model, broken lines are obtained by the oceanographic one which are multiplied twice and dotted lines are those by the fault model multiplied by eight times. It is noticed that the first oscillations reflect the different pattern of the source movement. For the oceanographic and the fault models, the negative waves appear at first at Takahoko and Hachinohe and the positive waves appear at Miyako and Kamaishi which are also reported in field survey. At Kuji the sign of the first waves is opposite with each other. The marigram of this tsunami supports the oceanographic model. Free oscillations of the water body on the continental shelf and those of the water body bounded by the Hokkaido and the Honshu are also noticed.

By the way, readings of actual marigrams are plotted in figures for Hachinohe and Miyako by lines connecting white circles. However they seem to be incorrect informations, since time scale of original recording is too much reduced to make possible one week long recording in a sheet which is attached around a drum rotating once during a week.

SPATIAL WAVE FORMS

Fig. 13 and fig. 14 show spatial wave forms of the 1968 tsunamis by the statistical and the fault models respectively, in which horizontal axis are taken along the 41°N latitude between the most eastward end of the wave source and the coastal boundary at Takahoko. Figures a) are on the progressive stage, figures b) are when the leading fronts have arrived just at the coast and figures c) are when the maximum waves appear there.

The non uniform distributions of the sea bed displacement are reflected on the wave forms in figures a) and b) for progressive stages. The steepness of the leading waves is the order of 10^{-5} , which is very small when compared with those of surface waves.

At the coast, there occurred standing waves and the maximum deviations from the still water are nearly twice of those of the progressive waves.

The spatial wave forms along the major and the minor axis of the source ellipse computed by the fault model for the 1933 tsunami are shown in fig. 15, in which lowest figures show the bottom topography. Along the major axis a depression wave is generated at first, which is disappeared in relatively short period. However along the minor axis, waves are propagated as if one dimensional waves, in which the leading part is composed of one negative and one positive wave. The dispersive nature is recognized and there seems to be so called ripples behind the leading part.

Fig. 13 Spatial Wave Forms of the Tokachi-oki Tsunami in 1968 by the Statistical Model.

Fig. 14 Spatial Wave Forms of the Tokachi-oki Tsunami in 1968 by the Fault Model.

Fig. 12 Surface Oscillations of the Tokachi-oki Tsunami in 1968.

WAVE PARAMETERS ALONG THE MINOR AXIS

Various wave parameters are computed for the leading wave along the minor axis, which are the non-linear parameter a/h , the long wave parameter $(h/l)^2$, the slope parameter $h_x l/h$ and the Ursell's parameter $U = al^2/h^3$, in which a , h and h_x are amplitude, depth and slope respectively and Ursell's parameters are computed by Dr. Raichlen and Dr. Hammack's method for which the inflection point of the leading waves is selected to define the slope and points of intersection of the tangent with the undisturbed and the highest wave elevations define the length l by their horizontal distance.

Fig. 16 shows these no-dimensional parameters with depth as abscissa. Where it is deeper than 3000 meters, the long wave parameter is nearly equal to the slope parameter and is much larger than the non-linear parameter. Shallower than 3000 meters, the slope parameters are dominant to the other two. So in a deep sea tsunami can be approximated by the long wave theory with modification by the slope effect. However in a shallower region theories which take into account the slope effect such as Green's law are most powerful for explaining tsunami waves.

TWO DIMENSIONAL PROPAGATION

Thus far various aspects of tsunami waves are discussed mostly in one dimensional. However computations are made in two dimensional horizontal scheme, so features on two dimensional propagation are studied here.

Fig. 17, 18 and 19 show wave contours at 10, 20 and 30 minutes after the outbreak of the Sanriku earthquake in 1933 in which contours are drawn in every 10 cms by thin full lines and those in every 50 cms by heavy lines from results by the fault model. In fig. 15 it is recognized that the first dropdown proceeds westwards followed by ascension as reaction and the first rising up proceeds eastward with the following falling limb with large size. In fig. 17 these are found in relatively limited area which are spindle-shaped. Behind them, corrugated patches parallel with the major axis are noticed. As shown in fig. 18 and 19, wave fronts are becoming distorted by effects of bottom topography tending to be parallel with bottom contours. However the frontal spindles seem their size and the maximum wave height unchanged remarkably during procession.

The theory of the long wave approximation in shallow water with constant depth derived by Dr. Kajiura gives the following equation for the surface elevations.¹⁰⁾

$$\zeta(x, y, t) = \iint_S H_S \cdot P \, ds \quad (9)$$

a) along the Major Axis. b) along the Minor Axis.

Fig. 15 Spatial Wave Forms of the Sanriku Tsunami in 1933 by the Fault Model.

Fig. 16 Wave Parameters of the Leading Wave along the Minor Axis.

Fig. 17 Wave Contours at 10 min. after the Outbreak of the Sanriku Earthquake in 1933.

Fig. 18 Wave Contours at 20 min. after the Outbreak of the Sanriku Earthquake in 1933.

Fig. 19 Wave Contours at 30 min. after the Outbreak of the Sanriku Earthquake in 1933.

Fig. 20 Wave Contours at 20 min. after the Outbreak of an Earthquake computed by Kajiura's Theory setting the Distributions of the Sea Bed Displacements at the Sanriku Earthquake in 1933. Depth is assumed uniformly 3000 m.

, in which $P = -\frac{1}{2\pi} \operatorname{ct}((ct)^2 - r^2) - \frac{3}{2}$, $c = (gh)^{1/2}$ and $r^2 = (x-x_0)^2 + (y-y_0)^2$. H_s is the water surface elevation above still water level at the wave source (x_0, y_0) , h is the water depth and ds is a surface element of the source area S respectively.

Assuming the same distributions of the surface elevation with those of the bottom displacements of the fault model for the 1933 tsunami and taking the water depth as 3000 m uniformly, wave height distributions 20 minutes after the outbreak of the earthquake are roughly estimated by eq. (9) which are shown in fig. 20. The spindle-shaped hump and depression around both ends of the minor axis and corrugated patches around both ends of the major axis are also noticed, which can be illustrated that contributions from source subelements are inaugurated along the minor axis and are cancelled along the major axis with each other since in the wave source the positive half and the negative half lie almost parallel with the major axis.

CONCLUSIONS

Although slight modifications are still necessary on the method of assuming locations and dimensions of wave sources, it is concluded that statistical models give reasonable wave heights at near-coast offshore points. Oceanographic model is not recommended since trial and error procedure to obtain it is troublesome and method of evaluation for selection of the most suitable model is doubtful.

Perhaps fault models are the most reliable ones as quoted by Dr. Kanamori on relative distributions of sea bed deformations. However the absolute values proposed until now are too much small.

The leading part of tsunami is generated so as to reflect the pattern of the sea bed dislocation, propagates under the effect of dispersion and exits the forced oscillation in near-coast region where free oscillations follow it which periods are governed by oscillation systems there.

For the Sanriku 1933 tsunami, it is found a depression wave generated along the major axis disappeared in relatively short period and one drop down and one ascension form the leading part along the minor axis which proceed to the shallower region without change the wave height remarkably. This leading part forms spindle-shaped two dimensionally. Such directivity of tsunami is illustrated by the bottom movement with opposite sign against the major axis.

ACKNOWLEDGEMENT

The author wishes his acknowledgement to Master of Eng. Akira Mano, a graduate student of Tohoku University for his excellent achievement of

numerical calculations employing NEAC 2230-700 and CDC 6600.

CHAPTER 63

3-D HYDRAULIC MODEL OF WAVES GENERATED BY DISPLACEMENTS

by

Shin-Lin Liu* and R. L. Wiegel**

ABSTRACT

Measurements were made of the water waves generated by the horizontal motion of submerged plungers. The results obtained in a three-dimensional hydraulic model experiment, using a plunger 0.5 ft. wide and 0.25 ft. high, were compared with both the experimental results and theory for the two-dimensional case. It was found that at a given location the ratio of the elevation above the still water level (SWL) of the first wave (the largest wave of the group for the range of variables tested) to the displacement of the plunger (H_3/λ) was found to be dependent upon the Froude Number N_{Favg} (based upon the average plunger speed and the water depth) and upon the ratio of the height of the plunger to the water depth (D/d). For a constant value of θ , H_3/λ increased with increasing N_{Favg} and D/d . A few additional tests were made using a plunger 2.0 ft. wide and 0.25 ft. high. The results show that H_3/λ depends also upon the ratio of water depth to the width of the plunger (d/W).

INTRODUCTION

The generation of waves by a tectonic displacement has been solved for the two-dimensional case by Garcia (1972) using a numerical model (ABMAC, Arbitrary Boundary Marker And Cell). Garcia compared the results from his

*Engineer, General Electric Company, San Jose, California

**Professor of Civil Engineering, University of California, Berkeley

numerical model with those obtained from a hydraulic model study of several types of boundary motions for a fairly large range of Froude numbers and found that the numerical model is quite good. It appears, however, that the largest existing digital computer in the U.S. does not have the capability to permit the use of ABMAC to solve three-dimensional problems of this type, except for the case of radial symmetry. The two-dimensional case is useful as an approximation to some prototype cases. For other cases it is not. Owing to this it was decided to test the applicability of the two-dimensional numerical results in three-dimensional cases, making use of a hydraulic model.

LABORATORY ARRANGEMENTS AND PROCEDURES

The experimental arrangements are shown in Fig. 1. The experiments were conducted in a tank which was 5.5 feet wide by 16 feet long by a little less than 3 feet deep. "Steps" were placed along one side wall of the tank. They were 0.50 ft. and 2.00 ft. wide, with both of them being 0.25 ft. high, containing a movable plunger. The design and operation of the mechanism used to cause the plungers in the steps to move horizontally has been described by Garcia (1972) and by Das and Wiegel (1972).

A rotating boom was constructed which pivoted about a pin connection which was located at the centerline of the step, above the front end of the plunger. Parallel wire resistance wave gages (Wiegel, 1953) were mounted on the boom to sense the disturbance of the water surface. A transducer to measure the displacement of the plunger was installed between the tank frame and the moving arm (Fig. 1). The outputs of the wave gages and the plunger displacement transducer were amplified and recorded on an 8-channel strip chart recorder. A number of tests were made to check the reproducibility of results, which was found to be excellent.

Falling weights were used to drive the plunger, with the total plunger displacement (λ) occurring during a time interval τ .

Wave-absorbing material was placed along the three sides of the tank to minimize reflections.

TWO-DIMENSIONAL TESTS

A series of tests were made to be certain that the new arrangements were such that Garcia's (1972) hydraulic model studies could be reproduced. To do this a vertical training wall was placed alongside the $W = 0.50$ ft. wide step, extending the entire length of the tank. Thus, a two-dimensional channel was formed, as in Garcia's tests. A typical example of a water surface profile is shown in Fig. 2. The agreement between

measurements and predictions made using the numerical model of Garcia was found to be very good.

THREE-DIMENSIONAL TESTS

The training wall described in the previous section was removed, and the waves were permitted to radiate in an entire half plane. The ratio of the first wave crest elevation above the SWL (measured along the wall) to the equivalent measurement for the two-dimension case (H_3/H_2), as a function of the normalized distance from the plunger (x/d) is shown in Fig. 3. In this figure, λ is the total displacement of the plunger, W is the width of the plunger, τ is the time required for the displacement to occur, N_{Favg} is the Froude number (V_{avg}/\sqrt{gd}), V_{avg} is the average speed of the plunger movement (λ/τ), g is the acceleration of gravity and d is the water depth in the tank. For the range of conditions tested (three values of Froude number, N_{Favg}), the first wave was the highest wave. It is evident for a source of the type tested, that H_3 is much smaller than H_2 , except near the source. The averages of the data shown in Fig. 4 have been plotted on logarithmic paper in Fig. 4. It can be seen that H_3/H_2 decreases as $(x/d)^{-3/5}$ for values for $x/d > 0.7$. For x/d greater than about 6, H_3/H_2 is less than 0.2.

Some data on the surface spread of the waves are given in Fig. 5. Data for two of these cases were plotted in Fig. 6. The elevations of the first crest above SWL were measured at a radius of 0.50 ft. for $0 \leq \theta \leq 90$ degrees. These values of H_3 were plotted versus $r \sin \theta$, and it was found that there was a nearly linear relationship between the two variables. In these tests $d = 0.50$ ft., and the water depth above the step was 0.25 ft. ($D/d = 0.50$).

A number of additional tests were made, for values of $d = 4, 5, 6, 7, 8$ and 9 inches. The relationship between the Froude number and H_3/λ is shown in Fig. 7. The data shown in Fig. 7 and tabulated in Table 1 were obtained along the centerline in the direction of the plunger motion. These data are for a constant average plunger speed, V_{avg} , with different water depths. The two-dimensional results obtained by Garcia (1972) for a constant water depth, at $x = 5$ ft., are also shown in Fig. 7 for comparison. Although the location at which the measurements were made is different, it is still interesting to note that the relationship between H_3/λ and N_{Favg} has a less steep slope than is the case for the results from the two-dimensional tests. It also can be seen from Fig. 7 that for a constant Froude number the ratio H_3/λ tends to vary only slightly with λ/d within the range of variables tested. Furthermore, the ratio H_3/λ tends to be linearly related to the Froude number for values of Froude number between 0.3 and 0.4.

The variables affecting the ratio of the normalized crest elevation of the first wave for the 0.50 ft. wide plunger are the ratios, x/d , D/d , λ/d , the angle θ as defined in Fig. 5, and the Froude number. In order to study the relationship between H_3/λ and D/d , the other dimensionless variables were kept constant. The Froude number was kept constant by varying the plunger speed for different water depths. The desired plunger speed was obtained by using different weights that were dropped to move the plunger. To hold x/d and λ/d constant, a set of appropriate distances along the x axis and plunger displacements were chosen. The values of these parameters are given in Table 2. The results for different values of θ are shown in Fig. 8 and tabulated in Table 3. The locations at which the measurements were made are shown in Fig. 9.

The work described above (Table 3 and Fig. 8) was extended to include additional values of θ , up to 180 degrees. The results are shown in Tables 4 and 5 and in Fig. 10. A comparison of the results given in the three tables for values of $\theta = 0, 15, 30, 45$ and 60 degrees shows that the results are closely reproducible.

The curves shown in Fig. 10 were cross-plotted in Fig. 11. For large values of D/d , no data for $\theta > 135$ degrees are shown as there was no or very little water over the step and measurements were nearly meaningless. Note that for small values of D/d the curves of H/λ versus θ were approximately symmetrical about $\theta = 90$ degrees, but were very nonsymmetrical for large values of D/d . Examples of the wave records are given in Figs. 12 and 13. It can be seen for large values of D/d that the shape of the wave is different for $\theta = 15$ than for $\theta = 165$ degrees, etc. Thus, the phenomenon is more complicated than one might expect from an observation of Fig. 11.

With the same experimental setup that was used for the 0.50 ft. wide and 0.25 ft. deep plunger, additional tests were made using a step and plunger 2.00 ft. wide and 0.25 ft. high to obtain some information on the effect of the width of the source on the height of the crest of the leading wave. Unexpected difficulties were encountered in constructing and operating the wider step and plunger, so that insufficient data were obtained. However, enough data were obtained to be of some value in understanding the phenomenon.

The locations at which the waves were measured are shown in Fig. 14. The experimental results given in Table 6 were obtained along the centerline of the step. Comparing these data with the results obtained for the 0.50 ft. wide step (Table 2) shows that H_3 for the narrow ($W = 0.50$ ft.) step and plunger was about 35 percent of the value for the wide ($W = 2.00$ ft.) step and plunger for a value of D/d of about 0.40, and a little more than 55 percent of the value for D/d equal to 1.0 (Fig. 15), all other conditions being equal.

Fig. 16 shows that for $D/d < 0.5$ and $d/W > 1$, values of ratio H_3/λ are fairly independent of y for the narrow plunger. The first wave crests in this region, behave as if they came from a point source and are nearly independent of θ . The same tendency is apparent for the wide plunger for the smallest values of D/d for which tests were made. For large values of D/d the values of H_3/λ become quite nonuniform with respect to a constant value of r/d for both the narrow and wide plungers. It also can be seen that the waves behave as if they were generated by a combination of a line source and a point source for the case of $W = 2.00$ ft. for large values of D/d .

The plots of H_3/λ versus y shown in Fig. 16 for the $W = 0.50$ ft. plunger were shifted to the left by a value of 1.50 ft., and replotted in Fig. 17. The values are plotted as if the edge of the $W = 0.50$ and the $W = 2.0$ ft. plunger were along the same line. It is interesting to note the similarity of the two sets of data. It is also evident that the waves for the $W = 2.00$ ft. plunger were always higher than the waves for the $W = 0.50$ ft. plunger.

CONCLUSIONS

1. For the source mechanism tested, the wave crest elevation is considerably less for the three-dimensional case than for the two-dimensional case, with H_3/H_2 decreasing in proportion to $(x/d)^{-3/5}$ for $0.7 < x/d < 10$ and $W/d = 1.0$.
2. For small values of D/d the values of H_3/λ are fairly uniformly distributed with respect to θ for a given value of r/d , but become very nonuniform for large values of D/d .
3. Measurements of H_3 at a given value of r/d for various values of θ from 0 to 90 degrees showed that H_3 decreased in a nearly linear manner with the $r \sin \theta$, that is with the projection of the measurement point on the y axis, at least for the narrow ($W = 0.50$ ft.) source.
4. Values of H_3 along the centerline of the step and plunger were substantially higher for the wide ($W = 2.00$ ft.) source than for the narrow ($W = 0.50$ ft.) source, all other conditions being held constant.
5. Whether the plunger acts like line source or point source depends on the values of W/d and r/d .

NOTATION

d = undisturbed water depth (except over step and plunger), feet (or inches, as specified)

D = height of step (also plunger) above bottom of tank, feet

H₂ = elevation of first wave crest above SWL, 2-dimensional case, ft.

H₃ = elevation of first wave crest above SWL, 3-dimensional case, ft.

N_{Favg} = Froude number, V_{avg}/\sqrt{gd} , dimensionless

r = radius, measured from origin, $r^2 = x^2 + y^2$

SWL = still water level

t = time, seconds

V_{avg} = average velocity of plunger (λ/τ), feet per second

W = width of plunger, feet

x = horizontal distance along the side wall of the tank measured from the front end of the step, feet

y = horizontal distance normal to the side wall of the tank, feet

z = vertical coordinate

λ = total plunger displacement, feet (or inches, as specified)

τ = total time of plunger motion, seconds

θ = horizontal angle, measured counterclockwise from the centerline of the step, degrees

CHAPTER 64

CALCULATIONS OF WAVES FORMED FROM SURFACE CAVITIES Charles L. Mader*

ABSTRACT

The wave motion resulting from cavities in the ocean surface was investigated using both the long wave, shallow water model and the incompressible Navier-Stokes equations. The fluid flow resulting from the calculated collapse of the cavities is significantly different for the two models. The experimentally observed flow resulting from explosively formed cavities is in better agreement with the flow calculated using the incompressible Navier-Stokes model. The resulting wave motions decay rapidly to deep water waves. Large cavities located under the surface of the ocean will be more likely to result in Tsunami waves than cavities on the surface. This is contrary to what has been suggested by the upper critical depth phenomenon.

I. INTRODUCTION

The prediction of water waves generated by large-yield explosions has been based on extrapolation of empirical correlations of small-yield experimental data, usually assuming the waves were shallow water waves. Because the accuracy of such predictions is questionable, the need exists for a detailed description of the mechanism by which waves are generated by explosions. In particular the "upper critical depth" phenomenon needs to be understood. The upper critical depth phenomenon is an experimentally observed wave height maximum that occurs when an explosive charge is approximately two-thirds submerged. The observed height at the upper critical depth is twice that observed for completely submerged explosive charges. If the waves formed are shallow water waves capable of forming Tsunamis, then the upper critical depth phenomenon is important to evaluating the probability of a Tsunami event from other than tectonic events.

Theoretical evaluation of the early interaction of the detonation products of an explosive charge with the water and air interfaces and the resulting wave profile near the detonation has been performed by Mader¹ using the multicomponent reactive compressible hydrodynamic code 2DE.² The pressure and velocity contours for the early interaction of the explosive with the water and air are shown in Fig. 1. The initial formation of the lip or splash wave on the water cavity is also numerically described and it has been suggested that the concentration of momentum near the water surface in the splash wave is a contributing

*Theoretical Division, Los Alamos Scientific Laboratory, University of California, Los Alamos, New Mexico 87545

factor in the upper critical depth phenomenon, resulting in a bubble cavity radius about the same as if the explosive bubble was completely confined by water. The high velocity present in the splash wave is a result of the initial water shock being quickly rarefied and permitting a second shock to be delivered from the explosive products. Subsequent shocks and rarefactions occur while the detonation products have high pressure. Each reverberation increases the particle velocity of the splash wave by an increment that decreases as the pressure of the driving detonation products decreases. The particle velocity of the remainder of the water cannot be increased by reverberations during the early high pressure motion because a free interface is not present. The consequence of this complicated interaction is that the maximum bubble radius achieved by a partially submerged explosive charge is slightly larger than one would expect to observe if the explosive sphere and its bubble was confined by water at one bar.

The bubble is observed to increase to a maximum radius of about 0.5 meter in 0.2 second and then take about 0.3 second to collapse as described in Refs. 1 and 3 for a 1.27-cm radius 9404 explosive sphere initiated at the center and immersed to a depth of 1.59 cm.

In this paper we shall describe an investigation of the flow after the cavity reaches its maximum dimensions. We assume that the flow is essentially incompressible at the times of interest and that the surrounding fluid is approximately at rest at maximum bubble radius.

The waves observed by Craig³ from the collapse of the bubble resulted in a train of waves moving at about 1.25 meters/second with a one-meter wavelength. Mass markers located one meter below the water surface and markers located half a meter below the surface and one meter from the explosive did not show any appreciable movement compared with those located nearer the surface or explosive charge. This result suggests that the fluid flow will not be well described by the usual shallow water-long wave model.

We have calculated the fluid dynamics of a cavity initially 0.5 meter in radius with and without a lip, using a shallow water long wave model and a model based upon the incompressible Navier-Stokes equations.

II. SHALLOW WATER, LONG WAVE MODEL

The long wave theory applies when the depth relative to the wavelength is small, and when the vertical component of the motion does not influence the pressure distribution, which is assumed to be hydrostatic. It is appropriate for Tsunami wave formation, propagation and early shoaling behavior as described in Ref. 4. The SWAN code described in Ref. 4 was modified to solve the long wave equations using an improved numerical difference technique.

The long wave equations solved by the SWAN code are:

$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial X} + V \frac{\partial U}{\partial Y} + g \frac{\partial H}{\partial X} = FV + F(x) - g \frac{U(U^2 + V^2)^{1/2}}{C^2(D + H)}$$

$$\frac{\partial V}{\partial t} + U \frac{\partial V}{\partial X} + V \frac{\partial V}{\partial Y} + g \frac{\partial H}{\partial Y} = FU + F(y) - g \frac{U(U^2 + V^2)^{1/2}}{C^2(D + H)}$$

$$\frac{\partial H}{\partial t} + \frac{\partial(D + H - R)U}{\partial X} + \frac{\partial(D + H - R)V}{\partial Y} - \frac{\partial R}{\partial t} = 0$$

- where U = velocity in X direction (i index)
 V = velocity in Y direction (j index)
 g = gravitational acceleration
 t = time (n index)
 H = wave height above mean water level
 R = bottom motion
 F = Coriolis force parameter
 C = coefficient of DeChezy for bottom stress
 F(x), F(y) = forcing functions of wind stress and barometric pressure in X and Y direction
 D = depth .

To obtain stable numerical solutions, the finite difference equations must not have negative diffusion. The following difference equations are stable but require that the time step be kept near the maximum or the numerical results will become smeared. C. W. Hirt⁵ suggested this approach when the difference equations described in Ref. 4 were found to be unstable in certain directions of the flow.

The wave height H and depth D are taken as cell centered and the velocities are centered at cell boundaries. The difference equations at each time step are in order:

$$H_{i,j}^{n+1} = H_{i,j}^n - \Delta t \left[\frac{U_{i+1,j}^n}{\Delta x} (TD1) - \frac{U_{i,j}^n}{\Delta x} (TD2) + \frac{V_{i,j+1}^n}{\Delta y} (TV1) - \frac{V_{i,j}^n}{\Delta y} (TV2) \right]$$

$$+ R_{i,j}^{n+1} - R_{i,j}^n$$

$$TD1 = D_{i+1,j} + H_{i+1,j}^n - R_{i+1,j}^n \quad (U_{i+1,j} < 0)$$

$$TD2 = D_{i,j} + H_{i,j}^n - R_{i,j}^n \quad (U_{i,j} < 0)$$

$$TV1 = D_{i,j+1} + H_{i,j+1}^n - R_{i,j+1}^n \quad (V_{i,j+1} < 0)$$

$$TV2 = D_{i,j} + H_{i,j}^n - R_{i,j}^n \quad (V_{i,j} < 0)$$

$$TD1 = D_{i,j} + H_{i,j}^n - R_{i,j}^n \quad (U_{i+1,j} > 0)$$

$$TD2 = D_{i-1,j} + H_{i-1}^n - R_{i-1,j}^n \quad (U_{i,j} > 0)$$

$$TV1 = D_{i,j} + H_{i,j}^n - R_{i,j}^n \quad (V_{i,j+1} > 0)$$

$$TV2 = D_{i,j-1} + H_{i,j-1}^n - R_{i,j-1}^n \quad (V_{i,j} > 0)$$

$$U_{i,j}^{n+1} = U_{i,j}^n - \Delta t \left[\frac{U_{i,j}}{\Delta x} (TU1) + \frac{TV}{\Delta y} (TU2) \right] - g \frac{\Delta t}{\Delta x} [THU]$$

$$+ \Delta t \left\{ -FV_{i,j}^n - F_{i,j}^{(x)} + S_{i,j}^B \right\}$$

$$TV = 0.25 (V_{i,j} + V_{i,j+1} + V_{i-1,j+1} + V_{i-1,j})$$

$$TU1 = U_{i+1,j} - U_{i,j} \quad (U_{i,j} < 0)$$

$$TU2 = U_{i,j+1} - U_{i,j} \quad (TV < 0)$$

$$TU1 = U_{i,j} - U_{i-1,j} \quad (U_{i,j} > 0)$$

$$TU2 = U_{i,j} - U_{i,j-1} \quad (TV > 0)$$

$$THU = H_{i,j} - H_{i-1,j}$$

$$v_{i,j}^{n+1} = v_{i,j}^n - \Delta t \left[\frac{TU}{\Delta X} (TV1) + \frac{v_{i,j}}{\Delta Y} (TV2) \right] - g \frac{\Delta t}{\Delta Y} [THV] \\ + \Delta t \left\{ F U_{i,j}^n - F_{i,j}^{(y)} + S_{i,j}^B \right\}$$

$$TU = 0.25 (u_{i,j} + u_{i+1,j} + u_{i,j-1} + u_{i+1,j-1})$$

$$TV1 = v_{i+1,j} - v_{i,j} \quad (TU < 0)$$

$$TV2 = v_{i,j+1} - v_{i,j} \quad (v_{i,j} < 0)$$

$$TV1 = v_{i,j} - v_{i-1,j} \quad (TU > 0)$$

$$TV2 = v_{i,j} - v_{i,j-1} \quad (v_{i,j} > 0)$$

$$THV = H_{i,j} - H_{i,j-1}$$

and

$$S_{i,j}^B = g U_{i,j}^n \left(\frac{u_{i,j}^n}{U_{i,j}^n} + \frac{v_{i,j}^n}{V_{i,j}^n} \right)^{1/2} / c^2 (D_{i,j} + H_{i,j}^n)$$

The calculations were performed with 69 cells in the X direction and 130 cells in the Y direction. The cells were .06 meters square and the time step was 0.001 seconds. The gravity constant was -9.8 m sec^{-2} . Although the problem described in this report was symmetrical and required only one direction, the calculations described were performed with the two dimensional SWAN code.

The computed wave profiles using the shallow water equations in the SWAN code for the collapse of a 0.5-meter radius hole are shown in Fig. 2 and for the collapse of a 0.5-meter radius hole with a 0.25-meter high and 0.50-meter wide triangular lip (which approximates the experimentally observed bubble profile) are shown in Figs. 2 and 4. Figure 4 also shows the velocity in the Y direction. The initial water depth was three meters.

III. INCOMPRESSIBLE NAVIER-STOKES MODEL

The Marker and Cell (MAC) method of Harlow and Welch⁶ is a numerical technique for calculation of viscous, incompressible flow with a free surface.

The method uses a finite-difference technique for solving the time-dependent Navier-Stokes equations.

These equations for two-dimensional flows are

$$\frac{\partial U}{\partial X} + \frac{\partial V}{\partial Y} = 0 \quad ,$$

$$\frac{\partial U}{\partial t} + \frac{\partial U^2}{\partial X} + \frac{\partial UV}{\partial Y} = - \frac{\partial \phi}{\partial X} + g_x + \nu \left(\frac{\partial^2 U}{\partial X^2} + \frac{\partial^2 U}{\partial Y^2} \right) \quad ,$$

$$\frac{\partial V}{\partial t} + \frac{\partial UV}{\partial X} + \frac{\partial V^2}{\partial Y} = - \frac{\partial \phi}{\partial Y} + g_y + \nu \left(\frac{\partial^2 V}{\partial X^2} + \frac{\partial^2 V}{\partial Y^2} \right) \quad ,$$

where ϕ is the ratio of pressure to constant density, g_x and g_y are the X and Y components of body acceleration, and ν is the kinematic viscosity coefficient. The MAC method is based on an Eulerian network of rectangular cells, with velocities centered at cell boundaries and the pressure cell-centered. Just as the differential equations of motion are statements of the conservation of mass and momentum, the MAC finite-difference equations express these conservation principles for each cell, or combination of cells, in the computing mesh.

After the introduction of MAC, much attention was given to devising more accurate treatments of the free surface boundary conditions. Chan and Street⁷ developed a technique for more accurate delineation of the free surface. This permitted the free surface pressure to be specified at the surface itself, rather than at the center of the surface cell. Nichols and Hirt⁸ modified the Chan and Street procedure, devising a technique for defining the fluid surface by a set of surface marker particles that move with local fluid velocity. These particles allow surface-cell pressures in MAC to be accurately specified by means of linear interpolation or extrapolation between the known values of pressure in the nearest full cell and the desired fluid surface.

A Simplified MAC (SMAC) has been described by Harlow and Amsden.⁹ The SMAC technique has been modified to include the Nichols and Hirt free surface treatment. The computing program used for the calculations is called ZUNI and is described by Amsden.¹⁰ The calculations were performed with 100 cells in the X direction and 60 cells in the Y direction. The cells were 0.05 meters square and the time step increment was 0.0003 seconds. The convergence criterion is the maximum permitted change in pressure from hydrostatic pressure in any cell between iteration steps divided by the sum of the changes at two iteration steps and was 0.01. Three or more surface particles were used in each cell. The gravity constant was -9.8 m sec^{-2} . The viscosity coefficient was $0.01 \text{ gm sec}^{-1} \text{ m}^{-1}$. Preliminary calculations showed that the results were independent of whether the water depth was 3.0 or 1.5 meters; therefore in the calculations presented in this paper the cavity was in

water initially 1.5 meters deep. The wave amplitude at late times and the details of the bubble collapse after first collapse and jetting were sensitive to the amount of viscosity used in the calculation so the value chosen was the smallest that would also permit numerically stable results. The computed wave profiles using the ZUNI code to solve the incompressible Navier-Stokes equations for the collapse of a 0.5-meter radius hole with a 0.25-meter high and 0.5-meter wide triangular lip are shown in Fig. 5.

IV. COMPARISONS

The experimental and calculated wave parameters are summarized in Table I. The experimental wave parameters are given for the first three waves after four meters of travel from the center of the explosive charge. The calculated wave parameters for the Airy wave were calculated using the WAVE code⁴ for a depth of three meters and using the experimentally observed wave height and wave length. Since the group velocity is almost exactly half the wave velocity, the Airy wave is a deep water wave. The deep water Airy wave is a good approximation to the experimentally observed wave.

The collapse of the cavity is quite different between the SWAN and ZUNI calculation as shown in Figs. 3 and 5. The shallow water cavity calculation collapses from the side in less than 0.1 second while the Navier-Stokes cavity calculation collapses from the bottom in about 0.5 seconds. The experimentally observed bubble collapses approximately symmetrically from the bottom in about 0.3 seconds, so the Navier-Stokes calculation is a more realistic description of the observed flow.

As shown in Table I the Navier-Stokes calculation results in wave parameters more closely approximating those observed experimentally than those calculated using the shallow water theory. The waves calculated using the incompressible Navier-Stokes equations have complicated wave patterns and the waves quickly decay into deep water waves with the particle motion rapidly decreasing with increasing depth below the water surface. This is also in agreement with the experimental observations of mass markers described in the introduction.

TABLE I
CALCULATED AND EXPERIMENTAL WAVE PARAMETERS

	<u>Experimental*</u>	<u>Airy Wave</u>	<u>Shallow Water</u>	<u>Navier-Stokes</u>
Wave Velocity (m/s)	1.25 ± 0.1	1.2489	5.42	1.50 ± 0.50
Amplitude (cm)	1, 1.8, 2.5	2.5 (input)	10.1	< 4.0
Wave Length (m)	1.5, 1.0, 1.0	1.0 (input)	1.0	1.0
Period (s)	1.2, 0.8, 0.8	0.8007	0.18	0.66 ^{+0.3} _{-0.2}
Group Velocity (m/s)		0.6244		

*First three waves observed.

V. CONCLUSIONS

The experimentally observed waves from the cavities formed by explosions near the water surface are better reproduced by models solving the incompressible Navier-Stokes equations than by models solving the shallow water, long wave equations. The experimentally observed waves are deep water waves and the observed upper critical depth phenomenon is apparently a result of a partition of energy near the water surface which results in high amplitude deep water waves (of high potential and low kinetic energy) and not the shallow water waves required for Tsunamis. As the explosive is detonated under the water surface, more of the energy is imparted to the water resulting in waves that have smaller amplitude but more of the energy is present in the water as kinetic energy rather than potential energy. The waves formed will more closely resemble shallow water waves and will not disperse as rapidly as waves formed from surface detonation.

The upper critical depth phenomenon is apparently not important to the formation of Tsunami waves. Large cavities located under the surface of the ocean will be more likely to result in shallow water Tsunami waves than cavities on the surface. A cavity would have to be quite large and reach very deep into the ocean before it could be an effective agent for forming significant Tsunami waves.

To obtain a more realistic solution to the problem of wave formation from explosions one would need to follow the hydrodynamics from the early compressible to late incompressible stages with one of the implicit continuous fluid methods currently under development. Of particular interest would be to determine the source and significance for wave formation of the water jet and root experimentally³ observed before the explosive bubble reaches maximum radius at depths similar to the upper critical depth.

QUANTITATIVE DESCRIPTION OF SEDIMENT TRANSPORT BY WAVES

by

Ole Secher Madsen⁽¹⁾, M.ASCE and William D. Grant⁽²⁾, A.M.ASCE

1. Introduction

With the apparent desire of man to move some of his activities into the offshore region the problems associated with the assessment of the impact of large structures in this environment will be of increasing importance. One of the impacts of a large offshore structure, such as for example the Atlantic Generating Station proposed by Public Service Electric and Gas Company of New Jersey, would be its effect on the wave and current pattern in the vicinity of the structure. These changes in wave and current conditions will induce changes in the sediment transport pattern and may disturb an existing equilibrium thus causing large changes in bottom topography in the vicinity of the structure. These topographical changes may extend all the way to the adjacent shoreline and thus cause deposition in some and erosion in other areas. To assess the severity and extent of topographical changes induced by an offshore structure an ability to quantify not only the effects of the structure on the wave and current pattern but also the mechanics of the interaction of the resulting fluid motion with the bottom sediment is clearly needed. The purpose of this paper is to establish quantitative relationships for the fluid-sediment interaction in this environment.

To avoid misunderstandings it should be pointed out from the outset that the results obtained in the following are limited to non-cohesive sediments and to reasonably well behaved wave conditions. The former of these limitations does not seem severe in view of the fact that the bottom sediments for the major part of the continental shelf may be characterized as cohesionless; the latter limitation excludes the direct application of the results in the immediate vicinity of the structure and in the surf zone where the conditions are complicated by the occurrence of wave breaking. It is, however, hoped that the results of the present research are of a sufficiently general nature to provide at least some insight also into these complicated processes.

With these limitations in mind the first question to ask if concerned with the sediment transport caused by a moving fluid would be: when does the sediment start to move? At the outset of this study a review of the literature on the initiation of sediment movement in oscillatory unsteady flow revealed that there were as many answers as there were publications pertaining to this question. By reanalyzing some of these previously published results

(1) Associate Professor, Ralph M. Parsons Laboratory, Massachusetts Institute of Technology, Cambridge, MA 02139

(2) Research Assistant, Ralph M. Parsons Laboratory, Massachusetts Institute of Technology, Cambridge, MA 02139

and making use of Jonsson's (1966) wave friction factor concept, which enables one to determine the magnitude of the maximum bottom shear stress associated with an oscillatory fluid motion, the differences between various investigations are essentially reconciled. In Section 2 it is shown that the Shields Criterion obtained for unidirectional steady flow is applicable as a general criterion for the onset of sediment movement also in oscillatory unsteady flow.

With a general criterion for the initiation of sediment movement established the next logical question to ask is: at which rate is sediment being transported once the critical bottom shear stress is exceeded? This question, in the context of purely oscillatory flow, has previously been addressed in a search for quantitative relationship by Einstein and co-workers at the University of California at Berkeley in the early sixties (Einstein, 1972), i.e., prior to the availability of the work of Jonsson (1966) on the wave friction factors. In Section 3 the Berkeley data is reanalyzed, using the wave friction factor concept, in terms of more fundamental parameters than those employed by Einstein and co-workers. It is found that their experimental data are well represented by a quasi-steady application of the empirical Einstein-Brown relationship (Brown, 1950) for sediment transport in unidirectional steady flow. Provided the equivalent sand roughness of the bottom is taken as the sediment grain size when evaluating the bottom shear stress for the purpose of predicting the rate of sediment transport it is found that the quasi-steady application of the Einstein-Brown relationship represents the Berkeley data obtained for a plane bed as well as for a bed exhibiting bed forms (ripples).

Some aspects of the application of the general sediment transport relationship, which was established in Section 3 based on experiments performed in purely sinusoidal flow, to predict net sediment transport rates in the coastal environment are discussed in Section 4. The net sediment transport in this wave dominated environment arises from differences in the rate at which sediment is transported back and forth with the wave motion. These differences arise from second order effects such as wave asymmetry, wave induced mass transport and superposed tidal or wind-induced currents. Due to our limited knowledge of the near-bottom turbulent flow conditions associated with unsteady boundary layer type flows the discussion of the factors producing a net sediment transport is rather qualitative, and serves primarily to identify topics in desperate need of further research. It is, however, felt that the quantitative relationships for the sediment transport by waves may serve as the framework for further quantitative studies of sediment transport in the coastal environment. The presentation is rather brief and a general reference is given to Madsen and Grant (1976) for a more detailed discussion.

2. Initiation of Sediment Movement in Oscillatory Flow

For unidirectional steady flow a widely accepted criterion for the initiation of sediment motion on a plane bed is given by Shields Criterion (Shields, 1936). This criterion essentially expresses the critical value of the ratio of entraining to stabilizing forces acting on a sediment grain on the sediment-fluid interface. The entraining force is related to the shear stress exerted on the bottom by the moving fluid, the stabilizing force is related to the submerged weight of a sediment grain and when the ratio of the two forces, re-

ferred to as Shields Parameter, exceeds a critical value sediment movement is initiated. The Shields Criterion is an empirical relationship which is quite general in that it applies for any fluid, flow and sediment characteristics so long as the sediment is cohesionless.

For oscillatory unsteady flows, such as the to and fro motion of the near bottom fluid particles under waves, several empirical criteria for the onset of sediment movement have been advanced. Bagnold (1946) and Vincent (1958) thus relate the amplitude of the near-bed fluid particle motion relative to the bed and the period of oscillation corresponding to the critical condition of initiation of sediment motion. A set of curves, each corresponding to particular sediment characteristics results. Relationships of this kind are usually limited by the range of experimental conditions from which they were derived and are not of the general nature of the Shields Criterion for unidirectional steady flow. The considerable differences between the critical conditions for initiation of sediment movement under waves exhibited by the comparison of some 13 such relationships (Silvester and Mogridge, 1971) clearly demonstrate this.

More general criteria for the initiation of sediment movement under waves have been proposed by Horikawa and Watanabe (1967) and Kajjura (1968). Both of these investigations evaluate the stability of a single grain on the sediment-fluid interface based on the concept of the maximum bottom shear stress associated with the oscillatory flow. Madsen and Grant (1975) presented Bagnold's data on initiation of motion in oscillatory flow in the form of a Shields Diagram in a discussion of a paper by Komar and Miller (1973). Madsen and Grant (1975) utilized the results of the comprehensive study of Jonsson (1966) to evaluate the maximum bottom shear stress associated with an oscillatory flow and this procedure was adopted by Komar and Miller (1975) in their reply. Despite the demonstration of the general validity of the Shields Criterion provided by Komar's and Miller's (1975) analysis their final recommendation for the quantitative description of the initiation of sediment movement under waves is essentially equivalent to their earlier paper.

In an unsteady flow one might expect that an inertia force in addition to a drag force, expressed by the bottom shear stress, contributes to the entraining force acting on a sediment grain on the sediment-fluid interface. An approximate analysis (Madsen and Grant, 1976) as well as a comparison with experimental data, however, shows that the entraining force is adequately represented by the bottom shear stress. Thus, adopting Jonsson's results, it is possible to evaluate the shear stress exerted on the bottom by the oscillatory fluid motion above the bed and present various experimental data for the onset of sediment motion in oscillatory flow in a Shields Diagram based on a Shields Parameter

$$\psi_m = \frac{\tau_{om}}{\rho g (s-1) d} \quad (1)$$

in which ρ is the fluid density, g is the acceleration of gravity, s is the specific gravity of the sediment material, d is the grain diameter and τ_{om} is the maximum bottom shear stress defined by

$$\tau_{om} = \frac{1}{2} f_w \rho u_b^2 \quad (2)$$

in which u_b is the maximum velocity of the fluid relative to the bed and f_w is the wave friction factor as given by Jonsson (1966).

From knowledge of the oscillatory motion, the fluid and sediment characteristics Jonsson's results may be used to evaluate the value of τ_{om} and hence the Shields Parameter given by Eq. (1). Rather than presenting the results in a conventional Shields Diagram the more practical presentation using the parameter

$$S_* = \frac{d}{4\nu} \sqrt{(s-1)gd} \quad (3)$$

in place of the boundary Reynolds number is used. The experimental results analyzed are summarized in Table 1 and presented graphically in Fig. 1.

All experiments on the initiation of sediment movement were performed using an initially flat bed and the equivalent boundary roughness was taken as the sediment diameter. From the sediment and fluid characteristics S_* is obtained from Eq. (3). When no information on the fluid temperature was available the kinematic viscosity of the fluid (in all cases water) was taken as 10^{-5} ft²/sec ($9.3 \cdot 10^{-3}$ cm²/sec). The various sets of experimental data are presented by the heavy vertical lines in Fig. 1 and are identified by a letter in the left hand side of the diagram indicating the investigator (e.g., M for Manohar, 1955) and by the symbol identifying the particular sediment (e.g., S1) whose characteristics may be found in Table 1.

The range of the critical values of the Shields Parameter obtained by a particular investigator for a given sediment indicates a variation of at most some 30% around the mean value. In the context of sediment transport and, in particular, when realizing the subjectiveness involved in determining the point of incipient sediment motion (defined as the condition when one or two grains are dislodged and move a few places) this scatter must be considered reasonable. The possibility, however, remains that the scatter exhibits a systematic variation with period of oscillation as suggested by Komar and Miller (1973). By examining the data it was, however, found that no general trend of the variation of the critical value of the Shields Parameter with period of oscillation was exhibited by the data. In some cases ψ_m increased with decreasing period (e.g., VPU, Vincent, 1958) in others the reverse was true (e.g., MS5, Manohar, 1955) and in some ψ_m varied randomly with period (e.g., Horikawa and Watanabe, 1967).

From the preceding discussing it is concluded that the variation exhibited by individual experiments is due primarily to experimental scatter. When comparing the sets of experimental data by Bagnold (1946) and Manohar (1955) who both used an oscillating plate in their studies, it is, however, seen that the results of Bagnold consistently plot below those of Manohar. This difference, which was also noted by Komar and Miller (1973), could be attributed to imperfect motion of the tray in the case of Bagnold's experiments. The close agreement between Bagnold's results and those of Rance and Warren (1968), who used an oscillating water tunnel, suggests that this reason must be discarded and the differences must be attributed to individual differences in determining just when initial sediment movement occurs.

Table 1: Experiments on Initiation of Motion Presented in Figure 1.

Figure 1: Experimental Observations of the Initiation of Sediment Movement in Oscillatory Flow.

When considering all the experimental data presented in Fig. 1 which were obtained from quite different experimental set-ups and for a wide range of periods (0.8-16 sec) and materials ($s = 1.052 - 7.90$) and keeping in mind the subjectiveness involved in obtaining the experimental results the overall scatter is not alarming. In this respect it should be pointed out that experimental results for unidirectional flow also exhibit some scatter. The general trend of the data indicate a critical value of the Shields Parameter slightly above that associated with the Shields Curve determined from unidirectional steady flow experiments. Despite this minor discrepancy, the conclusion of the results presented in Fig. 1 is that: Shields Criterion for the initiation of sediment movement as derived from steady unidirectional flow conditions serves as a quite accurate and general criterion for the initiation of sediment movement in oscillatory flow, provided the boundary shear stress is properly evaluated.

Since it is to be expected that a bed generally would exhibit bed forms rather than being flat the Shields criterion may seem to be of limited usefulness. The general applicability of Shields Criterion, as demonstrated in Fig. 1 for the purpose of defining the threshold conditions for a flat bed does, however, establish the importance of the Shields Parameter in quantifying the fluid-sediment interaction for unsteady flow conditions. Thus, when the critical value of the Shields Parameter is exceeded, sediment transport is initiated and the rate of sediment transport may be expected to be related to the value of the Shields Parameter.

3. Rate of Sediment Transport in Oscillatory Flow

For a unidirectional steady flow the sediment will, once it is set in motion, be transported in the direction of flow. Hence, in a steady current, the answer to the question of sediment transport rate once the critical shear stress is exceeded would be equivalent to establishing a relationship between fluid and sediment properties as well as flow characteristics and the rate at which sediment is transported. In the oscillatory unsteady flow associated with a wave motion the answer is somewhat more involved.

In an oscillatory flow, the flow above the bed and hence the sediment transport is constantly varying in magnitude as well as direction. To the first approximation the near-bottom fluid velocity associated with a wave motion may be described by linear wave theory as a purely oscillatory motion. Consequently, if the threshold value of the bed shear stress is exceeded during the wave period the amount of sediment transported forward (in the direction of wave propagation) during half of the cycle will equal the amount being transported backwards during the other half of the cycle by virtue of the symmetry of the motion. This means that, to the first approximation, no net sediment transport is associated with a wave motion. Now, water waves do not induce a purely sinusoidal flow near the bed. Nonlinear effects such as wave asymmetry and wave induced mass transport currents are likely to disturb the equilibrium between the amounts of sediment transported forward and backward during a wave period, thus producing a net sediment transport. It is, however, important to realize that such a net sediment transport is brought about by the, possibly small, difference between the, possibly large, quantities of sediment moving forward and backward with the waves.

The preceding qualitative discussion of the mechanics of sediment transport by waves points out the undesirable, but unavoidable, problem of determining a small difference between two large quantities, if one attempts to derive a relationship for the net sediment transport due to wave action. It does, however, pose the fundamental question: What is the rate at which sediment moves forward and backward in a purely oscillatory flow? The answer to this fundamental question is tantamount to the successful solution of the problem of net sediment transport caused by wave action.

As suggested by the analysis of the initiation of sediment motion data presented in the previous section one would expect the Shields Parameter defined by Eq. (1) to be a physically significant parameter in quantifying fluid-sediment interaction. For this reason the experimental data on the average rate of sediment transport in a purely oscillatory flow obtained at the University of California at Berkeley by Einstein and co-workers are reanalyzed in an attempt to establish an empirical relationship

$$\bar{\phi} = \bar{\phi}(\Psi_m) \quad (4)$$

in which

$$\bar{\phi} = \frac{\bar{q}_s}{wd} \quad (5)$$

is the average sediment transport rate, \bar{q}_s , nondimensionalized by the fall velocity w of an equivalent spherical sediment grain of diameter d .

For given sediment and fluid properties the fall velocity, w , may be obtained (Madsen and Grant, 1976, Fig. 6) and from the measured sediment transport rate the value of the dimensionless sediment transport function, Eq. (5) is readily evaluated. Since the experiments analyzed here were performed for an initially flat bed it seems reasonable to take the equivalent sand roughness of the boundary as the sediment grain size. Whether bed forms developed during the experiments is not quite clear; however, a particular set of experiments where bed forms definitely were present (Manohar, 1955) will be analyzed later. At this point we may regard the experiments performed by Kalkanis (1964) and Abou-Seida (1965) to correspond to a plane bed. From knowledge of the oscillatory motion of the plate, and taking the equivalent sand roughness of the boundary to be the sediment grain diameter Jonsson's (1966) results may therefore be used to obtain the value of the maximum boundary shear stress, and the value of Ψ_m may be determined. The results obtained in this manner are plotted in Fig. 2 of $\bar{\phi}$ versus Ψ_m .

From Fig. 2 it is noted that the sediment transport rate drops off for values of the Shields Parameter of the order 0.035. This is not surprising since the threshold of sediment movement in terms of the Shields Parameter as determined in Section 2 corresponds to values of Ψ_m of the order 0.04 to 0.05 for the sediments used by Kalkanis (1964). It is, however, worthwhile to note the fact that sediment transport does occur for these rather low values of the Shields Parameter, whereas Manohar (1955) as mentioned in Section 2 from direct observations of the movement of sediment grains consistently found critical values of the Shields Parameter higher than those indicated by

Figure 2: Empirical Relationship for the Average Rate of Sediment Transport in Oscillatory Flow (Plane Bed).

Shields Criterion. The difference between these results, both obtained from oscillating plate experiments, must therefore be attributed to the difference between the methods used to define the condition of incipient sediment movement.

For values of the Shields Parameter somewhat greater than the critical value the results presented in Fig. 2 indicate a rather well defined functional relationship among the two parameters of the type

$$\bar{\phi} \propto \psi_m^3 \quad (6)$$

as evidenced by the dashed straight line drawn onto the diagram.

The experimental data from which this empirical relationship is derived exhibit a scatter similar to the scatter exhibited by the same data when plotted in terms of the parameters used by Einstein and co-workers (Einstein, 1972). It should, however, be noted that the trend of the data in Fig. 2, for large values of the Shields Parameter, is in reasonable agreement with the empirical relationship suggested by the straight line, whereas the Einstein relationship (Einstein, 1972, Figure 16) in this region deviates from the experimental data. Furthermore, it should be noted that, in the present analysis of the Berkeley data, it was not found necessary to introduce any correction factor for the experimental results obtained by Abou-Seida (1965) with fine sediments. This very convenient finding may partially be attributed to the particular choice of the dimensionless sediment transport function, Eq. (5), made in the present analysis.

The rather well defined empirical relationship, Fig. 2, between the average rate of sediment transport in oscillatory flow and the Shields Parameter which was obtained in the preceding section bears a strong resemblance to the Einstein-Brown formula for the sediment transport in unidirectional steady flow. This empirical relationship, suggested by Brown (1950), reads

$$\bar{\phi} = 40\psi^3 \quad (7)$$

where the bar over ϕ and the subscript m have been omitted to indicate that this formula applies in steady flow.

In the context of fluid-sediment interaction a similarity between steady unidirectional and unsteady oscillatory flow was previously noted in Section 2 when establishing a criterion for the initiation of sediment movement. In the present context of rate of sediment transport in an oscillatory flow, the similarity between Eqs. (6) and (7) suggests that a quasi-steady application of the Einstein-Brown relationship may represent the Berkeley data. Hence, one is led to adopt a sediment transport relationship of the form

$$\phi(t) = 40\psi^3(t) \quad (8)$$

in which $\phi(t)$ is the instantaneous value of the sediment transport function

$$\phi(t) = \frac{q_s(t)}{wd} \quad (9)$$

$q_s(t)$ being the instantaneous rate of sediment transport and

$$\Psi(t) = \frac{\tau_o(t)}{(s-1)\rho g d} \quad (10)$$

is the instantaneous value of the Shields Parameter.

The basic assumption inherent in the application of the Einstein-Brown formula in this quasi-steady manner is that the response time of the rate of sediment transport, $q_s(t)$, is short relative to the time it takes the Shields Parameter, $\Psi(t)$, to change appreciably. Limited evidence for the very short response time of the sediment to the time varying forces associated with an oscillatory flow was found in Section 2 where the maximum value of the Shields Parameter was found to govern the initiation of sediment movement. Although this finding by no means constitutes a proof of the applicability of Eq. (8), it is taken to support the adoption of Eq. (8) as the basis for analyzing sediment transport rates in unsteady oscillatory flow.

The problem in applying Eq. (8) in oscillatory unsteady flow becomes that of determining the instantaneous value of the Shields Parameter or, as seen from Eq. (10), the instantaneous value of the boundary shear stress, $\tau_o(t)$, associated with an oscillatory flow. To tackle this problem, the expression for the maximum boundary shear stress given by Jonsson (1966) may be generalized to reflect the temporal variation associated with an oscillatory flow above the bed

$$\tau_o(t) = \frac{1}{2} f_w \rho |u(t)| u(t) \quad (11)$$

in which

$$u(t) = u_b \cos \omega t \quad (12)$$

is the near-bottom velocity relative to the bed, having a maximum value u_b and a radian frequency $\omega = 2\pi/T$ with T being the period of oscillation.

This simple form, Eq. (11) for the time-varying boundary shear stress preserves the varying direction as well as varying magnitude of the shear stress. It neglects a possible phase difference between the velocity and the shear stress, which according to Jonsson (1966) is small for fully turbulent flow in the boundary layer and immaterial in the present context. Furthermore, the assumption of f_w , the wave friction factor, being constant throughout the period of oscillation will be invoked in the following. Both of these assumptions indicate the applicability of Eq. (11) to be limited to conditions when the boundary layer flow is highly turbulent, which incidentally is the case for the Berkeley experiments presented in Fig. 2.

Introducing Eq. (12) in Eq. (11) and making use of Eqs. (1) and (2) lead to an instantaneous value of the Shields Parameter, Eq. (10), given by

$$\Psi(t) = \frac{\tau_{om}}{(s-1)\rho g d} |\cos \omega t| \cos \omega t = \Psi_m |\cos \omega t| \cos \omega t \quad (13)$$

The sediment transport formula, Eq. (8), may therefore be written

$$\phi(t) = 40\psi_m^3 (|\cos\omega t| - \cos\omega t)^3 \quad (14)$$

corresponding to purely oscillatory flow with a turbulent boundary layer.

This formula clearly has a zero mean value when averaged over a full period of oscillation. Thus indicating, as it should, that the amount of sediment transported in the positive direction (when $\cos\omega t > 0$) equals the amount transported in the negative direction (when $\cos\omega t < 0$) when the flow is purely sinusoidal. From the assumption, inherent in the adoption of Eq. (8), of instantaneous response of the sediment transport rate to changes in the transport function, $\Psi(t)$, it follows that sediment will be transported only when the value of the Shields Parameter exceeds the critical value for initiation of movement, ψ_{mc} , whose value is readily determined from Fig. 1. Hence, time-averaging Eq. (14) over the time interval during which $\cos\omega t > 0$ and $\Psi(t) > \psi_{mc}$ leads to a prediction of the time average transport rate, $\bar{\phi}$. The result of this analysis is the full line shown in Fig. 2! For values of ψ_m/ψ_{mc} greater than two the average sediment transport rate is closely described by the equation

$$\bar{\phi} = 12.5 \psi_m^3 \quad (15)$$

This equation is the equation for the straight line drawn in Fig. 2, which represents the experimental data reasonably well. The curved part of the line shown in Fig. 2 reflects the small value of the Shields Parameter relative to the critical value corresponding to initiation of sediment movement and has been drawn corresponding to $\psi_{mc} = 0.04$. Since the Berkeley experiments used in Fig. 2 were regarded as corresponding to conditions of a flat bed the boundary roughness was taken as the sediment grain diameter and the influence of turbulence is limited to a thin boundary layer. In fact, the boundary layer thickness can be estimated from Jonsson (1966) corresponding to the experimental conditions and it can be shown that the boundary layer thickness is of the order 5 times the boundary roughness. Hence, sediment movement is for the experiments analyzed so far restricted to a very thin layer near the bottom. This ensures a rapid response of the sediment transport rate to changes in the transporting forces as was assumed in the quasi-steady application of the Einstein-Brown formula. Furthermore, the limited vertical extent of the region in which sediment is being transported would suggest that if one were to characterize the transport as suspended or bed load, the present experiments would be categorized as bed load. That a bed load formula, here chosen as the Einstein-Brown formula, is successful in representing the experimental data can therefore hardly come as a surprise.

Experimental confirmation backed up by physical reasoning supported the quasi-steady application of the Einstein-Brown formula to describe sediment transport on a plane bed. Experimental evidence, Manohar (1955) and Carstens *et al.* (1969), however, shows that for flow conditions exceeding only slightly those corresponding to initiation of sediment movement the resulting sediment transport leads to the formation of bed forms, ripples. This points out that a sediment transport relationship restricted to plane bed conditions is of limited practical importance.

For a bed exhibiting bed forms, the equivalent sand roughness of the boundary will be related to the scale of the bed forms. The boundary layer thickness and hence the region of turbulent fluid motion may consequently be of considerably larger extent than corresponding to a plane bed. Kennedy and Locher (1972) thus report measurements of the sediment concentration in a layer of considerably thickness above a rippled bed. These observations may cast some doubt on the notion of the sediment transport being characterized as bed load as well as possibly invalidating the assumption of instantaneous response of the sediment transport rate to changes in the transporting forces. Even if these questions are disregarded there still remains the problem of determining the transporting forces, the bottom shear stress, which now may be a function of the scale of the bed forms.

The approach to the similar problems encountered in the context of unidirectional steady flow, Einstein (1950), is to separate the boundary resistance into two components: one, a skin friction component based on the sediment grain size the other being a form drag component which is associated with the bed forms. The former of these components is regarded as expressing the transporting force. In view of the similarities between steady unidirectional and unsteady oscillatory flow already uncovered in this investigation of fluid-sediment interaction it seems natural to pursue an analogous line of approach in the present context of unsteady flow. Hence, one may adopt Eq. (8) as the basic sediment transport relationship with an evaluation of the bottom shear stress, Eq. (11), appearing in the Shields Parameter based on the boundary roughness being taken as the sediment grain size, i.e., essentially disregarding the presence of the bed forms.

The approach outlined in the foregoing may be tested against some experiments performed by Manohar (1955) who undertook a study of bed form geometry and migration using the oscillating plate set-up. In contrast to the Berkeley experiments which were presented in Fig. 2, the oscillations of the sediment carrying plate were in this set of experiments not purely sinusoidal. An asymmetric motion was achieved by changing the radian frequency of the fly-wheel driving the plate when this was at its extreme positions while the excursion amplitude was held constant. The resulting forward and backward motions of the plate were essentially sinusoidal and choosing the subset of Manohar's (1955) experiments in which sediment transport occurred only during the forward motion a test of the procedure suggested above for sediment transport rates in the presence of bed forms is available. Thus, taking

$$\psi'_m = \frac{\tau'_{om}}{(s-1)\rho g d} \quad (16)$$

where the prime indicates that the boundary roughness is taken as the grain diameter, i.e., corresponding to skin friction, we may present Manohar's (1955) experiments whether bed forms were present or not as done in Fig. 3.

It is seen from Fig. 3 that the bed remained flat in some of the experiments. As shown by Manohar (1955) the reason for this is that ripples form only for a certain range of values of the transporting force. For low values of the transporting force, ψ'_m , the sediment transport is insufficient to cause the development of bed forms whereas the sediment transport is so intense for high values of ψ'_m that bed forms are washed away.

Figure 3: Empirical Relationship for the Average Rate of Sediment Transport in Oscillatory Flow (Plane and Rippled Bed).

The excellent agreement between the experimental data and the quasi-steady application of the Einstein-Brown relationship, the full line in Figs. 2 and 3, suggests that the procedure of disregarding the presence of the bed forms and taking the boundary roughness as the sediment grain size for the purpose of evaluating the transporting forces may be applied with some confidence.

4. Some Aspects of the Prediction of Net Sediment Transport and Resulting Topographical Changes in the Coastal Environment

The sediment transport relationship, Eq. (8), established in the previous section may be used as the basis for a discussion of the problems involved in quantifying the factors which produce a net sediment transport in the coastal environment. It is emphasized that the following discussion, despite the experimental support of Eq. (8) presented in Section 3, must be considered qualitative since it involves considerable generalizations which await experimental confirmation before they may be accepted with confidence. With this in mind the sediment transport relationship, Eq. (8), may be generalized to read

$$\vec{\phi}(t) = 40[\vec{\tau}'(t)]^3 \tag{17}$$

in which $\vec{\phi}(t)$ is the instantaneous dimensionless sediment transport vector given by Eq. (5) with the sediment transport rate, $q_s(t) = (q_{s,x}(t), q_{s,y}(t))$.

The instantaneous value of the bottom shear stress based on the grain roughness is given by

$$\vec{\tau}'(t) = \frac{1}{2} \rho f_s [\vec{u}(t)]^2 \frac{\vec{u}(t)}{|\vec{u}(t)|} \tag{18}$$

in which f_s is a generalized friction factor and $\vec{u}(t) = (u(t), v(t))$, is the instantaneous velocity vector.

Introducing Eq. (18) into (17) the following expressions in terms of the components of the sediment transport vector result

$$q_{s,x}(t) = 40wd \left[\frac{\frac{1}{2} \rho f_s (u^2(t) + v^2(t))}{(s-1) \rho g d} \right]^3 \frac{u(t)}{\sqrt{u^2(t) + v^2(t)}} \tag{19}$$

$$q_{s,y}(t) = 40wd \left[\frac{\frac{1}{2} \rho f_s (u^2(t) + v^2(t))}{(s-1) \rho g d} \right]^3 \frac{v(t)}{\sqrt{u^2(t) + v^2(t)}} \tag{20}$$

Eqs. (19) and (20) express the instantaneous rate of sediment transport in the x and y direction, respectively. In principle it is possible to evaluate these equations if the instantaneous velocity and the appropriate value of the generalized friction factor f_s are known.

In general there is little interest in knowing the instantaneous value of the sediment transport rate. The quantity of importance is the time averaged value of the transport rate, i.e., the net sediment transport rate, since this quantity through the sediment continuity equation determines the rate of topographical changes. For the purpose of predicting the net sediment transport rate one would therefore time average Eqs. (19) and (20)

$$\bar{q}_{s,net} = \frac{1}{T} \int_0^{T'} (q_{s,x}(t), q_{s,y}(t)) dt \quad (21)$$

where the integration is carried out over the time interval, formally identified as 0 to T' , during which the sediment is in motion, i.e., when $|\bar{\psi}'(t)| > \psi_{nc}$. For a periodic motion of period T the average is, of course, taken over the period.

Once the net sediment transport rates have been determined the sediment continuity equation may be used to evaluate the rate of change in bottom elevation, $\partial n / \partial t$,

$$\frac{\partial \bar{q}_{s,net,x}}{\partial x} + \frac{\partial \bar{q}_{s,net,y}}{\partial y} = -(1-\epsilon) \frac{\partial n}{\partial t} \quad (22)$$

in which the factor $1-\epsilon$, where ϵ is the porosity of the sediment, is introduced to account for the fact that the net sediment transport rates are obtained in terms of the actual volume of sediment transported.

The preceding discussion explains the general use of the sediment transport relationship for the prediction of topographical changes. If the water motion is a sinusoidal oscillation, as discussed in Section 3, the net sediment transport is, of course, zero. The second order effects which, when added to a basic sinusoidal wave motion, will produce a net sediment transport are: (1) effect of a sloping bottom; (2) wave asymmetry; (3) wave induced mass transport currents; (4) currents other than mass transport currents.

4.1 The Effect of a Gently Sloping Bottom. The influence of a gently sloping bottom on the rate of sediment transport may qualitatively be examined by considering the entraining forces acting on a sediment grain on the sediment-fluid interface. Even under the influence of a purely sinusoidal wave propagating towards shallower water (up-slope) the gently sloping bottom will give rise to an asymmetry in the forces acting on a sediment grain and hence induce a net sediment transport. Thus, under the wave crest the bottom shear stress acting up the slope will be counteracted by the component of the submerged weight of the particle acting down the slope whereas the two forces will both act in the down-slope direction under a trough. This asymmetry in entraining forces will result in a net sediment transport towards deeper water. No experimental data are available on the influence of bottom slope on the rate of sediment transport in oscillatory flow. Until such data are available this effect cannot be quantified with confidence.

4.2 The Effect of Wave Asymmetry. For a small amplitude wave progressing over a horizontal bed, linear wave theory predicts a purely sinusoidal orbital

velocity above the bed. However, if finite amplitude, i.e., nonlinear, effects are considered the wave profile is no longer symmetric about the mean water level. For nonlinear waves the wave crests become more peaked (higher and steeper) than the wave troughs (shallower and flatter). This lack of symmetry of the surface profile is also reflected in the near-bottom velocity which shows a larger forward velocity of shorter duration under the wave crests and a smaller backward velocity of longer duration under the troughs than predicted by small amplitude wave theory. In principle one might therefore take the friction factor, f_s , in Eq. (19) as Jonsson's wave friction factor f_w and evaluate the net sediment transport from Eq. (21). This procedure is applied to the experiments performed by Manohar (1955), of which a subset was presented in Fig. 3, with reasonably good agreement between predicted and observed net transport rates (Madsen and Grant, 1976, Fig. 9).

4.3 The Effect of Wave Induced Mass Transport Currents. When the analysis of the viscous flow in the bottom boundary layer associated with progressive waves is advanced to include second order effects a steady streaming in the direction of wave propagation is predicted based on the assumption of laminar flow in the boundary layer. This effect, which is referred to as mass transport, has been investigated theoretically by Longuet-Higgins (1953) and by Unluata and Mei (1970) under the assumption of laminar flow. For laminar flow in the bottom boundary layer this steady streaming, which immediately above the bottom is in the direction of wave propagation, will produce a non-zero time average shear stress in the direction of wave propagation acting on the bottom. This, in turn, would indicate that wave induced mass transport currents will result in a net sediment transport in the direction of wave propagation when the asymmetrical shear stress variation is introduced in the sediment transport relationship, Eq. (17).

Recent results reported by Bijker et al. (1974) clearly demonstrate that there are serious reasons to doubt the validity of Longuet-Higgins' solution in the case of a strongly turbulent boundary layer flow. As the roughness of the slope over which the waves propagate is increased from smooth to sand roughness to rippled bed the observed value of the near-bottom mass transport velocity is found to be increasingly smaller than the theoretical results based on a laminar flow assumption. In fact, the experiments with the slope roughness consisting of artificial ripples show a complete reversal of the direction of the near-bottom mass transport velocity. Bijker et al. (1974) conclude that much more data are needed to clarify the nature of mass transport in water waves when the boundary layer flow is turbulent.

In the present context of sediment transport by waves mass transport in addition to wave asymmetry discussed in Section 4.2 is undoubtedly an important factor in producing a net sediment transport. This makes it doubly unfortunate that the state of our knowledge is such that we cannot predict even the direction of this velocity with confidence not to mention its magnitude. For this reason further progress must be awaited before the effects of mass transport can be incorporated in the sediment transport relationship for the purpose of predicting net sediment transport rates associated with progressive waves.

4.4 The Effect of Currents. As a final second order effect which would produce a net sediment transport even if the wave motion were purely sinusoidal, the effects of a weak steady current superposed on the wave motion are considered. The action of these currents, for example, tidal or wind-induced, when combined with a wave motion will produce a net rate of sediment transport. If the current is weak, i.e., essentially a second order effect, the wave motion may be considered a stirring agent which by itself produces no net sediment transport. It does, however, make sediment available for transport by a current, although this current by itself would be incapable of even initiating sediment movement.

Assuming that the instantaneous velocity vector is known, this may be introduced in the general sediment transport relationship and one may numerically integrate Eq. (21) to obtain the time average value of the net sediment transport rates in the x and y direction, respectively. Thus, it is in principle quite simple to apply the general sediment transport relationship to determine the net sediment transport associated with the combined action of waves and currents. The major obstacle in performing this analysis is, however, the determination of the appropriate value of the generalized friction factor $f_s = f_{cw}$ for the combined action of waves and currents. Presently it is possible to estimate with some confidence the bottom shear stress only for a pure wave motion or for a pure current from knowledge of the bottom roughness. As shown by Madsen (1976) the friction factor, f_w , for a pure wave motion may be an order of magnitude larger than the friction factor, f_c , for a pure current of comparable magnitude, thus leaving the value of the friction factor f_{cw} for the combined action of waves and currents rather uncertain. In addition to this problem there is also some indication of a rather peculiar behavior of the sediment transport resulting from a weak current superimposed on a wave motion when the bottom exhibits bed forms. Thus, Inman and Bowen (1963) reported a net sediment transport in the direction opposite of the weak current superimposed on a wave motion. Although Inman's and Bowen's experiments and data analysis have certain deficiencies, as discussed by Madsen and Grant (1976), their observation and the experimental investigation of Natarajan (1969) show that the quantitative description of sediment transport over a rippled bed resulting from the combined action of waves and currents may present problems in addition to the problem of the determination of the wave-current friction factor f_{cw} .

Disregarding the problems mentioned above Grant and Madsen (1976) adopted a formula suggested by Jonsson (1966a) for the wave-current friction factor to investigate the topographical changes in the vicinity of the tip of a semi-infinite breakwater. The waves were assumed to be normally incident on the breakwater and a uniform current parallel to the breakwater produced with the diffracted wave pattern a spatially varying net sediment transport. The details of this investigation may be found in the above paper or in Madsen and Grant (1976). Here, the resulting prediction of erosion and deposition rates a distance of two wave lengths behind the breakwater are presented in Fig. 4. From Fig. 4 it is seen that no change, i.e., no sediment transport, occurs a distance of 3-4 wavelengths into the shadow region behind the breakwater. This is due to the decrease of wave activity in this region and emphasizes the importance of wave motion as being the stirring agent making sediment available for transport by currents which by themselves would be incapable of initiating sediment movement.

Figure 4: Diffraction Coefficient and Areas of Erosion and Accretion Two Wavelengths Behind Breakwater (From Grant and Madsen, 1976).

5. Concluding Remarks

It is not excluded that further analyses of the experimental data obtained by the Berkeley group may produce different sediment transport relationships for unsteady flow, just as the Einstein-Brown formula is far from being the only relationship for sediment transport in steady flow. Further documentation of the quasi-steady application of the Einstein-Brown sediment transport relation, suggested by the present investigation, is called for before this approach may be accepted with confidence.

The discussion given in Section 4 demonstrates an urgent need for further research and an improved understanding of the nature of the flow in the oscillatory turbulent bottom boundary layer associated with waves and currents in order to treat the problem of sediment transport in the coastal environment in a general manner. The problems of the quantitative description of the fluid flow and its interaction with a solid bottom in the coastal environment must be overcome before one can hope to establish an accurate sediment transport model for this environment. It is hoped, however, that the present study has produced a framework within which sediment transport in the coastal zone may be approached in a rational manner. At the very least the present research serves to point out that it is absurd to attack the problem of sediment transport in the coastal environment without considering the influence of waves.

CHAPTER 66

PREDICTIVE EQUATIONS REGARDING COASTAL TRANSPORTS

by

D. H. SWART*

1. INTRODUCTION

Morphological changes are the result of gradients in longshore and onshore-offshore sediment transport. The coastal engineer is continually faced with engineering problems in which a quantitative knowledge of these morphological changes is required. For this purpose predictive equations have been developed for both longshore and onshore-offshore sediment transport, which are being used in practical applications. In this paper a few of these predictive techniques, as well as one of their typical applications, viz. to a beachfill problem, will be discussed.

2. ONSHORE-OFFSHORE SEDIMENT TRANSPORT

2.1 General

The basics of Swart's *onshore-offshore sediment-transport theory* were described in detail in [14]. A paper about this subject was presented at the 1974 Coastal Engineering Conference in Copenhagen [13]. Subsequently it had become clear that the computational method described in [14] is too complicated for normal use, and that it could be modified to simplify the computations, without affecting the results significantly. In the present paper a summary will be given of the basic principles underlying the theory, as well as of the modified computational approach used at present. In Chapter 4 the method will be applied to a *beachfill problem*, to illustrate one of its typical applications.

2.2 Underlying principles

(1) The development in a normal beach profile is characterized into *three definite zones*, (Figure 1), each with its own transport mechanism, viz.

- (a) the *backshore*, i.e. the area above the wave run-up limit in which "*dry*" transport takes place,
- (b) a *developing profile* (D-profile) where a combination of *bed load- and suspended load-transport* takes place, and
- (c) a *transition area*, seawards of the D-profile, and landwards of the point where sediment motion by wave action is initiated, where normally only *bed load* transport takes place.

(2) The most basic assumption in the schematization of onshore-offshore sediment transport is that the developing profile (D-profile) will eventually reach a *stable situation* under persistent wave attack. This stable situation implies both an *equilibrium form* and an *equilibrium position* of the beach profile. This last concept is illustrated in Figure 2, where the *schematized* volume of sediment in the D-profile is plotted as a function of time. Similar variations are found for the different locations in the D-profile, thus also confirming the equilibrium form concept.

(3) The sediment transport rates into (or out of) the D-profile from (or to) the backshore and the transition area ($S_e(t)$ and $S_t(t)$ respectively) form the boundary conditions for the computation of profile changes in the D-profile. These transport rates were found in [14] to be given by :

* Coastal Engineering and Hydraulics Division
National Research Institute for Oceanology, South Africa

$$S_e(t) = s_e W_e \exp\left(\frac{-s_e t}{\delta_e}\right) \quad \dots (2.1)$$

$$\text{and} \quad S_t(t) = s_t W_t \exp\left(\frac{-s_t t}{\delta_t}\right) \quad \dots (2.2)$$

where s_e and s_t are the backshore- and transition area-coastal constants and

$$W_e = L_e(t=0) - L_e(t=\infty) \quad \dots (2.3)$$

$$W_t = L_t(t=\infty) - L_t(T=0)$$

$$t = \text{time}$$

The other variables are defined in Figure 1.

(4) With the aid of the assumption in step (2) above, the rate of onshore-offshore sediment transport S_{yit} at a specific location i in the profile at any time t can be shown to be a function of the difference between the values of a profile characteristic P at time t ($P(t)$) and time $t = \infty$ ($P(\infty)$).

$$S_{yit} \propto P(\infty) - P(t) \quad \dots (2.4)$$

(see Figure 3)

Experiments showed that the best description of the transport is found if the profile characteristic is taken to be a horizontal length in the profile $(L_2 - L_1)_{it}$.

$$S_{yit} = s_{ym} \left(\frac{s_{yi}}{s_{ym}}\right) (W_i - (L_2 - L_1)_{it}) \quad \dots (2.5)$$

where s_{ym} and s_{yi} are transport coefficients and

$$(L_2 - L_1)_{it} \xrightarrow{t \rightarrow \infty} W_i \quad \dots (2.6)$$

The meaning of $(L_2 - L_1)_{it}$ and the geometry of the beach profile at time t is defined in Figure 1. Relationships are presented in [13], whereby s_{ym} , (s_{yi}/s_{ym}) and W_i , as well as the limits of the D-profile (i.e. the area in which equation (2.5) is valid) can be found in terms of the boundary conditions.

(5) A subsequent study of the given relationships indicated that the computation of time-dependent profile development can be significantly improved and simplified if it can be assumed that at each location i in the developing profile the same fraction f_{it} of the total transport ($\int_0^\infty S_{yit} dt$) of sediment passing that location until time $t = \infty$, will have occurred at any given time t , i.e.

$$f_{it} = \left\{ \frac{\int_0^t S_{yit} dt}{\int_0^\infty S_{yit} dt} \right\} = f_t = \text{constant for all locations } i \text{ in the developing profile at time } t. \quad \dots (2.7)$$

The results of morphological tests with durations in excess of 1 000 hours, given in Figures 4 and 5, show that the above-mentioned assumption (equation (2.7)) is a *good engineering approximation*.

(6) With the principle of continuity of mass, and by using steps (1) - (5) above, it is possible to derive analytical expressions for the time variation of the length $(L_2 - L_1)_{it}$ and the sediment transport, viz. :

$$(L_2 - L_1)_{it} = W_i - (K_{ei} + K_{ti}) \exp(-X_b t) \quad \dots (2.8)$$

$$S_{yit} = s_{yi} (K_{ei} + K_{ti}) \exp(-X_b t) \quad \dots (2.9)$$

$$v_{yit} = \int_0^t S_{yit} dt = s_{yi} (K_{ei} + K_{ti}) X_b^{-1} (1 - \exp(-X_b t)) \quad \dots (2.10)$$

Substitution of equation (2.10) above into equation (2.7) yields an expression for f_t :

$$f_t = 1 - \exp(-X_b t) \quad \dots (2.11)$$

where

$$K_{ei} = \frac{W_e \delta_e}{\delta_{1i} (X_b^{-1} X_i - 1)} \quad \dots (2.12)$$

$$K_{ti} = \frac{W_t \delta_t}{\delta_{2i} (X_b^{-1} X_i - 1)} \quad \dots (2.13)$$

$$X_b = \frac{s_e}{\delta_e} = \frac{s_t}{\delta_t} \quad \dots (2.14)$$

$$X_i = \frac{\delta s_{yi}}{\delta_{1i} \delta_{2i}} \quad \dots (2.15)$$

(7) The theory is valid, not only for perpendicular waves, but also for oblique wave attack. In the latter case the transport coefficients s_{yi} and s_{ym} are increased, to allow for the effect of the increase in shear stress at the bed, due to the presence of nearshore currents, generated by the oblique waves. The data used to derive the relationship for the increase in s_{yi} and s_{ym} , as presented in [14] and [13], was derived from model tests in which a strong rip-current formation was found. A subsequent study into the effect of the rip-currents on the increase in offshore transport, showed that the increase in transport, which is due to the presence of longshore currents alone, can best be written in terms of the increase (due to longshore currents) of the sediment mobility F (refer to [17] and [1]).

$$\frac{(s_{yi})_{wc}}{(s_{yi})_w} = \frac{(F_i)_{wc}}{(F_i)_w} \quad \dots (2.16)$$

(see Figure 6)

where F_i is the sediment mobility at location i and the subscripts wc and w refer to *combined wave and current action* and *wave action only* respectively.

In order to comply with step (5) above, the mean value of equation (2.16) over the whole area of profile development will be applied to all transport coefficients.

$$\frac{(s_{yi})_{wc}}{(s_{yi})_w} = \left\{ \frac{(F_i)_{wc}}{(F_i)_w} \right\} \quad \dots (2.17)$$

Keeping in mind the normal uncertainty factor in the evaluation of sediment transport data, it can be stated that the validity of equations (2.16) and (2.17) is proved by the data in Figure 6.

2.3. Representative wave height

The theory described above was derived and verified for regular wave attack. In order to make it generally applicable to prototype conditions, the effect of irregular waves on the theory must be known. The irregular waves will affect not the underlying principles, but the empirical predictive equations which will be described in section 2.4 below.

Observations showed that the higher waves in the wave spectrum will define the profile limits described in section 2.2, step (1) above. The lower limits of the D-profile and transition area respectively are both found by using the significant wave height in the empirical formulae derived for regular wave attack, whereas the upper limit of the D-profile is found from the regular-wave formula by using a wave with a height twice that of the significant wave height

If it is assumed that the transport-formulae are still applicable in the transport zones defined by these representative wave heights, the single representative wave height which will yield the same resultant transport as the spectrum, can be computed (the wave heights are assumed to be Raleigh-distributed).

The formulae for irregular wave attack, derived in this manner, and those for regular wave attack, will be given in section 2.4.

2.4 Predictive equations

The various equations needed for the application of the theory in section 2.2, will be summarized below for the sake of convenience.

2.4.1 Limits of profile development (refer to Figure 1)

The upper limit of the backshore is chosen at the highest level from which sediment can be eroded indirectly by wave action.

h_e is chosen

upper limit D-profile :

$$h_o = 7650D_{50} \left[1 - \exp \left(-0.000143 \frac{H_{mo}^{0.488} T^{0.93}}{0.786 D_{50}} \right) \right] \quad \dots (2.18)$$

where H_{mo} = maximum wave height in the spectrum = $2(H_o)_{sign}$. ; T is the wave period and D_{50} is the median particle diameter. For regular wave attack, such as in small-scale hydraulic models, $H_{mo} = H_o$.
lower limit D-profile

$$h_m = 0.0063\lambda_o \exp \left(4.347 \frac{(H_o)_{sign}^{0.473}}{T^{0.894} D_{50}^{0.093}} \right) \quad \dots (2.19)$$

where λ_o is the deepwater wave length. For regular wave attack $(H_o)_{sign} = H_o$.

lower limit transition area

The maximum orbital velocity at the bed at the location where initiation of sediment movement takes place (u_{SEGAR}), is found from the following formula, which represents the weighted mean of a number of different initiation of movement-Formulae. [12], [16].

$$u_{SEGAR} = 4.58 D_{50}^{0.38} T^{0.043} \quad \dots (2.20)$$

The depth at which this velocity occurs is h_t . The corresponding wave length is λ_t . The first order wave representation of the orbital velocity can now be used to obtain a value for h_t/λ_t , whereafter it follows that :

$$h_t = \lambda_o \left(\frac{h_t}{\lambda_t} \right) \tanh \left(2\pi \left(\frac{h_t}{\lambda_t} \right) \right) \quad \dots (2.21)$$

In the case of irregular wave attack the significant wave height should be used for the computation of (h_t/λ_t) . Finally, with the aid of equations (2.18), (2.19) and (2.21), it follows that :

$$\delta_e = h_e - h_o \quad \dots (2.22)$$

$$\delta = h_o + h_m \quad \dots (2.23)$$

$$\delta_t = h_t - h_m \quad \dots (2.24)$$

(see Figure 1).

2.4.2 Equilibrium profile characteristics (refer to [14] and [13])

The computation of the equilibrium length w_i is subdivided into two parts, viz. :

- (1) the computation of a reference value $w_r (=w_i$ at the still-water level), and
- (2) the computation at all other locations in the D-profile of the ratio w_i/w_r .

in (1)

$$w_r = \frac{1.51 \times 10^3 D_{50}^{1.06} H_o^{0.39}}{\lambda_o^{0.71}} + 0.11 \times 10^{-3} \left(\frac{\lambda_o}{H_o} \right) \quad \dots (2.25)$$

$$W_r = \frac{\delta}{2m_r} \quad \dots (2.26)$$

In the case of irregular wave attack, equation (2.25) is rewritten as :

$$m_r = \frac{1.21 \times 10^3 D_{50}^{1.06} (H_o)^{0.39} \text{sign}}{\lambda_o^{0.71}} + 0.22 \times 10^{-3} \frac{\lambda_o}{(H_o) \text{sign}} \quad \dots (2.27)$$

re (2)

For any location *i* in the D-profile the ratio W_i/W_r is given by :

$$W_i/W_r = 0.7\Delta_r + 1 + 3.97 \times 10^7 b D_{50}^2 \Delta_r^{1.36} \times 10^4 D_{50} \quad \dots (2.28)$$

where
$$\Delta_r = \frac{\delta_{1i} - h_o}{\delta} = \frac{h_m - \delta_{2i}}{\delta} \quad \dots (2.29)$$

and
$$b = \begin{cases} 0 & ; \Delta_r < 0 \\ 1 & ; \Delta_r > 0 \end{cases} \quad \dots (2.30)$$

With the aid of equations (2.25) - (2.30) above the form of the equilibrium D-profile, measured relative to the position in the profile where $\delta_{1i} = 0$ (see Figure 1), can be written as :

$$Y_{i\infty} = W_r [2.1 z^2 - (1.4 + 2Q) z + P (1 - 2z)(h_r - z)^E EP (z^2 - z) (h_r - z)^{E-1} + (2Q - 0.7)] \quad \dots (2.31)$$

where $h_r = h_m/\delta \quad \dots (2.32)$

$z = \delta_{2i}/\delta \quad \dots (2.33)$

$Q = 0.7 h_r + 1 \quad \dots (2.34)$

$P = 3.97 \times 10^7 b D_{50}^2 \quad \dots (2.35)$

$E = 1.36 \times 10^4 D_{50} \quad \dots (2.36)$

The equilibrium slope $\alpha_{t\infty}$ of the deposited material in the transition area can be found from the equation of Eagleson et al [6] :

$$\alpha_{t\infty} = \frac{\Delta Z_t}{\Delta L_t} \quad \dots (2.37)$$

$$\Delta L_t = 42.73 \frac{J}{K} \lambda_o [\ln (0.01335 - 0.0161 \frac{d}{\lambda_o}) + 0.7271 (\frac{d}{\lambda_o})^2 + 1.206 (\frac{d}{\lambda_o}) - 1.50] \left\{ \begin{array}{l} h_m/\lambda_o \\ (h_m + \Delta Z_t)/\lambda_o \end{array} \right. \quad \dots (2.38)$$

where ΔZ_t is a depth increment and ΔL_t is the horizontal distance in the equilibrium depositional profile between the depths bracketing ΔZ_t .

The values of the schematized recession of the backshore (W_e) and the schematized growth of the transition area (W_t) can be found by drawing up equations for :

- (1) the conservation of mass (re Figure 7a)
- (2) the geometrical form of the equilibrium profile (re (Figure 7b), and
- (3) the distribution of the sediment in the transition area at equilibrium (re Figure 7b). The

reason why three equations are necessary to solve for the two unknowns W_e and W_t , is that δ_{tr} (see Figure 7a) is also an unknown.

2.4.3 Coastal constants (see [17])

At the elevation where $\delta_{li} = 0.5\delta$, the value of s_{yi} approximates s_{ym} very closely. s_{ym} is given by :

$$s_{ym} = \frac{D_{50}}{T} \exp [10.7 - 28.9 \left\{ (H_o)_{50}^{0.78} \lambda_o^{0.9} D_{50}^{-1.29} \left(\frac{(H_o)_{sign}}{h_m} \right)^{2.66} \right\}^{-0.079}] \quad \dots (2.39)$$

where $(H_o)_{50}$ is the median deepwater wave height and $(H_o)_{sign}$ is the significant deepwater wave height. In the case of regular wave attack, both $(H_o)_{50}$ and $(H_o)_{sign}$ are replaced by H_o .

With the aid of section 2.2, step (5), it follows that :

$$X_b = \left(\frac{s_e}{\delta_e} \right) = \left(\frac{s_t}{\delta_t} \right) = \left\{ \frac{(y_2 - y_1)_{io}}{W_{bi} + (y_2 - y_1)_{io}} \right\} X_i \quad \dots (2.40)$$

with as a result

$$\frac{s_{yi}}{s_{ym}} = \frac{4\delta_{li} \delta_{2i}}{\delta^2} \left[\frac{(y_2 - y_1)_{mo}}{W_{bm} + (y_2 - y_1)_{mo}} \right] \left[\frac{W_{bi} + (y_2 - y_1)_{io}}{(y_2 - y_1)_{io}} \right] \quad \dots (2.41)$$

$$\text{where } W_{bi} = \left(\frac{\delta_e}{\delta_{li}} \right) W_e + \left(\frac{\delta_t}{\delta_{2i}} \right) W_t \quad \dots (2.42)$$

$$(y_2 - y_1)_{io} = W_i - (L_2 - L_1)_{io} \quad \dots (2.43)$$

Subscript m refers to middepth ($\delta_{li} = 0.5\delta$) and subscript o refers to time $t = 0$.

The characteristic quantities K_{ei} and K_{ti} can now be found from equations (2.12) and (2.13) respectively.

2.4.4 Mobility number

(for a more detailed description of the mobility number and the following equations, reference should be made to [15] and [17]).

$$(F_i)_{wc} = \left\{ \frac{v_i I_{wc}^n}{C_D^{1-n} C_h^n (\Delta_s D_{35})^{\frac{1}{2}}} \right\}_i \quad \dots (2.44)$$

$$(F_i)_w = \left\{ \frac{2^{-n} f_w^{n/2} u_o}{C_D^{1-n} C_h^n (\Delta_s D_{35})^{\frac{1}{2}}} \right\}_i \quad \dots (2.45)$$

$$\text{where } I_{wc} = \left\{ 1 + \frac{1}{2} \left(\frac{\xi_J u_o}{v} \right)^2 \right\}_i^{\frac{1}{2}} \quad \dots (2.46)$$

$$\xi_{Ji} = \left\{ C_h \left(\frac{f_w}{2g} \right)^{\frac{1}{2}} \right\}_i \quad \dots (2.47)$$

$$C_{hi} = \left\{ 18 \log \left(\frac{12 d_i}{r} \right) \right\}_i \quad \dots (2.48)$$

$$C_{Di} = \left\{ 18 \log \left(\frac{10 d_i}{D_{35}} \right) \right\}_i \quad \dots (2.49)$$

$$f_{wi} = \left\{ \exp \left(-5.977 + 5.213 \left(\frac{a_o}{r} \right)^{-0.194} \right) \right\}_i \quad \dots (2.50)$$

(if $f_{wi} > 0.3$; $f_{wi} = 0.3$)

$$r = \text{hydraulic bed roughness}$$

$$= 25 \Delta_r \left(\frac{\Delta_r}{\lambda_r} \right) \quad \dots (2.51)$$

(See Figure 8)

a_o is the orbital excursion at the bed, Δ_r is the ripple height and λ_r is the ripple length.

$$n = 1 - 0.2432 \ln (D_{gr}) \quad (\text{with } 0 \leq n \leq 1) \quad \dots (2.52)$$

$$D_{gr} = \left(\frac{g \Delta_r}{\sqrt{2}} \right)^{1/3} D_{35} \quad \dots (2.53)$$

D_{35} = particle diameter which is exceeded in size by 65% (in weight) of the total sample.

In the case of irregular wave attack the median wave height (H_o)₅₀ should be used in the equations (2.44) - (2.50).

2.5 Computational Method

The computation of *time-dependent profile changes* (Y_{it}) and *onshore-offshore sediment transport rates* S_{yit} , as well as of *integrated onshore-offshore transport rates* ($\int_0^t S_{yit} dt$) up to any time t , can all be performed by using the following simple procedure :

- 1) compute the *equilibrium condition*,
- 2) compute the value of the *fraction f_t* as a function of time with the aid of section 2.4,
- 3) combine 1) and 2) to *predict time-dependent conditions*.

In the case of *profile-prediction*, the *location of the equilibrium profile* can be predicted, because the *initial profile* is given and the *equilibrium profile form* as well as the values W_e and W_t can be computed from section 2.4. The position Y_{it} of the profile at elevation Z_i and time t is then given by:

$$Y_{it} = Y_{i\infty} + f_t (Y_{i0} - Y_{i\infty}) \quad \dots (2.54)$$

(see Figure 9)

In the case of *transported-volume prediction* the total volume of transported material up to time $t = \infty$ ($V_{yi\infty}$) can be computed from equation (2.10) by putting $t = \infty$, whereafter V_{yit} , the total volume of sediment transported past the location in the profile with elevation Z_i , can be computed from :

$$V_{yit} = f_t V_{yi\infty} \quad \dots (2.55)$$

The *onshore-offshore sediment transport rate* at location i can also be found in terms of $V_{yi\infty}$ and f_t :

$$S_{yit} = V_{yi\infty} X_b (1 - f_t) \quad \dots (2.56)$$

3. LONGSHORE SEDIMENT TRANSPORT

3.1 General

Longshore sediment-transport computations can be used, either to gain an insight into the *overall sediment budget* of an area, or to study *detail problems* (such as deposition of sediment in an entrance channel to a harbour). The *total sediment load at various locations* will be needed in the first case, whereas the *vertical distribution of sediment load* (and specifically the division between bed and total load) will also be needed in the second case.

The available formulae for the prediction of longshore sediment transport rates can be classified into two groups, viz. :

- (1) *overall predictors*, such as the *SPM-formula* and the *Galvin-formula*, and
 (2) *detail predictors*, such as the *Bijker-formula* and the analogous *SWANBY-method*.

When a prediction of longshore sediment transport rates has to be made, it is useful to perform the computations with two or more of the available formulae, and to *base the final prediction* on the outcome of *all the results* obtained. In this chapter a detail-predictor method (SWANBY) will be described in detail, as well as a *modified version* of the SPM-predictor, which is used to back up the detail-predictor results.

3.2 Overall predictors

Although the overall predictors are by definition only applicable in areas with negligible longshore gradients, and cannot be used to obtain reliable estimates of the longshore transport rates in areas with strong longshore tidal flow, they can be useful in assessing the overall longshore sediment budget in an area. As such they can be used in conjunction with the detail predictors.

The SPM-formula, which relates the overall longshore transport rate S_{xtot} to a quantity resembling the longshore component of the wave-energy flux, is the best-known overall predictor available. This SPM-relationship can be rewritten to read :

$$S_{xtot} = K_o (T (H_o)_{rms}^2 k_r^2 \sin \theta_b \cos \theta_b) \quad \text{(see [19])} \quad \dots (3.1)$$

where k_r is the refraction coefficient, θ_b is the angle between the wave crest and the shoreline at wave breaking, and K_o is a coefficient which is assumed to be constant.

However, as lighter material will be transported more readily than heavier materials under the same wave conditions, it is to be expected that K_o will be a function of the grain size of the bed material. A re-evaluation of the data given in [19] and [3] yielded Figure 10, from which a clear tendency can be seen for K_o to vary with grain size. Although a steeper curve is to be expected intuitively, the data suggests K_o to vary as :

$$K_o = 365 \times 10^4 \log \left(\frac{0.00146}{D_{50}} \right) \text{ for } 0.1 \times 10^{-3} < D_{50} < 1.0 \times 10^{-3} \quad \dots (3.2)$$

Equations (3.1) and (3.2) are normally used to back up computations performed with the detail predictor, which will be described in section 3.3.

3.3 Detail predictors

3.3.1 Underlying principles

In 1966 Bijker [2] published a method for the computation of the longshore sediment transport at any specific location in the coastal environment, which constituted a major breakthrough in Coastal Engineering. Bijker assumed that it will be possible to use, in the coastal environment, a sediment transport formula which had been developed for uniform flow conditions, provided that the shear stress terms in the chosen formula are adapted to incorporate the effect of the wave action. He chose as basis for this adaptation the formula of Frijlink, which was at the time a much-used formula in river-flow problems in the Netherlands. Although the resulting Bijker-Frijlink equation sometimes yielded unrealistic results, it has been used since then with a reasonable amount of success in numerous applications in the coastal environment. However, the insight into the fundamentals of sediment transportation under wave action has increased over the past decade. Furthermore, various evaluations of the available predictor methods revealed recently ([5], [7], [18], [20]) that there are more reliable methods for the computation of sediment transport under uniform flow conditions than the Frijlink-equation, which can also be used over a wider range of boundary conditions. Therefore, a new pre-

dicator method was developed by Swart [15] under the auspices of the Coastal Sediment Group of the Dutch Applied Coastal-Research Programme, for application in the coastal environment. The basic differences between the new technique (called the SWANBY-method) and the old Bijker-Frijlink approach will be discussed below.

(1) The Frijlink-formula, used in the original approach, is a bed load formula. The total load was computed from the bed load by adding the suspended load, as computed with the aid of the Rouse/Einstein description of the vertical distribution of suspended sediment. The thickness of the bed layer is in such an approach an important parameter in the determination of the total load. Due to the uncertainty in the definition of the layer in which the bed load takes place, it will be more convenient to choose a total load formula as basis for computations in the coastal environment. If necessary, a definition can then be made of a bed layer thickness, and the amount of sediment transported in that layer can be computed.

(2) Various comparative investigations [5], [7], [18], [20], showed that the two most reliable total load formulae available for uniform flow conditions, are those of *Engelund-Hansen* and *Ackers-White*. Both these formulae give comparable results over a wide range of boundary conditions, the only exception being cases where the sediment transport rate was low (near initiation of motion). In such cases the *Engelund-Hansen method over-predicted* the transport rates, where *Ackers-White* showed a good comparison. *Engelund-Hansen will thus not yield proper scale relationships*, that can be used for the scaling of three-dimensional small-scale models. For the above-mentioned reasons the *Ackers-White approach was chosen* as the basic theory, which was to be adapted for use in the coastal environment.

(3) When evaluating the shear stress at the bed due to combined wave and current action, Bijker assumed the orbital velocity u_z , at the edge of the viscous sublayer to be :

$$u_z = p_B u_o \sin \left(\frac{2\pi t}{T} \right) \quad \dots (3.3)$$

where $p_B = \text{constant} = 0.45$ (see [2])

It is, however, to be expected that the effect of the wave motion on the shear stress will vary with a variation in the flow regime at the bed. Jonsson [9] defined the flow regime at the bed in terms of the ratio a_o/r where r is the hydraulic bed roughness and a_o the maximum wave particle excursion at the bed. Using Jonsson's work, it can be shown that

$$u_z = p_J u_o \sin \left(\frac{2\pi t}{T} \right) \quad \dots (3.4)$$

where $p_J = \left(\frac{f_w}{2k^2} \right)^{1/2}$... (3.5)

C_h is the Chezy-roughness value and f_w is the wave friction factor. In the SWANBY-approach equation (3.4) was used instead of equation (3.3).

(4) In the Bijker-Frijlink approach the hydraulic bed roughness was taken equal to one-half the ripple height. A subsequent study [15] has shown the relative roughness (r/Δ_r) to vary with the ripple steepness Δ_r/λ_r (see Figure 8). This was used in the SWANBY-theory. It was shown in [15] that the thickness of the layer near the bed in which vortices (filled with sediment) are formed and diffused, is of the same order of magnitude as the hydraulic bed roughness r . The thickness of the layer in which bed load takes place was thereafter also assumed to be equal to the hydraulic bed roughness r .

(5) A comparative study of the various methods for the computation of the vertical distribution of suspended sediment (\bar{c}_z/\bar{c}_r) in the coastal environment [15] showed that there is little difference

between the prediction of \bar{c}_z/\bar{c}_r by various theories. The *best correlation* with data covering a wide range of boundary conditions in the coastal environment was, however, obtained with a theory in which the *diffusion coefficient* for solids ϵ was assumed to *vary linearly* over the depth. The corresponding variation in \bar{c}_z/\bar{c}_r is :

$$\frac{\bar{c}_z}{\bar{c}_r} = \left(\frac{z}{r} \right)^{-b_1} \quad \dots (3.6)$$

where b_1 is a constant for each specific suspended sediment distribution over the depth.

With the assumption of a logarithmic variation in velocity over the depth, equation (3.6) yields an expression for the amount of suspended sediment which is transported, which is *easier to apply than any of the other* approaches tested. Due to these reasons it was decided to use equation (3.6) in the SWANBY-method instead of the Rouse/Einstein approach.

In Figure 11 longshore sediment transport rates, measured in a small-scale model, are compared with predicted transport rates, as given by the Bijker-Frijlink and SWANBY (Adapted Ackers-White) formulae. It is obvious that the SWANBY-method shows the better comparison with the data.

3.3.2 Predictive equations

The equations needed for the application of the SWANBY-method for the computation of the longshore sediment transport, will be given below.

total load

The total longshore sediment transport S_{xt} (bed plus suspended load) at any specific location is given by :

$$S_{xt} = \left(\frac{1}{1-p} \right) D_{35} v \left(\frac{C_h}{1} \right)^n I_{wc}^{-n} \frac{C}{A^m} (F_{wc} - A)^m \quad \dots (3.7)$$

where $\left(\frac{1}{1-p} \right)$ = determined by the porosity of the bed, normally taken = 1.45 and v = uniform current velocity in the longshore direction. The values of C_h , I_{wc} , F_{wc} and n are defined in section 2.4.4 (equation (2.44), (2.46) - (2.53)). Furthermore

$$m = \frac{9.66}{D_{gr}} + 1.34 \quad \dots (3.8)$$

$$A = \frac{0.23}{D_{gr}} + 0.14 \quad \dots (3.9)$$

$$C = \exp \{ 2.86 \ln (D_{gr}) - 0.4343 (\ln (D_{gr}))^2 - B.128 \} \quad \dots (3.10)$$

The hydraulic bed roughness r is related to the ripple dimensions as given in equation (2.51). The ripple dimensions can either be known from observations or be computed from one of the available methods (for instance [11] and [15]).

bed load

The bed load can be computed from equation (3.7) and points (4) and (5) in section 3.3.1 above, viz. :

$$S_{xb} = \left(\frac{K_b}{K_b + K_s} \right) S_{xt} \quad \dots (3.11)$$

where $K_b = \ln \left(\frac{er}{\Delta} \right)$ for $b_1 = 1$

and $K_b = \left(\frac{1}{1-b_1} \right) \left(1 - b_1 \left(\frac{\Delta}{r} \right)^{1-b_1} \right)$ for $b_1 \neq 1$... (3.12)

$$K_s = 0.205 \ln \left(\frac{9.12d}{r} \right) \ln \left(\frac{d}{r} \right) \quad \text{for } b_1 = 1$$

and

$$K_s = 0.41 (1-b_1)^{-2} \left[(1-b_1) \left\{ \left(\frac{d}{r} \right)^{1-b_1} \ln \left(\frac{30.2d}{r} \right) - 3.4 \right\} + \left\{ 1 - \left(\frac{d}{r} \right)^{1-b_1} \right\} \right] \quad \text{for } b_1 \neq 1 \quad \dots (3.13)$$

b_1 was found empirically to be [15] :

$$b_1 = 1.05 \left(\frac{w}{\kappa v_* w_c} \right)^{0.96} \left(\frac{r}{d} \right)^{0.013} \left(\frac{w}{\kappa v_* w_c} \right) \quad \dots (3.14)$$

3.4 Representative wave height

The *single representative wave*, which will yield the same resultant longshore sediment transport as the *complete wave spectrum* in the case of irregular wave attack, will again be a function of the boundary conditions. By assuming (1) a Raleigh-distributed wave height spectrum, and (2) the superposition of the transports generated by the individual waves in the spectrum, a *representative wave height* H_r was computed for the SHANBY-detail predictor in the same manner as in Chapter 2. A design curve is presented in Figure 12, whereby it becomes possible to determine the *representative wave height* H_r in terms of the rms - wave conditions. The representative height varies between the median wave height (H_{50}) and the significant wave height (H_{sign}), with a tendency towards H_{sign} at the lower transport rates. Seeing that the lower waves in the spectrum will not transport sediment as readily in cases near the initiation of motion, this tendency is to be expected. The single representative wave height for the SPM-overall predictor is by definition the rms wave height.

4. APPLICATION

4.1 General

Normally the losses from an area which had been replenished by a beachfill, can be estimated by using methods which are based on the *grain size distribution of the borrow and native material* only. The three most-used formulae in this category are those of *Krumbein-James* [10], which is suggested for use in the Shore Protection Manual [19], *Dean* [4] and *James* [8].

The *Krumbein-James* and *Dean* methods predict an *overflow ratio*, i.e. the ratio between the *volume of sediment* that has to be placed in order to retain the design volume and the *required design volume* of sediment in the fill. The *Krumbein-James* method assumes some portion of the borrow material (which has the same grain size distribution as the native material) to be absolutely stable and to stay on the beach indefinitely, whereas the rest of the borrow material will be lost. The *Dean*-method, on the other hand, assumes that the borrow material which is coarser than the native material will *not be lost*.

James assumes that no material is absolutely stable, and that fine material is less stable than coarse material. He then computes a *relative retreat rate*, which is basically the ratio between the *loss rate* of the borrow material in the fill and that of the native material in the original beach profile.

In order to allow the comparison of the losses, as predicted by the techniques described in this paper, and those given by the above-mentioned three beachfill methods [10], [4], [8], the following two definitions were made :

$$\text{Overflow Ratio (SEGAR)} = \frac{(\Delta S_y)_{\text{borrow}} + (\Delta S_x)_{\text{borrow}}}{V_{\text{fill}}} \quad \dots (4.1)$$

and

$$\text{Relative Retreat Rate (SEGAR)} = \frac{(\Delta S_y)_{\text{borrow}} + (\Delta S_x)_{\text{borrow}}}{(\Delta S_y)_{\text{native}} + (\Delta S_x)_{\text{native}}} \quad \dots (4.2)$$

where (ΔS_y) and (ΔS_x) are the losses in the offshore and longshore directions respectively, and V_{fill} is the volume of sediment placed in the beachfill. When computing (ΔS_y) it should be kept in mind that the dimensions of the transport rates S_y in chapter 2 are $\text{m}^3/\text{m}/\text{s}$, while those in chapter 3 (S_x) are m^3/s . In equations (4.1) and (4.2) sediment is considered lost when it moves out of the area in which it was placed, i.e. that volume of sediment which has to be replaced in, for instance, an *annually recurring replenishment*. Due to the fact that the sediment moved in the offshore direction will eventually build a new equilibrium condition, which will conform to the borrow material and the wave climate, the annual losses, i.e. the required recurring replenishment, as characterized by equations (4.1) and (4.2), will gradually diminish with time. The present calculations only show the losses during the first replenishment period. The longshore losses were computed by both the SWANBY-detail predictor method and the SPM-overall predictor, whereafter a representative loss was computed from these two figures.

Due to the fact that both the *overflow ratio (SEGAR)* and the *relative retreat rate (SEGAR)* are time-dependent, a time-duration of 10 days was chosen as basis for the comparison, during which time one wave condition took place. When doing an actual beachfill design, the wave conditions in an average year should be applied *consecutively* to the gradually developing profile.

4.2 Beachfill characteristics

A typical beach profile for Natal (situated on the South African east coast) was taken as the initial profile for the computations. The geometry of the initial profile and the two beachfills, as well as the grain size characteristics, are given in Figure 13. As can be seen, six different cases result, viz. $\alpha_{\text{borrow}} = 1/10$ and $1/5$, each with $D_{50} = 200 \times 10^{-6}$, 500×10^{-6} and 1000×10^{-6} m. It was assumed that the beachfill has a longshore length $l_x = 1000$ m, and is situated in an area with no updrift supply of sediment. No gradients initiated by the placing of the fill itself, will be considered, i.e. edge effects at the longshore extremities of the fill will be neglected.

The wave condition in the area was taken to be :

$$(H_0)_{\text{sign}} = 2 \text{ m} ; T = 10 \text{ s} ; \theta_b = 5^\circ .$$

4.3 Discussion of results

The computed losses, as given by the various methods, are represented graphically in Figure 14. The following general observations regarding the results are relevant :

(1) The beachfill methods of Krumbein-James, Dean and James are all independent of the profile geometry, whereas the Krumbein-James and Dean methods are also independent of the wave climate. In the James-method the wave climate can perhaps be included via the choice of the measure of selectivity of the sorting process Δ (as defined by James [8]). Both the wave climate and the profile geometry do, however, influence the losses. Consequently, the above-mentioned three methods can only be used to obtain comparative results for various possible borrow materials.

(2) If all the consecutive wave conditions in an average year are taken into account, the resultant

losses will be lower than those given by the higher waves only, due to the fact that the lower waves will initiate an *onshore* sediment movement.

(3) Both the relative retreat rate (as given by James) and the overfill ratio (as given by Krumbein-James and Dean) are equal to unity in the case of a borrow material which is *identical* to the native material. The method presented in this paper (called the SEGAR-method) yields higher values of both the relative retreat rate and the overfill ratio (of approximately 2) in the case where the native and borrow materials are identical. This higher loss rate seems logical, seeing that the initial profile with fill is steeper than the initial profile alone (see Figure 13). Offshore losses will thus increase (re chapter 2).

(4) The relative retreat rates predicted by the James-method are appreciably smaller than those predicted by the SEGAR-method, for all values of D_{50} except $D_{50} = 200 \times 10^{-6}$ m. A study of the original paper by James reveals that if $\Delta = 1.0$ as suggested in [8], the relative retreat rate is actually < 1 for 330×10^{-6} m $< (D_{50})_{\text{borrow}} < 1000 \times 10^{-6}$ m, which is unfeasible from a physical viewpoint. For $(D_{50})_{\text{borrow}} < 200 \times 10^{-6}$ m, on the other hand, the relative retreat rate R_b increases drastically to completely unrealistic values (for instance, for $D_{50} = 100 \times 10^{-6}$ m; $M_{\phi_b} = 3.23$, $\sigma_{\phi_b} = 1.08$:- $R_b = 6.8 \times 10^3$ if $\Delta = .6$ and $R_b = 9.2 \times 10^4$ if $\Delta = 1.0$). As was already pointed out by James [8], the relative retreat rate is very dependent on the value of Δ . As Δ is mostly unknown, this represents a serious restriction in the applicability of the theory.

(5) The overfill ratios predicted by Dean and especially by Krumbein-James for values of $D_{50} < 500 \times 10^{-6}$ m (in the present illustration), are exceedingly high. The Dean-method seems to have the soundest physical background of the two methods.

(6) The SEGAR-method described in the present paper can, if necessary, be used to obtain the relative losses in the offshore and longshore directions respectively, as the transports in both these directions are already computed. This is not possible for the Krumbein-James [10], Dean [4] and James [8] methods.

4.4 Concluding remarks

Although the SEGAR-method, which takes into account the local wave climate and the geometry of the beachfill, is more complicated to apply than the other three beachfill methods [10], [4] and [8], it yields results which seem to be more comparable with the known prototype behaviour of a beachfill area, than the results given by [10], [4] and [8]. It is accordingly suggested that the SEGAR-method is used for beachfill design. *Back-up computations, yielding comparative results only*, of both the *relative retreat rate* and the *overfill ratio*, can be made by using the *James-method* (provided that an appropriate choice of Δ can be made) and the *Dean-method* respectively. The Krumbein-James method generally over-predicts the overfill ratio, and is not recommended for use.

5. SUMMARY

Predictor techniques have been presented, whereby it is possible to compute *onshore-offshore* and *longshore sediment transports* respectively. These respective techniques can be used in combination to compute sediment losses in numerous applications. One such application, viz. to a beachfill problem, was described in detail. The results were shown to be realistic.

A *comparison of computed results with actual field measurements* at a beachfill location will be the logical next step in the testing of the techniques.

CHAPTER 67

LONGSHORE TRANSPORT PREDICTION — SPM 1973 EQUATION

Cyril Galvin¹, M. ASCE and Philip Vitale², A.M. ASCE

ABSTRACT

The 1973 Shore Protection Manual (SPM) predicts longshore transport rates that are 83% higher than its 1966 predecessor, for the same wave conditions. This upward revision is the result of concurrent increases due to (1) deletion of all laboratory data used to establish the 1966 prediction, (2) addition of Komar's (1969) field observations, and (3) limiting energy flux values computed from previously unused data obtained at Santa Barbara (Johnson, 1952). A derivation based on conservation of energy shows that P_{ℓ} is the longshore component of the energy flux confined between two wave orthogonals spaced a unit distance apart in the longshore direction, and that a term previously identified as the onshore component of energy flux is identical with the total energy flux in the direction of wave travel between these orthogonals. Use of submerged weight transport rates has no engineering benefit at the present time because: (1) all available data are in terms of volume rates, (2) conversion to submerged weight requires estimates of the void ratio and sand grain density which have been assumed constant in practice, and (3) the engineering problem needs volume rates which would require reconversion back to volume rates if an immersed weight prediction were established.

INTRODUCTION

Energy flux method. Experience indicates that the best way to predict longshore transport at a given site is to adopt proven values from nearby sites, or to estimate values from surveyed changes in sand volume at suitable places along the shore. However, such data are often not available. In the absence of actual field-based estimates, the recommended procedure is to use the energy flux method.

The energy flux method empirically relates longshore transport rate, Q , to a computed variable called the energy flux factor, $P_{\ell S}$, by an equation of the form:

$$Q = K P_{\ell S} \quad (1)$$

¹P.O. Box 623, Springfield, Virginia 22150

²CERC, Kingman Bldg., Fort Belvoir, Virginia 22060

The energy flux factor depends on some combination of wave direction, height, and period. The coefficient of proportionality, K , is empirically determined.

The relation between Q and $P_{\ell s}$ has been published in many forms, with wide variations in the suggested value of K . This paper compares two published versions of equation (1): the SPM and TR4 versions. (SPM is the "Shore Protection Manual" of the Coastal Engineering Research Center [CERC], U.S. Army Corps of Engineers. SPM replaces the CERC Technical Report Number 4 [TR4], "Shore Protection, Planning and Design". SPM has been issued under two dates [1973, 1975], but both editions are identical for the material referred to in this paper. The third, and final, edition of TR4 [1966] is used for comparison with SPM.)

Units. The units in this paper are those used in SPM. The longshore transport rate, Q , is a volume per unit time, reported as cubic yards per year (yd^3/yr). This rate measures volume of beach sand in place, including voids. This is the volume rate of importance in beach erosion and shoaling studies.

The other side of equation (1) is the energy flux factor, $P_{\ell s}$, a power per unit length of shoreline, reported here as foot - pounds per second per foot of shoreline ($\text{ft} - \text{lbs}/\text{sec}/\text{ft}$). The proportionality constant, K , has units to balance the equation ($\text{yd}^3 - \text{sec}/\text{lb} - \text{yr}$).

It is believed that these units give the most effective engineering formulation at the present time. A later section of this paper discusses the applicability of immersed weight rates of transport instead of volume rates, and the physical meaning of the longshore energy flux factor.

To convert the volume rate and the energy flux factor units of this paper to their metric equivalents, the following conversions are required:

$$Q: 1 \text{ yd}^3/\text{yr} = 0.76 \text{ m}^3/\text{yr} \quad (2)$$

$$P_{\ell s}: 1 \text{ ft} - \text{lb}/\text{sec}/\text{ft} = 4.45 \text{ newton-m}/\text{sec}/\text{m} \quad (3)$$

Purpose. The energy flux prediction in SPM (Figure 4-37 and equation 4-40 on pages 4-100 and 4-101) replaces the energy flux prediction in TR4 (Figure 2-22, page 175). A comparison (Figure 1) between the two versions shows that the SPM prediction yields transport rates that are 83% higher than those in TR4, for the same wave conditions.

The purpose of this paper is to document the reasons for this significant upward revision of the predicted longshore transport rate.

FIGURE 1. UPWARD REVISION OF LONGSHORE TRANSPORT PREDICTION

THEORY

For a field engineer applying a design curve to predict longshore transport rate, the background behind the curve is usually not of immediate interest. However, sooner or later questions arise about the method, or about the relation between the energy flux method and the apparently different methods available from other sources. For this reason, the following sections describe the basic theory behind the energy flux method and how it relates to the immersed weight rate of transport.

Derivation of P_{ls} . The energy flux factor, P_{ls} , is a quantity related to the power, P^* , supplied by the waves to the coast. The equation for P^* , from small amplitude wave theory, is

$$P^* = C_g E \quad (4)$$

where C_g is the group velocity of the wave and E is the energy density. Group velocity is related to wave speed, C , by

$$C_g = nC \quad (5)$$

where n is a factor that has a value of $1/2$ in deepwater and 1 in shallow water. The energy density depends only on wave height, H

$$E = \gamma H^2/8 \quad (6)$$

γ is the weight density of water.

The power, P^* , is in units of energy per second per unit length along the wave crest (ft - lb/sec/ft). In general, the value of P^* will change as the wave travels to shore. A point on a wave crest moving from deepwater to the shore describes a curved path that gradually approaches perpendicular to the bottom contours and the shoreline (Figure 2). This path is a wave orthogonal. Conservation of energy, according to the small amplitude wave theory used to obtain equation (4), requires that no energy can cross through a wave orthogonal, so that between any two orthogonals, the total wave power is constant in the direction of wave travel. Total wave power is the product of P^* and the length, w , along the wave crest between the orthogonals. Thus, from conservation of energy, with symbols from Figure 2,

$$w_0 P_0^* = w_1 P_1^* \quad (7)$$

For the remaining steps of the derivation, it is necessary to assume that the bottom contours are straight and parallel, although not necessarily evenly spaced. If this is the case, then for a given wave condition, any wave orthogonal has exactly

FIGURE 2. WAVE ORTHOGONALS EVENLY SPACED IN LONGSHORE DIRECTION OVER STRAIGHT, PARALLEL, BOTTOM CONTOURS

the same shape as any other. Thus, if the longshore distance between two orthogonals is b at the shoreline, then the longshore distance between those orthogonals remains b at any distance from the shoreline (Figure 2).

This constancy in longshore spacing, b , between orthogonals allows getting rid of the variable distance, w , in equation (7), since

$$w = b \cos \alpha \quad (8)$$

where α is the angle between the wave crest and the shoreline. Thus, the total wave power between wave orthogonals becomes

$$\text{Total Wave Power} = b P^* \cos \alpha \quad (9)$$

Divide both sides of equation (9) by b and set b equal to 1 foot. Equation (9) then becomes total wave power per unit length or shoreline, given as P

$$P = P^* \cos \alpha \quad (10)$$

P and P^* are both power per unit distance, but the unit distance is the longshore spacing between orthogonals in the case of P and a distance along the wave crest in the case of P^* . From energy conservation (equation [7]), the value of P defined by equation (10) is a constant that does not change along the wave path. Equation (10) for P is formally identical with the equation (7.2.5) of Longuet-Higgins (1972) for his F_x which is called the "onshore component of the energy flux" (Longuet-Higgins, 1972, p. 210). However, the derivation just shown indicates that P (or F_x) is constant in the direction of wave travel, rather than in the onshore direction.

At any point along the wave path, the wave power per unit shoreline has a magnitude (P) and a direction (α), and therefore P can be broken into components. The longshore component is

$$P_\ell = P \sin \alpha \quad (11)$$

from Figure 2. Since α will change as the wave refracts while P remains constant, it is evident that P_ℓ varies along the wave path. Equation (11) can be rewritten using equations (10), (4), and (5) and a trig identity to get:

$$P_\ell = \frac{1}{2} C_g E \sin 2 \alpha \quad (12)$$

Longuet-Higgins (1970, p. 210) has stated that P_ℓ has no obvious physical meaning, and that it should be banished from the literature. However, according to the derivation of this paper, P_ℓ has a physical meaning: it is the longshore component

of the energy flux between two wave orthogonals spaced a unit distance apart in the longshore direction.

Since P_{λ} has units of energy per second per foot, it is called a longshore energy flux. The basic assumption behind the energy flux method is that the longshore transport rate, Q , depends on P_{λ} evaluated at the outer edge of the surf zone where the waves break. This evaluation requires approximation, since wave breaking is outside the linear wave theory used to develop the equation for P_{λ} . To indicate the approximation involved, the subscript s (surf zone) is added to P_{λ} , and equation (12) is written

$$P_{\lambda s} = \frac{1}{2} C_b E_b \sin 2\alpha_b \quad (13)$$

The subscript, b , indicates evaluation of the group velocity (equation [5]), energy density (equation [6]), and wave direction (α), all at the breaker point.

The appropriate height to use for H in the energy density equation (6) is the root-mean-square height. However, by custom, most coastal engineers use the significant height which is proportional to the rms height. Because of this and other approximations, the term $P_{\lambda s}$ is described as the "energy flux factor", and in effect, it is calibrated for significant wave height.

Equation (13) has been formulated in explicit terms using wave direction, height, and period (SPM, Table 4-8, p. 4-97). These and other relations are the subject of a separate report in preparation by the authors which has as its aim a complete documentation of the energy flux method.

The derivation presented above benefited from the work by Walton (1972) and Longuet-Higgins (1970).

Immersed Weight. From a scientific viewpoint, a number of investigators (Bagnold, 1963; Komar and Inman, 1970; Longuet-Higgins, 1972) recommend using the immersed weight rate of transport, I_{λ} , rather than Q . The immersed weight rate leads to a dimensionally homogeneous equation with a dimensionless coefficient, instead of the peculiar units that K has in equation (1). The immersed weight is related to the volume rate by

$$I_{\lambda} = a' \Delta \gamma Q \quad (14)$$

where a' = volume solids/volume sand in place and $\Delta \gamma$ is the difference in specific weight between sand grain and water.

In practical application, the immersed weight formulation does not now improve the engineering prediction. The required engineering quantity is a volume rate of sand in place (Q), and all the existing data were originally measured in terms of Q , or in Q equivalents. Therefore, in order to develop the immersed weight formulation from existing data, it is necessary to estimate values of a' and $\Delta \gamma$ and convert Q values to I_{λ} by equation (14). Then, to use the immersed weight formulation to solve a problem, one must reverse the procedure and convert back to the required Q .

Available data have led those investigators who have worked with I_{λ} to assume that both a' and $\Delta \gamma$ are constants. To the extent that this is a fact, I_{λ} is directly proportional to Q , independent of any other variables. If this is the case, nothing is gained toward an engineering solution by using I_{λ} , and something may be lost since the procedure would add two unnecessary calculations.

It appears fairly certain that most sand grains on beaches with longshore transport problems are quartz, so that specific gravity in equation (14) is not expected to vary very much. It is less certain that the porosity of the littoral sands is effectively constant. The I_{λ} formulation will be necessary if future work on the soil mechanics of beaches shows that average a' varies significantly from one locality to another.

EVOLUTION OF ENERGY FLUX PREDICTIONS

The initial application of what has become the energy flux method to predict longshore transport rate appears to have been made by the Los Angeles District, U.S. Army Corps of Engineers in the 1940s (U.S. Army Corps of Engineers, Los Angeles District, 1948; Eaton, 1951).

Since then there have been a number of empirical equations that relate volume longshore transport rate to longshore wave energy flux. They range chronologically from Watts (1953) to the present form, SPM (1973), including the six which are listed in Table 1. Column A of Table 1 lists the published reference, column B gives the equation as presented in the original paper, with the original units described in column C. In column D, the equation is presented with the units used in the SPM (1973). Figure 3 is a graphical comparison of these column D equations.

Watts' (1953) equation (row 1, Table 1) was based on four monthly field data points collected at South Lake Worth Inlet in Florida. The longshore transport rate was measured by surveying the amount of sand pumped into a detention basin at the inlet. $P_{\lambda S}$ (E_T in Watts' paper) was computed using significant wave height and period taken from the analysis of the wave

TABLE 1. SIX ENERGY FLUX PREDICTIONS FOR LONGSHORE TRANSPORT RATE

FIGURE 3. FIVE PREDICTIONS OF Q
FROM ENERGY FLUX (1953 - 1973)

records of a pressure gage installed at the seaward end of a pier located eleven miles north of South Lake Worth Inlet. Wave direction was obtained from visual observations.

Caldwell (1956) calculated five more field data points. The longshore transport was measured by comparing successive sets of surveys of the beach along the 11,000 foot study area immediately south of the jetties at Anaheim Bay, California. $P_{\lambda s}$ (E_i in Caldwell's paper) was calculated from wave records of a step resistance wave gage installed on the seaward end of the Huntington Beach Pier, located about six miles south of Anaheim Bay. Wave direction was obtained from wave hind-casting and wave refraction analysis using synoptic weather charts. The equation in row 2 of Table 1 was determined by Caldwell using his five and Watts' four data points.

Savage (1962) added numerous laboratory data points to those of Watts (1953) and Caldwell (1956) to produce a curve described by the equation in row 3 of Table 1. This relation was eventually presented as Figure 2-22, page 175 in TR4 (1966), the only change being in $P_{\lambda s}$ units (E_a in Savage [1962] and TR4 [1966]) as is shown in column C of Table 1.

Das (1972) added field data points from Komar (1969) and Moore and Cole (1960) to those used by Savage (1962) to obtain the equation in row 5 of Table 1. However, in determining this equation, Das deleted those laboratory data based on experiments with lightweight sediment.

As can be seen in Table 1, Watts and Caldwell used $P_{\lambda s}$ raised to a power less than 1 (0.9 and 0.8 respectively). The other references showed linear equations in $P_{\lambda s}$. Das, in unpublished work leading to his 1972 paper, found no statistical advantage to using a power equation if the linear coefficient is chosen correctly.

Figure 3 shows that, in the range of the most commonly occurring values of longshore transport rate (10^5 to 10^6 yd³/year), Watts' (1953) prediction comes closest to the curve now given in SPM (1973). In this range of transport rates, both Watts and SPM predict the highest values of Q for a given $P_{\lambda s}$ of the six equations in Table 1. It is interesting that Watts' (1953) was the earliest equation; SPM (1973) the most recent.

CHANGE FROM TR4 TO SPM

Although the difference between the SPM curve and the early curve of Watts is small, the difference between SPM and its immediate predecessor, the TR4 curve, is large (Figure 3). As shown earlier on Figure 1, the SPM curve gives a transport rate that is 83% higher than the TR4 curve for the

same wave conditions. There are three principal reasons leading to the higher placement of the SPM curve, as illustrated on Figure 4 and described below.

Deletion of Lab Data. The TR4 curve is based on nine field observations and 150 laboratory data points (Table 2). The SPM curve is based on 23 plotted field observations, but no laboratory data. The laboratory data were deleted in SPM because additional field information had become available and because the numerous laboratory data overwhelmed the few field data in locating the curve. The effect of the laboratory points is indicated by the strippled field on Figure 4.

Caldwell, 1956	5	5
Komar, 1969	<u>0*</u>	<u>14</u>
	9	23

*Komar's data became available after TR4 curve was published.

Komar's Field Data. The field measurements of Komar (1969) added fourteen data points to the curve (Figure 4). In general, these field data plotted above the TR4 trend, which was heavily weighted by the lower laboratory results and the lower field data of Caldwell (1956). Caldwell's data fall in the lower part of the region identified as "Field Data, SPM and TR4" on Figure 4.

Santa Barbara Estimate. Johnson (1952) published values of Q , P_0^* , and wave period for intervals of high longshore transport rates at Santa Barbara. These Santa Barbara data have been identified as exceptional (M. P. O'Brien, personal communication, 1969), but they had not previously been used with longshore transport predictions because the data lack wave direction.

FIGURE 4. DATA USED TO ESTABLISH SPM AND TR4 LONGSHORE TRANSPORT PREDICTIONS

In order to benefit from the Santa Barbara data, the equation for P_{ℓ} , equation (12), was written as the product of two terms, one being P_{\circ}^* and the other dependent only on wave direction.

$$P_{\ell} = M P_{\circ}^* \quad (15)$$

where

$$M = \cos \alpha_{\circ} \sin \alpha_{\text{D}} \quad (16)$$

By using Snell's law, an estimated breaker depth, and trial and error, it is possible to get a maximum value of M (Galvin, 1969). Using this maximum value of M in (15) with Johnson's data for P_{\circ}^* yields equivalent values of $P_{\ell S}$ that are well above the TR4 curve and above even the SPM curve (Region I on Figure 4).

These Santa Barbara data were not plotted on the SPM curve (Figure 4-37 of SPM), but their existence added confidence to the placement of the SPM curve. Since 1972 when the SPM curve was developed, new data have come available from CERC studies at Channel Island Harbor, California, which also support the higher curve.

CONCLUSIONS

1. The SPM prediction for the volume rate of sediment transport, Q , as a function of the longshore energy flux factor, $P_{\ell S}$, is, in the recommended units,

$$Q = 7500 P_{\ell S} \quad (17)$$

This equation gives volume transport rates 83% higher than the rates from the predecessor curve in TR4, for the same wave conditions (Figure 1).

2. The 83% increase from TR4 to SPM is due to deleting the TR4 laboratory data (Table 2), adding Komar's (1969) field data, and determining feasible upper limits for Johnson's (1952) previously unused Santa Barbara data (Figure 4).

3. The recommended units for Q and $P_{\ell S}$ are yd^3/yr and $\text{ft} - \text{lb}/\text{sec}/\text{ft}$, respectively, or their metric equivalents in equations (2) and (3). The volume rate, Q , is preferred over the immersed weight rate, I_{ℓ} , at least until an I_{ℓ} curve can be constructed without assuming values for specific gravity and void ratio of the beach sands. Even if I_{ℓ} can be shown necessary because of significant variability in void ratio, Q is still the variable of engineering interest.

4. P_{ℓ} has a readily understood physical meaning. It is the longshore component of the energy flux conserved between two orthogonals spaced a unit distance apart in the longshore direction (Figure 2). $P_{\ell s}$ is P_{ℓ} evaluated at the seaward edge of the surf zone.

5. A review (Table 1) of six predictions of Q developed over a twenty-year interval indicates that the first prediction (Watts, 1953) is the one closest to the last (SPM, 1973).

CHAPTER 68

SAND TRANSPORT BY WAVES

by

E.W. Bijker^{*}), E. van Hijum^{***)} and P. Vellinga^{****)}

1 Summary

Sand transport parallel to the direction of wave propagation by waves of arbitrary form over a rippled bed has been investigated in a flume, at the Laboratory of Fluid Mechanics of the Dept. of Civ. Eng. of the Delft Univ. of Techn. The transport has been measured by means of a special procedure which does not disturb the process. The measured sand transport is related to the measured wave form parameters. The results indicate that the direction of net sand transport depends upon the form of the waves.

2 Introduction

This study has been carried out with the aim to understand the onshore and offshore movement of sand which determines the development of beach profiles. From movable bed model tests it has become clear that beach profile formation may be severely affected by secondary waves which, together with the primary wave always originate from a sinusoidally moving wave-board. Even a hardly measurable second harmonic free wave can cause bar formation over a horizontal bottom. Since secondary waves are present in nature the study of the effect is of great interest in the understanding of beach profile development.

3 Description of the tests

To obtain insight into the transport phenomenon 27 tests have been conducted in a flume (see Fig. 1) with a horizontal sand bed with a mean particle diameter of 250 μm with different combinations of water depths, wave periods and wave heights as shown in Table 1. The Ursell parameter ($Ur = HL^2/d^3$) ranged from 12 to 57. Since the presence of secondary waves results in a spatially varying wave form, the wave form parameters and the resulting sand transport have been measured at 0.50 m intervals along the flume.

Table 1

4 Measuring procedure

It is very difficult to measure sand transport under undisturbed conditions. The use of sandtraps usually causes such a discontinuity that the upwave as well as the downwave sandtrap is filled with sediment. An uncovered part in the flume bottom however causes hardly any discontinuity and creates an excellent boundary condition for the balance of sand volume (see Fig. 1).

Fig. 1 A schematic illustration of the model

An electronic bottom-profile indicator together with a recorder was used to measure the bottom profile along the flume. By integrating the measured profiles before and after the test, the sediment transport through any cross-section is known. The essence of this procedure is that it is assumed that the transport across the uncovered part is zero. To eliminate the initial effects, the $t=0$ measurements were done only after ripples of the equilibrium form were developed. Also the tests were finished before any secondary interaction processes influenced the results; disturbing processes may originate from the discontinuity at the uncovered part, while also bottom deformation may cause interaction effects on the wave parameters. Taking this into account, it was decided to use test durations between 20 and 60 minutes, depending on the transport intensity. During this period usually bottom elevation variations of the order of 1 mm had occurred. The accuracy of the measuring procedure is of the order of 0.1 mm.

As the bottom profile measurement was done along the length of the flume and as the width of the flume was 0.50 m, the bottom profile was measured along the

center line and the quarter lines and the volume change between two cross-sections was found by taking the average of the three quantities.

The sand transport rate was computed at intervals of 0.50 m. At the same cross-sections the wave parameters were measured: the velocity profile was measured with a micro propellor $1/3 d$ above the bottom, d being the waterdepth, and the wave heights were measured using a resistance type wave gauge.

During the analyses of the test results, only the velocity profile was used when relating the wave parameters to the resulting sand transport, because for sand transport, the velocity profile is of more direct interest than the surface wave form, especially since in latter tests a uniform current was superimposed on the oscillatory motion. Furthermore with waves only the form of the velocity profile is about the same as the form of the wave.

During the analyses no specific attention has been paid to the ripple pattern since the aim of the study is to find a relation between the wave parameters and the resulting transport; the ripple pattern is not an independent variable in this relation and as such not of direct interest in finding this relation. However, the ripple patterns were measured to enable comparisons with other experiments to be carried out on a different scale.

5 Test results

As described by Hulsbergen [1] and Buhr Hansen [2] the wave form varies along the length of the flume. When the velocity variation is analysed in harmonic components it appears that the variation is repetitive in the same form at certain distance intervals. The distance is equal to the distance which is required for the primary wave (period T) to overtake the secondary wave (period $T/2$). The repetition especially appears in the variation of the second harmonic component (see Fig. 2). To see how this overtake length is related to the measured overtake length by Hulsbergen [1] and the theoretical overtake length according to Miche, the distance between two places where the second harmonic component \hat{u}_2 reaches it's maximum (L_{ov-2}) is plotted against the waterdepth (see Fig. 3).

Because of the similarity it may be assumed that the wave form variation in these tests agrees with the theory as described by Hulsbergen [1] and Buhr Hansen [2]. According to Hulsbergen [1] one may separate the \hat{u}_2 component into a contribution from the second order Stokes wave and a contribution from the secondary wave. These contributions can be found by taking the average of \hat{u}_2 over an overtake length as the $\hat{u}_{2-stokes}$ and the amplitude of the variation as the $\hat{u}_{2-fontanet}$ (see Fig. 2).

Fig. 3 Dimensionless overtake length

Sand transport variation

From the experiments it is clear that the sand transport varies with the distance from the wave generator. Along the length of the flume sand transport in the direction of wave propagation alternates with sand transport opposite to the direction of wave propagation. For further analyses the sand transport along the flume is divided into the average \bar{S} and the amplitude of the variation \hat{S} (see Fig. 4).

Fig. 4 Variation of the sand transport with the distance from the wave generator

Relation between sand transport variation and wave form variation

To demonstrate that the variation of the sand transport corresponds with the behaviour of secondary waves, the overtake length (L_{ov-2}) is plotted against the distance over which the variation in sand transport is repeated (see Fig. 5). From this figure it is clear that the distances are about equal, hence it may be concluded that the variation in sand transport is caused by the occurrence of secondary waves.

Fig. 5 Overtake length of the secondary wave against the repetition distance of the sand transport variation

6 Analyses of the results

Mechanism of sand transport by waves

The sediment movement under a wave can be described as follows (see Fig. 6): a vortex is generated behind the ripple crest at t_1 . From t_1 to t_2 this vortex is filled with sediment. At t_3 the sediment of this vortex is brought into suspension and is carried backwards by the negative orbital velocity to the preceding ripples. At t_3 at the other side of the ripple crest, a new vortex is formed. At t_5 the sediment of this vortex is brought into suspension and is carried forwards by the positive orbital velocity, etc.

This way a big quantity of sand is in oscillatory motion. A resulting transport can be caused by a small asymmetry in the orbital motion.

In further analyses the following assumptions have been made:

- the quantity of sand moving back and forth under oscillatory motion is proportional to \hat{u}_1^2 .
- the difference between the two quantities is proportional to \hat{u}_2 .
- the resulting sand transport is related to the product of \hat{u}_1^2 and \hat{u}_2 .

Fig. 6 Sand movement over sand ripples

Relating sand transport to the second harmonic component of the velocity profile
 Fourier analyses of the velocity profile shows that the value of the second harmonic component varies with the distance from the wave board. This variation can be described by the average and the amplitude of the variation. Also the sand transport variation with the distance from the wave board can be described by the average and the amplitude of the variation. Now the averages and the amplitudes can be compared.

In Fig. 7 the average sand transport \bar{S} has been plotted against $\hat{u}_1^2 \cdot \hat{u}_{2-stokes}$. From this figure it is clear that the average sand transport under these test conditions is in all cases opposite to the direction of wave propagation and that there exists a rather consistent relationship with $\hat{u}_1^2 \cdot \hat{u}_{2-stokes}$. From this it may be assumed that a wave which can be described by second order Stokes theory causes a sand transport opposite to the direction of wave propagation and that the size of the transport can be described by an equation of the type

$$S = c_1 \hat{u}_1^2 \cdot \hat{u}_{2-stokes} + c_2$$

In Fig. 8 the variation of the sand transport has been plotted against $\hat{u}_1^2 \cdot \hat{u}_{2-fontanet}$. From this figure it is clear that a straight line with an equation of the type

$$\hat{S} = q_1 \hat{u}_1^2 \cdot \hat{u}_{2-fontanet} + q_2$$

may be fitted reasonably well through the plotted points.

Although in these comparisons the wave period has not been included it is shown that the measured results follow a trend which support the validity of the suggested relations.

Fig. 7 Average sand transport as a function of wave parameters (negative \bar{S} corresponds with sand transport opposite to the direction of wave propagation)

Fig. 8 Variation of sand transport as a function of the variation of wave parameters

A better way of analysing the results, however, is to compare the actual form of the velocity profile with the resulting sand transport. The velocity profile of the two interacting waves is only adequately described by the value of \hat{u}_1 , \hat{u}_2 and the difference in phase between the two. Since this amounts to three variables it makes the physical understanding of the problem more difficult. That is why a small simplification of the velocity profile has been introduced, such that the profile is described by \hat{u}_1 and the difference between the acceleration and the deceleration of the fluid particles as defined in Fig. 9.

Fig. 9 Definition sketch of acceleration (\overline{acc}) and deceleration (\overline{dec})

This simplification has been carried out for all the measured velocity profiles, and the difference between the acceleration and the deceleration of the fluid particles has been plotted for all tests as a function of the distance from the wave generator (see Fig. 10). In the tests it is apparent that the variation of the value of the $\overline{acc} - \overline{dec}$ is in phase with the variation of the sand transport along the flume (compare Fig. 4 with Fig. 10).

Now another relationship for the amplitude of sand transport can be tried. Like before \hat{u}_1^2 is proportional to the quantities moving back and forth but in this case the resulting transport is caused by the difference between \overline{acc} and \overline{dec} . In Fig. 11 the amplitude of the variation in sand transport has been plotted against the amplitude of the variation in $\hat{u}_1^2 \cdot (\overline{acc} - \overline{dec})$. For each wave period the proportionality constant is different. This is understandable from the fact that the simplification does not really hold for the longer periods. The relation for the shorter period: $T = 1.50$ sec holds very well since the coefficient of linear regression equals 0.995.

Fig. 10 Variation of the difference between acceleration and deceleration of the fluid particles with the distance from the wave generator ($T = 1.70$ sec, $d = 0.30$, $Hd^{-1} = 0.3$)

Fig. 11 Amplitude of variation in sand transport against \hat{u}_1^2 times the amplitude of $\overline{acc - dec}$

No attempt has been made to develop a relationship between the pertinent dimensionless parameters as the testing range is limited and the process may be different on another scale.

By the simplification of the velocity profile and comparing the result with the sand transport it has been found that there exists a qualitative relationship which holds for all the tests carried out with sand with a mean particle diameter size of 250 μm :

- Sand transport by waves is in the direction of wave propagation when the $\overline{\text{acc}}$ is greater than the $\overline{\text{dec}}$, and opposite to the direction of wave propagation when the $\overline{\text{dec}}$ is greater than the $\overline{\text{acc}}$.
- When the $\overline{\text{acc}}$ equals the $\overline{\text{dec}}$ and there is a second harmonic component present, the sand transport is opposite to the direction of wave propagation.

This phenomenon can be explained as follows: from visual observations it has become clear that the extent of vortex formation is closely related to the acceleration and the deceleration of the fluid particles, so that a small acceleration creates a large vortex whereas by the following large deceleration this sand laden vortex is brought up high in suspension and the sand is carried quite far backwards by the orbital velocity so transport opposite to wave propagation will result (see Fig. 12a). In the same way a small deceleration creates a large vortex on the upwave side of the ripple and the following large acceleration lifts the sand laden vortex high in suspension and the sand is carried quite far forwards by the orbital velocity, so transport in the direction of wave propagation will result (see Fig. 12c).

Fig. 12 c,d Velocity profile along the length of the flume ($T = 1.70$ sec, $d = 0.30$ m, $Hd^{-1} = 0.3$)

During tests with standing waves, conducted in the past, it has been possible to observe the vortex formation in photographs. Through this it has been possible to find a certain relationship between the phase of orbital velocity and the development of the vortex (see Fig. 13 and the corresponding photographs). It appears that due to inertial effects vortex formation starts at about $\frac{1}{4} T$ after the zero crossing of the orbital velocity. This means that with a small acceleration the developed vortex reaches its maximum during a high orbital velocity.

Fig. 13 Vortex development in relationship with orbital velocity (photographs 1-7 are shown at the end of this paper)

7 Sand transport when a small uniform current is superimposed in the direction of wave propagation

Under these circumstances sand transport in the direction of net water transport can be expected. From tests however, it appears that this is not always the case (see Fig. 14). When the uniform flow velocity is zero, the direction of sand transport can be in the direction of wave propagation, as well as opposite to it, depending on the wave form. Under the combined action of waves and current the sand transport can still be opposite to the direction of net water transport.

Fig. 14 Sand transport as a function of the velocity of uniform flow superimposed on waves

The explanation for the initial increase of the sediment movement in the direction opposite to wave propagation is the growth of the vortex at the fore-front of the ripple, so that more sand is brought into suspension and is carried backwards by the orbital motion. Only with large uniform flow velocities this effect is overruled. Because of this it can be concluded that insight into the vortex formation as a function of wave and flow parameters is essential for the understanding of sand transport caused by waves and currents.

8 Sand transport under standing waves

Under standing waves also it has been found that the direction of sand transport with sand having a mean particle diameter of 250 μm is in the direction corresponding with the largest temporal gradient of orbital velocity [3]. At first the difference in inertial forces on the grains was considered to be the cause of this. However, further tests showed that the difference in vortex formation was more likely to be the cause.

In the test series with standing waves, finer sand ($D_m = 150 \mu\text{m}$) was also used as bottom material. It was apparent that in this case the direction of sand transport did not agree with the results of the coarser sand. With the finer sand the transport direction was according to the net water transport close to the bottom as described by Longuet Higgins. These results show that two mechanisms of sand transport are present: a first mechanism where sand transport is caused by a small asymmetry in orbital motion and a second mechanism where sand transport is caused by a net water transport. With coarse sands the first mechanism will prevail whereas with finer sands the second mechanism will prevail. When the net water transport is large compared to the orbital velocity, then of course the second mechanism will dominate. The existence of these two mechanisms make it necessary to be very careful in extrapolating data since the domination of a certain mechanism will depend on the scale.

9 Conclusions

- A specially designed procedure for measuring sand transport by waves has given good results. This measuring procedure does not disturb the transport process and very small transports can also be measured.
- Secondary waves which together with the primary wave always originate from a sinusoidally moving wave board cause a spatially varying sand transport resulting in the formation of bars and troughs. The distance between the generated bars is equal to the distance which is required for the primary wave to overtake the secondary wave.
- In all tests with sand of a mean particle diameter of 250 μm , the average of the sand transport along the flume is opposite to the direction of wave propagation and is proportional to $\hat{u}_1^2 \cdot \hat{u}_{2\text{-stokes}}$, whereas the amplitude of the variation in sand transport is proportional to $\hat{u}_1^2 \cdot \hat{u}_{2\text{-fontanet}}$, where \hat{u}_1 is the first harmonic component of the velocity profile, $\hat{u}_{2\text{-stokes}}$ is the spatial average of the second harmonic component and $\hat{u}_{2\text{-fontanet}}$ is the amplitude of the variation of the second harmonic component.

- Throughout these tests it has been found that:
 - 1 sand transport is in the direction of wave propagation when the front of the wave is steeper than the rear face
 - 2 sand transport is opposite to the direction of wave propagation when the rear face of the wave is steeper than the front.
- With sand transport by waves two mechanisms are present; a first mechanism where sand transport is caused by a small asymmetry in orbital motion and a second mechanism where sand transport is caused by a net water transport.
- One should be aware of the different sand transport mechanisms when extrapolating results from movable bed wave-models since the dominating transport mechanism can be different under different scales. Recent tests with finer sands and propagating waves have already shown that the dominating mechanism with sand with a mean particle diameter (D_m) of 150 μm is different from the dominating mechanism with sand with a D_m of 250 μm .
- The test results can be of significant interest in the explanation of the origination of bars in model as well as in nature.

CHAPTER 69

WAVE ACTION AND BOTTOM MOVEMENTS IN FINE SEDIMENTS

Michael W. Tubman and Joseph N. Suhayda
Coastal Studies Institute, Louisiana State University
Baton Rouge, Louisiana 70803

Abstract

Mudbanks have been observed to have an extraordinary calming effect on the sea surface. In certain cases this effect is due primarily to the transfer of energy through the sea/mud interface and its frictional dissipation within the bottom sediments. This paper describes an experiment that measured wave characteristics and the resulting sea floor oscillations in an area where the bottom is composed of fine-grained sediments. The energy lost by the waves at the position of the experimental setup is calculated and compared with a direct measurement of the net energy lost by the waves in going from the point of the experiment to a station 3.35 km inshore. Results show that bottom motions in the range of wave-induced bottom pressures from near zero to 2.39×10^3 Pascal have the appearance of forced waves on an elastic half space. The apparent effect of internal viscosity is seen in a phase shift between the crest of the pressure wave and the trough of the mud wave. Measurements show this angle to be 22° ($\pm 11^\circ$) for the peak spectral component ($T = 7.75$ seconds). The energy lost to the bottom by the waves at the field site was found to be at least an order of magnitude greater than that resulting from the processes of percolation or that caused by normal frictional effects. This newly observed mechanism for the dissipation of wave energy is particularly important for waves in intermediate-depth water and could be a prime factor in determining design wave heights in muddy coastal areas.

Introduction

The extraordinary calming effect that mudbanks exert on surface waves has been recognized for at least two centuries. With the development of the offshore oil industry there also came a recognition that large vertical and horizontal dislocations of the sea floor could occur in areas where the bottom is composed of fine-grained sediments. That these large-scale movements might be linked to wave activity was dramatically suggested in 1969 when two oil platforms were toppled during Hurricane Camille (Sterling and Strohbeck, 1973). The problem of fine-grained sediment mass movements has led to both theoretical and laboratory studies of the interaction of surface-wave-induced bottom pressures and fine-grained sediments. However, direct measurements of wave-induced pressures and resulting bottom movements have not been reported prior to our work.

The results of our work describing the response of bottom sediments to wave pressures were first presented by Suhayda et al. (1976). The analysis

of the field data presented here concentrates on the effect that this interaction has on the loss of wave energy. In the area where our study was conducted (see Fig. 1), the sediment concentration of the water column was not a significant factor contributing to the loss of wave energy. It has been suggested that water column sediment concentration is the key factor in the calming effect of mudbanks (Delft Hydraulics Laboratory, 1962); however, the forcing of a mud wave by wave-induced pressures is also a part of the physical processes wherever fine-grained sediments occur. An understanding of this process is important not only in the Mississippi Delta but also in such coastal areas as the Guianas, the northern coast of China, and southwest India, where extensive areas of fine-grained sediments occur.

Methods

As a cooperative research effort by scientists of the Marine Geology Branch, United States Geological Survey, Corpus Christi, Texas, and the Coastal Studies Institute, Louisiana State University, two field sites were instrumented in East Bay, Louisiana. The primary experimental station and the location of a nearby soil boring are shown in Figure 1.

Results of analysis of the boring (Fig. 2) show the bottom sediments to be very soft, recently deposited material from the Mississippi River. Shear strengths range from 1.57 kilonewtons/meter² (kN/m²) near the water/sediment interface to 2.36 kN/m² 3 meters into the sediment. These low values of shear strength are common in the Mississippi Delta. The boring log shows no evidence of the crust zone that often occurs in these sediments between -3 and -10 meters. In places where the sharp increase in shear strength that defines a crust zone occurs, it is convenient to model the physical system as a light Newtonian fluid overlying a dense, non-Newtonian fluid with a rigid bottom.

The measurement of bottom movement was complicated by two factors. First, the measurements had to be made away from a platform to ensure that the motion of natural muds would be measured. Secondly, bottom motions under typically encountered wave conditions were thought to be small, and therefore high resolution was needed. Both problems were overcome by burying accelerometers in the mud. Though displacements were around 1 cm, accelerations were such that they could be reliably measured and required no fixed reference.

Three Bruel and Kjoer type 8306 accelerometers were mounted so as to measure the accelerations in three dimensions (Fig. 3). They were placed in a water-proof cylindrical PVC housing measuring 0.215 meter in diameter and 0.635 meter in length and having a submerged weight of 5.5 kg. The housing was pushed into the mud by a diver so that the top of the package was 0.15 meter below the mud line. The electronic cable coming from the top of the package was given 4.5 meters of slack, all of which was buried in the mud, and then fixed to a taut galvanized cable that was laid along the bottom between a nearby well jacket and our main instrumented site, Platform V. Platform V, in 19.2 meters of water, is shown in Figure 4. The cable from the accelerometer was brought along the galvanized cable and up the platform leg to the recorders. The location of the accelerometer was

Figure 1. Location of the field site in East Bay, Louisiana.

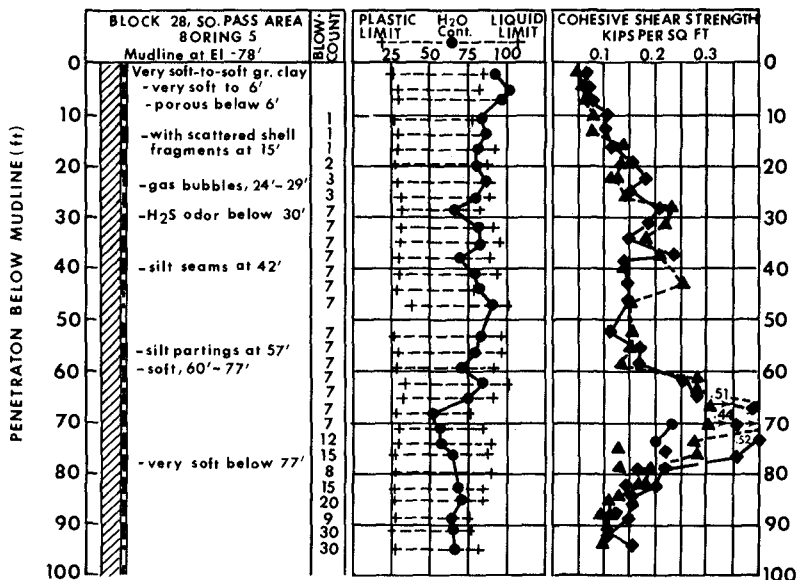

Figure 2. Results of soil boring taken near field site ($1 \text{ kip/ft}^2 = 48 \text{ kilonewtons/m}^2$). For location see Figure 1. (Boring courtesy U.S. Geological Survey, Marine Geology Branch, Corpus Christi.)

directly beneath the catwalk between the two structures so that a pressure cell attached to a weighted cable could be suspended over the package. Figure 5 is a schematic representation of the experiment and the physical system. The location of the pressure sensor was known to be within a radius of 2 meters from the accelerometer. This uncertainty in position could cause an error in the measured phase angle ϕ between the crest of the surface wave and the trough of the mud wave of $\pm 11^\circ$ for a characteristic wave with a period of 7.75 seconds. The importance of such an error will be seen in the calculation of the dissipation of wave energy. Wave properties were measured with a wave staff, a pressure sensor, and a two-axis electromagnetic current meter attached to wire cables that were suspended from the platform and anchored to the bottom through pulleys. A system of winches and pulleys allowed us to adjust the instruments to any depth.

Platform S (see Fig. 10), 3.35 km inshore of Platform V in 5.3 meters of water, was instrumented with an anemometer, a Bendix Q-15 ducted current meter, two pressure sensors, and a wave staff. By running the instruments on Platform S simultaneously with those on Platform V it was possible to compare the net energy lost by the waves while traveling between the two data

Figure 3. Array of three accelerometers.

stations with a rate of energy loss calculated from the measurements of mud movement at Platform V.

Results

Simultaneous measurements of wave height and wave-induced pressure resulted in the data represented in Figure 6. The term n is a correction

Figure 4. The main instrumented site, Platform V.

factor that matches linear theory with observed pressures and wave heights in the manner shown (where $K_p = \cosh k(h + Z) / \cosh kh$). If the observed data were in perfect agreement with linear theory, the data points would fall along the line n equal to 1.00. Further experimentation using two pressure cells placed at different depths in the water column showed that linear theory accurately predicts the change in wave-induced pressures from near the surface to within 0.5 meter of the bottom. The fact that other researchers have obtained similar results (Homma et al., 1966) supported the use of a corrected linear theory for determining surface wave heights from pressure measurements made in the water column above the accelerometer. The actual values of the correction factor n that were used were those values lying along the two least squares fit lines shown in Figure 6.

A sample of the data taken in the study is shown in Figure 7. The accelerations appear sinusoidal in form and have the same general appearance as the wave record.

The shape of the bottom pressure spectrum is similar to that of the spectrum of the vertical acceleration, and the peaks occur at the same

Figure 5. Experimental setup at Platform V.

frequency (Fig. 8). The low-frequency spectral components visible in the acceleration spectrum are believed to be electronic drift. (The phase angle between the crest of the mud wave and the crest of the pressure wave was 202° for the peak spectral component.) Horizontal mud motions are approximately 90° out of phase with the vertical motions, and a backward horizontal movement occurs at the crest of the bottom wave. Similar motion occurs for forced waves on an elastic half space. The ratio of vertical displacement to horizontal displacement over several sets of data averaged about 2.0.

A plot of the amplitude of the pressure wave at the bottom versus the amplitude of the mud wave (Fig. 9) reveals a roughly linear relationship for the range of pressures from near zero to 2.39×10^3 Pascal.

The average energy transmitted through the sea/sediment interface per unit and time over one wave cycle is (Gade, 1958)

$$D_m = -\frac{1}{T} \int_0^T P \frac{dh}{dt} dt \quad (1)$$

h = depth

L_0 = deep water wave length

$$n = \frac{\text{observed wave height}}{\text{observed pressure}} \rho g K p$$

Figure 6. Comparison of observed wave height and observed wave pressure with small-amplitude wave theory.

where T = wave period

P = wave-induced bottom pressure

dh = an infinitesimal increase in the height of the interface

The general characteristics of the data show that the following functions will accurately describe the motions:

$$P = P_a + A \cos (kx - \sigma t)$$

$$h = h_0 + MA \cos (kx - \sigma t + \psi)$$

where P_a = steady-state bottom pressure

A = amplitude of the wave-induced bottom pressure

h_0 = depth of mud over which motion occurs

M = proportionality constant between the amplitudes of the mud wave and the pressure wave

ψ = phase angle between the crest of the bottom pressure wave and the crest of the mud wave

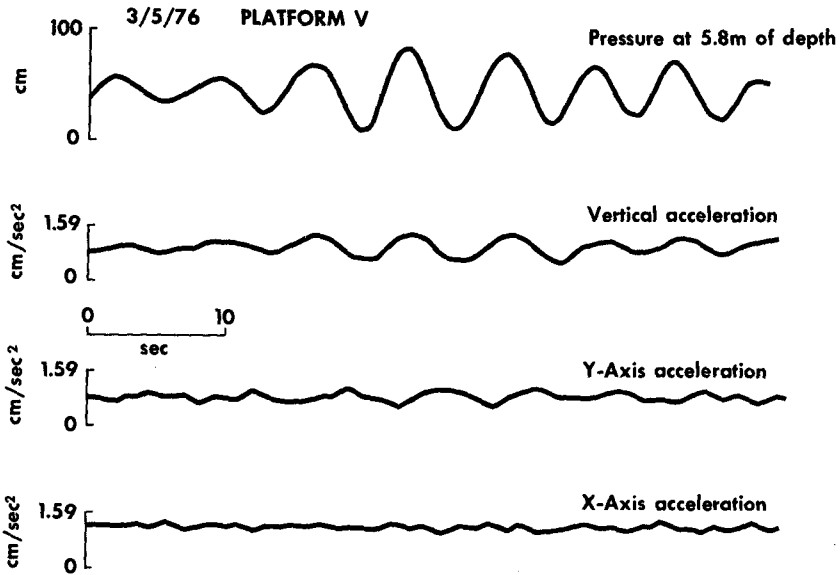

Figure 7. Sample of the data taken during the study.

After substituting equations (2) and (3) into (1) and integrating, and then using linear theory to put bottom pressures in terms of surface wave height, the equation for the rate of energy loss to the bottom is obtained:

$$D_m = \frac{\pi \rho g M H^2 \sin \phi}{4T \cosh^2 kh} \quad (4)$$

where $\phi = 180^\circ - \psi$.

For purposes of comparison with other theories for the dissipation of wave energy, the pressure correction factor for linear theory is not incorporated into the equation. At most this can change the energy loss rate by 20 percent. From equation (4) it can be seen that the dissipation of wave energy by the soft bottom involves only two important factors, determined by the physics of the sediment movement: (1) the relationship between the pressure force on the sediment and the resultant vertical displacement, given by M , and (2) the phase angle between the crest of the pressure wave and the trough of the mud wave, given by ϕ .

The results of the two-station experiment allowed us to estimate the energy lost from the waves. Conditions during the two-station experiment

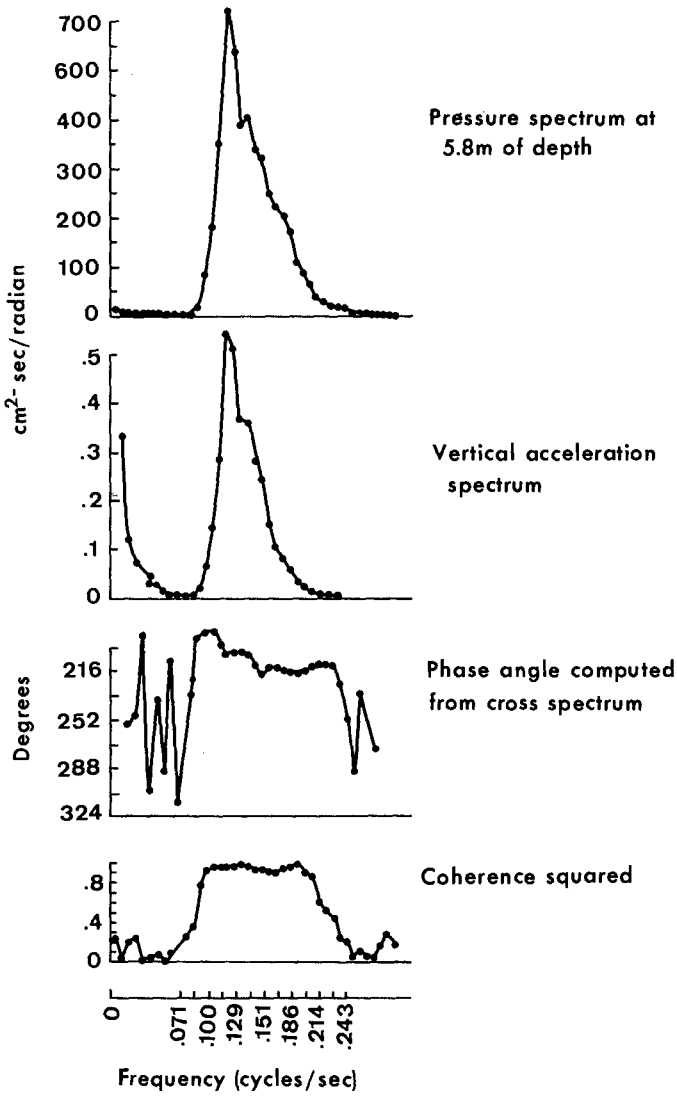

Figure 8. Results of spectral analysis of data.

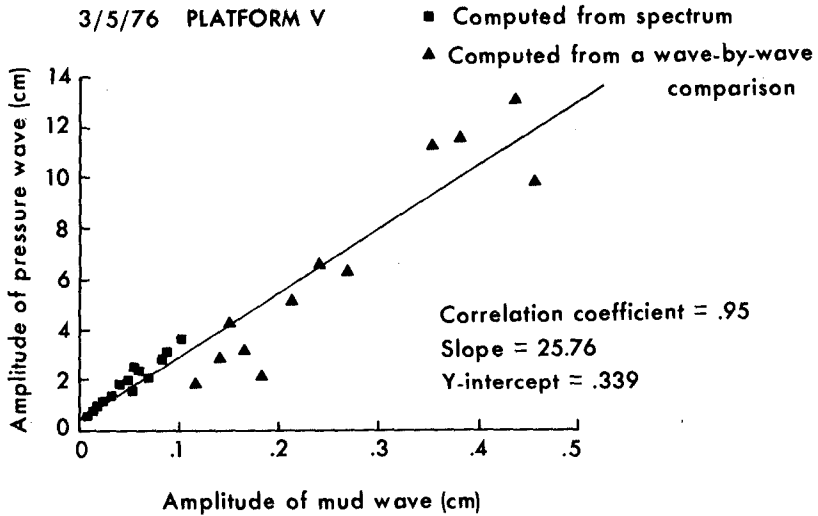

Figure 9. Amplitude of pressure wave plotted as a function of the amplitude of the mud wave.

are illustrated in Figure 10. The instruments on platform V and Platform S were run simultaneously, a procedure that resulted in a surface wave spectrum at V and at S and a bottom movement spectrum at V. For the experiment the effects of the wind, the current, and shoaling and refraction required a small correction to the measured wave height difference. The theoretical wave heights between Platforms V and S were calculated using the energy dissipation equation (4) derived for the forcing of a mud wave and taking into account shoaling and refraction based upon the period of the peak spectral component. The root mean square wave height at Platform V was used for the initial wave height. It was found that to produce agreement with the measured wave height at Platform S and keep M constant the value of the phase angle ϕ would have to be 10° .

Discussion of Results

A comparison of the results of our study with other theories for the dissipation of wave energy is shown in Figure 11. The phase angle ϕ between the crest of the surface wave and the trough of the mud wave is given two values: 22° is the angle that was actually measured at V, and 10° is the angle that results in the correct average dissipation of wave energy between Platforms V and S, assuming that M is constant. Note that the use of the smaller angle does not significantly reduce the magnitude of the dissipation

		$D_m = 4.99 \times 10^{-8} H^2$

Figure 11. Comparison of the rate of dissipation of wave energy for the soft bottom in East Bay with theories for dissipation rates for rigid bottoms (Putnam and Johnson, 1949; Reid and Kajjura, 1957).

rate. The dissipation rates for 19.2 and 4.57 meters of water are in joules/cm²-sec, and H is the wave height in centimeters. The relationship derived by Putnam and Johnson (1949) for dissipation by bottom friction is of particular interest because it is the one most often used even for energy dissipation on coasts. The presence of the mud is often taken into account by making the value of the frictional coefficient (f) larger than 0.01, which is the value commonly used for sandy coasts. It can be seen from this that for reasonable heights the effect of a flexible bottom is to cause an energy dissipation rate that is at least an order of magnitude greater than that for a rigid, impermeable bottom.

The results of the two-station experiment are illustrated in Figure 12. Using 10° in the formula for the dissipation of energy while holding M constant in order to make the total dissipation agree with theory is somewhat an arbitrary choice. It is entirely possible that the properties of the sediments change between V and S and cause changes in M as well as φ, but it should be remembered that because of the uncertainty in the

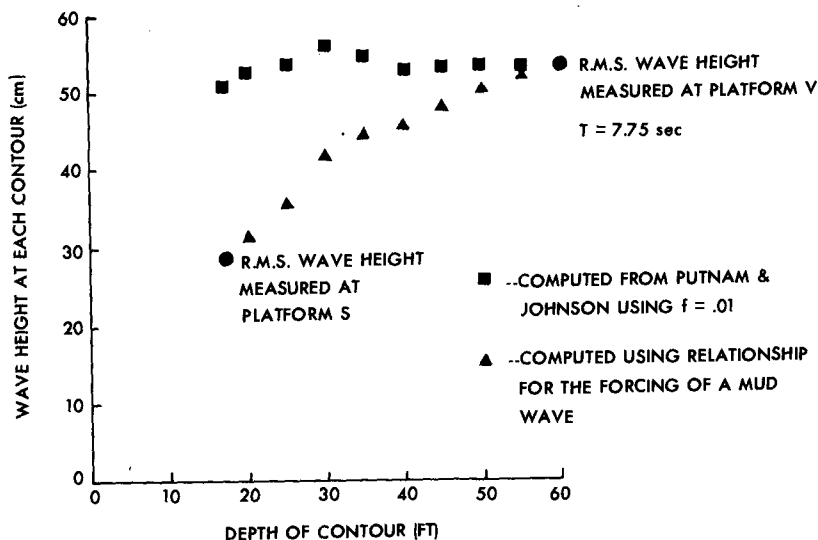

Figure 12. Comparison of the dissipation of wave energy for East Bay and that predicted using the theory of Putnam and Johnson (1949) with the measured wave height change.

position of the pressure sensor relative to the accelerometer it is possible that 10° was the true and constant phase angle.

Figure 12 also illustrates another important point concerning the dissipation of wave energy on muddy coasts. The predicted wave heights between Platforms V and S are shown in the figure as they would be predicted by Putnam and Johnson (1949). Certainly order-of-magnitude higher dissipation rates on sandy coasts can occur when well-formed ripples and the proper velocities are present (Tunstall, 1973), but even in such cases the contrasting trend, made more extreme by using Putnam and Johnson's theory, is present. By comparing the two curves in Figure 12 it can be seen that for bottom friction the dissipation of wave energy occurs mainly in shallow water, whereas for a flexible bottom a relatively greater amount of wave energy is dissipated in intermediate-depth water. Nearshore wave energy for muddy coasts can therefore be expected to be greatly reduced from that present on the outer shelf. Such coasts, in comparison to sandy coasts, tend to protect their shoreline by the dissipation of wave energy in the bottom sediments.

Summary

1. Bottom motions in the pressure range from near zero to 2.39×10^3 Pascal appear to be forced waves on an elastic half space, with the effect of internal viscosity being seen in a phase shift between the crest of the forcing wave and the trough of the mud wave. This results in the transfer of energy to the bottom sediments.
2. The energy loss at the field site was found to be at least an order of magnitude greater than that resulting from percolation over a typical sandy bottom or caused by normal frictional effects.
3. A relatively greater amount of wave energy is dissipated on a muddy coast at intermediate water depths than on a sandy coast.
4. Design criteria for offshore structures and predictions of sediment transport in the nearshore region of a muddy coast based on standard frictional dissipation rates may be significantly inaccurate.

CHAPTER 70

APPLICATION OF A SEDIMENT TRANSPORT MODEL

by C.A. Fleming* and J.N. Hunt**

Abstract

A mathematical model for sediment transport under waves has been developed from concepts that have been used successfully for unidirectional flow. This model has been combined interactively with numerical models of wave refraction, wave diffraction, longshore currents and circulation currents in order to predict local topographical changes in the vicinity of a cooling water intake basin for a nuclear power station. The sediment model is calibrated using field data of sediment concentration profiles. Verification and adjustments may be made by analysing deep water wave statistics corresponding to periodic beach and hydrographic surveys.

The model can be used to investigate the effects of any wave climate and consequently different layouts of coastal structures can be examined very rapidly. For the particular problem considered it was necessary to optimise the configuration of the breakwaters forming a cooling water intake basin in order to minimise the sediment concentration at the intake, estimate maintenance dredging quantities and investigate extreme events.

Introduction

A mathematical sediment transport model for unidirectional flow has recently been developed (1). This model assumes that sediment is transported in a bed load region, adjacent to the stationary part of the bed, where the grains are supported by inter-particle collisions, and a suspended load region where gravitational forces are overcome by fluid turbulence. Continuity of sediment concentration and velocity between the two regions was assumed and consequently the exact definition of the transition level is not of critical importance as the sediment flux immediately above and below the transition level will be similar. Whilst not attempting a complete physical description, the model relies on the simplest formulations of bed load and suspended load that are required for predictive use. The unidirectional model was tested against the best existing empirical theories and found to give comparable estimates of sediment transport rates.

* Mathematics Dept., Reading University, England, and Sir William Halcrow and Partners, Consulting Engineers, London, England.

** Professor of Mathematics, Reading University, England.

It is proposed that under certain conditions it is reasonable to assume that there are some basic physical similarities between the movement of sediment in unidirectional flow and in the combination of waves and currents. The latter case can be treated as a quasi-steady condition with respect to the shear stresses acting on the bed and the dispersion of shear stress due to the orbital wave motion. The wave motion is assumed to act principally in stirring up the sediment while the currents act principally in transporting the sediment. Some concepts from the unidirectional model have been extended in order to develop a model to predict sediment transport rates in the presence of waves and currents.

Attempts have been made to apply the theory to the prediction of local sediment movement and hence topographical changes over a coastal region situated on the S.W. coast of South Africa. Such an application requires the evaluation of wave heights, wave directions and near-shore currents over the region. This is achieved by using a wave refraction model combined with a longshore current model. Comparison of predicted and measured topographical changes can be made to verify and adjust the model parameters.

The model has also been used to optimise the layout of breakwaters forming a cooling water intake basin for a nuclear power station with a particular emphasis on minimising maintenance dredging. This requires the use of a wave diffraction model and a potential-flow model to determine the flow in the vicinity of the basin due to wave induced currents and the proposed cooling water recirculation currents. A physical model of the area has also been constructed and detailed comparisons will be made in due course.

Sediment Transport-Bed Load

The shear stress in excess of the critical shear must be dispersed within the bed load layer. Otherwise successive layers of material would be removed from the bed. This type of argument was substantiated experimentally by Bagnold (2,3) who proposed the relationship

$$\tau_d \approx p \tan \alpha \quad (1)$$

where τ_d is the dispersed shear stress, p is the normal pressure and α is a friction angle which may be approximated by static angle of repose. For the oscillatory case

$$\bar{\tau}_d = \bar{\tau}_w - \tau_c \quad (2)$$

where $\bar{\tau}_w$ is the mean wave shear stress, τ_c is the critical shear stress and generally $\bar{\tau}_w \gg \tau_c$.

The relationship proposed by Jansson (4 and recently reviewed 5) was used to evaluate the shear stress due to waves. A friction factor is given by

$$\frac{1}{4\sqrt{f_w}} + \log_{10} \frac{1}{4\sqrt{f_w}} = -0.08 + \log_{10} \frac{a_o}{R_N} \quad (3)$$

where a_o is the water particle orbital amplitude at the bed, R_N is a roughness length. f_w is the friction factor defined by

$$\hat{\tau}_w = \frac{1}{2} \rho f_w \hat{u}_o^2 \quad (4)$$

where $\hat{\tau}_w$ is the maximum shear stress acting on the bed, ρ is the fluid density and \hat{u}_o is the maximum particle velocity at the bed. It has been shown by Madsen and Grant (6) that the Shields criterion for incipient sediment motion in unidirectional flow can also be applied to oscillatory flow when the bottom shear stress is evaluated using equations (3) and (4).

If it is assumed that the bed load layer is supported entirely by grain interaction and that the local change in dispersed shear is proportional to the local concentration, a concentration distribution may be implied such as (1)

$$C = C_m \left(\frac{C_e}{C_m} \right)^{y/e} \quad (5)$$

C_e is the concentration at the upper boundary of the bed load layer and C_m is the maximum concentration at the bed (≈ 0.52 to be consistent with grain movement in all directions).

As the excess shear is to be dispersed within the bed load layer, the bed load thickness, assumed to be the height of the transition level, is

$$e = \frac{\bar{\tau}_d \ln(C_e/C_m)}{g(\rho_s - \rho)(C_e - C_m)(\tan \alpha + \tan \theta) \cos \theta} \quad (6)$$

where ρ_s is the sediment density and θ is the slope of the bed.

Hunter (7) has shown that, in the presence of tides, the current friction factor, for the case of a degenerate tidal ellipse, is twice as large in the direction parallel to the wave orbit plane as in the direction normal to the wave orbit plane. This analysis can also be applied to short period gravity waves so that the corresponding components of shear due to a current are

$$\begin{aligned} \bar{\tau}_{cw} &= 4 \rho f_c \hat{u}_o u_{cw} / \pi \\ \bar{\tau}_{cn} &= 2 \rho f_c \hat{u}_o u_{cn} / \pi \end{aligned} \quad (7)$$

where f_c is the current friction factor, u_{cw} and u_{cn} are the currents parallel and normal to the wave direction respectively. The bed load that should be transported by the combination of the wave and current shears can be determined from the thickness (e') required to disperse the resultant shear. However, for the application considered it is assumed that generally $\hat{u}_0 \gg u_c$ and that $e \approx e'$.

Due to the high concentration of sediment within the bed load layer the fluid and sediment mixture has an effective viscosity much greater than the normal fluid viscosity. This is dependent on and increasing with volumetric concentration. It is therefore assumed that the shape of the velocity distribution may be given by

$$\bar{v}_d = \mu_s \frac{du}{dy} \tag{8}$$

where μ_s is the effective viscosity of the fluid and sediment mixture. This is subject to the boundary condition, $u = u_{ce}$ at $y = e$. The bed load transport rate is therefore

$$T_b = \int_0^e c u dy \tag{9}$$

Sediment Transport-Suspended Load

The simplest one dimensional suspended load distribution may be found from

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial y} (E \frac{\partial c}{\partial y} + c \omega) \tag{10}$$

where E is a coefficient of eddy viscosity and ω the characteristic fall velocity of the sediment. For the assumed quasi-steady state in oscillatory flow the time dependent term may be omitted. It is also necessary to specify the vertical distribution of eddy viscosity. Johns (8) has developed a turbulent boundary layer model for which a Fourier analysis is carried out for the computation of time means (with respect to turbulent velocity fluctuations) of the distribution of eddy viscosity. He found that according to his model the eddy viscosity distribution is sensibly constant over the whole wave cycle. It is assumed that the distribution takes the form

$$\frac{E}{E_e} = \left(\frac{y}{e}\right)^\xi \tag{11}$$

where subscript e refers to values at $y = e$ and ξ is a positive non dimensional constant. Equation (11) should only be applicable to the lower regions of the depth as it cannot satisfy the necessary boundary conditions at the free surface. However, as the sediment concentration diminishes so rapidly away from the bed this inconsistency can be considered to be admissible. The solution of equation (10)

with $\frac{\partial c}{\partial t} = 0$ and equation (11) is

$$\ln \frac{c}{c_e} = \frac{\omega e}{E_e(1-\xi)} \left\{ 1 - \left(\frac{y}{e} \right)^{1-\xi} \right\} \quad (12)$$

when $\xi \neq 1$.

The current velocity distribution is assumed to be

$$u_c = \hat{u}_c \left(\frac{y}{h} \right)^{1/7} + \text{constant} \quad (13)$$

where \hat{u}_c is the maximum current velocity at the free surface and h is the total depth so that the suspended load transport rate is therefore

$$T_s = \int_e^h c u_c dy \quad (14)$$

By combining the bed load and suspended load models the unknown parameters are c_e , E_e and ξ . Using some results from Johns (8) a value for the exponent ξ was chosen to give the best overall fit to the theoretical distributions in the region adjacent to the bed. A suitable value was found to be approximately 0.25 for a fairly wide range of wave conditions.

The remaining two parameters may be evaluated from suitable experimental or field data.

It should be noted that due to equation (7) the resultant shear acting on the bed and hence bed load movement is not necessarily in the same direction as that of the suspended load which must move in the same direction as the current. However, this difference is generally quite small.

Application

An area of coastline some 6 km long on the S.W. coast of South Africa at Durnfontein has been studied. Site investigations (9) include periodic beach and hydrographic surveys, wave rider recordings, radar and sea bed observations of wave direction, current meter and drogue measurements and suspended sediment profiles (10). The foreshore is gently sloping at approximately 1:100 and has sensibly parallel contours. The wave climate is comparatively severe with a predominant wave period between 10 - 11 secs. and wave heights between 1.5 - 2.0 m but with frequent storms in excess of 4.0 m.

The beach and hydrographic survey data were interpolated onto regular grids so that successive surveys could be compared to give volume changes over the area. Figure 1 shows a typical plot of accumulative volume change that has occurred along the coast, calculated to a distance offshore of 1400 m, for the period February to June 1974 during which there has been general accretion. The broken line and full line show the

Figure 1. Beach Volume Changes Between Survey Lines , Feb.1974 - Jun. 1974

Figure 2. Total Beach Volume Changes

measured volume changes below geodetic mean sea level (GMSL) and below the beach survey station levels respectively, indicating that volume changes above GMSL are generally negligible. The survey stations are shown in Figure 5. Successive volume changes for each survey period could then be plotted to produce a time history of the beach with respect to accumulative volume changes for a common area. Figure 2 shows the results of this analysis of prototype data covering a period of two years and it can be seen that, although there is considerable seasonal variation, the net annual sediment movement is approximately zero.

Due to the wave conditions sediment sampling was extremely difficult. However, concentration profiles both inside and outside the surf zone and for a reasonable range of wave heights and periods were obtained. For each profile it is possible to evaluate a value for the coefficient of eddy viscosity at some arbitrary distance above the bed from equation (11). These values were found to be close enough to take an average for all of the profiles, although some trends with the ratio of wave height to depth can be detected. By combining the bed load and suspended load models and assuming continuity of sediment flux at the transition level it is possible to determine a reference sediment concentration at this level consistent with each set of field data. These values have been plotted against a dimensionless parameter $(\tau_w / g(c_s - c)T\omega$ where T is the wave period) and it can be seen from Figure 3 that a clearly defined relationship exists. Consequently using this relationship the sediment transport model can be used predictively given wave heights, periods, directions, current magnitudes and directions.

A wave refraction model is used to evaluate wave directions and heights over the region. The wave ray tracking method, developed by Abernethy and Gilbert (11), is used. In this method the wave speed is assumed to vary linearly over each triangular element so that the wave ray follows a circular arc across each element. Refraction coefficients are simultaneously calculated using the wave intensity equation of Munk and Arthur (12). The grid spacing is chosen according to the local topography and some initial topographical smoothing is applied as discussed by Coudert and Raichlen (13). The wave heights and directions are interpolated onto a regular sediment transport grid which is a sub-area within the refraction grid and, of necessity, completely covered by wave rays. The relative positions and dimensions of the grids are shown in Figure 4. The offshore topography for the area considered is uniform such that it is possible to assume that the sea bed is plane between the refraction grid boundary and "deep water" and consequently starting conditions for each wave ray can easily be established. A typical wave refraction plot is shown in Figure 5 together with the positions of instrumentation and field measurements.

Figure 3. Reference Concentration Fitted to Field Data

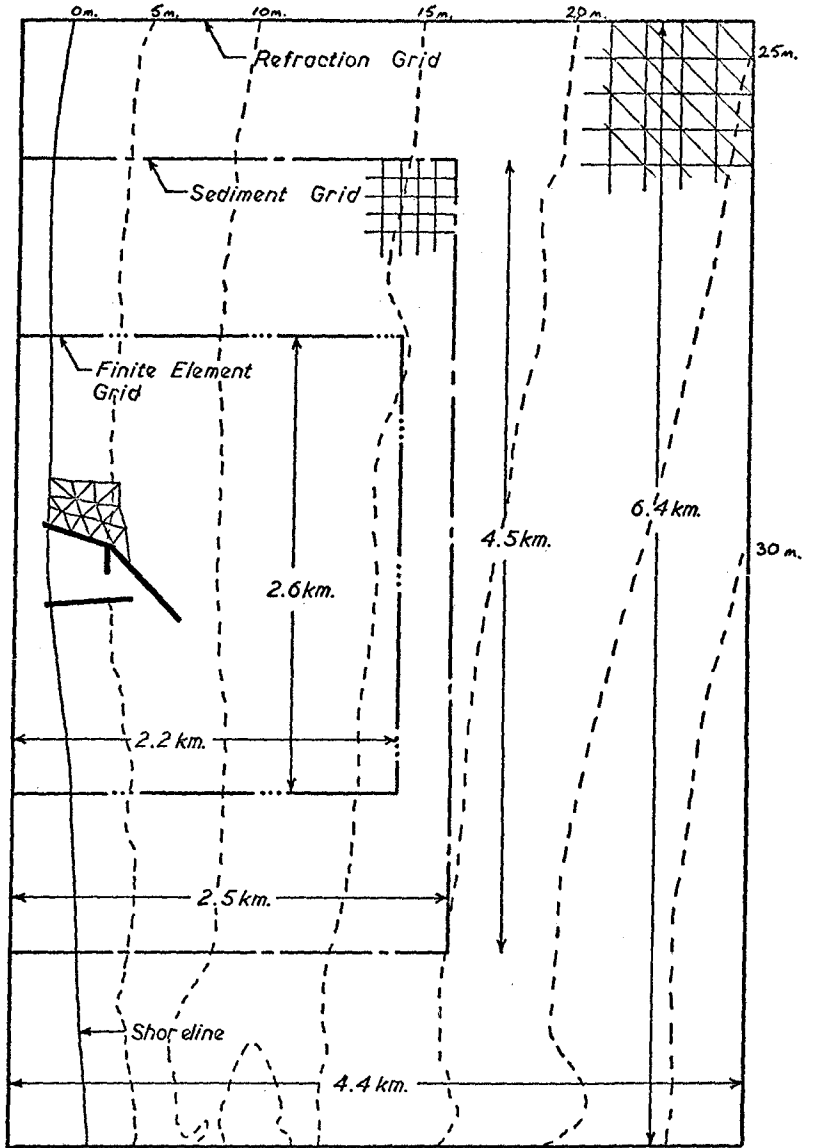

Figure 4. Interrelationship of the Numerical Schemes

Figure 5. Wave Refraction Diagram

There are very many published wave breaking criteria. However, for this application a relationship of the form

$$d_b = H_b / K_b \quad (15)$$

is used, where H_b is the breaker height, d_b is the breaker depth and K_b a constant coefficient estimated to be 0.7 from physical model tests and field observations.

The longshore current model after Longuet-Higgins (14,15) is then used to calculate wave induced currents inside and outside the surf zone. The foreshore is represented by a series of overlapping planes such that the longshore current profile is calculated at regular sections along the beach. These current vectors are then interpolated onto the discrete points forming the regular sediment transport grid.

Given any combination of offshore wave period, direction and height, the refraction and longshore current models are used to give the required parameters at each point in the mesh and by applying the sediment transport model at these points, predictions of local topographical changes can be made.

The wave data corresponding to each survey period was separately analysed into subsets of wave period, direction and height. These were used as input data and attempts to reproduce historic events, with respect to depth changes and hence volume changes, were made. Initially the model used the wave data for a complete survey period, of approximately three months duration, without intermediate depth adjustments. Consequently the sediment transport for each wave condition was assumed to be accumulative regardless of the order of events. This approach was found to give unrealistically large depth changes. Obviously refinements were necessary and the wave data was reduced to several incremental periods of approximately two weeks duration. Corresponding intermediate depth corrections to the region at the end of each of these periods were made. By comparing the historic and predicted topographical changes for several survey periods it is possible to optimise some of the unknown model parameters. These are

- (i) the current friction factor used in the calculation of longshore currents and reflected by differences in the magnitude of predicted and measured volume changes
and
- (ii) the coefficient of horizontal mixing which determines longshore current velocity profiles.

It is intended that a nuclear power station should be sited at Duynfontein and the breakwater formed intake basin is required to protect the intakes from unacceptable wave attack, alleviate associated cooling water recirculation problems and minimise the intrusion of sediment into the intakes.

The proposed layout of the intake basin as shown in Figure 5 consists of a leading breakwater arm giving shelter from the predominant wave direction. This allowed the use of a wave diffraction numerical model, assuming a semi-infinite breakwater, to define wave heights and directions around the entrance and within the intake basin.

The cooling water outfall is to be situated on the beach between 200 and 500 metres from the root of the southern breakwater with the intake located inside the basin. A finite element potential flow numerical model is used to calculate the currents due to the combination of longshore currents and cooling water recirculation currents in the vicinity of the basin. The finite element mesh, consisting of six noded triangular elements, was chosen to cover a sub-area of the sediment transport grid as shown in Figure 4. The offshore boundary was located at a distance where currents are assumed to be negligible and the boundaries normal to the beach are located at distances where the longshore currents would not be influenced by the presence of the coastal structure. The remaining inshore boundary was located along an idealized line corresponding to mean sea level. The longshore currents outside the finite element mesh are calculated as previously described. The current profile at the edge of the finite element mesh is then used as a boundary condition for the potential flow model together with the cooling water intake and outfall flows. The resulting current velocities and modified wave heights are interpolated onto the regular sediment mesh and estimates of local topographical changes and rates of sediment accumulation inside the basin can be made.

A framework for the sequence of operations for the analysis of field data, the overall mathematical model and the interaction between each activity is shown in Figure 6. The model can deal with many options allowing for numerous sets of wave data to be used successively to reproduce historic events or hypothetical sequences. Figures 7(a) and 7(b) show the current vectors (broken lines) and wave height vectors (full lines) for two examples of typical waves approaching the shoreline from the northern and southern sectors respectively. The generated longshore currents for the examples are in opposite directions and different current patterns around the basin are clearly shown.

The model may also be used to investigate equilibrium sea bed conditions by repeating the same wave data and updating the depth grid at each iteration. An example is shown in Figures 8(a) and 8(b) for a cooling water basin with a shortened outer breakwater arm. Figure 8(a) is a contour plot for November 1973 and Figure 8(b) shows the contours after running a 2.0 m wave of 10.0 seconds period from a direction of S.W. for 20 days in 5 day steps. It should be noted that these contour plots are produced by an automatic computer plotting program and there is some difficulty with the inclusion of discontinuities such as the breakwater arms. Consequently the contours cannot terminate on the breakwaters. However, it can be seen

that a bar is shown to be formed in the entrance to the basin, as would be expected. A bar and depression is also shown on the southern side of the southern breakwater indicating the influence of the cooling water outfall as well as some erosion to the north of the intake basin.

Another part of the intake basin investigation was to optimise the distance offshore and hence the depth at which the basin entrance should be situated. The results of this exercise are shown in Figure 9 where the predicted annual maintenance dredging quantities are plotted against entrance depth. The wave data used was based on the one year of complete records available and the range of values indicated by the hatched area represents upper and lower bounds for different assumptions with regard to the wave breaking criteria and wave data analysis. It can be seen that the general trend is for a large increase in predicted dredging quantities as the basin entrance depth decreases below 6 m, a negligible difference of dredging quantity between 6 m and 7 m entrance depth and a decrease in the dredging quantity as the depth is increased beyond 8 m. The shape of this curve is thought to result from the larger waves, possessing the larger sediment transport potential, breaking seaward of the basin entrance and losing much of their energy. The wave height reduces so that a basin entrance located in an intermediate water depth is to a certain extent protected from the larger sediment transporting waves. However, as the depth is further decreased the effect of waves on the bed becomes more pronounced and results in increases to the sediment transport rates. The comparative cost of maintenance dredging and capital cost of construction must be balanced when choosing the optimum depth for the basin entrance. The results of this type of analysis will depend very much on the wave climate for the area considered and in this case the design depth for the entrance was chosen to be 6 m.

Preliminary comparisons between the current patterns and wave heights measured in the physical model show a large measure of agreement. However, more detailed analyses will be carried out.

Conclusions

A mathematical model for sediment transport under waves has been developed from concepts that have been used successfully for unidirectional flow. The model has been applied to the problem of optimising the layout of a cooling water intake basin for a power station in order to minimise both sediment concentrations at the intake and maintenance dredging. This required the simultaneous development of numerical models for wave refraction, longshore currents, wave diffraction and cooling water recirculation as well as the sediment transport model. The longshore current model assumes plane beach sections and does not take account of variations in alongshore wave breaker height and is therefore capable of improvement. The potential

Figure 9. Predicted Annual Dredging Volumes against Entrance Depth

flow model does not account for frictional effects in the vicinity of the basin and the diffraction model should only be used for simple breakwater configurations. However, development work concerning all these aspects will be continued and it is hoped that it will be possible to include such phenomena as the formation of rip currents and mass transport and hence additional forces causing onshore-offshore sediment movement. Nevertheless results from the model are realistic and comparisons to the physical model are reasonable.

An important factor when considering the use of higher order models is the practical limits of computer time. However, there are few detailed field measurements available which do suggest that extra computing effort can be justified. A considerable part of the effort expended in the formulation of the present model was devoted to keeping the execution time to within reasonable bounds and still allow several wave conditions to be processed.

The sediment model is not universal in as far as there are certain parameters that must be calibrated from field data. The consistency of the in-situ sediment concentration profiles collected at Duynfontein and fitted to the model is very good. However, there is a general scarcity of detailed field or experimental data for either concentration profiles or sediment transport rates under waves and it was therefore not possible to generalise the model. Consequently the results from further development of the model to include such non-linear effects as mass transport will be difficult to confirm.

The overall model can be used to examine several different harbour or basin configurations very rapidly and is therefore a very useful engineering tool for the planning of new works or for investigation into modification to existing works.
