CHAPTER 71

LONGSHORE TRANSPORT AT A TOTAL LITTORAL BARRIER

Richard O. Bruno and Christopher G. Gable

ABSTRACT

Analysis of longshore transport at a littoral barrier is presented. Channel Islands Harbor, California was selected as the study site because its offshore breakwater and jetties form a unique complete littoral barrier. Through repetitive surveys an accurate determination of longshore material transport in one direction was made. Measured transport rates ranged from 160,000 to 1,284,000 cubic meters per year. Utilizing visual observations of surf parameters, estimates of longshore wave thrust were computed. The range of wave thrust was 145 to 1,988 Newtons per meter. Comparison of the relation of wave thrust and longshore sediment transport is made. This study indicates that in an environment of high transport, nearly twice as much transport is predicted under corresponding wave thrust as that of the data summarized in the Coastal Engineering Research Center's Shore Protection Manual.

INTRODUCTION

The relation between longshore material transport and nearshore wave thrust (energy) is of vital interest to coastal engineers concerned with design and maintenance of navigation and beach erosion control projects. Past field and laboratory studies have produced an empirical relationship now widely used. However, these studies were conducted in areas where total transport may not have been measured. In this study, Channel Islands Harbor, California was selected because an offshore breakwater and jetties form a unique sand trap (Figure 1). This site is considered a nearly total littoral barrier to longshore transport. A further advantage to this site is its exposure to a high wave energy climate and high transport rates not encountered in previous studies. Dredge records from this harbor show annual transport in excess of one million cubic meters. The objective of this study is to reevaluate the empirical relationship between nearshore wave thrust and longshore material transport.

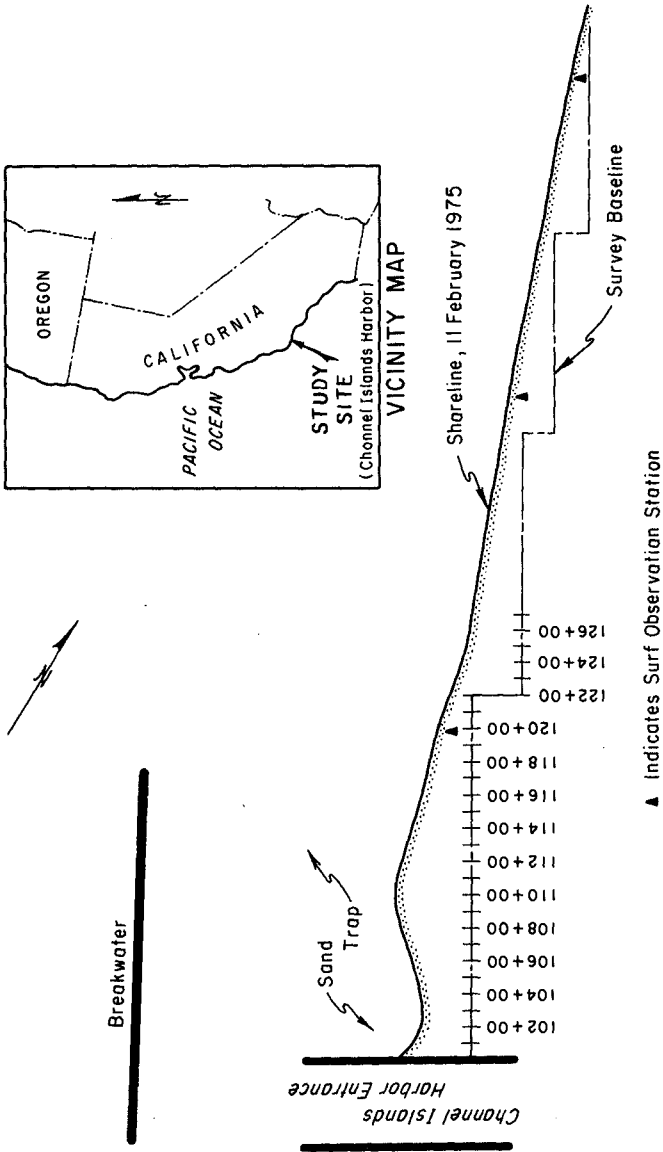

Figure 1. Longshore Transport Study Area .

DATA COLLECTION

The data collection program consists of periodic bathymetric and topographic surveys and routine collection of wave data from which longshore transport and wave thrust can be estimated.

Assistance in making surveys was provided by the Corps of Engineers, Los Angeles District. For these surveys a base line parallel to the shore was established. Profile lines, normal to the baseline, were spaced at about 30.5 meters (100 feet) for a distance of about 823 meters (2700 feet) as shown in Figure 1. At each of these stations elevations were measured from the baseline to the detached breakwater. Surveys were scheduled at intervals of 4 to 6 weeks although this scheduling was frequently modified due to survey crew availability, equipment failures, and unfavorable surf conditions.

Table 1 summarizes survey data, showing survey dates, ranges surveyed, type of fathometer calibration, survey method, and qualitative estimate of overall data quality. The notation "standard" survey indicates an analog fathometer record was made and the survey vessel was located by standard survey techniques of the Los Angeles District. For this method the vessel operator was directed by a man onshore to steer along the profile line. At ten second intervals the analog recording was marked and vessel position was recorded via plane table and alidade.

The notation "hybrid" indicates an analog fathometer record was made and position of survey vessel determined by use of electronic ranging equipment. Under this method the vessel operator was directed by a man onshore to steer profile lines, but the position of the vessel was monitored by telemetering the data to a field office where a minicomputer was used to produce a real time plot of position. By this monitoring of the survey in progress errors in positioning were determined and eliminated. For recording the data an electronic timer was used which simultaneously marked the analog record and recorded the vessel's position on magnetic tape every two seconds.

Both of these methods used an amphibious vehicle, known as LARC V for the bathymetric portion of the survey. The LARC enables measurement of the survey line to be continued through the surf zone by using rod and level methods when the vehicle's wheels contact the bottom. Profile lines were measured over the dry beach areas by standard level and rod transects.

Equally important to the data collection program are the

surf data. Figure 1 shows the sites where twice daily surf data were collected using procedures developed under the Coastal Engineering Research Center (CERC), Littoral Environment Observation (LEO) program (Bruno and Hiipakka, 1973; Berg, 1968). These data include observations of surf conditions, local winds and littoral currents. For this study the estimates of breaker height and breaker direction were of primary concern. To aid in estimating the breaker direction the observer is provided with a protractor on the data form. Longshore current data is also considered in this report. Longshore currents were measured using small packets of dye which disperse upon injection in the surf zone. The observer measures the distance the dye travels parallel to the shoreline. Current speed is estimated from the movement of the dye patch centroid over a one-minute period and current direction is noted. Surf zone current velocities are not uniform; therefore, the width of the surf zone is estimated as well as the distance from the shoreline to the point of dye injection. To augment the surf data two wave gages were installed 1300 meters upcoast of the trap at six meters depth. However, gage data have not yet been analyzed and are not used in this report.

ACCURACY

Late in the study it was found the "standard" surveying method was not providing the reliable, accurate data desired. Figure 2 shows profiles plotted from "standard" surveys. These data are on a line sheltered by the breakwater and at a point beyond normal sand deposition. To verify no deposition divers measured underwater reference stakes and determined there was no change in bathymetry at this point. These plots indicate that unacceptable errors were introduced on several surveys. These errors were a result of poor position data, poor fathometer calibrations, and errors in data reduction.

The "standard" surveying method assumes that the LARC is on line for all fixes and that the instrument man has precisely marked its position simultaneously with the fathometer mark. This is not always true and errors which occur can never be recovered. Even with no errors produced in field collection, reduction of working scale plane table data sheets is limited to an accuracy of about 3 meters which is seldom attained.

In the "hybrid" method an electronic timer was employed to simultaneously mark the fathometer at 2 second intervals and to control the recording of the LARC's position. As a result the human errors in determining position are eliminated. Position accuracy, which was limited by the electronic ranging equipment, was found to be about 2 meters and is consistently attained.

Figure 2. Illustrations of Survey Errors at Reference Station.

In addition to positional errors, fathometer calibrations and data reduction procedures were found to produce errors. Under the "standard" method leadline soundings were used for fathometer calibration. In taking leadline soundings numerous factors determine accuracy including skill and care of the operator, motion of the vessel, and roughness of the water's surface. Later surveys utilized a bar lowered at 5 foot intervals under the fathometer for calibration. This type of calibration removes human factors and is complete in that it shows any non-linearity which may occur in the fathometer readings.

Another source of error which was discovered lies with uncertainty in interpreting the fathometer records. Figure 3 shows two profiles both with similar features which appear to be waves, but in fact on one record these features are the irregular bottom left after dredging. For this reason under the "hybrid" method all data reduction was performed by the authors, who were present at the time of data collection and noted conditions as records were being made.

The last column in Table 1 labeled "survey quality" is a subjective rating from 0 (poor) to 10 (good). These values were determined by the authors after examining the data on hand, field notes, and all profile plots. By using this approach it was determined that data collected 18 June 1974 and 27 March 1975 should be discarded as unreliable.

ANALYSIS

Table 2 is a summary of the analysis showing the survey intervals selected for computations, transport rates, longshore thrust, longshore thrust times wave velocity, and longshore currents.

Transport rates were determined by calculating volume changes between surveys. It is assumed that all material deposited into the trap was a result of longshore energy from upcoast; effects of reversal in the wave direction and resulting diffraction around the detached breakwater have been ignored. Diffraction can be illustrated in the case where wave approach is directly onshore. In this case there would be no general longshore component of wave energy. However, due to diffraction, a local zone of longshore wave thrust would develop as shown in Figure 4, (Weigel, 1962). The expected results would be an erosional zone and a depositional area downcoast (to the southeast). If both the local erosion and deposition zones are included in the total area used to calculate volume changes, this shore-parallel wave approach would result in no net volume change. In this study, the area of volume computations was

extended 300 meters beyond the north end of the breakwater to include diffraction effects. Diffraction diagrams (Weigel, 1962), indicate that diffraction transport is included for all wave approaches from the West or North which are predominant at the study site. Under periods of wave reversals only small errors are introduced by diffraction since most of the erosion and part of the deposition are included in the area of volume calculation.

Deposition from upcoast (northerly) transport during times of reversals in wave direction can be examined. The area of the trap seaward and upcoast of the jetties will show deposition due to reversals. Figure 5 is a plot of the first profile upcoast of the jetties. Survey dates of spring 1974 and fall 1975 are plotted and show the total change at this profile over the period of the study. This plot shows little deposition at the end of the jetty. Detailed examination of all profile data enabled the authors to define the area of deposition attributable to influx of material from north (upcoast) to the trap. No significant deposition was measured at distances more than 425 meters from the baseline. By using 425 meters from baseline as an outward boundary to calculate volumes, errors due to influx of material from reversals is minimal.

The area used in volume change calculations is between the baseline and 425 meters offshore and the north jetty and 670 meters upcoast. Over this area we expect a volume accuracy of within 15,000 cubic meters.

In 1972 Longuet-Higgins summarized his earlier work and presented an expression for the momentum flux tensor component which he termed lateral thrust. This lateral thrust, or longshore wave thrust, is "the flux towards the shoreline of momentum-parallel-to-the-coast". It is given as:

$$H = E (c_g / c) \cos \theta \sin \theta \quad (1)$$

where E is wave energy density, c_g the local group wave velocity, c the wave velocity, and θ the wave angle. Longuet-Higgins gives an expression for E as:

$$E = 1/8 \rho g h^2 \quad (2)$$

where h denotes wave height, ρ the water density and g the acceleration of gravity. The expression for H , valid outside the breaker zone, implies the waves exert a longshore thrust on water and sediment inside the surf zone. It is therefore

Figure 5. Range 101 + 00 at Beginning and End of Study.

reasonable to expect a direct relation between longshore thrust and longshore transport. At the breaker line $c \cong c_g$, therefore by combining equations (1) and (2) above:

$$H = 1/8 \rho g h_b^2 \cos \theta \sin \theta \quad (3)$$

Unfortunately, previous works of this type have not used H, but rather, have plotted transport rates against an expression which is equivalent to H times the wave velocity c. This expression is given by:

$$Hc = 1/8 \rho g h^2 c_g \cos \theta \sin \theta \quad (4)$$

In shallow water $c_g \cong c \cong \sqrt{gd}$ where d is local depth and g is the acceleration of gravity. At breaking $d = 1.28h$ (Munk 1949); thus, equation (4) can be written as:

$$Hc = \sqrt{1.28}/8 \rho g^{3/2} h_b^{5/2} \cos \theta \sin \theta \quad (5)$$

For comparison with previous work Hc is computed. Values for H and Hc have been calculated using breaker height and angle from the two upcoast observation stations, (Figure 1). Each observation was time weighted to represent a period from mid-time of previous observation to mid-time of next observation. Only those values of "Hc" and "H" toward the trap are considered. These results are tabulated in Table 2.

To complete this analysis the longshore currents are also considered. Longuet-Higgins (1970) derived a theoretical relation for the average longshore current generated by obliquely incident waves which depends only on a horizontal mixing parameter "p" and a reference velocity, " v_0 ", (v_0 would be the longshore current velocity if there were no horizontal mixing). If one assumes a value for P then v_0 and the average current can be determined from the data collected in this study. Longuet-Higgins indicates that a reasonable value for P is 0.4 for the study area. Assuming $P=0.4$, average velocity is equal to $55/196v_0$. But v_0 is given by:

$$v_0 = \frac{v_x}{\left(\frac{10}{49} \frac{x}{x_b}\right) - \left(\frac{5}{7} \frac{x}{x_b} \ln \frac{x}{x_b}\right)} \quad (6)$$

where v_x is velocity at a distance x from the shoreline and x_b is the distance from shore to the breakers. Accordingly average currents toward the trap are given in Table 2.

RESULTS

Figure 6, a plot of transport rate versus time, shows the seasonal nature of the transport in this area. Maximum transport rates were measured during winter and early spring and minimum rates during summer and early fall. These results are consistent with other studies of Southern California. In contrast Figure 7, plot of longshore thrust versus time, does not show high wave thrust expected during winter/spring 1975. Yet this Figure does show the expected high value in spring 1974. However, the expected seasonal trends are evident in Figure 8, a plot of average current versus time. A reasonable explanation for the unexpected low longshore thrust values of winter/spring 1975 is observer error in surf estimates.

Our principal result is the relation between longshore transport and longshore thrust shown in Figure 9. The four outlying points indicated on this Figure represent those data obtained during winter/spring 1975 when high transport was measured but low biasing of observed wave conditions is suspected. Omitting those four points a simple regression line has been plotted. For comparison with CERC Shore Protection Manual (SPM), values of H_c are plotted against transport rate (Figure 10). Note that the regression line of this study predicts nearly twice the transport rate predicted in the SPM.

SUMMARY

In this study repetitive surveys were made at a littoral barrier. These survey data were carefully scrutinized to eliminate errors. Later surveys included the use of electronic positioning equipment for high accuracy. As a result these data represent an accurate determination of longshore material transport through a 16-month period. It is felt that these data are the best estimates of longshore transport measured under field conditions.

Estimates of longshore wave thrust were computed from visual wave observations. Poor agreement with transport rates and longshore currents measured during winter/spring 1975 indicates possible observer bias. These anomalies will be studied in future work.

Comparison of the relation in wave thrust and sediment transport is made. This study indicates that in an environment of high transport, such as the United States Pacific coast, nearly twice as much transport is predicted under corresponding wave thrust as that of the data summarized in the SPM.

Figure 6. Transport Rate versus Time.

Figure 9. Transport Rate versus Wave Thrust.

Figure 10. Transport Rate versus Wave Thrust X Wave Velocity .

This work has warranted further study and plans are to continue the data collection program through 1977. Future work will address the questions of accuracy of wave measurements, characteristics of sediment, influence of a dredged deposition basin, wave diffraction influence, and factors in addition wave thrust which contribute to longshore transport of sediment.

ACKNOWLEDGEMENTS

CHAPTER 72

CONCEPT FOR INFERRING THE LITTORAL DRIFT TREND

by

Bunkyo-ku, Tokyo, Japan

INTRODUCTION

To infer the rate and prevailing direction of littoral transport along a given coast is of prime importance in the functional and rational designing of coastal structures as well as in the environmental consideration of coastal zones. Many efforts have been made to develop the inferring method from field evidences such as 1) coastal landforms and shore configurations in the vicinity of existing structures¹⁾⁻⁶⁾, 2) along-shore variations in beach and bed sediment properties⁷⁾⁻¹²⁾, 3) statistical analysis of incident wave properties¹³⁾⁻¹⁶⁾, 4) movements of natural or artificial tracers¹⁷⁾⁻²⁰⁾, and so on.

Among these evidences, the alongshore variations of indigeneous beach materials have served as a powerful, practical and economical tool in the inference of general trend of littoral transport.

Properties of beach sediment, such as grain size of sand and volume and shape of gravels, indicate some progressive trends with along-shore distance from supply sources²¹⁾. Thus the littoral transport direction along a given coast is inferable from variations in beach sediment properties.

However, inferring criteria of prevailing direction from variations in various beach sediment properties have not yet been fully established. For example, the prevailing direction of littoral transport should be defined to be alongshore component of intergrated vector of littoral transport during several years or decades along a given coast. But this direction is often confused with the alongshore dislocating or traveling direction of beach sediment, which is indicated by the variations.

It has also been concluded simply that the variation series obtained from backshore samples show a long-term trend of littoral transport, whereas those from foreshore indicate a short-term trend such as seasonal changes. In this inferring procedure any considerations have never been paid on differences in grain size of beach materials (sand and gravels) and in wave conditions during the period of field study. Rate or intensity of littoral transport has scarcely been inferred from the variation series of beach sediment properties even quantitatively.

To solve these problems, the present study proposed a new concept on the basis of field evidences obtained on the Enshu Coast, Central Japan.

OUTLINE OF THE STUDIED COAST

The Enshu Coast extends about 115 km between Cape Irigo in the west and Cape Omae in the east and is separated into two arched beaches, at the junction of which the Tenryu River flows into the Pacific Ocean (Fig. 1). The Tenryu, one of the largest rivers in Japan, is 213.7 km in length, 5,093 km² in drainage area and 8,440 m³/sec in the maximum recorded discharge. Since its bed slope in the downstream part is about 1/800, the Tenryu supplies a huge amount of gravels and sand to the Enshu Coast during its flood period. The other rivers flowing into this coast during its flood period. The other rivers flowing into this coast are of very small scales in length, drainage area and discharge, hence they supply only a small amount of sand and silt.

On the western part of this coast, are developed actively receding coastal cliffs, which are composed of the lowest Pleistocene unconsolidated strata named Atsumi formation and are receded by wave actions at a rate of 0.6 to 1.0 m/year. These cliffs supply the weathered gravels of granite, sandstone, slate, rhyolite, etc. to the Enshu Coast. On the coastal plains from the Imakireguchi, an inlet of Lake Hamana, to the eastern end of the coast, some parallel or echelon rows of coastal dunes are developed (Fig. 1).

In the nearshore zone of the coast one or two rows of longshore bars are developed almost continuously²²⁾ (Fig. 2). This suggests that active sediment transports are occurred by breaking waves in this zone. Off the mouth of the Tenryu a submarine canyon exists below a water depth of about 20 m (Fig. 1). Excepting this canyon, offshore topography upto a water depth of 100 m is generally gentle in shape and its slope becomes smaller toward both ends of the Enshu Coast from the canyon.

Beach width is 100 - 170 m in the central part of the Enshu Coast, but becomes narrower toward both ends of the coast²³⁾. The beach consists of sand and gravels. Petrologically the beach gravels are composed of sandstone, slate, granite, and others, and their frequency percentages are 68%, 13%, 11%, and 8%, respectively. This petrological composition agrees fairly with that of the Tenryu River. Yamanouchi²³⁾ demonstrated the variation diagrams of the mean weight of the largest beach gravels along the coast and concluded that most of the beach gravels supplied from the Tenryu are distributed on the central part of the Enshu Coast, between Imakireguchi and the mouth of Bezaiten River. This conclusion is supported by the authors' results described later.

In view of the above-mentioned outline of the Enshu Coast, the authors carried out field surveys for the central part of the Enshu Coast (Fig. 3) and investigated the variations in beach sediment properties.

Only a few data on the wave climate on this coast are available. Figure 4 indicates the occurrences of heights and periods of incident waves observed at Akabane fishery port located at the western part of this coast. According to Fig. 4, the significant wave height and period are about 1.5 m and 10 sec. Swell generated by typhoon often attacks the Enshu Coast and its period observed at Akabane varies in a range from 9 to 15 sec.

Dominant direction of incident waves to the studied coast was in a range of the south-west to the south during the field surveys. To

(Wave period: 10 sec)

Fig. 4 Distributions of wave heights and periods. Irrespective direction

predict the trend of littoral transport along the coast, refraction diagrams are prepared for a case of wave period of 10 sec (Fig. 5).

It appears from Fig. 5(a) that waves from the south-west are strongly refracted and give rise to the eastward longshore component of energy flux due to incident waves along all over stretch of the studied coast. For waves from the south, negligible refraction occurs (Fig. 5(b)). Along the west coast adjacent to the Tenryu River, the westward longshore component of energy flux is predicted from the refraction diagram.

In addition, construction of many dams along the Tenryu since 1950's results in a remarkable reduce in sediment supply to the coast, and hence in erosion on the west coast adjacent to the river mouth (Hamamatsu Coast, Fig. 6). To prevent the beach recession some coast protection works such as groins and offshore breakwaters have been constructed on this coast.

Littoral transport direction can be inferred from the configuration of river mouth. The changes in migration of river mouths on the Enshu Coast are obtained from the topographic maps surveyed in 1946 and 1970 (Fig. 7).

SAMPLING AND ANALYSIS OF BEACH MATERIALS

Sand and gravel samples were collected from the surface layer of beach both at foreshore and backshore of 28 stations at an interval of about 2 km in June, August and November, 1973 (Fig. 3).

At each station large gravels scattered on the beach surface in an area of about 20 m x 20 m were sampled. Their nominal volumes were calculated from measurements of their long, intermediate and short diameters. The nominal volume is defined as the product of these three diameters. Thus, alongshore variation diagrams of mean nominal volume of the largest ten gravels for three dominant kinds of gravels are obtained (Fig. 8).

Median diameter of beach sand was determined by the sieve analysis of dried samples in the laboratory. By using the Hallimond 5-Pole Magnetic Separator, sand grains ranging from 0.25 to 0.125 mm in diameter were separated into the following three groups: A) ferro-magnetic minerals, most of which are magnetite and hematite, B) feeble-magnetic minerals such as pyroxene, hornblende, sircon and olivine, and C) non-magnetic minerals such as quartz and feldspar. Their specific gravities range from 5 to 4, 4 to 3, and 3 to 2, respectively. Accordingly, variation diagrams of the weight percentage of these three groups can be taken as these of the heavy mineral composition of beach sand.

CRITERIA FOR INFERRING LITTORAL TRANSPORT TREND

Criteria based on the variation diagram of gravel volume

Since the grain size of beach materials generally decreases with increasing distance from the supply source, the littoral transport direction is inferable from the variation diagram showing the size-distance relationship along a given coast.

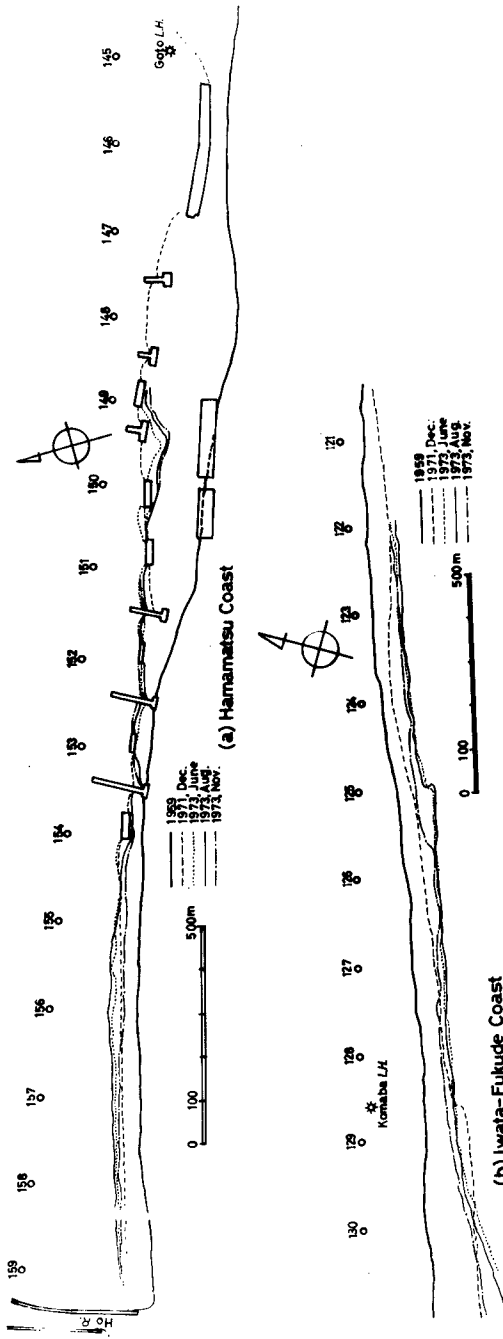

Fig. 6 Shoreline changes of the studied coast (1959-1973)

Black arrow: 1970)

(a) Foreshore

(b) Backshore

Fig. 8 Variation diagrams of mean volume of the largest ten gravels, and inferred directions and intensities of littoral transport. Ss: Sandstone, Sl: Slate, Gr: Granite.

It is therefore inferred from Fig. 8 that littoral transport directions within extents of about 16 km from the Tenryu River along the coast are eastward and westward, respectively. These inferred directions seem to be independent of the sampling position, kind of gravels and seasonal change.

As seen in Fig. 8, however, the variation diagrams of gravel volume on a semi-logarithmic graph are generally divided into some straight segments with different slope, average over certain stretch of several kilometers long. For example, in case of the backshore gravel in November (Fig. 8(b)), the slope is very gentle within a stretch of about 9 km from the Tenryu River in the westward direction along the coast, but beyond that point the slope becomes steeper abruptly. Such abrupt changes are seen in the other cases of studied coast and also known on the other coasts such as Sagami 24), Niigata 25), and Ishikawa 26) coasts in Japan.

The slope of the variation diagram indicates a ratio of size-decreasing per unit alongshore distance. This ratio must depend both on the intensity of littoral transport parallel to shoreline and on the resistivity of gravels for attrition.

The intensity of littoral transport must imply the net or integrated effects of the following three factors: 1) alongshore velocity component of the swash on the beach, 2) directional frequency distribution of incident waves, and 3) duration of beach sediment dislocation. The factors of 1) and 2) must be affected mostly by the wave climate and the coastal topography.

The resistivity of gravels for attrition is related to the mechanical properties of gravels 27), but the effect of the original size of gravel on the rate of attrition has not been clarified. The relationship of the alongshore transport rate of gravels with various sizes to the alongshore energy flux of incident waves has not been known. Thus, interrelationships among these various factors can not be discussed qualitatively from our present knowledge.

For this reason, in the present paper, the term of intensity is used to express the above-mentioned net effects of various factors. It is assumed that the difference in the segment slope of the variation diagram implies that in the intensity of littoral transport, if the size-distance relationship of gravels of the same lithology is concerned.

On this assumption, the magnitude of the intensity of littoral transport is divided qualitatively into three degrees: strong, moderate and weak, which are represented by thick, thin and dotted arrows on Fig. 8, respectively. The arrow direction indicates the inferred dislocating direction.

Prevailing direction of littoral transport on a given coast should be inferred from asymmetry of the variation diagram with respect to the supply source of beach gravels; that is, from asymmetry of the intensity and/or from asymmetry of the stretch length with the same intensity. The magnitude of the asymmetry can be called prevailingness of littoral transport.

Based on this consideration, proposed criteria for inferring the prevailing direction and the prevailingness of littoral transport are given by Fig. 9(a). On this figure, ideal variation diagrams of gravel volume for nine cases are shown in semi-logarithmic graph, and the inferred magnitude of intensity is shown by the three kinds of black arrow mentioned

(a)

(b)

Fig. 9 Inferring criteria of the prevailing direction and prevailingness of littoral transport from the variation diagram of gravel volume.

before. The inferred prevailing direction for each case is shown by a white arrow, of which the length and thickness represent the prevailingness qualitatively.

Figure 9(b) shows some inferred examples of prevailing direction in cases where two or more supply-sources exit on a coast. In case of the top of this figure, the prevailing direction is inferred to be toward the right on the figure as shown by a white arrow, based on asymmetry of the intensity with respect to the source of S_2 . If S_2 is lacking in this case, the variation diagram may change into that shown by dotted line. But the inferred prevailing direction is the same, because in this case asymmetry of the intensity with respect to the descending nodal point of dotted line becomes the key for inference. Similarly, prevailing directions of the other cases are inferred to be toward the right.

Criteria based on the variation diagram of sand properties

Generally speaking, the variation diagrams of beach sand properties such as median diameter, sorting coefficient, and heavy mineral composition display a cyclic pattern which has a very shorter pitch as compared with that of beach gravels, as exemplified by Figs. 10 and 11. This seems to be dependent on the following two reasons: (1) Position of the sand-supply source can not be determined easily, because the beach sand is supplied not only from rivers and coastal cliffs, but also from receding beach and sea bottom. (2) Sand properties vary with minor beach topography such as beach cusps owing to sorting effect by wave actions. Therefore, the variation diagrams of beach sand are influenced largely by sampling technique. Beach sand seems to play a less important role than beach gravels as an indicator of littoral transport trend.

However, the inference of littoral transport direction from the variation diagram of sand properties is made on the basis of the conventional concept, in which the littoral transport direction is considered to coincide with the decreasing direction of grain size and heavy mineral component of beach sand. The prevailing direction is inferred from the same concept as the case of beach gravels discussed in the previous section (Figs. 10 and 11).

SEQUENTIAL MODEL FOR INTERPRETING THE DIFFERENCE AMONG THE INFERRED RESULTS

Figure 12 shows the summary of inferred directions and intensities of the littoral transport along the studied coast from the variations in beach sediment properties together with those from the river mouth deviation.

It is noticed from this figure that the inferred results display different tendencies according to the sampling position or elevation (fore-shore and backshore) and to the grain size of beach sediments (sand and gravels). On the other hand, seasonal effect on the inferred results seems to be relatively weak.

The alongshore processes of beach sediment transport are closely related with the size of beach sediment and the position of the zone in which

Fig. 13. Littoral transport trends under four sea conditions on the Enshu Coast.

the dislocation occurs²⁸). In addition, the wave runup height on beach and the tractive force acting on beach grains depend on properties of incident waves.

The alongshore variations in beach sediment properties are conceived as the consequences of complex interactions among these factors. The differences in the inferred results, as seen in Fig. 12, can be explained by taking account of differences in sea conditions governing the dislocation of beach sediments.

Based on this concept, a following sequential model is proposed here, as shown in the inset of Fig. 13 schematically: Stage A shows a climax state of rough to high sea condition, in which the littoral transport trend is inferred from the variation diagram of backshore gravels; Stage B is a decay state of the stage A, from backshore sand; Stage C is a slight sea condition, from foreshore gravels; Stage D is a smooth sea condition, from foreshore sand.

According to this model, the directions and intensities of littoral transport along the studied coast under the four sea conditions are concluded to be shown in Fig. 13 by thick and thin arrows.

CONCLUSIONS

Overall prevailing direction and intensity of the littoral transport along a given coast can be inferred from asymmetry both of the slope of variation diagram and of the alongshore distance of the same slope segment on the diagram with respect to the sediment supply source or to the ascending or descending nodal points on the variation diagram.

The prevailing direction along the studied coast is concluded to be eastward clearly under the slight and smooth sea conditions, whereas under the rough to high sea conditions prevailingness is not found, according to the criteria proposed in this paper. This conclusion is supported by the fact that the west coast adjacent to the Tenryu River (Hamamatsu Coast) has been receded severely, whereas the east coast (Iwata-Fukude Coast) has been proceeded (Figs. 6 and 14).

CHAPTER 73

FIELD INVESTIGATION OF SEDIMENT TRANSPORT PATTERN IN A CLOSED SYSTEM

by
Tsuguo Sunamura and Kiyoshi Horikawa

Coastal Engineering Laboratory
Department of Civil Engineering
University of Tokyo
Bunkyo-ku, Tokyo
Japan

INTRODUCTION

In order to elucidate the transport pattern of sediment in a closed system, a pocket beach was chosen and investigated from various aspects. This investigation included the following studies: (1) bathymetric survey by an echo sounder, (2) survey of submarine geology using an acoustic probe, (3) observation of nearshore current systems using floats, (4) documentation of the transport pattern of suspended sediment by aerial photographs, (5) examination of depositional environments of bottom and beach material by sieve analysis, (6) inference of long-term alongshore sediment transport pattern from the grain size properties of beach sand, and measurement of short-term trends by use of fluorescent sand, and (7) examination of long-term shoreline change using old and recent maps.

STUDY AREA

A study area was located at the bay head of Katsu'ura bay, Chiba prefecture, Japan, facing the Pacific Ocean (Fig. 1). The bay is a semicircular shape (approximately 2 km in diameter) having a south-oriented bay axis, and is bordered by coastal cliffs made of Pliocene sedimentary rocks (Fig. 2). The coastal cliff

in the study area is made of Katsu'ura formation which is the alternation of sandstone and siltstone strata; these strata strike N40-50°E and dip 5-10°N. In front of the cliff a narrow sandy beach stretching 1.3 km develops. Little seasonal change of this beach has been observed. There is no major supply source of beach sand in or near the study area. The direction of wave approach is nearly normal to the beach. Tidal range at spring tide is about 1.5 m, while at neap tide is about 0.7 m.

SUBMARINE TOPOGRAPHY AND GEOLOGY

The topographical and geological surveys revealed that (1) the submarine topography consisted of portions having smooth submarine contours and irregular ones (Fig. 3), (2) the former portion was of sandy sediment, while the latter of exposed bedrock (Fig. 4), (3) from the shoreline up to a water depth of about 5 m, there was little difference between the depths of the bedrock surface and the adjacent sand bottom, while in deeper regions there existed a marked topographic break that the bedrock surface was located 2-3 m higher than the sand bottom (Fig. 5), (4) the submarine bedrock was also made of Katsu'ura formation, and (5) a veneer of sandy sediment developed spottedly on the bare bedrock.

Submarine bedrock configuration shows the existence of a large depression in the western part of the study area (Fig. 6). Figure 7 is an isopach map of sandy sediment, which was plotted on the basis of Figs. 3 and 6; the western portion constitutes a notable sedimentary region.

NEARSHORE WATER CIRCULATION PATTERN

For the measurement of nearshore current pattern, floats with current-crosses were released and traced by transits. The result showed a characteristic pattern: in the areas of exposed bedrock onshore currents developed, while in the adjacent sandy areas offshore currents occurred. This water circulation pattern is shown in Fig. 8, in which H_b = breaker height, T = wave period, U = average wind velocity obtained by the observatory located near the study area, and the letters in brackets show wind direction. Since the nearshore bedrock areas are higher than the adjacent sand areas, it is clear that the underwater topography gives rise to wave convergence in the bedrock regions and to divergence in the sandy areas; longshore currents flowing away from the zones of convergence

turn seaward in the zones of divergence, forming the offshore currents.

Since the surface of exposed bedrock has changed little, submarine topography has determined the nature of wave-induced current fields: in the areas of the bedrock onshore currents dominate, while in the adjacent sandy areas the prevailing offshore currents occur.

SUSPENDED SEDIMENT TRANSPORT PATTERN

The transport pattern of suspended sediment was investigated by air-photo interpretation. Photographs were taken on Nov. 27-29, 1974 by attaching a blue-cut filter to an air-born camera in order to obtain clear underwater information (Lockwood et al., 1974). The photo scale was 1/10000. Figure 9 shows the transport patterns obtained from these photographs.

On the basis of ordinary black and white aerial photographs (scale: approx. 1/10000) taken at several different times, the locations of offshore transport of suspended sediment were depicted (Fig. 10).

Figures 9 and 10 indicate that the prevailing offshore transport occurs in the regions of sand bottom, irrespective of input wave conditions. This result reconfirms the occurrence of offshore currents in the sandy regions, and furthermore suggests the existence of onshore currents in the bedrock regions.

DEPOSITIONAL ENVIRONMENTS OF BOTTOM AND BEACH MATERIAL

On the basis of sieve analysis of submarine and backshore sand samples, the mean diameter in phi scale, $M\phi$, as a grain size parameter and its standard deviation, $\sigma\phi$, as a sorting measure were calculated. Figure 11 shows the areal distribution of $M\phi$ of 63 underwater samples; $M\phi$ in the bedrock regions is generally smaller than that in the sandy area. Namely, sediment in the former is larger than that in the latter. On the other hand, $\sigma\phi$ did not show such a distinctly zonal distribution.

The existence of coarser sediment in the zones of the exposed bedrock suggests that this material would probably be produced by bedrock erosion, although its quantity would be very small due to high resistivity of the bedrock to wave erosion.

Figure 12 illustrates the alongshore variation of $M\phi$ and $\sigma\phi$ of the backshore sand samples which were taken from 24 locations shown in Fig. 3; there is larger and poorly sorted beach sand in the vicinity of location Nos. 5 and 13. Since the areas of bare bedrock in the seaward regions of these localities are larger (Fig. 4), this result suggests that the coarser material on the bedrock could be transported to the beach by the onshore currents dominating in the bedrock regions.

ALONGSHORE SEDIMENT TRANSPORT PATTERN

Considering the beach locations of Nos. 5 and 13 as supply sources of littoral drift to the whole beach, the direction of alongshore sediment transport was inferred from the variation series of $M\phi$ and $\sigma\phi$ (Sunamura and Horikawa, 1972). The result is shown by arrows in Fig. 12: westward transport dominates in the western part of the beach, while transport pattern in the eastern part is complicated.

In addition to this study of long-term trends of transport pattern, short-term phenomena were investigated by tracing different-colored fluorescent sand which was released at three different alongshore locations (Fig. 13). Figure 13 shows that the transport direction at each location varies according to wave conditions.

LONG-TERM SHORELINE CHANGE

The examination of shoreline change during the period of 87 years from 1883 to 1970 indicated that the beach had been suffering erosion at a mean annual rate of 0.1-0.4 m/year (Fig. 14). Since (1) the study area was uplifted 30 cm at the time of Great Kanto Earthquake in 1923 (Omura, 1926) and (2) it was also uplifted about 5 cm during the period from 1923 to 1965 (Fujii, 1968), it is clear that this whole beach has been eroded more severely. This means that all the material once washed away from the beach has not been returned to the beach, i.e. that the pattern of long-term sediment transport has not formed a closed loop.

INFERRED SEDIMENT TRANSPORT PATTERN

Figure 15 is an illustration of the sediment transport pattern inferred from the above various investigation results. Material resting on the exposed bedrock is transported shoreward by the on-shore currents, drifted alongshore on the beach or in the surf zone, and eventually transported offshore by the offshore currents. The characteristics of submarine topography tell that the material transported offshore to the regions shallower than a water depth of 5 m has the possibility of being carried to the bedrock regions again by circulating currents; this transport pattern would probably form closed loops. On the other hand, the material once transported to deeper regions has less possibility of returning due to the existence of the marked topographic break. Therefore, the transport pattern would not be closed.

CONCLUSION

In the present study area, submarine topography greatly influences nearshore current fields and also governs the resultant sediment transport pattern.

ACKNOWLEDGMENT

A part of this study was supported by National Institute of Resources, Science and Technology Agency, Japan.

CHAPTER 74

EQUILIBRIUM PROFILES AND LONGSHORE TRANSPORT OF COARSE MATERIAL UNDER OBLIQUE WAVE ATTACK

by E. van Hijum *

Abstract. In order to obtain design criteria for artificial gravel beaches, a research programme was drawn up to study the behaviour of gravel beaches under wave attack. The present paper gives the main results of the investigations into beach formation and equilibrium profile characteristics, including the longshore transport rate of beach material under regular wave attack with varying angles of wave approach.

1 Introduction. Coarse material, such as gravel and light rubble, has recently been applied in the Netherlands as a bank protection in areas exposed to wave attack. An example is the gravel beach at the Zuidwal, the southern bank of the harbour entrance to Rotterdam (Figure 1). In order to reduce the waves inside the new harbour mouth and the connected basins, a wave-damping beach is now planned. To achieve the desired energy absorption, such a beach should consist of granular material under a small angle of inclination. For nautical and hydraulic reasons it is not possible to make the beach slope flatter than about 1:10. If loose material is used as slope protection such a slope can only be achieved by using gravel. Contrary to conventional types of bank protection, the profile of such a gravel layer will be deformed when exposed to wave attack. Data on the fluctuation of the profile under design wave conditions are required to ensure an adequate design. For this reason the Public Works Department, Harbour Entrances Division, of the Dutch Government commissioned the Delft Hydraulics Laboratory to investigate the behaviour of gravel beaches under wave attack. The tests were performed in the De Voorst Laboratory of the Delft Hydraulics Laboratory.

2 Beach formation. The process of beach formation has been described extensively by Zenkovich [1] and many others. Changes in coastline are a result of the displacement of beach material along the shore. This process is governed by the size of the material and the position of the zone in which the displacement occurs. Bottom transport, which occurs on the submarine slope under the action of waves that have not yet broken, differs fundamentally from shore transport, which takes place in the surf zone. Silt and fine sand are displaced by both wave and currents; coarser sand and gravel are affected to a lesser extent by currents, whilst larger material is displaced only by wave action. Perhaps due to percolation, gravel

* Project engineer, Maritime Structures Branch, Delft Hydraulics Laboratory, Laboratory de Voorst, The Netherlands.

beaches are rather steep: in general steeper than about 1:8. The mass of water that is formed after a wave breaks on this slope, the swash, is driven by inertia up the beach and then flows back by gravity to meet the following wave (Figure 2). The swash, which has completely lost the nature of wave motion, is exposed to the continuously interchanging forces of inertia and gravity. When the waves approach the shore obliquely, these forces operate differently. As the swash reaches its upper limit it slows down, describes a curve and flows back directly to the sea along the line of steepest gradient. Dependent on the coarseness of the material and the wave conditions, either a thin layer of material or only a few grains are set in motion. The path traversed by particles of material depends on the following factors:

- The wave conditions: wave height, wave period, angle of wave approach;
- the diameter of the particle;
- the shape of the particle and affixtures;
- the initial positions on the beach;
- the time; and
- the initial beach slope.

As an example Figure 3 shows the influence of the initial position of a particle on an equilibrium beach, beyond the breaker-line. The length of the path parallel to the coast traversed by particle 3 is much shorter than that of particle 1. The influence of the time is demonstrated in Figure 4. If the wave conditions alter, the bed will create a new equilibrium. If the waves decrease, path 1 is followed; if the waves increase, path 3 is followed and in the equilibrium phase path 2 is followed.

3 Problem schematization. In the research programme a line was followed as demonstrated in Figure 5. For correct profile development and longshore transport the sediment motion in the model had to fulfil the following conditions:

- The mechanism had to be the same as in nature, and
- in this mechanism scale effects had to be of such an order that they could be neglected.

As the mechanism of sediment transport changes completely once ripples appear, and it is up to this moment impossible to scale down this mechanism, the diameter of the material and the wave conditions were chosen in such a way that no ripples were formed.

Step 1 of the research programme, on deducing scale effects and fluctuation of the profile at perpendicular regular wave attack, has been reported in [2].

The present paper will be restricted to step 2.

4 Problem analysis. In describing profile formation and longshore transport, two groups of parameters may be composed:

a. The external parameters, characterizing the wave attack and the initial beach geometry, viz., wave height and wave length on deep water (H_0 , L_0), wave period (T), depth of foreshore (h), height of beach top (k), initial slope ($\text{tg } \alpha$), grain diameter (D) and angle of wave approach on the foreshore (ϕ). Because of the fact that the larger grains of a grain distribution seem to be determinant for the bed load transport, the D_{90} was chosen to characterize this grain size distribution. D_{90} means that 90% of the weight of a sample has a diameter smaller than D_{90} .

b. The internal parameters, characterizing the resulting equilibrium profile and the sediment transport during the formation of the profile. These parameters are shown in Figure 6:

- h_A = height of wave run-up above the still-water level on the initial (straight) slope
- h_F = height of the beach crest \approx height of wave run-up above the still-water level on the equilibrium profile
- h_B = depth below the still-water level of the point of initial movement on the initial slope
- l_S and l_K = defining the position of the step or bar
- l_E = defining the height of the bar
- $\text{tg } \gamma$ = gradient of the equilibrium profile at the still-water level
- β = angle of repose under water
- $S(y)$ = mean resulting sediment transport in y-direction between two points in time. The time between these points has to be much longer than the wave period
- $S(x)$ = mean resulting sediment transport in x-direction.

For equilibrium of the external parameters in the model the Froude law of similarity was chosen. From [2] it follows that under the conditions tested the Froude law of similarity is also applicable for the internal parameters provided $D_{90} > \sim 6 \times 10^{-3}$ m. The equilibrium profile may show either a bar-type or step-type form, of which the first one has a more pronounced bar, located in the vicinity of the breaker point (see Figure 6). Appearance of a beach crest depends on the initial beach geometry and the erosion rate. If $\phi \neq 0$, then, between two points with $S(x) = 0$, three characteristic sections can be distinguished on a beach (see Figure 7): section A (erosion), section B (equilibrium) and section C (accretion). During a test the section lengths A and C increase and section length B decreases. It is a requirement that the test is finished before section B has

vanished and after the perpendicular cross-section in B has reached an equilibrium condition. These two factors determine the minimum length of the gravel beach section.

5 Description of the model. The model, a straight beach section, was built in a wave basin with the dimensions length * width * depth = 40 * 24,5 * 1,5 m³. The gravel section of the model beach was located between two concrete sections. A carriage with an echo-sounder could be moved over two rails parallel to the beach to make soundings of the profile. In the model two points with $S(x) = 0$ were made (gravel traps). Figure 8 gives a plan view of the model.

6 Tests. A summary of the test program is shown in Table 1. This table includes the two-dimensional tests from step 1. In choosing the external parameters the following four conditions were taken into account:

1. The dimensions of the wave basin.
2. The H-L diagram of Galvin [3], in order to avoid the area of secondary waves.
3. The requirement to remain below the ripple criterion.
4. The condition $D_{90} > \sim 6 * 10^{-3}$ m in order to avoid scale effects in the mechanism of the bottom transport.

Measurements were made of the waves, the wave run-up, the critical velocities at the point of initial movement of the gravel, the changes in time of the beach profile, and of the sorting of the gravel. The waves were measured in 3 rows of about 20 points each. $S(y)$ and $S(x)$ were calculated from frequent profile soundings, being the only way to determine these transports without disturbing the dynamical action of the gravel under wave attack. The procedure used to compute $S(y)$ is shown in Figure 9. In section B, with $\frac{\partial S(x)}{\partial x} \rightarrow 0$, $S(y)$ can be calculated via the continuity equation in y-direction:

$$\frac{\partial S(y)}{\partial y} + \frac{\partial z}{\partial t} = 0, \text{ if } \frac{\partial S(x)}{\partial x} = 0.$$

In x-direction $S(x)$ can be calculated via the continuity equation:

$$\frac{\partial S(x)}{\partial x} + \frac{\partial 0}{\partial t} = 0,$$

where 0 stands for the area of a cross-section in y-direction (see Figure 10).

7 Test results. Only the main results of the tests are given here. In Figure 11 the equilibrium conditions as reached in one of the tests is shown, together with the measured mean incident wave height in the 3 measuring rows. The symbol H_v stands for the wave height on the foreshore. The three characteristic sections A, B and C can clearly be distinguished. $S(x)$ as function of x , in the equilibrium phase, is shown in Figure 12. $S(y)$ as function of y , in section B, is given in Figure 13.

Summarizing all tests, the following conclusions can be drawn:

- It appears to be possible to determine an optimum initial beach profile in y -direction which shows minimum erosion and accretion for a given wave condition. Profile characteristics described in terms of the external parameters are shown in Table 2. The wave run-up on the initial slope (l_A), a vertical profile parameter (h_b), and a horizontal profile parameter (l_s) are shown in their relationships with the external parameters on the Figures 14, 15 and 16 respectively. The transition from step-profile to bar-profile is demonstrated in Figure 17. This criterion only yields for profiles in areas with $\frac{\partial S(x)}{\partial x} \rightarrow 0$. The behaviour of erosion and accretion profiles can deviate considerably, so it will be difficult to check the criterion from Figure 17 with data from beaches in nature.
- The total longshore transport of material in x -direction can be described in terms of grain diameter and design wave conditions (regular waves) by the relationships between internal and external parameters as shown in Table 2 and Figure 18. Both parameter groups in this figure are achieved by simply supposing that a layer of sediment moves along the beach with a velocity proportional to $c_b \sin \phi_b$, where c_b stands for the phase velocity of the breaking wave and ϕ_b for the angle between breaking wave and shoreline. The moving layer is supposed to have a width perpendicular to the coast proportional to l_s and a thickness proportional to D_{90} . The coefficients of proportionality appear to be related to the external parameters too. As shown in Figure 19 there exists a very poor relationship between longshore gravel transport and the so-called "energy flux". In this Figure the model conditions are enlarged with a length scale = 4. As a comparison between longshore sand transport and longshore gravel transport some measurements by Komar are also shown (from [4]).
- Sediment sorting along the equilibrium profile in y -direction seems to be a function of wave height and wave period. At low waves the coarsest material is found on the beach crest and at higher waves in the vicinity of the breaker

point. In x-direction no sorting was found.

- Measurements of critical velocities at the point of incipient motion on the initial slope support the conclusion drawn after the two-dimensional tests, indicating an increase of the critical velocity with increasing water depth.

8 Limitations in use of the results. It is clear that it is only permissible to use the obtained results within the tested range of the parameter groups. An important factor is the translation from a wind-wave field to the regular wave conditions as used in the tests. At the moment at the Delft Hydraulics Laboratory tests are being performed concerning step 4 of the research programme. In the meantime at a project in Italy (see Figure 20) good results were obtained in predicting the longshore transport rate of a natural gravel beach by characterising the wind-wave field by the significant values H_s and T_s .

CHAPTER 75

STUDY OF EQUILIBRIUM BEACH PROFILES

by

Robert A. Dalrymple¹ and William W. Thompson²

Abstract

The use of the dimensionless fall velocity for determining equilibrium foreshore slopes, modeling of natural beaches in the laboratory, and for determining shoreline erosion rates is examined. Encouraging results are found for relating foreshore slope uniquely to the dimensionless fall velocity and possible model law is proposed.

Introduction

At the University of Delaware, work has been progressing on the development of computer models for nearshore processes and coastal modification (Wang, Dalrymple and Shiau, 1975; Birkemeier and Dalrymple, 1975). During the course of the work it was necessary to be able to predict equilibrium beach slopes, based not only on the grain size of the material that comprised the beach as was done by Bascom (1951), but also as a function of the incident wave characteristics. Work of this nature has been conducted previously by Kemp (1968), Nayak (1970) and Carter, Mei and Liu (1973). This paper presents the foreshore slope as a function of the dimensionless fall velocity of the sediment, a parameter introduced by Nayak on dimensional grounds and by Dean (1973), based on a physical argument.

Based on the success of the dimensionless fall velocity as a measure of the beach slope and also as an indicator of the reflection from the beach (see Nayak, 1970), numerous model laws were developed for the modeling of beaches in the laboratory, keeping the dimensionless fall velocity ratio constant. Several of these relationships were tested in the laboratory and compared against prototype data in the same manner as Noda (1972) and Paul, Kamphuis and Brebner (1972).

¹Assistant Prof., Dept. of Civil Engineering, Univ. of Delaware, Newark, DE 19711.

²Formerly, Graduate Student, Univ. of Delaware, now with Transworld Drilling Co., Morgan City, La.

A major area of coastal engineering that is still not adequately understood is onshore-offshore sediment transport. From the laboratory tests mentioned above, a speculative empirical relationship is presented for foreshore erosion/deposition based again on the dimensionless fall velocity, which has been shown to be an indication of when erosion or deposition will take place.

Equilibrium Beach Profile and Foreshore Slope

Equilibrium profiles have been studied extensively through the history of coastal engineering, and as early as 1939, Waters postulated that the type of profile (that is, whether a normal profile, with steep foreshore slope and possibly a step at the breaker line, or a bar profile, with a milder foreshore slope and a longshore bar at the breaker line) was determined by the deep water steepness, H_0/L_0 , the ratio of the deep water values of the wave height and wave length. For many years it has been held as a basic tenet that $H_0/L_0 = 0.025$ is the dividing wave steepness between profile types with barred profiles resulting from steeper waves, despite some evidence to the contrary (e.g., Saville, 1957; King, 1972). In 1973, Dean found that the wave steepness separating bar profiles from normal profiles varied with the fall velocity of the sediment, V_f , divided by the deepwater celerity, $C_0 = L_0/T$, where T is the wave period.

$$\frac{H_0}{L_0} = 0.85 \frac{V_f}{C_0}$$

which can be written as $H_0/V_f T = 0.85$. The fall velocity was calculated using the median grain size, d_{50} . Köhler and Galvin (1973) using different data recommended, $H_0/V_f T = 0.70$, while the CERC Shore Protection Manual (1973) recommends 1.0 - 2.0.

The physical significance of the dimensionless fall velocity, $H_0/V_f T$, as presented by Dean is that the parameter is a measure of whether a particle lifted into suspension by the passage of a wave can fall to the bottom during the time when its net displacement due to the horizontal water particle motion is shoreward. If so, the net sediment transport in the surf zone is shoreward, or zero, and we expect a summer profile to develop or to have been developed. Also the parameter can be viewed as the tangent/ π of the angle made by the maximum horizontal velocity in deepwater and the fall velocity.

If the parameter, $H_0/V_f T$, is an important parameter for profile type, it follows (by dimensional analysis) that it is also important for determination of the foreshore slope, θ , measured in degrees at the still water line. Collecting data from different experimenters, including Rector (1954), Fairchild (1959), Raman and Earattupuzha (1972), van Hijum (1974) and Thompson (1976), foreshore slopes were measured and are presented in Fig. 1 versus the dimensionless fall velocity. The figure shows a reasonable trend despite the significant scatter which could be attributed to any number of things including inaccuracy in our

Figure 1 Foreshore Beach Slope Versus Dimensionless Fall Velocity

measurement of θ from the experimenter's figures, profile measurement errors, lack of equilibrium³ and spurious tank reflections. The scatter, however, is less than was obtained by attempting to plot the data versus H_0/L_0 with a third parameter, such as d_{50}/H_0 , d_{50}/L_0 and C_0/V_f .

Nayak's (1970) curve is also shown in the figure, but only over the range for which he used quartz sand. When he used much lighter material, his beach slopes became very mild and, in fact, the whole beach itself was in motion with the waves. Also Kemp (1968) has plotted θ versus a dimensional parameter, $H_b/Td_{50}^{1/2}$, which is similar to the dimensionless fall velocity as V_f is directly proportional to $d_{50}^{1/2}$ for large sand sizes. Ours appears to be significantly different from his, particularly for larger values of $H_0/V_f T$.

Modeling Relationships

From Fig. 1, which indicates a unique foreshore slope for a given value of $H_0/V_f T$, it follows that in order to reproduce in a model the same equilibrium profile that occurs in the prototype (neglecting tidal effects) that the parameter $H_0/V_f T$ should be the same in model and prototype. Based on different modeling requirements seven model laws were developed and are presented in Table 1. The derivations are shown in the Appendix.⁴ Four of the model laws (#3,5,6,7) accommodate the same sand in model and prototype and were tested in the laboratory. However, of these, only #7 maintains geometric similarity (that is, the horizontal length scale, λ , is equal to the vertical length scale, μ), and, therefore, only it should yield a corrected modeled beach slope, while it was hoped that the others might adequately model other features of the profile.

Experiments were conducted in a 21.3 m long x 0.61 m wide wave tank with a piston wavemaker at one end and the sand beach at the other. The experimental program was to run prototype tests for a normal and barred profile and then to model these with tests based on the model laws. The beach material consisted of a quartz sand with a median diameter, d_{50} of 0.40 mm (a Trask sorting coefficient of 1.38 and a skewness of 1.0). Due to tank size restrictions, the maximum practical scaling was only $\mu = 1/2$. Most of the tests were initiated with a plane profile (1:10 for the prototype tests) and allowed to run to equilibrium which was defined as a lack of significant profile change with time in the foreshore region. For the foreshore region,

³ Chesnutt and Galvin (1974) report never achieving equilibrium in their tests despite holding H_0/L_0 constant as the air temperature and hence $H_0/V_f T$ changed.

⁴ The derivation of the model laws utilized the Stokes equation for fall velocity which is valid only for low Reynolds numbers. For larger Reynolds numbers, a different fall velocity relationship is necessary and, in fact, for Model Laws 1 and 2, it is only necessary to scale the fall velocity as $\mu^{1/2}$ and then choose the sand size accordingly.

TABLE 1 SUMMARY OF MODEL LAWS
(See Appendix A for Derivation)

Law	$n\gamma'$	$n_{d_{50}}$	n_T	λ	Note
1	1	$\mu^{1/4}$	$\mu^{1/2}$	μ	Preserves Froude No., H_0/L_0 , geometric similarity, Stokes fall velocity
2	$\mu^{3/2}$	$\mu^{-1/2}$	$\mu^{1/2}$	μ	Preserves bed particle Reynolds number, densimetric Froude number, H_0/L_0 .
3	1	1	μ	$\mu^{3/2}$	Assumes laminar boundary layer. Preserves bed shear stress, Froude No.
4	$\mu^{-0.1875}$	$\mu^{+0.063}$	$\mu^{1.0625}$	$\mu^{1.5625}$	Assumes turbulent boundary layer.
5	1	1	μ	$\mu^{3/2}$	Preserves Froude No.
6	1	1	μ	μ^2	Preserves bed particle Reynolds number, bed shear stress.
7	1	1	μ	μ	Preserves geometric similarity, H_0/L_0 .

$n_{\text{parameter}, a} = \frac{a_{\text{model}}}{a_{\text{prototype}}}$	d_{50} = median grain size diameter
$\gamma' = \frac{\gamma_{\text{sediment}} - \gamma_{\text{fluid}}}{\gamma_{\text{fluid}}}$	T = wave period
	λ = horizontal length scale
	μ = vertical length scale

the foreshore slope and the related profile was achieved quickly, in the matter of several hours; however, the offshore region, dominated by migratory ripples, equilibrium took much longer to achieve, particularly for the barred profile.

A summary of the tests is presented in Table 2, including the initial variables and the time to equilibrium, t_e . The resulting model beach profiles obtained for the different model laws (note that #3 and 5 have the same scaling relationships despite different assumptions) were scaled up to prototype scale and plotted with a common still water line intersection. The results are shown in Figs. 2 and 3 for the normal and barred profiles. As can be seen

Figure 3 Comparison of Model Laws for Barred Profile. Station 0 = Intersect of SWL and Equilibrium Profile

despite the small scaling ($\mu = 1/2$), there are wide discrepancies in the results, despite the fact that the dimensionless fall velocity was nearly the same (varying due to temperature effects on the fall velocity). The "best" model law of the four tested appears to be #7, as it predicted the location of the primary bar for the steep waves (bar profile) and it follows the normal profile reasonably well for the milder waves. A discrepancy occurs in the model in that it predicts a bar for this case also, however, the problem lies (experimentally) in the fact that $H_o/V_f T$ differs slightly between model and prototype, and both values are near the transition line between profile types as discussed in the first section. The primary reason for the inability of the other models to predict the prototype equilibrium profile appears to be the distortion of these models.

The only difference between the four models is the length scale and, therefore, only the initial slopes were varied to start each test. Comparing the model test results prior to scaling to prototype gives an indication of the effect of initial slope on final profile. Fig. 4 shows the results for the normal profiles. In the onshore region the initial slope makes no difference at all, and, thus, has no effect on the foreshore slope. However, in the offshore region it is important as it is a measure of the amount of sand available to be moved by the waves. For model tests where the depth of water at the toe of the beach is deeper than the depth at which material is moved by the waves then the initial slope will have no effect on the final equilibrium profile.

Three of the proposed models' laws were not tested. Of them, Model Laws 1 and 2 appear to be better ones in that they, like Model Law 7, are undistorted models. As Model Law 1 only requires modeling the sediment size, it appears to be the most practical.

Onshore-Offshore Sediment Transport

The amount of material transported between the foreshore and the offshore region is of importance for beach erosion considerations. Based on dimensional analysis, an erosion parameter, $Q/H_o d_i$, was chosen to represent this volumetric transport. The variable, Q , is the volume of material per unit width of tank eroded or deposited onshore of the breaker line and d_i , the product of the depth of water at the toe of the beach and the initial beach slope is a measure of the amount of material in the tank. The initial slope, i , is also important as the erosion or deposition in the onshore zone depends on whether or not the initial slope is greater than or less than the equilibrium slope. The results which are extremely speculative are shown in Fig. 5. Clearly more data is necessary to verify if the form of the curve is correct.

Figure 4 Comparison of Initial Slopes for Normal Profile

Figure 5 Inshore Erosion Versus Dimensionless Fall Velocity

Conclusions

The foreshore slope angle is uniquely related to the nondimensional parameter $H_o/V_f T$ which accounts for the major wave and material properties. For mild waves, the beach slope will be steeper than for steeper waves. Based on experimental results, the slope is independent of initial conditions and can be repeated for similar laboratory conditions. The slope is also a very important characteristic feature of the application to natural beaches as the region inshore of the Breaker line is the region of most concern to the users of the beach. The slope angle is relatively easy to identify and measure in the field as compared to the identification of an offshore bar.

A model law preserving the parameter, $H_o/V_f T$ has not been proven experimentally although Model Law #1 apparently includes the most important assumptions. Based on the experimental verification of four of the proposed model laws, the model should be geometrically similar to the prototype and should preserve the wave steepness ratio and the parameter, $H_o/V_f T$. To preserve both the wave steepness ratio and $H_o/V_f T$, the material size must also be modeled and the same material used in the model and prototype to eliminate the alien effects of light-weight materials.

APPENDIX A

DEVELOPMENT OF EQUILIBRIUM PROFILE MODEL LAWS

To completely define the following model laws, the horizontal scale, the median grain diameter, the submerged specific weight of the beach material and the time scale will be expressed in terms of the vertical scale. As only equilibrium profiles are considered, the time to equilibrium is not modeled. The variable H_0/V_{FT} will be preserved in all model laws. Further, the scale ratio of a parameter $n_{\text{parameter}}$, equals the ratio of the parameter in the model to the same parameter in the prototype. The following notation will be incorporated in the derivations:

$$n_{\text{vertical length}} = \mu$$

$$n_{\text{horizontal length}} = \lambda$$

$$n_{\text{time scale}} = n_T$$

$$n_{\text{median grain diameter}} = n_{d_{50}}$$

$$n_{\text{sediment relative specific weight}} = n_{\gamma'}$$

$$\text{where } \gamma' = \frac{\gamma_{\text{sediment}} - \gamma_{\text{fluid}}}{\gamma_{\text{fluid}}}$$

The resulting model relations are summarized in Table 1.

1. Model Law #1

The deepwater wave steepness, H_0/L_0 , has been shown to be a governing factor in the shaping of beach profiles. Preserving H_0/L_0 and defining $n_{H_0} = \mu$ and $n_{L_0} = \lambda$,

$$\mu = \lambda \quad (1.1)$$

Modeling the deepwater wave length, $L_0 = g/2\pi T^2$, or requiring Froude similitude

$$n_T = \mu^{1/2} \quad (1.2)$$

From Equation 1.2, the modeling of $H_o/V_f T$ yields $\mu = n_{V_f}^{1/2}$ or

$$n_{V_f} = \mu^{1/2} \quad (1.3)$$

This defines a model law in terms of n_{V_f} , n_T , μ , λ . The scale parameter $n_{d_{50}}$, may be obtained from curves of V_f versus d (see, e.g., Shore Protection Manual).

For low Reynolds numbers, the Stokes equation for the sediment fall velocity is

$$V_f = \frac{1}{18} \frac{d_{50}^2 g \gamma'}{\nu} \quad (1.4)$$

Preserving the Stokes equation and using the same fluid in the model and the prototype, $n_\nu = 1$,

$$n_{V_f} = n_{d_{50}}^2 n_{\gamma'} \quad (1.5)$$

For the same material in the model and the prototype, $n_{\gamma'} = 1$, Equation (1.5) reduces to upon substitution of Equation (1.3),

$$n_{d_{50}} = \mu^{1/4} \quad (1.6)$$

2. Model Law #2

Eagleson, Glenne and Dracup (1963) concluded that the equilibrium profile shape is a function of the incipient point for sediment movement. This point is determined by the relative magnitudes of the sediment weight and the bed shear stress. A nondimensional ratio of the gravitational force and the shear stress, the densimetric Froude number is defined as $F_* = \mu_* / (g \gamma' d_{50})^{1/2}$. Modeling F_* ,

$$n_{\mu_*}^2 = n_{\gamma'} n_{d_{50}} \quad (2.1)$$

Preserving the bed particle Reynolds number which is defined as $R_{e_s} = \mu_* d_{50} / \nu$ and using the same fluid in the model and the prototype,

$$n_{\mu_*} = \frac{1}{n_{d_{50}}} \quad (2.2)$$

Simplifying Equation 2.2 by means of Equation 2.1,

$$n_{\gamma'} = \frac{1}{n_{d_{50}}^3} \quad (2.3)$$

Preserving the Froude number, $F = V/(gd)^{1/2}$,

$$n_V = \mu^{1/2} \quad (3.5)$$

Upon the substitution of $n_V = \mu^{1/2}$ in Equation 3.4,

$$n_{u_*} = \mu^{1/4} n_T^{-1/4} \quad (3.6)$$

Modeling the bed particle Reynolds number, $n_{u_*} = 1/n_{d_{50}}$, Equation 2.2,

$$n_{d_{50}} = \mu^{-1/4} n_T^{1/4} \quad (3.7)$$

From the modeling of the densimetric Froude number, $n_{u_*}^2 = n_{\gamma} n_{D_{50}}$, Equation 2.1,

$$n_{\gamma} = \frac{\mu^{3/4}}{n_T^{3/4}} \quad (3.8)$$

upon the substitution of the expressions for n_{u_*} , Equation 3.6 and $n_{d_{50}}$, Equation 3.7. For the same material in the model and the prototype, $n_{\gamma} = 1$, $n_T = \mu$. Preserving $H_o/V_f T$, $n_{V_f} = 1$ and subsequently, $n_{d_{50}} = 1$. A kinematic condition proposed by LeMehaute (1970) stipulates that the ratio of the horizontal, V , and vertical velocity, V_f , be scaled as the ratio of the length scales, λ and μ , $n_V/n_{V_f} = \lambda/\mu$. For $n_V = \mu^{1/2}$, Equation 3.5,

$$\lambda = \mu^{3/2} \quad (3.9)$$

4. Model Law #4

Assuming a turbulent boundary layer, the friction factor is defined by Kamphuis (1973) as

$$f = .47 \left(\frac{k_s}{a_\delta} \right)^{3/4} \quad (4.1)$$

Modeling f ,

$$n_f = n_{k_s}^{3/4} n_{a_\delta}^{-3/4} \quad (4.2)$$

The term a_δ is defined as the wave orbital amplitude at the top of the boundary layer. For shallow water waves, the orbital amplitude equals

$$\delta = \frac{HT}{4\pi} \sqrt{\frac{g}{d}} \quad (4.3)$$

The scale factors λ and n_T are modeled similarly in accordance with Equations 1.1 and 1.2 for the modeling of H_o/L_o . By modeling of $H_o/V_f T$,

$$n_{V_f} = \mu^{1/2} \quad (2.4)$$

Again a model law now exists for the general case with $n_{d_{50}}$ determined

from the V_f-d_{50} curve. In this case the same material could even be used in model and prototype provided a different fluid or possibly different temperature is used. For low Reynolds numbers modeling the Stokes equation for fall velocity, $n_{V_f} = n_{d_{50}}^2 \gamma'$,

$$n_{d_{50}} = \mu^{-1/2} \quad (2.5)$$

$$\text{and} \quad n_{\gamma'} = \mu^{3/2} \quad (2.6)$$

upon substitution of Equations 2.3 and 2.4. For this model law, both the sediment specific weight and the size are modeled.

3. Model Law #3

Assuming a laminar boundary layer, the bed shear stress for incipient motion will be formulated differently from Model Law #2 based on the definition of the bed friction factor. The friction factor for a laminar boundary layer for gravity wave flow is expressed by Jonsson (1966) as

$$f = \sqrt{\frac{\pi}{2}} \frac{v^{1/2}}{V\sqrt{T}} \quad (3.1)$$

Modeling f and assuming the same fluid in the model and the prototype,

$$n_f = n_V^{-1} n_T^{-1/2} \quad (3.2)$$

Henderson (1966) defined the bed shear velocity, u_* , as

$$u_* = \frac{f^{1/2}}{\sqrt{8}} V \quad (3.3)$$

Modeling u_* and simplifying per the Equation 3.2 for n_f ,

$$n_{u_*} = n_V^{1/2} n_T^{-1/4} \quad (3.4)$$

Modeling a_δ ,

$$n_{a_\delta} = \mu^{1/2} n_T \quad (4.4)$$

The term k_s is defined as the bottom sand grain roughness and is assumed proportional to the median grain diameter. Defining the scale ratio as k_s as $n_{k_s} = n_{d_{50}}$ and incorporating the relations for n_{k_s} and n_{a_δ} , the expression for n_f , Equation 4.2, reduces to

$$n_f = \frac{n_{d_{50}}^{3/4}}{\mu^{3/8} n_T^{3/4}} \quad (4.5)$$

Modeling the bed shear velocity, $u_* = (f^{1/2}/\sqrt{8}) V$, as previously defined by Henderson (1966),

$$n_{u_*} = n_f^{1/2} n_V \quad (4.6)$$

Preserving the Froude number, $n_V = \mu^{1/2}$, n_{u_*} simplifies to

$$n_{u_*} = \frac{\mu^{5/16} n_{d_{50}}^{3/8}}{n_T^{3/8}} \quad (4.7)$$

upon the substitution of the equations for n_V and n_f . Preserving the bed particle Reynolds number, $n_{u_*} = 1/n_{d_{50}}$, n_{u_*} reduces to

$$n_{d_{50}} = \frac{n_T^{3/11}}{\mu^{5/22}} \quad (4.8)$$

Using the equations, $n_{u_*} = 1/n_{d_{50}}$ which preserves the bed particle Reynolds number and $n_{u_*}^2 = n_\gamma$, $n_{d_{50}}$ which preserves the densimetric Froude number,

$$n_\gamma = \frac{1}{n_{d_{50}}^3} \quad (4.9)$$

Modeling the Stokes equation for the fall velocity, $n_{V_f} = n_{d_{50}}^2 n_\gamma$,

$$n_{V_f} = \frac{1}{n_{d_{50}}} \quad (4.10)$$

per the substitution of $n_{\gamma'}$, Equation 4.9. Expressing n_{V_f} in terms of $n_{d_{50}}$, Equation 4.8,

$$n_{V_f} = \frac{\mu^{5/22}}{n_T^{3/11}} \quad (4.11)$$

Reexpressing the equation for n_{V_f} based on the modeling of the Stokes fall velocity in terms of $n_{d_{50}}$, Equation 4.8 and n_{V_f} , Equation 4.11,

$$n_{\gamma'} = \frac{\mu^{15/22}}{n_T^{9/11}} \quad (4.12)$$

For the modeling of $H_o/V_f T$,

$$n_T = \mu^{17/16} = \mu^{1.0625} \quad (4.13)$$

for the expressions of $n_{H_o} = \mu$ and n_{V_f} , Equation 4.11. Therefore, Equation 4.12 reduces to

$$n_{\gamma'} = \mu^{-0.1875} \quad (4.14)$$

and Equation 4.8 reduces to

$$n_{d_{50}} = \mu^{+0.063} \quad (4.15)$$

For the modeling of the horizontal velocity, $n_V = \lambda/n_T$. Substituting $n_V = \mu^{1/2}$ which models the Froude number and Equation 4.13 for n_T into the expression for n_V ,

$$\lambda = \mu^{25/16} = \mu^{1.5625} \quad (4.16)$$

This model law scales both the grain size and the particle specific weight. For a small scale model, the model grain size would be smaller than the prototype but the specific weight would be larger.

5. Model Law #5

For the same material in the model and the prototype, $n_{\gamma'} = 1$, and for the same median diameter, $n_{d_{50}} = 1$, $n_{V_f} = 1$. Modeling $H_o/V_f T$,

$$n_T = \mu \quad (5.1)$$

Preserving the Froude number,

$$n_V = \mu^{1/2} \quad (5.2)$$

Modeling the horizontal velocity, V ,

$$n_V = \frac{\lambda}{n_T} \quad (5.3)$$

Introducing the expressions for n_T and n_V ,

$$\lambda = \mu^{3/2} \quad (5.4)$$

6. Model Law #6

Open channel flow can be represented by the Chezy equation as

$$V^2 = C_h^2 RS \quad (6.1)$$

where R , the hydraulic radius, equals the water depth, d , for wide channels and S , the slope of the channel bed, equals the change in vertical elevation per horizontal length. Defining the water depth, d , and the slope, S , in terms of λ and μ , the modeling of the Chezy equation yields

$$n_V^2 = n_{C_h}^2 \frac{\mu^2}{\lambda} \quad (6.2)$$

Modeling the Froude number, $n_V = \mu^{1/2}$, and introducing this expression into Equation 6.2,

$$n_{C_h}^2 = \frac{\mu}{\lambda} \quad (6.3)$$

The Chezy coefficient is defined as $C_h^2 = \frac{8g}{f}$. Modeling the Chezy coefficient, $n_{C_h}^2 = 1/n_f$ and substituting Equation 6.3 for n_{C_h} ,

$$n_f = \frac{\mu}{\lambda} \quad (6.4)$$

Modeling the bed shear velocity, u_* ,

$$n_{u_*} = n_f^{1/2} n_V \quad (6.5)$$

Introducing $n_V = \mu^{1/2}$ per the modeling of the Froude number,

$$n_{u_*} = n_f^{1/2} \mu^{1/2} . \quad (6.6)$$

Substituting Equation 6.4 for n_f in Equation 6.6,

$$n_{u_*} = \frac{\mu}{\lambda^{1/2}} . \quad (6.7)$$

Preserving the bed particle Reynolds number, $n_{u_*} = \frac{1}{n_{d_{50}}}$ and substituting this expression into Equation 6.7 for n_{u_*} ,

$$n_{d_{50}} = \frac{\lambda^{1/2}}{\mu} . \quad (6.8)$$

Per the preserving of the densimetric Froude number,

$$n_{u_*}^2 = n_\gamma n_{d_{50}} . \quad (6.9)$$

Introducing Equations 6.7 and 6.8 into Equation 6.9,

$$n_\gamma = \frac{\mu^3}{\gamma^{3/2}} \quad (6.10)$$

Substituting Equations 6.8 and 6.10 into the model expression for the Stokes fall velocity, $n_{V_f} = n_{d_{50}}^2 n_\gamma$,

$$n_{V_f} = \frac{\mu}{\lambda^{1/2}} \quad (6.11)$$

Preserving $H_o/V_f T$,

$$n_T = \lambda^{1/2} . \quad (6.12)$$

For the same material in the model and the prototype, $n_\gamma = 1$, Equation 6.10 reduces to

$$\lambda = \mu^2 \quad (6.13)$$

Equation 6.8 for $n_{d_{50}}$ reduces to $n_{d_{50}} = 1$ and Equation 6.12 for n_T reduces to

$$n_T = \mu . \quad (6.14)$$

7. Model Law #7

Preserving the wave steepness ratio, H_o/L_o ,

$$\mu = \lambda . \quad (7.1)$$

For the same material in the model and the prototype, $n_p = 1$, and the same grain size, $n_{d_{50}} = 1$, $n_{V_f} = 1$ and the modeling of γ'

$H_o/V_f T$ yields $\mu = n_T$. In this case, however, the Froude number is not modeled.

CHAPTER 76

BEACH PROFILES AT TORREY PINES, CALIFORNIA

David G. Aubrey, Douglas L. Inman and Charles E. Nordstrom
Scripps Institution of Oceanography, University of California
La Jolla, California 92093

ABSTRACT

Beach profiles have been measured at Torrey Pines Beach, California for four years and correlated with tides and accurate spectral estimates of the incident wave field. Characteristic equilibrium beach profiles persist for time spans of up to at least two weeks in response to periods of uniform incident waves. These changes in the beach profiles are primarily due to on-offshore sediment transport which can be related to variations in wave characteristics and tidal phase. The most rapid readjustment of the beach profile occurs during high wave energy conditions coincident with spring tides. Alternatively, the highest berm building is associated with moderate to low waves that coincide with spring tides.

INTRODUCTION

The movement of sediment in the nearshore zone can be divided into two distinct directional modes: transport along the shore and transport onshore-offshore. It is convenient to think in terms of these two orthogonal modes when evaluating the erosion and accretion of sediment on a coast exposed to waves having seasonal variations in both energy and direction. Prediction of the longshore transport of sediment as a function of incident wave parameters is possible using empirical relations (e.g., Inman, Komar and Bowen, 1968; Galvin, 1976) and quasi-theoretical considerations (Inman and Bagnold, 1963; Komar and Inman, 1970; and Longuet-Higgins, 1970). However, at this time it is not possible to predict the magnitude of onshore-offshore sediment motion given a knowledge of sediment characteristics, tidal variations, and incident wave characteristics. The present study represents an attempt to provide empirical correlations between incident wave and tidal characteristics and onshore-offshore sediment motion.

It is necessary initially to determine whether the concept of an equilibrium beach profile is valid in a natural environment. The equilibrium energy profile is defined by Inman and Bagnold (1963) as the profile (depth as a function of distance offshore) which would eventually be attained when a nearshore area with a particular set of environmental characteristics (e.g., sand size, shelf width, and slope) is acted upon by a given set of driving forces (e.g., waves, currents, and tides). The equilibrium concept implies that the profile has ceased to vary with time and the driving force is constant. The equilibrium profile has been generated in the laboratory, but never fully documented in the field. Winant and Aubrey (1976) and Winant, Inman and Nordstrom (1975) verify the existence of characteristic stable beach forms for summer and winter wave conditions at Torrey Pines Beach, California, by analyzing the profiles using the objective analytical technique of empirical eigenfunctions.

The seasonal onshore-offshore motion of sediment has been previously described by numerous investigators (e.g., Shepard, 1950; Zeigler, et al, 1959; Gorsline, 1966; Sonu and Van Beek, 1971). Shepard (1950) measured seasonal beach changes along the Southern California beaches of the order of two meters vertically. A comprehensive study by Nordstrom and Inman (1975) along a section of coastline north of La Jolla, California, described changes at the location of the summer berm and winter bar of the order of 1 meter. Other researchers have found similar changes in different geographic locations. The beaches cited in the above references respond to the energetic waves characteristic of winter conditions by eroding the berm and moving the sediment offshore. The less energetic waves typical of summer conditions move sediment shoreward, building up the berm. Besides these seasonal large scale motions, the beach responds to smaller time scale events such as storms or long periods of extremely low wave energy. No field studies to date have been able to adequately quantify these wave-related sediment redistributions.

Laboratory studies have been undertaken in an attempt to delineate the erosional and accretionary regimes. These studies emphasize the importance of the wave steepness in determining the form of the profile. The results are given in terms of a critical wave steepness: for wave steepness above this value, a barred (no berm) profile develops, while for a wave steepness below this critical value, a profile with a berm develops (Johnson, 1949; Rector, 1954; Scott, 1954; Watts, 1954; Saville, 1957). The laboratory results are not directly applicable to natural beaches because of an inability to correctly scale both kinematics and dynamics in laboratory experiments. Kemp (1961) suggested that the critical wave steepness is inversely proportional to the wave period, so the critical steepness on natural beaches with a 10 second wave period would be only 10 percent of the critical steepness of a one second wave.

Field experiments have not yet defined the critical wave steepness for natural beaches, primarily because intensive beach profiling projects have not been complemented by good wave measurements. The general observation is that large waves create a barred profile, but the effect of wave period is uncertain. The present study attempts to determine empirically the effect of seasonally varying incident waves on a fine-grained sand beach at Torrey Pines Beach, California. Figure 1 shows the location of the study area. The beach is a long, relatively straight stretch of coastline backed by 100 meter high cliffs. In general, the cliffs contribute little to the sediment budget in the area. The net direction of longshore transport is to the south, where sediment is lost down the La Jolla and Scripps Submarine Canyon systems (Inman, Nordstrom, and Flick, 1976). The direction of littoral drift is seasonally dependent. During the winter, the waves are primarily from the north, while during the summer, there is a high incidence of waves coming from the south. The mean energy density for the area, as defined by the variance, $\langle \eta^2 \rangle$, is approximately 550 cm^2 ; where the variance is related to the energy per unit surface area of the waves $E = \rho g \langle \eta^2 \rangle = 1/8 \rho g H_{\text{rms}}^2$. This is equivalent to a root-mean-square wave height of 66 cm.

Figure 1. Location map of Torrey Pines Beach, California, showing position of the three rangelines (from Nordstrom and Inman, 1975).

DATA COLLECTION

The profile data was taken over a four year period along the three rangelines shown in Figure 1. For the first two years, the profile data was taken at monthly intervals, while in the succeeding two years, the profile data was taken at daily, weekly, or biweekly intervals. The surveying technique is described in Nordstrom and Inman (1975). Briefly, the surveys consist of an onshore profile extending from the beach backshore at the base of the sea cliffs out to a depth of approximately 1.5 meters. The profile is taken at low tide with a surveyor's rod and transit. Since the survey line is well defined by rangeline marker, this part of the survey is extremely accurate. At least once a month, an offshore survey is also made on the same day as one of the onshore surveys. The method is shown schematically in Figure 2. At high tide, a fathometer survey is made along the rangelines. The boat position is defined by the rangeline and a sextant angle. As soon as practical after the fathometer survey, scuba divers measure a series of arrays of four brass reference rods extending from the bottom at depths of 5, 7, 10, 15, and 20 meters along each rangeline. Since the change in length of the reference rods from survey to survey is an accurate measure of the actual change in sand level, the fathogram can be corrected to minimize the errors that are inherent in fathometer surveys (Inman, 1953). This surveying combination is sufficient to define almost all portions of the profile. During periods of intense wave activity, it is not always possible to measure the profile in the breaker zone, so there is some uncertainty about the profile at this point while the storm waves are present.

Figure 2. Schematic diagram of the onshore-offshore profiling technique employed in this study (from Nordstrom and Inman, 1975).

The wave data consists of both frequency and directional spectral estimates. The wave measuring system was described by Lowe, Inman and Brush (1972). Data is collected at one of the shelf stations of the Shelf and Shore (SAS) System depicted in Figure 3, and telemetered directly to the laboratory four times a day, each run having an hour duration. The data is automatically stored on digital magnetic tape. The shelf station consists of a surface piercing buoyant spar which is connected by a universal joint to an anchor assembly. The spar contains the transmitting package, which transmits the output of two accelerometers, mounted on the spar, and the output from a linear array of pressure sensors mounted on the bottom. Both frequency and directional spectral estimates are derived from the pressure sensor array (Pawka, Inman, Lowe and Holmes, 1976).

The shelf station is located in 10 meters of water off Torrey Pines Beach. The wave data cited in this study is the energy measured at the 10 meter depth location, corrected to energy density at the water surface. Since directional data were obtained, the resolution into on-offshore and longshore components, and the effect of breaker characteristics will be considered in a later paper. The solid lines in the figures to follow which refer to wave energy represent the energy variance, $\langle \eta^2 \rangle$, as measured by the SAS system. The dashed lines were taken from visual wave observations of breaker height at Torrey Pines Beach, at times when the SAS system was inoperative. The dashed values represent estimates of the energy density at the 10 meter depth calculated from the observed breaker heights.

Figure 3. Shelf station portion of the Shelf and Shore (SAS) System used to collect frequency and directional spectral estimates. The pressure sensors are aligned in a linear array parallel to the beach in a water depth of 10 meters (from Pawka, et al, 1976).

The beach profile data is stored on magnetic tapes, and is processed on an Interdata Model 70 minicomputer. The volume calculations plotted on the following figures were evaluated by the computer. Tide data was taken from local tide calendars.

RESULTS

As a further test of the validity of the concept of equilibrium profiles on natural beaches, a series of profiles associated with high and low energy waves are compared. Figures 4 and 5 show equilibrium beach configurations for a high energy wave condition (winter type) and a lower wave energy condition (summer type), respectively. These profiles were taken at Indian Canyon Range. Figure 4 shows a sequence of three profiles taken over a two week time period during the winter of 1975-76. The wave energy was high immediately preceding each of the surveys. On 30 December 1975, there was an intense winter storm with an energy variance of 2100 cm^2 . Prior to the 9 January 1976 survey, wave energies were greater than 600 cm^2 , while before the 15 January 1976 survey, wave energies were about 750 cm^2 . The maximum change in sand volume above mean sea level (MSL) between any of the two profiles during this two week period was 2.5 m^3 per meter length of beach. It has been established that the seasonal summer to winter beach changes for this beach are about $120 \text{ m}^3/\text{m}$ beach length (Nordstrom and Inman, 1975). Thus, this small change implies that after the storm eroded the beach on 30 December 1975, the beach above MSL maintained itself in a constant, or equilibrium, configuration.

Figure 5 shows a sequence of three profiles taken over a two week period in August 1975, showing an equilibrium configuration for summer conditions. The maximum volume change among these profiles was $5 \text{ m}^3/\text{m}$ of beach length. During this time period, the waves were uniform and had an average energy density of about 250 cm^2 . Although a little accretion occurred at depths of approximately -2 meters, the beach face slope was extremely constant.

Both of these examples demonstrate that in natural beach environments, a dynamic equilibrium can be established given the same input wave conditions acting on a stable profile over a period of time. The presence of tidal variations complicates the situation, but does not alter the essential concept of a dynamic beach equilibrium.

INDIAN CANYON RANGE

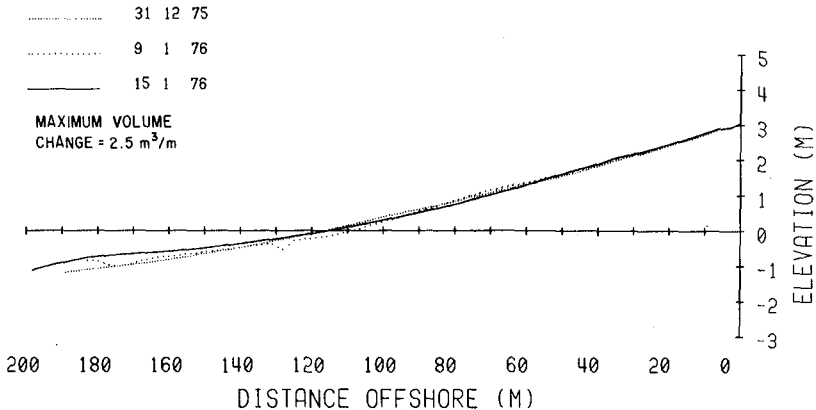

Figure 4. Typical equilibrium beach profiles for Torrey Pines Beach during winter wave conditions.

The second part of this study examines the response of the beach to varying wave and tidal conditions. Figures 6, 7, and 9 show three examples of the response of the beach to these varying forcing conditions. Figure 6 covers the time period from November 1973 through March 1974. The top part of the figure is a plot of the sand volume changes on the beach for the three ranges. The sand volume changes are those above a datum of 1 meter below mean sea level, and are relative to the surveys of 6 June 1972 as reported in Nordstrom and Inman (1975). The sand volume change is calculated from the backshore out to approximately 1 meter depth in these figures. The middle part of the figure plots the maximum daily tidal range (the tide at Torrey Pines is mixed with a pronounced diurnal inequality). The lower part of the figure is a plot of the wave energy variance $\langle \eta^2 \rangle$. The storms during this period were intense, and pronounced beach erosion occurred. After the storms of late December 1973, the beach eroded along all three ranges, and a winter-type profile was established. After that, North and South Ranges remained at a nearly constant level, while Indian Canyon continued to erode due to the action of rainwater flowing down the canyon immediately behind the rangeline. The maximum erosion is normally associated with the coincidence of large waves and high spring tide. The lower energy waves in late March were accompanied by accretion at all three ranges.

INDIAN CANYON RANGE

Figure 5. Typical equilibrium beach profiles for Torrey Pines Beach during summer wave conditions.

Figure 7 shows the gradual accretion of a summer beach by the lower energy waves that occurred during the spring and summer of 1975. As before, the bottom portion of the figure shows the wave energy density. The maximum daily tidal range is shown in the middle part of the figure, while the top part shows the sand volume changes for all three ranges. Several large wave events occurred during this time period. Except for these five events, the energy density is low. The volume changes indicate a gradual accretion on the beaches. The slow accretion during the summer is due in part to the periods of erosion of the beach associated with the occasional large waves of summer. Note that the high energy waves of 20-21 July 1975 which coincided with a spring tide caused erosion at all three ranges. The erosion accompanying the large waves of 5 May, 21 May, and 18 June 1975 was minimized in part because the large waves were coincident with neap tides, so that the waves were not as effective in eroding the berm. Had the tidal range been large, more erosion would have taken place.

Figure 8 shows a series of profiles measured from April through July 1975 at South Range. The berm that is evident in the 24 April 1975 (24-4-75) profile is gone in the 7 May profile, following the passage of the storm of 5 May 1975. Between 4 June and 27 June, there is a net progressive accretion of sand on the beach face, and a migration of sand shoreward as shown by the middle portion of Figure 8. The three profiles in July 1975 illustrate the pronounced berm accretion associated with spring tides and moderate wave action (compare profiles 8-7-75 and 15-7-75); and the subsequent rapid erosion associated with a brief period of high waves on 20 July 1975 (see profile 22-7-75).

BEACH FACE SAND VOLUME CHANGES

Figure 6. Changes in sand volume above the datum of 1 m below mean sea level relative to the surveys of 6 June 1972, compared with the maximum daily range and total wave energy density for the period of November 1973 through March 1974. The data for this figure was obtained from Nordstrom & Inman (1975).

BEACH FACE SAND VOLUME CHANGES

Figure 7. Changes in sand volume above the datum of 1 m below mean sea level relative to the surveys of 6 June 1972, compared with the maximum daily tidal range and total wave energy density for the period of May through July 1975.

SOUTH RANGE

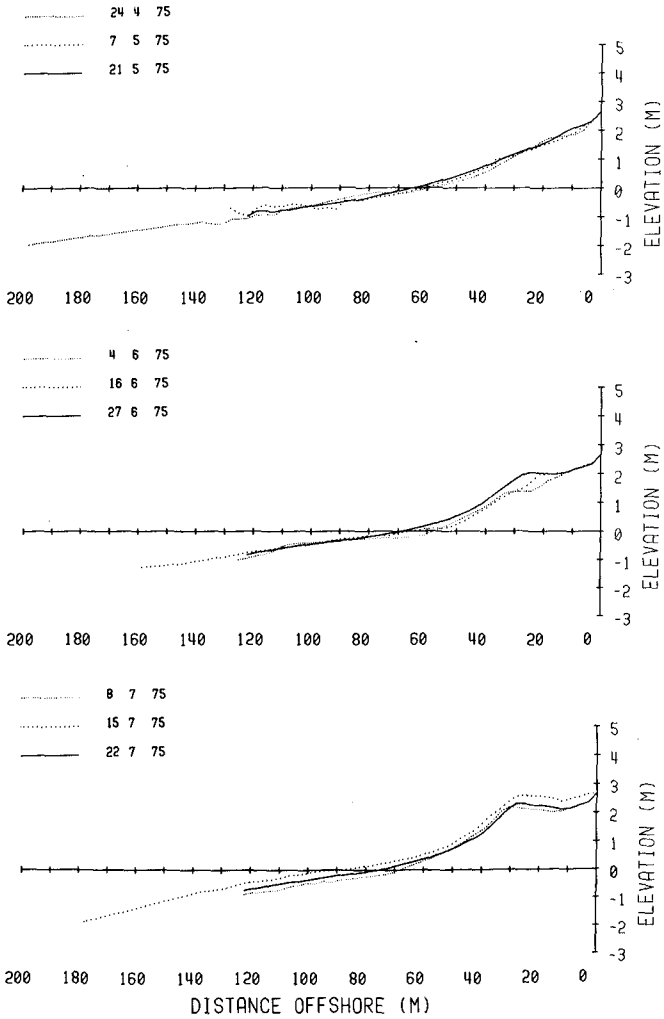

Figure 8. Sequence of beach profiles at South Range for period of May through July 1975.

Figure 9 shows the beach response for the period of December 1975 through February 1976. As before, the lower portion of the figure shows the wave energy density, the middle portion shows the maximum daily tidal range, and the upper portion shows the sand volume changes for the three ranges. Two distinct storms dominate the wave activity, one on 27 December and one on 30 December 1975. The first of these occurred during a period of neap tides and was accompanied by erosion at all three ranges. The second storm occurred during spring tides and was accompanied by more intense erosion at all three ranges. Following these storms, the volume changes at North and South Ranges were similar, and responded to the lower wave energies in the aftermath of the storms. Indian Canyon Range showed some erosion in mid-January, contrary to the trend at the other two ranges. This was due to erosion from rain runoff channeled onto the beach by the canyon behind the rangeline. The rain was accompanied by low energy waves, but the stream discharge was sufficient to erode the beach at Indian Canyon Range. Stream discharge across the beach was also responsible for the erosion in mid-February 1976 at Indian Canyon Range. North and South Ranges both eroded following the coincidence of large waves and spring tides on 14 February 1976. Indian Canyon showed an apparent accretion as the cut in the beach due to rain runoff was beginning to fill in.

Figure 10 shows a sequence of beach profiles at South Range for this same time period. The erosion associated with the storm of 30 December 1975 is apparent in the upper plot of the figure. The berm was totally eroded and the material deposited at a depth greater than -2 meters. The beach face slope decreased during the storm. The slight erosion associated with the 27 December 1975 storm can also be seen. The central plot shows that there was little change in the profile during January 1976, as the wave energy was similar during this time span. The lower plot shows a migration of sediment shoreward between 28 January and 11 February 1976, while there was slight erosion accompanying the larger waves of 14 February 1976. Similar plots for North Range and Indian Canyon Range show the same trends, except for the aforementioned erosion at Indian Canyon due to stream discharge across the beach.

CONCLUSIONS

A condition of approximate dynamic equilibrium is attained on natural sand beaches when the incident wave field remains approximately uniform over sufficiently long periods of time. Once achieved, a condition of approximate equilibrium may exist for periods of two weeks or longer, as evidenced by a minimal redistribution of sediment of 2 to 5 m³ per meter length of beach. Also, the variation in the distribution of sediment along a range perpendicular to the beach can be explained in large part by assuming these variations are due to onshore-offshore movement of sediment, and not a divergence or convergence in the longshore drift. Furthermore, these changes are correlated with the input wave conditions; in this paper they were examined only in terms of the total energy density of the waves, $\langle \eta^2 \rangle$.

The profile associated with large, winter-type waves is most rapidly achieved when large waves are coincident with spring tides. Large waves coincident with neap tides do not maximize the foreshore erosion.

Waves of low energy density build up the beach face and berm, creating a steep beach face slope. The most pronounced berm accretion is associated

with the coincidence of low to moderate wave intensity and spring tides. The profile which is associated with these low waves is rapidly modified by changing wave conditions such as storms.

CHAPTER 77

STABILITY AND IMPULSE RESPONSE OF EMPIRICAL EIGENFUNCTIONS

Clinton D. Winant and David G. Aubrey
Scripps Institution of Oceanography, University of California
La Jolla, California 92093

ABSTRACT

The statistical method of empirical eigenfunctions has been applied to four years of beach profile data. The eigenfunctions associated with the three largest eigenvalues are shown to be stable for data sets of one, two, three, and four years length, and they correctly describe beach changes caused by storm activity. The usefulness of the eigenfunction representation is confirmed as a concise means of representing beach profile variability.

INTRODUCTION

The onshore-offshore movement of nearshore sediments in response to changing incident wave energy makes an important contribution to coastal zone variability. The basic motivation for this paper is to concisely describe the nearshore variability associated with selected beach profiles by means of empirical orthogonal eigenfunctions. In this manner the seasonal onshore-offshore movement of sediment can be distinguished from shorter-term changes in beach profiles. In addition, the method has the advantage of describing all of the variability of the beach profiles by means of just a few simple functions.

The data set consists of four years of beach profile data taken at Torrey Pines Beach, California, at monthly intervals. These profiles were taken by the method described by Nordstrom and Inman (1975), and include measurements from the backshore out to a depth of 20 meters. The study location is a fine-grained sand beach approximately 3 km north of Scripps Institution of Oceanography. The beach is straight with uncomplicated offshore bathymetry exposed to wave energy coming from all offshore quadrants.

Figures 1 and 2 illustrate the magnitude of the seasonal changes in Southern California. Figure 1 shows a portion of the beach in La Jolla at the end of winter, 1975, when the "winter" beach was fully developed. The rocks are exposed approximately one meter. Figure 2 shows the same beach at the end of summer, 1974, when the "summer" beach was fully developed; the rocks are completely covered with sand.

More quantitatively, seasonal changes at North Range, Torrey Pines Beach, are shown in Figure 3 for two successive winter and summer profiles. The summer berm is built up about one meter above the sand level present at the same place during the winter. Similarly, the bar at a depth of 5 meters builds up approximately one meter. These seasonal trends can be obscured by short-term events, such as storms or periods of extremely low wave energy. The method of empirical eigenfunctions can be used to distinguish between variability on these different time scales.

Figure 1. Beach in La Jolla in winter of 1975 with rocks exposed one meter.

Figure 2. Beach in La Jolla in summer of 1974 with rocks fully covered with sand.

Figure 3. Comparison of winter and summer beach profiles showing seasonal erosion and accretion of sand.

An earlier attempt to depict the seasonal variability of beach profiles using an objective statistical technique was described in Winant, Inman and Nordstrom (1975). The method of empirical eigenfunctions was used to describe the first few modes of variability in two and one-half years of beach profile data taken at monthly intervals. This data set was subsequently expanded to four years (Aubrey, Inman, and Nordstrom, 1976). Over 99.75% of the variability of the data can be accounted for by the three eigenfunctions associated with the three largest eigenvalues. Figure 4 shows the spatial and temporal variation of these eigenfunctions. The first eigenfunction is the mean beach function which reflects the mean beach level. Its time dependence is nearly constant. The second function is the bar-berm function, which shows a large maximum at the location of the summer berm as well as a minimum in the area of the winter bar. The time dependence of this function shows a one year periodicity. The third function is the terrace function, which shows a broad maximum over the low-tide terrace. Its time dependence cannot be simply interpreted.

The present paper addresses two problems not considered in previous work. In order to usefully represent beach variability, the spatial and temporal behavior of the eigenfunctions must be stable with respect to various data sample lengths. Data sets of one, two, three, and four years of beach profiles are examined, and their eigenfunctions are compared. In addition, the first few eigenfunctions should correctly yield the magnitude of beach erosion due to storm waves. This point is investigated by analyzing the first winter storm in October 1974, and its effect on the beach.

STATISTICAL METHOD

One seeks to represent the variability of the beach profile data in terms of a set of orthogonal functions. Obviously any one of a number of such orthogonal series can be generated, one example being a Fourier series. One could then ascribe the variability associated with a one year period to the seasonal variations. Unfortunately, there is no *a priori* reason to suspect that the seasonal dependence of onshore-offshore sand movement is sinusoidal. In fact, there is evidence to the contrary, as when the beach erodes rapidly as the first winter storm waves erode the "summer" beach.

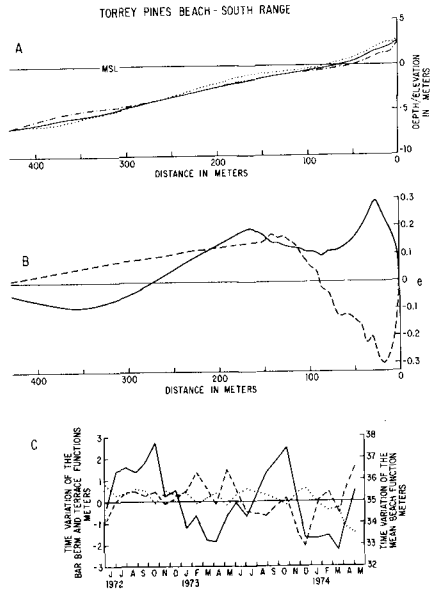

Figure 4. Spatial and temporal dependence of the first three eigenfunctions for a two year period. (a) solid line, mean beach function; dash-dot line, profile of 11 April 1973; and dotted line, profile of 23 October 1972. (b) solid line, bar-berm function; and broken line, terrace function. (c) time variation of bar-berm function (solid line), terrace function (broken line), and mean beach function (dotted line).

A better choice is a set of empirical eigenfunctions which most concisely describe the beach profile variability. The properties of these functions have been summarized by Davis (1976):

(a) They provide the most dense representation of a data set in the sense that the first n terms in the expansion represent more of the data variability than the first n terms of any other orthogonal expansion.

(b) Both the spatial and temporal eigenfunctions are orthonormal sets, so that each corresponding set (λ_n, c_n, e_n) may be regarded as representing a mode of variability which is uncorrelated with any other mode.

The method has been described by Winant, et al (1975). In brief, one seeks an eigenfunction expansion in the form

$$h_{xt} = \sum_n c_{nt} e_{nx} (\lambda_n n_t)^{\frac{1}{2}}$$

where h_{xt} are the beach profile data, c_{nt} represent the temporal eigenfunctions,

e_{n_x} represent the spatial eigenfunctions, n_x represents the number of data points per profile, n_t represents the number of different profiles, and the λ_n are the eigenvalues. In this study, $n_x = 51$ and $n_t = 46$.

The spatial correlation matrix A is formed by the elements

$$a_{ij} = \frac{1}{n_t} \sum_{t=1}^{n_t} h_{it} h_{jt}$$

Similarly, a time correlation matrix B is formed with the elements

$$b_{ij} = \frac{1}{n_t} \sum_{x=1}^{n_x} h_{xi} h_{xj}$$

Both A and B are real symmetric matrices with only positive real eigenvalues. In fact, A and B can be easily shown to have the same non-zero eigenvalues λ_n . The functions e_n then are the eigenvectors of A and the functions c_n are the eigenvectors of B:

$$Ae_n = \lambda_n e_n$$

$$Bc_n = \lambda_n c_n$$

The physical interpretation of the first few of these eigenfunctions has been previously discussed by Winant, et al (1975).

STABILITY OF THE EIGENFUNCTION REPRESENTATION

In order to evaluate the stability of the eigenfunction representation, the spatial eigenvectors were calculated for data sets of one, two, three, and four years length, while the temporal eigenvectors were calculated for data sample lengths of two years and four years. If the eigenfunctions are to accurately represent the beach variability, they should exhibit similar features for the different data sets.

The results of the analysis for the mean beach function are shown in Figure 5. The spatial eigenvectors for the four different data sets are nearly indistinguishable, so this function has no dependence on the length of the data sample. Figures 6 and 7 show the time dependence of the first three eigenfunctions. Figure 6 is for a two year data set; Figure 7 is for a four year data set. The time dependence of the mean beach function is almost constant and is independent of the length of the data set.

Table 1 shows the percentage of the total mean square value of the data associated with each of the first five eigenvalues. The percentage represented by the eigenvalue associated with the mean beach function is essentially independent of the length of the data set. This suggests that the mean

beach function is constant at North Range. No appreciable net erosion or accretion is seen in this function for the four year period.

Figure 5. Spatial dependence of mean beach function for data sets at one, two, three, and four years length.

Figure 6. Temporal dependence of first three eigenfunctions for a two year data set.

Figure 7. Temporal dependence of first three eigenfunctions for a four year data set.

Table 1. Results of Eigenfunction Analysis. The numbers describe the percentage of the total mean square value of the data associated with each of the five largest eigenvalues.

	One Year	Two Year	Three Year	Four Year
MEAN BEACH FUNCTION	99.33	99.32	99.39	99.43
BAR-BERM FUNCTION	0.30	0.24	0.27	0.24
TERRACE FUNCTION	0.21	0.17	0.18	0.16
EIGENVALUE 4	0.07	0.06	0.07	0.07
EIGENVALUE 5	0.04	0.03	0.03	0.03

The results for the spatial dependence of the bar-berm function are shown in Figure 8 where this function is plotted for each of the four data sets. The shape of the function is the same, except for the tendency of the extrema to broaden. This broadening occurs because the summer berm and winter bar do not form in the identical locations every year. The magnitude of this function also varies somewhat, reflecting the variability in heights of the berms and bars. Figures 6 and 7 show the time dependence of this function for the two data sets. In the two-year overlap in these graphs, the time dependence is nearly identical. The time dependence has a distinct seasonal trend. Table 1 shows that, for the spatial dependence of this function, the same amount of variance is accounted for by the associated eigenvalue in all four data sets.

Figure 8. Spatial dependence of bar-berm function for data sets of one, two, three, and four years length.

Figure 9 shows the variation in the spatial dependence of the terrace function for the four data sets. The general shape of the curves is conserved, as are the relative magnitudes of the extrema. The location of the extrema vary slightly in response to the fact that sand erosion and deposition occur in slightly different locations along the profiles in response to different wave conditions. The dominant feature in the spatial dependence is the broad maximum across the low tide terrace. Figures 6 and 7 show the temporal dependence of this eigenvector. Table 1 shows that approximately the same percentage of the total variability is explained by the eigenvalue associated with this eigenvector.

Figure 9. Spatial dependence of terrace function for data sets of one, two, three, and four years length.

IMPULSE RESPONSE OF THE EIGENFUNCTIONS

The response of these empirical eigenfunctions to impulses in the form of storm waves has been examined. Several examples demonstrate that the first few eigenfunctions are sensitive to short-term events. Two qualitative results are shown in Figure 9. On 27 August 1973, the time dependence of the bar-berm function became more negative instead of increasing according to the normal seasonal trend. This reflects the occurrence of a major summer storm on 23 August 1973 which eroded the developing summer profile. Similarly, the large positive values for February and March of 1976 reflect the anomalous occurrence of long, low waves which began to build the beach toward its summer configuration before it was eroded again by the more energetic waves more typical of winter conditions.

In October of 1974 the first large winter storm to hit the Southern California coast was generated off the low pressure center in the Gulf of Alaska. Storm front positions on 27, 28 and 29 October 1974 are shown in Figure 10. Significant environmental parameters measured at or near Scripps Institution of Oceanography during this time period are shown in Figure 11. The barometric pressure dropped from 1017 to 1005 mb and wind speeds reached 15 ms^{-1} . Coincidentally the rms wave amplitude increased to 0.5 m in 10 m of water. Wave energy spectra for the period just preceding and during the

storm are shown in Figure 12. The storm spectra are characterized by an order of magnitude higher spectral peak as well as a broader frequency band.

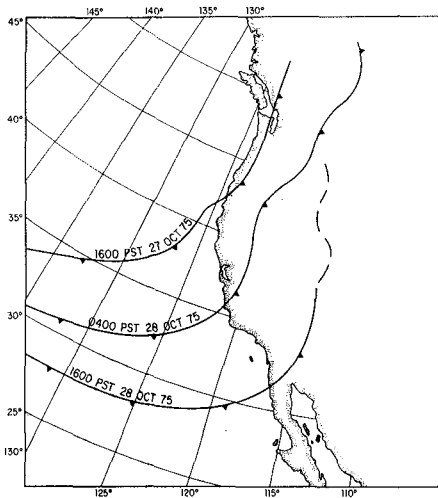

Figure 10. Storm front positions for first winter storm in late 1974.

The increased wave energy was coincident with spring tides of 2 m amplitude. These combined occurrences maximized the erosion on the beach. Figure 13 shows a comparison of a series of beach profiles at North Range taken before, during, and after the storm. The well-developed "summer" profile on 24 October was rapidly eroded as the storm passed through the area. At a distance of 70 m from the profile benchmark where the berm was located, 46 cm of sand was eroded.

This rapid erosion is reflected in the behavior of the temporal dependence of the bar-berm function shown in Figure 14. The 31 October profile shows an erosion in the beach on the order of 15 cm. For this particular storm, the terrace function showed an erosion of 17 cm, while the fourth eigenfunction showed an erosion of 13 cm. The bar-berm function correctly responds to the wave energy impulse, while the magnitude of the beach change can be fully accounted for in the first few eigenfunctions.

Figure 11. Environmental parameters measured at or near Scripps Institution of Oceanography during first winter storm in late 1974.

Figure 12. Frequency spectra of ocean surface waves measured before and during the first winter storm of late 1974.

Figure 13. Beach profiles measured at North Range before, during, and after the first winter storm of late 1974.

Figure 14. Time dependence of the bar-berm function for a two and one-half year data set at North Range.

CONCLUSIONS

The method of empirical eigenfunctions has been shown to be of great value in analyzing beach profile data. Using no a priori assumptions on the structure of the orthogonal functions, the most concise orthogonal set is generated by the data. The first three eigenfunctions describe over 99.75% of the variability in the data, and can be used instead of the data themselves to quantify the variability. The functions are stable with respect to the length of the data set examined, so an analysis of one year of data will indicate significant trends in the eigenfunctions. Erosion or accretion caused by short term events such as storms can be accurately predicted by the behavior of the temporal dependence of the bar-berm function, while the magnitude of this impulsive change is correctly given by the first four eigenfunctions.

CHAPTER 78

RIP-CURRENT AND COASTAL TOPOGRAPHY

Mikio Hino

Professor, Department of Civil Engineering,
Tokyo Institute of Technology,
O-okayama, Meguro-ku, Tokyo, 152,
JAPAN

SUMMARY

At the 1974 Conference on Coastal Engineering (Copenhagen), the writer proposed a new theory on the mechanism of generation of rip-current and cuspidal coast that the alongshore homogeneous structure of wave field and movable sedimental bottom (that is two-dimensional wave setup and bottom topography) is unstable to a small perturbation, the motive force of instability being the radiation stresses caused by incident wave.

In this paper, based on the response concept and the mathematics already presented at the previous conference some improvements in solving the fundamental equations are attempted, since the direct solution of the full system of basic equations did not necessarily result in the sufficient conclusion.

The response of water-wave system to an infinitesimal perturbation in bottom boundary is quick enough compared with that of sediment system to a change occurring in water-wave system. Consequently, the water system is treated as quasi-stationary. By solving the equation of mass conservation of sediment transport under the prescribed boundary conditions, the preferred wavelength of rip-current as well as the profiles of velocity distribution and the bottom perturbation have been determined as an *eigenvalue* problem.

INTRODUCTION

Recently, various theories have been proposed on the mechanism of rip-current generation. These theories may be grouped into three categories; The forced formation theory, the variational principle of the energy dissipation and the instability or eigenvalue theory.

Bowen and Inman's theory published in 1969 is based on the forced mechanism caused by standing edge waves which induce the spatially periodic distribution of radiation stress.

On the other hand, the writer (Hino 1972) has proposed a hydrodynamic instability mechanism. The writer does not necessarily deny the mechanism proposed by Bowen & Inman. However, there may be a possibility of another mechanism for generation of rip-current system.

In 1971, the writer was staying about a month at the Louisiana State University where the writer and Dr. Sonu who is now at Tetra Tech, frequently discussed on this problem. Dr. Sonu considered that the bottom material would change to sinusoidal forms by the action of alongshore current, as if sandbars on river bed are formed by the unidirectional flow. While, the writer asserted on the instability of uniform wave setup.

ESSENCE OF THE PRESENT THEORY

The basic idea of the writer's theory is as follows;

(a) If waves are incident on a straight coast, and if the water depth is uniform along the shore, the uniform wave setup along it should be formed, caused by the radiation stress of incident waves.

Such a uniformly long wave setup may be unstable to an infinitesimal disturbance, as if a slender elastic cylinder compressed axially becomes buckled when a critical compressive stress is exceeded. This is the *buckling analogy*.

In other words, the wave system itself on a rigid plane bottom may be unstable to form the periodic rip-current. However, in real situations, the rip current is accompanied by the corresponding periodic perturbations in the bottom topography.

As has been indicated in the previous paper, the direct solution of the full system of equations yields the two types of instability; one with the high increase rate and the rapid translation velocity along the shore is called the "*fluid mode*", while the other with the slow rate of increase and the low convection velocity is terminated the "*bottom mode*". Except for the normal wave incidence or the standing wave case caused by positive and negative progressive waves, the fluid mode could not manifest itself because of the too rapid alongshore translation for the perturbation to grow into appreciable intensity.

(b) In solving for bottom mode the basic equations, a physical interpretation of the phenomenon concerned will be introduced. One important way of analysis of the modern fluid dynamics is to attack complicated problems not necessarily purely mathematically but to solve them after the simplification of original equations through the physical interpretation of the basic equations. This attitude has been established by L. Prandtl when he proposed the concept of boundary layer in 1904.

Turning to our problem, the response of water-wave system is quick enough to the deformation of bottom boundary, while the bottom materials respond very much slowly to the change in the water-wave system. Therefore, the state of fluid system may be considered to be quasi-stationary. This is the *concept of response time* (Hino 1974). This idea has already been presented and applied in the writer's first paper (Hino and Hayashi 1972).

(c) Consequently, the flow field for an arbitrary bottom profile is solved from the continuity and momentum equations which include the radiation stress terms introduced by Longuet-Higgins and Stewart (1964). The resulting solutions of velocity components and the water surface elevation still contain the undetermined parameters which describe the bottom profile.

(d) Finally, the above solutions are substituted into the balance equation of bottom material transport. The problem is thus reduced to the *eigenvalue problem*. The rate of increase in the bottom perturbation is determined by the real part of eigenvalues dependent on the alongshore wavenumber of perturbation. On the other hand, the imaginary part of the eigenvalue predicts the propagation velocity of bottom perturbation, that is sand bars.

The components of an eigen-vector determine the unknown coefficients to describe the resulting perturbation in bed profile and thus velocity distribution.

In this way, we can determine not only the predominant spacing of rip-current but also the resulting bottom shape, the velocity field and the water surface elevation.

The idea of the response concept and a simplified mathematical treatment have already been presented at the previous Copenhagen conference.

THEORY

(a) Basic Equations

The basic equations are the same as the previous paper ;

[Equations of motion]

$$\begin{aligned} \frac{\partial [\rho(h+\eta)u]}{\partial t} + \frac{\partial [\rho(h+\eta)u^2]}{\partial x} + \frac{\partial [\rho(h+\eta)uv]}{\partial y} + \frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{xy}}{\partial y} \\ = -\rho g(h+\eta) \frac{\partial \eta}{\partial x} - \rho \zeta u \end{aligned} \quad (1)$$

$$\begin{aligned} \frac{\partial [\rho(h+\eta)v]}{\partial t} + \frac{\partial [\rho(h+\eta)uv]}{\partial x} + \frac{\partial [\rho(h+\eta)v^2]}{\partial y} + \frac{\partial S_{xy}}{\partial x} + \frac{\partial S_{yy}}{\partial y} \\ = -\rho g(h+\eta) \frac{\partial \eta}{\partial y} - \rho \zeta v \end{aligned} \quad (2)$$

[Continuity equation]

$$\frac{\partial (h+\eta)}{\partial t} + \frac{\partial [u(h+\eta)]}{\partial x} + \frac{\partial [v(h+\eta)]}{\partial y} = 0 \quad (3)$$

[Radiation stress relationship]

$$\begin{aligned} S_{xx} &= \frac{3E}{2} - Ec^2 \left(\frac{\sin\theta}{c}\right)^2 \\ S_{yy} &= \frac{E}{2} + Ec^2 \left(\frac{\sin\theta}{c}\right)^2 \\ S_{xy} &= Ec \cos\theta \left(\frac{\sin\theta}{c}\right) \end{aligned} \quad (4)$$

$$E = (\rho g \gamma^2 / 8) (h + \eta)^2 \quad (5)$$

$$c = \{g(h + \eta)\}^{1/2} \quad (6)$$

where $\tilde{\gamma}=1$ inside of breaker zone and zero outside of it.
[Balance equation of bottom material transport]

$$\frac{\partial h}{\partial t} = \frac{\partial(C_s u)}{\partial x} + \frac{\partial(C_s v)}{\partial y} \quad (7)$$

In the above equations, the coordinate system is chosen as shown in Fig. 1 ; u, v mean the velocity components in the x - and y -direction, respectively ; η and h are the mean water-level elevation above still water surface and the depth of bottom, respectively ; S_{xx}, S_{xy} , and S_{yy} represent the radiation stress tensor components ; c is the wave velocity, E the wave energy per unit area, \tilde{C} and C_s are the coefficients of bottom friction and bottom material transport, respectively.

(b) Perturbation Equations

Variables are expressed as sum of equilibrium states ($0, V_0, \eta_0$, and h_0) and small perturbations (u, v, η and h)

$$\begin{aligned} u(x, y, t) &\rightarrow u(x, y, t) \\ v(x, y, t) &\rightarrow V_0(x) + v(x, y, t) \\ \eta(x, y, t) &\rightarrow \eta_0(x) + \eta(x, y, t) \\ h(x, y, t) &\rightarrow h_0(x) + h(x, y, t) \end{aligned} \quad (8)$$

Furthermore, variables are nondimensionalized by L_b (the distance from shore to breaker) and $\sqrt{gL_b}$,

$$\begin{aligned} u/\sqrt{gL_b} &\rightarrow u, \quad v/\sqrt{gL_b} \rightarrow v, \quad V_o/\sqrt{gL_b} \rightarrow V_o \\ x/L_b &\rightarrow x, \quad y/L_b \rightarrow y, \quad h_o/L_b \rightarrow h_o \\ t\sqrt{g/L_b} &\rightarrow t, \quad c/\sqrt{gL_b} \rightarrow c, \quad C_s/L_b \rightarrow C_s \end{aligned} \quad (9)$$

Substituting eq.(8) into eqs.(1) through (7) and linearizing, a set of the linear partial equations are derived,

$$\begin{aligned} \frac{\partial w_i}{\partial t} + A_{i1}(x) \frac{\partial u}{\partial x} + A_{i2}(x) \frac{\partial u}{\partial y} + a_i(x)u \\ + B_{i1}(x) \frac{\partial v}{\partial x} + B_{i2}(x) \frac{\partial v}{\partial y} + b_i(x)v \\ + C_{i1}(x) \frac{\partial \eta}{\partial x} + C_{i2}(x) \frac{\partial \eta}{\partial y} + c_i(x)\eta \\ + D_{i1}(x) \frac{\partial h}{\partial x} + D_{i2}(x) \frac{\partial h}{\partial y} + d_i(x)h = 0 \end{aligned} \quad (10)$$

(i=1,2 and 3)

$$\frac{\partial h}{\partial t} = \frac{\partial C_s u}{\partial x} + \frac{\partial C_s v}{\partial y} \quad (11)$$

where $w_1=u$, $w_2=v$ and $w_3=\eta$, and V_o and $d\eta_o/dx$ which are given as the zero-th order approximation of the perturbation mean the alongshore current velocity and the gradient of wave-setup, respectively ;

$$\begin{aligned} V_o(x) = - \frac{5\gamma^2}{16C_d} (\cos\theta \cdot \sin\theta_b \cdot \sqrt{h_{ob} + \eta_{ob}}) \\ \cdot \frac{h_o + \eta_o}{h_{ob} + \eta_{ob}} \frac{d(h_o + \eta_o)}{dx} \end{aligned} \quad (12)$$

$$\frac{d\eta_o}{dx} = - \left(\frac{3\gamma^2}{8} \right) \frac{\cos^2\theta}{[1+(3\gamma^2/8)\cos^2\theta]} \cdot \frac{dh_o}{dx} \quad (13)$$

Coefficients A_{ij} , B_{ij} etc. are generally functions of x (For details, reference should be made to a paper (Hino 1975).).

(c) Quasi-steady Solution of Water System to Bottom Perturbation

The perturbation in depth profile $h(x,y)$ is expressed by the orthogonal Hermite functions as eq.(14),

$$h(x,y) = \delta \sum_n \mu_n / (\sqrt{(n-1)!}) \cdot H_{n-1}(x) e^{-x^2/4} e^{iky} \tag{14}$$

where δ expresses a parameter of amplitude, H_n is the Hermite function of n -th order and the expansion coefficients μ_n are unknown arbitrary constants to be determined later as a result of the eigenvalue problem.

The solution of fluid system (the velocity components u and v , and the mean surface elevation η) is assumed to be expanded also by the Hermite series as

$$\begin{aligned} u(x,y;t) &= \sum \frac{\alpha_{2n'}}{\sqrt{(2n'-1)!}} H_{2n'-1}(x) e^{-x^2/4} e^{iky} \\ v(x,y;t) &= \sum \frac{\beta_n}{\sqrt{(n-1)!}} H_{n-1}(x) e^{-x^2/4} e^{iky} \\ \eta(x,y;t) &= \sum \frac{\gamma_n}{\sqrt{(n-1)!}} H_{n-1}(x) e^{-x^2/4} e^{iky} \end{aligned} \tag{15}$$

where the boundary condition that u equals zero at $x=0$ is considered by using only the odd-order Hermite functions ; and the boundary conditions that at infinite x variables approach zero by the property of Hermite

functions ($H_n(x)e^{-x^2/4} \rightarrow 0$, when $x \rightarrow \infty$).

Substitution of eqs.(14) and (15) into eqs.(10), and applying the Galerkin method, i.e. integrating them between $(0, \infty)$ after multiplication of both hand side by $H_{m'-1}(x)e^{-x^2/4}/\sqrt{(m'-1)!}$ and putting the residue equal to zero, a set of simultaneous equations for coefficients vector $X = [\alpha_2, \alpha_4, \dots, \beta_1, \beta_2, \dots, \gamma_1, \gamma_2, \dots]^T$ is obtained as a function of $h(x,y)$ or coefficients μ_n ,

$$\begin{aligned} X &= -\delta(A^{-1}B)\mu \\ &= \delta D\mu \end{aligned} \tag{16}$$

$$\begin{aligned} X &= [\alpha_2, \alpha_4, \dots, \alpha_{N'}, \beta_1, \beta_2, \dots, \beta_N, \gamma_1, \gamma_2, \dots, \gamma_N]^T \\ & \quad ((N'+2N)+1 \text{ matrix}) \end{aligned} \tag{17}$$

$$A = \begin{bmatrix} I^{(1)} & J^{(1)} & K^{(1)} \\ I^{(2)} & J^{(2)} & K^{(2)} \\ I^{(3)} & J^{(3)} & K^{(3)} \end{bmatrix} \begin{matrix} ((N'+2N) \\ \times (N'+2N) \text{ matrix}) \end{matrix} \tag{18}$$

$$B = \begin{bmatrix} L^{(1)} \\ L^{(2)} \\ L^{(3)} \end{bmatrix} \quad (19)$$

$$D = \begin{bmatrix} a'_1 \\ \vdots \\ a'_N \\ b_1 \\ \vdots \\ b_N \\ c_1 \\ \vdots \\ c_N \end{bmatrix} \quad (20)$$

$$\begin{aligned} a'_k &= [a_{k1}, a_{k2}, \dots, a_{kN}] \\ b_k &= [b_{k1}, b_{k2}, \dots, b_{kN}] \\ c_k &= [c_{k1}, c_{k2}, \dots, c_{kN}] \end{aligned} \quad (21)$$

$$\mu = [\mu_1, \mu_2, \dots, \mu_N]^T \quad (22)$$

The elements of submatrices $I^{(i)}$, $J^{(i)}$, $K^{(i)}$ and $L^{(i)}$ are given in terms of coefficients A_{ij} , B_{ij} , \dots , a_i , b_1 and so on (Hino 1975).

Matrix D ($(N'+2N) \times N$ matrix) which can be decomposed into row vectors represents the contribution rate of bottom perturbation component $H_{n-1}(x)e^{-x^2/4}$ to velocity and mean surface elevation, u , v and η .

(c) Stability of Bottom Perturbation (Eigenvalue Problem of Bottom Mode Instability)

From the response concept, the amplitude factor δ of eq.(14) is assumed now a slowly varying function of time. Substitution of equations of u , v , η and h where the unknowns are the coefficient vector μ and the amplitude factor δ into eq.(11) yields

$$\begin{aligned} \dot{\delta}(t) & \sum_{n=1}^{\infty} \frac{H_n}{\sqrt{(n-1)!}} H_{n-1}(x) e^{-x^2/4} e^{iky} \\ & = \delta(t) C_s \left[\sum_{n=1}^{\infty} a_n \mu \{ H'_{n-1}(x) - \frac{x}{2} H_{n-1}(x) \} \right. \\ & \left. + (ik) \sum_{n=1}^{\infty} b_n \mu H_{n-1}(x) \right] e^{-x^2/4} e^{iky} \end{aligned} \quad (23)$$

Again applying the Galerkin technique, the following equation is obtained,

$$T\mu = p\mu \quad (24)$$

where p is the exponential growth rate

$$p = (d\delta/dt)/(C_s \delta) \quad (25)$$

and matrix T is composed of coefficients in matrix D (eqs.(43) through (47) in Hino, 1975).

Eq.(24) poses an eigenvalue problem for matrix T , the unknowns p and μ being eigenvalues and eigenvectors, respectively. These are solved numerically by a digital computer HITAC 8700/8400 of Computer Center, Tokyo Institute of Technology.

Two non-dimensional parameters, χ and ψ , are defined from factors affecting the phenomenon,

$$\begin{aligned} \chi & = s(\sin \theta/c)^2 \\ & = (h_b/L_b) \cdot (\sin \theta_b / \sqrt{h_b/L_b})^2 \\ & = \sin^2 \theta_b \end{aligned} \quad (26)$$

$$\begin{aligned} \psi & = s^2(\sin \theta_b/c) \\ & = (h_b/L_b)^{3/2} \sin \theta_b . \end{aligned} \quad (27)$$

RESULTS

(a) Instability diagram:

Fig. 2 shows some examples from the instability diagrams. The exponential growth rates (the maximum values of the real part of eigenvalues), $(Pr)_{\max}$, are plotted against the alongshore wavenumber k of perturbation for a selected combination of bottom slope $h_b = sL_b$ (L_b : distance to breaker zone). In these graphs, the parameter θ expresses the incident angle of waves.

It is shown that the perturbation in bottom configuration and consequently in wave field is most unstable to a certain wave number k_* of alongshore periodicity. Except for the normal incidence, $\theta=0$, the amplification rates become maximum at the nondimensional alongshore wave number of about $k=1.5$ or at the wave length of about 4 times the distance from shore to breaker.

Fig. 3 shows the relation between the most preferred alongshore wavenumber (nondimensional) k_* , the angle of incidence θ and the slope of the initial bottom s . As the bottom slope becomes steep, the preferred nondimensional spacing of rip current ($L_R = 2\pi/k_*$) increases. However, since the distance of breaker from shore also reduces, the real spacing of rip current (L_R)

$$\begin{aligned} L_R &= (2\pi/k_*) L_b \\ &= 2\pi h_b / s k_* \end{aligned} \quad (28)$$

(where h_b is the breaker depth) is estimated generally to become shortened.

(b) Propagation celerity of sandbars:

Moreover, it should be added that the present theory gives the celerity of alongshore translation of bottom perturbation as

$$C_* = p_i C_S / k \quad (29)$$

where p_i represents an imaginary part of the eigenvalue. Fig. 4 is a plot of the propagation velocity of sand bars.

(c) Rip-current and rip-channel:

By substituting the eigenvectors μ which determine the coefficients of perturbed bottom profile in eq. (24), into the series expression (eqs.(14) and (10)) of variables u , v , ζ and h , we are able to obtain the profiles of sand bars and the velocity fields.

Fig. 5 is the cross-sectional profile of a sand bar at various position along the shore. From this graph, a conclusion is derived that sand bars seem to progress onshore when observed at a cross-section perpendicular to the shore, although in reality they are propagated alongshore.

In Fig 6, the upper solid line gives the velocity of offshore current u , that is the rudimentary rip-current. The strength of velocity is the highest at the breaker zone. The lower thin solid curve is the change of bottom profile. This is the so-called rip-channel. The bottom is eroded inside and near the breaker zone, while sand materials are deposited offshore.

These results of theoretical analysis (Figs. 5 and 6) agree well with observed facts.

(d) Effect of initial bottom shape:

The initial bottom profiles are assumed to be represented by

$$h_0(x,y) \propto x^n \quad (30)$$

The upward convex bottom and the upward concave bottom are represented by $n > 1$ and $0 < n < 1$, respectively. Fig. 7 shows the instability diagrams for both cases, indicating that the upward convex shallow bottom is apt to change into rip current system.

(e) Relative importance of wave-setup, alongshore current and bottom friction:

The writer is interested in the relative importance of various intrinsic factors, such as those,

- (i) the wave setup which is caused by the radiation stress,
- (ii) the intensity of alongshore current which is also driven by the radiation stress,
- (iii) the friction factor which influences the intensity of alongshore current.

Since these factors are closely inter-connected each other, it is difficult separated them experimentally. However, in the theoretical analysis, it is possible to change artificially, for instance, the intensity of alongshore current alone, keeping the radiation stress or wave setup unchanged.

Fig. 8 (b) is the instability diagram when the radiation stress parameter γ is varied, keeping the alongshore current (lsc) unchanged. As the intensity of radiation stress is decreased the amplification rate of perturbation decreases. In reality, as the intensity of radiation stress is decreased, the alongshore current is also reduced. The left hand side figure (Fig. 8 (a)) shows the theoretical result for this case ($lsc = \text{real}$).

Fig. 8 (c) gives the instability diagram for a hypothetical case of no alongshore current ($lsc = 0$) even if there is the wave setup, when waves are incident obliquely. In this hypothetical case, the infinitesimal perturbation is also unstable; however there exist no predominant preferred wave number. The tendency is similar to the case of normal wave incidence ($\theta = 0$).

Fig. 9 (a) and (b) summarizes the results on the relationship between the radiation stress intensity and the preferred wavenumber of rip-current spacing ($\gamma \sim k_*$) and the exponential growth rate ($\gamma \sim \rho_*$), respectively.

One the other hand, Fig.10 examines the effects of the bottom friction, keeping the wave setup unchanged ; i.e. $\gamma=1$. Fig.10 (a) is the result for real case, Fig.10 (b) and (c) being the results for hypothetical cases of unchanged and no-alongshore current, respectively.

Fig. 11 (a) and (b) summarizes these results.

From these analytical computation, the following conclusion may be deduced ;

- (i) The main trigger of rip-current generation is the wave-setup caused by the radiation stress, rather than the alongshore current.
- (ii) The spacing of rip-current is dependent on the strength of alongshore current. If there were no alongshore current, there occurs no predominate wavenumber. As the intensity of alongshore current is increased, or the bottom friction is decreased, the preferred wavenumber of rip-current decreases. In other words, the spacing of rip-current becomes longer.
- (iii) When there is no wave-setup, the rip-current would not be formed, even if there were the alongshore current (c.f. especially, Fig. 8 (b) where the intensity of the alongshore current is as strong as for the case of real case caused by the radiation stress).

CHAPTER 79

A SAND BYPASSING SYSTEM USING A JET PUMP

by

E. C. McNair, Jr.¹

INTRODUCTION

All harbors and tidal inlets that are located in coastal areas have one characteristic in common--the need to bypass littoral materials that collect nearby. If natural harbors and tidal inlets are left unattended, bypassing will often occur naturally, but in the process, the harbor or inlet is usually rendered unfit for commercial or navigation purposes. Quite often, the inattention results in the total closure of the inlet. Therefore, at almost all harbor entrances and controlled tidal inlets, the natural bypassing must be augmented by secondary, usually mechanical, means.

The customary technique for bypassing sand and maintaining harbors and inlets is the use of floating dredge equipment. This equipment is rugged, reliable, has been proved over and over, and appears to be irreplaceable for many applications and locations. However, there are many locations and situations for which this floating equipment is not suitable and may, in fact, be detrimental or prohibitively costly. Waves of even moderate height, moderate-to-high tidal excursion and currents, draft limitations, limited maneuvering area, and interference with normal navigation operations are examples of conditions which decrease the desirability and application of floating dredge equipment. Small volumes of material to be bypassed are an economic liability for the floating plant since mobilization and demobilization costs contribute extraordinarily to the unit cost for bypassing work.

THE PROBLEM

In general, it is at the larger harbors and tidal inlets where the floating dredge equipment can be used effectively, efficiently, and economically.

¹Chief, Research Projects Group, Hydraulics Laboratory, U. S. Army Engineer Waterways Experiment Station, Vicksburg, MS.

Also, it is usually at the smaller harbors and tidal inlets that the use of floating dredge equipment to accomplish the desired bypassing activities becomes questionable.

Until the present time, the coastal engineer with the responsibility for maintaining the smaller coastal harbors and inlets had little choice in the selection of the mechanical means for bypassing sand. Floating dredge equipment was usually scheduled regardless of economy except in isolated cases where land-based pumping plants could be effectively used.

Obviously a need for improved operations and maintenance techniques and equipment for bypassing sand at tidal inlets and other littoral barriers exists. The problem is one to which the methods and procedures of research and development may be profitably applied. Therefore, a research program, sponsored by the Office, Chief of Engineers (OCE), was formulated and implemented for the purpose of improving operations and maintenance techniques specifically to develop effective and economical methods for sand bypassing at tidal inlets and other obstructions to littoral drift.

A review of existing equipment and proposed concepts identified the jet pump as having great potential as a primary component in a sand bypassing system. The survey conclusion was that a jet pump bypassing system requiring limited watercraft and personnel and capable of great portability and reliability can be assembled at a reasonable cost using off-the-shelf equipment. The research program was therefore designed to provide performance criteria, systems design parameters, and deployment and operational techniques for sand bypassing systems using jet pumps.

JET PUMP THEORY

Currently, jet pumps are, in general, used as suction boosters on centrifugal dredge pumps. There are several instances where eductors have been used alone for sand and gravel mining, but all of the equipment in use to date has been designed to meet low head applications. However, there is adequate theory and empirical information to show that the jet pump is capable of producing the higher discharge heads required for a bypassing installation.

The basic principle behind the operation of the jet pumps is the exchange of momentum. High-pressure fluid, normally supplied by a centrifugal pump, is forced through a converging jet nozzle and is converted into a high-velocity, low-pressure jet stream. This jet stream contacts the suction fluid at the nozzle exit and drags it into the pump, thus initiating and sustaining secondary flow of suction fluid from the surrounding water mass. If the surrounding water mass contains solids, or if solid particles are entrained in the secondary flow approaching the jet pump intake, then solids are introduced into the pump mixing chamber. In the mixing chamber, the high-energy jet stream and the suction fluid mix further, exchange momentum, and experience a pressure recovery. The mixed fluids or slurry then pass through a diverging diffuser and into a discharge pipe for delivery to a booster or to a discharge point.

Operational characteristics of the slurry jet pump can be described by three dimensionless ratios^{1,3}:

$$\text{Area ratio } B = \frac{\text{nozzle area}}{\text{mixing chamber area}} = \frac{A_j}{A_{mc}} \quad (1)$$

$$\text{Flow ratio } \phi = \frac{\text{pumping capacity}}{\text{driving capacity}} = \frac{Q_{suc} \gamma_{suc}}{Q_{sup} \gamma_{sup}} \quad (2)$$

$$\text{Head ratio } H = \frac{\text{net jet pump head}}{\text{net driving head}} = \frac{h_{dis} S_{dis} - h_{suc} S_{suc}}{h_{sup} S_{sup} - h_{dis} S_{dis}} \quad (3)$$

where

- A_j = nozzle area
- A_{mc} = mixing chamber area
- Q_{suc} = suction flow rate, gpm
- γ_{suc} = unit weight of suction slurry
- Q_{sup} = supply flow rate, gpm
- γ_{sup} = unit weight of drive fluid
- h_{dis} = total discharge head in feet of slurry
- S_{dis} = specific gravity of discharge slurry

- h_{suc} = total suction head in feet of slurry
- S_{suc} = specific gravity of suction slurry
- h_{sup} = total supply head in feet of drive fluid
- S_{sup} = specific gravity of drive fluid

Using conservation of momentum, mass, and energy, Govatos¹ derived the following equation to give the relationship between H , \emptyset , and B .

$$H = \frac{U - V - W}{W - U + X} \quad (4)$$

where

$$U = 2B + \frac{2(\emptyset B)^2 \gamma_w}{(1 - B) \gamma_{suc}} - \frac{B^2 (1 + \emptyset)^2 \gamma_w (2 + K_{mc})}{\gamma_{dis}} \quad (5)$$

$$V = \frac{\emptyset B}{1 - B} \frac{2(1 + K_s)}{S_{suc}} \quad (6)$$

$$W = B^2 (1 + \emptyset)^2 \frac{K_{dis} - 1}{S_{dis}} \quad (7)$$

$$X = 1 + K_j \quad (8)$$

and

- γ_w = unit weight of water, pcf
- K_{mc} = loss coefficient due to the mixing chamber
- γ_{dis} = unit weight of discharge slurry, pcf
- K_s = loss coefficient due to the suction nozzle
- K_{dis} = loss coefficient due to the diffuser
- K_j = loss coefficient due to the drive jet nozzle

A set of curves similar to those in Figure 1 (from Reference 2) can be plotted by using the above equations and assuming a suction concentration and average loss factors for water.

The efficiency of the jet pump is dependent on several factors, but primarily on pump geometry. The four major geometrical parameters affecting

Figure 1. The relationship between dimensionless head ratio H , dimensionless flow ratio ϕ , and dimensionless area ratio for assumed arbitrary loss factors in the jet pump

efficiency are area ratio, the nozzle distance or distance from the tip of the nozzle to the entrance of the mixing chamber, the mixing chamber length, and the diffuser angle. With the exception of the area ratio, which can be varied by changing the nozzle characteristics, the geometry of the jet pumps tested was not altered in the research program.

LABORATORY TESTS

A laboratory test program was begun in 1973 and is continuing at this time. The purpose of these tests is to verify the theoretical and empirical relationships describing jet pump performance, to develop pumping techniques and methods for deployment and application, and to develop auxiliary devices such as hydraulic cutting assists and flow measuring techniques. The laboratory tests are designed to develop practical, reliable components and techniques for field evaluation as well as criteria for system design.

The laboratory facility, shown on Figure 2, consists of an excavation with sloping sides approximately 150 ft square. The facility is lined with plastic membrane to prevent local soil contamination of 2400 cu yd of medium sand (400 μ) used in the test. The size of the facility allows testing of prototype-size (6-in. discharge line) equipment to eliminate problems in scaling and also to provide valid information on deployment techniques.

The pipe network consists of 6-in. schedule 40 steel pipe, 6-in. floating rubber hose, and 6-in. PVC hose. The rubber hose is commonly used in dredging and gives the laboratory system sufficient flexibility to be moved about the basin. Instrumentation of the pumping system consists of magnetic flowmeters on the supply and discharge lines, a nuclear density meter to measure the sand concentration in the discharge line, and pressure transducers which monitor supply pressure, discharge pressure, suction pressure, and ambient pressure.

The flotation system for the jet pump assembly consists of a hollow spherical buoy attached to the jet pump, 6-in. rubber hose, air lines, and an air compressor. Through the use of a simple valving system on the pier, the air compressor can be used to regulate the buoyancy of the sphere. Air can also be pumped into the 6-in. rubber hoses to increase their buoyancy.

Figure 2. Artist's concept of laboratory facility showing 150-sq ft basin, work platform and piping arrangement

The initial series of laboratory tests were performed to verify the observations and accounts of other investigators as reported in the literature. Tests were first performed by pumping only clear water. In later tests, mixtures of sand and water were pumped and system parameters were observed for those conditions. Examples of the results of some of these tests are shown on Figures 3a and 3b.

A sufficient number of observations were obtained from the initial laboratory experiments to support the design of a prototype system for field testing. It was expected that the ideal conditions of the laboratory facility would be only an approximation of field conditions and that many of the conclusions reached and techniques developed in the laboratory tests would be modified or discarded after field testing of the system.

FIELD TESTS

Several potential field sites were evaluated for their suitability for initial field testing. Among the sites considered were: Santa Cruz and Oceanside, California; Port Mansfield and Colorado River Mouth, Texas; Perdido Pass, Alabama; Michigan City, Indiana; Moriches, New York; Masonboro, North Carolina; and Mexico Beach, Florida. The evaluation procedure determined that Mexico Beach, Florida, was the most suitable site for our initial field testing.

Mexico Beach is located in the Florida Panhandle approximately 30 mi east of Panama City. The test site is adjacent to a small navigation inlet maintained by the township. Local conditions at the inlet (see Figure 4) consist of a sizable sand accretion westward of the two jetties protecting the inlet and eroding beach conditions to the east of the inlet. The littoral drift is estimated to be almost entirely eastward and is in the order of 40,000-50,000 cu yd annually.

A field test unit comprised of a truck-mounted centrifugal pump, instrumentation, discharge and supply lines, and a single four-inch-diameter intake jet pump was put into operation at Mexico Beach in 1973 (see Figure 5). These tests immediately revealed the need for improved deployment techniques, a more manageable buoy system, more efficient operational techniques, and cutting

Figure 3a. Head ratio, H, flow ratio, ϕ , relationships for clear water data

Figure 4. Mexico Beach, Florida, field site in 1972

Figure 5. Artist's concept of sand bypassing installation at Mexico Beach, Florida

assists to overcome the cementing agents found in most natural beach sands. Other problems were also identified, including that of plugging of the jet pump intake port by shell fragments or other foreign materials and weaknesses in the various system components.

The jet pump, rigidly attached buoys, and flexible hoses were deployed from the beach using a vehicle winch and two anchors on the offshore bar with a block attached. A system of two or more permanent anchors with blocks can readily be used to reposition the jet pump. A 1/2-in.-diameter pipe was tapped into the supply side of the jet pump and teed into a two-jet cutting assist. The cutting assist was required to initiate a crater when the suction pipe was oriented other than perpendicular to the bottom. The jet pump will self-enplace in its own crater. The pump can also be shut down at any time by balancing the supply flow and discharge flow (zero suction flow) for a sufficient time to flush the sand from the discharge line. The jet pump was left in a crater bottom on several occasions until the crater was completely filled. When the sand was about 8 ft over the suction pipe, several hours of pumping were required before the flotation buoys could free the jet pump. When temporary clogging of the suction pipe was encountered, a valve in the discharge line was closed and the supply water forced out of the suction pipe. This technique is termed backflushing and was required frequently due to significant amounts of large shells blocking the suction pipe. Backflushing is also useful in jetting the suction pipe into the bottom in order to obtain an overburden on the suction pipe.

Most problems were satisfactorily worked out for the Mexico Beach site, and the system was put into a more-or-less operational mode. Over a period of several months, approximately 20,000 cu yd of material were bypassed from the fillet west of the entrance. The production rate of the operational system varied considerably with local conditions, but averaged about 75 cu yd per hour of operation.

The concept of overland portability where the relatively expensive drive-water and booster pumps are used to service several jet-pump locations in a local area was also evaluated during the Gulf of Mexico field tests. A site at Destin, Florida, which is within reasonable driving distance of Mexico

Beach and which has problems with maintenance of a small navigation channel into a harbor area was selected for this evaluation. A jet pump with associated supply and discharge lines was deployed at the Destin site (see Figure 6). The truck-mounted pump was uncoupled at Mexico Beach, driven to the Destin site, and recoupled to the jet-pump piping. The discharge point at the Destin site was such that a booster was added to the system. Otherwise, operational procedures at the Destin site and at the Mexico Beach site were similar.

The overland portability concept was successfully demonstrated at the Gulf of Mexico sites. This technique is to be recommended when several bypassing problems exist in a local area.

The experience, knowledge, and techniques derived from the initial laboratory work and the Gulf of Mexico field work were called upon for design of a system for an Atlantic coast site. Rudee Inlet, Virginia, which has a low-weir sand impoundment basin, was selected as the research site.

The system, as finally configured (see Figure 7), consisted of two electrically driven centrifugal-pump jet-pump units coupled with a single diesel-driven slurry booster pump. The jet pumps and associated piping are suspended from a row of piling near the center of the deposition basin. By maneuvering the jet pumps, the deposition basin can be cleared of most sand deposits. During the field test at Rudee Inlet, approximately 75,000 cu yd of sand were pumped from the impoundment basin to the beach area north of the inlet.

The entrance to Santa Cruz Harbor, California, shown in Figure 8, has been selected as a Pacific coast research site with tests beginning in the summer of 1976. The installation consists of dual-jet-pump, single-booster system with bypassing being accomplished from the shoals which form near the entrance channel. The pumping system will be based on the west jetty of the harbor, and the jet pumps will be maneuvered either by cables from shore or by a small work boat.

DISCUSSION

The jet pump sand bypassing system is simple in design and application and offers the coastal engineer an additional option in his search for solutions

Figure 6. Artist's concept of sand bypassing installation at East Pass (Destin), Florida

Figure 7. Artist's concept of sand bypassing installation at Rudee Inlet (Virginia Beach), Virginia

Figure 8. Sand bypassing test site at Santa Cruz Harbor, California

to coastal problems. The system has been demonstrated to be rugged, reliable, and effective. During the field tests on the Gulf of Mexico and at Rudee Inlet, Virginia, the system operated successfully in the surf zone, in areas where the currents exceeded 2 knots, and in one instance, through a squall where wind speeds exceeded 50 knots and breaker heights were estimated at 8 ft. Principle advantages of the system are: its relatively low first cost; its tremendous flexibility in location of the jet pump intakes; its relative immunity to wave and current action; its simplicity of operation; and its noninterruption of navigation activities at a bypassing site. Disadvantages are: its proneness to plugging by shell fragments or other debris; and its relatively low production capacity (requiring perhaps continuous operation).

The research program is scheduled for completion in 1978 and publications to be released by that time will include systems design criteria.

ACKNOWLEDGEMENT

The work described herein is a portion of the Improvement of Operations and Maintenance Techniques research program of the U. S. Army Corps of Engineers, sponsored by the Office, Chief of Engineers, and performed at the U. S. Army Engineer Waterways Experiment Station. Permission to publish this description of this work is hereby acknowledged and is appreciated.

CHAPTER 80

SAND-BYPASS AND SHORE EROSION, BRIDGMAN, MICHIGAN

BY

C. N. JOHNSON AND L. W. HIIPAKKA¹

The objectives of this paper are two-fold:

- a. Demonstrate by means of a well-documented full-scale case history in the Great Lakes that beach nourishment can mitigate shore damage due to a littoral barrier;
- b. Detail a methodology for analysis of the effectiveness of mitigation measures which lead to conclusions on the needed frequency of nearshore soundings as a tool for monitoring.

In 1970 a temporary harbor was installed by private interests along the southeastern Lake Michigan shoreline near Bridgman, Michigan, (Figure 1). The harbor was necessary to protect floating plant involved in building a large privately-owned electric generating facility. The harbor was constructed of steel sheet pile and extended lakeward about 125 meters from the water's-edge to a depth about 3 meters below low water datum (LWD)². Net littoral transport is about 75,000 cubic meters per year southward. The updrift and downdrift lakebed and bluff materials consist of sand.

To ensure that this littoral barrier would not have an adverse effect on adjacent properties it was necessary for the Corps of Engineers to impose stringent requirements for issuance of a Federal permit for the installation. Bypass of at least 75,000 cubic meters per year of sand was required to mitigate potential erosion of downdrift beaches due to interruption of littoral transport. The permit also required intensive monitoring of the shoreline to ensure that any adverse effects of the harbor would be promptly detected and remedied. The monitoring consisted of:

- a. Monthly 1:3000 scale aerial photographs of the shoreline sixteen kilometers north (updrift) to sixteen kilometers south (downdrift) of the harbor.
- b. Monumenting and thrice-yearly measurement of backshore-nearshore profiles spaced 150 meters apart, for a distance of 2450 meters north and 2450 meters south of the harbor, extending about 900 meters lakeward to about -8 meters LWD (Figure 2). The nearshore soundings were made by acoustic sounder every 30 meters along each profile. The survey boat was located along the profile by triangulation. Backshore profiles were provided by photogrammetric mapping.

¹The authors are Hydraulic Engineers in the Coastal Engineering and Hydraulic Design Branch, U. S. Army Engineer Division, North Central, Chicago, Illinois, USA.

²Low water datum for Lake Michigan is 175.81 meters (576.8 feet) above mean sea level at Father Point, Quebec.

Figure 1. Location Map

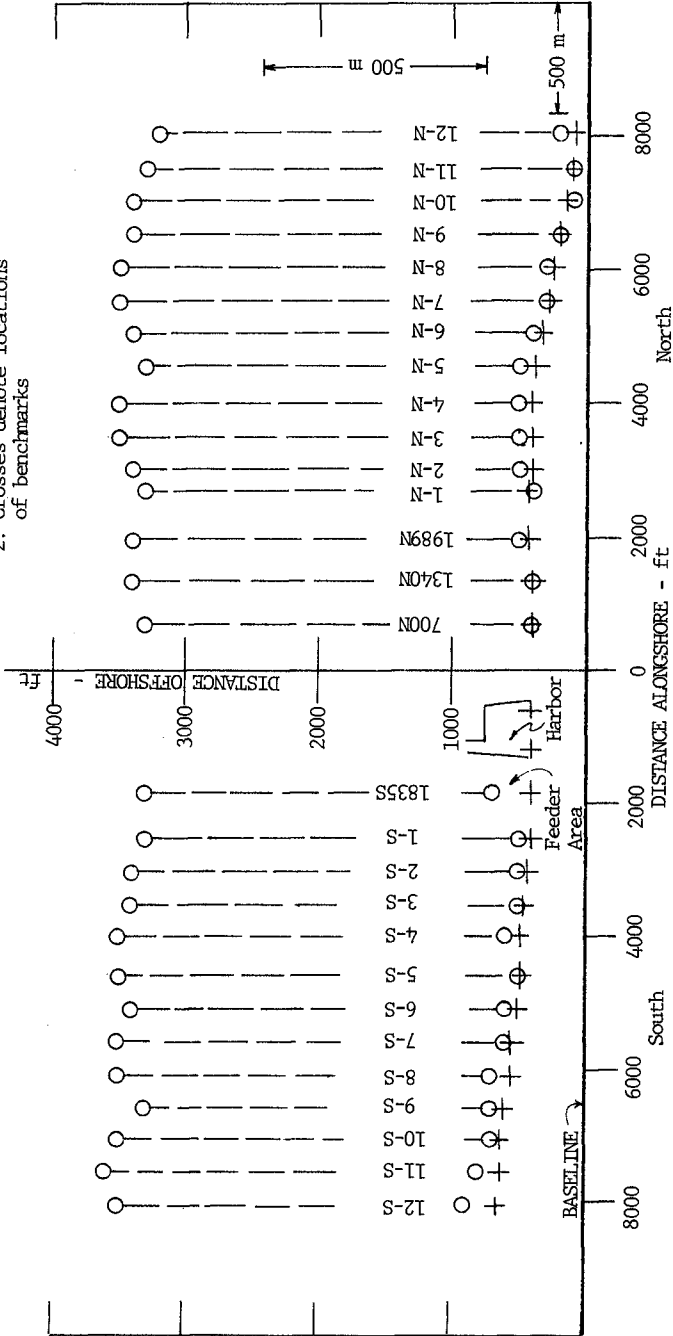

Figure 2. Layout of Harbor and Profiles

- c. Sand samples were taken during May 1973 at the water's edge, on the first and second sandbars for each profile and from the borrow sites. Additional water's-edge samples were taken during October 1973 near the property lines updrift and downdrift from the harbor.
- d. Wind speed and direction were recorded hourly near the water's-edge at an anemometer height of about 10 meters above LWD.

The permit went into effect and the temporary harbor was constructed in late 1970. The harbor was removed in late 1973. The monitoring program continued until December 1974. Tanner (1974) reported on an analysis of some of the resulting data. There is little overlap between his work and that of the authors.

The power company emplaced the following approximate quantities of sand in the feeder beach south of the harbor: 129,000 cubic meters in 1971, 143,000 cubic meters in 1972, and somewhat more than 230,000 cubic meters in 1973. About 40,000 cubic meters of those quantities were obtained by hydraulically bypassing sand from the accretion fillet. The remainder came from mining of the backshore dunes. The dune sand was used to comply with the permit requirements for a total of at least 75,000 cubic meters bypassed per year. The mined sand was much finer and better sorted than that of the beach north of the harbor. About 90% of the mined sand would be lost from the beach, based on overfill-ratio calculations (Shore Protection Manual, 1973) from the May 1973 sampling.

A thorough interim analysis of the data obtained as of October 1972 was done in early 1973 to determine if the sand-bypassing operation was mitigating the effects of the structure.

The results were as follows:

- a. There was no detectable net nearshore erosion or accretion. The nearshore profiles exhibited large volumetric fluctuations with time but little net change. Figures 3, 4, and 5 are examples. The straight lines on the plots are the regression lines of volume with time. Nearly all of the net changes were shown by t-test (Li, 1964) to be statistically insignificant at about the 80 percent level (Figure 6). There was no perceptible seasonal pattern.
- b. Volumetric bluff erosion varied considerable from profile to profile, but the average rate was essentially the same on both sides of the harbor (Figure 7). The symmetry of the average bluff erosion rates about the harbor indicate that the sand-bypassing and dune-mining operation compensated for sand entrapment by the littoral barrier.
- c. The analysis represented in Figure 8 shows that the nearshore profiles which eroded or accreted the most from July 1970 to

Figure 7. Beach and Bluff Volumetric Erosion Rates

Figure 8. Lack of relation between bluff profile-area changes and nearshore least-squares profile-area changes

October 1972 did not coincide with the bluff profiles which exhibited the greatest changes. The profiles chosen for this figure are those whose correlation coefficients fell outside of 95 percent lines and the 80 percent lines, respectively, in Figure 6.

- d. The lack of any perceptible trends in Figures 6 and 8 indicate that no net deposition of eroded bluff material could be detected in the nearshore zone.

A second analysis was done in late summer 1973, using additional data from April and July 1973. Two unusually severe storms occurred during the 1972-73 storm season. These two storms evidently eroded about 1.5 times as much bluff material as had occurred in the preceding 2.5 years. However, average erosion was the same on both sides of the harbor (Figure 7). This symmetry indicates the continuing success of the sand-bypassing operation since natural updrift bluff erosion equalled bluff erosion downdrift of the harbor.

The third and final analysis, using data from October 1973 through July 1974, was done in late 1974. The harbor was removed early in this period. Storm-season water-levels were about 1.0 meters above LWD, the same as during the 1972-73 storm season. This level was about 0.3 meters higher than during the 1970-71 and 1971-72 storm seasons. There were no storms during the 1973-74 storm season as severe as in the preceding storm season. Bluff erosion took place at roughly the same rate as during the first two years, even though the water level was much higher (Figure 9). Average erosion rates were lower south of the harbor (1.7 m³/m) than north of it (5.3 m³/m). Much of this difference may be due to the large volume of sand emplaced when the harbor was removed.

The sand samples were not taken over a sufficient number of years to justify making firm conclusions from them. However, a few working hypotheses for future research seem to be noteworthy.

- a. Figures 10 and 11 show typical particle-size gradations from the May 1973 samplings. These samples were taken at the end of the severe storm-season discussed above. For all profiles, the median particle sizes were larger at the water's-edge than on the bars. Figure 12 compares the May 1973 water's-edge computed composite and borrow samples with the October 1973 samples (Krumbein, 1957, describes how computed composites are derived). The May water's-edge samples are coarser than the October ones. The May borrow-material gradation was similar to the October water's-edge gradation. If the observed changes in water's-edge material from May to October are typical of seasonal effects, considerable caution should be used in specifying artificial beach-fill gradations based on summertime beach samples.
- b. Trend estimates of nearshore erosion in Lake Michigan and, probably, the other four Great Lakes can be very misleading if

Figure 9. Variation of Bluff Erosion Rate with Time

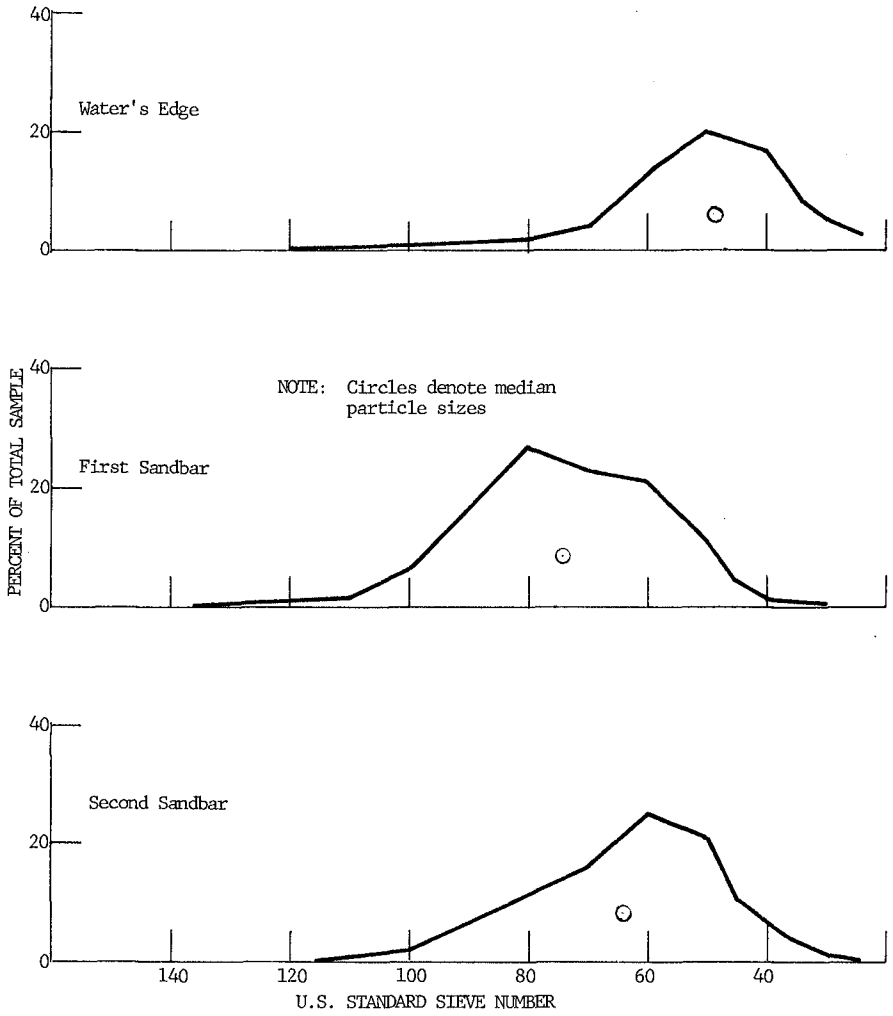

Figure 10. Particle Size Gradations as Function of Location
 - May 1973 Sampling, Profile 10-N

Figure 11. Particle Size Gradations as Function of Location
 - May 1973 Sampling, Profile 10-S

Figure 12. SAND PARTICLE SIZE DISTRIBUTION

based on soundings taken one or more years apart. As a consequence, soundings every three months apart for at least two years may be necessary to estimate the effects of random fluctuations on nearshore profiles.

- c. There was only weak correlation between Lake Michigan water levels and bluff erosion rates. Bluff erosion rates were highly variable from profile to profile. Severe storms seem to be the dominant factor in Lake Michigan shore erosion. Limited beach accretion, not erosion, took place when water levels were seasonally highest (summer). Erosion was severest during the late autumn and early spring when water levels were about 0.2 to 0.3 meters lower than their summer highs.
- d. Large quantities of finer-than-native sand, in excess of the longshore transport rate, were placed on the shore south (downdrift) of the harbor. Downdrift bluff erosion rates were the same as updrift in spite of the excessive quantities. These results imply that beach nourishment with finer-than-native sand may be an inefficient way to control erosion. In spite of the massive quantities of material, erosion still proceeded at the natural rate.

CHAPTER 81

DESIGN AND BEHAVIOUR OF SANDTRAPS IN REGIONS OF HIGH LITTORAL DRIFT

By

P.C.Saxena, P.P.Vaidyaraman, and R.Srinivasan

Central Water and Power Research Station, Pune, India.

1. Introduction :

Siltation in harbours and their approach channels is one of the major problems connected with the development of harbours. The economics of harbours are directly related to their annual maintenance dredging, and as such a proper assessment of the quantity of siltation and provision of adequate measures for the maintenance of depths would form an important part of planning the development programmes.

Siltation could occur due to various reasons viz. deposition of littoral drift which is interrupted by the approach channel, deposition of sediments brought into suspension by wave action (including during storm/cyclone) Whenever the alongshore drift is large, wave action obviously is quite substantial which renders the maintenance of depths during this period by dredging difficult. In such cases it would be necessary to make adequate provision to ensure that the depths are not deteriorated to any substantial extent by the movement of the drift. One of the common means for achieving this is the provision of sandtraps on the updrift side of the approach channel which would 'store' the drift material temporarily and from where the material could be dredged at convenience. The design of the sandtrap would be governed by a number of factors such as the extent over which a major part of the drift takes place, quantity of material transported, size distribution of sediments, velocity of currents, mode of dredging etc.

Waves of moderate to high intensity occurs along the eastern coast of India from south and south west direction during south west monsoon period from May to September and from North Easterly direction during North East monsoon beginning from November. In view of this climate the direction of drift along the shore changes with season. The quantities of drift during these periods are also different owing to the magnitude and periods of wave action which differs between the two seasons.

The net drift along this coast varies from 0.60 million m^3 at Madras on the south which increases progressively to 1.00 million m^3 at Paradip further North (Fig. 1).

Sandtraps are successfully employed for a number of ports along this coast to prevent the drift from deteriorating the channels. In this paper the case histories of some of these ports are discussed together with reference to the model studies carried out at the Central Water and Power Research Station, Pune for the design and layout of these sandtraps.

2. Methods of tackling littoral drift :

The method adopted for the tackling of littoral drift would be governed by the wave climate, the quantum of drift, the nature of operation of the port etc. The configuration of the coastline would also be modified by the drift as shown by Silvester *(1) who has made a comprehensive study of the sediment movement along the various coastlines of the world. Though this information is qualitative, it helps in a broad sense for the identification of the length of coastline which can affect the sediment supply to any specific location.

An idea of the rate of drift is generally obtained by making observations of the rate of accretion updrift of jetties as well as from the records of maintenance dredging. Johnson (2) has used this method of analysis in order to tabulate the rates of drift along the coastlines of the world. It could be seen from his tabulation that the littoral drift along Madras coast obtained by the measurement of rate of accretion south of the breakwater of Madras port is of the order of 0.60 million m³ (0.74 million cubicyards).

It is also well known that a major portion of the littoral transport occurs within the breaker zone. Hence other things remaining the same, the rate of drift per unit width of the coastline would be higher along a steeper coast as compared to a flatter one.

One of the methods adopted to maintain the inlets for navigation in a littoral drift zone has been by use of sand pumps. The material dredged from the entrance to the inlet by the sand pumps are generally pumped on to the down drift side for re-establishing the littoral drift cut off by the inlet. This method has been found to be successful along the Atlantic coast of USA for the maintenance of small inlets. Similar method was also adopted for the maintenance of the approach channel to Durban Harbour South Africa. In India, this type of dredging for a major harbour was considered for the first time in the case Paradip port (in Orissa State) on the east coast.

Though a Sand pump mounted on a trestle forms a fairly simple method for tackling the drift problems, various difficulties connected with the maintenance of the pumps, cavitation and their limited mobility render them unsuitable for universal adoption. Accordingly, provision of sand traps of maintenance by mobile dredger etc. have been found to be more favourable during recent times.

*. References are given at the end of the text.

3. Types and sizes of sandtraps :

Depending upon the site conditions, the orientation, size and location of the sandtraps would vary from place to place. A shallow irregular natural depression at Durban Harbour has been utilised to serve as a sandtrap whereas at Paradip and Visakhapatnam Ports trapezoidal shapes have been adopted. As already mentioned earlier, the inability to dredge during the period of occurrence of littoral drift necessitates storage of the drift material in the trap. The quantum to be stored (and the allowable extent of sand bypassing) would depend upon the individual site conditions. Where the coastline is steep the available space for provision of the trap would also be limited in the seaward direction.

The provision of an island breakwater would considerably help in overcoming this difficulty in that the capacity requirement of the trap could be somewhat reduced since the tranquillity conditions made available by the breakwater would help in continuing the dredging operations over a longer period of time than otherwise possible. Such an example is found in the case of Visakhapatnam Outer Harbour, a major port on the east coast of India, as well as in the case of the Port of Gopalpur also located along the same coast (Fig. 1). The following illustrations are given in order to highlight the aspects mentioned above.

4. Case histories:

4.1 Visakhapatnam Port:

The Port of Visakhapatnam is located on the eastern coast in the State of Andhra Pradesh at a distance from 12.50 km north of the tip of the Indian Peninsula. This port is one of the oldest ports in India and was originally brought into operation in order to cater to vessels drawing upto 10 m for a traffic of 4 million tonnes of general cargo (Fig. 2). The littoral drift being large, a sandtrap existed updrift of the approach channel from where the material was periodically dredged. During 1967, with the advent of iron ore mining industry and the mechanisation of mining at Baladilla, Madhya Pradesh and the expansion of the harbour facilities the development of an Outer Harbour for deep draft ocean carriers was found essential. The total traffic anticipated was then estimated to be of the order of 12 million tonnes of iron ore. The layout of the outer harbour consisting of three breakwaters (southern, northern and eastern) providing thereby a sheltered basin for the development of berths was envisaged to cater for this traffic. The net littoral drift in this region is estimated to be of the order of 0.70 million cubic metres per annum with the predominantly northerly drift of 0.88 million cubic metres during the SW monsoon period

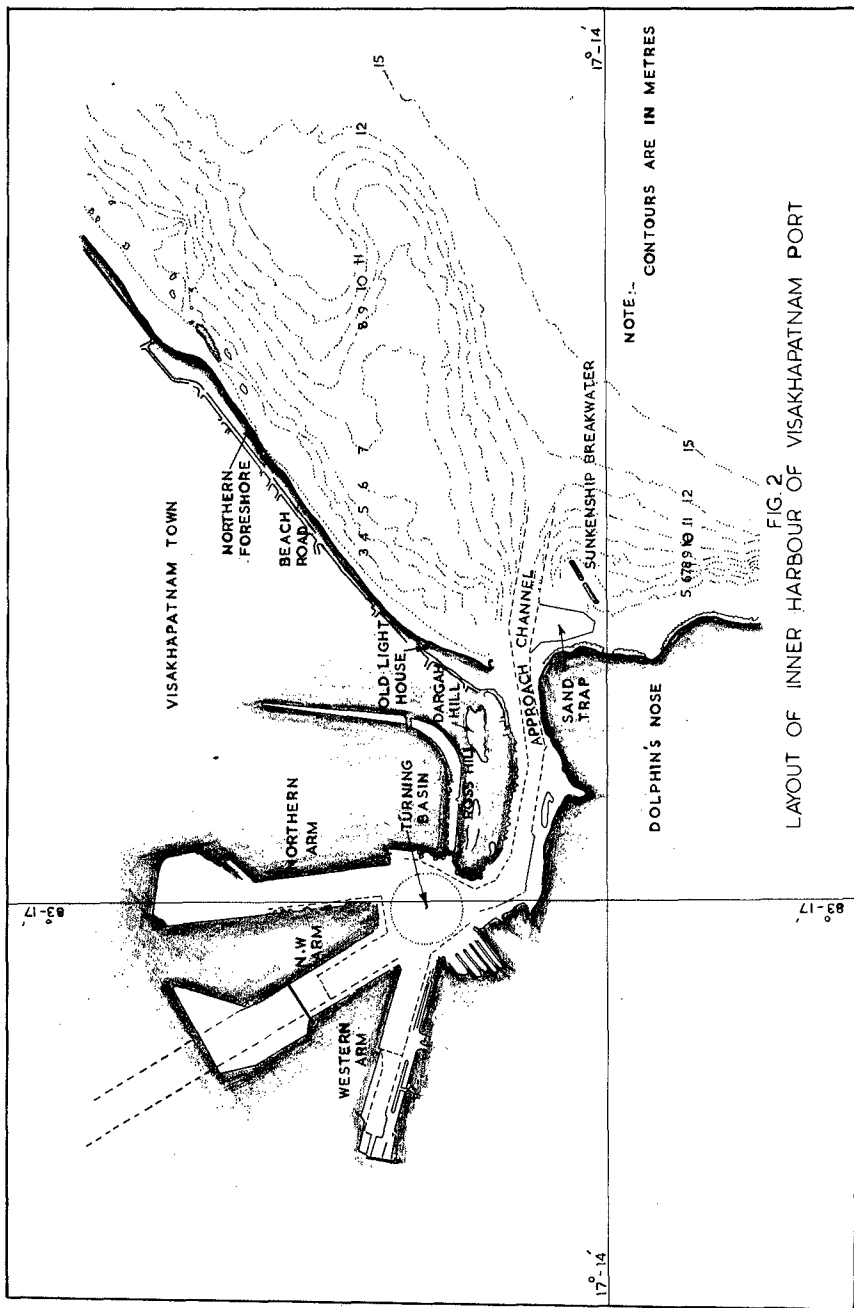

FIG. 2 LAYOUT OF INNER HARBOUR OF VISAKHAPATNAM PORT

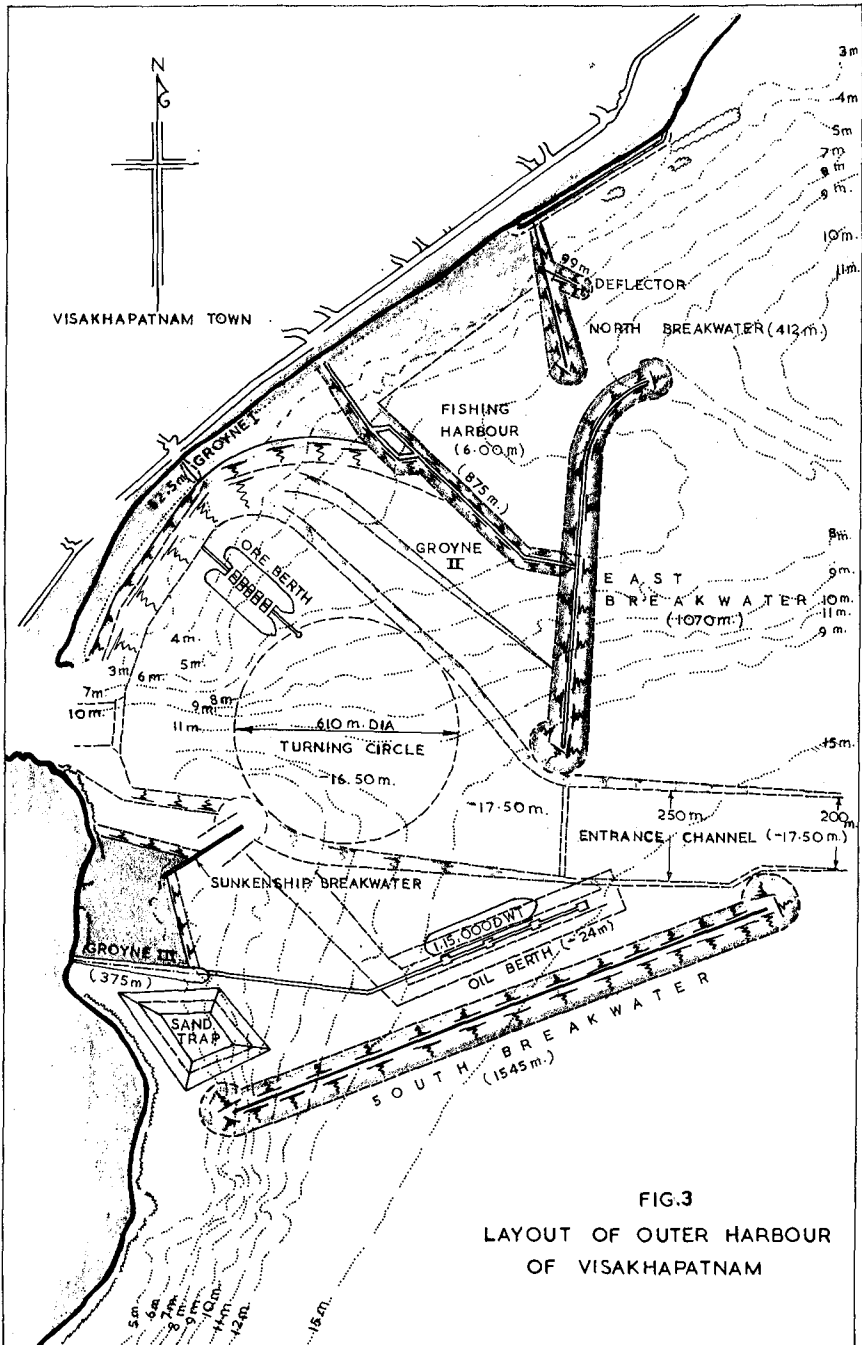

FIG.3
LAYOUT OF OUTER HARBOUR
OF VISAKHAPATNAM

from April to September and weaker return drift of 0.18 million cubic metre during the NE monsoon period from November-January. The coastline in this region is very steep being of the order of 1:10 in the nearshore region, and the 6 m contour is only at a distance of 150 m from the coastline. This obviously would result in the establishment of the breaker zone near the shoreline. As a major part of the drift is confined only to the region between the shoreline and the breaker zone, the conditions for locating the sandtrap are critical and accordingly a sandtrap was located in the gap between the sunken ship breakwaters and the shoreline as shown in Fig. 2. With the development of the outer harbour, this sandtrap originally provided no longer served the needs and its location had to be changed.

Extensive model studies were carried out at the CWPRS in order to determine the best location and the alignment of the sandtrap. The southern breakwater was located in this layout in such a way as to provide the necessary width for the entry of littoral drift into the sandtrap. It was found necessary to ensure that consequent upon the filling of the sandtrap the entrance does not get choked which, if allowed to happen, would have the result of making the trap ineffective during subsequent seasons. A mobile bed wave model built to scales 1:240 H, and 1:80 V was utilised for these studies and the sediment movement was reproduced by using crushed walnut shell having a specific gravity of 1.36 and a median diameter of 0.50mm. Deposition in different areas with the drift reproduced was ascertained from these model studies from which it was ensured that the trap having dimensions of 260m x 180m should provide a capacity of 0.62 million cubic metre which would be quite effective in trapping the material. The final layout is shown in Fig. 3. The sandtrap has been recently dredged at the Port and it is understood that its performance is satisfactory.

4.2 Paradip Port:

Paradip, another major harbour on the eastern coast of India is located 450 km north of Visakhapatnam Port. The main export through this port is iron ore to Japan to an extent of 2 million tonnes. The facilities at present consist of an iron ore jetty capable of accommodating 60,000 DWT ore carriers and a cargo berth for 18,000 tonne cargo vessels. The physical conditions at Paradip are somewhat different from those existing at Visakhapatnam. The slope of the beach at Paradip is much flatter, of the order of 1:80. The frequency and intensity of cyclones at Paradip are also much higher as compared to Visakhapatnam. Flatter beach slopes at this Port result in much longer approach channel for this port and as the littoral drift will be taking place over a much wider region, the size of the sandtrap would also have to be larger to trap a substantial part of the drift. This would necessitate providing a much wider gap between the shoreline and the island breakwater which would increase the transmission of wave energy into the harbour entrance and consequently create more wave disturbance. Accordingly it was necessary to modify the location of the sandtrap and the layout of

the breakwaters to overcome this problem. This layout is shown in Fig. 4. In order to bypass the northerly drift material which would get accumulated south of the southern breakwater, it was proposed to use a sand pump having a capacity of 350 cubic metres per hour moving on a trestle 250 m long for pumping sand and discharging the same to the northern side for nourishment by means of a floating pipeline across the harbour entrance. This would also help in minimising erosion of the coastline north of the harbour.

The harbour construction was completed during 1965 and the port started functioning formally from March 1966. However, due to various problems, the sand pump could not come into operation within the stipulated time. Consequently considerable accretion on the southern side of the breakwater took place besides erosion on the northern side. By 1967 the fillet on the south side was completely saturated with drift material and gradually the material found its way into the approach channel around the tip of the roundhead resulting in the formation of a shoal in the approach channel restricting the entrance width and depth considerably.

Detailed studies were carried out in a hydraulic model and it was considered that a sandtrap having a capacity of 0.8 m cubic metre as shown in Fig. 4 was necessary for this port. This sandtrap could intercept the drift during the south-west monsoon period and could be dredged during the subsequent fair weather season by the port's dredger (cutter suction hopper dredger). Accordingly the sandtrap was dredged during 1969-70 by a contract dredging. The data available subsequently has been analysed in order to examine the behaviour of the trap. Fig. 5 shows the differential depth contours during the monsoons from 1970 to 1974 at the sandtrap. It could be seen from this figure that during the year, 1970 and 1971, the loss of depth outside the sandtrap is practically negligible, whereas considerable loss of depth is found to occur east-wards beyond the confines of sandtrap subsequent to 1971 thereby indicating that the zone of pre-dominant sediment movement is extended east-wards due to the flattening of the beach slope. Fig. 6 shows a comparison of the cross sections of the beach updrift of the trap. It may be mentioned that the design of the sandtrap is evolved assuming that the sand pump could come into the operation so that it could help in maintaining the beach slope updrift of the trap. However, even after the installation of the pump during 1971, the dredging was not very satisfactory resulting in the flattening of the slope mentioned earlier. Fig. 7 shows the loss of mean depths during different monsoons at various sections of the channel. It could be seen from this figure, that during the initial periods after the dredging of the trap, the loss of depth was confined only to a small distance from the approach channel from the tip of the breakwater, the length extending further east-wards during the subsequent periods for reasons already mentioned.

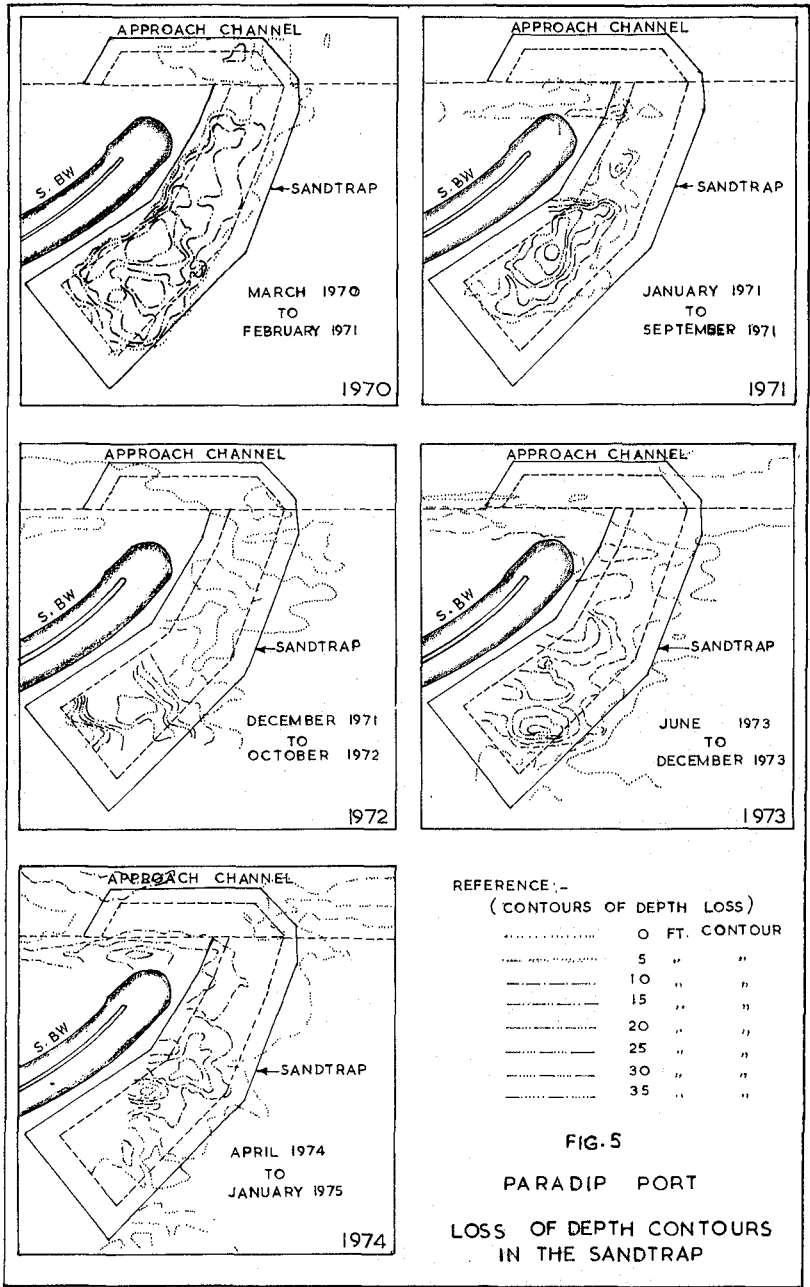

FIG. 4
APPROACHES TO PARADIP PORT

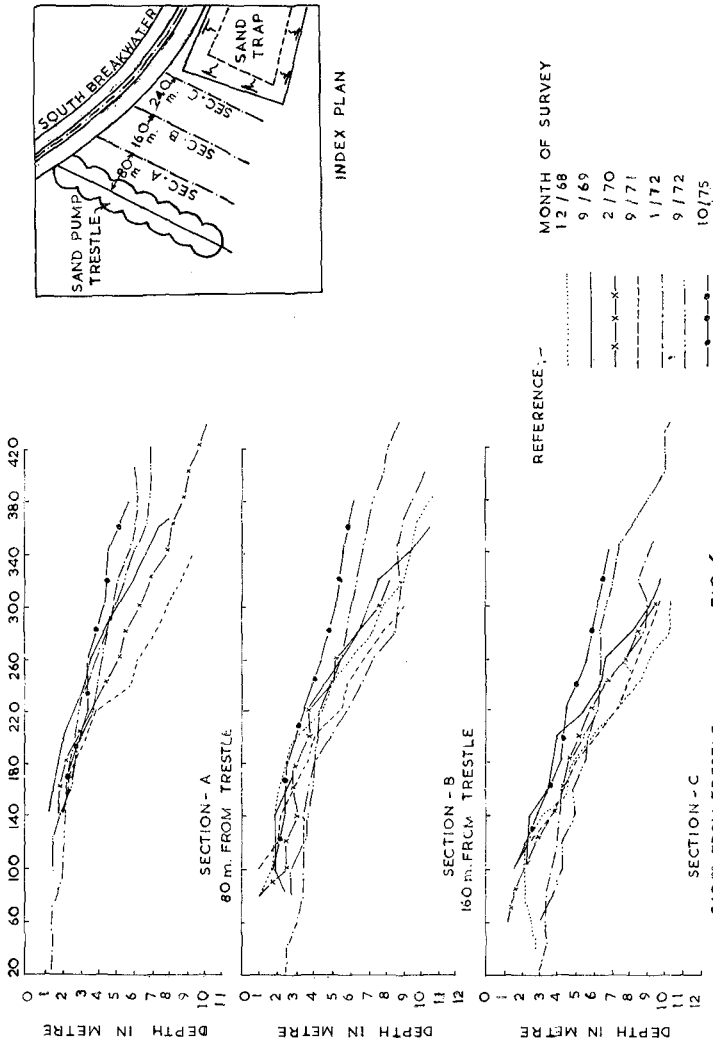

FIG. 6
CHANGE OF CROSS SECTIONS BETWEEN THE TRESTLE AND THE SANDTRAP DURING DIFFERENT PERIODS.

Since this region is situated in an intensely cyclonic zone, the effect of cyclones on the siltation pattern in the approach channel also needs consideration. The currents due to cyclones some times tend to act in a direction opposite to the prevailing littoral currents and affect siltation in the approach channel. This could be seen from the effect of a typical cyclone which occurred during 1-10-1971, during which the siltation was along the northern edge of the channel. An additional sandtrap in continuation with the approach channel along the northern edge of the approach channel was dredged by the port authorities in order to provide for such eventualities.

4.3 Kakinada Port:

The Port of Kakinada is an intermediate port located at Kakinada to a distance of 120 km south of Visakhapatnam. The total traffic through this port is of the order of 0.3 million tonnes consisting mainly of iron ore, rice bran etc. The old port is located 4 km inside a canal into which barges requiring upto 2 m draft navigate. The canal meets the bay called the Kakinada Bay which is formed by a sandspit about 10 km long bordering along the eastern side (Fig. 8).

The history of the sandspit is very interesting from the engineering point of view. Before 1850 the sandspit was completely absent in this region and subsequently due to the changes in the outfall in the River Godavari the formation of the sandspit took place gradually. Fig. 9 shows the formation of the sandspit at different times. With the absence of river flows into the Kakinada bay, the flushing characteristics changed considerably, and siltation of the bay started taking place from the south and SW side. The bay was gradually converted into a tidal bay. The opening at the mouth of the bay would therefore be the function of the relative flushing ability of the bay vis a vis strength of the littoral drift. The cross section area of the mouth of the inlet would therefore follow a law similar to O'Brien (3) who studied the effect of tidal prism in maintaining the inlets in the number of cases.

Recently, expansion of the port has been envisaged by the port authorities for traffic upto 1.5 million tonnes. One of the proposals for this expansion is the provision of mooring facilities west of the sandspit taking advantage of the shelter offered by the spit from wave action. The development and the stabilisation in the sandspit would therefore be of major importance in this programme.

Extensive model studies were conducted in a tidal-cum-wave model built to scales 1:600 Horizontal and 1:40 Vertical and injecting crushed walnut shell for reproducing littoral drift. It

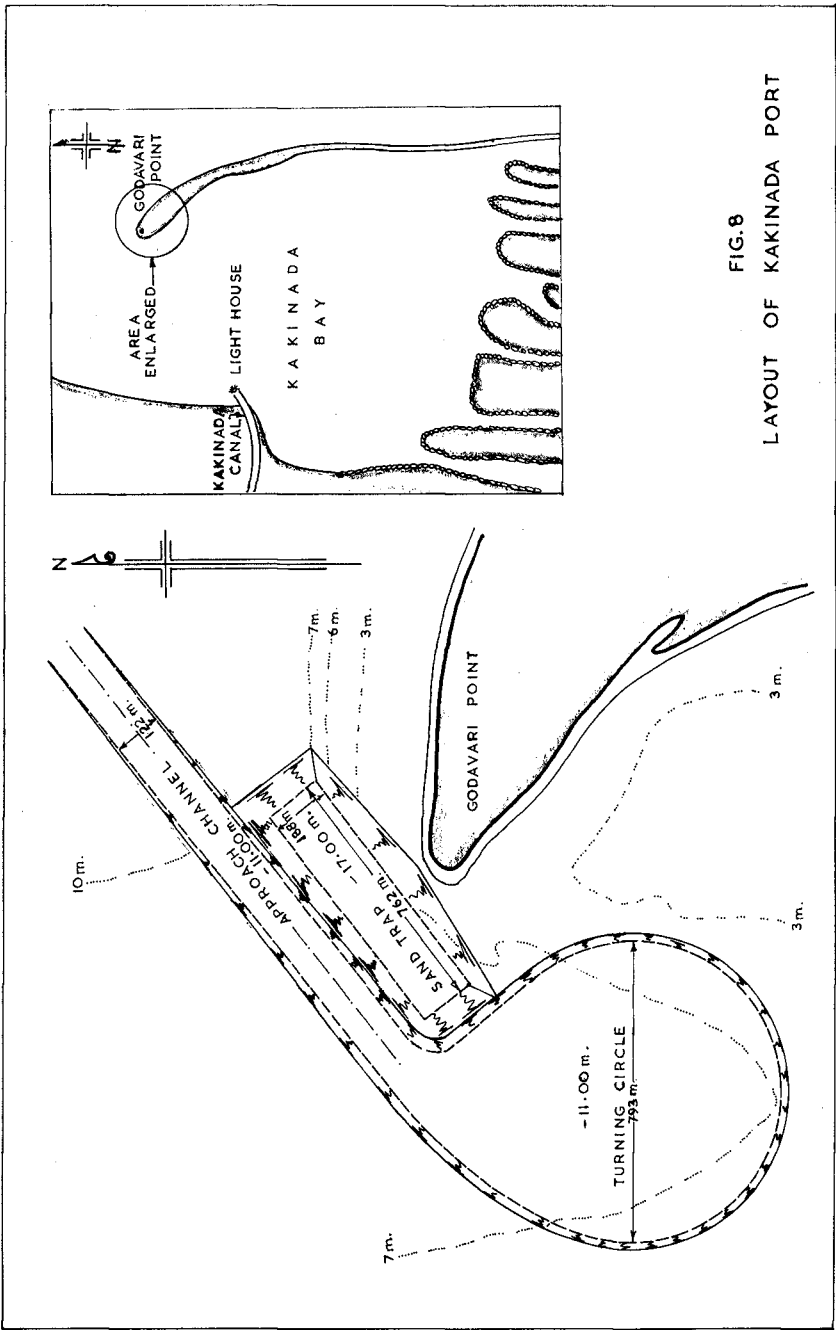

FIG.8
LAYOUT OF KAKINADA PORT

was found that the provision of a sandtrap in the vicinity of the tip of the sandspit would be helpful in preventing the deterioration of the channel due to littoral drift.

These experiments were carried out reproducing in the model a duration equivalent of 25 years in the prototype. The annual maintenance dredging was also reproduced during these tests. It was found that during initial years when the tip of the sandspit is away from the edge of the sandtrap the quantity of siltation in the trap is low and a major part of the drift is utilized only in shallowing of the regions between the edge of the trap and the tip of the sandspit. As this region becomes shallower, the quantum of siltation in the trap increased progressively so that after a period of 10 years, the total quantity of siltation is 60 % of the drift which increases to practically the entire drift after a period of 20 years.

These studies illustrate the long term experiments that would be required as a progressive increase in the quantum of siltation necessitate a corresponding increase in the capacity of the trap.

A proposal to construct a breakwater across the bay from the shore and provide berthing facilities near the entrance where depths are adequate is also under consideration. Studies in the model indicated that this would result in increasing the flushing velocities to a considerable extent because of the constriction of the bay and the area at the mouth. As a consequence it was also found necessary to alter the orientation and location of the sandtrap since a shifting of the direction of extension of the sandspit was seen to take place towards the easterly direction.

5. Conclusions:

The above examples are intended to illustrate the means of effectively maintaining the channel and prevent the drift from affecting depths at the approach channel and the harbour entrance. The variation in the meteorological, geomorphological and physical conditions would require different considerations in their design and where one type would be suited, it may prove to be unsuitable in a different location even along the same coast because of the different physical factors. Further the fact that the slope of the beach on the updrift side should be maintained without too much of a change for an efficient functioning of sandtrap is well brought out in the case of Paradip. The experience in Paradip also indicates that besides the pre-dominant direction of drift due to wave action the effects of currents generated by storms would also need to be carefully considered. The sandspit development in the case of Kakinada is a unique feature which calls for a different type of analysis and studies in the proper location and design of sandtrap. The need for studying the behaviour of the sandtrap over a long term period has also been brought out.

The above studies also indicated the relatively minor role played by sand pumps in the regions where the littoral drift are substantially large. It is necessary to go in for more reliable dredging equipment and methods in order to ensure the infallibility of the proposals.

Acknowledgements:

The data obtained from the respective project authorities have been made use of in the above discussions which is gratefully acknowledged. Extensive use has also been made of the various reports and notes of the Research Station prepared from time to time.

The authors also acknowledge the help received from Mr. V.V.Vaze in the analysis of the data and carrying out the model studies.

CHAPTER 82

HEADLAND DEFENSE OF COASTS

Richard Silvester, University of Western Australia
Nedlands, 6009, W.A.

ABSTRACT

Crenulate shaped bays are ubiquitous and constitute the largest proportion of coastline length. The characteristics of stable bays (i.e., no littoral drift) are known, so that realistic encroachment limits can be defined. Allowances for long term changes in direction of persistent swell and annual attack from multidirectional storm waves may have to be made. The exposure of a rock outcrop during an erosive sequence will create a new fixed point on the coast and hence a new bayed system. An existing non-stable bay can be prevented from indenting to its equilibrium shape by the construction of one or more fixed points around its periphery. Research should be conducted to minimise the cost of headlands which might start off as offshore breakwaters, even mobile units.

INTRODUCTION

Observance at the shoreline itself, or better still hydrographic charts of same, will immediately highlight the predominance of bays as coastal features. These sandy stretches are strung between headlands, with outlines that are produced by the incoming persistent waves (generally the swell). The presence of such features, together with other obvious indicators, has been used by the author in 1962 to determine net-sediment movement around the coastlines of the world (1) (2).

A worthwhile analogy appears to be clothes hanging loosely on a clothesline. When the wind arrives normal to the wire, the edges of the fabric assume a symmetric cartenary between the pegged points. No matter what the spacing some curvature will occur. The degree of indentation of the cartenary is dictated by the length of fabric caught between the pegs, as illustrated in Figure 1A. In coastal terms the variable is the volume of sand available to construct the beach. Sometimes when there is a surfeit of sand in a batch supply a spit may be formed which encloses a body of water in the form of a lake or lagoon. This is exemplified in Figure 2A, a feature which exists along many sea margins.

There is no equivalent to the sand spit in the cloth hanging analogy but it can be pursued with advantage a little further. When the wind blows obliquely to the peg line the cartenaries are skewed as depicted in Figure 1B. A large section of the cloth edge is pulled normal to the wind vector, causing the remainder to be stressed into a curve. The indentation as before is dependent upon the tautness of the original pegging. Again the analogy can breakdown, by nature constructing spits to form the crenulate shape that has the characteristics of an equilibrium bay. (See Figure 2B)

Fig.1. Analogy for crenulate shaped bays of clothes pegged to a line.

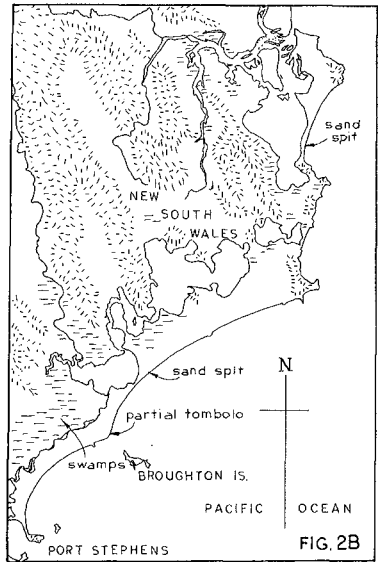

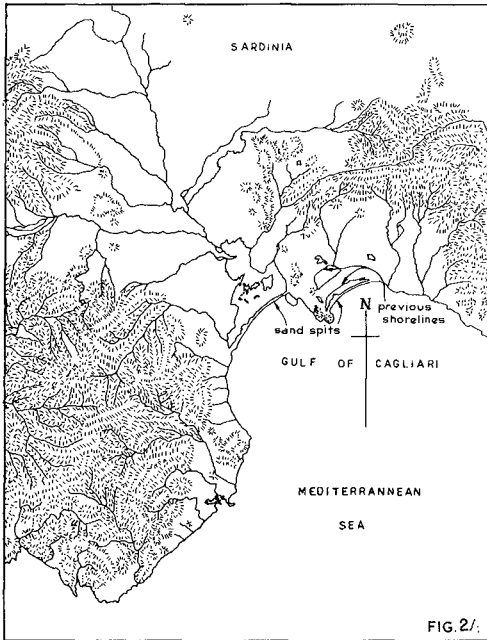

Fig.2 Sand spits formed between headlands enclosing bodies of water. A: with normal wave approach B: with oblique wave approach.

Where a clothesline changes direction, say at right angles as in Figure 1C, the fabrics will be skewed differing amounts and perhaps in differing directions by a given wind. The author has noted this drastic change in two adjacent bays at Point Reyes, California (3) but a further example is illustrated in Figure 3.

The forcing function in the clothesline case is the wind, which produces immediate results on the clothes. The sculpturing strength for shorelines also originates from the wind but is effective per medium of the waves it generates, both locally and far away. As noted by the author elsewhere (4) the generation of waves in the various oceans is reasonably repetitive and hence natural bays exhibit the integrated influence of swell over decades and centuries.

BAY FEATURES

The characteristic of crenulate shaped bays produced by waves arriving obliquely to the alignment of two consecutive headlands has been detailed already (4) (5) but should be recapitulated here. As seen in Figure 4, such a bay comprises a tangential downcoast section and a curved upcoast zone. The resultant shoreline shape is caused by both wave diffraction and refraction (6) in the lee of the upcoast headland. The degree of indentation (termed a in Figure 4) is dictated by a number of variables, namely, the obliquity of the predominant waves (β) to the headland alignment the spacing (b) between the headlands and the supply conditions of sand from upcoast or from river mouths within the bay.

As illustrated in Figure 4 the angle β between the incoming wave crests and the headland alignment is similar to the angle between the tangential coastline and this alignment. This is easier to measure because wave approach from deep water to some representative depth along the seaward extremity of the bay is difficult to determine, even if the predominant 12 second swell is adopted (7) for this purpose. It is the value of β at the fully stable condition that should be used in relationships to be discussed later. However, at the downcoast extremity of the tangent zone this angle is exhibited even in a bay still eroding to its final stable shape. Progressive indentation is achieved by the lengthening of this beach line angled β to the headland alignment.

The spacing (b), within which the bay can form, is related to (a) and (β) by a graph as in Figure 5. This has been derived (6) from model tests and measurements made of natural bays known to be in equilibrium, from their location on a coast and obvious lack of sediment supply. Although the ratio a/b tends to zero as β decreases there will always be a little indentation even with normally approaching swell. This is because a net longshore drift of zero may be made up of an annual drift in each direction of similar magnitude. The other limit of 50° for waves arriving parallel to the headland alignment is not likely ever to be realised because of prior refraction across the continental shelf. It could only result in a lake situation where the predominant waves are locally generated and they are of short period. In this case the curved shoreline will be almost circular in character due to diffraction dictating the crest curvature in this shadow zone.

It has been shown (4) (8) that the curved portion of the coast generally follows a logarithmic spiral, the details of which are illustrated in Figure 6. The ratio of successive radii (R_2/R_1) results from the angle (θ)

Fig.3. Variable shape and orientation a/b of crenulate shaped bays for a specific approach direction of predominant swells in deep water.

Fig.6. Definition sketch of logarithmic spiral.

Fig.5. Indentation ratio a/b versus wave approach angle β .

Fig.4 Definition sketch of crenulate shaped bay.

between them and the constant angle (α) between the radius and the tangent. The degree of curvature is given by α whence a logarithmic spiral can be drawn once θ has been chosen. A series of such spirals have been provided by the author (4). It should be noted that the size of the bay or of the plan being examined is of little consequence as the same value of α or R_2/R_1 will result, only a different section of the curve will be utilised. For equilibrium conditions the curve relating β to α is given in Figure 7. Whilst a bay is receding to this stable shape, values of α vary in a consistent manner with angle β as shown elsewhere (3) (4).

When in equilibrium a bay suffers no littoral drift since the predominant waves are arriving normal to the beach at all points around the periphery. This does not preclude the possibility of batches of sediment arriving sporadically from upcoast. This will mainly be transmitted across the bay to the intersection of the tangent curved zones as proven by tracer tests in Australia (9). Because of the almost normal approach of the waves the longshore component of their energy is slight, so requiring the offshore zone to accrete to the stage where the waves can handle the load to be transmitted.

The offshore shoaling lessens the demand for material to construct the bar during storm sequences. This reduces the berm width which is indicative of the active beach which goes to sea and back again in the course of each two or three years. The good protection so afforded makes little or no demand on the sand dunes being constructed by wind blown sand which therefore grow to much greater height along the tangential section of the bay than along the curved zone.

USE OF CHARACTERISTICS

Whilst the evaluation of a/b and α for a measured β may indicate a bay to be in a non-stable condition, this is not the case if the present sand supply to the bay equals the rate of removal by the waves. If an embayment is not fully receded the plotted point will fall below the curve in Figure 5 and above the curve in Figure 7. By using the a/b and α values on the curves an equilibrium shape can be drawn for this bay which indicates the limit of erosion if and when all sediment supply is stopped. It is on this basis that more realistic encroachment lines may be determined than setting back fixed distances along the whole periphery of a bay.

When so determining building lines, due allowance should be made for annual give-and-take by storm waves. These waves can arrive from almost any seaward direction. The erosive effects of arrival from three major obliquities are illustrated in Figure 8, where the width of lost beach varies according to this angle. The presentation does not take into account the likely offshore slope variation around the bay. The tangential stretch should have a milder bed slope than the curved zone, which infers that less material is demanded to construct the protective offshore bar during storm sequences.

A point to note about Figure 8 is that a rip current will form in the vicinity of the greatest indentation. This means that longshore drift brought from both directions towards this zone will quickly construct a shoal and the seaward current will also aid the dissipation of storm waves.

Fig. 7. Logarithmic spiral constants (α and R_2/R_1) versus wave approach angle β .

Fig. 9. Typical wave orthogonal across the continental shelf.

Fig. 8.

This most landward region is therefore better protected than other sections of coast closer to the headlands.

In Figure 4 it is seen that for a non-stable bay the greatest future retreat of the shoreline will take place near the intersection of the curved and tangential zones. But even the whole curved section must erode to accommodate enlargement of the bay. The portion least affected by future progression to an equilibrium shape will be the tangential strip adjacent to the downcoast headland. This reaches its final alignment long before the remainder of the bay. Only a drastic change in the long-term approach angle of the swell or predominant wave system could cause erosion of any significance in this region. With this observation must be considered the added volume of sand offshore due to the milder bed slope, as already discussed.

It is worth working an example on the deep-water changes in direction necessary to effect a given change in approach angle β to the headland alignment. Figure 9 shows a wave orthogonal traversing the continental shelf to arrive at the line joining the headlands at its deepest point. If a wave period of 12 seconds is assumed (7) and the operative depth as 30 ft., the relevant $d/L_0 = 0.04$ as illustrated. Table I shows that for increments of 5° in deepwater obliquity (ϕ_0) the variation in $\phi = \beta$ at $d/L_0 = 0.04$ is around 2° . If a β change of 5° were considered significant, this implies a ϕ_0 variation of 12.5° .

TABLE I - Variations in ϕ at $d/L_0 = 0.04$ for 5° increments in ϕ_0 at $d/L_0 = 0.5$

ϕ_0°	20	25	30	35	40	45	50
ϕ°	9.6	11.7	14.0	16.	18.	19.9	21.7
$\Delta\phi^\circ$		2.1	2.3	2.1	1.9	1.9	1.8

If the storm source for this persistent swell were 1500 nautical miles distant this implies a lateral change in position of 300 NM_s or 6° latitude. Whilst seasonal changes of this order can occur in storm location, it would take a dramatic change in climatic pattern to effect such a shift in the long term. It is difficult to verify such changes by swell observation and any 7 to 10 year cycle of bay erosion due to this source would possibly be overshadowed by more local changes perpetuated by man.

COASTAL DEFENSE

It has been illustrated above that there is a limit to which a bay will erode when all sources of sand are intercepted by whatever means, natural or man-made. If during the course of this recession a rock outcrop is exposed it will become a new fixed point in the coastal system. Such a case is exhibited in Figure 10 which is a bay on the border of South and Western Australia, where a predominant South West swell is known to exist. It is seen that the reef in the curved section of the bay has prevented the removal of material in its vicinity. It has, in fact, created two bays where one would have existed otherwise. Take the reef away and the shoreline would recede to the line indicated in Figure 11 as "major bay profile". This figure is a tracing of Figure 10, in which reefs have been identified by breaking waves.

Fig.10. Natural bay showing the influence of intermediate reef serving as a headland.

Fig.11. Tracing of features in Fig.10. showing characteristics A: of major and minor bays and B: of proposed bays from headland construction.

It can be gathered from Figures 5 and 7 that this major bay or its larger minor bay have not reached equilibrium due to the deviation of their points from the curves. The relevant values for stability produce the two logarithmic spiral curves shown in Figure 11A. The possible retreat from the present water line indicates an erosion area which is hatched. It is seen that this encompasses even the existing vegetation line which is where the primary dune is located. Whilst the natural reef in the figure is at present retaining quite a modest piece of real estate, it will have saved substantially more as full equilibrium is reached.

There is a lesson to be learnt from this example, namely that reefs or headlands occurring naturally or synthetically within a large eroding bay can prevent its recession to an equilibrium limit. To illustrate this point two further fixed points have been suggested at C and D in Figure 11B. They have been located just seaward of the present waterline. The appropriate headland alignment lines have been drawn and the approach angle β determined from the normal orthogonal to the equilibrium coastline in that region. Hence for bay BC with $\beta = 30^\circ$ a limiting indentation ratio of 0.33 was used (see Figure 5). In bay CD for $\beta = 12^\circ$ the a/b value is 0.15, whilst accepting E as the continued downcoast fixed point the angle $\beta = 6^\circ$ for bay DE results in a/b = 0.08.

It can be observed that with these headlands set close to the present shoreline progressive erosion to an equilibrium state entails some loss of the present beach zone. However it is much less than would occur under natural conditions, as illustrated by the zone of hatching in Figure 11A. If no beach loss between DE were to be permitted the better solution would be to construct a headland at E. The resultant shoreline is shown dotted. This probably implies a reclamation since the volume of material now available from bays BC and CD for natural accretion appears insufficient. Of course a headland or groyne in this case, at E can be constructed to any point between E and E¹ or may be progressively built to catch any sediment that is still passing through the bay system. In so intercepting this drift the influence on the next downcoast bay must be taken into account.

If the suggested erosion within bays BC and CD were deemed undesirable the new headlands at C and D could be located further seaward. This could be carried out to provide equal erosion and accretion areas or even net gain in beach volume (10). This might demand more sand than is available from external sources, in which case supply from the adjoining dunes may be necessary.

This proposal of utilising sand dunes in a stabilization programme is submitted as a squeak from the proverbial mouse who is addressing the environmental lions. When ever such a valuable piece of real estate is wanted for some commercial or even recreational use there is a tumult of opposition from lay persons, and even some engineers, to retain the dunes for safety of the coast. It has already been noted that where the bay is most stable, along the tangential section, the dunes are highest. This is one of nature's anomalies, that she has not engineered the coast efficiently.

The retention of dunes for some future unknown erosion event is equivalent to using factors of safety. The point to be made is that as progress is made in stabilizing coasts by natural and scientific means, such as through adding headlands, there is less need for such factors of ignorance. The necessary reserve of sand for present and future storm activity can be stored in the form of new beach area where in the meantime it is useful. This is equivalent to commercial enterprises keeping their reserve funds in use rather than stacking them in a vault for the rainy day. As long as they are liquid enough to serve the day to day fluctuations in demand their employment in commercial activities is to the benefit of all.

In the process of levelling sand dunes in order to construct wider beach zones the problem of wind blown sand must be overcome. This calls for a big "think tank" involving coastal engineers, geomorphologists, soil scientists and botanists. The costs of vegetating these areas, plus the investment in the associated headlands, must be balanced against the long term gain in land area and the greater protection of facilities through a stable coastline. To this must be added the value of previously dined area which is now put to use for residential, commercial or recreational purposes. Another saving is the continual cost in trying to maintain these mounds of sand in their natural state.

The structures involved in this stabilization programme are necessarily large and may not be undertaken simultaneously. This situation calls for an overall plan which is then implemented in stages. For this purpose it is wise to start construction at the downcoast end of an eroding coast in order quickly to retain sediment within the system to be treated. This is assuming that further downcoast the lack of sand nourishment will have no political or financial repercussions.

The lengths of coast involved in a headland-control system will generally be greater than where groynes or seawalls are attempted. This may call for co-operation between a number of local councils and even between adjacent State Legislatures. Such sharing of costs and profits has been forthcoming for rivers and other waterways and hence its extension to the seacoast should not prove too difficult. In this regard it is to be remembered that littoral drift is a "river of sand" extending hundreds or even thousands of miles, over widths varying from a few hundred yards to many miles. This inter-dependence applies equally to pollution as it does to sediment supply.

If a long enough section of shoreline can be treated at once, or the downcoast zones can be discarded, the ultimate goal should be to stop all littoral drift, at least close to the coast if not further out on the continental shelf. The bulk of coastal engineering problems emanate from longshore sediment transport. It causes erosion in one area, siltation in another, and during transmission from the former to the latter constructs bars across river and harbour mouths or blocks dredged channels. Even with stabilized bays, with no net drift, there will be annual longshore and lateral movement to be controlled, but this will be predictable soon after the major equilibrium shape has evolved.

HEADLANDS

Offshore breakwaters have been advocated by the writer as a starting point for headlands. These can cause accretion on their lee side without becoming attached to the mainland. This occurs frequently in nature as illustrated in Figures 2B and 12, which is a sandy protuberance

known as Quinns Rock on the Western Australian coast near Perth. The offshore reef is a half mile in longshore dimension and a mile from the mainland. The displacement of the apex northwards from the centre line of the reef is due to the persistent swell arriving from the Southwest. The diffraction of such waves is exhibited in the figure. In spite of the lack of local controls at the beach itself such triangular features are exceedingly stable, since they have been produced and are maintained by a wave system that alters very little decade after decade.

Man-made islands or offshore breakwaters are more likely to be closer to shore and smaller in dimension. If a sand spit or tombolo is to be formed, which then acts like a groyne and subsequently as a headland, the further offshore the structure the larger should be its longshore length (11). This seaward location implies deeper water and hence massive mounds of rock. This tendency can cause the whole proposition to become uneconomical, especially when considered in concert with a mammoth reclamation task to prevent downcoast erosion. The prizes of area won from the sea or saved from the sea are gained long after the investment has been made. The larger the outlay the more convincing must be the argument that the rewards are actually obtainable.

Because of the expensive nature of marine structures, especially those for dissipating wave energy, much thought must be given to minimizing their cost. This hydrodynamic requirement only demands reef-type structures which trigger the waves, particularly the persistent swell. The sporadic storm waves will readily break over such a shoal. Any contact with the mainland through a tombolo may quickly be broken in these circumstances, but will just as quickly be remade when subsequent swell arrives. This low profile structure not only saves in volume of material but is also more aesthetic in that a synthetic mound is not imposed on the sea panorama.

But even a mound rising to a foot or two below low water can become expensive if set initially in a deeper zone, where its length is around one wave length in order for a tombolo to form. One solution to this problem is to create a horizontal platform which will break the predominant waves. If such a submerged platform breakwater were buoyant it could be relatively mobile. After accreting sand at a point on the coast, and perhaps upcoast from it, the structure could be towed seawards to continue the action (10). When a suitably indented bay were formed a rubble mound headland could be constructed on the beach. This need not be of a high profile, only sufficient to be at mean sea level after subsidence has occurred. The mobile platform could then be hauled to a new site.

Research has been carried out for some years at the University of Western Australia on submerged platform breakwaters (12). This concept is more economical than the surface floating structure because to attenuate the same swell wave it need be only a fraction of the width. An example will illustrate this: To reduce the energy of a 10 second wave in 15 ft., depth of water a floating breakwater must be at least one wave length or 105 ft., in width. A similar platform, either impervious or perforated, moored at a level 5 ft., below the water surface will require a width of only 30ft., since it need be only half the length of this 10 second wave in 5 ft., of water. The submerged platform can be slung from floats or if buoyant held down with weights. Research is being aimed at minimizing the mooring forces and coping with stresses imposed by maximum waves at the site.

In respect to the final wave tripper to be built on the accreted beach apex, it would appear that the cheapest material to use is sand at the site. The cartage of rubble stone is costly at any time, but especially when roads must be provided in remote locations to the breakwater site. To provide vehicular access the structure must be constructed to a meter or two above high water mark and be of such a width to carry such large trucks. The seaward and landward forces as well as the top must be protected by armour units of such a weight as to withstand the fiercest storm waves. A degree of interlocking, plus dissipation of wave energy within large voids, are desirable characteristics sought when designing concrete units for this purpose.

A more economical approach has been reported in the literature for groyne and seawall construction of sand confined in a flexible sheath. Plain sand or cemented material has been employed in this large scale "sand-bag" approach. Perforated polyethylene tubes are available up to about 7 ft., in diameter. Sand is flushed in whilst the water percolates through the skin. Use of these sausages singly or in heaps as headlands or reefs provides a new outlook for coastal engineers.

When cement additives are used the sausages become a solid rock mass immediately. This obviates the problem of splitting or cutting of the polymer during construction, or later through human vandalism. Research is needed into the most effective mixtures to achieve the minimum strength required in such massifs. Lime may be found a better proposition than cement in this saline situation. Means of pumping beach sand into tubes whilst adding chemicals at a fixed rate needs investigation.

There is little question that coastal defense structures need a new outlook since conservatism has proved very costly in the decades gone by.

CHAPTER 83

PROTECTION BY MEANS OF OFFSHORE BREAKWATERS

by I. Fried, C.E., Director
Civil & Marine Engineering Co. Ltd., Haifa - Israel.

INTRODUCTION

The coast of Tel-Aviv is characterised by a narrow sandy beach, and the seabed in the nearshore shallow waters is strewn with rocky ledges and outcrops. These rocks are of a marine conglomerate type and are covered with layers of fine to medium grained sand of various thickness. At depths greater than 5 m the seabed is predominantly sandy. During the summer season, when waves and swells seldom exceed 2 m in amplitude, the sandy strip of the beach maintains its minimum width of about 20 m. However, winter storms reduce the width of the beach in some places to zero, and there is a marked tendency to erosion and scour of the beach in front of the retaining walls of the alongshore promenade or in front of the coastal bluff.

In order to prevent this erosion and at the same time to enlarge the sandy beach area, we have proposed to erect in front of the beach a series of offshore breakwaters, either detached or groyne-connected. (Fig. 1)

The first of the series was erected off the Tel-Baruch beach just north of Tel-Aviv. There beach sand was practically non-existent, and in order to enable bathers to enter the water, a breach in the shallow rocky belt had to be blasted.

The Tel-Baruch breakwater is of a rubble-mound type, 200 m long and connected with the shore by a 100 m long groyne. It is founded on a rocky seabed at -3.0 m below M.S.L. and consists of a quarry-run core (0.5 to 250 kg units), protected on its seaward slope by a rock armour (2-6 tons units) laid on a 1:3 grade, and on its landward slope by a secondary armour (1-2 tons units) laid on a 1:1.5 grade. Its crown is topped by R.C. 0.25 thick slabs to a level of +1.0 m above M.S.L.

Shortly after its erection in 1965, a sandy tombolo has formed at both sides of the groyne, increasing in area until a permanent equilibrium has been achieved. Erosion of the beach on both sides of the breakwater was avoided, owing to a belt of beach rock which protects the foreshore to the south and to the north of the breakwater.

The second system was erected in front of the Tel-Aviv Sheraton and Hilton hotels. (Fig. 2)

It consists of twin breakwaters here connected by groins. Each of the rubble-mound type breakwaters is about 250 m long and 200 m distant from the shore. They are based on a practically rocky seabed at a -4.0 m level and constructed of quarry-run (0.5 - 500 kg units) core and blanket, a seaward armour slope 1:2.5, consisting of 4-8 tons rock units and a landward slope 1:1.5 of 3-4 tons rocks. The crown of the breakwaters is capped by R.C. slabs, 0.25 m thick, and reach a level of +1.25 m. The gap between the breakwaters' heads is 135 m wide.

Soon after the completion of these breakwaters in 1968 the barren rocky foreshore behind them was transformed into a wide sandy beach protected from summer swells and safe to bathers. The sandy tombolos expanded steadily, reaching an equilibrium in about 3 years time, thus permitting the erection of beach amenities (wardrobes, services, showers, refreshment stands) on the vast sandy areas. Behind both these breakwaters the apices of the tombolos from a permanent contact with their inner edge, thus obstructing free passage of water, even during the winter season.

For this and other reasons it was decided to create protected beaches at the central coast of Tel-Aviv south of the newly built "Gordon" boating marina in such a way that all the year round ample gaps should be left between the breakwaters and the sandy tombolos behind them. Moreover, it was deemed desirable from the aesthetic and beach utilisation points of view to form the new shoreline behind the row of detached breakwaters in a sinusoidal shape. The crests of such sinusoids should lie behind the breakwaters at a distance of about 60 m from the actual shoreline, whilst their troughs, situated opposite the gaps between the breakwaters, should be about 20 m distant from the original shoreline. (Fig. 5)

This new concept put before the designers a dilemma how to proportionate the row of detached breakwaters (their length, distance from the shore and between each other) in order to fulfil the basic requirements of the new beach. In order to help the designers to find the right answers to these questions it was decided to resort to movable bed tri-dimensioned hydraulic model tests.

MAIN CHARACTERISTICS OF THE LOCAL CONDITIONS

In order to build a suitable movable bed model in a hydraulic laboratory wave basin and to submit it to a series of tests, it is necessary to collect as many data as possible concerning the physical conditions ruling in the coastal zone under investigation.

For this purpose a series of preliminary surveys and studies of the central Tel-Aviv coastal zone has been undertaken, consisting of:

- a. Topographic and hydrographic mapping;
- b. Wave observations and recordings;
- c. Longshore currents measurements at various depths; littoral transport evaluation;
- d. Sampling of sand from the beach and from the seabed at various depths;
- e. Pricking into the seabed in order to ascertain the depth of hardpan underneath the sandy layers.
- f. Assembly of meteorological and geomorphological data.

The results of the above-mentioned surveys and studies have made it possible to characterise and to analyse the coastal conditions as follows:

The tidal range seldom exceeds 50 cm; however, strong easterly winds may lower the water level to -50 cm below M.S.L., whilst persisting westerly storms may cause a temporary piling up of coastal waters, bringing their level to 70 cm above M.S.L.; but these are extreme events.

The shore of Tel-Aviv is basically sandy with an underlying rocky bottom, which is partly based in shallow water, and in some places near the coastline rocky ledges protrude above M.S.L. The sand cover above the rocky bottom increases in thickness from 1-2 m at the coastline to about 7 m at the -12 m contourline. The seaward slope ranges from an average of 1 to 40 nearshore, to 1 to 75 beyond the -7 m contour. Between the two zones there is a sand bar with a levigation ditch at about -4 m to -5 m depth. The orientation of the shoreline is about 19° East of North. The grain-size distribution of sand samples taken at the foreshore and at certain depths indicates uniformity and sediment sorting, the foreshore samples being much coarser than the offshore samples. The mean diameter changes with the depth as follows:

Depth (m)	foreshore	-5	-7	-13
d (mm)	0.26	0.17	0.16	0.14

The maximum 90% diameter of foreshore samples reaches 0.40 mm.

The winds blow mainly from the NW to SW sector, i.e. from the open sea. Winds above 5 Beaufort (16 knots) strength blow only 5% of the time.

The distribution of significant waves amplitudes and periods shows that most of the storms and all waves higher than 5 m occur between November and April. Their direction is from the WSW and WNW sector, and they account

only for 1% of all waves. The average number of moderate storms (3-4 m high waves) during the summer period is 2 or 3 (1.5% of all waves).

The frequency of amplitudes and periods were found as follows:

Amplitudes									
(m)	6-8	5-6	4-5	3-4	2-3	1.5-2	1-1.5	0.5-1	0-0.5
%	0.37	0.45	1.1	1.58	4.1	9.9	28.0	11.9	42.6

Periods									
(sec)	10-12	9-10	8-9	7-8	6-7	5-6	4-5	3-4	Calm
%	2.0	2.8	7.9	16.5	19.6	23.3	14.4	3.1	10.4

The pattern of wave distribution around the year had to be simulated in the model in order to find the movements of the bottom observed in nature. The currents were measured, both at the surface and at various depths. The results of these measurements have shown that their pattern is irregular and their maximum velocities seldom exceed 25 cm/sec. These low velocities point to the fact that the currents themselves play only an auxiliary role in the movement of sediments put into suspension by shoaling waves.

The estimates concerning the littoral drift at the coast of Tel-Aviv were as follows:

The northward transport - about 400,000 cu.m. a year, the southward transport - much less, about 80,000 cu.m. a year. This leaves a net northward littoral transport of at least 320,000 cu.m. a year.

HYDRAULIC MODEL TESTS

The movable bed hydraulic model was built in the wave basin of the hydraulic Engineering Laboratory of the Haifa Technion (Israel Institute of Technology). The basin's dimensions were 40 m x 25 m x 0.9 m, and it was equipped with a 30 m long movable wave generator, capable of turning in various directions; an overflow level regulator and a movable measuring bridge spanning the area occupied by the model. Frequency and amplitude modulations were effected according to a prescribed program.

The model study began at the end of May 1971 and was completed 16 months later, i.e. October 1972.

The choice of the model scales was influenced by many factors, the most important being the relation between the length of the coastal strip to be tested and the actual dimensions of the wave basin. It was decided to reproduce the model beach with a distortion 1:2, using ground ebonite

as model sand. Thus the adopted horizontal scale was 1:150 and the vertical scale 1:75, while the model sand, the average specific gravity of which being about 1.8, was prepared with a grain size distribution found in the prototype, using a 1:1 scale. The scale of the sand is based in principle on the similitude of fall-velocities, assuming that the major part of the sand transport is usually carried in suspension, and the setting in the protected area is basically governed by the fall velocity - carrying capacity relation, too.

Calibration of the model was effected relative to the sedimentological processes observed in the vicinity of the existing structures (Tel-Aviv lighter basin, Sheraton and Hilton breakwaters). (Fig. 3) There were some indications in the calibration tests that the velocities reproduced on the Froudian scale with the adopted distortion were insufficient for the establishment of a reasonably small sedimentological time scale. Therefore it was decided to increase the model scale for waves, using a scale of 1:50 for wave heights, which were calculated on an energy basis. However, breaking of waves and overtopping of low breakwaters by them are governed by Froudian similitude. Therefore, the breakwaters had to be heightened in the model in such a way that the height of their crest above mean water level corresponds to a 1:50 scale, too. The most difficult problem was to establish a sedimentological time scale. It could not be made before the reproduction of sedimentological changes around the existing structures. Therefore, at the beginning of the calibration a tentative wave program was adopted, which corresponded to the statistical distribution of wave energy and wave direction, but the corresponding wave cycle did not necessarily represent a model year. Then theoretical calculations were made as to the possible sedimentological time scale, and the overall time of the wave cycle was modified accordingly.

Practically the time-scale was found by comparing the time-rate of the tombolo formation at the two existing breakwaters with their development rate in the model. Comparing model to prototype has led to the unavoidable conclusion that two different time scales have to be applied relative to the tombolo formation - one for the initial stage, when the changes are due to shifting of the local sand stock and to longshore transport, and the other when the development of the tombolos is due to the trapping of sand which arrives mainly from the unprotected offshore area. This is because an offshore transport was observed in the model, which was believed to be in excess of the corresponding offshore transport in the prototype and which could not easily be eliminated. However, the final equilibrium state of the tombolos was correctly reproduced, and this indicates that the similitude of the sedimentological process to be studied in the model was basically correct. The basic sedimentological time scale adopted in the beginning was $1:2190 = 1:2200$, i.e. 4 model hours equivalent to one prototype year.

Inasmuch as the development of the tombolos in the first year was correctly reproduced on the adopted time scale, however, the additional growth caused by accretion of sand supplied by onshore transport was slowed down by about 1:3, as proved by the Hilton-Sheraton breakwaters test. At a later stage the sedimentological time scale was re-checked, and as average of 12 hrs. equivalent to one prototype year adopted. Altogether 14 different alternatives were tested in the model study.

TEST RESULTS

The original concept of the outlay of a complete system was a row of offshore breakwaters parallel to the shore with evenly distributed gaps between them, except two wider gaps: one 225 m and the other 310 m long. Also the existence of the first northernmost breakwater, which was erected at the same time as the "Gordon" marina breakwaters, had to be accounted for. The breakwater is situated about 250 m from the original shoreline. Therefore, alternatives 1 to 9 have shown breakwaters situated all at this distance from the shore.

Testing the first alternatives with two wide gaps between the breakwaters indicated serious erosion opposite these gaps. Therefore, other solutions were sought that would provide sufficient widening of the beach. It was made clear by the results of the tests that the proportion between breakwater lengths, gaps and distances from the original shoreline must have definite values, to be found by testing procedure, in order to meet the prescribed requirements concerning controlled tombolo formation. The fact that the hydrographic conditions are quite uniform along the shore section in question, and architectural considerations as well, lead to a symmetrical outlay of similar breakwater units equally spaced.

Alternative 9 was tested with six uniform breakwaters, 130 m and 120 m long gaps, all aligned with the existing northernmost breakwater (Fig. 4).

The result of the tests with this alternative seemed to be quite satisfactory, except that the tombolos showed an undesirable tendency to reach the northern units of the system, contrary to requirements.

Another alternative, No. 10, was then composed, similar to alternative No. 9, of six 130 m long breakwaters; however, the five intermediary breakwaters were displaced offshore by 45 m. Thus a wider lagoon was created, which made the connection of the tombolos with the breakwaters unlikely, except with the existing one, the position of which could not be changed anymore.

In addition, two oblique gaps were formed, which made the penetration of longshore currents, and thus circulation and exchange of water, easier. It was then decided to choose alternative No. 10 as the most suitable outlay of the system.

The choice of the best outlay was based on comparative tests using artificial fill; however, the final version had to be re-tested with a natural process, when the building schedule of the system is correctly reproduced in the model. Owing to the considerable differences in the sedimentological time-scales at the beginning and at the end of the construction period, a mixed average of 12 hours, equivalent to one prototype year for the building period of the whole breakwater system, was finally adopted.

The testing of the natural sedimentological process in the chosen outlay was repeated with three different versions, called alternatives Nos. 12, 13 and 14, differing between them in the time sequence of the construction and other details. Alternative 12 was tested for a construction period of one year for the whole system. In alternative 13 two other time schedules were tested, building of 3 breakwaters per year and building 3 breakwaters in 2 years. This would mean extension of the building period to two and a half and five years, respectively, considering additional five offshore breakwaters and the southern end unit.

The purpose of alternative No. 14 was to improve the distribution of sand accumulating along the protected beach by partition of the protected water area, leaving the groin of the central unit in place, or dismantling, if only partially. The nearshore part of it would very soon be covered, while the gap left between the groin and the breakwater would facilitate the exchange of water between the northern and the southern parts of the lagoon.

In the final version the central breakwater was moved back by 45 m to its position in alternative No. 9, i.e. in line with the end units. (Fig. 5) Thus two inter-connected symmetrical lagoons were formed with considerably improved sedimentological and hydraulic behaviour. The results of the test have shown that the accumulation of sand in the protected area is caused partly by the longshore transport. With an open ended system more sand is attracted from the longshore current, and consequently sedimentation is quicker than in a closed one. If the system is closed, this sand will probably by-pass the breakwaters, apart from the small part trapped behind them. This means that the influence of the construction of the system on the coastline is spread over a longer period, which is certainly beneficial to the coast. Consequently, the building schedule has a direct influence on the rate of sand accretion, though not on the final state of equilibrium. Construction of the whole scheme can be sped up by using artificial feeding. However, if the rate of construction is not exceeding one breakwater a year

(as it actually is), sufficient widening of the beach will be achieved by a natural process. After completion of the model study it was decided to extend the breakwater scheme to the south in order to connect it with the "Clöre" park reclamation. It was suggested on the basis of the model study that this can be done by adding one more breakwater to the system, maintaining however the dimensions of the breakwater units and of the gaps, which were found to be optimal. Thus the finally recommended outlay is composed of seven offshore breakwaters and an end unit shore connected to the seawall of the "Clöre" park reclamation. The head of the southern end breakwater No. 8 and the central breakwater No. 4 are aligned with the existing breakwater No. 1, nearest to the Gordon marina. The remaining five breakwaters are displaced by 50 m in the offshore direction. The length of each offshore breakwater is 130 m, and the gaps between their heads are 120 m long.

The central groin No. 4 will be dismantled only partially, leaving a distance between its head and the central offshore unit. The crests of the offshore breakwater are at +1.75 m above M.S.L.

With an outlay of the system described above, the shore development of the protected beach was expected to satisfy the basic requirements when its new equilibrium is established. (Fig. 6)

The model indicated a 100 to 200 m wide lagoon for swimming purposes, protected from waves mostly in the leeward (the "shadow") of the breakwaters where the beach widens, and to a lesser extent opposite the gaps where the beach narrows. At any rate, the average wave energy along the beach should actually be less than 50% of the energy in the open sea. As long as the waves do not overtop the breakwaters - and this will not happen if the wave heights are less than 2.0 m, as they actually are during the summer season - the water in the lagoon will be calm in general. If overtopping occurs during stormy periods, the reduction of wave heights by the breakwaters is less effective.

FIELD CONSTRUCTION WORKS

Breakwater No. 1 was completed in 1971, and a tombolo has formed that was very similar to the one predicted by the model for the same period of existence. In 1972 No. 2 breakwater was completed and its groin dismantled, using the rock to build the groin of No. 3 system. However, due to war and the policy of the authority concerned, No. 3 breakwater was completed only in 1975. It was decided to proceed with the construction, and this year No. 4 breakwater is in the process of being completed. (Fig. 6)

The method of constructing the offshore breakwaters is as follows:(Fig. 7)

First, rubble-mound type groins are constructed from the shore outwards by dumping on the seabed a core material to a +0.75 m level. This core material consists of a well graded quarry-run (0.5 to 500 kg units), protected on both sides by 3-5 ton rocks placed at a 1:1.5 stope. The width of the groin crest is about 5 m (a minimum necessary to enable the passage of crawler cranes, which place rock armour on the breakwaters). Then the construction of the breakwaters proceeds from their mid-section outwards by laying first on the seabed a 1.0 m thick quarry-run blanket, which is to protrude 3 m outside the outer toe and 2 m outside the inner toe of the breakwater mound. This blanket constitutes an anti-scour device, protecting the toes of the breakwaters and preventing excessive penetration of the armour rock into the sandy seabed.

The quarry-run core of the breakwaters is then dumped on the blanket and protected on its outer (offshore) slope by rock armour (5-8 ton units), placed on a 1:3 grade on its inner (inshore) slope by a somewhat lighter armour (3-5 ton units) laid on a 1:1.5 grade. The breakwater crests are capped to a +1.75 m level by the heavier armour rocks. Also the heads of the breakwaters are protected all around by 5-8 ton rock units placed on a 1:3 grade. The width of the breakwaters at their crest level is 5.25 m.

After completion of each breakwater, the connecting groin is dismantled and the rocks transferred to the next groin. These rubble-mound type structures have proved to be very stable, and even after heavy storms no significant damage have been observed until now.

Periodical hydrographic surveys executed in the area, as well as air photos, indicate that the sedimentation process is generally well in accordance with the prediction of the model study. Now one can see a substantial widening of the protected beach and the appearance of a convenient new bathing area. There has, however, been less sand accumulation at the two northernmost tombolos just behind breakwaters No. 1 and No. 2 than anticipated in the model study. This indicates that sand distribution along the protected shore is more balanced than predicted. No permanent erosion was observed on the adjacent shore due to the above development. This fact corroborates the preliminary assumption that the newly developed beach will not be widened on account of the neighbouring shore sectors, but on account of the differential alongshore sand transport, reducing only the quantity of sand that would otherwise be carried offshore due to the local hydrographical and sedimentological circumstances. (Fig. 8)

The implementation of the offshore breakwaters scheme, together with a substantial widening of the sandy beach behind them, will enable the establishment of a new ample alongshore promenade seawards of the existing one without jeopardising the newly created beach.

CONCLUSIONS

Many factors are involved in the reproduction of natural sedimentological processes in a wave basin with movable bed, and a misinterpretation of some of them may lead to erroneous conclusions. In the long run, the exact definition of the sedimentological time-scale is less important than the reproduction of seabed configuration, representation of sand grain particles and of wave spectra.

The exact full-scale sedimentation processes in the prototype are hardly known in detail. However, we can assume that the formation of sandy tombolos in the lee of offshore breakwaters results mainly from the interception of the littoral drift. Some of the sand enters directly downdrift the onshore zone behind a breakwater, whilst other sand particles by-pass the breakwater on the outside and are then directed by waves diffraction around its opposite head into the calm foreshore zone as a result of onshore movement caused by waves agitation. The accelerated sedimentological process in the model enables however to reproduce quite exactly the natural development of tombolos formation in the prototype, which, in order to reach a state of equilibrium requires a considerable period of time. Nowadays, even a well experienced designer of coastal structures requires a corroboration of his ideas by model studies, which by themselves are not substitutes for a careful and sound design, but serve as practical indicators of their behaviour in the prototype.

ENCLOSING SCHEME FOR BATHING-BEACH DEVELOPMENT

by

Joseph Tauman
J. Tauman, Coastal and Harbour Eng. Ltd.
Consulting Engineers, Ramat Hasharon, Israel

ABSTRACT

This paper refers to bathing beaches. It presents a method for beach design which provides both coastal protection and protection for the bathing public. Reasons are pointed out as to why the open sea foreshores are, in many cases, not suitable for recreation.

The method uses an enclosing submerged breakwater coupled with short groins to provide a bathing beach with a safe swimming area and a controlled sand plaza. Economical in execution and maintenance, the method can be used for sandy or rocky coasts.

Fig. 1. Enclosed Sela Beach at Bat-Yam. General View. 400 m. long by 175 m. wide.

INTRODUCTION

The use of beaches for recreation has assumed tremendous proportions (Ref. 1) and, with growing frequencies of heat waves, it may be expected that sea bathing will continue to rise in demand.

Various coastal protection measures (Ref. 2) used in coastal engineering emphasize mainly the protection and creation of sandy plazas. The problems of sea bathing were left open. This paper is devoted foremost to the human aspect of coastal protection rather than to sedimentation or to structural problems.

Bathing in the open sea foreshore (where most bathing takes place) is in many cases a safety hazard, and swimming or other recreational activities are hardly possible. Besides the good swimmers, the surfers and those who enjoy jumping to the rhythm of breakers, there is a vast public of ordinary people, including families with children, the handicapped and the elderly, which require controlled sea conditions for bathing, swimming, rubber boating and just playing around in the water. This last group of people is often deterred from bathing in the sea by conditions and warnings of waves, currents, changing depths and rocky sea bottoms, pollution, reappearing sludges dumped in deep sea, sharks, jellyfish, fear of drifting out into the sea, strict lifeguard discipline, etc.

The Enclosing Scheme is aimed at developing a method by which bathing beaches will provide side by side enclosed and open sea coastal protected sections for the benefit of almost all groups of bathers. The following paragraphs describe the results of two built, enclosed beaches. They also describe general open sea conditions, emphasizing the need for beaches, public and private, to be properly utilized.

DESCRIPTIVE SUMMARY OF RESULTS

In general, the Scheme was meant to provide beaches with safe bathing areas, sand plazas and hinterlands protected against winter storms. In the Scheme, the submerged breakwater encloses a water area of reduced wave heights, cut off from open sea dangers. The short groins maintain the plaza sands and the seawall protects the hinterland at the back of the plaza. For rocky beaches, sand has to be brought in.

The Scheme was introduced at two locations of differing coastal characteristics along the Mediterranean shores of Israel. In 1969, an area about 400 m. long by 175 m. wide was enclosed at the sandy Sela Beach of Bat-Yam, at the central west coast of the country (Fig. 1). A rocky pocket beach about 75 m. long by 50 m. wide was enclosed, in 1974, at Achziv in the north of the country (Fig. 2). This enclosure is the first part of a planned future development and, being limited in size and water depth, it mainly serves families and children visiting the adjacent park.

Fig. 2. Enclosed Achziv Beach. General View. 75 m. long by 50 m. wide.

Sela is a very popular beach and from the time of its enclosure, seven years ago, soundings, field observations and water quality tests have been performed. The following summary of results and respective layout of the Scheme refer to Sela Beach, with occasional reference to Achziv Beach.

1. Layout. Fig. 3 presents the general layout of the Scheme and of the structural elements. The overall enclosed area is some 65,000 sq. m. (Achziv 4,000 sq. m.). The water area is about 40,000 sq. m., at present. The enclosure follows the lines of existing submerged beach rock. The reason for this was mainly economical. (In Achziv, too, advantage was taken of existing beach rock.) The submerged breakwater was based partially on sandy seabottom and partially on rocky bottom. The outer groins, on top of the beach rock, were designed to top the sides of the submerged breakwater. The location of the inner groins was influenced by the existence of the refreshment kiosk. The inner groins are not yet at their proposed full length. The sea wall follows the front line of the refreshment kiosk, leaving a limited hinterland up to the cliff. The plaza is some 25 m. wide at its narrowest, between the mean sea water line and the sea wall. The plaza is expected to be widened an additional 15 m. by lengthening the inner groins and by adding a groin at the southern sector.

Fig. 3. Sela Beach. Layout of Enclosure, Structural Elements, Cross Sections and Soundings. Dated October 1972 and October 1974.

Long beaches can be developed step by step as was proposed for the whole beach length of Bat-Yam (Fig. 4).

Fig. 4. Proposed Development for Bat-Yam Coast.

2. Waves and Currents. Wave heights in the enclosed area are considerably reduced, compared to outside wave heights. Those measured in the enclosed area were a maximum of 0.5 m., while estimated heights outside were around 1.5 m.

During most of the bathing season, bathing, swimming and rubber boating were safe inside, whereas they were hardly possible outside.

Waves sliding over the breakwater re-form in the area, some distance from the breakwater. The re-formed waves are of an oscillatory nature and swimming is pleasant. There are almost no currents. In certain wind conditions, relatively weak currents were occasionally reported between the breakwater and re-forming line.

During winter storms, wave heights in the area may reach up to 1 - 1.5 m. and currents of significant strength were reported by good swimmers.

The difference between wave and current conditions inside and outside are significant (Fig. 5). Bathing in the enclosed area is possible throughout the year, except during winter storms.

Fig. 5. Sela Beach. Difference in Agitation Between Inside and Outside the Enclosed Area. Limited Bathing Outside.

3. Water Depth and Sediment Movement. In most of the enclosed area, water depth is no more than 1.0 m. from mean sea level, i.e., about 1.5 m. from inside, still, high water level. In some areas, the water is deeper, up to 2.5 m. The shallow areas are usually preferred by the majority of the visitors. Figures 3 and 6 show soundings related to mean sea level, taken at beginnings and ends of bathing seasons. The depth lines seem to be relatively stable and the slopes gentle.

During and after construction of the breakwater and groins, sand movement took different forms. During the construction period,

sand drifted into the area and a tombolo was formed in the lee of the Rock of Adam. During the first two years after construction, the sand of the tombolo moved to the northern corner creating there a wide plaza. During the same period - prior to building the inner groins and prior to securing the southern outer groin against outflanking - the whole center and southern plaza areas were washed out, leaving beach rock exposed above and below sea level. Since the construction of the inner groins and the placing of sand between them, the plaza width became relatively stable, the beach rock became covered with sand, and seasonal sand movement takes place in the enclosed area. During the summer months, sand drifts from the plaza towards the breakwater creating shallow water areas near the breakwater, opposite the southern and central groins (Fig. 6).

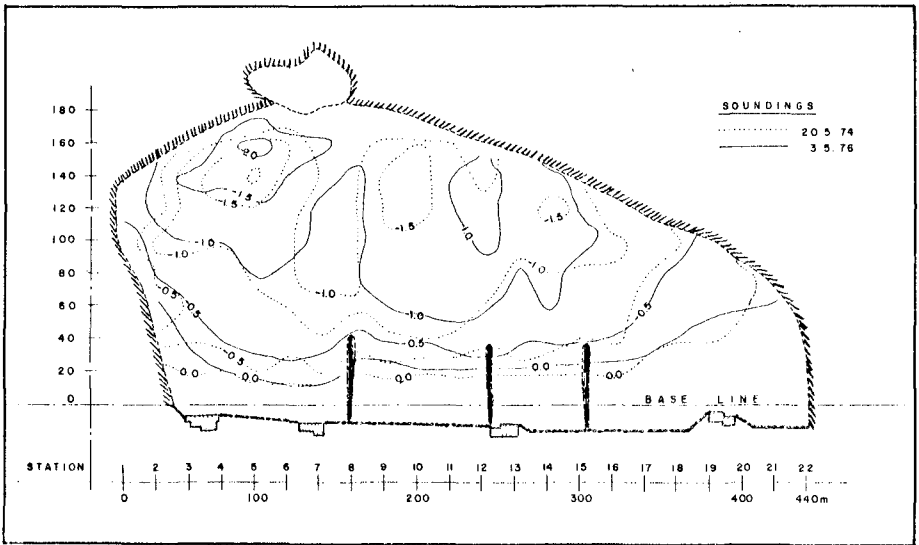

Fig. 6. Sela Beach. Soundings May 1974 and May 1976, (also see Fig. 3), Related to MSWL.

These shallow water areas may reach a height of -0.5 m. below mean sea level. The winter storms push the sand back, but it appears that not all of the sand goes back and not to its original plaza sections. During the last two years, some 2,500 cu. m. of sand remained in the water area. So far, no maintenance has been done in the water area, but it is expected that in years to come sand will have to be shifted from the water area back to the plaza. Shifting of sand in the plaza area takes place at the beginning of each bathing season for shaping up the area after winter storms. So far, since the building of the inner groins, there have been no noticeable changes in the overall balance of the sand in the enclosed area.

Outside the area, at the sides of the outer groins, accretion took place. This accretion undergoes seasonal changes within the general on- and off-shore movement of the sediments. The littoral drift appears to bypass the area around the breakwater.

4. Water Quality. Water quality inside is the same as outside and the enclosed area cleanses itself. The still water level is higher inside than outside, resulting in a constant out-flow of water.

A water temperature difference of 2°C, higher inside than outside, was measured during the bathing season.

During construction, contamination from the open sea penetrated into the enclosed area resulting in an odour in the northern part of the enclosure. This odour faded during the first bathing season after construction.

Afterwards, the following facts were reported: a) A pipeline, located some 150 m. to the south of the area, discharges fluid spoil of brown color. Even under southwesterly winds, a small part of this fluid was seen penetrating the area. The bulk of it was seen bypassing outside the breakwater; b) Before the beginning of the 1975 bathing season, the Bat-Yam beaches were accidentally flooded by untreated sewage. In July, the waters were retested and all the beaches, including the Sela, were found clean - fit for bathing; c) This 1976 season, the Sela Beach was declared open for bathing whereas the other two beaches to the south were closed due to contamination.

5. Recreation. The enclosed area provides sea bathing recreation also to a public which, in open sea conditions, could not bathe. It has been noticed at many locations that wide, sandy, open sea plazas are used to capacity by visitors, while actual sea bathing is very limited.

In the enclosed area, a considerable part of the visiting time is spent in the water and a wide range of recreational activities are available. Bathing, swimming and swimming lessons, rubber boating and shallow water diving are exercised inside; amateur fishing takes place from the breakwater to the outside.

Enterprise could still broaden the recreational activities of the water and hinterland areas. It should be emphasized that the enclosed area gives the impression and feeling of open sea bathing and not of a swimming pool. The sand plaza, sea water, sandy bottom, space, low waves, open horizon, onshore breeze, security and lenient attitude of the lifeguards provide sea bathing and recreation in a relaxed atmosphere. For the good swimmers, entrance to the open sea can be either through the open sections of the beach at both sides of the outer groins or, in order to avoid bypassing the dangerous foreshore, from specified places along the breakwater.

Most bathers prefer shallow water. In the enclosed beach, bathing is spread over wide areas, whereas outside it is limited to narrow strips and only as directed by the lifeguards (Fig. 7).

Fig. 7. Sela Beach. Bathing Mostly in Shallow Areas. Outside Bathing Limited to Narrow Strips. Inside Bathing Spread Over Wider Areas.

6. Design and Construction. Design of the enclosed Sela Beach started in 1968, and continued through the construction period and until the inner groins were built. At that time, wave data and personnel experience with submerged breakwaters and enclosed sea areas were available from the building of Ashdod Port, about 30 km. to the south of Bat-Yam. Partial soundings of the Sela area were taken at the beginning of the design, and field observations in the area and along other bathing beaches were made through the whole design period. No laboratory tests were made because of lack of local data, time and the high cost in foreign currency in comparison to the overall cost of the structure.

The beach rocks at both ends of the area were thought to serve as parts of the enclosing structure, but a closer survey during construction indicated the necessity of full enclosure by means of dumped rock and the necessity of elevated outer groins at both ends.

The necessity of the inner groins became evident during the first winter of construction. The inner groins were built only after serious damage occurred to the inner plaza. Close observations were made as to sand movement prior to and after the building of the groins.

The submerged breakwater was built at a water depth of approx. 2.5 - 3 m. The nominal crest elevation was designed to be at mean sea level. In reality, some rocks are lower and some are up to +0.6 m. and more (Fig. 3). The armour rock, of 5 - 8 ton class, was designed for wave heights of 3.5 m. The placing of the rocks was carried out from both ends, simultaneously. The equipment operated from an overbuilt elevation of 1.5 - 2.0 m. above mean water. After enclosure was achieved, the overbuilt rock was removed and used as berms at both sides of the breakwater. The quantities of rock were about 100 tons per lineal meter of breakwater. The work was done during one summer season.

OPEN SEA CONDITIONS

Open sea bathing is in many cases a safety hazard and of limited recreational value. Along our Mediterranean coast, the foreshore is particularly dangerous and there most drownings occur.

1. The Foreshore. The foreshore is the area between the

*The author served as supervising engineer for design and construction of breakwaters at the Port of Ashdod

water line and the outer limit of the nearshore bar. The assumed conditions in the foreshore, as described, are based on observations during a bathing season prior to the construction at the Sela Beach.

During most days of the summer months, the eastern coast of the Mediterranean Sea is exposed to onshore winds resulting in waves 0.6 - 1.2 m. high and sometimes up to 2.0 m. high (Fig. 8).

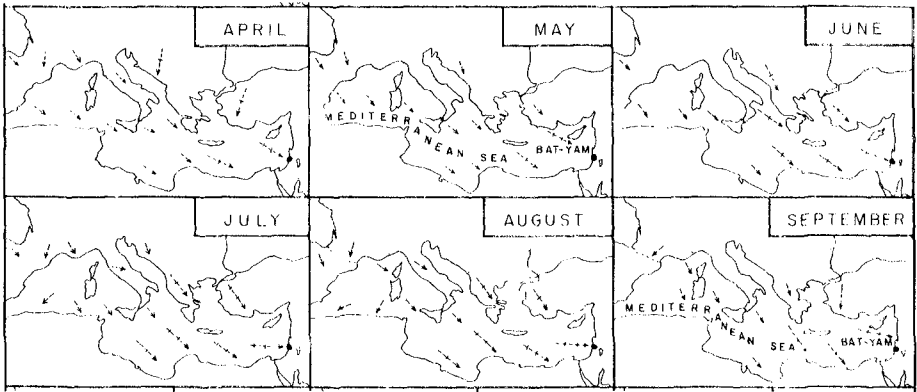

Fig. 8. Monthly Wind Conditions at Mediterranean Sea.

At the same time, a nearshore bar with a crest elevation of about 1.0 m. below sea level exists parallel to the coast.

The nearshore bar was sounded (Ref. 3)(Fig. 8a) and appears to be in fair agreement with the assumptions based on previous observations.

The waves break to the seaside or on top of the bar and almost the entire width of the foreshore is covered by surf. It appears that the area between the water line and the inner limit of the bar acts as a current velocity field in which flow takes place in all directions (Fig. 8b). Studies made in the past provide a wider range of information (Ref. 5 & 6).

Along the bar, there are breaks or rip-passes through which rip-currents are forced out into the sea. On top of the bar the water seemed to be air entrained, absorbing currents from both sides (Fig. 8c). The bar configuration, the rip-passes, current velocities and current directions seemed to be changing under changing wave conditions. In the area, drownings occurred as near as 5 m. from the water line and difficulties in returning

to shore were experienced by ordinary bathers, while rip-currents endangered even fairly good swimmers. Because of frequent drownings during bathing seasons, a law was enforced banning entrance into the sea except under supervision and as directed by lifeguards.

Fig. 8. Schematic Diagram of Nearshore Bar and of Nearshore Current Velocity Field.

2. Open Sea Bathing. Open sea bathing is in many cases confined to jumping to the rhythm of the breakers. The ordinary bathers' time in the water is short and at a very limited distance from the water line. The great responsibility resting with the lifeguards results in their enforcing stringent restrictions on the movements of the bathers, and bathing takes place in narrow areas perpendicular to the shore.

Swimming, rubber boating or other recreational activities are hardly possible during most days of the bathing season (Fig. 9). Visitors often spend their time on the plazas without going into the water, or they wade for short periods. In many cases, even wide beaches with lifeguards cannot be rated as bathing beaches.

Fig. 9. Open Sea Beach Near Achziv. August 1976.

SUMMARY

With the increasing demand for recreational beaches, beach design should include the problems of sea bathing and related recreational activities.

During its seven years of existence, the Enclosing Scheme proved that safe sea bathing and recreation for private and public beaches can be achieved and long sections of shore can be developed step by step with relative economy.

ACKNOWLEDGEMENTS

Sincere thanks to the Municipality of Bat-Yam, to the National Parks Authorities and to Sulam-Zur Council for their permission to use material prepared for them.

CHAPTER 85

EXPERIMENTAL VERIFICATION OF GROUYNE THEORY

by

C.H. Hulsbergen¹, W.T. Bakker² and G. van Bochove³

1 Abstract. In order to check the results of Bakker's theory [1], [2] concerning the influence of groynes on a sandy beach, a comparison is made with experimental results obtained in model tests performed in the Delft Hydraulics Laboratory [3], and in the Laboratorio Nacional de Engenharia Civil, Portugal [4]. The theory gives the bathymetric development in terms of a set of two schematized contour lines, representing the onshore and offshore parts of the model where longshore sand transport occurs. As input in the theory the characteristics of the undisturbed sand transport should be known, i.e. without groynes. This is achieved by computing the longshore sand transport according to Bijker's method [5] and the transverse sand transport according to Swart's method [6], starting from the hydraulic conditions as measured in the model without groynes. In order to make a comparison with the theoretical lines, the bathymetric development as measured in the model with groynes is also schematized to a set of two contour lines. In some cases the result is quite good, whereas in other conditions the theory does not even show the right trend; see [7] for details. Possible causes are discussed, and shortcomings of the model as well as of the theory are mentioned.

2 Theory. For details of the theory reference is made to [1] and [2]. Only a few basic assumptions and limitations are mentioned here. The theoretical approach may be summarized as follows:

- a) The coastal profile is schematized according to Fig. 1. The active zone of the profile, i.e. from an upper dune erosion level down to a depth where relevant changes are no longer significant, is split into two layers with a thickness D1 and D2. Each layer extends seaward from a common base line over a certain distance, L1 and L2, respectively. The area of the schematized step-type cross-section is equal to the area of the actual profile. The elevation of the horizontal interface is defined by the point where the seaward toe of the groyne intersects the actual beach profile. In top view, the two layers appear as a set of two lines, referred to as beach-line and foreshore-line respectively (Fig. 2).
- b) The rates of littoral drift S1 and S2 along beach and foreshore each have a linear relationship with the local angle of wave incidence:

$$S1 = \underline{So1} - \underline{s1} \frac{\partial y1}{\partial x} \quad \text{and} \quad S2 = \underline{So2} - \underline{s2} \frac{\partial y2}{\partial x} \quad (1)$$

where So1 (So2) = undisturbed longshore transport along beach-line (foreshore-line); s1 (s2) = factor of proportionality; $\partial y1/\partial x$ ($\partial y2/\partial x$) = local angle between beach-line (foreshore-line) and base line.

- c) The transport Sy perpendicular to the coast, taking place between the beach and the foreshore, depends on the steepness of the (schematized) profile. Whenever the distance L2 - L1 is smaller than a certain equilibrium distance W, the profile is too steep, causing a seaward transport. In the opposite case there is a landward transport (Fig. 2):

1 Delft Hydraulics Laboratory, Project Engineer.
2 Rijkswaterstaat, Head Study Department Flushing.
3 Rijkswaterstaat, Coastal Research Engineer.

$$S_y = \underline{s_y} \left[\underline{W} - (L_2 - L_1) \right] \quad (2)$$

where s_y is a factor of proportionality.

In (1) and (2) the underlined terms are "coastal constants", which control both the time scale and the geometric scale of the coastal development, and which have to be determined in order to achieve quantitative results. Here, the "coastal constants" are quantified from:

- experiments without groynes
- Bijker's theory [5] for longshore transport
- Swart's theory [6] for perpendicular transport.

d) Continuity of the sand volume is specified by

$$- \frac{dS_1}{dx} - S_y = D_1 \frac{\partial y_1}{\partial t} \quad \text{and} \quad - \frac{dS_2}{dx} - S_y = D_2 \frac{\partial y_2}{\partial t} \quad (3)$$

e) The main boundary condition is formed by the complete obstruction of that fraction of the littoral drift which moves along the beach-line. Moreover, there is continuity in the location and in the orientation of the foreshore-lines on both sides of every groyne.

A visualization of a typical theoretical result is given in Fig. 3. It gives rise to a few comments. The theory, in its basic form as outlined above, gives only one type of coastal evolution, i.e. a certain amount of accretion upstream and an equal amount of erosion downstream, in a pattern which is basically fixed. That is so, because the hypotheses concerning the sand transport tacitly assume a quite neat and "nicely" behaving breaking wave and longshore current. In fact, the theory is not dealing with any detail of the coastal current system or the sand transport phenomenon. In order to make the theory more realistic, the possibility has been added to include such influences as rip-currents, stream refraction, and diffraction. However, except for a single case (Chapter 4), these options have not been used here, because their application presumes detailed a priori knowledge about the current pattern, which was not available. For this reason Chapter 3 gives the experimental results against the background of the theory in its basic form, as represented by Fig. 3. The procedure for this comparison is outlined in Fig. 4.

3 Experiments in Delft Hydraulics Laboratory

3.1 Model facility and test procedure

The lay-out of the model basin is given in Fig. 5. A large amount of various conditions were installed, details of which are extensively discussed in [3]. As bed material dune sand was used with $\rho = 2650 \text{ kg m}^{-3}$ and $D_m = 0.220 \text{ mm}$. Either 0, 1 or 3 impermeable groynes were present, with their crests well above the water level, with rough 1:1 slopes and aligned perpendicularly to the coast. The spacing was 6 m and their length so that they obstructed the longshore current partly or completely. The regular waves had a period of 1.55 s or 1.15 s, and a height between 0.07 m and 0.14 m. Depending on the wave steepness and the local beach slope, either spilling or plunging breakers occurred, under an angle of appr. 5° with the shore line. Water and sand were fed upstream and caught downstream in order to represent an infinitely long, straight beach.

In short, the procedure was to try and establish a dynamic equilibrium along a straight beach without groynes, and to assess meanwhile the development of the wave heights, the current velocity, the morphology and the trapped sand distribution. Then, after adding a groyne system, the new hydraulic and bathymetric development were recorded and subsequently compared with the theory. Here only a limited, though typical, selection of the numerous test results is presented, while in Chapter 5 a discussion is given, making use of some more selected measuring

data which are deemed useful for a good interpretation of the results.

3.2 Tests with a single groyne.

Representative as a "good" tests is T22, where the main conditions were: wave height 0.075 m, wave period 1.55 s, water depth 0.38 m in front of the wave generators. The average rate of sand nourishment was $71 \text{ dm}^3\text{hr}^{-1}$, while $55 \text{ dm}^3\text{hr}^{-1}$ was caught in the traps. The rate of water supply was constant at $30 \text{ dm}^3 \text{ s}^{-1}$ in order to feed the longshore current. The groyne extended seaward to 4.2 m, whereas the waves broke at appr. 3.5 m. Fig. 6 and 7 depict the beach, looking upstream, after 0.5 hr and 50 hrs. They show a quite regular accretion upstream, and erosion downstream of the groyne. This is also represented by Fig. 8, a difference chart displaying the extent and the locations of erosion and accretion during the 50 hrs of the test. In an attempt to monitor the actual longshore sand transport by local measurements, the wave height and the longshore current distribution were frequently measured in sections perpendicular to the shore. These data, together with the local depth and the bed material characteristics, are enough to compute the longshore sand transport according to Bijker. Examples are given in Figs. 9 and 10 for a section 8 m upstream of the groyne, and at the groyne itself, respectively. The obvious decrease of the longshore sand transport capacity is in good accordance with the observed accretion of the beach. Fig. 11 shows both rates of longshore sand transport in the course of time. Typical accreting and eroding coastal profiles are given in Figs. 12 and 13, respectively, the latter together with the distribution of the longshore sand transport as caught in the sand traps.

From Bijker's and Swart's theories, together with the appropriate data from the experiment, the following quantities were derived for application of the theory:

upper level of beach	: 0.51 m	}	with respect to the level of the wave generator floor.
elevation of interface	: 0.24 m		
lower level of foreshore	: 0.18 m		

$S_{01} = 87 \text{ dm}^3\text{hr}^{-1}$, $s_1 = 994 \text{ dm}^3\text{hr}^{-1}$, $S_{02} = 29 \text{ dm}^3\text{hr}^{-1}$, $s_2 = 332 \text{ dm}^3\text{hr}^{-1}$, $W = 7.62 \text{ m sy} = 0.0338 \text{ dm hr}^{-1}$.

The resulting schematized beach- and foreshore-lines for 0.10 and 50 hrs are given in Fig. 14, together with the comparable theoretical lines. The fit is quite good, especially for the beach-lines. It is thought that this favourable result was reached under the influence of an extraordinarily regular breaker type (plunging), which was accompanied by a very regular longshore current. Moreover, the groyne interrupted the longshore current almost entirely, thus obstructing the longshore transport of sand to a great extent.

Another test with a single groyne, T18, contrasted sharply with the above result. Its main conditions were: wave height 0.10 m, wave period 1.55 s, water depth 0.38 m in front of the wave generators, average rate of sand nourishment $88 \text{ dm}^3\text{hr}^{-1}$, while $106 \text{ dm}^3\text{hr}^{-1}$ was caught in the traps. The water discharge was constant at $55 \text{ dm}^3 \text{ s}^{-1}$. In Fig. 15 the contours after 60 hrs are shown, where the attention is drawn to the clear accretion, but this time downstream of the groyne. Locally even a new beach line appeared seaward of the original one. The development can be followed on Figs. 16 and 17, where difference charts of 0-20 hrs and 20-60 hrs are showing how the bulk of the longshore sand transport moved around the groyne in two stages. In the intermediate stage the maximum accretion amounted to 20 cm at some distance downstream and seaward of the head of the groyne. After 20 hrs the bulk of this sand deposit was removed and shifted in shoreward direction, and somewhat more downstream. Fig. 18 shows that neither the upstream nor the downstream overall profile was subject to large changes. It also points towards a possible reason for the remarkable developments encountered here: the trapped sand distribution, averaged over 60 hrs, indicates that the groyne could hardly be expected to stop the longshore transport. However, the average trapped sand distribution in the preceding test T17 (without groyne), was used

to design this groyne length such that it would stop approximately 50% of the existing longshore sand transport.

After the above explanation it is not surprising that the experimental results are not well covered by the theoretical beach- and foreshore-lines (Fig. 19), which are based on the following data:

upper level of beach	: 0.46 m	} with respect to the level of the wave generator floor.
elevation of interface	: 0.235 m	
lower level of foreshore:	0.06 m	

So1 = 73.5 dm³hr⁻¹, s1 = 840 dm³hr⁻¹, So2 = 65 dm³hr⁻¹, s2 = 743 dm³hr⁻¹, W = 10.08 m, sy = 0.029 dm hr⁻¹.

The impression exists from various observations (see also Chapter 5) that secondary wave formation, caused by the bar at a distance of 11 m (Fig. 18), may have played an important part in re-establishing the original coastal profile after 20 hrs. It is felt that this type of secondary waves has an important influence on coastal profile dynamics.

3.3 Tests with a row of three groynes.

In Fig. 20 the contours after 50 hrs of test T23 with three groynes are presented. The conditions were: wave height 0.075 m, wave period 1.55 s, water depth 0.38 m in front of the wave generators. The average rate of sand nourishment was 44 dm³hr⁻¹, while 27 dm³hr⁻¹ was caught in the traps. The average rate of water supply was 25 dm³s⁻¹. The groynes extended to 3.7 m. Until 20 hrs a plunging breaker occurred at appr. 3.7 m, whereas later on the spilling type dominated, with variations in breaker location. In Fig. 21 a clear rhythmic behaviour is revealed by the difference chart, both in longshore direction (as caused by the groynes) and in perpendicular direction (as caused by an overall coastal profile development). The various quantities with respect to the theoretical computations are:

upper level of beach	: 0.51 m	} with respect to the level of the wave generator floor.
elevation of interface	: 0.255 m	
lower level of foreshore:	0.160 m	

So1 = 87 dm³hr⁻¹, s1 = 995 dm³hr⁻¹, So2 = 29 dm³hr⁻¹, s2 = 331 dm³hr⁻¹, W = 8.10 m sy = 0.032 dm hr⁻¹.

Fig. 22, displaying the experimental and theoretical lines representing the beach and the foreshore, reveals a reasonable equality as far as the beach is concerned. However, large deviations occur in the foreshore, where the typical rhythmic variations are not found back in the theory.

Test T34 had unusual conditions in so far that the water level fluctuated in a one-hour cycle 0.025 m plus and minus the average of 0.38 m above the wave generator floor. This was done in order to shift also the type and the location of the breaking waves, in an attempt to avoid rip-current formation at fixed locations. The other conditions were: wave height 0.115 m, wave period 1.15 s, average rate of caught sand 74 dm³hr⁻¹. The rate of sand nourishment was constant at 70 dm³hr⁻¹, and the rate of flow was constant at 50 dm³s⁻¹. The groynes extended to 3.27 m, whereas the breaker location varied widely during the test.

The quantities for the theoretical analysis were:

upper level of beach	: 0.49 m	} with respect to the level of the wave generator floor.
elevation of interface	: 0.27 m	
lower level of foreshore:	-0.01 m	

So1 = 32.4 dm³hr⁻¹, s1 = 370 dm³hr⁻¹, So2 = 35.6 dm³hr⁻¹, s2 = 407 dm³hr⁻¹, W = 8.11 m, sy = 0.108 dm hr⁻¹.

The result was not much better than that of test T23, as can be seen on Figs. 23, 24 and 25. Fig. 24 is a special chart, displaying the difference between test T34 and test T33 (without groynes but further with exactly the same conditions as T34) after 30 hrs. The pattern of alternating erosion and accretion between the groynes is opposite to what should be expected from the theory. This is most probably caused by an intricate and unstable pattern of currents, stagnation areas, rip currents and regions of lower and higher waves.

4 Experiments in Laboratorio Nacional de Engenharia Civil.

4.1 Model facility and test conditions.

Reference is made to [4] for details. Fig. 26 shows the lay-out of the model. A convex beach profile of pumice-stone ($\rho = 1670 \text{ kg m}^{-3}$, $D_m = 1.25 \text{ mm}$) was molded between two rockfill groynes E1 and E3. These groynes had 2:1 absorbent slopes and acted as training walls for the beach. A smaller groyne E2 in between with steep 1:5 slopes completely obstructed the littoral drift. The waves were 0.02 m high, had a period of 1 s and were generated under an angle of 20° in a water depth of 0.40 m.

4.2 Test results and theoretical beach lines.

Various beach line positions were recorded during the 35 hr test, as presented in Fig. 27. These are compared to theoretical lines, which were determined as follows [8]. The active profile was schematized to a single beach line, because perpendicular transport across the 0.063 m depth contour was assumed negligible. This depth is twice the breaker depth as calculated for straight, parallel depth contours. Diffraction calculations were performed in the deeper, horizontal part of the basin, whereafter refraction was calculated up to the 0.063 m contour line, again assuming straight and parallel depth contour lines, remaining so during the whole test. The resulting values for the wave height H_1 and the angle of wave attack ϕ_1 at the 0.063 m depth contour are given in Fig. 28.

The final position of the beach is now assumed to be defined by ϕ_1 and H_1 in a first approximation. By ϕ_1 alone, the final beach line is determined by being parallel to the local wave crest as defined by ϕ_1 , because only then the net transport along any part of the beach is equal to zero. By H_1 alone on the other hand, differences in wave set-up will develop, causing a varying longshore current velocity V_l along the beach, where V_l is a function of various parameters among which the beach line orientation [9]. By putting V_l equal to zero, the final beach alignment is found. After adding the partial solutions for H_1 and ϕ_1 , the final coastline is found as Y_0 in Fig. 29. By comparing this line to the experimental 35 hrs-line in Fig. 27, some differences can be found:

- In the experiment a certain amount of material does disappear into deeper water. Because Barcelo reports a rip-current near groyne E2, the theoretical line is adapted by taking a sand transporting rip-current into account near E2 with an adequate transport capacity. This will at the same time increase the theoretical beach line angle near groyne E2, bringing it closer to the measured position.
- Differences near groyne E1 are likely to be caused by a very low transport capacity in the model, whereas in the calculation no critical velocity for beginning of movement is used.

For the calculation of the coastline after 1, 4, 7, 15 and 35 hrs the dynamic equation is used (with $s_y = 0$), together with equation (1). Relevant quantitative parameters are: $S_{\text{ripcurrent}} = 3.4 \text{ dm}^3\text{hr}^{-1}$, $S_{01} = 27.8 \text{ dm}^3\text{hr}^{-1}$ acc. to Barcelo, $s_1 = 150 \text{ dm}^3\text{hr}^{-1}$. The resulting theoretical lines are given in Fig. 29; they fit quite well with the experimental lines of Fig. 27.

5 Discussion of the results. The above examples are typical in so far that they indicate the rather large variation in the ability of the theory to fit with the experimental results. One should not be too surprised, in view of the wide deviations which were often present in the actual experimental conditions, as compared to the ideal conditions which were (tacitly) assumed in the theory. The main causes of deviation are discussed below.

- Variations in wave height as measured in cross-sections very close to each other, were frequently noted and were judged to have a strong negative effect on the homogeneous conditions sought. Fig. 30 shows a rather dramatic example, in which the wave height variations are at least partly due to the varying bed profiles. Of course there exists a strong mutual interaction between wave behaviour and coastal profile development.
- An example of the progressively deteriorating homogeneity in longshore direction of the coastal profiles is given in Fig. 31. It shows the envelopes of all cross-sections after 10, 30 and 50 hrs in test T19 (without groyne).
- An effect, and simultaneously a cause, of the above mentioned non-homogeneity is present in the chaotic current pattern in the same test, as presented in Fig. 32. This test, too, began with a nice homogeneous and steady longshore current.
- Apart from being non-homogeneous, the current pattern was unsteady, as is shown in Fig. 33. It gives values of the longshore current in test T25, measured in two points 1 m apart perpendicular to the coast. The measurements were performed by timing floats over a distance of 1 m.
- Secondary waves were present under certain conditions. Apart from those, generated by the sinusoidally moving wave board [10], also secondary waves were generated while the regular waves passed over a large bar without breaking. In this respect it is interesting to not that Byrne [11] reports the same wave behaviour (long regular swell conditions) in the prototype (Fig. 34). Fig. 35 presents a coastal profile of test T19, with a bar and with the wave height over it; the wave breaks only at a distance of appr. 5 m. The respective wave forms as shown in Fig. 36 clearly show the presence of secondary waves (with period $T/2$) which are overtaken gradually by the faster main waves. Their presence has undoubtedly a large influence on the perpendicular sand transport [10], and further on the type of breaking and the kinematic results thereof. It is felt that the presence of those secondary waves can have a dominating effect on the formation and the stability of coastal profiles.
- The pair of Fig. 37 and 38 illustrates the strong relationship between secondary waves, bar formation, type of breaker, and subsequently the rate and distribution of the longshore transport. The conversion of the breaker type from spilling to plunging was in very good agreement with Galvin's results as far as the influence of the seaward slope of the breaker bar is concerned [12]. After this conversion the rate of longshore transport was appr. three times as large as before, and much more concentrated.
- The most obvious visible result of the increasingly non-homogeneous conditions in many tests was the formations of beach cusps. Both small (Fig. 39) and large (Fig. 40) examples have been recorded. It goes without saying that this is most unwelcome in tests which are meant to verify the effect of groynes on a sandy beach. Fortunately, the presence of a groyne appeared to induce a more stable condition, in which the cusp formation was partly suppressed.

6 Conclusions. The conclusions which follow from these tests and their comparison with the theory can be summarized as follows.

- The theory is good in cases with a stable, neat, and well defined longshore current system, and if the groyne(s) intercept a substantial part of the longshore sand transport.
- In other, more complex systems, the theory in its present form is not adequate on a forecast basis. However, if the current pattern is well enough defined and specified, the theoretical result may be improved by taking into consideration the effects of stream refraction, diffraction, and rip-currents.
- The coastal current system should be studied in more detail in order to improve the theory of Bakker.

CHAPTER 86

GROIN LENGTH AND THE GENERATION OF EDGE WAVES

Michael K. Gaughan¹ and Paul D. Komar²

ABSTRACT

A series of wave basin experiments were undertaken to better understand the selection of groin spacings and lengths. Rather than obtaining edge waves with the same period as the normal incident waves, subharmonic edge waves were produced with a period twice that of the incoming waves and a wave length equal to the groin spacing. Rip currents were therefore not formed by the interactions of the synchronous edge waves and normal waves as proposed by Bowen and Inman (1969). Rips were present in the wave basin but their origin is uncertain and they were never strong enough to cause beach erosion.

The generation of strong subharmonic edge waves conforms with the work of Guza and Davis (1974) and Guza and Inman (1975). The subharmonic edge waves interacted with the incoming waves to give an alternating sequence of surging and collapsing breakers along the beach. Their effects on the swash were sufficient to erode the beach in some places and cause deposition in other places. Thus major rearrangements of the sand were produced between the groins, but significant erosion did not occur as had been anticipated when the study began.

By progressively decreasing the length of the submerged portions of the groins, it was found that the strength (amplitude) of the edge waves decreases. A critical submerged groin length was determined whereby the normally incident wave field could not generate resonant subharmonic edge waves of mode zero with a wavelength equal to the groin spacing. The ratio of this critical length to the spacing of the groins was found in the experiments to be approximately 0.15 to 0.20, and did not vary with the steepness of the normal incident waves.

INTRODUCTION

Rational criteria for selecting groin lengths, spacings, heights, and angles to the shoreline for a given beach and wave conditions are not well developed. Some general criteria, founded on past experience, are mentioned in the literature. For example, Coastal Engineering Research Center (1973) recommends that groins be spaced two to three times the offshore groin length. A general review of beach protective structures, including groins, can be found in Bruun (1972).

In this study a series of wave basin experiments were undertaken for the purpose of better understanding the selection of groin spacings and lengths. It was initially supposed that a certain groin spacing would cause resonant conditions with the incoming waves such that strong edge waves would be generated with the same period as the normal waves. As shown by Bowen (1969) and Bowen and Inman (1969), such edge waves can interact with the incident waves to generate steady rip currents. Our working hypothesis was that such resonant conditions should be avoided as the resulting rip currents would be a hazard to swimmers and the rips would wash the sand offshore, defeating the purpose of the groins. We felt that some groin failures might have been an inadvertent selection of a groin spacing that resonated with the existing beach and wave conditions.

Our experiments quickly demonstrated that our initial hypothesis was incorrect, at least for the wave-basin scale and groin geometry tested. Rather than obtaining edge waves with the same period as the normal waves in the basin, subharmonic edge waves were produced with periods twice those of the incoming waves so that rip currents were not formed by the interactions of the edge waves and normal waves as proposed by Bowen (1969) and Bowen and Inman (1969). Rip currents were present in the wave basin but their origin is uncertain and they were not strong enough to cause beach erosion. They commonly originated at the node position of the subharmonic edge waves, but then migrated alongshore to the antinode positions, obtaining their best development when adjacent to a groin.

Guza and Davis (1974), Guza and Inman (1975) and Guza and Bowen (1975) had previously demonstrated theoretically and experimentally that the subharmonic edge wave with a period twice that of the incident waves is most

easily generated and the one most often occurring. The second most likely edge wave to be generated is that with a period equal to the incoming wave (termed the synchronous edge wave) of low modal number. Our wave basin experiments, therefore, agree with their conclusions. In all our experiments, subharmonic edge waves were easily generated in the wave basin, while synchronous edge waves were not detected even when the appropriate boundary conditions were employed. Guza and Inman (1975, p. 3005) found that when the incident wave period was chosen so that the groin and beach geometry excluded subharmonic resonances, synchronous edge waves were sometimes clearly visible in the run-up. This was not the case in our study. The reason is unknown; perhaps it is due to the smaller scale of our wave tank.

Our finding strong subharmonic edge waves in the wave tank tests also agrees with the field studies of Huntley and Bowen (1973, 1975a). Through measurements of the horizontal water particle velocities across the near-shore on a steeply sloping beach, they obtained clear evidence for the existence of subharmonic edge waves; synchronous edge waves were not detected.

Because we obtained only subharmonic edge waves, our study shifted to an investigation of their effects on the beach between the groins, and to the strength of the edge waves as a function of the groin geometry and wave conditions. The strength of the edge waves was taken as indicated by its swash distance up the beach face and its amplitude computed from this swash distance. As will be seen, the strength was found to be a function of the groin length and spacing.

A series of experiments were conducted with a thin layer of sand covering the otherwise evenly sloping solid beach for the purpose of determining what effects the presence of the sand might have on the edge wave strength and how the sand is redistributed on the beach by the combination of edge waves and incoming waves. The interest was whether general erosion or accretion of the beach would result from the presence of the subharmonic edge waves, and therefore whether they are to be avoided in the design of groin fields.

COMBINED FLOW OF EDGE WAVES AND NORMALLY INCIDENT WAVES

Recent research by Bowen (1969), Bowen and Inman (1969, 1971), Guza and Davies (1974), Guza and Inman (1975), Guza and Bowen (1976), and Huntley

and Bowen (1973, 1975a) have shown that waves incident on a beach can generate standing edge waves. Standing edge waves have their crests normal to the shoreline and their wave lengths from crest to crest parallel to the shoreline. Thus they are rotated ninety degrees in orientation to the incident swell waves. As shown in Figure 1, there are alternate positions

Figure 1: One possible type of standing edge wave (zero mode) with nodes and antinodes along the beach length, and decreasing in amplitude offshore. Higher-mode edge waves have a more complicated offshore variation in amplitude.

of nodes and antinodes along the beach. At the nodes there is no up and down motion of the water surface due to the edge waves, and at the antinodes the full edge wave height can be observed. The edge wave oscillations are best detected as run-up on the sloping beach. The edge wave height is maximum at the shoreline and decays offshore in a manner depending on the offshore modal number (Ursell, 1952).

Since in our experiments we obtained only subharmonic edge waves, our discussions will be limited to their interactions with the incoming waves and the resulting effects on the beach. The combined motion of the incident waves and the generated subharmonic edge waves is shown in Figure 2. The groins are located along the right and left hand boundaries, defining a

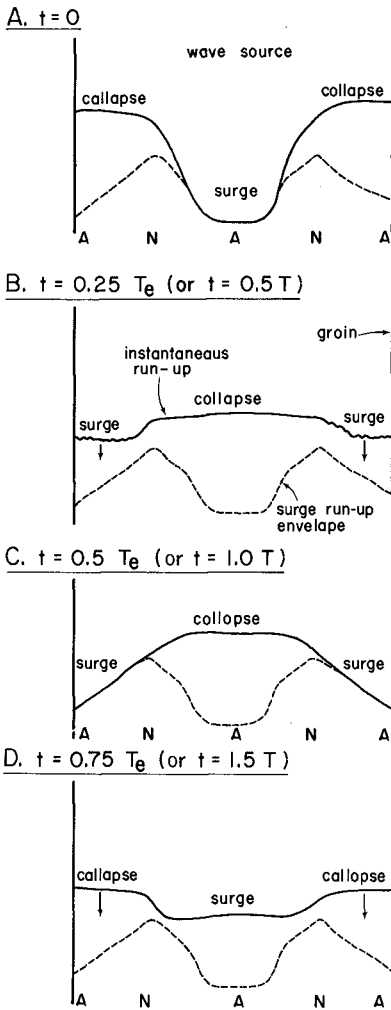

Figure 2: The interactions of the subharmonic edge waves with the normal waves to give a varying pattern of run-up and breaker type. Note that the edge wave period T_e is twice the period T of the paddle-produced waves.

limited length of beach. Figure 2 is based on actual photographs of the wave basin tests. The continuous line indicates the instantaneous position of the leading edge of the combined wave run-up, while the dashed line depicts the maximum wave run-up envelope. The groin spacing is 3.0 meters, and antinodes (A) are located at each groin and midway between them. The two nodes (N) are midway between the antinodes. The wave run-up at the edge wave nodes is approximately equal to the run-up due to the paddle-driven waves alone.

In Figure 2A the run-up is maximum at the central antinode where the breaker surged up the beach face. Figure 2B shows the next wave collapsing at the central antinode due to its interaction with the backwash from the previous surging breaker. In addition, in Figure 2B the breakers at the bounding antinodes can be seen beginning to surge up the beach slope. In Figure 2C the run-up is maximum at the bounding antinodes and minimum at the central antinode; this run-up pattern occurs one half of an edge wave period (equal to one period of the incident waves) after the run-up pattern in Figure 2A. Figure 2D displays the run-up approximately one-fourth edge wave period later. The incident wave at the central antinode is beginning to surge up the beach face while the breakers at the bounding antinodes are of a collapsing type.

As the wave height of the incident paddle-driven waves was increased, the breaker types become more plunging, and the edge wave amplitude decreases until it is no longer observable in the run-up pattern. Guza and Inman (1975) obtained the same results. The indication is then that under larger waves on beaches the edge waves will be relatively less important and may disappear altogether. However, the measurements by Huntley and Bowen (1973, 1975a) of standing subharmonic edge waves even under plunging wave conditions suggest that they do not disappear entirely, although they may not be observable in the swash run-up.

Reflection of the incident waves from the beach face is important in the generation of edge waves according to the theoretical considerations of Guza and Davis (1974) and Guza and Bowen (1975). This again appears to be borne out by the field measurements of Huntley and Bowen (1973, 1975b) who did not find incident-wave related edge waves on a low sloping beach (slope

tangent 0.014) but did on a steep beach (slope tangent 0.13). Our laboratory tests are limited to a steep beach (slope 0.125) where wave reflection and edge wave development can be expected to be important.

Longshore periodicities observed on laboratory beaches may be due to cross waves produced at the wave paddle and extending down the entire wave basin length (Garrett, 1970). Cross waves can be ruled out as producing the run-up patterns observed in the present study. In most tests, wave periods were selected so as to give resonant conditions for the generation of sub-harmonic edge waves. In addition, the run-up patterns already described closely conform to those recounted by Guza and Inman (1975) for edge waves.

GROIN LENGTH ON NONERODABLE BEACHES

A series of experiments were conducted to determine the effect of the groin length and spacing on the run-up and amplitude of the generated edge waves. As in the other tests, the wave basin in the hydraulics laboratory of the School of Engineering, Oregon State University, was employed. This wave basin is 6.1 m wide and 9.1 m in length along the direction of wave propagation. Wave guides were placed parallel to the side walls and adjacent to the paddle edges to eliminate wave reflection and diffraction as the waves travel toward the sloping beach. Because of the relatively short length of the basin, a steep beach slope $s = 0.125$ had to be used. Wooden impermeable groins were placed perpendicular to the shoreline a distance b apart.

To satisfy the boundary conditions of no flow through the groins,

$$b = m L_e / 2 \quad (1)$$

for the groin spacing b , where m is an integer equal to the number of half edge wave lengths in the longshore direction, L_e denoting the full edge wave length in the longshore direction. Using this equation and the dispersion relationship for standing edge waves (Guaz and Inman, 1975), the relationship

$$b = g T_e^2 m (1 - 2p) s / 4\pi \quad (2)$$

is obtained where g is the gravitational acceleration, T_e is the edge wave

period, m the modal number of equation (1), p is the slope truncation effect, and s is the beach slope. For the conditions of these experiments, $m = 2$ and $p = 0$, yielding the simplified equation

$$b = \frac{g T_e^2 s}{2\pi} \quad (3)$$

To generate the resonant edge waves associated with a groin spacing b , the normally incident paddle-driven waves must have a period equal to one half the edge wave period T_e in equation (3). For the groin spacings used, $b = 2$ m, 2.5 m, 3 m, and 3.5 m, the corresponding edge wave periods are $T_e = 3.20, 3.60, 3.92,$ and 4.24 sec respectively.

In order to observe the maximum possible run-up at the antinodes due to the edge waves alone, very long groins were initially used. The run-up due solely to the edge wave was determined at the central antinode by measuring the total maximum run-up at time intervals equal to the incident wave period. Subtracting two successive run-up measurements eliminated the run-up due to the incident waves and yielded the edge wave run-up portion. These measurements were repeated for ten waves and averaged. Once a run-up value for the long groins was obtained, both groins were shortened and the measurements repeated. The groins were thus progressively decreased in length until edge waves were no longer observed in the run-up.

Figure 3 and Table 1 summarize the results of these experiments for the series of groin spacings $b = 2.0, 2.5, 3.0$ and 3.5 m. The beach slope tangent was held at $s = 0.125$, and the deep-water wave steepness remained nearly constant at $H_{\infty}/L_{\infty} = 0.005$ to 0.0064 . The ordinate in Figure 3 is the run-up R_e due to the edge waves, divided by the maximum edge wave run-up R_{e-max} which occurred for the longest groin length. The abscissa is the ratio of the groin length L_g to the groin spacing b . The submerged groin length is used for L_g , and is defined as the offshore length measured from the intersection of the still-water line with the beach face.

From Figure 3 it is seen that for all four groin spacings, as the submerged groin length L_g is decreased, the run-up due to the edge waves is decreased. When the submerged groin length is decreased to about $0.15b$,

Figure 3: The strength of the subharmonic edge waves as indicated by their run-up R_e , the strength decreasing as the length of the grains L_g are decreased relative to the grain spacing b .

Figure 4: Experiments similar to those of Fig. 3 but where the grain spacing is held constant at 3 meters and the wave steepness varied.

TABLE 1: Edge Wave Run-up Versus Groin Length

A. Experiments on nonerrodable smooth slope

1. $b = 2.0$ m; $T_i = 1.58$ sec; $H_i = 2.2$ cm; $h_i = 37.0$ cm; $R_{e-max} = 65.0$ cm; $H_\infty/L_\infty = 0.005$;

Definitions: L_g = submerged groin length; R_e = edge wave run-up; b = groin spacing; T_i and H_i are incident wave period and height; h_i = water depth in constant-depth portion of basin.

the characteristic combined flow pattern of subharmonic edge waves and normal paddle waves is no longer observed. There is some variation in this critical groin length, the value of L_g/b being 0.15 for three of the experimental groin spacings, and about 0.25 for $b = 3.5$ m. The decrease in the edge wave run-up is sharp, indicating an abrupt termination in the edge wave's presence. For groins shorter than the indicated critical value of L_g/b , the side-wall boundary conditions imposed by the groins are no longer effective in the generation of edge waves with a wavelength equal to the groin spacing.

Figure 4 and Table 1 contain a similar series of experiments, but where the groin spacing was held at $b = 3$ m and the wave steepness H_∞/L_∞ varied. Although the scatter is large, the experiments yield the same range of critical L_g/b values for the termination of edge wave run-up as found in Figure 3. The indication in Figure 4 is that if there is any dependence of the critical L_g/b ratio on the wave steepness, it must be small. In the case of $H_\infty/L_\infty = 0.011$, Figure 4, as L_g/b approached the critical value, the edge waves were observed to be episodic, appearing for a time and then disappearing. These are labeled Ep. in the diagram.

Our results then indicate that there is a critical groin length to spacing ratio, L_g/b , below which subharmonic edge waves apparently are not generated, or are at least not observed in the run-up. This critical condition is not appreciably affected by the steepness of the normal incident waves. The basin utilized in our experiments is not sufficiently long to install low beach slopes, so we were not able to test for a beach slope dependence of the critical L_g/b value.

The reduction in the edge wave amplitude at the shoreline as the groin length is decreased can be related to the edge wave's amplitude dependence on the offshore distance. When the long groins are installed the edge wave is fully developed with its amplitude maximum at the shoreline and, according to theory (Guza and Inman, 1975), decaying exponentially offshore as shown by the dash-dot curve in Figure 5. The nondimensional offshore distance is zero at the intersection of the beach slope and the still-water level. Also graphed in Figure 5 is the measured edge wave amplitude at the shoreline for two of the groin spacings as functions of the nondimensional submerged groin length. The

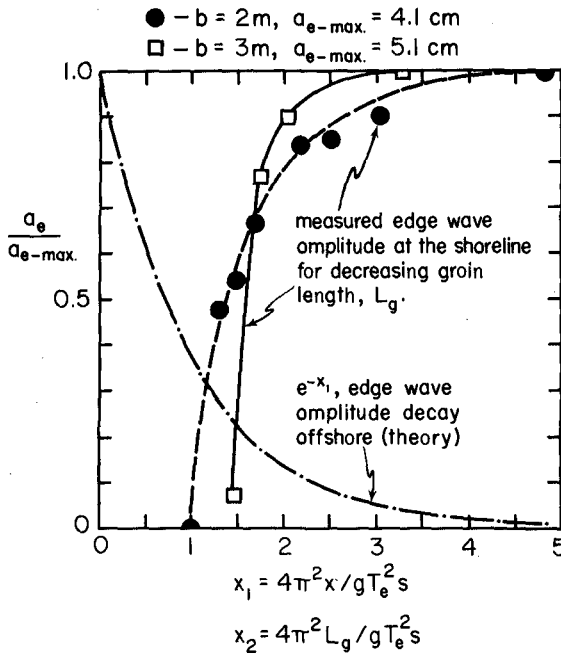

Figure 5: The edge wave amplitude a_e , obtained from the measured run-up, as functions of the submerged groin length and distance x offshore from the still-water line, both expressed in nondimensional form.

edge wave amplitude, a_e , is obtained from the measured run-up R_e by the equation (Guza and Inman, 1975)

$$a_e = R_e s / 2 \tag{4}$$

where s is the beach slope.

The measured edge wave amplitude at the shoreline ($x_1 = 0$) decreases to zero for nondimensional groin lengths between 1.0 and 1.5 (Figure 5). These lengths correspond to an offshore distance where the edge wave amplitude is equal to e^{-1} and $e^{-1.5}$ of its value at the shoreline for the fully developed state (which in these experiments occurred with the longest groin lengths). In other words, subharmonic edge waves were not generated when the groin

lengths did not extend seaward of the offshore distance where the maximum edge wave has an amplitude equal to approximately e^{-1} of its value at the shoreline. For groins shorter than the defined critical length the boundary condition of no flow through the groin wall is not a factor in enhancing the generation of the subharmonic edge wave corresponding to the groin spacing b .

EXPERIMENTS ON NONERODABLE BEACHES COVERED WITH SAND

A series of experiments were undertaken with a thin veneer of sand initially uniformly covering the solid evenly sloping beach. These were performed to determine if the presence of the sand appreciably changes the edge wave run-up values. The results also allow insight into the possible effects of the edge wave's existence on erosion or accretion between the groins.

For each groin length the sand was initially smoothed out 1 to 2 cm thick, covering the beach slope between the groins from the still-water level to depths beyond the influence of the waves. After 1.5 to 2 minutes of normally incident, paddle-driven waves arriving at the beach, edge waves would appear, beginning the redistribution of the sand alongshore as well as in the on-offshore direction. After about 15 minutes the sand would reach an approximately unchanging configuration, although the sand diameter was not in equilibrium with the beach slope.

The general tendency of the combined edge wave and incident waves is to reform the sand into the characteristic pattern shown in Figure 6. The sand extends much further up the beach slope from the still-water level at the antinodes (located near both groins and midway between them) than at the nodes (located midway between the antinodes). This sand has been removed from the now barren slope section (Figure 6) at and just shoreward of the breaker zone. Most of the total volume of sand accumulated on the upper beach is at the edge wave antinode positions not only because it extends further up the beach there, but also because the sand is at least three times as thick. For the groin length in Figure 6, the maximum sand depth at the antinodes is 2.0 cm whereas at the nodes it is only about 0.5 cm. Note

Figure 6: Redistribution of sand on beach face by subharmonic edge waves. Sand initially covered the solid beach in a thin even layer below the still-water level. A and N denote respectively the edge wave antinode and node positions.

that the barren section of the beach slope (the sand source to the upper beach) is very nearly uniform in the longshore direction, indicating that some of the sand seaward of the nodes is transported to the sand accumulations at the adjacent antinodes. The much larger flow velocities occurring at the antinodes are indicated by the sand ripple formations seaward of the barren slope; definite ripple patterns exist offshore of the antinodes while only very weak ripples or none at all exist seaward of the nodes.

When the beach slope is initially entirely covered with a thin layer of sand, rather than covered just below the still-water line as before, the subharmonic edge waves together with the incident waves reform the sand into a series of beach cusps. The intense swash at the antinode positions hollows out the beach sand, producing the embayments; the cusp horns were located at the nodes of the edge waves. This has already been demonstrated by Guza and

Inman (1975), also in a wave basin (see their Figure 8, page 3007). Beach accretion occurs at each cusp while erosion occurs in the embayments at the antinode positions of the subharmonic edge waves; this is just opposite to our previous test with sand initially only below the still-water line. Either way, the presence of the strong subharmonic edge waves caused local rearrangements of the sand on the beach face and local areas of erosion and beach accretion. However, there was no significant offshore losses of sand from the beach face as might have been the case had strong rip currents been produced as originally envisioned.

Experiments similar to those conducted on the nonerodable beach were executed to determine the effect of groin length on edge wave generation in the presence of the sand. For each groin length the maximum combined wave run-up at the central antinode was measured for successive waves and used to compute the edge wave run-up portion R_e as before. Because the sand is not in complete equilibrium with the beach slope, some difficulties were encountered in obtaining realistic edge wave run-up values for all groin lengths.

The general result of these measurements (Table 1) is that the critical groin length determined for the nonerodable solid beach (Figures 3 and 4) is still adequate in the presence of the sand. Although the $R_e/R_{e-\max}$ values tend to decrease with decreasing groin length, a larger amount of variability about this trend is exhibited as compared to the experiments using no sand cover. Part of this variability is due to the uneven distribution of the sand cover alongshore; run-up just to the sides of the antinode positions is not opposed by as thick a sand cover. This run-up, in many cases, flows as high or higher up the beach face than the run-up at the antinode position. This pattern of run-up occurred for the steady sand cover condition described above.

The greatest effect of the sand on the run-up can be seen by comparing the maximum edge wave run-ups with and without the sand present. The $R_{e-\max}$ value with the sand was 36.4 cm, and without the sand it was 86.5 cm.

The decrease in the edge wave run-up as a function of decreasing groin length is demonstrated in Figure 7, obtained from overhead photographs, where

Figure 7: The decrease in the edge wave run-up as a function of the groin length L_g . Run-up lines determined from overhead photographs of sand cover, the sand initially being a uniform thin layer below the still-water level. Lines terminate on left due to inadequacy of photographic coverage.

the beach was again initially covered with sand only below the still-water line. Contours of the maximum distance up the slope of the sand covered beach are plotted for three groin lengths. The general trend of lower maximum contour with decreasing groin length is apparent. For $L_g = 64$ cm, the edge waves developed after two minutes and decayed after six minutes.

SUMMARY AND DISCUSSION

In all our wave basin experiments, we obtained subharmonic edge waves of period twice that of the incident paddle-produced waves. This lends additional support to the theoretical and experimental work of Guza and Davis (1974), Guza and Inman (1975), and Guza and Bowen (1975, 1976), who found that the subharmonic edge wave is most easily generated and the one most often occurring.

We were unable to generate synchronous edge waves with the same period as the paddle-driven waves. This precluded the formation of rip currents as outlined by Bowen (1969) and Bowen and Inman (1969), where the synchronous edge waves interact with the incident waves to produce longshore variations

in breaker heights and therefore a cell circulation. Rip currents were present in our tests, but at all times they were very weak, too weak to cause any erosion of beach sands between the groins. Initially, we set out to study the resonant conditions leading to strong rip currents, producing beach erosion and thereby defeating the purpose of the groins. Under prototype conditions rip currents do appear to be particularly strong between groins, causing offshore losses of sand. For example, Per Bruun (pers. communication, July 1976) indicated that rip currents were important in sand losses in the groin field at Miami Beach, Florida. Thus our initial working hypothesis seems to have been correct, but our inability to generate strong rip currents in the laboratory wave basin precluded its study. Why we were unable to generate synchronous edge waves and strong rip currents is uncertain; perhaps our wave basin (6.1 m by 9.1 m) is too small.

Subharmonic edge waves were readily produced so our study shifted to an examination of how the groin spacings and lengths control their strength, as manifested in the run-up on the beach face, and how they rearrange sand between the groins. We found that as the submerged lengths of the groins are decreased relative to the spacing, the edge wave strength and run-up decreased. When the ratio of groin length to spacing reached about 0.15 to 0.20, the effects of the subharmonic edge waves on the run-up were no longer observable. Thus subharmonic edge waves can be avoided in groin fields by making the groin lengths sufficiently short relative to their spacings.

A series of tests were undertaken with a thin covering of sand on the otherwise solid beach face to determine how much redistribution of the beach sand would be produced by the subharmonic edge waves. In all tests the edge waves produced a cusped shoreline so there were local areas of erosion and deposition. However, there were no offshore losses of sand from between the groins so the presence of the subharmonic edge waves posed no threat to the groins nor defeated their purpose. When the beach was initially entirely covered with a thin layer of sand the beach cusps formed had their embayments at the antinode positions of the subharmonic edge waves and the cusp horns at the node positions. This agrees with the results of Guza and Inman (1975) and supports their contentions concerning the origin of beach cusps by subharmonic edge waves.

CHAPTER 87

COMPREHENSIVE MONITORING OF A BEACH RESTORATION PROJECT

by

O. H. Shemdin (1), H. K. Brooks (2),

Z. Ceylanli (3), S. L. Harrell (4)

ABSTRACT

This paper outlines the results obtained from monitoring the Beach Nourishment Project at Jupiter Island, Florida. Jupiter Island is a 16 mile long barrier island on the east coast of Florida. Five miles of the beach were nourished in two stages in 1973 and 1974. A total of 3.4 million cubic yards of sand were dredged from an offshore borrow area and placed on the beach. The monitoring program included: seasonal hydrographic surveys of beach and offshore profile to 3000 feet offshore; climatological monitoring of wind, waves, tides and currents over a one-year period; tracer and dye studies; and sand sampling and coring at selected beach and offshore locations. The results indicate that beach restoration has a groin effect in the sense of producing favorable changes in littoral drift due to shore alignment changes. A net accretion updrift of the restored area occurs. The results demonstrate the importance of the offshore profile in accounting for the total sedimentary balance. Shoreline recession coupled by a build up in the offshore profile may reflect accretion rather than erosion. Finally, the results show that the littoral drift formula using the wave climate as input provides inadequate prediction estimates for erosion or deposition following construction of a beach restoration project.

I. INTRODUCTION

Jupiter Island is a barrier island about 16 miles long on the east coast of Florida. The island lies between St. Lucie inlet, on the north, and Jupiter inlet, on the south, Figure 1. The island has had a long history of erosion problems and has been a subject of extensive studies (see references 1, 2, 3, 4, and 5). In the past several years the residents of Jupiter Island, Florida have financed the construction of seawalls, revetments and groins in an effort to prevent loss of beach-front property. In addition to structural protection, several beach fill techniques have been tested including scrapers and draglines recovering material from the surf zone. These efforts were not successful - [6]. It was proposed that a long term solution to the problem was artificial nourishment of the beach from offshore borrow.

In 1973 the town of Jupiter Island agreed to restore a 5 mile portion of the beach with about 2.4 million cubic yards of sand to be obtained from an offshore borrow area about 3000 feet from the shore [5]. Due to construction difficulties the restoration project was completed in two stages, 68% of restoration completed in the summer 1973 (Stage I), and 32% completed in the summer of 1974 (Stage II) and a total of 3.4 million cubic yards of sand was placed on the beach. About 1000 feet of beach, public beach in Figure 1, was left unrestored because of an alleged biologically important reef in the surf-zone immediately offshore.

Artificial beach nourishment from offshore borrow as a method to combat beach erosion and provide recreational areas is now utilized over most other engineering practices. The costs of placing large volumes of suitable beach fill are high. It is therefore important that criteria be developed for evaluating and predicting the effectiveness of borrow material from offshore sources. At the present time no completely satisfactory test for evaluating the feasibility of utilizing available offshore borrow has been developed. Though much more work must be done, it has become evident that more emphasis must be given to total onshore and offshore volumetric transport and the range in size gradation of the borrow material.

II. MONITORING OF THE RESTORED BEACH

A monitoring program was undertaken to evaluate the fill performance. The specific objectives were to observe the changes in the sand balance, shoreline shape, sand characteristics, and to explain these changes in terms of causative factors. The monitoring study was initiated in March, 1974 and included the following:

- (1) Seasonal hydrographic surveys of the beach and the offshore profile to 3000 feet offshore along six miles of the restored beach and adjacent areas.
- (2) Continuous monitoring of wind, waves, tides and currents over a one year period.
- (3) Tracer and dye studies.
- (4) Sand sampling and corings at selected beach and offshore locations.

(1) The Hydrographic Surveys

Hydrographic surveys including the offshore profile were conducted along six miles of beach before construction, after first construction

Figure 1. Location Map .

and at different intervals afterwards. Pre-construction and post-construction surveys of stages I and II were conducted by Arthur V. Strock & Associates, Inc. of Deerfield Beach, Florida. Their surveys were limited to 1200 feet from shore. More frequent and detailed surveys were conducted by the Coastal and Oceanographic Engineering Laboratory (COEL), covering the offshore profile to 3000 feet. Table I shows the summary of hydrographic surveys conducted.

Table I. Summary of Hydrographic Surveys.

Date	Description	Surveyed By	Reference Date
June-Sept., 73	Pre-Construction stage I	Strock&Assoc. Inc.	June, 1973
July-Nov., 73	Post-Construction stage I	Strock&Assoc. Inc.	Nov., 1973
May-June, 74	Follow-up (This also serves as pre-constr. for stage II)	COEL, Strock & Assoc., Inc.	May, 1974
June-July, 74	Post-Construction stage II (This is a partial survey covering only stage II fill area)	Strock&Assoc. Inc.	June, 1974
Aug., 74	Summer survey	COEL	Aug., 1974
Nov., 74	Fall survey (after Oct.	COEL	Nov., 1974

(2) Monitoring of Wind, Waves, Tide, and Currents

- a) Continuous recordings of wind speed and direction were obtained from March 1974 to May 1975. Use was made of a MRI Anemometer Model 1071. The anemometer was installed on a tower 30 feet above ground level inside the study area, shown as square number 1, in Figure 2.
- b) Continuous recordings of the tide were obtained from March 1974 to May 1975. A Leopold Stevens tide gauge, type F, was placed at the end of a pier 10 miles south of the south end of the study area.
- c) The monitoring of waves presented a more troublesome task than anticipated. No piers or other convenient structures could be found near the study area. It was decided to use a self recording pressure type wave gauge, Bass Engineering model WG/100M, which was installed in 20 feet depth within the study area (square number 2 in Figure 2). This gauge did not perform satisfactorily and no significant data was collected during the period of use. An Ocean Applied Research (OAR) Telemetry Wave Gauge was subsequently installed at a depth of 30 feet in October 1974 (square number 3 in Figure 2). It operated satisfactorily until January 1975. In April 1975 a Hydroproducts Wave and Tide gauge, Model 621, was installed. The shore based monitor was connected to an offshore pressure transducer by a 3000 foot armored cable. The location of this installation is shown as square number 4 in Figure 2. The latter gauge operated satisfactorily

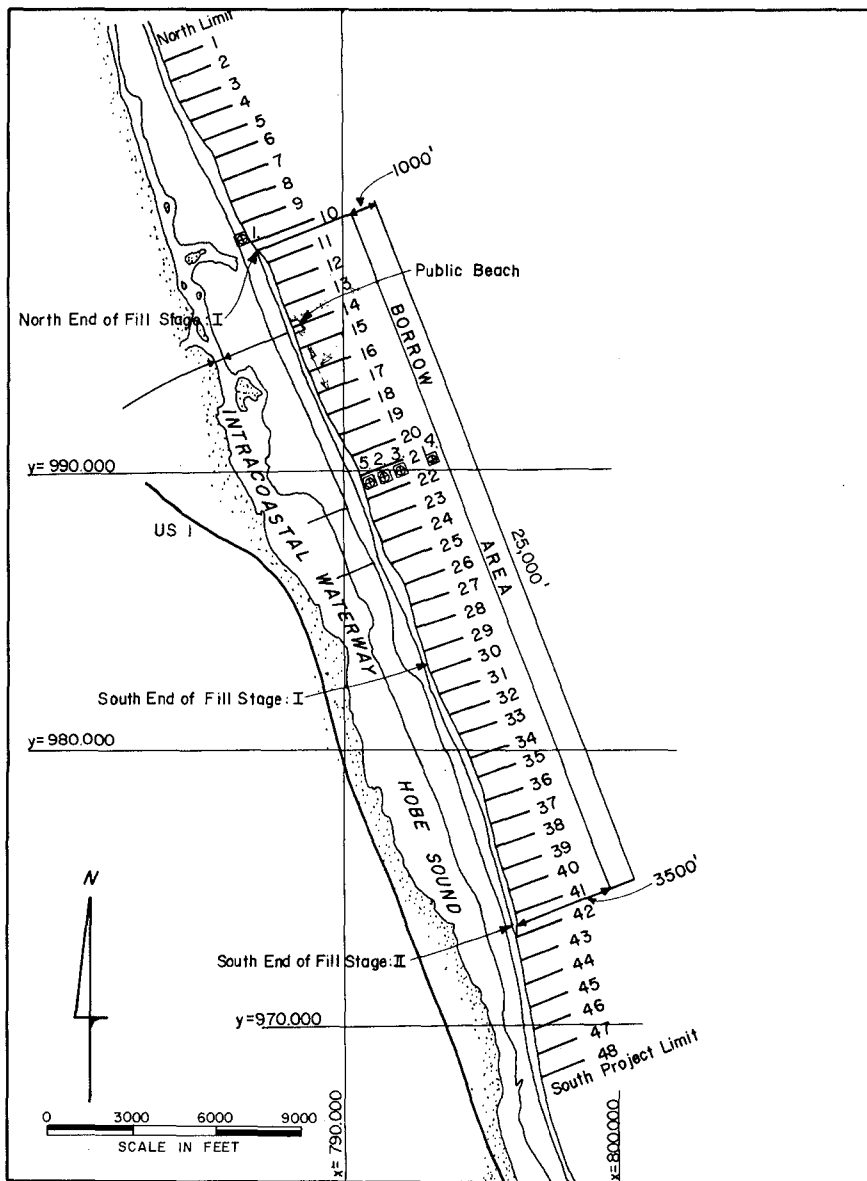

Figure 2. Profile lines and instrument location map.

until the end of the study period (May 1975). Wave directions were obtained by measuring the angle between the shoreline and the breaker line. These measurements were obtained at two locations two to five times a day during the periods of wave recording. One observation post was immediately shoreward of the wave gauge and the other was at the pier near the tide gauge installation.

- d) Current measurements were obtained using a Bendix Model Q-16 self-recording current meter. This meter was installed in 11 feet water depth. The impeller duct was placed 3 feet above the bottom (square number 5 in Figure 2). Current magnitudes and directions were continuously recorded from October 1974 to May 1975 with only intermittent failures.

(3) Tracer and Dye Studies

The littoral drift pattern and longshore velocities in the study area were periodically measured. Fresh water filled balloons with attached fluorescent dye bags were placed at different distances from shore. Each balloon was followed along its travel path and its speed recorded. At the same time wave characteristics, beach profiles and wind speeds were recorded.

In August 1974 a tracer study was conducted in the study area. Four tons of original borrow material were treated in the Laboratory. The sand was sieved into three different diameter size categories and each size dyed with different fluorescent dye colors. The quantities dyed and their respective diameters were: 4000 lbs. with a median diameter of 0.13mm, 1350 lbs. with a median diameter of 0.21 mm and 1350 lbs. with a median diameter of 0.50 mm. The various color sands were then mixed and point injected at the beach face during low tide. The position of the tracer particles in the dynamic zone were monitored after 1/2, 2, 10 and 40 tidal cycles by taking sand samples at established grid points. Profile locations were sampled at high water mark, low water mark, and at depths 3 feet, 5 feet, 10 feet, 15 feet, and 20 feet.

(4) Sand Sampling and Coring

A limited coring program was completed in May 1974 in which continuous cores, four to ten feet in length were obtained from the beach face, the breaker bar and at distances of 500 and 1000 feet offshore. Relatively undisturbed subsurface samples were obtained by utilization of a double walled piston coring device which employed circulating drillers mud to overcome external friction on the core barrel. It was anticipated that sampling lines at the north, center and southern end of the beach fill would best represent the adjusted areal and stratigraphic distribution of the artificially placed sediment. However, bedrock was encountered at a shallow depth in the first two cores attempted at the north end of the project and the line of sampling was not completed. Thus, multiple cores were obtained only from lines 31 and 37, Figure 2.

Grain size frequency, bulk density, grain density and percent shell were determined in subsequent laboratory analysis. The cores were zoned and analyzed based upon evident changes in the physical parameters of the sediment with depth in the core.

One set of surface sediment samples obtained in the August 1974 tracer study was analyzed for size frequency only. Certainly, more intervals of sampling would have been desirable. The core samples do, however, represent depositional changes through time. From the cores obtained in May 1974 from the "adjusted" 1973 beach fill and the August 1974 surface samples, consistent results were obtained. Thus, we believe the sampling program provided data upon which evaluation of the behavior of the artificial beach fill at Jupiter Island could be made.

III. DATA ANALYSIS AND RESULTS

(1) The Hydrographic Surveys

The hydrographic surveys were analyzed to yield information on the total sand volume in the nourished area and its gradual depletion with time. Figure 3 shows a summary of the total sand volumes in the study area during the different stages of construction and post construction periods. It is surprising to see no net loss of sand after one year following completion of the first stage. This was not expected since it is believed that a net littoral transport towards the south prevailed in this area of the shoreline, see reference [7].

Although unexpected at the outset the above result is easily explained by the fact that both the shoreline and the offshore profile advanced following restoration. The latter produced a groin effect at the northern extremity of the fill. The shoreline alignment with respect to breaking waves is altered and induces a net decrease in the longshore current at the north end of the restored section. The nourished area therefore received sand from the then prevailing littoral system at its north end. The gain is evidently equal to the loss from the central and southern segments of the fill during the first year. The analysis of the hydrographic surveys indicated a small net gain during this first year.

The distribution of volumetric changes along the study area is shown in Figure 4(a). As indicated before, the shore area at the public beach was left unrestored to satisfy biological concerns for a reef offshore. Both sides of the public beach were restored, however. It is evident from Figure 4(a), that large quantities of sand were transported by littoral drift from the nourished area north of the public beach to the void in front of the public beach. This is shown in Figure 4(a) as erosion north of the public beach and accretion at the public beach. The groin effect discussed previously is also evident by the accretion pattern at the north end of the fill. The central region of the fill (south of the public beach) shows minor erosion as expected because of prevailing southerly longshore drift. Near the south end of the fill a net accretion occurred. This is probably due to the wave refraction pattern generated in the vicinity of a recessed shoreline.

Figure 4(a) shows that erosion patterns can not be determined by observing changes in the shoreline profile alone. Two shoreline contours obtained from the November 1973 and May 1974 surveys are drawn with respect to the reference prefill shoreline of June 1973. Near the north end of the fill the shoreline is receding while a net volumetric gain is computed due to the groin effect discussed before. A similar pattern is observed near the southern end of the fill. In the central

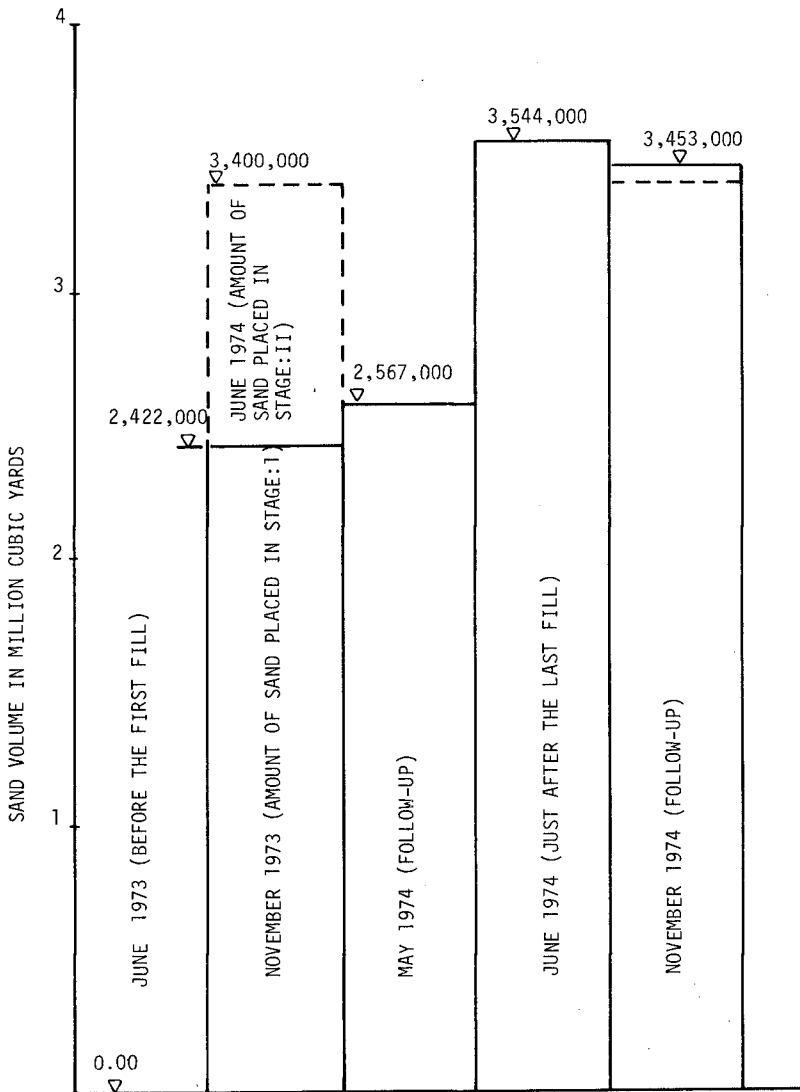

Figure 3: Summary of volume calculations obtained from hydrographic surveys.

(a) OBSERVED VOLUME CHANGES ALONG THE SHORELINE FROM NOVEMBER 1973 TO MAY 1974. (+ ACCRETION; - EROSION); (b) SHORELINE POSITIONS AS REFERENCED TO 1973 PREFILL SHORELINE

Figure 4

region (south of the public beach) on the other hand, the shoreline contour is advancing towards offshore while the volumetric curve shows a net erosion. This can only be explained by the shoreward retreat of the offshore profile.

Further insight on the advance of the offshore profile and the simultaneous retreat of the shoreline contour is presented in Figure 5. In the top portion 11 foot depth contours are depicted to show the advance of the offshore profile. During the same period a general recession in the shoreline contour occurs and is shown in Figure 5(b). Figures 4 and 5 clearly demonstrate the role of the offshore profile; the central conclusion being that shoreline advances and recessions are poor indicators of accretion or erosion in a nourished area.

The borrow area and the locations of borrow holes also produce substantial variations in the offshore profile. These are shown in Figure 6. Five foot contours are drawn to show variation of the offshore bar during the period of the study. This depth is typical of the near shore bar. The May 1974 contour shows the beginning of a cyclic variation which has correspondence to the offshore borrow holes. The variation is accentuated in the November 1974 contour following the October 6-7, 1974 storm. The borrow holes induce nearshore concentration of energy by uneven refraction of wave rays in the vicinity of borrow holes. The refraction calculations were not carried out due to lack of hydrographic data in the vicinity of borrow holes.

(2) The Wave Climate and Longshore Transport

The analysis of the wave data was aimed at determining the monthly averages of the long shore current (and sand transport) at different stations along the restored beach. The in situ measurements were supplemented by available wave statistics corresponding to the period of study from NOAA, Surface Marine Observations, National Climatic Center. This data was found to be especially useful in filling in situ measurement gaps. The measured wind speeds and directions were found helpful in producing correlations between different wave data sets. Hydrographic information was obtained from monitoring surveys and USGS boat charts.

The analysis procedure consisted of generating equivalent deep water wave heights and directions from nearshore point measurements of wave height, period and breaking angle. A modified Dobson [8], refraction program was utilized with a nested grid system. A nearshore fine grid network was used to relate the measured breaker angle to a mean wave direction at the wave measuring station. Then using a large grid the measured wave heights and the derived wave directions were used to yield deep water wave heights, and directions.

The surface Marine Observations of NOAA were calibrated by correlating the derived deep water wave heights and directions during the periods when both data sets were available. Calibration constants were derived to make the ship observations compatible with in situ measurements.

The monthly averages of equivalent deep water wave parameters were computed and are shown in Table 2. The period covered is bounded by two hydrographic surveys. The intent was to predict the net erosion or deposition during this period by using the wave climate and the littoral drift formula and to compare with corresponding erosion or deposition patterns calculated directly from the hydrographic surveys.

(a) CHANGES IN 11 feet CONTOUR; (b) CHANGES IN SHORELINE, BOTH AS REFERENCED TO 1973 PREFILL SHORELINE

Table 2. Deep Water Wave Climate.

Date	T (sec.)	H _o (ft.)	θ (deg.)
March	8	1.0	109
April	8.5	1.48	110
May	7.4	1.04	119
June	7.7	0.84	120
July	8.2	0.96	98
August	9.1	0.99	110
September	7.9	0.99	106
October	8.9	2.6	69

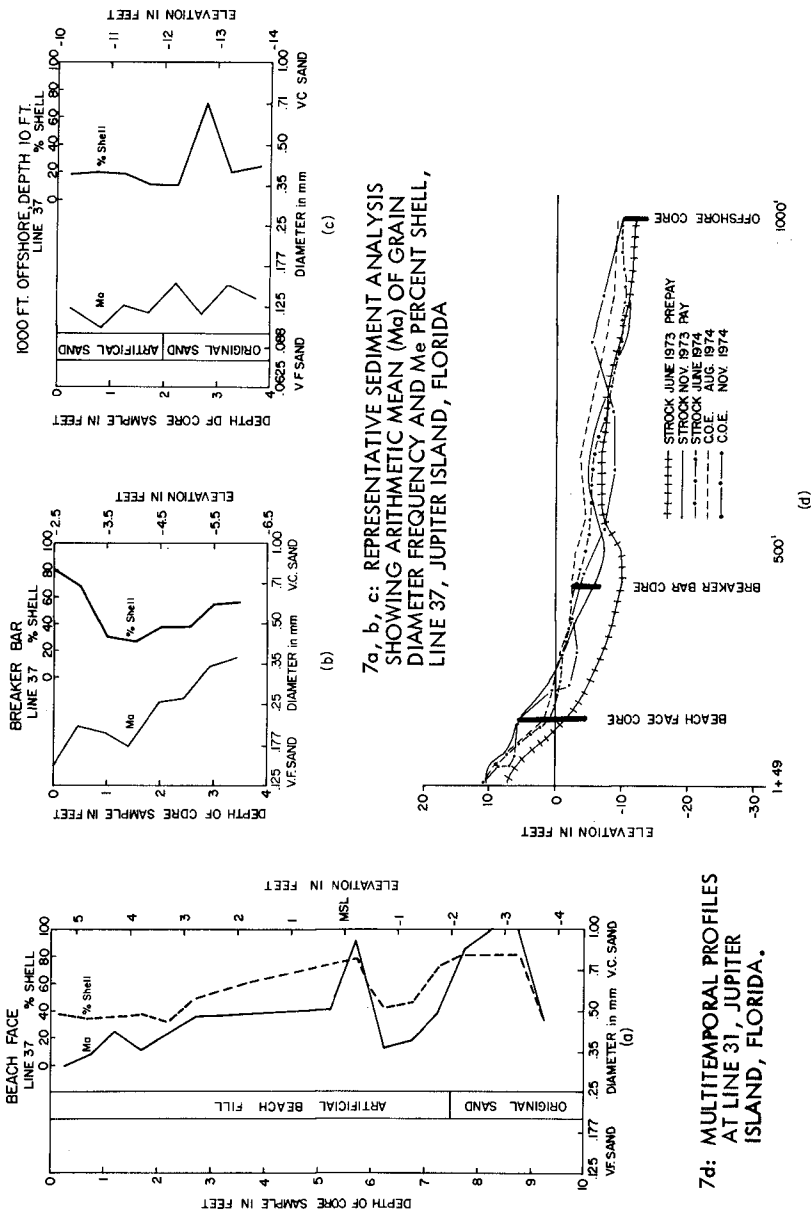

The predicted volumetric changes using the littoral drift formula were found to be one order of magnitude larger than calculated values from hydrographic surveys. The discrepancy raises a number of questions regarding present technical capability to predict erosion and deposition patterns following a beach restoration construction. Two primary areas of concern are suggested:

- a) The littoral drift formula in present form is empirically derived from gross volumetric sand accumulation near littoral drift barriers. The formula is very useful for gross calculations but evidently less useful for more detailed changes along a shoreline with varying longshore wave activity. Research is needed to develop more detailed relationships for sand transport due to waves, current, wind, and grain size distribution.
- b) The wave climate as determined from deep water wave measurements is only part of the total climate affecting littoral drift. The local wind, for example, plays an important role in a manner not completely understood yet. Definition of the total climatological factors in impacting sand movement and the consequent collection of pertinent data remains prerequisite to adequate prediction of sand movement following a restoration project.

(3) Sedimentological Results

At present, relatively little is known about the nature of onshore-offshore movement of sand in the surf zone. An indication of the onshore-offshore movement is found in the analysis of the sediment cores. As indicated these cores were taken at the beach face, the breaker bar and at distances 500 and 1000 feet offshore.

The mean diameter and shell content of the beach face core is shown in Figure 7 (a). Underlying the beach face there are layers representing different

7a, b, c: REPRESENTATIVE SEDIMENT ANALYSIS SHOWING ARITHMETIC MEAN (Mg) OF GRAIN DIAMETER FREQUENCY AND Me PERCENT SHELL, LINE 37, JUPITER ISLAND, FLORIDA

Figure 7

energy conditions. There are even differences in the layers deposited during high and low tides. The beach face consists of medium to coarse sand with layers of shell.

The near-shore bar is composed of fine sand as shown in Figure 7(b); and very fine sand is found 100 feet offshore as shown in Figure 7(c). The shell content was found useful in distinguishing between the native sand and the new sand that moved towards offshore.

It is clear from these sedimentological results that the fine and very fine sand is moved offshore and is the main constituent for building the offshore profile. This sand is not totally lost to the system as volumetric computations such as those of Krumbein and James [9] would suggest. The beach face has been protected by coarser particles and the winnowed fine sand has contributed to energy dissipation through the buildup of the profile in the dynamic zone, especially the breaker bar.

The project engineer [8] stated the mean grain diameter in the proposed borrow area was 0.23 mm. whereas the native receding beach material had a mean grain size of 1.20 mm. When the size gradation, i.e. standard deviation, of these sand bodies are taken into consideration by utilization of the "critical ratio" formula of Krumbein and James [9], it is determined that 7.8 cubic yards of fill material would be required to yield one cubic yard of sand comparable to the original sand on the unstable beach. Fortunately, the project has developed better than preliminary statistics predicted. This is because a material with favorable parameters was placed on the beach.

IV. CONCLUSIONS

The conclusions derived from this monitoring study are the following:

- (1) Beach Fills Have a Groin Effect - The placement of sand on a beach has the effect of extending the shoreline seaward and therefore inducing shoreline alignment changes at both extremities of the restored area. The restored beach consequently interferes with the previously prevailing littoral drift balance and induces a net deposition near the updrift end. The groin effect increases the half life of the restored beach.
- (2) The Offshore Profile Serves an Important Role - Shoreline recessions do not reflect the true state of erosion or accretion following a beach restoration. The total sand volume contained in a restored area is critically dependent on the offshore profile. Shoreline recessions are normally accompanied by a buildup of the offshore profile.
- (3) Borrow Holes Cause Energy Focusing on Shore - Local concentrations of wave energy at the shoreline are induced by wave refraction in the vicinity of borrow holes when they are located close to shore. Lateral variations in the shoreline contour and the offshore profile are induced by close to shore borrow holes.

- (4) Prediction of Erosion or Accretion along a Restored Beach Is Not Possible by the Littoral Drift Formula - The presently used littoral transport formula does not give a reasonable prediction of erosion or deposition along a restored beach. The formula is derived empirically from gross transport rates and cannot be expected to provide accurate predictions for relatively detailed shoreline erosion following a restoration construction.
- (5) The Need for Research in Nearshore Dynamics - This study points out the need for continued research on dynamical aspects of offshore-onshore and along-shore transport of sand. Relevant contributions were reported at the Hawaii conference; it will be instructive to apply the techniques proposed.

CHAPTER 88

LABORATORY INVESTIGATION OF SHORE EROSION PROCESSES

by

E. F. Brater¹ and David Ponce-Campos²

The laboratory investigation was undertaken as part of a shore protection demonstration program sponsored by the Michigan Department of Natural Resources. Subsequently funding was also provided by the Sea Grant Program. The laboratory work is being done in the Lake Hydraulics Laboratory, a facility of the Department of Civil Engineering of the University of Michigan. The field demonstration program consists of 19 field installations at locations on Lakes Michigan, Huron and Superior. The laboratory program was planned to supplement information from the field installations by testing over a wider range of variables and to test procedures not included in the field program. This program has also proven to be useful in the demonstration of shore erosion processes to groups concerned with shore problems. Although erosion rates determined in a model cannot be converted quantitatively to nature it was reasoned that if natural shore erosion processes could be simulated and if repeatable erosion rates could be produced in the model the results could help to evaluate the relative effectiveness of many protective methods. The advantages of using a model are the much lower cost compared with field installations, the control over such variables as wave height and water level and the speed with which results can be obtained.

The Testing Arrangement

The tests were conducted in a wave tank located in the University of Michigan Lake Hydraulics Laboratory. The tank is about 40 feet (12 m) square. The testing arrangement is shown in Fig. 1. The movable bed area indicated as "sand" in Fig. 1 was about 11 feet (3.3 m) by 16 feet (5 m). The test section consisted of six feet (1.8 m) of bluff. The area of the model outside of the movable bed portion was surfaced with concrete. At the beginning of each test the sand bottom was formed to a slope of 1 to 20 which conformed with the surrounding concrete

WAVE TANK SET-UP

bottom. The sand bluff test section was formed with a smooth surface having a slope of 60° with the horizontal. The waves were created by a plunger type wave machine and projected at an angle of 35° with the shoreline in order to produce a natural littoral current. In order to prevent lateral dispersion of the wave energy the portion of the waves which attacked the test section were confined in a channel until near the testing zone. Waves outside of the test section were destroyed by dampening material placed along the walls of the tank.

The Testing Procedure

The wave selected as a standard for most of the tests had a deepwater height of 0.20 feet (6.1 cm) and a period of 1.0 seconds. At a scale ratio of 1:50, which was the basis for constructing the model protective devices, this model wave would correspond to a prototype wave having a height of 10 feet (3 m) and a period of 7 seconds. The standard water surface elevation which was used in most of the tests was the elevation of the junction between the bluff face and the bottom which is designated as a_1 in Fig. 2. The standard test durations were 30 and 60 minutes. At a scale ratio of 1:50 these durations correspond to storms lasting 3.5 and 7 hours, respectively. The preliminary tests showed that 60 minute tests provided sufficient data to meet the objectives of the program. At the end of 30 minutes of testing and again at 60 minutes the bluff and bottom profiles were determined and the littoral drift was measured. The distance along the test section starting at the updrift end was designated as x (See Fig. 1) and six profiles were taken at one foot (0.3 m) intervals with the first one at $x = 0.5$ feet (0.15 m). The rate of littoral drift was measured in 12 sand traps extending 6 feet (1.8 m) from the shore line at the down-drift end of the test section as shown in Fig. 1.

The first tests were made with a well graded sand which was too coarse to produce a typical continuous erosion pattern. The bluff erosion started in a typical manner but the coarser eroded material could not be readily moved by the littoral currents and therefore created a protective revetment which prevented further erosion. This problem was overcome by using a finer sand. This sand was quite uniform in size with about 80 percent less than 0.4 mm and about 20 percent less than 0.3 mm. No noticeable portion of this sand went into suspension during the tests. Thereafter, the most difficult modelling problem was the development of a procedure for re-forming the bluff and bottom which was not too time consuming and would produce repeatable results of a given set of conditions. The procedure which gave satisfactory results consisted of forming a rectangular volume of sand after which the front form was removed and the face of the bluff was cut at the desired angle. Uniform compaction of the sand was achieved by simultaneous vibration and saturation.

Creating a Typical Repeatable Natural Shore Process

As previously stated, the experimental arrangement produced typical bluff erosion. Similarity between the model processes and natural processes is illustrated in Fig. 2 by six profiles which show the decreasing bluff recession as one proceeds down-drift along the bluff. This is due to the protection provided by the increasing amount of littoral drift in the down-drift direction. As shown in Fig. 1 a section of the bottom just up-drift from the test section was a plate rather than a sand bed. Therefore the only source of littoral drift along the bluff test section was the erosion and slumping of the bluff itself. Consequently at the first test section ($x = 0.5$) there was virtually no littoral drift and at each successive section the amount of littoral drift was greater thus providing increasing natural protection by the presence of this increasing amount of beach material. It may be seen in Fig. 2 that the recession was a maximum at $x = 0.5$ and decreased at successive sections to nearly zero at $x = 5.5$ feet. Checks on wave height along the breaker zone indicated no significant orderly change in wave height along the test section. Other indications that the model was creating typical natural shore processes were the creation of typical sand bars in the breaking area, as shown in Figs. 2 and 3 and the increase in recession rates with an increase in water surface elevation as illustrated in Fig. 3. The profiles in Fig. 3 show bluff recession at the same section ($x = 1.5$) for the normal water level, and for levels 0.02 feet (0.6 cm) above and below normal respectively. This change in level in the model corresponds to an increase in level in nature of 1.0 feet (0.3 m). In studying the profiles shown in Figs. 2 and 3 it should be noted that the vertical and horizontal scales differ in a ratio of 1 to 5.

The investigation of the repeatability of the tests required that consideration be given to the fact that it was impossible to reproduce identical test conditions. This was because there was no control over the water temperature in the wave tank and because the actual average wave height was not known until the end of the test when it was determined from the oscillograph charts. In order to take into account these variables an application of dimensional analysis was made to develop a parameter which would include the effect of small variations in wave height and viscosity as well as the duration of the tests. The following parameter was found to serve the purpose of coordinating the test results.

$$N = k \left(\frac{gTH}{\nu} \right)^2 \quad (1)$$

In this parameter g is the gravitational acceleration, T is the wave period, H is the wave height, ν is the kinematic viscosity and k includes various constants and the duration of the tests. Since the only variable in k was the duration of the tests k was taken as unity for 30 minute tests and as two for 60 minute tests. The presence of H in the numerator is a measure of the original wave energy and ν in the denominator is related to the energy dissipation. The usefulness of this parameter will be demonstrated

but it should be noted that additional work is in progress which indicates that a more rational parameter can be developed which will also include the distance from the breaker zone to the bluff.

In order to relate bluff recession to the parameter N , the recessions at any section was represented by r_b , the recession of the toe of the bluff. As illustrated in Fig. 2, r_b is the recession of a_1 to the new position a_2 . The parameter r_b was considered to be the best single measure of the recession of the bluff. The use of this procedure is illustrated in Figs. 4 and 5 where values of r_b are plotted against N for three test conditions. In Fig. 4 the results are for section $x = 1.5$ and Fig. 5 shows the results at section $x = 2.5$. Consider first the center group of nine points in each figure. These show the results of tests made with a standard wave height on the free shoreline. The five points with the smaller values of N show the recessions produced in 30 minutes and the four with the greater values of N give recessions produced by 60 minute tests. The lines drawn through the values plotted in Figs. 4 and 5 were determined by a least squares analysis. The correlation coefficients shown are much higher than the values required for a one percent confidence level, thus indicating that these lines represent a logical relation between recession and important variables. Considering the random nature of the sand slumping process it was concluded that these correlations provided satisfactory evidence that repeatable recession rates were being obtained. The upper and lower graphs in Figs. 4 and 5 give two additional examples of groups of test points, the upper sets being for a smaller wave height with a free shoreline and the lower sets show the effect of a groin system using the standard wave height. Again, the high correlation coefficients indicate that the linear relationship is a reasonable interpretation of the trends and that a good repeatability was being obtained.

It is of interest to note in Figs. 4 and 5 that the smaller wave height of 0.12 feet (3.7 cm) produced greater bluff recession than the normal wave height which was 0.20 feet (6.1 cm). This is believed to be because the larger waves broke nearly twice as far from the bluff as the smaller waves and therefore had nearly twice as much energy dissipation. This research did not include sufficient tests on variable locations of the breaker zone to permit drawing conclusions. However, as previously mentioned, it is expected that future work may provide more information on this important variable.

The relations between bluff recession, r_b , and the parameter N provide a better way of presenting test results than the comparison of beach profiles because the effect of small variations in wave height and viscosity do not obscure the trends and because the two different test durations can be included in one graph. For example, the difference in bluff recession between the up-drift and downdrift portion of the model which was demonstrated

FIG. 4

with individual profiles from a single test in Fig. 2 is shown in Fig. 6 by lines relating r_b to N . Each of these lines is the best fit line for all the values of r_b determined at a given section from a series of test runs. The individual test points are not shown in order to simplify the presentation. The information in Fig. 6a is for a free shoreline. The lines are for successive test sections from $x = 0.5$ to $x = 5.5$. Again, the protection provided by increasing littoral drift is demonstrated. Figure 6b shows a similar set of curves for the same wave conditions but with a groin system which was initially nourished. Again, the maximum erosion occurred at the updrift sections, $x = 0.5$ and $x = 1.5$. However, section 5.5 experienced slightly more erosion than sections $x = 2.5, 3.5,$ and 4.5 . The reason for this is believed to be that the groin system delayed some of the littoral drift near the center of the groin system and there was slightly less sand present at $x = 5.5$.

Another indication of the reproduceability of the tests is obtained by plotting total sand transport against the parameter N as shown in Fig. 7. Here again, there is some random scatter as one would expect in a process so susceptible to variations in behavior but points fell well within the one percent confidence level based on the statistical test provided by the linear correlation coefficient. It should be reiterated that except for the difference in the test duration (30 to 60 minutes) the variations in N within each group of points are due to variations in the viscosity of the water and to minor variations in wave height.

The Effect of Shore Protection Procedures

Various procedures were tested and compared with recession rates for free shoreline conditions. Some of the procedures were selected to supplement data from the demonstration projects, others because of ideas advocated by public groups and some to check procedures observed in the field.

Some results of tests on groin systems are shown in Fig. 8. The curves of recession versus N are shown for two locations $x = 1.5$ (Fig. 8a) and $x = 2.5$ (Fig. 8b). The results are shown for three groin systems having different lengths and spacing and for one of these systems combined with a permeable wall. In all cases the freeboard of the groins was 0.02 feet (0.6 cm) in the model which corresponds to one foot (0.3 m) in nature. For each set of tests the length of the groins (g) as well as the ratio of length to spacing (g/s) is shown. Comparison with the free shoreline results which are also shown in Fig. 8 shows that the erosion rate was reduced by means of all the groin systems. The two sets of tests for the same length to spacing ratio ($g/s = 0.8$) give approximately the same results and when g/s was increased to 1.0 the protection was much greater. While this is as would be expected the range of variables used in the tests may be too limited to warrant reaching any general conclusion regarding groin spacing. It should be noted that the two groins

$$N = k \left(\frac{q_{TH}}{y} \right)^2$$

FIG. 7

FIG. 8a
x = 1.5

FIG. 8b
x = 2.5

r_b
(ft.)

$$N = k \left(\frac{g \cdot T_H}{v} \right)^2$$

lengths used in the tests correspond to lengths of 40, 80, and 100 feet (12, 24 and 30 m) in nature. The greatest reduction in erosion occurred when a permeable wall was combined with the groins. The system was tested because it has been extensively used with considerable success on the Michigan coast. The location of the pervious wall is shown in Fig. 8c. The wall had a porosity of 30 percent which simulated a wall made with 2 inch x 8 inch (5 cm x 20 cm) lumber placed vertically with 3 inch (7.5 cm) gaps. The addition of the pervious wall to the groin system brings the cost up to the upper range of "low cost" shore protection.

Some of the graphs from Fig. 8 are repeated in Fig. 9 where results are also shown for groins with sand fill, pervious walls without groins and for a submerged breakwater. The sand fill consisted of the same sand used in constructing the model bluff and bottom. It was placed in the space between the groins, with the top of the sand at the elevation as the tops of the groins. At the outer ends of the groins the sand was allowed to assume its natural slope. It will be seen in Fig. 9 that this provided very effective protection through the full 60 minutes of testing. Note that at $x = 1.5$ the pervious wall with groins is more effective than the nourished groins, whereas at $x = 2.5$ the reverse is true. The pervious wall for which results are shown in Fig. 9 had a porosity of 40 percent and was located a distance from the shore line which corresponds to 20 feet (6.1 m) in nature. It may be seen in Fig. 9 that this wall provided considerable protection.

The submerged breakwater was tested because of considerable public interest in this type of protection. It was installed in the breaker zone. When originally installed the ratio of its height above the bottom to the depth was 1:3.4. After the model was in operation for a few minutes this ratio became about 1:2.5. The use of such a low barrier produced no noticeable reduction in bluff recession.

The effect of groin systems on littoral drift is shown in Fig. 10. The ordinates of the graphs are rate of transport and the abscissas are distance from the shore line, zero being point a_1 in Fig. 2. The twelve plotted points give the rate at which sand was collected in the twelve individual pans and each point is plotted at the center of the pan. The values of total transport plotted in Fig. 7 were obtained by integrating the area under one of the curves. Each of the curves in Fig. 10 represents an average of the curves for that series of repeated tests. The free shoreline curve shows that the littoral drift is large in the uprush zone near shore and in the breaker zone. The curve for a groin system shows that the groins stopped most of the littoral drift in the near shore area and reduced the drift in the breaking zone. However, the curve for groins with sand fill shows that when nourishment was supplied to the groin system the littoral drift is even greater than with the free shoreline. It should be recognized that the transport during tests with the

$$N = k \left(\frac{qTH}{y} \right)^2 \times 10^{12}$$

FIG. 10
SAND TRANSPORT

groins, without and with nourishment, would probably change if the tests were continued longer. The un-nourished groins would be expected to fill with sand naturally and then littoral drift could be expected to resume in the near shore area. On the other hand, the nourished groins would eventually lose enough of the fill material so that the littoral drift could be expected to drop back to a more normal rate. Some tests were made with higher groins. These created wave reflections which directed the wave energy toward shore on the updrift sides of the groins. This is illustrated by the shorelines plotted for high and low groins in Fig. 11.

Tests were also made to gain more information on one of the field demonstration projects. This project consisted of an off-shore breakwater constructed of zig-zag concrete walls. The structure provided considerable protection for a number of years but during a large storm severe erosion occurred behind the structure. The model studies also showed that some protection was being provided by this structure when compared with a free shoreline. However, when the water level in the model was raised one foot (0.3 m) to the top of the structure the bluff erosion was more than doubled. This information showed that the wind tide which occurred during the destructive storm was an important factor in reducing the effectiveness of the structure.

Summary

A laboratory investigation of shore erosion processes was undertaken to supplement a shore protection demonstration project in Michigan. The purpose of both the field project and the laboratory studies was to familiarize individuals and public agencies with shore protection methods and to provide information on the selection and construction of protective procedures. Although it was recognized that erosion rates could not be converted quantitatively from the model to nature it was hoped that the relative effectiveness of various protective procedures could be evaluated. If this could be done, the advantage of the model over field projects would be lower cost, the control over variables such as wave height and water surface elevation and the shorter time required. One of the chief difficulties with field demonstration projects is the random nature of the occurrences of on-shore storms of a size sufficient to test but not destroy the structures.

The preliminary tests showed that natural processes were simulated in the model and after considerable experimentation in constructing the model it was found that repeatable results could be obtained. Because, even in the model, it was impossible to control wave height exactly and because there was no control over the water temperature it was necessary to test for repeatability by plotting bluff recession against a parameter which was related to the ratio of original energy and energy dissipation.

FIG. 11: PLAN VIEW OF EROSION PATTERNS

This parameter also included the duration of the model storms. It was found that comparison of results of tests on various methods of shore protection with the erosion of a free shoreline could also be made by means of plotting bluff recession against this parameter. This parameter also served to coordinate rates of littoral drift. The model was used to evaluate some well established procedures such as groin systems and beach nourishment. Tests were also made to provide additional information on one of the demonstration projects and to determine the effectiveness of some procedures which had considerable public interest but were not included among the field projects.

CHAPTER 89

Cape Hatteras Beach Nourishment

John S. Fisher¹

Wilson N. Felder²

Abstract

The 1973 beach nourishment at Cape Hatteras placed approximately 465,000 m³ on the subaerial beach. Eighteen months later, about 51 percent of this material remained on the beach. During this period there were relatively few major storms, and this mild wave climate is largely responsible for this high retention. At the end of this monitoring period the beach was stable and fully capable of providing shoreline protection and recreation.

A correlation is presented relating storm erosion with the complete storm wave climate, including a post-storm period. A new parameter is defined which includes a measure of wave steepness and longshore current velocity.

²Research Assistant, Department of Environmental Sciences, University of Virginia, Charlottesville, Virginia

Introduction

The placement of sand as beach nourishment is one of coastal engineering's most successful techniques for the short-term arresting of coastal erosion. This practice is particularly popular when the endangered beach is primarily valued for recreation, including motel sites, piers, etc.. In these situations the use of groins, seawalls, and other alternatives is often undesirable and to be avoided when possible. Of course, the suitability of a beach nourishment plan depends upon the availability of nearby sand, as well as several legal and economic considerations.

This paper describes a recently completed beach nourishment project at Cape Hatteras, North Carolina. During an eighteen month period ending in the fall of 1973, approximately 1.25 million cu yds ($956,000 \text{ m}^3$) were placed along a 1.5 mile (2400 m) stretch of shoreline at Buxton, North Carolina, Figure 1. This particular beach at Cape Hatteras has experienced a relatively high erosion rate in recent years. As a consequence, several different coastal engineering schemes have been tried, including groins, sand bags, and two previous nourishment projects. Although some of these projects have had limited success, the beach has continued to erode, necessitating this latest project. This paper describes the scope of the project, and the condition of the beach eighteen months after its completion. We have included the beach volume changes, the observed wave climate and the frequency and dimensions of the severe storms during this period. Finally, we present some preliminary thoughts on how these data can be used in developing a rationale for the prediction of nourishment retention.

Figure 1 Location map and project dimensions

Project Description

Cape Hatteras is well known for its dramatic series of barrier islands and their beaches, as well as the large waves and severe storms which frequent them. Most of this shoreline is included in the Cape Hatteras National Seashore, as is the beach nourishment site at Buxton, on Cape Point. The fill area is located on the northern side of Cape Point, where Hatteras Island makes an abrupt change in orientation, turning to the west, Figure 1. The predominant longshore drift on the northern side of the point is to the south, in part forming this classic spit feature. This spit provided an excellent source of fill material, being both nearby and similar in texture to the beach sand. The nourishment sand had a mean diameter of .37 mm, and the area to be filled a diameter of .38 mm.

A borrow pit was excavated at the spit and the material was pumped 4 miles (6400 m) to the north. At the completion of the dredging and pumping, the borrow pit was approximately 2500 ft (762 m) by 1000 ft (304 m) with an average depth of 15 ft (4.6 m). There was no connection with the ocean initially, but an inlet cut into the southwest side at a later date and has remained open.

The fill material was placed along a 1.5 mile (2400 m) segment of shoreline. The dredge pipe was located so that the discharge was immediately above the mean high water line, with no effort made to shape or bulldoze the sand into a designed profile. In general, the nourishment resulted in an increase in subaerial beach width of roughly 250 feet (76 m) along the 1.5 mile (2400 m) beach, Figure 1. This material was intended to provide some immediate shoreline protection to the lighthouse, Naval Station, and public and private property. To a limited extent, this goal was accomplished, and the previously eroded and narrowed beach at Buxton

was restored to a width providing more shoreline protection and increased recreation.

In order to assess the impact and performance of the nourishment project, a program of field studies was initiated by the National Park Service. This monitoring program included frequent surveys of the beach, portions of the nearshore bathymetry, the borrow pit, as well as daily wave climate observations. Dolan, et al. (1) summarize this data for the period from the project beginning to completion of pumping. Fisher, et al. (2) report on the survey results for the succeeding 18 month period. In addition to the measurement of volume changes, an analysis of the ecological impact of the fill material on the native beach was undertaken, Hayden and Dolan (3). Their study suggests that there is no significant damage to the beach ecology as a result of the fill activities.

As with many coastal engineering projects, the measurement of the wave environment proved to be one of the most difficult problems in the monitoring program. The nearest wave gage is 60 miles (97 km) north of the fill area at Nags Head. The wave conditions at the site were estimated according to the LEO, Littoral Environment Observation Program, as developed by the Coastal Engineering Research Center, CERC, Bruno and Hipakka (4). The LEO program includes the daily observation of wave period, angle and height of breaking, as well as a simple estimate of the longshore current velocity. These wave observations suffer from the usual symptoms of non-instrumentated data collection, nonetheless, they did provide an important reference in documenting significant changes in the wave climate. In particular, they enabled us to observe the change in wave conditions associated with storm systems.

The survey program included the borrow pit, the beach and the offshore. The latter two areas included the immediate fill area as well as adjacent areas to the north and south, for a total of 4.5 miles (7200 m). The entire borrow pit was surveyed once during the study period, and the southern end was surveyed five additional times, when possible change was suggested. The offshore was profiled with a Raytheon Fathometer a total of five times during the 12-month period discussed here. Unfortunately, the survey vessel was unable to cross the inner bar, and therefore the beach profile could not be extended out to the Fathometer profiles. The data for both the borrow pit and offshore are not presented here.

The subaerial beach was surveyed bi-weekly as well as immediately after a storm. Fifty-three survey stations were established on 500 ft (152 m) intervals from Mile Post 40.0 to Cape Point, Figure 1. Nine of these stations were north of the fill area, 16 in the fill area, and 28 to the south. The profiles were made with level and rod, and extended from a project baseline on the backshore into the swash to the mean low water level.

Figure 2 illustrates the changes at three of these stations, one in the fill area, and one both north and south of the fill. Station 2200 is located approximately in the middle of the nourishment area, it also is the site of the LEO wave observations. The post pumping profile, September 1973, clearly shows the increase in beach width with the additional material, at this site, over 300 ft (91 m). The depression landward of the beach crest is a result of the decision not to shape the fill material or otherwise attempt to develop a predetermined beach profile. At this particular site, this depression was within the National Seashore boundaries. Further to the south, the resulting depression was within private property, and

Figure 2 Subaerial beach profiles

thus there was no intentional placement of fill outside of the National Seashore. The profile for February 1975 at this same station illustrates the extent of subaerial beach erosion during this period. The 50 per cent decrease in beach width is typical of the fill area, with the bulk of the material transported offshore, as evidenced by the relatively small change in the dimensions of the landward depression.

Station 2140 is one mile (1600 m) north of station 2200, and is about .5 mile (800 m) north of the limits of the nourishment area. There was a relatively small increase in beach width just after the completion of nourishment, and a more recent erosion, with only a modest net increase in width by February 1975. The beach to the south of the fill area, is illustrated by station 2310, about one mile (1600 m) south of the fill area. Again, there is only a small net change in beach dimensions outside of the fill area.

Wave and Storm Climate

According to the record from the CERC wave gage, the annual mean wave height along Cape Hatteras is the largest for the mid-Atlantic coast. The gage at Nags Head, 60 miles (97 km) north of Buxton has a mean value of 3.0 ft (.9 m), CERC (4). Our LEO observations covered the period from April 1974 to February 1975, and were made at station 2200, 3.4 miles (5.4 km) north of Cape Point, Figure 1. The mean wave height from this data is 2.2 ft (.67 m), the mean period is 7.9 sec, and the mean longshore current is approximately zero. This latter parameter does not accurately reflect the net longshore drift, which is clearly from the north, towards the point. This low net current magnitude does suggest that large wave conditions, i.e., during storm periods transport the bulk of the littoral

material. This observation is consistent with the literature, including the discussion presented in the Shore Protection Manual, CERC (5).

Figure 3 illustrates a portion of the LEO data, including the wave period, longshore current velocity squared, and the square of the wave height. Of particular interest in this data are the episodes of high waves and large currents, both from the north and the south. These dates are associated with storms, although the correlations are not as high as one might expect for this coastline. It is difficult to assemble a reasonable model for wave observations and storm intensity when the available data is this limited. However, by simply using a hindcast deep water wave height, one can gain a limited feeling for this system.

The bottom graph on Figure 3 is the SMB hindcast deep water wave height H_0 for all storms with H_0 greater than 5 feet (1.5 m). This technique, Bretschneider (6), depends upon the available meteorological observations for the estimation of the storm fetch and duration, as determined from the synoptic weather charts. Figure 3 shows the storms to be generating the larger waves and currents, although there is some noise in the data. A notable exception occurs during the period from October 19th to the 21st. In fact, a small low pressure did move rapidly up the coast during this period, but its deep water waves were only hindcast to be 4 ft (1.2 m). This event helps to dramatize the weakness of this simple model. Although the storm's deep water waves were relatively small, its LEO waves were the same magnitude as some of the larger events.

As stated above, the mean net longshore current is almost zero, although the shoreline geometry indicates significant longshore sediment transport to the south. Of the larger storms, all but one had a longshore current towards the south, the exception being the early December storm.

Figure 3 Wave and storm climate.

This storm developed off of the South Carolina coast and maintained its strongest winds while still south of Cape Hatteras, hence the south to north current direction. This direction, although followed for approximately one half of the LEO observations, is unusual during periods of high wave energy. It is probable that this strong northerly flow was in part responsible for the overall impact this storm had on the subaerial beach volume change.

For the observation period from April 1974 to February 1975, there were ten storms with deep water waves hindcast greater than 5 ft (1.5 m). As will be discussed in the following section, only a few of these storms had any significant impact on the nourished beach. In terms of storm frequency, 1974 was a relatively mild year for Cape Hatteras. According to Dolan and Hayden (1) this section of the mid-Atlantic coast averages about 34 storms per year, whereas 1974 had a total of only twenty.

Nourishment Retention

From June to September 1973, approximately 1.25 million cu yd (956,000 m³) of fill were pumped. Using surveys made immediately preceding and following the completion of pumping, the volume of fill which contributed to the accretion of the subaerial beach has been calculated. This data fails to account for the material which was washed into the inshore zone, which must have been a large percentage of the original fill volume. The lack of data in this zone because of the difficulty of surveying in the breakers, is an obvious handicap to our computations of fill retention and overall project performance. The following discussion and analysis, limited to the beach above the mean low water level, must be recognized as only a portion of the complete sand budget.

Table 1 presents the net volume of sand accumulated at each of the 16 stations within the fill area. The total for this area was 646,667 cu yd (494,442 m³), an average gain of 243 cu yd/yd (203 m³/m). During this same period, stations to the north and south of the fill area accreted an average of 14 cu yd/yd (12 m³/m). Using this mean value outside the fill area as an estimate of natural deposition throughout the study area, we have assumed the mean gain due to fill was 229 cu yd/yd (191 m³/m) between stations 2165 and 2240, and the total deposition above MSL of 608,480 cu yd (465,243 m³), or 49 percent of the material pumped. The remaining material was deposited below sea level at each station.

In terms of beach restoration and protection, the volume accumulated below MSL is an important component of the overall nourishment project. This material, the bulk of which was presumably retained within the nearshore zone, provides a source of material to the beach, and helps maintain the inner bar system and hence wave energy dissipation. Because of the inability to accurately survey the nearshore, no data is available to analyse the volume changes in this zone.

The remainder of this retention discussion deals with the volume of nourishment sand on the beach itself, above MSL. Figure 4 shows the volume changes along the entire project, both for before and after pumping, and from completion of pumping to 18 months later. The significant area of change is within the fill area itself. Eighteen months after the completion of the pumping, 51 percent of the nourishment sand remained in place in this area, or 307,343 cu yd (235,000 m³).

Outside of the fill area the changes have been relatively small. To the north, there has been no significant erosion or accretion. South of the nourishment area there has been a small amount of accretion.

TABLE 1

VOLUME OF MATERIAL REMAINING ON THE
SUBAERIAL BEACH UPON COMPLETION OF PUMPING

Station	Cu Yds/Yd
2165	63
2170	160
2175	270
2180	250
2185	250
2190	210
2195	330
2200	350
2205	230
2210	280
2215	270
2220	300
2225	240
2230	290
2235	260
2240	27

Mean accretion in fill area:	243 cu yds/yd
Mean accretion outside fill area:	14 cu yds/yd
Net accretion of fill:	229 cu yds/yd
Total accretion:	608,480 cubic yards
Total pumped:	1,250,000 cubic yards
Net percent of fill material retained on subaerial beach:	49 percent

Inasmuch as the longshore drift during high wave conditions is towards the south, we can reasonably assume that this accretion is derived in part from the nourishment area. There are three short groins just south of the fill area. The volume change within the groin field both during and after nourishment has been rather small. The impression one gets from Figure 4 is that this groin field is behaving like a filter in that it appears to have dampened the volume changes immediately downdrift from the fill area.

Figure 5 shows the post-fill volume changes over the 18 month period of our surveying. The shoreline is divided into four increments, north, fill, groins, and south, and the combined changes are also shown in this figure. Again, it is clear that the only section undergoing significant change during this period is the fill area itself. And in fact, even the fill area appears relatively stable with the exception of the loss in early November. This large loss of sand occurred at all four of the project areas, although it was most severe within the nourished beach. From Figure 3 we can relate this large volume of erosion to a single November storm, with H_o of about 10 ft (3 m). This figure presents the volume change for the combined project area as well as the hindcast wave height and longshore current. It is apparent that this relatively large November storm, with its strong north to south current is responsible for the erosion. However, there are two other events illustrated on this figure which tend to confuse the correlation. During mid-October, a smaller storm generated longshore currents just as strong as the November event, but the beach accreted. And in early December, an even larger storm, $H_o > 15$ ft (4.6m) caused considerably less erosion than the November storm. Thus, from this series of events, we are presented with a rather

Figure 4 Volume changes for project period

Figure 5 Pre and post fill volume changes

complex set of relationships regarding the impact of individual storms on the beach.

There is one interesting difference between these three storms and their associated beach changes which we feel is notable. The longshore drift immediately after the November storm was from the south whereas the post-October drift was from the north. If we consider the principle source of sand for this beach to be from the north, as suggested by its morphology, then it follows that a post-storm wave climate generating a drift to the south will be an ideal condition for beach recovery. Conversely, a post-storm drift from the south will not provide the beach with an equivalent quantity of sand. In addition the characteristics of the post-storm waves, i.e., their period, steepness, etc., should also play a role in this recovery process.

As a preliminary analysis of this hypothesis, we have made a simple correlation of the post-storm waves and drift. A dimensionless parameter, S, has been defined which includes the fall-time parameter $\frac{H}{V_f T}$ with the square of the longshore current normalized by the fall velocity,

$$S = \left(\frac{H}{V_f T} \right) \left(\frac{U}{V_f} \right)^2$$

As stated above, our assumption is that the impact of an individual storm is a function of the post-storm drift direction, i.e., from a source or sink of sand. To evaluate this assumption we have correlated the surveyed beach volume changes with this parameter S, assigning the sign of the post-storm drift.

$$\hat{S} = \bar{S} \operatorname{sgn} (U_{ps}),$$

where \bar{S} is the mean of S over the survey period. Figure 6 shows the correlation of \hat{S} with the mean volume change ΔV for the study period. The solid dots are for surveys which bracketed storms. There appears to be a high correlation, suggesting that we should take a serious look at this assumption and its implications for evaluating storm impact. We are presently analysing this data in this context, and will present our results in a forthcoming paper.

Conclusions

The success of a beach nourishment project cannot reasonably be measured in terms of the percent retention of material at a specified period after placement. There are too many political and social questions which must be included in the final appraisal. We have not looked at these problems, and will not comment on them. However, if we restrict our view to the impact of the fill on the subaerial beach, we can comment on the measured changes.

Eighteen months after pumping, about 50 percent of the subaerial nourishment was still in place. In as much as this period included a relatively mild storm climate, we consider this volume of sand to be greater than what might have been predicted. The remaining sand is providing a wide beach for recreation as well as some additional protection to the various public and private structures. The immediate threat of storm damage present prior to the nourishment has been, and continues to be alleviated.

The problem of designing future fill projects, and predicting their project life has been addressed in this paper in the context of identifying the impact of individual storms on the beach. We are presently able

Figure 6 Correlation of volume change and wave conditions

to make crude predictions of storm and wave climates for a given stretch of shoreline. The problem is in estimating the erosion or accretion resulting from this simulated climate. Our analysis at Cape Hatteras suggests that in attempting to develop a relationship between storms and volume changes, that the post-storm wave conditions may be important. The preliminary results presented here indicate a strong correlation between volume change and direction of post-storm littoral drift.

Finally, we note that the analysis of aerial photography presented at the conference is being prepared for separate publication, as space limitations precluded its inclusion in this paper.

CHAPTER 90

THREE DIMENSIONAL TESTS ON DYNAMIC EQUILIBRIUM AND ARTIFICIAL NOURISHMENT

by

J.W. Kamphuis
Professor of Civil Engineering
Queen's University, Kingston, Canada

and R.M. Myers
Engineer, MacLaren Atlantic Ltd.
Halifax, Canada

ABSTRACT

A three dimensional facility for testing dynamic equilibrium and artificial nourishment of beaches was developed. Specific conclusions are drawn with respect to trap location and re-reflection of waves. It was found that dynamic equilibrium is achieved faster in three dimensional tests than in previous two dimensional work and that the profiles are eroding profiles rather than potential (limit) profiles. It was seen that profiles develop around the offshore bar which is shaped early in the experiments. Also the depth of the summer step was found predictable from critical shear stress considerations. Finally, onshore nourishment of eroding beaches was found to be successful.

SYMBOLS

- D = particle diameter; D_{90} - 90% of the particles are smaller;
 d_G = depth of water at the wave generator;
g = gravitational acceleration;
H = wave height;
 n_{t_s} = sediment transport scale for wave action only (Ref. 8);
 n_{t_m} = sediment transport scale for bed morphology and littoral transport;
R = runup distance; distance from SWL to maximum limit of uprush;
SWL = still water line; distance from an arbitrary measuring base line to the intersection of the still water level and the beach;
 S_{SWL} = beach slope at SWL ;
T = wave period;
 v_* = shear velocity;
 α = angle of approach of the waves; α_G - at the wave generator;
 α_0 - in deep water;
 β = distance from the still water level to the crest of the offshore bar;
 γ_s = sediment unit weight under water ($= (\rho_s - \rho)g$);
 θ = distance from the still water level to the trough behind the offshore bar;

- λ_b = bar distance; distance from SWL for a winter profile to the point where the bar rises suddenly out of the offshore beach slope;
 λ_s = step length measured between the intersections of the summer step with the offshore beach slope and the onshore beach slope;
 ν = kinematic viscosity of water;
 ρ = density of water;
 ρ_s = density of sediment;
 Σ = distance from the still water level to the summer step;
 τ_o = bottom shear stress; $(\tau_o)_c$ - critical value; $\hat{\tau}_o$ - maximum value;

INTRODUCTION

In an earlier paper (7) the first of a series of two dimensional tests on artificial beach nourishment were presented. The tests were performed on a model beach made up of the relatively coarse sand shown in Fig. 1.

($D_{50} = 0.61$ mm). This material was subjected to a simulated Great Lakes wave climate (neglecting tidal fluctuations and seasonal water level changes).

Since an equilibrium profile in the usual sense of the word is never achieved in the prototype, the term "dynamic equilibrium profile" was coined. Dynamic equilibrium is said to occur when a beach is acted upon long enough by a simulated, annually recurring cycle of waves so that each year, the profile returns to the same shape at the same time of year. For the simulated Great Lakes wave climate it was assumed that the total annual wave climate could be subdivided and grouped into three wave categories:

- a. approximately 250 days of "background wave action", where the wave height is equal to or less than 0.3 m and the wave period of the order of 4 seconds,
- b. approximately 15 days of "small storm waves" with a wave height of about 1.2 m and a wave period of 6 seconds,
- c. about one and one half days of "large storm waves" with a wave height of about 3 m and a wave period 7.5 seconds.

Figure 1: Grain size distribution of beach material used.

Figure 2: Sediment trap.

Although the background and small storm wave action may occur any time, the large storm waves are strictly confined to late autumn and winter. For modelling purposes, however, it was necessary to group the classes of waves together and run them in a cyclical pattern. Thus dynamic equilibrium in these studies occurs when the above wave action simulated in neat cyclical form has taken place long enough so that the profiles at the same time during each cycle are the identical. From preliminary tests it was found that the background waves moved very little or no material and thus the model wave cycle was reduced to alternate small storm waves and large storm waves. The model scale chosen was 25, i.e., the wave time scale was equal to 5. The ideal wave sediment transport time scale for two dimensional sand models (8) was found to be 210, for an assumed field particle size of 1 mm: not an unreasonable size for Great Lakes beaches under relatively heavy wave attack. Therefore the annual wave climate was simulated by a cycle of 110 minutes of 4.6 cm waves at 1.2 seconds followed by 11 minutes of 12.2 cm waves of 1.5 second period. The beaches were essentially shaped in the first five minutes of the large storm wave cycle and in the first fifteen minutes of the smaller storm wave cycle. Therefore the beach movement was correctly modelled with each of the above portions of the cycles coming to a pseudo equilibrium and errors in the estimate of sediment transport time scale resulting from the above assumptions did not result in errors in the beach profile development.

Because of the simplification of the wave climate as a two phase cycle it is difficult to define real time accurately. It may be postulated that spring or early summer occurs when the large storm wave portion of the cycle is completed. The profile resulting after the 11 minutes of large storm waves was therefore called the "winter profile". This would mean that late summer and autumn occur just before the start of the large wave portion of the cycle and thus the profile after the 110 minutes of small storm waves was called the "summer profile".

It was concluded from these earlier tests (7) that the dynamic equilibrium (even with only two phases) was much to be preferred over the normal long term equilibrium as an aid to understanding the prototype. With respect to beach nourishment, it was found that offshore nourishment (material placed seaward of the offshore bar) could be instrumental in accreting the beach as long as the material was placed in early summer and above the normal summer step level.

Nourishment placed offshore in late summer (before the large storm waves) remained trapped in the breaking zone and would not move onshore; it would only lengthen the profile. Onshore nourishment was only successful on long profiles which are normally associated with erosion. When the profile became shorter than a limiting value, called the "potential profile", onshore nourishment was totally unsuccessful. The combination of offshore nourishment to lengthen the profile and onshore nourishment yielded excellent results.

The initial impressions gained from these early tests are obviously highly incomplete without considering the presence of transport in the longshore direction as well as grain size sorting which takes place as the profile forms. Therefore, the next series of tests were performed in a three-dimensional basin. This paper is a description of the gradual development of a workable three-dimensional test basin to perform these tests and of the dynamic equilibrium achieved. Also the results of some preliminary applications of beach nourishment are described.

TEST BASIN DEVELOPMENT

Three-dimensional testing basins have been used in many studies (including Refs. 4,13,14,15,17) and each of these layouts had its own peculiarities and shortcomings as described by the various authors. At Queen's the major limitation was space, thus requiring a highly efficient sediment trapping-feeding system to give a workable beach length.

Sediment Trap

The sediment trap, as shown in Fig. 2, consisted of three boxes covered with a hinged lid, leaving a 15 cm wide slot. This slot was covered with perforated plates to allow the sediment to pass into the trap while causing as little interference as possible with the wave pattern. The leading edge of the trap (end of the beach) consisted of 30 cm long, vertically adjustable plates which were moved up and down to match the existing beach profile.

Originally the trap was placed outside of the downdrift wave guide to yield as much usable beach as possible but it was soon noted that the littoral drift was forced seaward as it approached the trap. This left a buildup of material

offshore at the downdrift end of the model causing the beach to rotate in the direction of wave approach. This phenomenon could be explained using the concept of wave set-up and set-down (2), which takes place in the basin but not over the trap (Fig. 3). The set-up, landward of the breaking zone, causes a current toward the trap while within and seaward of the breaker zone, the set-down causes a current away from the trap. By continuity, the water level at point A will be high, forcing the longshore transport to seaward. This problem was rectified by placing the trap inside the downdrift wave guide, as shown in Fig. 4, so that the trapping zone was subjected to the same set-up and set-down conditions as the remainder of the beach.

Sediment Feeder

For a short laboratory beach to behave like an infinitely long beach, the trapped material must be re-introduced with complete similarity at the upper end of the beach. This similarity must pay particular attention to variations in sediment volumes and grain size distributions with respect to distance offshore. The feeder system used in this study is shown in Fig. 5 and consisted of a conveyor belt which sheared sand from the bottom of a hopper onto a vibrating plate which in turn distributed the sand on the beach so that the waves could sort the material before it actually reached the test section.

Wave Re-reflection

Some earlier studies (4,11,14) noted that wave heights were not constant across the basin but had a tendency to increase in the downdrift direction. This was found also to be the case in this study. Most of this wave variability may be explained by re-reflection of waves within the model basin.

The incident wave in the model, as well as in the prototype, is partially reflected by the beach, resulting in a reflected wave which is approximately one order smaller than the incident wave. In the model, however, this reflected wave is re-reflected off the wave generator and the wave guides. The magnitude of this re-reflected wave depends on the quality of the wave filters used, but will be of the same order as the reflected wave. Considering only the first re-reflected wave (since subsequent reflections at the beach again reduce the wave by approximately one order) it may be seen that the simple model beach in

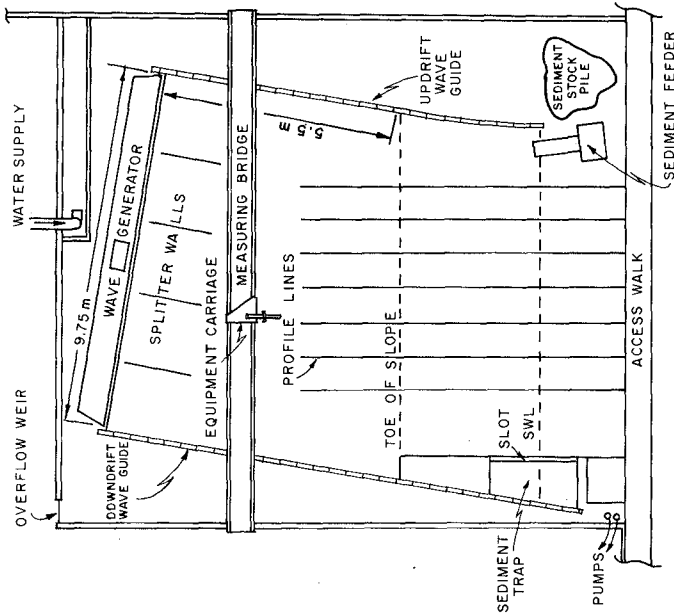

Figure 4: Basin layout.

Figure 3: Induced current at trap.

FIGURE 5: SEDIMENT FEEDER.

FIGURE 6: LIMITS OF RE-REFLECTED ORTHOGONALS.

Fig. 6 consists of a section AB where only the incident wave at angle α occurs (like in the prototype), a section BC where the reflected wave, re-reflected by the generator only is superimposed at an angle 3α and a further section CD where the reflected wave after suffering a double re-reflection from the wave guide and wave generator is superimposed at an angle $-\alpha$. Thus it may be expected that wave heights (and wave steepnesses) increase in the downdrift direction. This has important implications with respect to erosional patterns and the formation of the offshore bar, as shown in Fig. 7. An increase in wave height in the downdrift direction tends to rotate the model beach parallel to the wave generator. This phenomenon is completely independent from set-up problems near the trap as outlined above. Further, since littoral drift is a function of twice the angle of incidence, the littoral transport will increase considerably in the downdrift direction as a result of the large angle of incidence of the wave which is re-reflected off the generator only. In order to eliminate most of this model effect the basin was reconstructed for the last few tests to triple the shortest distance between the toe of the beach and the wave generator from 5.5 m as shown in Fig. 4 to 16.5 m. This resulted in elimination of the wave from direction 3α while the wave at $-\alpha$ came completely across the whole beach, yielding more uniform conditions. The wave splitter walls shown in Fig. 4 are also conducive to spreading the re-reflected waves more successfully across the whole basin.

THE DYNAMIC EQUILIBRIUM PROFILE

Most of the tests were carried out in the basin shown in Fig. 4. A beach consisting of 12 cm of sand (Fig. 1) laid over a concrete beach sloping at 1:10 was subjected to a simulated wave climate shown in Table 1.

TABLE 1 Simulated Great Lakes Wave Climate Used

	Duration min	H cm	T sec	d_G cm	α_G degs	α_0 degs
Large Storm Waves	11	14.0	1.5	48.5	9.4	11.8
Small Storm Waves	110	4.6	1.2	48.5	9.4	10.4

where d_G is the depth of water at the wave generator
 α_G is the angle between the generator and the beach
 α_0 is the extrapolated deep water angle of incidence

Figure 8: Profile definition.

Figure 9: Beach profile after the initial half cycle of large storm waves.

Figure 7: Effect of increasing wave height.

Soundings were made every 5 cm and to the nearest millimeter along the profile lines in Fig. 4 after each portion of the wave cycle was completed and these profiles were plotted to determine when dynamic equilibrium was reached. An "average profile" was also plotted. This can only be done meaningfully if model is so well controlled that the beach is relatively straight and does not rotate. The profiles may be summarized by a number of key parameters shown in Fig. 8.

The first waves (large storm waves) shaped the beach so that the longshore bar was formed exactly where the breaking process takes place and Fig. 9 shows the relationship between the bar location and d_b , the depth of breaking, and X_p , the breaker travel distance, as derived using the methods of the Shore Protection Manual (16, Ch 7).

After one completed wave cycle very little change took place in the profiles and the equilibrium profiles were set up much more rapidly than in the two dimensional tests. This is a direct result of modelling the littoral processes in these tests. In the two-dimensional tests supply and removal of material could only take place in the onshore-offshore directions and a great deal of moving back and forth and balancing from cycle to cycle accomplished a final equilibrium. In the three-dimensional tests excess material was removed promptly by littoral drift and conversely, material was brought in rapidly to the areas needing supplies. The only parameter with a definite trend after one complete cycle was λ_b which slowly decreased until the seventh wave cycle. The final equilibrium parameters are listed in Table 2.

TABLE 2 Dynamic Equilibrium Parameters

Parameters Units	λ_b cm	λ_s cm	θ cm	β cm	Σ cm	SWL cm	R cm	S_{SWL}
Winter Profile	147		15.7	9.5		96	56	.21
Summer Profile		76			12.3	106	36	.20

Comparison with the two-dimensional dynamic equilibrium profiles (7) yields some interesting results. The two-dimensional λ_b was found consistently to be in the range 112 ± 10 cm. This was achieved by redistributing the 1:10

initial slope in the onshore-offshore direction using as an anchor the offshore bar which was no doubt established by the initial breakers, as in this study. The two-dimensional profile represented a "potential profile" - a limiting condition. In the three-dimensional case, however, this lengthy redistribution process was not allowed to take place since littoral transport removed all excess material quickly leaving an eroded profile with a dynamic equilibrium considerably short of the potential profile developed in the two-dimensional work. It will be seen later that upon nourishment, the potential profile is achieved. The longer λ_b also resulted in a longer λ_s in three-dimensional work. The slope at still water is somewhat greater than in the two dimensional case, again because material is removed by littoral drift. The uprush R is somewhat smaller in three dimensions because of the steeper SWL slope as well as the angle of approach of the waves. The other parameters are quite comparable.

The littoral transport during the period of larger storm waves at the time of equilibrium was $.05 \text{ m}^3$ while for the longer period of smaller storm waves it was $.13 \text{ m}^3$. Scaling up to prototype these figures represent a littoral drift rate of $2800 \text{ m}^3/\text{yr}$ which is quite low for coarse beaches subjected to Great Lakes wave climates. This needs further investigation. Two factors will contribute to this low and distorted value of littoral transport. The simulation of a wave climate by grouping similar waves together as portions of cycles causes considerable scale effect in the littoral drift rate. Littoral drift is greatest at the beginning of each individual storm and decreases with time. As a result of the grouping of storms, these individual time histories are modelled by one time history, causing considerable distortion. Further, Ref. 8 gives two time scales, n_{t_s} the time scale for sediment transport by wave action only and n_{t_m} the scale for coastal morphology, and for sediment transport in the littoral direction. For this study using the assumptions mentioned earlier, the ideal time scales are

$$n_{t_s} = 210 \quad \text{and} \quad n_{t_m} = 38.4$$

The first time scale was used in the three-dimensional study for two reasons. First, it would allow comparison with the two-dimensional study. Second, although it is more likely that the second scale is the correct scale to use in the three-dimensional work, the wave durations would be increased by a factor of about 5.5.

During the experiments it was noticed that all the beach shaping took place in the first three minutes of the larger storm waves and the first 10 minutes of the smaller storm waves. Again this can be ascribed to the littoral transport effectively removing excess material and supplying depleted material rapidly. Thus it was felt that using the scale of 210 gave sufficiently long durations to model the process properly even though the term "year" might not be directly applicable. Using the second time scale, the annual littoral drift would be $15000 \text{ m}^3/\text{yr}$ which is very close to the value observed in the field for the assumed conditions.

CRITICAL SHEAR STRESS AND THE SUMMER STEP

Since the summer step is flat in the two-dimensional as well as three-dimensional tests it was decided to use the work of Refs. 6 and 8 to determine the shear stress on the summer step to find out if a critical shear stress existed. The shear stress used is $\hat{\tau}_o$, the maximum value of the shear stress on the bottom during the wave cycle. A number of tests varying H and T were specifically run for this purpose and for 19 two-dimensional tests with wave periods in the range $0.95 \leq T \leq 2.96$ sec and wave heights $3.6 \leq H'_o \leq 6.6$ cm the mean value of the critical maximum shear stress $(\hat{\tau}_o)_c$ was 1.26 N/m^2 with a standard deviation of 0.12 N/m^2 . A further six tests in the three-dimensional basin, keeping T constant at 1.2 seconds but varying H'_o from 3.3 to 5.5 cm indicated a mean value of $(\hat{\tau}_o)_c$ of 1.39 N/m^2 with a standard deviation of 0.13 N/m^2 . The critical shear stress appeared to be constant. Dimensional analysis indicates for unidirectional flow that

$$\frac{(\tau_o)_c}{\gamma_s D} = f_1 \left(\frac{v_* D}{v} \right) \quad (1)$$

which is represented by the Shields diagram. It is not unreasonable to assume that for wave motion

$$\frac{(\hat{\tau}_o)_c}{\gamma_s D} = f_2 \left(\frac{\hat{v}_* D}{v}, \text{ wave-inertia interaction} \right) \quad (2)$$

Since only one particle size was used in these tests, other profile tests from the literature (5,10,12) and at Queen's (9,11) were used in conjunction with the methods of Refs. 6 and 8 to determine the effect of particle size. Because of armouring of the beach surface D_{90} was used in the analysis and Fig. 10 shows that

Figure 12: Comparison with permissible tractive force.

Figure 13: Variation of depth of summer step with increasing wave height.

Figure 10: Critical shear stress on summer step as a function of particle size.

Figure 11: Comparison with shields curve.

$$(\hat{\tau}_o)_c = 1000 D_{90} \quad (3)$$

in S.I. units, or

$$\frac{(\hat{\tau}_o)_c}{\gamma_s D_{90}} = 0.061 \quad (4)$$

Since $(\hat{\tau}_o)_c$ is a maximum value and considering that a number of assumptions were made about the tests performed by the other authors, this is quite close to the normal Shields condition for incipient motion at higher Reynolds numbers:

$$\frac{(\tau_o)_c}{\gamma_s D} = .05 \quad (5)$$

In order to assess the validity of the Shields criterion in this work, the points were replotted as in Fig. 11 which shows all points above the Shields line reflecting the use of the maximum value of τ_o as well as some wave-inertia effect. The points were also plotted in Fig. 12 to compare them with "critical tractive force" work (3, p 173). The USBR line implies some sediment motion and all points are below this line.

Further attempts were made to relate the summer step depth, Σ directly to wave parameters as was done by Bagnold (1) and Hijum (5). Figure 13 shows the results considering wave heights only. The scatter in this figure is mostly due to ignoring the wave period effect.

ARTIFICIAL BEACH NOURISHMENT

After dynamic equilibrium was reached and much time was expended in developing a basin, there was only time for a few nourishment tests. Although only few tests were performed, the test results will be given and these should be considered tentative until further work has been completed. In order to maximize the usefulness of the results, the winter profile was nourished in the onshore region. This had been found to be the most efficient method of nourishment under two-dimensional conditions (7). The nourishment material had the same grain size characteristics as the parent beach material (Fig. 1) but because the waves had sorted the original beach material, many of the fines had been removed from the onshore zone of the parent beach and transported offshore. Thus the nourishment material contained more fines than the native beach in the nourishment area.

The original average dynamic equilibrium, the average profile of the nourishment and the average equilibrium profiles subsequent to another 10 test cycles, are shown in Fig. 14. The test cycles were kept the same as before (including the sediment feed rate). During the first cycle after nourishment, the small storm waves eroded the new foreshore and planed off the offshore bar. This resulted in an excess of material in the summer step region, which in turn resulted in a more violent summer breaker, which yielded a summer bar corresponding to X_p and d_b of the summer wave. The new SWL slope returned to 20% immediately although the nourishment material had been placed at 29%. Figure 14 shows that no nourishment material ended up seaward of the bar and that 72% of the original nourishment remained, while the rest was removed from the test section by increased littoral drift.

The parameters for the new dynamic equilibrium are given in Table 3

TABLE 3 Dynamic Equilibrium Parameters after Nourishment

Parameters Units	λ_b cm	λ_s cm	θ cm	β cm	Σ cm	SWL cm	R cm	S_{SWL}
Winter Profile	116		11.4	8.8		119	50	.19
Summer Profile		32			12.9	128	36	.21

and comparison with Table 2 shows that λ_b has now decreased to 116 cm, close to the potential value for the two-dimensional tests. This has resulted in an attendant decrease in λ_s . Further, θ and β have both decreased indicating much more material present behind the offshore bar, SWL has moved out an average of 22.5 cm showing a net benefit at the shoreline. The other parameters remained the same.

The littoral drift during the period of larger storm waves was 0.067 m^3 while during the smaller waves it was 0.128 m^3 which makes for a total prototype drift of $3050 \text{ m}^3/\text{cycle}$, up slightly from the value for the initial dynamic equilibrium.

A further nourishment was subsequently applied to the dynamic equilibrium winter profile described in Fig. 14 and Table 3. During the first summer, the

Figure 15 Summary plot of second nourishment

Figure 14: Summary plot of first nourishment

original nourished slope at SWL of 37% was reduced to about 20% again. The much shorter profile could not support the material eroded from the vicinity of SWL as had been the case in the previous nourishment and material was moved offshore of the existing bar. Here it was shaped by the first winter waves into a new bar 18 cm seaward of the previous bar. Equilibrium profiles occurring after a further nine cycles are given in Fig. 15 and the parameters are given in Table 4.

TABLE 4 Dynamic Equilibrium Parameters after a Second Nourishment

Parameters Units	λ_b cm	λ_s cm	θ cm	β cm	Σ cm	SWL cm	R cm	S_{SWL}
Winter Profile	113		10.9	8.5		131	51	.21
Summer Profile		31			12.6	137	34	.20

It may be seen that SWL has moved out an average distance of 10.5 cm and all other parameters are very much the same. This would indicate that the previous equilibrium profile was close to a potential profile which was shifted bodily to seaward by the nourishment. In this case only 8% of the material was removed by increased littoral drift and thus the profile behaved very much like the two-dimensional tests of Ref. 7. The littoral drift during the period of larger waves was $.091 \text{ m}^3$ (up from the previous time) while for the period of smaller waves it was $.104 \text{ m}^3$ (down from the previous time). The total drift still represents $3050 \text{ m}^3/\text{cycle}$ as before.

CONCLUSIONS

With respect to development of a three-dimensional testing facility it was learned that

1. The sediment trap must be within the area subjected to wave action.
2. Wave re-reflection from the generator alone causes superimposed waves at an angle of incidence of (3α) , while re-reflection from both the generator and the wave guides results in waves at angle $(-\alpha)$. The waves at $-\alpha$ cannot be avoided but the waves at 3α should be avoided in order to
 - a. bring about uniform wave heights across the basin
 - b. cause uniform littoral drift across the basin

- c. prevent rotation of the beach in the direction of the wave generator.

With respect to dynamic equilibrium profiles it was found that

3. Dynamic equilibrium is achieved faster in three-dimensional tests.
4. The profiles resemble eroding profiles rather than potential profiles in three-dimensional tests. Potential profiles are defined as those profiles which are as short as possible.
5. The profiles develop around the offshore bar which is shaped early in the experiments at the breaking position of the large storm waves.
6. The depth to the summer step is a function of critical shear stress resulting from wave action on the beach material.

With respect to artificial beach nourishment,

7. Onshore nourishment on eroding beaches is successful.
8. Onshore nourishment on potential profiles results in a seaward shift of the whole profile.

Further study of many of these aspects is continuing at Queen's.

ACKNOWLEDGEMENTS

The funding by the National Research Council of Canada is gratefully acknowledged. Comments and suggestions by colleagues of both authors were also very helpful.

CHAPTER 91

PROPOSED "IMPROVEMENT" OF KAIMU BEACH, HAWAII

By Doak C. Cox, Frans Gerritsen, and Theodore T. Lee*

Abstract

Proposals to "improve" a pocket beach at Kaimu, Hawaii have been under active consideration for a decade. The beach, which is famous for its jet black color has been receding for at least a century. The plans proposed have called for its enlargement, and most of them for its protection by an offshore breakwater. Advantages of a larger beach area, and of the improvement of swimming conditions if the breakwater were constructed, are undeniable. Loss of surfing sites would, however, have resulted from the adoption of any of the plans involving breakwater. Other disadvantages associated with some of the plans proposed would have included alteration of beach color, other visual impacts, and threats to archaeological sites from the quarrying of breakwater stone. Sand-loss estimates and breakwater construction criteria dependent on them were based on probably erroneous interpretations of historical evidence. Possible alternative sites for the provision of the swimming opportunity were not investigated.

Serious question was raised whether the project would result in overall improvement. However, recent coastal subsidence has rendered all of the plans obsolete and the question is probably moot.

Fig. 1 Photograph of Kaimu Beach in 1968 (Corps of Engineers)

*Respectively Environmental Center, Department of Ocean Engineering, and Look Laboratory of Ocean Engineering; University of Hawaii, Honolulu, Hawaii, USA

Introduction

Kaimu beach (fig. 1) is a pocket beach in the Puna District on the southeast coast of the island of Hawaii (fig. 2). Although no more than about a quarter mile in length (fig. 3), the beach would be considered important simply because of the scarcity of beaches on that island and especially in that district. It is in fact famous, but primarily because of the jet black color of its sand. It has been a visitor attraction longer than there has been a recognized tourist industry in Hawaii. However, the beach has long been retreating--indeed measures to control the erosion of its sand were considered as early as the 1910's or 1920's. This paper relates primarily to proposals for its "improvement" dating from 1966 when the Mayor of the County of Hawaii requested the Corps of Engineers to investigate possibilities for its restoration and preservation.

Fig. 2 Topographic and geologic map of Puna District, showing location of Kaimu Beach

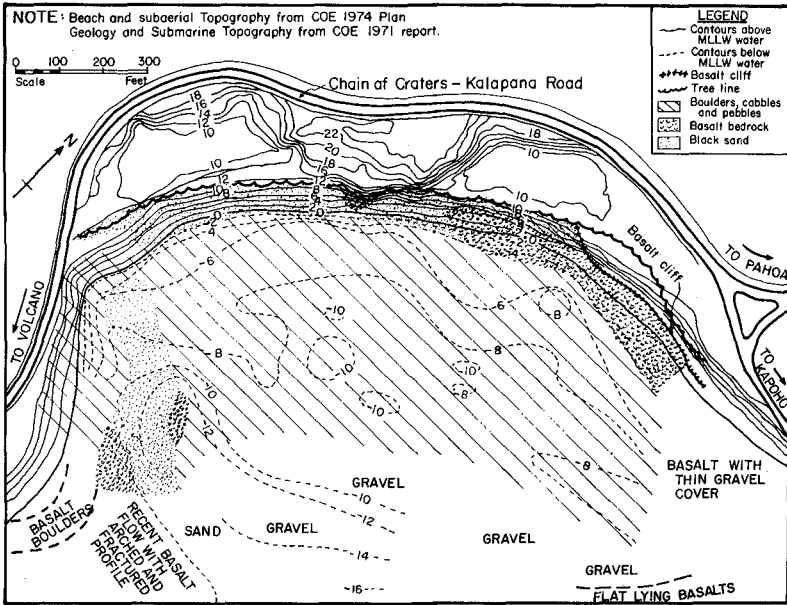

Fig. 3 Topography and geology of Kaimu Beach

In the subsequent decade, plans for enlarging and protecting the beach have been made and revised several times by the Corps. At one time or another, in spite of considerable controversy, all approvals for a construction project were secured, and federal, state, and county funds were released, but the necessary simultaneous correspondence of plans, approvals, and funding was never secured. All of the plans were rendered obsolete by coastal subsidence associated with an earthquake in late 1975 and the future of what is left of the beach may now be left primarily to nature to determine.

The likelihood of an event such as has thus intervened was foreseen, but this likelihood was but one of several environmental aspects that led us, before the event, to propose a Kaimu discussion as a case history of a project whose characterization as an "improvement" was highly questionable. It seems best, even though it appears that the project will not be undertaken, to use a historic outline for this discussion.

Origin and natural fate of the beach

The Island of Hawaii consists essentially of the peaks of five predominantly basaltic volcanoes rising from the ocean floor. Kilauea volcano, whose east rift is the source of lava flows forming most of the Puna district (fig. 2), is one of three that have been active in historic times.

Significant geologic events that have affected this district in historic times are listed in table 1 (Stearns and Macdonald, 1946; Macdonald and Abbott, 1970; Macdonald and Hubbard, 1974). As will be noted, several of the historic lava flows reached the coast.

Table 1. Significant historical geologic events in Puna district

<u>Year</u>	<u>Event</u>	<u>Effects</u>
1750	Eruption	Lava flow from rift to S. coast
1790	"	Lava flow on rift
1840	"	Lava flow N. from rift
1868	Earthquake	Subsidence of S. coast
1884	Eruption	Brief shallow submarine eruption
1923	"	Small lava flows on rift
1955	"	Cones and lava flows covering 6 sq. mi., 3 reaching S. coast
1960	"	Cones and lava flow covering 4 sq. mi. and extending to N. and S. coasts near Cape Kumakahi
1961	"	Small lava flows on rift
1962	"	Small lava flows on rift
1963	2 eruptions	Mostly lava fills in pit craters on rift
1965	2 eruptions	Lava flows covering 3 sq. mi. on rift
1968	Eruption	Small lava flows on rift
1969	2 eruptions	Lava flow from first eruption covering 2 sq. mi. near rift. Lava flows from second eruption, which continued into 1971, covering 22 sq. mi., 3 of them reaching the S. coast
1972	Eruption	Lava flows covering 14 sq. mi., one extending to S. coast
1973	3 eruptions	Lava flows covering 4 sq. mi. near rift
1974	Eruption	Lava flows covering 1 sq. mi. on rift
1975	Earthquake	Subsidence of S. coast

Kaimu beach resulted from the entrance of a lava flow into the sea. Upon such entrance, lava often explodes forming deposits of volcanic ash. To the extent these deposits are within wave reach, the ash fragments are subject to reworking and transport. The resulting sand may be deposited, at least temporarily, in a beach at some relatively protected part of the coast. Such a beach is, however, an evanescent feature. The sand is subject to further comminution and transport by waves and wind, and the beach is certain to recede if not covered by a later lava flow.

It is uncertain what lava flow was responsible for the ash from which the black glass sand of Kaimu was derived. The flow may have been a pre-historic one (Stearns and Macdonald, 1946). If so, the ash deposits that were the source of its sand may have been covered by the lava flow of approximately 1750, which entered the sea just northeast of Kaimu beach (fig. 4). In this case the beach has probably been somewhat protected by the coastal extension resulting from the lava flow. Alternatively, the 1750 flow itself may have both been responsible for both the bay in which it was

Fig. 4 Aerial photograph of Kaimu in 1959 (U.S. Navy)

deposited and the source of the sand (COE, 1971). In this case the ash deposits have subsequently been eroded away.

In either case, the beach has been subject to erosion since the sand source was exhausted or covered. Some of the sand has been blown inland at Kaimu, some of it has undoubtedly moved into deep water offshore, and much of it has been transported northwestward to Kalapana (fig. 2) where it has been blown inland to form dunes.

Evidence of the subsidence of Kaimu beach, possibly combined with retreat, was reported as early as the 1870's by Nordhoff (1874) in the form of coconut tree stumps sticking up out of the surf. Photographic evidence of coconut trees being toppled into the water in the 1880's was published by Agassiz (1889) (Fig. 5). Similar photographs have been taken at numerous times since (figs. 6-8); and rough or precise estimates of the rates of retreat may be made by comparisons of shoreline maps dating from 1892 to 1968 and from beach profile surveys made in 1968 and subsequently (fig. 10). By the mid-1960's a rock ledge was exposed near the middle of the beach, and by the mid-1970's this ledge formed a conspicuous promontory (fig. 7).

Table 1 does not include the several tsunamis that may have accelerated the beach retreat temporarily. Tsunamis accompanying the earthquakes of 1868

(Rick Scudder)

and 1975 had runup heights of several tens of feet on the coast farther northwest, but the latter tsunami, at least, was of slight importance at Kaimu. Recent beach erosion was evident after the 1946 tsunami, but it is not clear that any significant addition to rate of retreat resulted.

Project as proposed in 1971

Proposal

In response to the 1966 request of the Mayor of Hawaii for investigation of means to restore and protect Kaimu Beach, the Corps of Engineers issued a favorable reconnaissance report in 1967. Detailed project plans were then prepared which were described in a report issued in September 1971 (COE, 1971).

From shorelines supposedly mapped in 1910 and 1938 and a 1968 shoreline survey, average beach retreat was estimated at about 4 ft. per year, and average sand loss at 2000 cu. yds. per year. The Corps proposed enlargement of the beach, its protection by an offshore breakwater, and periodic replenishment of sand to replace subsequent losses that would occur in spite of the protection.

The enlargement proposed would have required 40,000 cu. yds. of sand, which was to be produced by crushing and screening cinders from a nearby cinder cone, Kaakepa. With this volume, a dry-beach area of 100,000 sq. ft. would have been created. The breakwater proposed would have been about 1350 feet long, extending across the entire bay and would have had a crest height of 2.5 ft. above mean lower low water. Use of stone of at least 6 tons was proposed. The beach enlargement would have been similar and the breakwater alignment identical to those shown in figure 11. Sand losses after breakwater construction, necessitating periodic sand replenishment, were estimated at 600 cu. yds. per year.

The Corps pointed out that this plan would produce, not only an enlarged and protected beach, but a protected swimming area where swimming has been hazardous because of the waves and a rip current. They recognized that the breakwater would have a visual impact, and that its construction would interfere with two surfing sites.

Alternatives to the proposed plan included enlargement of the beach without a breakwater, with a submerged breakwater on the same alignment and with the same length as the proposed exposed breakwater, and a submerged breakwater on the same alignment but extending only 450 feet from the southwest shoreline.

Objections

Although the swimming opportunity that would have been created by the proposed project would clearly have been advantageous, there were expectable objections to the visual impact of the breakwater, the loss of surfing sites, and other alleged detriments. The University of Hawaii Environmental Center, in reviewing the proposal, pointed out the scarcity of surfing sites on the island of Hawaii, and also the traditional importance of surfing at Kaimu as a spectator as well as participant sport (Fig. 9) (Bretschneider et al, 1972).

Fig. 9 Surfing at Kaimu
(Rick Scudder)

In addition, the Center called attention to the effects of using the crushed cinders for the beach enlargement. Spread on the beach, this material would have been harsh underfoot, and because it was brown, the jet black appearance on which the fame of the beach depended, would have been lost. The Center also questioned the Corps estimates of historic rates of beach retreat and sand loss.

The source of the stone for the breakwater was described in the Corps report merely as within 10 miles of Kaimu. It later appeared that the principal source in mind was a lava ledge at Kalapana. The Center pointed out the existence of archaeological sites in the vicinity and questioned whether the quarrying operation could be carried out there without disturbance to these sites or esthetic detriments.

The Center also commented that, although beach enlargement without a breakwater and use of lower or shorter breakwaters on the proposed alignment had been considered as alternatives, there was no evidence of consideration of

alternative modes of beach protection or of alternative sites at which the swimming opportunity could be created. The Center called attention to the opinion of the Look Laboratory of Oceanographic Engineering that the choice among alternative breakwater designs should be based on hydraulic modeling (Bretschneider et al, 1971).

Project as proposed in 1972

Proposal

In response to some of the objections and questions mentioned above, and others, the Corps of Engineers revised its estimates and its proposed plan (COE 1972a) and prepared and issued an environmental impact statement on the project (COE 1972b, 1973). Estimates of beach retreat and sand loss, were revised on the basis of shoreline positions mapped in 1892, 1915, and 1940, and beach surveys in 1968 and 1972. From the description of the 1892 shoreline, it is assumed to have been that dated 1900 in the earlier Corps report (COE 1971). This shoreline and those plotted in the 1972 Project Report (COE 1972a) are shown in figure 10. The histories of the position of the beach front and of the sand volume in the beach as estimated by the Corps are shown in figure 12.

Fig. 10 Shoreline history of Kaimu Beach

The revised plan called, in sequence, for:

- 1) Removal and stockpiling of 5,800 cu. yds. of sand from the beach.
- 2) Adding 38,000 cu. yds. of new sand to the beach.

3) Monitoring for about two years, during which sand loss at a rate of 3000 cu. yds. per year was expected.

4) Construction of the breakwater to the same length and on the same alignment as in the original plan, but with its crest at mean lower low water (fig. 11).

5) Adding an additional 5,000 cu. yds. of new sand to the beach and topping off with the 5,800 cu. yds. of original stockpiled sand.

6) Periodic replenishment of sand, averaging 1,200 cu. yds. per year, to compensate for continuing sand losses.

The dry beach area on completion was estimated at 133,000 sq. ft., an increase of 101,000 sq. ft. over the existing area. It was recognized that the breakwater would still interfere with surfing. It was also recognized that the water inshore of the submerged breakwater (crest at mllw) would not be as quiet as in the case of the exposed breakwater originally proposed (crest at 2.5 ft. mllw), but considered that this would not seriously detract from the swimming opportunity.

Recognizing the importance of the color of the sand, the Corps proposed, as a possible alternative to the use of crushed cinders, the use of greenish-black sand-sized ash derived from shoreline explosions of the 1960 lava flow at Kumukahi (fig. 2).

Objections

In reviewing the 1972 proposal, the Environmental Center called attention to the fact that the original sand removed from the beach, stockpiled, and later replaced on top of new sand, would be most immediately affected by subsequent erosion (Johnson, 1973). The estimation of sand loss rates was again questioned. The Center pointed out that the Corps had assumed that the 1915 and 1940 shorelines were mean high water lines, whereas in Hawaiian usage they were more likely to be wave wash lines, and that the rates of retreat and sand loss had probably slowed as the beach retreated.

The matter of alternatives was again brought to attention. An alternative of gradual sand replenishment without a breakwater, either at a rate just sufficient to balance the erosion or at a larger rate to induce increase in beach width, was pointed out as having seeming economic advantage (Cox, 1973). In addition, the importance of geologic hazards to the beach and the proposed project was discussed, with special reference to the hazards of lava flows and coastal submergence or emergence.

Project as proposed in 1974

Initiation

Weighing the benefits, detriments, and uncertainties, the Environmental Council, advisory to the Governor of the State of Hawaii, recommended initially against the undertaking of the proposed project. However, on the request of the Hawaii County Council, the Environmental Council reconsidered

the matter, and in June 1973 recommended the planning of a project similar to that proposed in 1972, but with the breakwater construction to be contingent on the results of monitoring:

- 1) Construction phase I: Beach enlargement
- 2) Monitoring phase of two or, preferably, three years
- 3) Contingent construction phase II: Breakwater construction
- 4) Periodic replenishment of sand to compensate for continuing losses.

The Corps of Engineers was requested to "apply, whenever possible, the recommendations of geologists, ocean scientists, and other experts from the University of Hawaii" to the design of the first phase, and to consult with University experts on the monitoring program and the design of the breakwater.

First proposal

An initial proposal was presented to the Environmental Council by the Corps in November 1974. Enlargement of the beach (fig. 11) was to be accomplished using 30,000 cu. yds. of sand from the Kalapana ash deposits, which approached the Kaimu sand in color and size distribution. Stability of the enlarged beach was an important consideration in the design configuration (fig. 11). A monitoring period was called for with monthly surveys for three months after completion of sand emplacement, bimonthly for the rest of a two-year period, and annually thereafter for 10 years, unless it were decided earlier to construct the breakwater.

It was proposed that the breakwater would not be constructed if all of the following sand-loss criteria were met:

- a) Initial rate: less than 10,000 cu. yds. per yr.
- b) Rate during each subsequent monitoring interval: less than 3,000 cu. yds. per yr.
- c) Average rate from completion of enlargement to any survey date in the first two years: less than 1,300 cu. yds. per yr.
- d) Rate during any subsequent year: less than 3,000 cu. yds. per yr.
- e) Average rate to any subsequent survey: less than 1,300 cu. yds. per year.

A decision to construct was to be made at the end of two years if any of the first three criteria were not met, and at any time thereafter if either of the last two criteria were not met. The breakwater, if constructed, was to be a submerged one as in the 1972 plan (fig. 11).

Beach-retreat and sand-loss estimation

The Environmental Center considered that, in the light of the Council's recommendation to defer the breakwater construction pending actual observation of the rate of sand loss after beach erosion, the criteria for

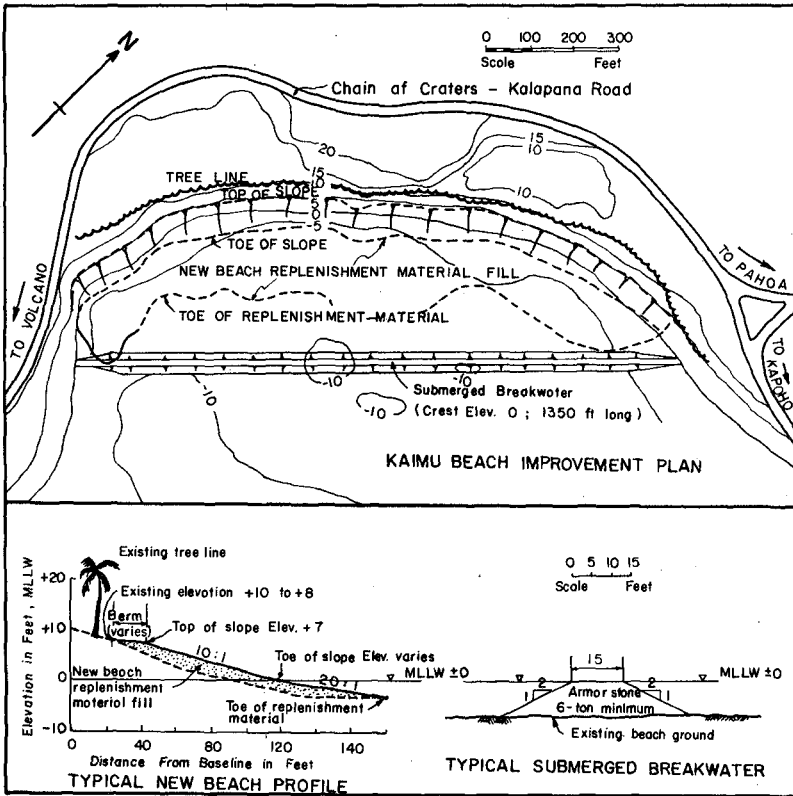

Fig. 11 Kaimu breakwater as proposed in 1972 and beach enlargement as proposed in 1974

determining whether or not the breakwater should be built were critical, and that for this reason the estimates of beach retreat and sand loss should be reexamined. In the Center's opinion, the criteria should exceed, but not exceed greatly, the loss rates expectable considering average natural loss rates at beach front positions equivalent to post-enlargement positions, expectable short-term departures from average loss rates, and some increase over natural loss rates due to non-equilibrium configuration of the beach, especially immediately after construction.

The Center developed estimates of long-term beach retreat and sand loss rates, that were based on Corps of Engineers data, including the approximate position of the shoreline in 1892 and the results of a 1974 survey that had

just been completed (Cox, 1974b). Like the Corps, the Center was forced to assume that, in profile, the shape of the beach at the times when only shorelines had been mapped was similar to the shape when the entire beach front was surveyed in 1968, 1972, and 1974. Beach retreat and sand loss rates were related through use of a smoothed curve of loss-retreat ratios, obtained from Corps data, plotted against shoreline position. However, the Center assumed that the shorelines mapped in 1892, 1915 and 1938 were not the high water line, as assumed by the Corps, but the "kahakai" or mark of the sea, the uppermost reach of waves as indicated by the vegetation line, as was conventional in Hawaiian cadastral surveying.

The histories of beach retreat and sand loss in accordance with the Center assumption are compared with those in accordance with the Corps assumption in figure 12. In this figure the beach-front positions and beach-sand volumes at the times of successive shoreline and beach-front surveys are plotted relative, respectively, to the 1972 position and volume. Beach-retreat and sand-loss rates as estimated by the Center are compared with those estimated by the Corps in figures 13 and 14. In these figures, retreat rates and loss rates are plotted over the respective ranges in beach-front position between successive mapping or survey dates. It will be seen from the latter figures that much more regular relationships between retreat and sand loss rates and beachfront position resulted from the Center estimation than the Corps estimation.

Fig. 12 Historic beach front-positions and sand volumes in accordance with Corps of Engineers and Environmental Center assumptions

Fig. 13 Beach retreat rates as estimated by Corps of Engineers and Environmental Center assumptions

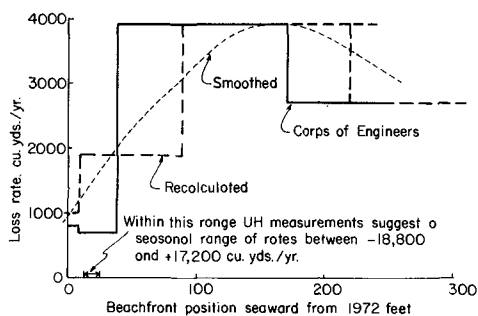

Fig. 14 Sand-loss rates as estimated by Corps of Engineers and Environmental Center in relation to beachfront positions

The Center also made use of profiles of the beach surveyed by the Hawaii Institute of Geophysics in June and September 1962; January, April, and July 1963; and July 1971 (Moberly and Chamberlain, 1964). Because the Institute of Geophysics surveys were made on a single range, it was necessary to assume that, in plan, the shape of the beach was essentially the same on the various survey dates.

Unfortunately, the position of the Institute range was never related to the positions of the ranges used by the Corps. Hence the relation in figure 12 between the beach-front history based on Institute data and the longer term history is somewhat uncertain, and the implications of the Institute data are shown in figures 13 and 14 merely as ranges of uncertainty.

The Institute data were, however, of use, together with the Corps beach surveys of December 1968, May 1972, and February 1974, in estimating short-term departures from long-term beach-retreat and sand-loss rates. From the rates of sand loss indicated by various pairs of surveys, the normal (long-term) rates indicated by figure 14 were subtracted, and the resulting departures were compared, without regard to sign, in a log-log plot against the time intervals between the respective surveys. Retreat rates were treated similarly. The results indicated that departures from normal sand-loss rates

could well be as large as 25,000 cu. yds./yr. over a period of 2 months, 5,000 cu. yds./yr. over a period of 6 months, 1,800 cu. yds. per year over a period of a year, and 600 cu. yds. per year over even a period as long as two years.

The combination of normal rates of sand loss for various beach-front positions as plotted in figure 14, expectable departures from normal rates for periods of various durations, and sand-loss/retreat-rate ratios for various beach front positions, provided a basis for estimating the expectable rates of sand loss after the beach was enlarged and as it subsequently retreated (fig. 15), if it were assumed that the effects of any failure to attain an equilibrium configuration in construction would be small or of short duration. Expectable cumulative sand losses after beach enlargement, estimated as indicated, are shown in figure 15. This figure also shows the losses implied by the criteria for breakwater construction originally proposed by the Corps, and the losses that the representatives of the Corps and Environmental Center agreed jointly should be reflected in revised criteria.

Fig. 15 Expectable cumulative sand loss after beach enlargement and proposed breakwater construction criteria

Revised proposal

The Corps-Center conferees reported back to the Environmental Council in December 1974 (Beishe et al, 1974). In brief their joint recommendations, if the project were to proceed, were as follows:

1. The 30,000 cu. yds. of sand to be placed on the beach should be drawn in accordance with the earlier plan (fig. 11) from the Kalapana ash deposits.
2. A first monitoring survey should be made before beach enlargement, a second as soon as possible after completion of the enlargement, and subsequent surveys at two-month intervals during the first year thereafter, four-month intervals during the second year, and annually thereafter for 10 years.
3. The breakwater would be built if, and only if, the cumulative loss of sand after the as-built-survey exceeded 4,000 cu. yds. at any time during the first year or 2,400 cu. yds. plus the product of 1,600 cu. yds. per year and the time in years elapsing from the as-built-survey (fig. 15).
4. The breakwater, if built, was to be constructed in accord with the submerged breakwater plans (fig. 11) using stone quarried from sites of no archaeological significance where scenic detriments and nuisance would be minimized.

No estimate was reported of the rate of continuing sand loss after the breakwater was constructed, if it were constructed. Assuming the validity of the Corps estimate of the ratio of loss rates with and without the breakwater, the periodic replenishment of sand needed to compensate for sand losses continuing after breakwater construction would have averaged about 1,100 cu. yds. per year.

Independently, the Center suggested that the Council should reconsider its decision to approve any modification of Kaimu Beach, calling attention to some of the objections that had been raised previously but seemingly not adequately considered. However, the joint Corps-Center recommendations were approved by the Council and transmitted to the Governor of the State of Hawaii and the Mayor of the County of Hawaii.

Project as proposed in 1975

Although the County Council of the County of Hawaii had approved the staged project, as proposed by the Corps in 1972, and had not objected to the proposal of the Environmental Council to make the breakwater construction contingent on monitoring results, and in spite of the subsequent planning efforts of the Corps and Environmental Center and endorsement of their recommendations by the Environmental Council, the County Council rejected the recommendations, in favor of a plan in which the breakwater would be constructed first and the beach enlargement accomplished second. In spite of the State Environmental Council's position, the State Department of Land and Natural Resources, which controlled the necessary state funds, concurred with the County Council.

The breakwater was presumably to be a submerged one, and the sand used for beach enlargement was presumably to come from Kumukahi, but it is not clear what volume of sand would have been placed on the beach nor where the breakwater stone would be obtained because, during the long delay, the federal funds originally allocated to the project had been committed elsewhere, and the preparation of revised plans and undertaking of construction had to await a further allocation.

Natural intervention

Nature then intervened. On 29 November 1975 there was an earthquake with a magnitude and effects similar to those of 1868. A tsunami was generated that was responsible for two deaths on the coast southwest of Kaimu. The coast again subsided to a maximum of about 10 feet to the southwest and about 3 feet at Kaimu. Some subsidence seems to have continued since the quake, although the results of surveys have not as yet been published.

As had been reported after the 1868 subsidence, the erosion of Kaimu beach accelerated after the 1975 subsidence (figs. 16 and 17). However, the height of the beach above sea level was reduced by about 3 feet and the depths along the proposed breakwater alignment as well as elsewhere were increased by the same amount. Hence neither the plans for beach enlargement nor those for breakwater protection could be considered at all appropriate. In addition County plans for other aspects of coastal development at Kaimu, private and public, were rendered questionable by the subsidence and the obvious exposure to the effects of earthquakes and tsunamis. Hence the economic justification for the project appeared to need reexamination.

No final decision has yet been made that the construction project affecting Kaimu Beach should not be undertaken. The Corps of Engineers has indicated its possible availability for further planning. However, the County has decided that no further planning effort should be made for a while, at least until the question of continuing coastal subsidence has been settled.

Figs. 16 and 17 Kaimu beach in December 1975 (Joseph Halbig)

Analysis and conclusions

As in the case of most projects intended to modify natural conditions or processes, the Kaimu Beach project, in any of the plans proposed, would have resulted in a combination of benefits and detriments, some of both accruing as side effects, incidental to the benefits for which the project was proposed. The weighing of such benefits and detriments is supposed to be facilitated by the combined availability of project reports and environmental impact statements, after public review and resulting response, to decision makers. The process seldom approaches perfection, and this review of the Kaimu case was undertaken to call attention to some sources of imperfection to which special attention might usefully be paid in reviewing the process or applying it to similar cases.

The benefit originally sought by the County of Hawaii was the restoration and protection of Kaimu Beach. All of the plans called for enlargement of the beach, but in a strict sense none of them could have restored the beach to its natural condition at some time in the past. It is quite doubtful that, without public review, the color change which would have resulted from the implementation of the 1971 plan would have come to general attention until the change had been effected, although there is little doubt that preserving the natural color of the beach was considered important. When the color change detriment was called to attention, the plans were revised to call for the use of sand more nearly matching the natural sand in color.

More or less protection of the beach would have been afforded by any of the plans that incorporated a breakwater, and all of the plans called for sand replenishment after the project was complete to compensate for the lack of complete protection. The loss of surfing sites that would result from breakwater construction was recognized from the outset by the Corps, but the importance of these sites, on account of their traditional and continuing use, was highlighted in the public review process and more or less well recognized in the final environmental statement.

The potential detriments associated with quarrying for breakwater rock, which came to light in the public review process, were circumvented by changes in the plans for quarry sites in response to the review comments.

The swimming opportunity that the breakwater would have provided was identified by the Corps from the outset as a major benefit. Retention of the breakwater in the plans probably resulted from considerable public agreement with the importance of this benefit. However, in spite of the requirement in federal environmental law for the consideration of alternatives, possible alternatives for the provision of this benefit were never investigated because the Corps is not authorized to investigate the creation of beaches or swimming sites, but only their restoration and protection, and the state and county could not have counted on federal support for the investigation or construction where there was not an existing beach.

Some of the detriments of the project that were alleged in the public review process were examined and shown to be of little consequence--an alleged loss of fishing opportunities, for example. Some alternatives suggested in review were, however, brushed aside as being impractical without evidence of adequate investigation, for example, alternative types and alignments of breakwaters. Trial dumping of sand cinders (or of cinders from which sand might be generated) east of the beach to nourish the beach indirectly (Johnson, 1973) was dismissed simply because "this alternative is not a positive approach to the problem and there is a possibility that the introduced sand would bypass the eroded areas completely" (COE, 1973).

The questions initially raised in the first public review about the retreat and sand loss estimates, on which the benefit and cost appraisals of the project depended, were not satisfactorily addressed until the Environmental Council intervened.

Of three geologic hazards, only the least consequential, that of tsunamis, was initially recognized. The lava-flow hazard, to which attention was called in the review process, was never analyzed, although historical statistics on which a reasonable analysis could be based became increasingly available during the planning period. Attention was called in the review process to the hazard of subsidence, but this hazard could not have been analyzed because there had been but one prior incidence of this hazard at Kaimu. Oddly, it was a second incidence of this hazard, that brought the project planning to a halt, at least temporarily.

It seems quite questionable that, if all of the detriments, hazards, and alternatives had been recognized at the outset, any of the plans formally proposed would have been considered as representing, overall, an improvement. During the long planning period, however, increasing public and private commitments were made for land uses in the vicinity under the assumption that the Kaimu beach would be enlarged and a swimming opportunity created there. The decisions in early 1975 were almost certainly biased by developments that were stimulated by the initial proposal of 1971, although this would be difficult to document. Unfortunately the event that led to the halt also hastened the end of Kaimu beach, of which there are left only remnants.

Acknowledgements

Many members of the University of Hawaii community contributed to the Environmental Center reviews on which this paper is based, and several members of the staff of the Corps of Engineers were helpful in supplementing and clarifying the information in official reports in the review process. Information and photographs provided by Joseph Halbig and G. A. Macdonald of the University of Hawaii, Rick Scudder of the Office of Environmental Quality Control, and Clarence Fujii and Karl Keller of the Corps of Engineers were used in the preparation of this paper. The assistance of all, whether here named or not, is gratefully acknowledged.

CHAPTER 92

CHANGES OF SEA BED DUE TO DETACHED BREAKWATERS

Osamu Toyoshima

Director, Public Works Research Institute, Akabane Branch
Ministry of Construction

Ex-Director, Sea Coast Division, River Bureau
Ministry of Construction, Japan

INTRODUCTION

Since most of the coast lines of Japanese Islands are faced on the open sea and are always attacked by severe waves, beach erosion is one of serious problems in the coastal engineering field. Although Japan has all types of coastal land-forms except the glacial shoreline, remarkable recessions of coast line have been observed at sea cliffs and sandy beaches. The recession of sea cliffs has been found at several districts in Japan since old times. But, beach erosion has become increasingly severe since the early 1950's. The main causes of beach erosion are the reduction in sediment supply from rivers and the interception of the longshore paths of sediment. The former is caused by the river improvement works and by the construction of dams and debris barriers or Sabô works. The later is caused by the coastal structures, such as jetties, groins, breakwaters, and flood-control outlets. In addition a new type of beach erosion has been observed at the coast where coast protection works such as seawalls and bulkheads exist.

The beach erosion defence works are being executed at more than 300 sites in Japan. Considerable number of the works were commenced in the 1960's.

The author proposed ten years ago a detached breakwater system to develop the sand deposition behind the breakwater. Up till now, about fifty or more works of the detached breakwater system have been constructed under the guidance of the author, and most of them have brought about successful results. The details of the design method about a detached breakwater system were presented by the author at the fourteenth International Conference on Coastal Engineering, titled "Design of a detached breakwater system".

The paper takes an example in Kaike coast, and describes the changes of coastal protection works against beach erosion and the changes of sea bed after the construction of the detached breakwaters.

OUTLINE OF THE KAIKE COAST

Kaike, one of the most famous hot spring resorts, located on the root of the Yumiga-hama Peninsula which has been believed to be a sand spit formed by sand deposition discharged from the Hino River that fed sand to this coast.

Rough waves from the east-northeast is refracted in Miho Bay as a result of the offshore topography and configuration of the coast as shown in Figure 2. These refracted waves give rise to the longshore current in the western direction along the Yumiga-hama Peninsula.

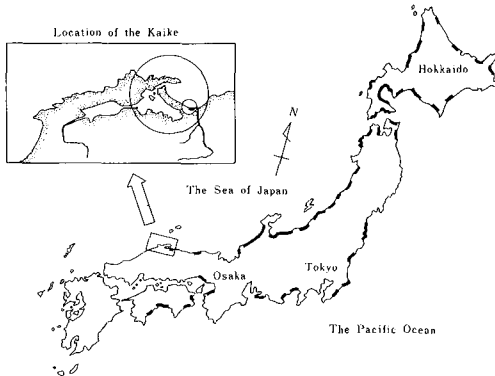

Fig.1 Location map showing the Kaike coast and sites where beach erosion has been comparatively severe.

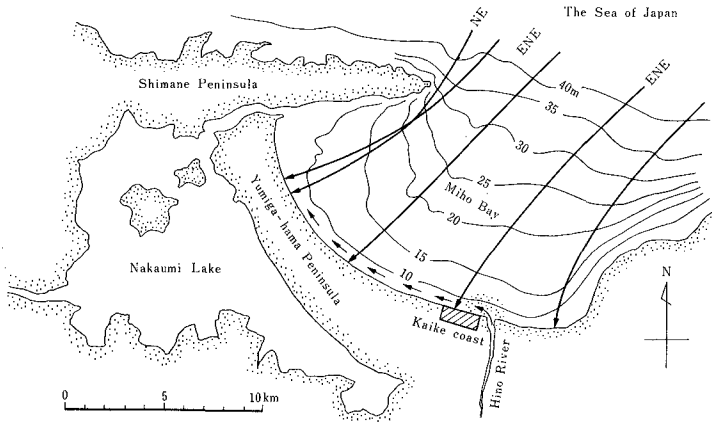

Fig.2 The longshore current formed the Yumiga-hama Peninsula in ancient times, and now-a-days it erodes the Kaike coast on account of reduction of sand supply from the Hino River.

In the early 1870's, a fountainhead of hot spring was discovered by fishermen in shore of the Kaike coast by chance. In those days, the shoreline of the Kaike coast had been advancing offshorewards year by year. In the 1910's, the former sea bed where the fountainhead of hot spring was discovered, changed into backshore, and the first spa was built on the beach. At that time, Kaike had sandy beach of width of more than 200 meters.

About 1920, iron sand collecting for Japanese traditional steel making was abandoned in the upper reaches of the Hino River. In addition to this, a number of Sabô dams and agricultural weirs were constructed along the Hino River. These facts brought a remarkable reduction in sediment supply from the Hino River and the advancing tendency of the Kaike coast turned into the receding one. The shoreline at Kaike has receded more than 200 meters during the last half century.

CHANGES IN COASTAL PROTECTION WORKS AT THE KAIKE COAST

In the face of acute construction material shortage during the World War II, an attempt was made to weaken the rate of beach recession by means of primitive crib works using pine logs which had commonly

used in the river bank protection works in Japan.

Unfortunately almost of the works were destroyed soon after their completion by very strong actions of stormy waves.

Fig.3 In 1942, people in the seabord tried to weaken the longshore current by means of primitive crib works using pine logs, but these works were destroyed soon.

In 1947, after the War, Tottori Prefecture organized a research committee on the littoral drift control with experts and engineers representing the universities and central and local governments. There have never been any attempts to organize the technical and research committee concerning with the problems in the coastal engineering until the establishment of this committee.

Before the establishment of this committee, Tottori Prefecture had constructed an experimental groin composed of rubble stones on the Kaike coast. But this groin subsided under the sea water level soon after its completion.

In paralleling with the committee's research work, between 1949 and 1950, the local government constructed more five experimental groins which composed of large scale concrete blocks.

Figure 4 indicates the change in the shoreline configuration during that period together with locations of constructed groins. It is noticed from this figure that groins resulted in accretion on the up-drift side and in erosion on the downdrift. However the shoreline in front of Kaike Spa advanced seawards in comparison with that before the scheme commenced. The fountainhead of hot spring, indicated in the figure, was the No. 3. Nos. 1 and 2 fountainhead, located more off-

shore side than the No.3, had been destroyed by the heavy beach erosion, and vanished under the sea bed before 1940.

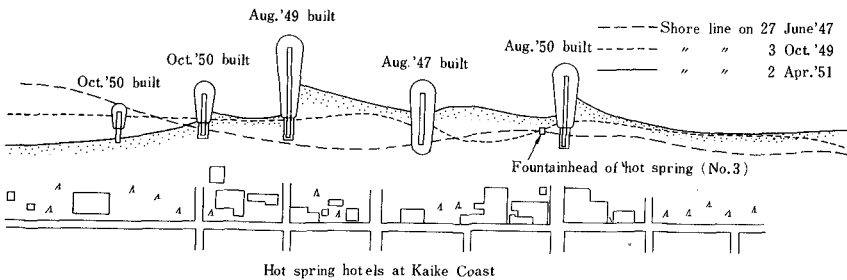

Fig.4 Five groins were constructed between 1947 and 1950 in front of the Kaike Spa. Their performances in the initial stage were very effective and shoreline advanced seaward compared with that before the construction.

Based on the proposal of the research committee and the success in the construction of groin system, Tottori Prefecture decided to construct eight groins in addition to that previously constructed. As seen in Figure 5, the function of groin system gave the satisfactory effect in 1954.

Fig.5 In the next summer after the completion of the construction of the groin system, August 1955, the Kaike coast was eroded again.

In August 1955, the Kaike coast was heavily eroded by rough waves caused by Typhoon and the shoreline was in full retreat.

Immediately after the heavy erosion due to Typhoon, Tottori Prefecture constructed seawalls along the shoreline to withstand severe wave actions. Based on the technical consideration in those days,

concrete stepped face seawalls illustrated in Figure 7 have been adopted as a suitable prevention structures against beach erosion in Japan. The construction of the seawalls had been made between 1955 and 1961.

Fig.6 The seawalls have been constructed between 1955 and 1961, and most of the Kaike Spa have been protected from the severe waves by the seawalls in length of about 1300 meters.

Fig.7 Concrete stepped face seawall was adopted in 1955.

For several years after the completion of the seawalls, the Kaike coast had been seen like a stable beach, where very wide sandy beach extended in front of the seawall.

Fig.8 In 1957, the Kaike beach had been seen a stable wide sandy beach. The berm height of sandy beach in front of the seawall was nearly equal to that of the crest of the seawall.

Even when the Kaike coast was seemed to be stable, a large amount of beach sediment carried offshoreward with every attack of severe wind waves in winter. As the result of wave attacks groins and seawalls on the Kaike coast were damaged locally in January 1961.

Fig.9 In December 1960, most of the sandy beach were vanished. The arrow mark on the center of the picture shows the fountainhead No.3 shown in Figure 4.

Fig.10 In January 1961, the stepped face seawall had been partly destroyed by the winter strong wave force. Waves had scoured beach at the foot of the seawall, and the body of the seawall had been scattered. The seawall had been reconstructed at once.

Fig.11 Reinforced inclined-face type seawall was adopted as the restored seawall.

The profile of seawall restored by the local government was an inclined-face type seawall with sandtight cutoff wall by steel sheet pile as shown in Figure 11.

After a lull in beach retrogression Kaike coast begun to retreat again in the early 1960's. Incident waves directly struck seawalls and overtopped. In order to reduce wave overtopping, wave defence works composed of artificial concrete blocks were constructed in front of the seawalls.

Fig.12 As the wave defence works, armour concrete blocks, named Hexa-leg block, were piled up in front of the seawall. But a number of these blocks have sank under the sea bed (photo in 1970).

As severe waves have repeatedly hit the Kaike coast, the combination system of groins and seawalls with wave defence works has shown its inadequacy in the protection function against beach erosion. When incident waves approach normally to the shoreline, some portions of incident wave energy are reflected from the seawall.

This wave reflection results in considerable scour in front of seawalls and receding waves take away beach sediment seawards. Due to these unfavourable effects by the seawall, groins and wave defence works settled and scattered. Therefore the local government often faced to restore and reinforce the protection works on the Kaike coast. In the early 1970's, the Kaike coast severely eroded again.

Then, the author proposed to construct detached breakwaters as a countermeasure against beach erosion.

Fig.13 The shoreline of the Kaike coast in 1970.

PROPOSAL OF A DETACHED BREAKWATER SYSTEM

For more than twenty years, in Japan, as a countermeasure against beach erosion, many preventive constructions, such as seawalls and groins, have been built. However, it turned out that the seawalls and groins are not necessarily effective measures to prevent beach erosion, and that they have even accelerated beach erosion in some cases. Then the author proposed a detached breakwater system ten years ago.

This system has two major functions. One is the dissipation of incident wave energy, by which beach erosion due to wave actions can be stopped. The other is generation of diffraction waves, by which development of a tombolo, sand deposition behind a breakwater, is encouraged. A detached breakwater system consists of a group of breakwaters, parallel with the shoreline, and is usually located in the surf zone.

The first experimental work of this system was carried out at Ishizaki coast Hokkaido Prefecture under the direction of the author in 1966. Soon after the completion of the work, the tombolo was formed behind the breakwater, and the system were effective in the restoration of shoreline. Further twenty or more experimental works had been carried out on another coasts, and most of them have been successful.

Although a considerable experimental works were carried out, this system is comparatively new and there are fewer examples compared with groins. Generally, of cause, construction work of the detached breakwaters is not easy and maintenance cost is also high, when they

are constructed on steep and deep sea bed.

CONSTRUCTION OF THE DETACHED BREAKWATERS AT KAIKE

The detached breakwaters at Kaike were positioned in water considerably deeper than that where the previous experimental breakwaters constructed. Therefore, the adoption and its positioning were determined after long series of field surveys and researches.

In June 1971, the construction of the first breakwater at Kaike was commenced under the direct administration of the Ministry of Construction, and was completed in September the same year. The breakwater with the length of 150 meters was constructed at the water depth of about 5 meters where was 110 meters offshoreward from the seawall. The breakwater as seen in Figure 14 was comprised of rubble stones and armoured by tetrapods.

Fig.14 Cross-section of the detached breakwater at Kaike.

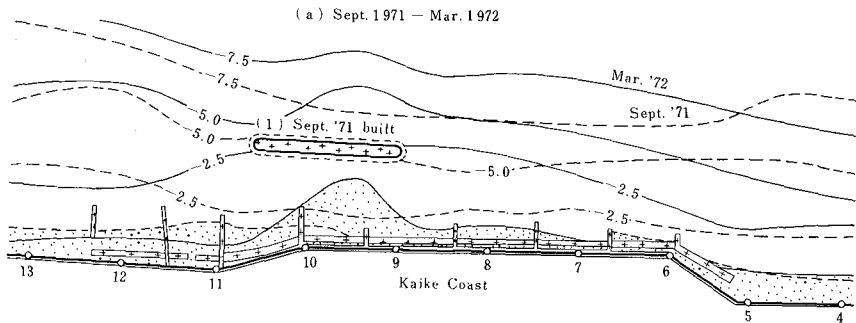

Fig.15 Changes of shoreline and equi-depth line before and after the construction of the No.1 detached breakwater at Kaike.

After the construction of the first breakwater, the tombolo was formed in front of the seawall, and every equi-depth line around the breakwater greatly advanced offshoreward in comparison with that before the construction. The thickness of deposit sand was about 4 meters at the apex of the tombolo, and about 2 meters in front of the seawall.

According to the changes of sea bed before and after the construction of the breakwater, it was estimated that most of the deposit sand was carried from the offshore sea bed at a depth of more than 12 meters.

Encouraged by the successful result of the first experimental detached breakwater, the No.2 breakwater was constructed in the following year, on the updrift side of the No.1 breakwater. The No.2 breakwater was also effective in bringing back sand transported from offshore zone and in forming a large scale tombolo behind it.

Fig.16 Changes of sea bed after the construction of the No.2 breakwater.

In progress of No.2 breakwater construction it was observed beach retrogression in the downdrift zone of No.1 breakwater. To eliminate the undesirable effect by Nos. 1 and 2 breakwater, No.3 breakwater was sited on the downdrift side of No.1 breakwater. The No.4 breakwater was in the updrift side of the No.2 breakwater in order to increase the covering area.

These two breakwaters were constructed in the following two years, and were positioned at equal spaces of 50 meters.

Fig.17 Changes of sea bed after the construction of the Nos. 3 and 4 breakwater.

Before the construction of the breakwaters, the shoreline has usually been retreated by attacks of strong waves in winter. But after the construction, the sand depositing action of the breakwaters has continued and tombolos have become larger in their sizes even under the severe wave condition.

At the Kaike coast, the progress of the construction of the breakwaters and changes in shoreline features have frequently been recorded by means of the radio controlled model plane. From the sequential aerial photographs, we can see the development of the tombolos and the refracting wave patterns due to the breakwaters.

Fig.18 Aerial view of the Nos. 1 and 2 breakwater and tombolos by means of a radio controlled model plane.

1) July 27 '72
No.2 breakwater is under the construction.

Small tombolo appears.

- 4) Sept. 29 '72
The tombolo grows larger
gradually.

- 5) March 9 '73
Strong waves attack the
breakwaters and tombolos.

6) April 25 '73
The tombolos are stable.

CHANGES OF SEA BED DUE TO DETACHED BREAKWATERS

In order to investigate the changes of sea bed, the survey of beach profile on each section have been made since 1958. Before the construction of the breakwaters, there were considerable changes in the sea bed configuration. However, since the construction, the changes of the sea bed have become very little.

Figure 19 are a typical example of survey results for the section No.8 which is located at the center of the Kaike Spa. There had been severe erosion on the sea bed between March 1963 and August 1963, and it had continued. After the construction of the detached breakwater (No.2), large amount of sand deposition have accumulated on the shore.

Fig.19 Changes of sea bed on the section No.8.

Fig.20 Annual changes of shoreline and sea bed on the section No.8.

Figure 20 shows the annual changes of the sea bed on the same profile line No.8. In this figure, (S) represents the horizontal distance of shoreline from the seawall, and (A), (B) and (C) the water depth from the still sea water level at the points of 100, 200 and 300 meters distant from the seawall. The No.2 breakwater was constructed on the profile line No.8 in August 1972, and it was very effective for depositing sand. After its construction, the sea bed at the point (A) indicated a remarkable shoaling, and the shoreline (S) greatly advanced.

Above-mentioned severe erosion are also expressed in this figure, and the point (B) indicates remarkable change of sea bed three times during the period from 1962 to 1965.

Similar changes of sea bed occurred at the same time within the nearby area. Figure 21 also shows the annual changes of sea bed at the points of 200 meters distant from the seawall (like point (B)) on each profile line. We can see remarkable erosion of sea bed in 1963 on the profile lines No.6 to No.12. On the other hand, there were violent rise of sea bed on the profile lines No.2 and 4 in 1966, and we cannot find out significant changes of sea bed in 1963 on these profile lines such as the profile line No.8.

There are furthermore noticeable facts in this figure that, every sea bed have been going to rise since 1971, after the first detached breakwater was built, in spite of those offshoreward situation.

Fig.21 Annual changes of sea bed at the points of 200 meters distant from the seawall on each profile line.

The survey of sea bed, that is sounding, have been made within the limits of about 600 meters offshoreward from the seawall. After the construction of the detached breakwaters, a lot of sand were transported from offshore zone to the nearby area of the detached breakwaters not only onshore side but also offshore side of the breakwaters. However, we cannot find out the eroded zone as the source of the sand supplied to the onshore zone.

Table 1 Volumetric changes in the sea bed after the construction of the detached breakwaters at the Kaike Coast.

Unit : cubic meters			
Number of breakwater	Onshore side of breakwater	Offshore side of breakwater	Total volume
No.4 break-water zone	+ 41,260	+ 61,845	+ 103,105
No.2 break-water zone	+ 39,790	+ 99,770	+ 139,560
No.1 break-water zone	+ 35,835	+ 101,575	+ 137,410
No.3 break-water zone	+ 1,200	+ 45,265	+ 46,465
Total	+ 118,085	+ 308,455	+ 426,540

Table 1 shows volumetric changes in the beach profiles calculated from the survey results during the period from September 1971, before the construction, to March 1975, after the construction of the fourth breakwater. It is noticed from this table that a considerable volume of sand has been deposited on the sea bed in the onshore and offshore zones of the breakwaters since the construction scheme of detached breakwaters commenced. And now, the Kaike coast has gained a stable sea bed by virtue of this detached breakwater system.

CONCLUSION

The detached breakwater system at the Kaike coast is one of the symbolical work in the countermeasure against the beach erosion in Japan. It is very effective in the shoreline protection, however, some problems involved this system still remain to be solved. The most important problem is subsidence of the breakwaters. Up to now, the subsidence of the breakwaters on the Kaike coast is considered to be moderate, but it is urgently needed to develop methods by which the speed of subsidence can be minimized.

Hereupon, our efforts must be continued without a break, so that the re-created beach may not be lost again.

Coastal Engineering, Vol.II pp. 1419 - 1431, 1975.

CHAPTER 93

LOCAL SCOUR AND CURRENT AROUND A POROUS BREAKWATER

By

Shintaro Hotta* and Nobuo Marui**

ABSTRACT

Scour at the foot of vertical homogeneous crib style walls which were used as models for detached breakwaters, and the rise of mean water level in the shoreside region of the breakwaters were experimentally investigated, and the experimental results were compared to some field data.

Introduction

Scour around coastal structures has been studied by many researchers. For examples, the scour at the foot of or in front of solid sea walls have been of special interest to many coastal engineers and researchers, and a quite good number of papers concerning it have already been presented. [Sawaragi and Kawasaki(1960), Sato, Tanaka and Irie(1969), Herbick, Murphy and Van Weels(1965), Herbick and Ko(1968) and many others] The scour around breakwaters due to construction of harbors at sandy coasts were investigated by Sato(1972), Sato, Tanaka and Irie(1969) and Wada, Nishimura and Nirei(1970). The scour around the pier structures in the surf zone was observed by Hotta, Uda and Sasaki(1976).

Recently, the construction of permeable detached breakwater systems of concrete blocks has become widely practiced as a counter-measure against beach erosion. Most of these breakwaters function effectively. It is, however, reported that some of them exhibit unexpected defect in their construction. Many factors are related to the construction of the breakwaters and interact with one another in complicated ways. Of these, the local scour and wave-induced currents around the breakwaters are especially considered to be very important in successful construction of the breakwaters. In relation to these problems, the scour at openings of detached breakwaters systems was studied by Toyoshima(1972) and Kawaguch and Sugie(1972), and a series of excellent

field works on the scour at foot of the breakwaters have been carried out by the First Port Construction Bureau, The Ministry of Transport, at Nigata Coast where continuous detached breakwaters of concrete blocks about 5 km in length are situated 150m offshore. [Katayama, Irie and Kawakami(1973)] However, the problems of these breakwaters are still not fully understood, and thus, the problems still remain unsolved.

The purpose of this study is an attempt to clarify the characteristics of the local scour and wave-induced currents, and the interactions between them around permeable detached breakwaters by laboratory experiments. A difficulty in experimental study is the similarity problems between the laboratory and the field. As a means of solving this problem, some researchers have used light specific gravity bed materials in their experiments. Horikawa and Sasaki(1970) reported in their experiments concerning a study of artificial nourishment of beaches that the Mesalite, which is a kind of light-weight concrete aggregate with a specific gravity of 1.65, was a good movable bed material. Due to Horikawa and Sasaki(1970)'s results, fine Mesalite was used in these experiments as a bed material.

Detached breakwaters usually have a trapezoid cross section. To simplify the scouring phenomenon, however, vertical homogeneous crib style walls were used as the model of the breakwaters in these experiments. Details about the model breakwaters will be described in succeeding section.

Experimental Facilities and Procedure

Experimental Facilities

Experiments were carried out in a rectangular glass walled wave tank 0.8 m deep, 0.5 m wide and 27 m long. At one end, the tank is equipped with a piston type wave generator. The wave height can be changed by varying the stroke of the piston arm, and the wave period can be changed by adjusting the rotation of a rotary disk. At the other end of the tank model beaches were moulded with a compound slope, 1/10 and 1/40.

Measurements and Observations

Wave heights were measured by hook point gauges, electric platinum wire resistance wave meter and 16 mm memo-motion cameras. The former two of these were used in the offshore zone. To take the mean water level and the envelopes of wave crest and trough, beach and wave profiles were photographed by a 35 mm camera and 16 mm memo-motion cameras each measurement time. The scouring depths and beach profiles were measured by a point gauge which ran along fixed rails on the wave tank and which was able to measure the water depth by moving up and down a rod with constant speed automatically. Manometers were used as another way to measure the mean water levels, and their results were compared with the results gained from the 16 mm cameras.

Bed Materials and Model Beaches

Two bed materials were used in these experiments. One was the Mesalite mentioned above and the other was a fine natural sand, specific gravity, 2.65. These were used to discover how the scouring patterns and beach changes differ with different bed materials. Grain size distribution curves of the two bed materials are shown Figure 1. As an initial beach slope, a compound slope with 1/10 and 1/40 was used. This initial slope was chosen to produce a wide surf zone similar to these of natural beaches in rough sea conditions within the limited wave tank length.

Figure 1 Grain size distribution curves.

Model Breakwaters

It would seem that scouring patterns and beach changes would be affected by the hydraulic properties of the breakwaters. From this reason, four kinds of vertical homogeneous crib style walls were experimentally investigated. Two thicknesses of model breakwaters and three kinds of filler were used. The characteristics of the model breakwaters are shown in Table 1.

Table 1

symbol of the walls	thickness of the walls	filler materials
W_1	2 cm	gravel 5-8 mm
W_2	2 cm	gravel 10-13 mm
W_3	2 cm	glass ball 18 mm
W_4	5 cm	glass ball 18 mm

Experimental Conditions

Only one type of wave was used in this experiment. The wave characteristics were as follows;

wave period, T , = 1.1 second
deep water wave height, H_o , = 10.8 cm
wave steepness, H_o/L_o , = 0.057

The deep water wave height was calculated from the shallow water wave height which was decided by means of Hely's method from wave data taken at constant water depth of the tank, 0.45 meters.

Experimental Procedure

After moulding the model beaches carefully, the walls were installed. First at 50, 100, 130 and the at 250 cm from the shoreline. After a wall was installed, the waves were started. At the time of each measurement, the waves were first observed, then the wave generator was stopped, and the scouring depths and beach profiles were measured by using the point gauge. A first series of experiments was finished, the Mesalite bed was removed, and it was replaced by the fine natural sand for the next set of experiments. Each test was run until wave number t/T , was over 70,000, where t was experimental duration. This number was decided on the basis of the following consideration; that is, we assumed that if storm wave periods would be within from 6 to 8 seconds, and storms would not continue over three day, the number of waves which would attack the breakwaters during a single storm would be roughly about 70,000.

Experimental Results and Discussion

Relationship between local scour and beach change (sea bottom topography change)

One difficulty in the study of local scours is that both beach change and local scour exist together. That is, the local scour is superimposed on the bottom topography, and their changes are complicatedly interacted. Figure 2 shows an example of the local scour around a pier structure surveyed by the Authors, and P shows positions of piers. In this case, we can easily recognize that local scour is superimposed on the natural beach profile, and that the pier will not influence major changes in the beach profile because it is understood that the disturbance of wave motion around pier is small. It is, however, not hard to imagine that the existence of a system of detached breakwaters on beaches will greatly influence wave motion, and it is difficult to predict the beach changes accompanying the change of the wave motions at the present time. In fact, this prediction is an important problem with which we are confronted right now and which must be solved. As of right now, the correlationship between local scour and beach change from this study has not become clear.

Figure 2 An example of local scour around pier structure.

Scouring Process

The authors defined the scouring depth at the foot of the walls as the vertical distance from the sand surface of the initial slope to the scoured bottom. Figure 3 shows the processes of scouring depth. According to Sawaragi and Kawasaki(1960) the scouring process at the foot of vertical solid walls could be classified as 4 types depending on the position in which wall was situated. Sato, Tanaka and Irie (1969) classified it as 5 types. However, in the case of permeable vertical walls, it is hard to find a tendency by which the scouring process can be classified according to the differences in the positions of the walls, bed materials or hydraulic properties of the walls.

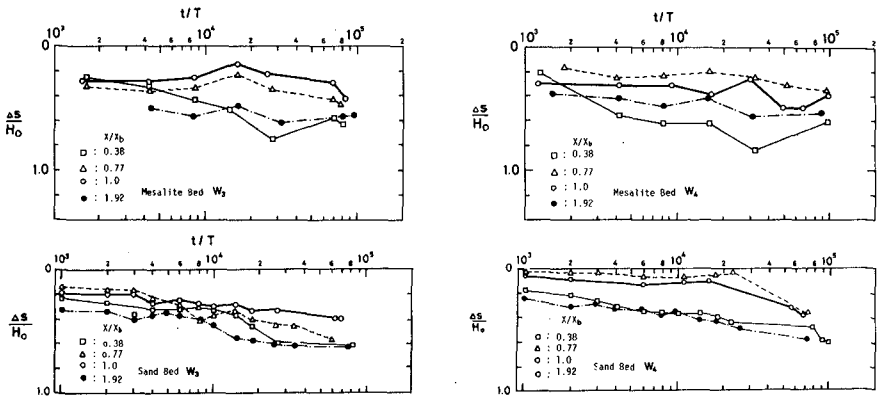

Figure 3 Scouring process.

Figure 3 Scouring process.

Change of Beach Profile

Figure 4 shows examples of final beach profiles and the ratios between wave heights with walls to wave heights with no wall at each point, X . From this figure, the following are pointed out;

(1) Influence of bed material appears on the final beach profile when no wall are used, that is, the retreat of shoreline of a Mesalite bed is much larger than that of the sand bed. When a wall is used the retreat of the shoreline is small. However this retreat does not necessarily mean that the beach in the shoreside of wall is being eroded. The retreat makes the swash zone steeper, and a swash bar is formed. After that the shoreline retains its stability. Walls exhibit a sufficiently effective function.

(2) On the offshore side of walls, waves become much larger than when no wall was used and become partial standing waves, and the loops and nodes of

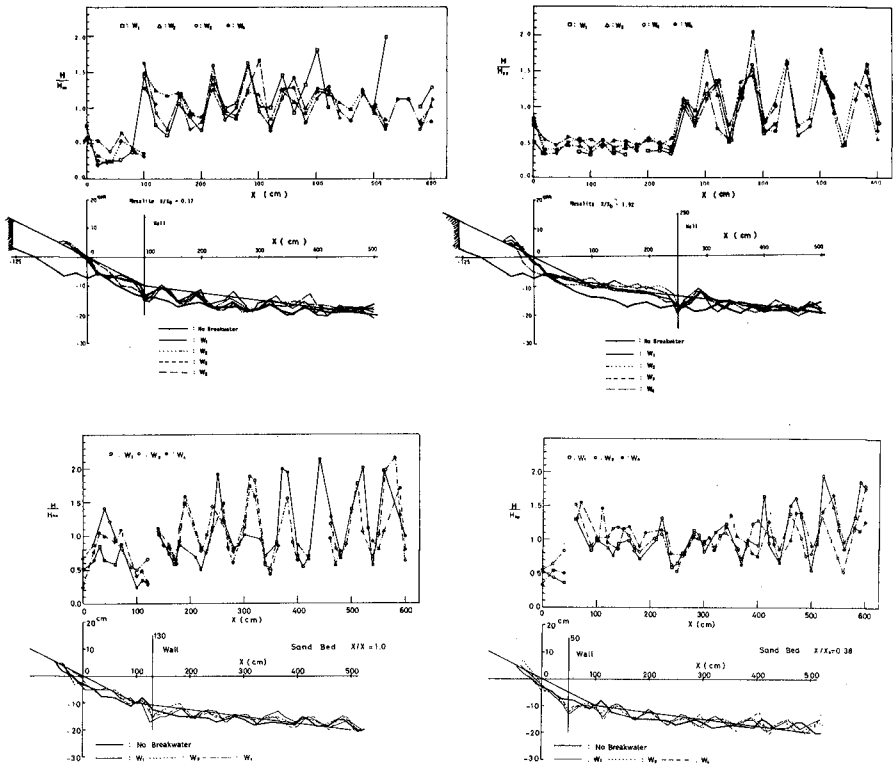

Figure 4 Beach profiles and ratios between wave height with walls to wave height no wall.

the standing waves closely correspond to the troughs and crests on the beach profile. This result agrees with that on scour in front of solid seawalls obtained by Herbich and Ko(1968).

The configuration of beach profiles in front of walls suggests that large sea bottom changes on natural beaches will occur in front of detached breakwaters.

The Maximum Scouring Depth

In Figure 5, the ratios of scouring depths to deep water wave height, $\Delta S/H_o$, are plotted against the relative positions of the walls, X/X_b , where X is the distance from the shoreline to the positions at which the walls are situated, and X_b is the distance from the shoreline to break-point. As seen from Figure 5, the scouring depths are largest at $X/X_b = 0.38$ and are small in the neighborhood of the break-point regardless of the bed materials and hydraulic properties of walls. It is not clear why the scouring depths are the largest at $X/X_b = 0.38$. However, it may depend on beach change. As seen in Figure 6 and Figure 4, the initial beach slope of this position, $X/X_b = 0.38$, was steeper, and the bed material moved largely offshore. That is, one may say that the local scour overlapped on the lowering of initial slope due to beach change. Might the local scour be $\Delta S'$ in Figure 6? In any cases, the scouring depth is not greater than the order of the deep water wave height.

Figure 5 The maximum scouring depth.

Figure 6 Examples of beach profile at $X/X_b = 0.38$

Figure 7 shows the relationship between $\Delta S/H_0$ and X/X_b in the case of solid walls. In this case, the maximum scouring occurs when the walls are situated at the break-point or a little inside the break-point. On this point, there is a remarkable difference between solid and porous walls. Conversely, the fact that maximum scouring depth is not greater than the deep water wave height under stormy conditions is the same for each.

Figure 8 shows scouring depths with $\Delta S/h$ instead of $\Delta S/H_0$. An advantage of this expression is that one can see the percent of scouring depths for the water depth in relation to the positions of the walls. From this Figure 8, $\Delta S/h$ is not greater than 0.6 without $X/X_b = 0.38$. A maximum of about 2 m scouring depths was observed at Nigata Coast where detached breakwaters were situated in water depth of 3 m about 150 m offshore. [Katayama, Irie and Kawakami (1973)] In this case, the ratio of $\Delta S/h$ was about 0.66. This figure almost agrees with the results gained in our experiments.

Figure 7 The maximum scouring depth of solid seawalls.

Figure 8 The ratios between the maximum scouring depth to the water depth.

Transmitted Wave heights

Figure 9 shows the ratio between the wave height transmitted to the inside region of walls and the deep water wave height. As seen in the Figure 9, the ratio depends on the size and shape of the filler materials and the width of the wall. The larger the size of the filler, the larger H_t/H_0 becomes. The greater the width of the wall, the smaller H_t/H_0 becomes. H_t/H_0 is smallest at $X/X_b = 0.77$ regardless of the hydraulic properties of the model breakwaters. In the same Figure, the field data observed by The First Port Construction Bureau at Nigata Coast are also plotted. In this plot, X/X_b is decided as follows: That is, because the position of the breakwaters is fixed X is constant ($X = 150$ m). The wave heights observed offshore at 10 m water depth were taken as the deep water wave height, H_0 . Using Goda's Breaking Index [Shore Protection Manual, U.S. Army, Coastal Engineering Research Center, pp 2-121] and assuming $K_f = K_r = K_d = 1$, the water depths of the break-point were read from the Figure. Then X_b were read from the sounding map.

Field data show similar tendencies to those of the experiments.

Figure 9 Transmission coefficient.

Rise of the Mean Water Level inside the Wall

A rising of the mean water level was observed in the shoreside region of the breakwaters. On the contrary, a lowering of the mean water level was observed in the offshore region of the breakwater. This rising and lowering has a great influence on the current around the breakwaters. Figure 10 shows a dimensionless plot of η/H_o and X/X_b . It seems that the rising of the mean water level depends on the position and hydraulic properties of the model breakwaters, but these influence are not clear within this experimental works. The magnitude of the rising of the mean water level is about 5 - 10 % of the deep water wave height. Field data [Katayama, Irie and Kawakame(1973)] are also plotted in the Figure 10. X/X_b in Figure 10 is decided in the same way as that described the previous section. The results of the field data are a little larger than those of the experiments. From Figure 10, it seems that the rise of mean water level in the shoreside of the wall is not beyond 10 % of the deep water wave height. The lowering of the mean water level in the offshore region from the wall fluctuated according to nodes and loops of the partial standing waves.

Figure 10 Rise of mean water level inside of walls.

The rising of the mean water level was analyzed. Authors assumed the wave to be shown in Figure 11. In equilibrium condition, if the Forchheimer's formula is assumed, the four equations in Figure 11 are given. From these equations, finally, the rise of mean water level, η , is approximatedly given by a equation 1. In this equation, a problem is to give μ and K (coefficient of permeability). It seems that the equation 1 will predict the rise mean water level in shoreside of the breakwaters, but it remains in discussion.

*** DEFINITION ***

(1) WHEN THE CREST OF WAVE COME IN TOUCH WITH THE WALL

$$q_1 = \frac{K}{2l} \{ (h + \mu H)^2 - (h + \eta_1)^2 \} \dots\dots (1)$$

$$\frac{dq_1}{dt} = \frac{q_1}{A}$$

$$= \frac{K}{2lA} (2h + \mu H + \eta_1)(\mu H - \eta_1) \dots\dots (2)$$

$$\therefore \frac{d\eta_1}{(2h + \mu H + \eta_1)(\mu H - \eta_1)} = \frac{K}{2lA} dt$$

(2) WHEN THE TROUGH COME IN TOUCH WITH THE WALL

$$q_2 = \frac{K}{2l} \{ (h + \eta_2)^2 - \{ h - (1-\mu)H \}^2 \} \dots\dots (1)$$

$$- \frac{dq_2}{dt} = \frac{q_2}{A}$$

$$= \frac{K}{2lA} \{ 2h - (1-\mu)H + \eta_2 \} \{ \eta_2 + (1-\mu)H \} \dots\dots (2)$$

$$\therefore \frac{d\eta_2}{\{ 2h - (1-\mu)H + \eta_2 \} \{ \eta_2 + (1-\mu)H \}} = - \frac{K}{2lA} dt$$

$$\boxed{ \eta = \frac{H^2}{h} \mu(1-\mu) - \frac{Kl\mu H}{lA} \mu(1-\mu)^2 \left(1 + \mu \frac{H}{h} \right) \dots\dots\dots }]$$

CHAPTER 94

PREDICTION OF WAVE-INDUCED SEAFLOOR MOVEMENTS

by

Leland Milo Kraft, Jr.¹, M. ASCE and David James Watkins², A.M. ASCE

ABSTRACT

Foundation design for offshore structures in areas where wave-induced bottom pressures cause submarine mud slides requires a knowledge of the potential depth of slide and of the magnitude and distribution of soil movements below the slide. Several methods have been developed to evaluate the stability of the seafloor due to wave-induced bottom pressures. These methods are reviewed and an improved procedure is presented. This procedure makes use of finite element analysis and combines in a rational manner oceanographic information on wave statistics with stress-strain behavior of soils under cyclic load conditions in order to evaluate the effects of a given storm history on the behavior of submarine sediments.

INTRODUCTION

Storm-generated surface waves can cause cyclic variations of pressure on the seafloor that trigger large scale soil movements manifested by massive soil failures to penetrations as deep as about 100 ft (30 m) below seafloors with slopes of one degree or less. Seafloor sediments most susceptible to these bottom pressure induced movements are the very soft to soft, underconsolidated clays found at the mouths of many major river systems, such as the Mississippi, Amazon, Niger, Ganges-Brahmaputra and Mekong, where active deltaic development results in a rate of sediment accumulation that exceeds the rate of pore pressure dissipation by consolidation. Fig. 1 illustrates that many of these deltaic regions are the site of major activity related to the installation and operation of offshore oil and gas production platforms and pipelines.

FIG. 1-MAJOR PETROLEUM ACTIVITY ON THE CONTINENTAL SHELVES

1 Manager, Special Projects Group, McClelland Engineers, Inc., Houston, Texas

2 Project Engineer, McClelland Engineers, Inc., Houston, Texas

When the seafloor is unstable the moving soil mass exerts lateral forces on offshore structures that can exceed the combined wind, wave and current force. Fig. 2 illustrates the soil loading mechanism. This paper outlines procedures currently used to assess the depth of the failure zone and the magnitude and distribution of accumulated soil movements produced by a given storm history. The application of these results to analyses of soil-structure interaction, which is required for reliable and economic structural design of foundations in these sediments, is beyond the scope of this paper.

FIG. 2—LOADS DUE TO STORM WAVE AND SUBMARINE SLIDE

HISTORICAL DEVELOPMENT

Fig. 3 shows the failure of a 30-in. (76 cm) diameter flare pile that occurred during Hurricane Carla in 1961. This failure was an early demonstration of the potential depths of soil failure and the magnitude of lateral soil movement that may occur in very soft deltaic sediments. In August 1969, Hurricane Camille demonstrated convincingly the devastating impact of a submarine slide on offshore platforms. In about 300 ft (90 m) of water in South Pass Block 70 one platform was overturned and displaced about 100 ft downslope, and significant lateral soil movements occurred to at least 80 ft (24 m) below the seafloor (20). A second platform was displaced about 3 ft (1 m) downslope without overturning, and a third platform was destroyed in nearby South Pass 61.

These failures stimulated extensive and continuing programs to study submarine slides caused by storm-induced bottom pressure perturbations. The current state-of-the-art has evolved through many studies with contributions from and support by governmental agencies, academia, the petroleum industry and geotechnical consultants. To set the stage for the current state-of-the-art, the significant developments and results of earlier studies are highlighted.

FIG. 3—FLARE PILE FAILURE CAUSED BY SEAFLOOR SLIDE (After McClelland and Cox, 1976)

Limit Equilibrium Analysis

One of the earliest published contributions that demonstrated the significance of storm-induced bottom pressures on submarine slope stability was presented by Henkel(7), who used a limit equilibrium method with an assumed circular failure surface. This concept, which is illustrated in Fig. 4, has been extended in practice to other shapes of potential failure surfaces and is used to estimate the depth of submarine slides, defined by the location of the deepest potential failure surface having a safety factor of one. Fig. 5, which shows the results of a limit equilibrium stability analysis for a location in the Mississippi Delta, illustrates that the potential failure surface with the minimum safety factor may underestimate the depth of the potential slide.

FIG. 4-LIMIT EQUILIBRIUM ANALYSIS FOR WAVE INDUCED SUBMARINE SLIDES

FIG. 5-RESULTS OF TYPICAL LIMIT EQUILIBRIUM ANALYSIS

The depth of slide zone is affected by the shear strength and unit weight profiles of the soil, and the amplitude and wave length of the bottom pressures. The interdependence between the influence of the amplitude and wave length of the bottom pressure anomaly on the stability of seafloor slopes for a very underconsolidated soil mass is illustrated in Fig. 6. Greater bottom pressures associated with longer wave lengths tend to cause deeper slides. If the design wave spectrum is known, analysis using combinations of wave lengths and amplitudes are made to determine the combination of wave data yielding the maximum depth of slide.

Limit equilibrium analyses, however, do impose certain approximations that challenge the accuracy of the depth of slide predicted with this procedure. Limit equilibrium analyses treat the soil as a rigid-plastic material and do not account for either soil softening and strength loss produced by a large number of successive waves or for dynamic effects. Nevertheless, limit equilibrium analyses are useful during preliminary studies to assess the likelihood of submarine slides for a given oceanographic and geotechnical environmental setting. Results of limit equilibrium analyses, however, do not provide estimates of the magnitude and distribution of soil movements.

Shear stresses computed using the theory of elasticity with a sinusoidal loading have also been used to evaluate stability. In this case the computed profile of maximum shear stress is compared to the shear strength profile.

Model Studies

To gain further insight into the stability and deformational patterns of seafloor soils subject to wave-induced bottom pressures and to evaluate the applicability of limit equilibrium approaches, model studies have been performed using wave tanks(4,7,15,19,22). Results of these model tests have demonstrated the validity of the failure mechanism and have shown that the vertical component of the movement decays more rapidly with depth than the horizontal component, but there is a net lateral translation downslope. Below the failure zone the net downslope movement decreases to about zero where the soil experiences nearly elastic behavior.

Results of these model studies demonstrated also that the yielding and movements of the seafloor soils can influence the development of bottom pressure amplitudes, which are usually computed from oceanographic data using linear wave theory that assumes a rigid seafloor. Doyle(4) found the bottom pressures on the soils in the wave tank were about 0.27 of those

FIG. 6-DEPTH OF FAILURE ZONE FOR ANOMALIES OF VARYING AMPLITUDE AND LENGTH

computed for a rigid bottom. Gade(6) discusses the importance of soil yielding on the interaction between the water and soil. Due to the complex interaction between wave length, water depth and soil properties, the bottom pressure amplitude computed for a rigid bottom may not always exceed the value experienced on a yielding bottom. Since the magnitude and distribution of soil movements are strongly influenced by the amplitude and wave length of the bottom pressure, more attention is required, as will be discussed subsequently, on the interaction between the water and soil.

The qualitative results obtained from the wave-tank studies provided insight into a complex phenomenon and served to confirm general findings from analytic techniques in view of the limited field data available.

Finite Element Analysis: First Generation

At the time some of the wave-tank studies were being made the finite element analysis was being applied to the problem, and laboratory studies were initiated to develop stress-strain data for soft soils subjected to cyclic loads having periods coincident with storm loads. Wright and Dunham (25) first applied a finite element method with a nonlinear stress-strain response for the soils to evaluate seafloor response to wave-induced pressures. Since this model does not include the effects produced by gravity loads, the lateral boundaries are located one-quarter wave length apart for reasons of symmetry and antisymmetry, as shown in Fig. 7. In this case, displacements are allowed parallel to but not normal to the boundary under the crest, and below the null point displacements are allowed normal to but not parallel to the boundary. The lower boundary of the mesh is located at a penetration where soil movements are negligible so that restricting soil movements at this penetration in the model provides a reasonable approximation to in situ conditions. The distribution and size of the elements are selected to be compatible with soil property variations and the wave length and to provide reasonable numerical accuracy.

FIG. 7-QUARTER WAVE LENGTH FINITE ELEMENT MESH

The nonlinear and inelastic behavior typified by the undrained behavior of cohesive soils were incorporated into the finite element model using an interactive-incremental procedure(5,25) and a hyperbolic approximation(8) of the soil stress-strain response for loading conditions:

$$\sigma_1 - \sigma_3 = \frac{\epsilon}{\frac{1}{E_i} + \frac{R_f \epsilon}{2 S_u}} \quad , \quad \epsilon \leq \epsilon_f$$

$$\sigma_1 - \sigma_3 = 2 S_u \quad , \quad \epsilon \geq \epsilon_f \quad \dots \dots \dots (1)$$

where $\sigma_1 - \sigma_3$ = deviator stress; ϵ = axial strain; E_i = "elastic" tangent modulus at $\epsilon = 0$; S_u = undrained shear strength; and R_f = failure ratio, influence of the failure strain ϵ_f . The comparison in Fig. 8 between

Eq. 1 and laboratory measured stress-strain response of a Gulf of Mexico clay shows remarkable agreement. For unloading conditions, a decrease in maximum shear stress, the soil modulus value, E_{ur} , is approximately constant with a value that generally equals or exceeds E_i . The parameters associated with Eq. 1 were based on stress-strain data obtained from isotropically consolidated data.

Even though in situ gravity stresses were unaccounted for in these early finite element analyses, it was recognized that with vertical displacement of the seafloor mass under the action of a bottom pressure anomaly the gravity forces would tend to retard the tendency for instability, especially in very soft sediments where larger vertical displacements may occur. The counter pressure due to the buoyant weight of the elevated soil is illustrated in Fig. 9. Wright and Dunham(25) describe an approximate procedure for adjusting displacements to account for the counter buoyant effect. Arnold(1) and Bea and Arnold(2) used the finite element method to evaluate soil movements at a site in South Pass Block 70. Fig. 10 shows some results of their analyses to give perspective to the magnitude and distribution of computed movements due to wave-induced bottom pressures.

FIG. 8—COMPARISON BETWEEN MEASURED AND THEORETICAL STRESS-STRAIN RESPONSE

FIG. 9—COUNTER BUOYANT EFFECT DUE TO LARGE SEAFLOOR MOVEMENTS

Finite Element Analysis: Second Generation

Although results from the first generation finite element studies provided reasonable assessments of the distribution of stresses and displacements in a soil mass subjected to bottom pressure anomalies, the previously reported finite element analyses did not accurately account for either alterations in the soil properties due to the storm history or for gravity

stresses on the predicted soil movements. These factors were addressed, but only accounted for in a very approximate way. In addition, the interaction between the soil and water on the development of bottom pressures was neglected. Recently, Wright(24) described a procedure, based on a finite element analysis that includes initial gravity and geologic stresses, for predicting stress distribution and soil movements.

In situ shear stresses due to gravity and geologic stresses influence the seafloor response to wave-induced bottom pressures in three ways. The magnitude of soil stiffness is influenced by the shear stress in the soil due to its non-linear stress-strain behavior, and the increment of additional shear stress that the soil can sustain due to wave-induced loading may be reduced as the initial in situ shear stresses increase. Furthermore, when the gravity and geologic stresses are included, the stiffness moduli in the slope are usually not symmetrical about any parallel lines oblique to the slope. This lack of symmetry exists also when the wave-induced stresses are superposed. For an infinite train of uniform waves and negligible changes in soil properties with each wave cycle, the displacement patterns on lateral boundaries oriented perpendicular to the slope and separated by one wave length should be identical. Therefore, results of finite element analyses are based on equal displacements at corresponding penetrations on the two boundaries. An example finite element mesh for one wave length is shown in Fig. 11 together with the boundary conditions normally used.

FIG. 11-FINITE ELEMENT MESH - ONE WAVE LENGTH

The seafloor may often be approximated as an infinite slope inclined at an angle i , as illustrated in Fig. 12. In an underconsolidated soil mass, excess hydrostatic pore pressure, u_e , results in a hydraulic force; the resultant hydraulic force being perpendicular to the surface. As shown in Fig. 12, the excess pore pressure, which is required to determine the effective stress state, may be related to the ratio of undrained shear strength of a normally consolidated soil to effective consolidation pressure (referred to as the c/p ratio), the buoyant overburden pressure, and the in situ undrained shear strength of the underconsolidated soil, S_u .

An additional assumption, which is used to compute the complete state of stress in the soil mass, is that the effective normal stresses on some two planes are proportional. For slopes less than a few degrees and for either the principal planes or planes parallel and perpendicular to the slope, the constant of proportionality between normal stresses on these planes may be about equal to the effective coefficient of earth pressure "at rest". These stress conditions are summarized in Fig. 12.

Early finite element results suggested that the magnitude of initial stress can have a significant influence on the computed soil movements. These previous analyses, however, have used stress-strain response measured on isotropically consolidated specimens. The soil in situ experiences anisotropic consolidation, and the stress-strain response of an anisotropically consolidated specimen may differ appreciably from the response of an isotropically consolidated specimen, as illustrated in Fig. 13. The comparison of secant moduli at equal levels of mobilized shear stress, shown in Fig. 13, indicates that larger soil movements may be computed with the smaller secant moduli associated with the isotropically consolidated specimen. Wright(24) attempts to include the effects of both anisotropic consolidation and cyclic loading on the soil

- γ_b : Soil Buoyant Unit Weight
- u_e : Excess Hydrostatic Pore Pressure
 $= \gamma_b z - S_u / (c/p)$
- S_u : In situ Undrained Shear Strength of Underconsolidated Soil
- c/p : Ratio of Undrained Shear Strength of Normally Consolidated Soil to the Effective Consolidation Stress, p

FIG. 12-EFFECTIVE STRESSES IN AN INFINITE SUBMERGED SLOPE

FIG. 13-COMPARISON OF STRESS-STRAIN CURVES

stress-strain response by combining the shear stresses computed from finite element analysis on a plane parallel to the slope with strains obtained from cyclic simple shear tests that simulate the computed stress history.

The second generation finite element procedure for computing wave-induced seafloor movements does not account for:

- (1) the soil stress-strain behavior for an anisotropic-consolidated condition, which is more representative of in situ conditions than the isotropic-consolidated condition;
- (2) the degradation in soil strength and stiffness that occurs due to cyclic stress reversals induced during the passage of a storm; and
- (3) the interaction between the water and soil on the development of the amplitude of wave-induced bottom pressure.

A procedure for overcoming the first two limitations is presented in subsequent paragraphs. A procedure to overcome the third limitation has been developed, but will not be reported here.

CURRENT PROCEDURE

Stress-Strain Model

The finite element model currently used is basically the same as the second generation model with the exception that the stress-strain behavior is described by a hyperbolic expression that accounts for anisotropic consolidation. Results of a recent study by Donaghe and Townsend⁽³⁾ showed that the undrained response of cohesive soils consolidated under a deviatoric stress σ_{dc} could be mathematically described by the modified hyperbolic expression:

$$\sigma_1 - \sigma_3 - \sigma_{dc} = \frac{\epsilon}{\frac{1}{E_i} + \frac{R_f \epsilon}{2S_u - \sigma_{dc}}} \dots \dots \dots (2)$$

Eq. 2 represents soil stress-strain response for a single application of a static load. With the passage of a number of waves the soils may soften and lose strength. This degradation in soil resistance is influenced by the spectrum of bottom pressure anomalies and in general decreases with penetration. The cumulative soil displacements, however, can be estimated using Eq. 2 with appropriately modified parameters, which are determined from the spectrum of bottom pressures, estimates of induced stresses from finite element analysis using unmodified stress-strain parameters, and results from laboratory cyclic testing.

Spectrum of Bottom Pressures

A spectrum of bottom pressure anomalies is developed from deep-water wave statistics and characteristics of the seafloor in the vicinity of the site. A deep-water storm wave record, such as the one in Fig. 14, can be defined by a spectrum, the number of storm waves with various combinations of periods and heights. Depending on the water depth and soils at the site, the shorter period waves

FIG. 14—FOUR MINUTE PORTION OF A TYPICAL STORM WAVE RECORD (After Tricker, 1964)

of smaller heights that do not cause significant bottom pressure amplitudes are not considered in the analysis.

The wave length L at a site with water depth D is computed for each wave period T from linear wave theory(23).

$$\left(\frac{2\pi}{T}\right)^2 = \frac{2\pi g}{L} \tanh\left(\frac{2\pi D}{L}\right) \dots \dots \dots (3)$$

where g is the acceleration of gravity. Analyses, which include the effects of refraction, reflection, shoaling and bottom friction, are then made to determine the changes in heights of storm waves as they prograde from deep water across the continental shelf and over the site. After determining the heights and lengths of waves at the site for each wave period, the bottom pressure amplitude, Δp, produced by this storm-wave spectrum is computed from

$$\Delta p = \gamma_w H/[2 \cosh(2\pi D/L)] \dots \dots \dots (4)$$

As previously mentioned, the yielding of the seafloor with the passage of waves affects the development of wave heights and bottom pressures. Although analyses are not available to fully account for this effect, through a cooperative and interactive effort between the oceanographer and geotechnical consultant, approximate methods are available to evaluate the relative influence of a yielding seafloor on the development of bottom pressure amplitude for a given wave height. These methods are based on a dynamic visco-elastic model(14). The term "yielding" refers to a failure of the soil mass and not simply "elastic" deformations for which analytic methods are available.

A 100-year storm wave spectrum along with its spectrum of wave-induced bottom pressure at a site located in about 200 ft (60 m) of water in the Gulf of Mexico is shown in Table 1. This data demonstrates that the maximum deep-water wave height does not always induce the maximum amplitude of bottom pressure.

Initial Finite Element Analyses

To obtain data for planning a laboratory test program of cyclic loading and to evaluate and interrelate cyclic tests data with finite element analyses for predicting the cumulative soil displacements during a storm, finite element analyses are first performed for a range in amplitudes and wave lengths typical of the expected spectrum on bottom pressure anomalies. Usually results are obtained for 3 to 5 wave length conditions and for 5 to 15 amplitudes. The stress-strain-strength properties of the soils used in these initial analyses are usually based on Remote Vane data(9) and on laboratory data obtained from the SHANSEP concept(10) for a single load cycle preferably applied at a rate representative of the mean period of wave loads. For a given spectrum of bottom pressures, a spectrum of stresses at any location

below the seafloor can be determined from the stress distribution computed with the finite element method.

Fig. 15 illustrates a profile of computed lateral movements and the cyclic variation of shear stress on planes parallel to the slope for one wave length, but different amplitudes of bottom pressure. Fig. 15 also includes the soil properties and initial in situ stress conditions. The variation in stresses experienced by an element of soil during one wave cycle is shown in Fig. 16.

FIG. 15—SOIL PROPERTIES, LATERAL MOVEMENTS AND STRESSES

The depth of soil failure determined from the finite element results for the conditions described in Fig. 15 was approximately 45 ft less than the depth determined from a limit equilibrium analysis. Deviations between the predicted depth of slide from limit equilibrium and finite element results depend on several factors including the strength profile. The predicted depths obtained from the two procedures tend to better agree when the failure occurs in a relatively weaker soil layer at some depth⁽²⁾.

To illustrate the importance of using a stress-strain model representative of anisotropically consolidated conditions, a finite element analysis was made for the conditions shown in Fig. 15, but using stress-strain data representative of isotropically consolidated conditions. The results of this comparison, shown in Fig. 17, demonstrate that stress-strain response in terms of isotropically compared to anisotropically consolidated conditions may result in much larger predicted displacements, but

the differences in stresses computed with both data sets deviated by less than about 30 percent.

Stresses and displacements below the seafloor due to wave-induced bottom pressures can be computed for the other wave lengths in the spectrum, and combining these with the results in Fig. 15, an initial estimate of the soil stress spectrum can be developed. During the progress of a storm the seafloor response to a bottom pressure perturbation depends on the history of cyclic stresses due to previous wave action. The degree of progressive softening and loss of strength affects the stress distribution and the development of soil displacement that may accumulate during the storm. Knowing the spectrum of induced stress, a laboratory testing program is designed to provide modified stress-strain data for incorporation into the finite element analysis to predict cumulative soil displacements with the passage of a storm over a site.

FIG. 16-STRESS VARIATIONS

Modified Stress-Strain Response

A series of cyclic stress pulses can be superposed on the initial consolidation stress in the laboratory to determine the accumulation of strain with each additional stress pulse. Laboratory tests are generally performed by either cycling with a constant stress or by applying a spectrum of stress pulses. Fig. 18 shows data obtained from cyclic tests on a Gulf of Mexico clay.

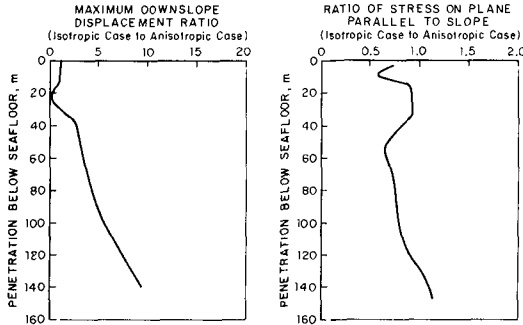

FIG. 17-COMPARISON OF RESULTS FOR ISOTROPICALLY AND ANISOTROPICALLY CONSOLIDATED STRESS-STRAIN DATA

The amount of cumulative strain and reduction in shear strength due to cyclic loading with a constant stress is shown in Fig. 19. If an element of soil experiences an equivalent of 10 stress cycles, the

FIG. 18-CYCLIC LOADING TEST RESULTS

stress-strain curve marked $N = 10$ provides a realistic estimate of the expected cumulative displacement. Studies by Lee and Focht⁽¹²⁾ and Norwegian Geotechnical Institute^(17,18) summarize the current experience of cyclic load test data for cohesive soils. The stress-strain response of soil subjected to cyclic loading is a function of the initial stress condition about which the cyclic stress oscillates. Preliminary research results⁽¹⁸⁾ demonstrate that cyclic test data obtained for equal magnitudes of cyclic stress about different initial stresses can be equated if the results are interpreted with a normalized stress R ,

$$R = \frac{\tau_c}{S_u} \left[\frac{1}{1 - (\tau_i/S_u)^4} \right] \dots (5)$$

where τ_c = cyclic maximum shear stress; τ_i = mean maximum shear stress; and S_u = static undrained shear strength.

The degradation to soil stress-strain-strength properties induced by a series of N cycles of variable stresses can usually be equated to an equivalent number of cycles, N_{eq} , of some reference stress τ_{ref} . Combining this premise with laboratory cyclic test data and the profile of stress spectra, modified stress-strain-strength data can be generated for use with the finite element analysis to determine the accumulation of soil movements due to a spectrum of bottom pressures. The procedure used

FIG. 19-STRESS-STRAIN RELATIONSHIPS AFTER CYCLIC LOADING

to determine the appropriate modified stress-strain responses to predict these cumulative displacements, representative of the complete storm or some fraction of its history, is explained for a given penetration. The process is repeated to determine the degree of degradation for other penetrations.

For the purpose of analysis, it is necessary to find a cyclic stress of uniform amplitude that has the same effects as the random stress history due to the storm loading. Lee and Focht(11) have presented a method for determining this equivalency, which is based on Miner's damage potential concept(16) developed for the study of metal fatigue. The essential elements of the method are presented in Fig. 20. As shown schematically in Fig. 20(a), the cyclic stress history, which was estimated from initial finite element analysis, contains

N_i cycles of amplitude S_i . The number of cycles of stress of this amplitude, N_{if} , required to produce some predetermined strain, ϵ_p , is determined from the results of laboratory cyclic loading tests as shown in Fig. 20(c). If superposition is assumed then the same strain, ϵ_p , is produced by N_e cycles of stress with amplitude S_e . Thus, N_{if} cycles of stress of amplitude S_i are equivalent to N_e cycles of amplitude S_e . Therefore, N_i cycles of amplitude S_i are equivalent to $(N_i \cdot N_e) / N_{if}$ cycles of amplitude S_e . This procedure is repeated for every cycle in the irregular stress history to yield the number of uniform cycles of stress, N_{eq} , of amplitude S_e that produce the same accumulated strain as the irregular stress history. The equivalency is expressed by:

FIG. 20-CONVERSION OF IRREGULAR STRESS HISTORY TO EQUIVALENT UNIFORM STRESS HISTORY

$$N_{eq} = \sum (N_i / N_{if}) N_e \dots \dots \dots (6)$$

Theoretically the amplitude S_e of the uniform stress history equivalent to the random stress history may be selected arbitrarily. Changing S_e leads to a change in N_{eq} in Eq. 6, but any combination of N_{eq} and S_e is equivalent to any other. Each defines the number of uniform cycles required to produce a specified accumulation of strain. However, a program of laboratory tests to confirm the validity of the procedure for a given soil is recommended.

Reference Anomaly

When computing the equivalency, it is convenient to convert the irregular stress history into an equivalent number of cycles of stress corresponding to the stress induced by the "most severe" anomaly present in the spectrum being analyzed because analysis of the effects of this anomaly are used for the basic studies of seafloor response. The term "most severe" refers to the anomaly that induces the largest stresses and displacements in the seafloor. The anomaly of greatest amplitude is not necessarily the "most severe", nor does the anomaly of maximum amplitude

necessarily coincide with the surface wave of maximum height. The "most severe" anomalies are usually those of long wave length and large amplitude. The anomaly used to compute the equivalency is called the "reference" anomaly. Because the anomaly-induced stresses are a function of penetration below the seafloor, the equivalency number, N_{eq} , also varies with penetration.

Fig. 21 shows the profile of N_{eq} values representative of the conditions shown in Fig. 15 for the wave spectrum in Table 1. Fig. 21 also shows a comparison of profiles of downslope movement computed with the appropriate stress-strain curves shown in Fig. 19 for the N_{eq} profile and with the unmodified stress-strain curves. Above approximately 135-ft penetration the downslope movements accumulating with the passage of the storm exceeds the movement due to one application of a larger wave with unmodified soil properties. Below about 135-ft penetration the reverse is true. As the storm develops, the reduction in strength and softening in the upper material prevents transmission of the greater stresses due to larger waves, which generally occur near the middle of the storm.

If sufficient degradation of the soil occurs the material in the failure zone acts essentially as a fluid-like mass. Once this occurs additional accumulation of displacements below the failure zone are very small. When displacement analyses are conducted to assess the forces that must be sustained by structures founded in the seafloor, it is necessary to determine at what stage of the storm the combined effects of progressive softening and changes in the magnitude and distribution of soil movements result in maximum structural loading.

CONCLUDING COMMENT

The depth of submarine slides and profiles of soil movements, such as those illustrated in Fig. 15 and 21, are important input for analyses of soil-structure interaction and for the design of foundations at sites susceptible to submarine slides. Evaluation of the soil movement problem and the effect of soil movements on offshore platform design requires an interaction between the oceanographer, marine geologist, geotechnical engineer, and structural engineer. The scope of this paper has been limited to only oceanography and geotechnical considerations required to estimate soil movements.

The state-of-the-art for prediction of soil movements due to wave-induced bottom pressures has improved significantly during the past eight years. The procedures presented here were based on a static analysis, even though the wave-induced bottom pressures are dynamic loads. Although static analyses are often appropriate for the 10 to 15-second period loads, prediction of soil response in the failure zone and the transfer of stresses into the unfailed soils would be better modelled with a dynamic analysis. More work, however, is required to better define the behavior of soils in post-failure conditions before further improvements in the state-of-the-art can be expected.

CHAPTER 95

SCOUR AROUND MODEL PIPELINES DUE TO WAVE ACTION

by

John B. Herbich, Ph.D., P.E.
Professor of Ocean and Civil Engineering
Ocean Engineering Program
Texas A&M University
College Station, Texas

ABSTRACT

The size, number and application of offshore pipelines are steadily increasing. At the same time, the incidence of reported pipeline failures is also increasing. There appear to be several reasons for these failures, and they can be placed in two basic categories:

1. inadequate cover, and
2. low "specific gravity" of the pipeline.

Under the first category the depth of burial may be insufficient, the type of burial material may be inferior to the material alongside the trench, or the compaction of cover material may be inadequate. Under the second category the pipe may actually float up to the surface from the ocean bottom as material around the buried pipe liquifies.

An extensive literature search revealed that many studies were conducted by Meyers (1936), Waters (1939), Johnson (1940), W.E.S. (1940), Rector (1954), Wiegel, et al (1954), Saville (1957), Iwagaki and Noda (1962), Nayak (1972), Noda (1972), and Earattupuzha (1974). In general, two types of "equilibrium profiles" were developed in the laboratory flumes, the "ordinary" and the "storm" (sometimes referred to as summer and winter profiles). Despite numerous previous investigations, knowledge of the "scale effects" involved in equilibrium beach profiles is inadequate. Many authors have analyzed model data without stating the relation between model and prototype dimensions. In addition, many have claimed certain phenomena observed in the model to be independent of initial slope.

An extensive laboratory study was conducted to evaluate the development of underwater bars and scour patterns with the pipeline buried at various depths below the ocean bottom. Pictures of the beach profile were taken at specific time intervals through the glass wall of the wave tank.

Attempts were made to correlate equilibrium profile geometric quantities, such as depth of offshore bar, scour depth and berm height with the wave characteristics. Qualitative agreement between laboratory and natural beach profiles were demonstrated by trial and error fitting of one to the other.

INTRODUCTION

In more recent times, the energy crisis has caused acceleration of exploitation and exploration of the oil and gas reserves under the continental shelf. The most economical way of transporting oil and gas is through pipelines from offshore platforms or underwater completions to shore.

In another widespread application of pipelines, environmental considerations and regulations call for the disposal of municipal and industrial waste in deeper water, both in lakes and oceans, than previously. Here, as in all engineering design work, a better understanding of soil-pipe interaction and magnitudes of various forces acting on an unburied pipe is required before good design criteria and engineering practices can be well defined.

Experimental studies, mainly in the laboratory, but some in the field, have been conducted in many countries, notably in the U.S.A., the Netherlands and Japan.

While the petrochemical industry is evaluating pipeline failures and design practices, such technical information is generally restricted and not available. Since design engineers have been made more conscious of failures in more recent years, pipelines are sometimes over-designed and excessively expensive to construct. Over the past 10 or so years, the incidence of reported submarine pipeline failures, particularly of large diameter pipelines, has increased markedly.

The American Society of Civil Engineers appointed a Task Committee on Pipelines in the Ocean in 1969 to define the problems of pipelines in the oceans and to determine the state-of-the-art in the design and construction of pipelines in the oceans.

This effort, which has not been sponsored financially, has attempted to define the problem and review the current state-of-the-art in the areas of environmental factors, design factors and construction factors. The deficiencies were uncovered in the state-of-the-art¹, in

- (a) structural and external pressure effects,
- (b) depth of burial,
- (c) economics of submarine pipelines, and
- (d) documentation.

The current project deals with the aspects described in (a), (b), and (d).

The American Gas Association has been sponsoring a study on offshore pipelines², particularly those in water depths greater than 200 ft. The conclusions of the study to date indicate that

- (a) considerable additional data are required to more fully evaluate pipeline-soil interaction, and

- (b) field measurements of storm-driven bottom particle velocities and accelerations should be obtained.

Recent pipeline failures include the following:

- (a) One gas line, one telephone line and two water lines have moved upward through silty sand at the bottom of a ship channel from an elevation -51 ft to elevation -41 ft. These lines were subsequently cut by maintenance dredging operations.
- (b) One 10-ft diameter steel bitumen-coated pipeline failed three times during construction. The failure, which occurred during one major and two minor storms, was probably due to liquifaction of the silty sand sediment around the pipe. One section of the pipe, weighing about 80 tons was found some 150 ft away from the trench in which it was placed and partially backfilled.
- (c) One 48-inch sewer outfall pipe failed during its first year of operation. Higher than design wave forces are thought to be responsible for failure. The pipeline was unburied.
- (d) One 48-inch water intake pipe was damaged and three sections of it displaced. The pipe was buried and an analysis is being made as to the possible causes of failure.
- (e) One 60-inch intake pipe at a nuclear power plant failed before the plant was placed in operation. Scour of sediment around the pipe exposed the buried pipe which was then subjected to forces for which the pipe was not designed.

The information on pipe failures is difficult to obtain as construction companies or owners are reluctant to discuss or even admit failure occurred. The problem is complicated by the fact that disputes arise as to who is responsible for failure -- the designer or the contractor. It is not unusual for some cases to be taken to court. It is hoped that permission will be obtained to eventually summarize and document recent pipeline failures.

LITERATURE REVIEW

The relationship between many variables which govern beach deformation are quite complex as was pointed out by many researchers studying beach formation, beach erosion, scour around piers and piles, and in front of seawalls, etc. A large number of variables and their mutual interaction further complicate analysis of experiment data.

Assuming a two-dimensional approach, a review of the literature revealed numerous studies of model beach profiles conducted by Meyer³ (1936), Waters⁴ (1939), Johnson⁵ (1940), Rector⁶ (1954), Wiegel, et al⁷ (1964), Saville⁸ (1957), Iwagaki and Noda⁹ (1962), Nayak¹⁰ (1972), Noda¹¹ (1972),

and Earattupuzha¹² (1974). Figure 1 shows a classification scheme developed by Sunamura and Horikawa¹³ (1974) for model beach profiles. Type II profile was generally observed in this study. Despite numerous previous investigations, knowledge of scale effects is inadequate.

A literature survey relating to scour and stability of submarine pipelines was conducted and reported by Ralston and Herbich¹⁴ (1968). The present study is partially an outgrowth of previous work which was supported in part by the U.S. Corps of Engineers. An additional survey dealing with the design of offshore pipelines was conducted in 1971-73 and reported by Manley and Herbich¹⁵ (1976).

Coastal deformations can be divided into two general groups: long-term and short-term. Long-term changes are those changes in a coastline which occur over hundreds of years and result in a general prograding or recession of the shoreline. Of more interest to the coastal engineer is the short-term change which is associated with the variable wave climate and resulting sediment motion. Wave induced sediment motion can be divided into two components: alongshore motion and motion normal to the coast. This paper is concerned with the onshore-offshore motion.

As waves progress onto a beach sediment motion occurs. The magnitude of the sediment transport depends on the wave characteristics. The resulting changes in the beach have a feedback control on the incident waves. For example, changes in depths caused by breaking waves require changes in location of the breaking waves. Intuitively, it would seem that when a given beach is subject to waves of constant characteristics for a sufficient length of time, an equilibrium state will develop. In nature, the variable meteorological conditions and resulting variable wave conditions probably seldom allow an equilibrium to be attained. In the hydraulic model, where one has control over wave parameters, such as wave height and wave period, and beach parameters, such as grain size and size distribution, the concept of the equilibrium profile can be more readily studied. Thus, in nature the equilibrium profile needs to be defined in terms of statistical averages. However, in the laboratory the equilibrium profile is defined as a stable configuration in which the oscillatory motion of a given sediment particle is about a mean position, the sorting action of waves presumably having reached an equilibrium. The net transport across any section parallel to the beach is zero.

The objective of this part of the study was to determine, through physical modeling, the effect of storm waves on buried pipelines approaching the shoreline. Scour depth and scour patterns have been evaluated in a two-dimensional wave tank. Three-dimensional effects have also been studied in a larger wave basin. The number of variables included wave characteristics such as height, period, wave crest direction, water depth, pipe burial depth, and beach slope. Preliminary results on three-dimensional effects indicate that local scour may be quite significant when pipes are placed at an angle to the approaching waves.

FIGURE 2. NOTATION USED IN THE STUDY.
(FROM REFERENCE 16)

EXPERIMENTAL STUDY

Experimental studies were conducted to assess the required depth of burial for a pipeline through the surf zone. The problem was approached by using a two-dimensional beach profile. Beach profiles were allowed to come to equilibrium in a 2-ft wide wave tank. Two-dimensional profiles were recorded for a number of wave conditions and initial slopes of 1:10, 1:20, 1:30 and 1:60. The 1:60 slope study was limited because of instability of profiles associated with minor water level variations as observed by Smith¹⁶ (1975).

A sample dimensionless plot of beach profiles for the slope of 1:20 is shown in the Appendix (Fig. A-1).

Attempts were made to correlate equilibrium profile geometric quantities, such as the maximum depth of the nearshore trough (T_{max}) and maximum height of the beach crest (C_{max}) with the wave characteristics. Figure 2 indicates the notation used in this study. It was found that wave height varies spacially and temporally in the tank making it an unsuitable independent variable for determining linear regressions. Deep water wave length (a function of wave period), however, was found to exhibit constant characteristics throughout a given test. Thus, the deep water wave length was used as the independent variable in the linear regression analysis.

Of the four attempted regressions, three were determined significant at the 5% significance level. Table I shows the correlation coefficients and regression results¹⁶.

Table I

L_o vs. C_{max}	r	r ²	v	r(.05, v)	significant
1:20	.94	.88	8	.632	yes
1:30	.86	.75	14	.497	yes
L_o vs. T_{max}					
1:20	.708	.502	8	.632	yes
1:30	.002	.048	10	.576	no

Where r = correlation coefficients; v = degrees of freedom = no. of obs. - 2; r(.05, v) = tabulated values of r at 5% significance level; r² = % variance explained by the linear relationship of C_{max} and L_o ; C_{max} = maximum height of the beach crest above the still water level; T_{max} = maximum height of the nearshore trough below the still water level, and L_o = deep water wave length.

Confidence intervals were determined for the C_{max} regression slopes and intercepts. The 95% confidence intervals for the slope and intercept of the 1:20 data are: $b_1 = .014 \pm .003$, $a_1 = .085 \pm .028$. Similarly for

1:30 data, $b_2 = .025 \pm .006$, $a_2 = .030 \pm .061$. Based on a 2-tailed t-test it was determined that at the 95% confidence level the populations represented by the 1:20 and 1:30 data are significantly different. Thus, for the range of tested variables, the dependence of C_{max} on L_0 is not independent on initial slope of the model beach. The failure of the T_{max} regression for the 1:30 data indicates that possibly some of the 1:30 T_{max} values had not reached equilibrium. This is in agreement with earlier observations indicating that steeper beaches reached equilibrium in a shorter time.

Hence the following relationships were obtained for a 1:20 initial slope: $C_{max} = .085 + .014 L_0$, for a 1:30 initial slope; $C_{max} = .030 + .025 L_0$, for a 1:20 initial slope: $T_{max} = .001 + .075 L_0$.

Qualitative agreement between laboratory and natural beaches was demonstrated by trial and error fitting. Figure 3 shows such a fit. The required distortion of scales results in an unnatural repose angle at the foreshore. In addition, the wave parameters responsible for the natural profile are unavailable. However, the trial and error method is useful in determining a general scale factor. For example, a comparison between laboratory-obtained profiles and field profiles near Sabine Pass, Texas, indicate a horizontal scale of 1 to 25 and vertical scale of 1 to 8, or a distortion of about 3 to 1.

PIPELINE STABILITY

An offshore pipeline must have sufficient horizontal and vertical stability against all environmental and imposed forces. Although environmental and gravitational forces are of primary importance, constructional and operational loadings should also be taken into account.

The gravitational forces include the weight of the pipe (either steel or concrete), weight of the corrosion protection coating, weight of the concrete coating (in case of steel pipe), and weight of the fluid in the pipeline.

The environmental forces depend on the storm severity, location of the pipeline and water depth. They are quite complex and variable. The forces acting on the pipeline include those due to storm or hurricane waves, vortex shedding and foundation strength.

Since forces due to waves may be considerable, particularly in shallow water, the most obvious solution is to place the pipeline in an excavated trench and cover it with suitable material up to the original underwater beach profile. There is no easy answer to this question as the depth of cover required will depend on a great many variables, including the wave climate, sediment size, littoral current, liquefaction potential, etc.

Buried pipelines approaching and passing through the surf zone must be placed below the storm beach profiles, or below the "winter" profiles. Such profiles must be determined prior to the design of the pipeline's profile and selection of burial depth. It has been found that in many cases

FIGURE 3. COMPARISON OF EXPERIMENTAL AND NATURAL PROFILE.

offshore pipelines failed due to inadequate cover or due to the fact that the pipeline profile generally followed the underwater beach profile observed at one time of the year, sometimes only during the summer period (or having a "summer" profile).

DEPTH OF COVER OVER PIPELINES

For safe design the pipeline should be buried under the storm beach profiles. The actual depth of burial would depend on the storm frequency selected, the importance of the project, and on possible environmental impact should the pipe fail, etc. The forces induced by waves on the buried pipe are generally not large, particularly as compared with unburied or partially buried pipe. Figure 4 indicates the coefficient of drag (C_D), coefficient of inertia (C_M) and coefficient of lift (C_L) on pipes located above the bottom, touching bottom and partially buried (2). For example, the forces due to drag on a pipe suspended 20 inches above the bottom are five times as large as on the pipe partially buried (protruding 0.25 of its diameter above the bottom). The effects of drag causing scour are shown schematically in Figure 5.

In order to develop safe design criteria for pipe cover two types of profile characteristic dimensions were considered:

1. (a) Maximum depth of trough below initial slope - T_{max} ,
 (b) Maximum height of offshore bar above initial slope - B_{max} ,
2. (a) Depth of trough below mean low tide - h_T ,
 (b) Depth of bar below mean low tide - h_C .

Ideally, all measurements should be taken either during the storm or as soon as practical after the storm. If no measurements are available, laboratory developed "equilibrium" profiles may be used provided a distorted scale is determined on the basis of laboratory-field comparisons.

Plots of h_T as a function of h_C have been determined from both field and laboratory data (Figure 6). The experimental laboratory data for beach profiles of 1 on 10, 1 on 20, and 1 on 30 are shown in Table II. A summary of recent laboratory results indicates that beach slope affects the ratio of h_T to h_C (Tables III and Figure 7). For example, the h_T/h_C value for 1 on 10 slope is 1.80 with a 95% confidence interval of ± 0.21 while the value for 1 on 30 slope is 1.35. Previously analyzed profiles are shown in Figure 6.

Pipe Position with respect to Mudline		C_D	C_M	C_L
	$L^* = 20^*$	1.0	1.5	0.5
	$L = 3^* - 20^*$.95	1.5	0.5
	Pipe Touching Bottom	.75	1.5	1.0
	$L = 0.25$ Diameter	.50	1.5	.85
	$L = 0.50$ Diameter	.25	1.5	.75
	$L = 0.75$ Diameter	.20	1.5	.20

* L = Distance from bottom of pipe to mudline.

CHAPTER 96

HYDRAULICS OF GREAT LAKES INLET - HARBORS SYSTEMS

Robert M. Sorensen¹

and

William N. Seelig²

Abstract

Reversing currents in inlets on the Great Lakes are generated primarily by long wave seiching modes of the lakes rather than by the tide. In order to investigate the nature of long wave excitation and the generating mechanism for significant inlet velocities, to establish techniques for predicting inlet-harbor system response, and to develop base data for future planning and design studies, field measurements were conducted in 1974-75 at several harbors on the Great Lakes. Data collected includes continuous harbor water level measurements at all sites, inlet velocity measurements at the primary site (Pentwater, Michigan), and channel hydrographic surveys at the sites where more recent data were needed. Historic water level and velocity data for some of the harbor sites was also available.

Amplification of harbor oscillations and generation of the highest inlet velocities are caused by the Helmholtz resonance mode which has a period of 1 to 3 hours for the inlet-harbor systems studied. A recently developed simple lumped-parameter numerical model is shown to be quite effective in predicting inlet-harbor response over the range of excitation periods encountered. Selected data from Pentwater are presented to demonstrate the hydraulic response of the inlet harbor system and the applicability of the lumped-parameter numerical model.

Introduction

Situated along the coastlines of the U.S. - Canadian Great Lakes are several inlet-harbor systems that consist of lakes or other embayments which are connected to the adjacent Great Lake by one or more artificial jettied inlets. There are also a few inlet-harbor systems that have natural uncontrolled inlets, but most inlets are jettied and periodically dredged to maintain adequate navigation channels.

Higher velocity reversing currents at these inlets are generated in response to storm-generated seiching of the individual Great Lakes. Of particular importance to the generation of higher velocities is the resonant amplification of Great Lakes seiches by the inlet-harbor systems. Although high

¹Chief, Coastal Structures Branch, US Army Coastal Engineering Research Center, Ft. Belvoir, Virginia 22060

²Research Hydraulic Engineer, Coastal Structures Branch, US Army Coastal Engineering Research Center, Ft. Belvoir, Virginia 22060

velocities can be generated by excitation of resonant conditions, a cumulative frequency distribution of channel velocities at most Great Lakes inlets will show that velocities in excess of 1 ft/sec typically occur less than 5 percent of the time.

A field data collection program was conducted at nine inlets on the U.S. coast of the Great Lakes. Also, historic field data were available for some of these nine inlets as well as for three additional inlet sites. Historic and project field data includes continuous measurements of Great Lake and harbor water levels and inlet velocities over periods of a few weeks to nearly a whole ice free season, and hydrographic surveys at inlet channels where insufficient hydrographic data were available. The primary site for field data collection was at Pentwater, Michigan.

The three objectives of this project were: (1) to define the hydraulic mechanisms that generate the dominant inlet currents and related harbor oscillations, (2) to establish analytical techniques for prediction of inlet-harbor response to Great Lakes oscillations, and (3) to develop background data that will demonstrate the hydraulic behavior of these inlet-harbor systems as well as the validity of analytical prediction techniques, and that will provide base data for guidance in future project design studies.

This paper will summarize the hydraulic behavior of Great Lakes inlet-harbor systems and the techniques used herein to predict the hydraulics of these systems; it will outline the field data collection program; and it will present results from the data collection program at the primary study site in order to demonstrate details of the hydraulic response of these inlet-harbor systems as well as the ability of analytical techniques to predict this response.

Inlet-Harbor System Hydraulics

Figure 1 schematically depicts a prismatic inlet channel that connects a large body of water such as a sea or one of the Great Lakes to a much smaller bay, lake or harbor (herein referred to as the harbor). The inlet channel has a length, L , width, B , average depth, d , cross-sectional area, A_c , and time dependent instantaneous horizontal velocity, V . A_h is the surface area while η_s and η_h are the time dependent instantaneous sea and harbor surface elevations. The harbor surface is assumed to remain horizontal as it rises and falls in response to excitation from the sea. This assumption requires that the harbor surface response period be long compared to the time required for a shallow water wave to propagate from the inlet to the farthest point in the harbor.

Fig. 1 Inlet - harbor system

For purposes of discussion it is helpful to write a simple inlet-harbor continuity equation and the one-dimensional equation of motion for flow in the inlet channel. The continuity equation

$$Q = VA_c = A_h \frac{\partial \eta_h}{\partial t}, \quad (1)$$

where Q is the instantaneous channel discharge, equates the volumetric flow through the inlet to the harbor water surface rise or fall needed to balance that flow. An accurate record of the harbor surface elevation time-history can thus be used to calculate the instantaneous channel discharge and velocity using Eq. 1 (provided that the harbor surface remains horizontal as it oscillates).

The one-dimensional equation of motion along the inlet channel axis can be written

$$-g \frac{\partial \eta}{\partial x} = \frac{f V |V|}{8R} + V \frac{\partial V}{\partial x} + \frac{\partial V}{\partial t} \quad (2)$$

where R is the channel hydraulic radius, x the distance along the channel axis from some reference point, f the channel friction factor, and g the acceleration of gravity. Eq. 2 equates the horizontal driving force due to the water surface slope with the three terms on the right which are the channel frictional resistance, the convective acceleration owing to velocity variation along the channel axis, and the temporal acceleration (or inertia) owing to velocity variation at a point with time. In nearly prismatic channels the convective acceleration is often negligible.

At U.S. tidal inlets, because of the magnitude of common tidal periods and amplitudes, friction strongly dominates the effects of inertia. The result is that at most tidal inlets inertia can be neglected in hydraulic calculations, the harbor tidal range is less than the range at sea, and the phase lag between the sea and harbor tides is much less than 90° .

On the Great Lakes, the components of the long wave energy spectrum that excite the dominant inlet-harbor system response modes typically have amplitudes in the order of 0.1 to 0.2 ft and periods of less than 3 hours. This causes the inertia term to be larger than the friction term throughout most of the cycle of oscillation. (Friction will dominate only around times of peak ebb and flood velocity, which are also the times of minimum temporal acceleration.) As a result, the harbor response is amplified and its phase lag can exceed 90° .

The inlet-harbor system response is analagous to the response of a slightly damped spring-mass system or its acoustic counterpart, the Helmholtz resonator (see Kinsler and Frey, 1950). The motion of the mass of water in the inlet channel corresponds to the motion of the mass of the spring-mass system, and the action of gravity on the rising and falling harbor water surface corresponds to the restraining force of the spring. Details of the response characteristics of this mode of oscillation (usually called the Helmholtz mode) are demonstrated by Figure 2 which depicts the classical behavior of a single-degree of freedom oscillating system.

In Figure 2, the phase lag between the sea and harbor surface elevations as well as the amplification of the harbor surface response are plotted as a function of excitation period divided into the frictionless resonance period, T_H . The series of curves represents different degrees of frictional damping of the system. Note that increased friction tends to shift the resonant or Helmholtz period to slightly higher values. For excitation at periods much longer than the Helmholtz period (A) the harbor amplitude

equals the sea amplitude and the phase lag is small (pumping condition). With decreasing excitation periods and significant friction (B) the ratio of

Fig. 2 Amplification, phase lag for inlet - harbor system

harbor to sea amplitude is less than unity and the phase lag less than 90° . This is the typical response of most tidal inlets. As the Helmholtz period is approached, particularly with lesser frictional damping (C), the harbor response is amplified and the lag increases toward (or above) 90° . A significant decrease in the harbor response occurs for all levels of frictional dissipation when the excitation period is much less than the Helmholtz period (D). At a harbor on the Great Lakes, excitation will occur at a number of periods in the long wave energy spectrum (typically $\frac{1}{2} T_H$) and cause a range of responses for these different periods as indicated in Figure 2.

The Helmholtz period is longer than the fundamental free seiching period of the harbor. A simple equation for the Helmholtz period can be derived (Carrier, Shaw and Miyata, 1971) by neglecting the friction and convective acceleration terms in Eq. 2 and solving this equation and continuity for the conditions depicted by Figure 1. This yields

$$T_H = 2\pi \sqrt{\frac{L A_h}{g A_c}} \quad (3)$$

Eq. 3 ignores the water mass that is just outside each end of the inlet channel but is part of the mass of water set in motion at resonance. Miles (1948), using an acoustic analogy, developed an equation for the added channel length, L' , necessary to account for this additional water mass where

$$L' = \frac{-B}{\pi} \ln \left[\frac{\pi B}{\sqrt{gd} T_H} \right] \quad (4)$$

Thus, an improved form of Eq. 3 can be written as

$$T_H = 2\pi \sqrt{\frac{(L + L') A_h}{g A_c}} \quad (5)$$

The inclusion of end effects is particularly important for short channels (i.e. $L < L'$). For the inlet-harbor systems encountered in this study Eq. 5 proved to be reasonably effective for determining the Helmholtz period. A numerical method for determining the Helmholtz period for a harbor with more than one entrance channel is given by Freeman, Hamblin and Murty (1974).

Note from Eq. 5 that the Helmholtz period increases as the channel length or the bay surface area increases and as the channel cross-sectional area decreases. The Helmholtz mode of oscillation is independent of the harbor depth which is not the case for the free seiching modes of harbor resonance.

A recently developed simple lumped-parameter numerical model for inlet hydraulic calculations has been used at CERC to predict inlet-harbor response to Great Lakes long wave motion. Details of the development and application of this model are given by Seelig et al. (1977).

In the lumped-parameter model the oscillating harbor water surface is assumed to remain horizontal and continuity of flow is defined by Eq. 1

written in finite difference form. The equation of motion is integrated along the channel axis to yield

$$\frac{\partial Q}{\partial t} = \frac{FQ^2}{2} \left(\frac{1}{A_{cs}^2} - \frac{1}{A_{ch}^2} \right) + gF(\eta_s - \eta_h) - \frac{Fg}{2} \sum_{i=1}^S \frac{1}{\sum_{j=1}^C A_{ij}} \sum_{j=1}^C \frac{n_{ij} |W_{ij} Q| W_{ij} Q B_{ij} L_{ij}}{(d_{ij})^{1/3} A_{ij}^2} \quad (6)$$

The inlet channel is divided into C subchannels and S sections along its length by construction of a flow net to yield SXC grid sections. Each grid section is assigned a Manning's n (n_{ij}), depth, d_{ij} , width, B_{ij} , length, L_{ij} , area normal to flow, A_{ij} , and flow weighting factor, W_{ij} . The flow weighting factor determines what fraction of the total flow, Q, passes through each grid. It may be selected (1) to distribute flow equally in all subchannels (2) to distribute flow across subchannels so friction is minimized at each section or (3) to distribute flow in each subchannel (no cross over between subchannels) so friction is minimized in each subchannel. F is a channel geometry factor that develops from integration of the equation of motion and A_{cs} and A_{ch} are the inlet channel cross-sectional areas at the sea and harbor ends respectively.

Given the harbor surface areas, inlet hydrography, and $\eta_s = f(t)$, the channel flow net is drawn, n_{ij} and W_{ij} distributions are established and the model is solved in time steps by a fourth order Runge-Kutta-Gill technique to yield η_h at $t, t+1, \dots$ and Q (or V distribution) at $t + 1/2, t + 3/2, \dots$. If (η_s, η_h and V) = $f(t)$ data are available for an inlet-harbor system the model can be calibrated by adjusting n_{ij} .

The lumped parameter model is particularly appropriate for Great Lakes inlet-harbor system hydraulic calculations because of the nature of the harbor water level response during Helmholtz resonance and because the model allows input of irregular sea level time-histories common to Great Lakes long wave spectra. Also, because it has the capacity to handle harbors with more than one inlet channel as are found at some locations on the Great Lakes.

Field Data Sites and Collection Program

A field data collection program was conducted during October and November 1974 and July through November 1975. The harbor sites where data were collected are shown in Figure 3 along with the sites where usable historic data are available.

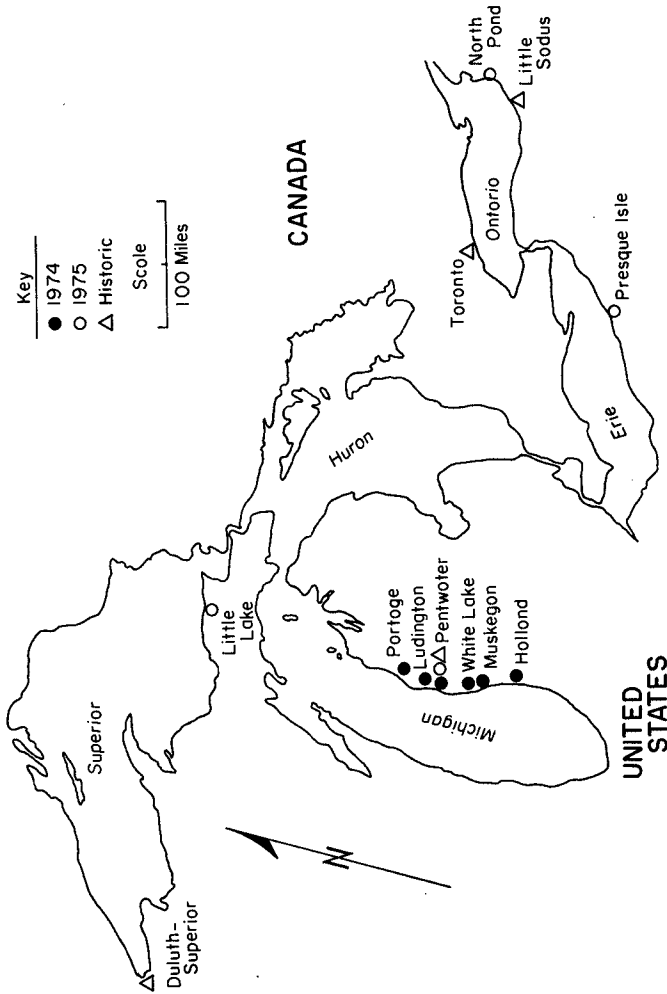

Fig. 3 Field data collection sites

The field program included harbor water level and inlet channel velocity measurements as well as inlet channel hydrographic surveys. The water level measurements were taken at 2 or 5 minute intervals on a continuous basis at the harbors indicated in Figure 3. Continuous current velocity measurements were made in the Pentwater inlet channel at a point middepth, midlength and 7 ft from the north jetty.

Historic lake and harbor water level and channel velocity data at Pentwater are available (Duane and Saylor, 1967) for July and August 1967. Figure 4, a map of Pentwater Lake, shows the locations where water level and

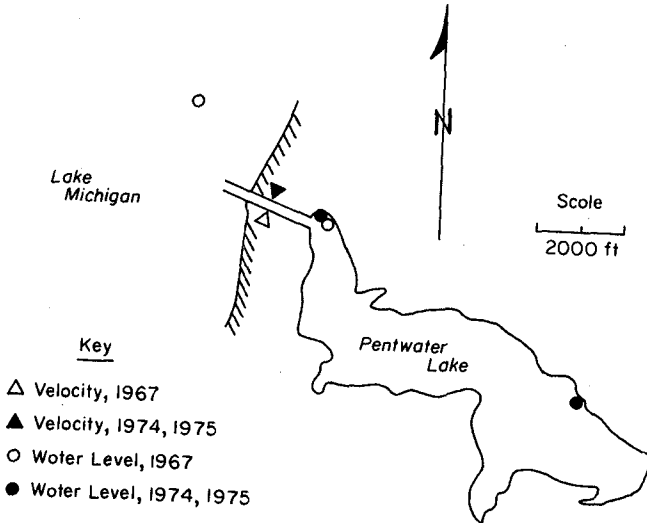

Fig. 4 Pentwater Lake, Michigan

current data were measured. Pentwater was chosen as the primary site for this study (and paper) because of its uncomplicated inlet channel geometry, the availability of the 1967 data, and the existence of concurrent field studies at Pentwater by other CERC personnel.

Pentwater Lake has a surface area of 1.81×10^7 ft² and is connected to Lake Michigan by a jettied inlet channel 2000 ft long and 145 feet wide. The average inlet channel depth at the time of the field data collection was 12.8 ft while Pentwater Lake has an average depth of 30 ft. A report by Seelig and Sorensen (1977) gives additional information on the field data collection sites, measurements made, instrumentation used, and results obtained.

Table 1 lists the Helmholtz period for each of the six field study sites located on the eastern shore of Lake Michigan. The Helmholtz period was calculated by Eq. 5 so the true period will be somewhat higher than listed owing to frictional resistance in the channel. Also listed in Table 1 are the fundamental seiching periods, T_1 , in each harbor calculated by the classical Merian equation.

Table 1 - Helmholtz and fundamental seiching periods

<u>Location</u>	<u>Helmholtz period (hrs)</u>	<u>Fundamental seiching period (hrs)</u>
Portage	2.17	0.16
Ludington	1.22	0.32
Pentwater	1.39	0.13
White Lake	2.55	0.37
Muskegon	3.80	0.27
Holland	2.23	0.63

At most locations on the Great Lakes the amplitude of the astronomical tide is less than 0.3 ft. The amplitudes of the various components of the longwave spectrum on the Great Lakes are of the same order of magnitude but their periods (particularly for higher harmonics) are significantly lower and closer to the resonant period than are the tidal periods. Thus, Great Lakes seiching is more likely to generate noticeable inlet velocities.

Table 2 lists the periods of the longitudinal free seiching modes in Lake Michigan (information is from a variety of field data and numerical model analyses). Owing to the geometry of Lake Michigan, the transverse seiching modes are hard to generate. Note that the 6th through 9th longitudinal modes have periods around the Helmholtz period for Pentwater. It appears (see Mortimer, 1965) that the 7th and 9th modes have nodes near Pentwater while the 6th and 8th modes have antinodes and thus should cause greater hydraulic activity at Pentwater.

Table 2 - Longitudinal free seiching periods, Lake Michigan

Mode:	1	2	3	4	5	6	7	8	9
Period (hrs):	9.0	5.2	3.7	3.1	2.5	1.85	1.58	1.44	1.25

Field Data Measurement and Analysis

Water level data were measured by stilling well-float type gages and recorded digitally (at 5-minute intervals) on punch tape with a Fisher-Porter Model 15-42 level recorder. Vertical resolution of the water level records was to the nearest 0.01 ft. Extreme care must be taken in the design of a stilling well-recorder combination when digital water level measurements are made because the signal of interest is of much lower amplitude than that of the higher frequency "noise" owing to wind waves. Special linear damping stilling wells (Seelig, 1976) with a design based on the work of Noye (1974) were used in this study. The punch tape water level records were machine converted to standard computer punch cards for spectral and other analyses.

Inlet current speed and direction data at Pentwater were measured with a Bendix Q-9 current meter and recorded on strip chart. The velocity records were digitized for analysis at 5-minute intervals timed to coincide with the nearby water level data. Owing to the uniform geometry of the Pentwater inlet channel, measured current velocities should give a good indication of the average channel velocities.

Spectral analyses of water level and velocity data were conducted using the Cooley and Tukey Fast Fourier Transform algorithm with a cosine bell window (Harris, 1974). As a compromise, a record length of 1.78 days (512 data points) was used to maintain the assumption of a weakly stationary system and still give good resolution for the range of periods of interest.

Field Data Results

Selected data from Pentwater are presented in this section to demonstrate the response of the inlet-harbor system to Lake Michigan water level oscillations. Figure 5 shows records of storm generated water levels in Lake Michigan at Pentwater along with the resulting Pentwater Lake levels and channel velocities. These data are typical of storm conditions at Pentwater. High wind waves at Pentwater will often occur when the wind is from the west but during this time inlet velocities will remain low. When the wind shifts to parallel the axis of Lake Michigan and generate seiching action in the Lake, harbor oscillations and inlet velocities increase.

Fig. 5 Lake Michigan water level and resulting Pentwater channel velocity and harbor water level

As demonstrated by Figure 2, higher frequency oscillations are strictly damped by the inlet-harbor system so the harbor water level record is smoother than the Lake Michigan record. The harbor water level oscillation in Figure 5 has a predominant period of 1.5 to 2 hours and is approximately 180° out of phase with the oscillation of Lake Michigan. Harbor response like that shown in Figure 5 typically lasts for a period of 2 to 3 days.

Fig. 6 Velocity cumulative frequency distributions at Pentwater inlet

The cumulative frequency distributions of velocities measured at Pentwater in 1967, 1974 and 1975 are plotted in Figure 6. Although the data were collected during the summer and fall they should be somewhat representative of a typical year at Pentwater. Because of the low frequency of occurrence of significant velocities, inlet currents should only rarely cause concern for navigation. Also, velocities high enough to flush sediment from the inlet (say $V > 1$ fps) occur only about 1 percent of the time so continuous inlet maintenance would likely be required.

Inlet velocity cumulative frequency distributions at all of the other inlets studied (except Duluth-Superior) were approximately the same or lower than the distribution at Pentwater. These distributions were constructed from velocity measurements, when available, or from velocities calculated (by Eq. 1) from harbor water level records. A comparison of measured and

calculated velocity cumulative frequency distribution from Pentwater showed the distributions to be quite compatible.

The Duluth-Superior harbor is located at the end of Lake Superior (see Figure 3) where the shorelines converge and seiche antinodes occur. Oscillation with amplitudes greater than 0.5 ft and periods close to the resonant period have been measured at Duluth-Superior. Inlet velocities up to 7 fps were generated.

Lake Michigan and Pentwater Lake water level spectra for a period bracketing that in Figure 5 are shown in Figure 7. Spectral peaks in the Lake Michigan record occur at 5.3, 1.8, 1.44, 1.0 and 0.85 hours - the second, sixth and eight longitudinal seiching modes plus two undetermined higher frequency modes. As expected, the 5.3 hour mode is only very slightly amplified, the 1.8 and 1.44 hour modes which are near the Helmholtz period are strongly amplified, and the 1.0 and 0.85 hour modes are strongly damped.

Water level spectra for several of the storms that occurred during the periods of record at Pentwater showed responses similar to Figure 7. Quite often the 1.44 hour period was dominant although occasionally other periods such as the 5.3 hour mode would dominate. Of course, the 5.3 hour mode would not be significantly amplified and lower velocities could be expected because of the lower amplitude of harbor oscillation and the longer oscillation period.

Application of Lumped Parameter Numerical Model

The lumped parameter model was calibrated for Pentwater (with $C = 1$, $S = 5$, $n_{ij} = n$, $W_{ij} = 1$) by adjusting the friction term (Manning's n) until there was agreement with the field data. This was accomplished by comparing the amplification predicted by the model for incident sinusoidal waves

Fig. 7 Lake Michigan and Pentwater Lake spectra,
18 - 20 August 1967

having a 0.1 ft amplitude and a range of periods, to the amplification observed in the field. The calculated amplification for the calibrated condition (solid line) and the amplification determined from the field data (circles) are plotted in Figure 8. The numerical model usually had to be run for two or three cycles for the harbor response to build to equilibrium. In the prototype harbor it is likely that equilibrium (full amplification) is never fully achieved. Thus, the calibration curve in Figure 8 forms the upper envelope of the field data.

Fig. 8 Response to long wave excitation
at Pentwater (wave amplitude = 0.1 ft)

A Manning's n (see Eq. 6) of 0.036 was required to calibrate the model. This value is probably somewhat higher than the true prototype value because Eq. 6 is applied from the sea to the harbor and inlet channel entrance and exit losses thus become incorporated in the friction term.

The peak resonant period in Figure 8 is 1.8 hours as compared to a period of 1.39 hours predicted by Eq. 5; the difference being due to the effects of friction. Also plotted on Figure 8 are the calculated maximum channel velocities for the range of excitation periods and a Lake Michigan excitation amplitude of 0.1 ft. Because inlet velocity is dependent on both the period and amplitude of the harbor oscillations, the peak velocity occurs at the lower period of 1.4 hrs (which is coincidentally close to the resonant period predicted by Eq. 5).

The harbor level and inlet velocity time-histories computed for an incident sinusoidal wave of 0.1 ft amplitude and 1.5 hour period are plotted in Figure 9. As indicated by Eq. 1 and shown in Figure 9 the inlet velocity is maximum when the gradient of the harbor water level time-history curve is maximum and the velocity is zero at the instant of high and low slack water in the harbor. The phase lag between the sea and harbor water levels is about 0.35 hours or 84° which conforms to Figure 2.

Also plotted in Figure 9 are the magnitudes of the channel friction, head differential and temporal acceleration terms of the equation of motion, normalized by dividing by the highest instantaneous value among the three. Note that the temporal acceleration or inertia term exceeds the friction term over more than half of the cycle.

Figure 10 shows a selected water level record from Lake Michigan along with the measured and calculated ($n = 0.036$) water level response in Pentwater Lake. After three to four hours of record the numerical model stabilized and quite accurately predicted the remaining portion of the measured harbor water level record. This further confirms the model calibration based on Figure 8. The high frequency oscillations in the measured harbor water level record were not predicted by the numerical model. Perhaps these oscillations are due to harbor seiching ($T_1 = 0.13$ hrs) which is not accounted for in the model.

Conclusions

Field and historic hydraulic data for several Great Lakes inlet-harbor systems were collected and analyzed. The primary conclusions from this effort are:

Reversing inlet currents are generated in response to various modes of low amplitude (<0.4 ft) seiching of the Great Lakes. The strongest currents develop when Great Lake seiching excites the Helmholtz resonance mode of the inlet-harbor system and when the seiching mode has an antinode in the vicinity of the system.

Other than a few percent of the time, at most inlets on the Great Lakes current velocities are less than 0.5 fps.

The simple lumped-parameter numerical model used in this study is effective in predicting the hydraulic response of most inlet-harbor systems of the type found on the Great Lakes.

CHAPTER 97

CHARACTERISTICS OF TIDAL INLETS ON THE PACIFIC COAST OF JAPAN

By Toshiyuki Shigemura¹, M. ASCE

ABSTRACT

Tidal inlets on the Pacific coast of Japan were studied with respect to three characteristic variables of the throat section: (1) Throat area, A; (2) Throat width, B; and (3) Direction of throat section, θ_{ts} . For each of these three variables, multiple regression analysis was performed stepwise by introducing external variables such as tidal prism, mean flow rate of tidal flow, wind energy, wave energy and so on into a linear regression model. Exposure condition of throat section to open sea was also introduced into the analysis.

First step analysis derived quite reliable result on the direction of throat section; $\theta_{ts}(\text{degree}) = -60.0 + 0.88 \theta_{pwv}(\text{degree}), r=0.964$

where θ_{pwv} is the direction of wave energy which penetrates into a backed bay through tidal inlet and r the correlation coefficient between θ_{ts} and θ_{pwv} . However, results on both throat area and throat width were not satisfactory enough even after the performance of more than eighth step analysis on them.

Similar analysis was further performed on both throat area and throat width of the classified data due to the magnitude of geometrical parameters r_{as} and r_{hxb} respectively, where r_{as} is the ratio of throat area to mean surface area of backed bay and r_{hxb} the ratio of the maximum depth at the throat section to throat width. As a result, the former regressions on both throat area and throat width were improved remarkably. Multiple correlation of the regressions were all greater than 0.930.

INTRODUCTION

Tidal inlet problems have been a big concern for coastal engineers who are engaged in maintaining or developing water basins such as bays, lagoons, and estuaries. Especially, characteristics of the minimum flow section or throat section of tidal inlet have been the most important subjects to be investigated since they govern the functional operation of various facilities built inside the basins above.

Many distinguished works have been done on the characteristics of throat section. In 1931, M.P.O'BRIEN(4) made a survey on the tidal inlets located on sandy beaches on the Pacific coast of the United States, and found the following well known relationship between the cross sectional area of throat section and the corresponding tidal prism;

$$A(\text{km}^2) = 4.063 \times 10^{-2} P(\text{km}^3)^{0.85} \dots\dots\dots(1)$$

where A is the cross sectional area of throat section measured below mean sea level and P the corresponding tidal prism for spring tidal range. In 1969,

¹ Dr-Engrg., Asst. Prof. of Ocean Engrg., National Defense Academy of Japan.

O'BRIEN(5) further found that the same relationship held for a large number of additional jettied inlets located on sandy beaches of the Pacific, Atlantic and Gulf coasts of the United States although a slightly different relationship did for a limited number of unjettied inlets;

$$A(\text{km}^2) = 6.65 \times 10^{-2} P(\text{km}^3) \dots\dots\dots(2)$$

In 1973, J.W.JOHNSON(3) made similar analysis on the tidal inlets located on sandy beaches on the Pacific coast of the United States and found the following relationship between their throat areas and corresponding tidal prisms;

$$P(\text{km}^3)/A(\text{km}^2) = 1.729 \times 10^1 P(\text{km}^3)^{0.1} \dots\dots\dots(3)$$

He also showed that different relationship held for a limited number of unjettied inlets on the above coast;

$$P(\text{km}^3)/A(\text{km}^2) = 1.676 \times 10^1 \dots\dots\dots(4)$$

Here, it should be noted that JOHNSON used mean tidal range for the evaluation of tidal prism instead of spring tidal range. These are similar results obtained by O'RRIEN since Eq.(3) and (4) would be transformed into the following equations respectively;

$$A(\text{km}^2) = 5.784 \times 10^{-2} P(\text{km}^3)^{0.9} \dots\dots\dots(5)$$

$$\text{and } A(\text{km}^2) = 5.965 \times 10^{-2} P(\text{km}^3) \dots\dots\dots(6)$$

On the other hand, P.BRUUN and F.GERRITSEN(1) analysed the throat areas of tidal inlets on sandy coasts of the United States, Holland, Denmark and Portugal by introducing the idea of so called "Stable shear stress". As a result, they pointed out that stable throat area could be better described by the maximum flow rate of tidal flow than by tidal prism.

Through the brief review of the previous works, the following facts can be noticed;

- 1). Tidal inlets on sandy beaches were mainly investigated.
- 2). Throat area was the major concern among the characteristics of tidal inlet.
- 3). Effects of a single external variable such as tidal prism or the maximum flow rate was introduced into the analysis of throat area although investigators pointed out the necessity of evaluationg the effects of (1) Other external variables;(2) Geometrical features of both inlets and backed bays; and (3) Geological features of tidal inlets and backed bays in the analysis of throat area.

Similar statistical analysis on tidal inlets are quite few in Japan. So, the author will perform a statistical analysis on the characteristics of tidal inlets located on the Pacific coast of Japan. Here, it should be noted that most tidal inlets on the Pacific coast of Japan are not on sandy beaches but on the rugged rocky coasts. In this study, characteristics of throat section will be investigated as well. Figure 1 shows a model of throat section. Investigation will be made on the following three variables;

- 1). Throat area, A, measured below mean lower low water, in square kilometers.
- 2). Throat width, B, measured below MLLW, in kilometers.
- 3). Direction of throat section, θ_{ts} , measured in azimuth, in degree.

Among these variables, the last two are those added specially in this study since often usage of tidal inlets by super-tankers or big container

Fig.-1. Model of throat section.

ships has necessitated to obtain full information on both throat width and direction of throat section for both functional operation of ports and safety navigation.

On the other hand, the following ten external variables will be provided for the analysis of the characteristic variables;

- 1). Wind energy off the tidal inlet :E_{owd}
- 2). Direction of wind energy off the tidal inlet : θ_{owd}
- 3). Wind energy penetrating into throat section :E_{pwd}
- 4). Direction of wind energy penetrating into throat section : θ_{pwd}
- 5). Wave energy off the tidal inlet :E_{owv}
- 6). Direction of wave energy penetrating into throat section : θ_{owv}
- 7). Wave energy penetrating into throat section :E_{pwv}
- 8). Direction of wave energy penetrating into throat section : θ_{pwv}
- 9). Volume of tidal prism for mean tidal range :P
- 10). Mean rate of tidal flow at the throat section :V_n

Multiple regression analysis will be performed stepwise on each of the characteristic variables by introducing external variables one by one into a linear regression model preset. The details of the analysis will be presented in the following Chapters.

SURVEY OF THE BASIC DATA

Figure 2 shows the map of Japan. Along the Pacific coast of Japan, ninety five tidal inlets were chosen for analysis.

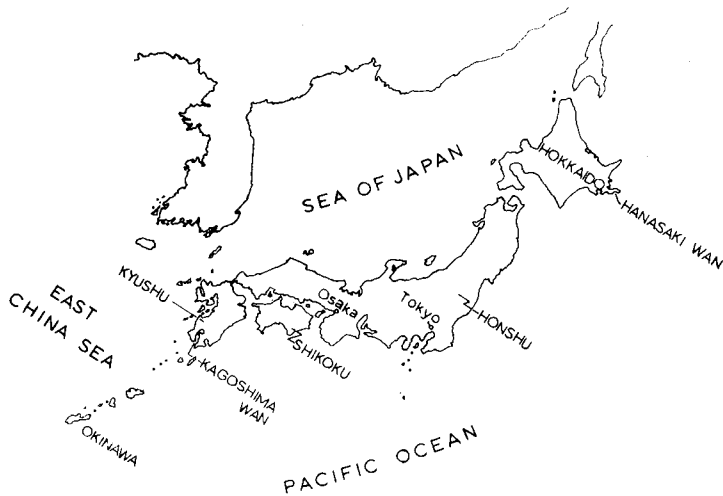

Fig. 2. Map of Japan and her adjacent areas.

Those inlets are distributed almost evenly along the Pacific coast of Japan from Hokkaido to Kagoshima. The inlets whose throat sections are stabilized either by jetties or other artificial works were not considered in the sampling stage. For each inlet selected, the following data were collected through

the various sources;

- A). Geometrical features of inlets and their backed bays.
- B). Geological features around inlets and their backed bays.
- C). Wind data around the inlets.
- D). Wave and tidal data around the inlets.

Details of the data survey will be described in the following sections.

A. Geometrical features of inlets and their backed bays.

Basing on the most recent nautical charts, published by the Japan Maritime Safety Agency, the following data were measured;

- 1). Surface area of bay measured below mean higher high water: $S_h(\text{km}^2)$
- 2). Surface area of bay measured below mean lower low water : $S_l(\text{km}^2)$
- 3). Shore length of the bay measured below MLLW : $l_s(\text{km})$
- 4). Principal axial length of bay measured below MHHW : $l_p(\text{km})$
- 5). Width of the throat section measured below MLLW : $B(\text{km})$
- 6). Direction of the throat section : $\theta_{ts}(\text{degree})$
- 7). Opening angle of tidal inlet against open sea : $\theta_{op}(\text{degree})$
- 8). Throat area of tidal inlet measured below MLLW : $A(\text{km}^2)$
- 9). Maximum depth of the throat section measured below MLLW : $h_x(\text{m})$
- 10). Mean tidal range at the bay : $2a_n(\text{m})$

B. Geological features around the inlets and their backed bays.

Geological information along beaches were surveyed through the "Geological Maps of Japan"(6) published by the Economical Planning Agency of Japan. Information on bottom materials were checked through the "Bottom Sediment Chart of the Adjacent Seas of Japan"(10) published by the Japan Maritime Safety Agency. Those information were also referred to those shown in the corresponding nautical charts.

C. Wind data around the inlets.

Thirty four meteorological stations were chosen along the Pacific coast of Japan. These stations are all located near the selected inlets. At each station, the monthly maximum winds recorded during the period of 1967 to 1971 were picked up through the "Annual Report of the Japan Meteorological Agency". At the inlets where stations were not located nearby, wind data were estimated by the interpolation method basing on the monthly maximum winds obtained at the close stations.

D. Wave and tidal data around the inlets.

Wave data available were all collected through various sources(2,7,8,9, 11,12). However, reliable data were obtained only at a few spots where waves were recorded continuously during the period of 1967 to 1971. Among these data, the monthly maximum waves were picked up for the analysis. At the inlets where reliable wave data were not obtained, waves were estimated by the method of SVERDRUP-MUNK-BRETSCHNEIDER basing on the data of monthly maximum winds at the corresponding inlets. The monthly maximum waves recorded continuously during the other period than the above were also referred to the waves estimated by S-M-B method, and the larger ones were adopted as the monthly maximum waves.

Data of tidal range at each inlet were collected through the correspond-

ing nautical charts.

EVALUATION OF THE EXTERNAL VARIABLES

As shown in INTRODUCTION, ten external variables were provided. These are the variables related to wind energy, wave energy, tidal prism, and mean rate of tidal flow at the throat section of tidal inlet. In the following sections, derivation of the equations on these variables will be described briefly.

A. Equations of wind energy and the related terms.

Basing on the monthly maximum winds, wind diagram at the offshore of each selected inlet was produced. Figure 3 shows a wind which blows from the i th direction.

Suppose the velocity of this wind to be $V(i)$ and its frequency of occurrence over five years to be $f(i)$. Then, the horizontal component of wind energy off the inlet, $E_{owdh}(i)$, is evaluated by

$$E_{owdh}(i) = \frac{1}{2} \rho_a V(i)^2 (f(i)/60) \sin(22.5(i-1)) \dots (7)$$

where ρ_a is the air density. Similarly, the vertical component of this energy, $E_{owdv}(i)$, is evaluated by

$$E_{owdv}(i) = \frac{1}{2} \rho_a V(i)^2 (f(i)/60) \cos(22.5(i-1)) \dots (8)$$

then, the probable wind energy off the inlet, E_{owd} is evaluated by

$$E_{owd} = \sqrt{\left(\sum_{i=1}^{16} E_{owdh}(i)\right)^2 + \left(\sum_{i=1}^{16} E_{owdv}(i)\right)^2} \dots (9)$$

The direction of this energy, θ_{owd} , can be obtained by

$$\theta_{owd} = \sin^{-1}\left(\frac{\sum_{i=1}^{16} E_{owdh}(i)}{E_{owd}}\right) \dots (10)$$

Figure 4 shows a wind which penetrates into the throat section from the i th direction. The penetrating energy, E_{pwd} , and its direction, θ_{pwd} , are then obtained through Eqs. (9) and (10) respectively by summarizing the corresponding terms over the opening angle of the tidal inlet instead of full range.

B. Equations of wave energy and the related terms.

Basing on the monthly maximum waves, wave diagram was produced at the offshore of each inlet. Now, suppose the height of wave coming from the i th direction to be $H(i)$, wave length to be $L(i)$, wave period to be $T(i)$, and the frequency of occurrence over five years to be $f(i)$. Then, the horizontal component of wave energy off the tidal inlet, $E_{owvh}(i)$, is given by

$$E_{owvh}(i) = \frac{1}{2} \rho_w g H(i)^2 L(i) (f(i)/60) \sin(22.5(i-1)) \dots (11)$$

Similarly, the vertical component of this energy, $E_{owvv}(i)$, is given by

Fig.-3. Wind data which blow from i th direction.

Fig.-4. Wind data which penetrates into throat section from i th direction.

$$E_{OwVv}(i) = \frac{1}{8} \rho_w g H(i)^2 L(i) (f(i)/60) \cos(22.5(i-1)) \dots\dots\dots(12)$$

where ρ_w is the density of sea water. The probable wave energy off the inlet is then given by

$$E_{OwV} = \sqrt{\left(\sum_{i=1}^{16} E_{OwVh}(i)\right)^2 + \left(\sum_{i=1}^{16} E_{OwVv}(i)\right)^2} \dots\dots\dots(13)$$

The direction of this wave energy, θ_{OwV} , is given by

$$\theta_{OwV} = \sin^{-1} \left(\frac{\sum_{i=1}^{16} E_{OwVh}(i)/E_{OwV}}{\dots\dots\dots} \right) \dots\dots\dots(14)$$

Penetrating wave energy, E_{pWV} , and its direction, θ_{pWV} , can be obtained through Eq.(13) and (14) respectively by summarizing the corresponding terms over the opening angle of the tidal inlet instead of full range.

C. Equations of tidal prism and mean rate of tidal flow.

Tidal prism, P, was evaluated by the following equation;

$$P(\text{km}^3) = S_n(\text{km}^2) \times 2a_n(\text{m})/1000 \dots\dots\dots(15)$$

where S_n is the mean surface area of the backed bay which was obtained by averaging the surface area measured at MHHW and that measured below MLLW, and $2a_n$ the mean tidal range in the backed bay.

The mean rate of tidal flow at the throat section, V_n , was evaluated by the following equation;

$$V_n(\text{m/sec}) = \frac{P(\text{km}^3)}{A(\text{km}^2) \times T/2(\text{sec})} \times 1000 \dots\dots\dots(16)$$

where T is the duration of tidal cycle.

STEPWISE MULTIPLE REGRESSION ANALYSIS ON THE CHARACTERISTIC VARIABLES

The following equation shows a linear regression model assumed between each of the characteristic variables and external variables;

$$Y = C_0 + \sum_{i=1}^m A_i X_i \dots\dots\dots(17)$$

where Y indicates one of the characteristic variables, C_0 the regression constant, X_i the *i*th external variable introduced into the regression model, A_i the partial regression coefficient of X_i , and m the number of the external variables introduced into the analysis. Thus, Eq.(17) actually shows the linear regression model assumed for the *m*th step analysis on Y.

Analysis is performed stepwise by introducing external variables one by one at each step of analysis into the regression model above. A variable is introduced into the regression model at each step of analysis in such an order that the maximum multiple correlation may be obtained by its introduction. F test is performed at each step of analysis by setting the significance level of 5 %, and the analysis will be proceeded until the introduction of new variable becomes insignificant.

The actual analysis was initiated by checking the correlation coefficients between the characteristic variables and external ones. Correlation coefficients between each of the characteristic variables and external ones were investigated on the following cases;

1). When the values of both characteristic variables and external ones are

original ones.

2). When the values of characteristic variables are original although the values external variables are converted into logarithmic values.

3). When the values of both characteristic variables and external ones are all converted into the logarithmic values.

Exposure condition of throat section was also introduced into the analysis. Table 1 summarizes the results of correlation analysis. In this table, exposed inlets mean the inlets whose throat sections are exposed to open sea, and protected inlets indicate the ones whose throat sections are protected against the intrusion of winds and waves by either islands or peninslas.

Table 1. Correlation coefficients between each of three characteristic variables and ten external variables.

External variable	Exposed inlets(N=66)						Protected inlets(N=29)					
	A B θ_{ts} (orig. values)			A B θ_{ts} (log values)			A B θ_{ts} (orig. values)			A B θ_{ts} (log values)		
P	.643	.718	-.133	.844	.873	.062	.928	.777	.187	.824	.772	.276
V _n	.268	.413	-.124	.286	.443	-.075	.560	.439	-.058	.051	.162	-.182
E _{owd}	.095	.077	.002	.030	.112	-.024	.132	.030	.048	.239	.132	.100
θ_{owd}	.170	.154	.043	.148	.219	.085	.244	.175	.480	.357	.147	.471
E _{pwd}	-.136	-.093	-.127	-.199	-.144	-.130	--	--	--	--	--	--
θ_{pwd}	.081	.098	-.149	-.031	.067	-.003	--	--	--	--	--	--
E _{owv}	-.137	-.086	-.082	-.263	-.161	-.085	-.162	-.021	.123	-.090	.010	.113
θ_{owv}	.132	.158	.044	.018	.097	.273	.120	.055	-.252	-.160	-.138	-.196
E _{pwv}	-.022	-.035	-.055	-.154	-.148	-.139	--	--	--	--	--	--
θ_{pwv}	-.036	-.052	.964	-.007	-.032	.849	--	--	--	--	--	--

From this table, the following facts can be seen;

- 1). In case of throat area and throat width, log converted variables generally show higher correlation coefficients than do the original values of them.
- 2). In case of the direction of throat section, original values of the variables generally show higher correlation coefficients than do the log converted variables.
- 3). Influence of exposure condition to correlation coefficients is not clear in case of both throat area and throat width although it is significant in case of the direction of throat section.

Basing on these findings, it was decided to use log converted variables for the analysis of both throat area and throat width, and original variables for the analysis of the direction of throat section. Details of the analytical results will be shown in the next Chapter.

RESULTS ON THE STEPWISE MULTIPLE REGRESSION ANALYSIS

Multiple regression analysis was performed stepwise on each of the characteristic variables of (1) Whole inlets; (2) Exposed inlets; and (3) Protected inlets. Table 2 shows the regressions obtained by the first step analysis together with those obtained by the final step analysis. In this table, R indicates the multiple correlation of the regression on each characteristic variables, and numerals in each colomun show the partial regression coefficients of the corresponding external variables.

Table 2. Results of multiple regression analysis on the characteristic variables of throat section.

$$Y = C_0 + \sum_{i=1}^m A_i X_i$$

Step	C ₀	P	E _{owd}	θ _{owd}	E _{pwd}	θ _{pwd}	E _{owv}	θ _{owv}	E _{pwv}	θ _{pwv}	V _n	R	Groups
Regressions on throat area; All variables-logarithmic values													
1 st	-.063	.600										.835	Whole
8 th	-.165	.586	-.085	.368	.069	-.261	-.028	.021	-.012			.862	
1 st	-.071	.579										.845	Exposed
8 th	-.189	.564	-.091	.239	.061	-.127	-.187	.008	.058			.865	
1 st	-.001	.655										.824	Protected
Regressions on throat width; All variables-logarithmic values

2 nd	-.557	.573									-.411	.933	
9 th	1.292	.573	-.063	.173	.073	.092	.048	.060	-.036			-.407	.945
1 st	1.154	.411										.772	Protected
2 nd	-.842	.569									-.459	.864	
Regression on the direction of throat section; Original values													
1 st	-60.0										.880	.964	Exposed

From this table, the following facts can be found;

A. On the regressions of throat area.

- 1). Tidal prism has been introduced into every regression obtained by the first step analysis. This indicates that tidal prism is the most predominant external variable for throat area.
- 2). The first step regressions are barely improved by introducing additional external variables into the analysis. In case of exposed inlets, R of the first step regression is 0.845. However, R of the eight step regression is only 0.865.

B. On the regressions of throat width.

- 1). Tidal prism is the most predominant external variable for throat width. In case of exposed inlets, R of the first step regression is 0.873.
- 2). Mean rate of tidal flow is the next predominant variable for throat width. The first step regressions are all improved considerably by the introduction of mean rate of tidal flow into the analysis. In case of exposed inlets, R of the second step regression is improved to 0.933 from 0.873.
- 3). Second step regressions, however, are barely improved by the performance of further step analysis. In case of exposed inlets, R of the ninth step regression is improved only to 0.945 from 0.933.

C. On the regression on the direction of throat section.

- 1). Direction of the penetrating wave energy is the most predominant external variable for the direction of throat section.
- 2). The first step analysis gave quite satisfactory regression on the direction of throat section as shown below.

$$\theta_{ts} \text{ (degree)} = -60.0 + 0.88 \theta_{pwv} \text{ (degree)}$$

where R of this regression is 0.964.

Figure 5 shows the relationship between the measured values of throat area of whole inlets and those estimated by the eighth step regression shown

in table 2. In this figure, abscissa indicates the scale for the measured values of throat area, and ordinate the scale for the estimated values of throat area. As it can be seen from this figure, measured values of throat area scatter considerably around the estimated values of them. This fact shows that multiple regression analysis could not derive the satisfactory regression even after the introduction of eight external variables into the analysis.

In figure 6, measured values of throat width are plotted against the corresponding values of throat width estimated by the ninth step regression shown in table 2. In this figure, abscissa shows the scale for measured width and ordinate the scale for estimated width. Measured values of throat width still scatter around the estimated values of throat width. This fact also indicates that ninth step regression on throat width was not satisfactory enough.

Figure 7 shows the result of the first step analysis on the direction of throat section. In this figure, abscissa indicates the scale for the direction of penetrating wave energy and ordinate the scale for the direction of throat section. As it can be seen from this figure, data of θ_{ts} fall fairly close around the first step regression. Standard deviation of θ_{ts} from the regression was 28.4° . This fact indicates that the first step regression on θ_{ts} is quite satisfactory one. Here, some explanation should be added on the magnitude of θ_{pwv} . Figure 8 shows the mutual relationship between θ_{ts} and θ_{pwv} for the various magnitude of θ_{ts} . As it can be seen from this figure, θ_{pwv} becomes greater than 360° when θ_{ts} becomes greater than 260° . In this case, $\theta_{pwv} + 360$ was used for the analysis of θ_{ts} instead of θ_{pwv} .

Fig.-8. Measurement of θ_{pwv} against θ_{ts} .

DISCUSSION

In the previous Chapter, the author showed that the first step analysis or the simple regression analysis derived quite satisfactory regression on the direction of throat section. He also showed that satisfactory regressions were not obtained on both throat area and throat width by the performance of multiple regression analysis into which more than eight external variables were introduced.

This may be caused by the effects of the following factors which were not taken into account in the previous analysis;

- 1). Geometrical features of inlets and their backed bays.
 - 2). Geological features around the inlets and their backed bays.
- In these two factors above, geometrical features may control the contribution rate of the external variables to throat section. Thus, tidal inlets with different geometrical features will probably behave differently even if external variables of the same magnitude were induced on them. If this is true, more reliable regressions may possibly be obtained on both throat area and throat width by performing multiple regression analysis on the data of tidal inlets classified by certain parameters representing geometrical features of tidal inlets and their backed bays.

Then, the author provided the following twelve parameters which are all dimensionless;

- 1). r_{as} : Throat area/Mean surface area of backed bay
- 2). r_{bp} : Throat width/Principal axial length of backed bay
- 3). r_{bs} : Throat width/Shore length of backed bay
- 4). r_{es} : l_{es} /Shore length of backed bay
- 5). r_{hna} : Mean depth at throat section/Mean tidal range
- 6). r_{hnb} : Mean depth at throat section/Throat width
- 7). r_{hnp} : Mean depth at throat section/Principal axial length of backed bay
- 8). r_{hxa} : Maximum depth at throat section/Mean tidal range
- 9). r_{hxb} : Maximum depth at throat section/Throat width
- 10). r_{hxp} : Maximum depth at throat section/Principal axial length of bay
- 11). r_{op} : Opening angle of tidal inlet/ 360°
- 12). r_{ps} : Principal axial length/Shore length of backed bay

In these parameters above, l_{es} means the circumference of a virtual circle whose area is equal to mean surface area of backed bay.

On the other hand, the following two variables were provided to measure the reliability or the fitness of the final step regressions on both throat area and throat width which were obtained in the previous Chapter;

$$A_{fit} = A_{est}/A \times 100(\%)$$

$$\text{and } B_{fit} = B_{est}/B \times 100(\%)$$

where A_{est} and B_{est} are the values of throat area and throat width estimated by their final step regressions shown in table 2.

In order to see the influence of the geometrical parameters upon A_{fit} and B_{fit} , correlation analysis was performed among them. Table 3 summarizes the results of analysis. From this table, the following facts can be noticed;

- 1). A_{fit} of both exposed inlets and protected ones has relatively high correlation with r_{as} or the ratio of throat area to mean surface area of backed bay.
- 2). B_{fit} of both exposed and protected inlets has considerably high correlation with r_{hxb} or the ratio of the maximum depth at throat section to throat width.

Table 3. Correlation coefficients between each of A_{fit} and B_{fit} and twelve parameters representing geometrical features of inlets and bays.

Parameters	(Exposed inlets, N=66)						(Protected inlets, N=29)

r_{op}	-.056	-.249	-.036	-.193	-.061	-.196	.025	-.187	.047	-.223	.064	-.219
r_{ps}	.057	.030	-.015	-.000	.073	-.019	-.457	.173	-.470	.211	-.495	.187

Note: (1). Both-orig; Values of A_{fit} , B_{fit} and parameters are original
 (2). Both-log; Values of A_{fit} , B_{fit} and parameters are logarithmic
 (3). Pars-log; Values of parameters are logarithmic although values of A_{fit} and B_{fit} are original

Figure 9 shows the distribution of A_{fit} of both exposed and protected inlets plotted against their corresponding values of r_{as} . From this figure, it can be seen that tidal inlets may be classified into the following three groups due to the magnitude of r_{as} .

- 1). Group in which throat area is always overestimated by the final step regression.
- 2). Group in which throat area is always underestimated by the final step regression.
- 3). Group between the two above.

On the other hand, figure 10 shows the distribution of B_{fit} of both exposed and protected inlets plotted against their corresponding values of r_{hxb} . From this figure, it can be noticed that tidal inlets may also be classified into similar groups due to the magnitude of r_{hxb} .

- 1). Group in which throat width is always overestimated by the final step regression.
- 2). Group in which throat width is always underestimated by the final step regression.
- 3). Group between the two above.

Fig.-9. Relationship between A_{fit} and r_{as} .

Fig-10. Relationship between B_{fit} and r_{hxb} .

Basing on these findings, tidal inlets were classified into the following groups shown in table 4 for the analysis of throat area.

Table 4. Classification of tidal inlets due to both exposure condition and magnitude of geometrical parameter, r_{as} .

Range of r_{as}	Groups classified	Sample number
$r_{as} < 0.004$	Exposed-1	14
	Protected-1	10
$0.004 \leq r_{as} < 0.016$	Exposed-2	50
	Protected-2	15
$r_{as} \geq 0.016$	Exposed-3	2
	Protected-3	4

For the tidal inlets involved in Groups 1 and 2, stepwise multiple regression analysis was performed on their throat areas. Table 5 summarizes the final step regressions on them.

Table 5. Final step regressions on throat area of the classified inlets due to both exposure condition and geometrical parameter, r_{as} .

$Y = C_0 + \sum_{i=1}^m A_i X_i$												
Step	C_0	P	E_{owd}	θ_{owd}	E_{pwd}	θ_{pwd}	E_{owv}	θ_{owv}	E_{pww}	θ_{pww}	R	Groups
8 th	-1.652	.681	-.103	.902	.375	-1.049	-.012	.707	-.176		.970	Exposed-1
8 th	.181	.831	-.134	.299	.135	.016	-.153	-.022	.039		.945	Exposed-2
1 st	.153	.856									.933	Protected-1
1 st	.430	.819									.976	Protected-2

As it can be seen through the values of R in table 5, the former regressions on throat area were improved significantly by introducing geometrical parameter, r_{as} , into the analysis.

Figure 11 shows the distribution of throat areas of tidal inlets (Exposed-2) estimated by the corresponding final step regression plotted against their corresponding values of measured throat areas. From this figure, it can be noticed clearly that the regressions shown in table 5 are quite reliable ones.

Similar analysis was performed on throat width. Namely, tidal inlets were classified into the following groups due to both exposure condition and magnitude of geometrical parameter, r_{hx} .

Fig.-11. Relationship between A and A_{est} .

Table 6. Classification of tidal inlets due to both exposure condition and magnitude of geometrical parameter, r_{hxb} .

Range of r_{hxb}	Groups classified	Sample number
$r_{hxb} < 0.007$	Exposed-1	11
	Protected-1	9
$0.007 \leq r_{hxb} < 0.030$	Exposed-2	41
	Protected-2	14
$r_{hxb} \geq 0.030$	Exposed-3	14
	Protected-3	6

For the inlets of each group, multiple regression analysis was performed stepwise on their throat width. Table 7 summarizes the final step regressions on them.

Table 7. Final step regressions on throat width of the classified inlets due to both exposure condition and geometrical parameter, r_{hxb} .

$Y = C_0 + \sum_{i=1}^m A_i X_i$													Groups
Step	C_0	P	E_{owd}	θ_{owd}	E_{pwd}	θ_{pwd}	E_{owv}	θ_{owv}	E_{pwv}	θ_{pwv}	V_n	R	Groups
9 th	-.833	.387	-.225	.540	-.061	-.168	.116	.447	.041	-.077	.999		Exposed-1
9 th	-1.058	.478	-.027	.106	.060	.140	.018	.051	-.023	-.341	.971		Exposed-2
6 th	.341	.583	.241	--	.200	--	-.293	--	.093	-.184	.822		Exposed-3
2 nd	-1.770	.594								-.693	.993		Protected-1
2 nd	-.630	.529								-.395	.983		Protected-2
2 nd	-2.996	.937								-.150	.990		Protected-3

In this analysis, quite high value of multiple correlation was also obtained for each group of tidal inlets except the case of Exposed-3. This fact indicates that former regressions on throat width were improved significantly by introducing geometrical parameter, r_{hxb} into the analysis.

Figure 12 shows the distribution of throat width(Exposed-2) estimated by the corresponding final step regression in table 7 plotted against their corresponding values of measured throat width. From this figure, it can be noticed clearly that the regressions shown in table 7 are quite reliable ones except the regression for Exposed-3.

Fig.-12. Relationship between B and B_{est} .

CONCLUSION

Tidal inlets on the Pacific coast of Japan were studied with respect to three characteristic variables of their throat sections:(1) Throat area;(2) Throat width; and (3) Direction of throat section. For each of these three variables, multiple regression analysis was performed stepwise by introducing external variables such as tidal prism, mean rate of tidal flow, wind energy, wave energy and so on one by one into a linear regression model. Exposure condition of throat section to open sea and geometrical parameters of inlets and bays were also introduced into the analysis. As a result, the following facts were found;

- 1). Quite reliable regressions are found between throat area and external variables if the tidal inlets are classified due to the magnitude of geometrical parameter, r_{as} which is the ratio of throat area to mean surface area of the backed bay. These regressions are shown in Table 5.
- 2). Quite satisfactory regressions are found between throat width and external variables if the tidal inlets are classified due to the magnitude of geometrical parameter, r_{hxb} which is the ratio of the maximum depth at the throat section to throat width. These regressions are shown in Table 7.
- 3). Direction of the penetrating wave energy is the most predominant external variable for the direction of throat section, and quite reliable regression shown below is obtained for the exposed inlets.

$$\theta_{ts}(\text{degree}) = -60.0 + 0.88 \theta_{pw}(\text{degree})$$

ACKNOWLEDGEMENT

This is a part of the author's doctoral dissertation submitted to the Graduate Division, University of California, Berkeley in 1975. The author is greatly indebted to Professor J.W. JOHNSON for his continual guidance to the completion of this work.

CHAPTER 98

TIDAL INLET FLOW DYNAMICS AND SEDIMENT MOVEMENT

J. L. Machemehl, N. E. Bird and A. N. Chambers
Center for Marine and Coastal Studies
North Carolina State University
Raleigh, North Carolina 27607

ABSTRACT

A numerical simulation model for the computation of tidal and fresh water flow exchange through a coastal inlet (developed by Amein¹) was modified and calibrated with field data (current, water surface elevation and bottom topography) for Lockwoods Folly Inlet, North Carolina. The calibrated model was then used to predict the changes in the flow regimes brought about by natural and manmade changes such as storms and dredging, respectively, and to predict the changes in flow regimes caused by the Lockwoods Folly River.

A generalized hypothesis of the patterns of sediment through and bypassing the inlet were formulated from an evaluation of the flow data and from an analysis of the orientation and structure of the bedforms observed in the inlet and on the offshore bar. The bedforms were analysed in the field and from an uncontrolled mosaic made from multi-spectral aerial photographs. Confirmation and refinement of the transport rates and movement patterns during ebb tide were made by introducing 454 kilograms (1000 lbs.) of fluorescent tracer sand in two colors into the inlet channels. The sediment movement through the inlet was established and correlated with the numerical simulation model. Confirmation and refinement of the transport rates and movement patterns during flood tide were made by introducing 680 kilograms (1,500 lbs.) of fluorescent tracer sand in three colors into the surf zone on the updrift beach and on the offshore bar. The sediment movement indicated the existence of bar bypassing (which was the dominant bypassing mechanism) and tidal flow bypassing. The bypassing mechanism of the inlet was found to agree with other atlantic coast inlets.

When used in conjunction with an analysis of bedform and tracer sand data the numerical simulation model was found to be a valid method for monitoring the high energy inlet environment.

INTRODUCTION

Description of the Study Area

Lockwoods Folly Inlet is approximately 10 miles west of the Cape Fear River and 9 miles east of Shallotte Inlet in Brunswick County, North Carolina. Holdens Beach borders the Inlet on the west while

Long Beach borders the Inlet on the east as shown in Figure 1. The beaches are almost east-west in direction. Holdens Beach is approximately 13,400 meters (44,900 ft.) long and has an average width of 490 meters (1600 ft.) while Long Beach is approximately 14,000 meters (46,000 ft.) long and has an average width of 400 meters (1300 ft.). Both the eastern end of Holdens Beach and the western end of Long Beach have been the victim of extensive and severe erosion. The Corps of Engineers² has stated that the eastern 1,800 meters (6,000 ft.) of Holdens Beach has experienced the highest rate of shoreline erosion in Brunswick County. Shoreline positions in the vicinity of the Inlet are shown in Figure 1.

The Atlantic Intracoastal Waterway (AIWW) separates the beaches from the mainland. The Lockwoods Folly River enters the AIWW 2100 meters (6900 ft.) east of the Inlet. In 1672 the Inlet was aligned with the Lockwoods Folly River.

Meterological and Oceanographical Data

On an annual basis the winds blow almost equally onshore and offshore with winds from the east occurring less frequently. During the period of this study the predominant wind was south to southeast at an average speed of 1.9 meters per second (3.7 knots). Wave height and direction data were available from the Corps of Engineers. The waves observed had a period of less than 9 seconds and a height of less than 5 ft. Unusual conditions during the study included a period of squalls and several days of storms.

The mean tidal range at Lockwoods Folly Inlet was 1.3 meters (4.2 ft.). The spring tidal range is 1.5 meters (4.8 ft.). The tides are semi-diurnal. The current velocities in the Inlet channel ranged from 129 to 160 cm/sec. (2.0 to 2.5 knots).

Objectives of Study

Lockwoods Folly Inlet is of particular interest as a study area. The Inlet is included in a proposed Corps of Engineers project for erosion control and hurricane protection of adjacent beaches. The Inlet is very active with strong tidal currents and shoaling sand bars. Wave energy is frequently concentrated near the Inlet due to refraction around the offshore sand bar which tends to aggravate the erosion.

The objectives of this study were:

- (1) To adapt Amein's numerical model to the Inlet,
- (2) To develop a generalized sediment movement pattern for the Inlet, and
- (3) To evaluate the natural bypassing system at the Inlet.

Numerical Simulation Model

Flow Computations. Amein's¹ numerical simulation model was modified and adapted to Lockwoods Folly Inlet. The numerical simulation model is based on the equations of unsteady flow with an implicit method for numerical simulation of the flow equations. A system of 28 nonlinear equations were solved using the generalized Newton iteration method.

The equations of unsteady flow are based on the conservation of mass and momentum. For the flow between Section 1-1 and 2-2 as shown in Figure 2, the equations can be written:

$$\frac{\partial Q}{\partial x} + \frac{\partial A}{\partial t} - q = 0 \dots \dots \dots (1)$$

And

$$\frac{1}{A} \frac{\partial Q}{\partial t} + \frac{V}{A} \frac{\partial Q}{\partial x} + V \frac{\partial V}{\partial x} = -g \frac{\partial y}{\partial x} -g \frac{\partial z}{\partial x} -g S_f \dots \dots \dots (2)$$

Where Q is the discharge, q is the point discharge, V is the velocity, g is the acceleration of gravity, y is the depth of flow and s_f is the friction slope.

A non-uniform rectangular grid in the x and t plane as shown in Figure 3 was used to simulate Equations 1 and 2 for numerical solution. The differential equation were simulated for a finite time Δt and a finite distance Δx . Equation 1 is simulated by

$$\frac{Q_{i+1}^{j+1} - Q_i^{j+1}}{\Delta x} + \frac{A_{i+1/2}^{j+1} - A_{i+1/2}^j}{\Delta t} - q_{i+1/2}^{j+1} = 0 \dots \dots \dots (3)$$

where

$$A_{i+1/2} = \int_{x_i}^{x_{i+1}} A(x) \Delta x \dots \dots \dots (4)$$

$A_{i+1/2}$ is approximated by $\frac{1}{2} (A_i + A_{i+1})$

Equation 2 is simulated by

$$\frac{1}{A_{i+1/2}^{j+1}} \frac{Q_{i+1/2}^{j+1} - Q_{i+1/2}^j}{\Delta t} + \frac{1}{(\bar{A}_{i+1/2})^2} \frac{1}{2\Delta x} \left\{ (Q_{i+1}^{j+1})^2 - (Q_i^{j+1})^2 \right\} +$$

FIGURE 2. Definition Sketch for Open Channel Flow.

FIGURE 3. Definition Sketch for a Network of Points on the x, t Plane.

$$\frac{1}{2\Delta x} \left\{ \left(\frac{Q_{i+1}^{j+1}}{A_{i+1}^{j+1}} \right)^2 - \left(\frac{Q_i^{j+1}}{A_i^{j+1}} \right)^2 \right\} + g \left[\frac{(y_{i+1}^{j+1} + z_{i+1}) - (y_i^{j+1} - z_i)}{\Delta x} \right] + \bar{S}_{f_{i+1}}^{j+1} = 0 \dots \dots \dots (5)$$

where

$$\bar{Q}_{i+1/2}^{j+1} = \frac{1}{\Delta x} \int_{x_i}^{x_{i+1}} Q(x, t) dx \dots \dots \dots (6)$$

and

$$\bar{S}_{f_{i+1/2}}^{j+1} = \frac{1}{\Delta x} \int_{x_i}^{x_{i+1}} S_f(x, t) dx \dots \dots \dots (7)$$

or

$$\bar{Q}_{i+1/2}^{j+1} = \frac{1}{2} \left\{ Q_{i+1}^{j+1} + Q_i^{j+1} \right\} \dots \dots \dots (8)$$

and

$$\bar{S}_{f_{i+1/2}}^{j+1} = \frac{1}{2} \left\{ S_{f_{i+1}}^{j+1} + S_{f_i}^{j+1} \right\} \dots \dots \dots (9)$$

The approximations of \bar{A} , \bar{Q} and \bar{S}_f are based on a linear assumption, and if Δx is sufficiently small the result would be valid.

The unknown variables in the simulation equations are the ones with the superscripts $(j + 1)$. The independent unknowns are the values of discharge and stage at grid points $(i, j+1)$ and $(i+1, j+1)$. For an inlet system the part of equations with four unknowns can be evaluated because the additional equations obtained from the boundary conditions and channel junctions will result in the same number of equations as there are unknowns.

Application: to Lockwoods Folly Inlet

For problem purposes the inlet was represented by 14 stations as shown in Figure 4. The channel system was divided into five channels with two junctions. The channel sections are:

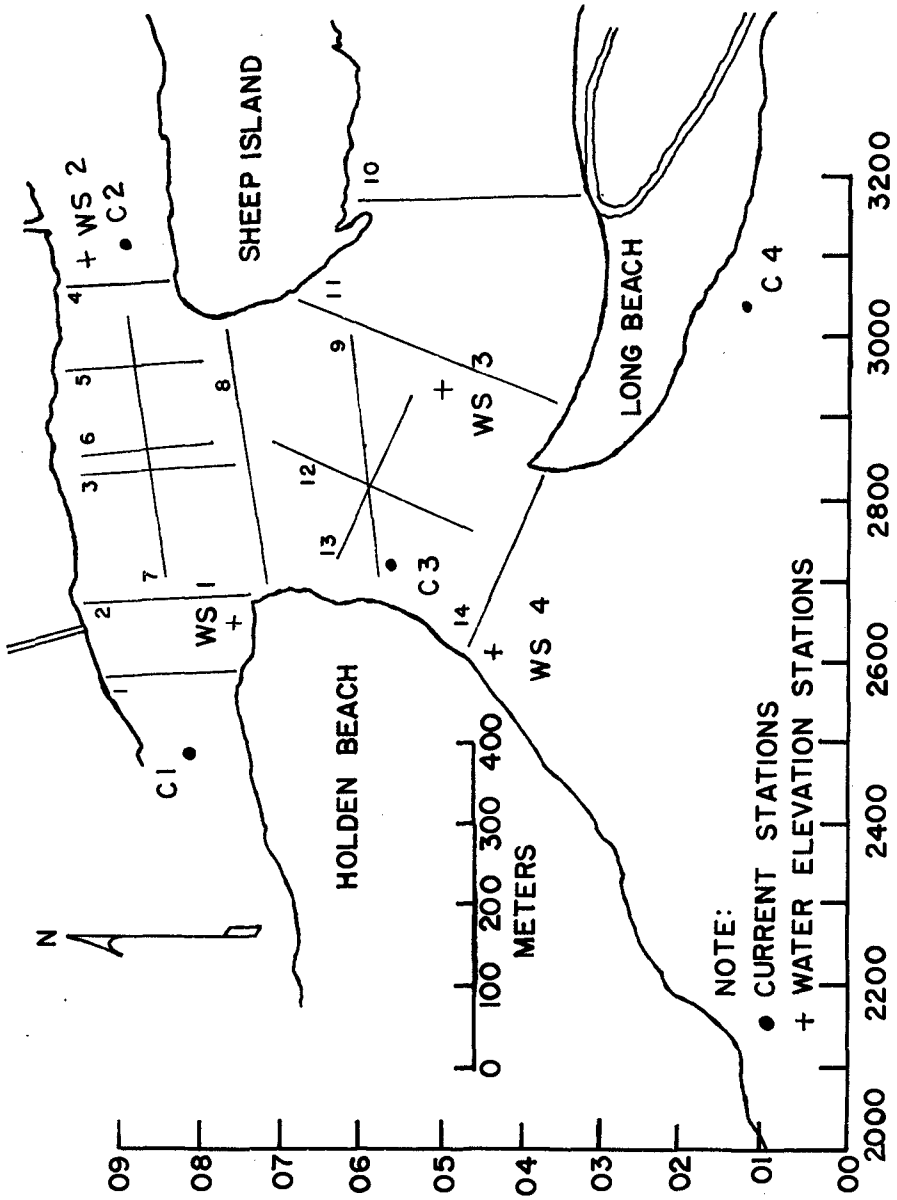

FIGURE 4. Flow Stations.

- 1, 2, 3
- 4, 5, 6
- 7, 8, 9
- 10, 11, 12
- 13, 14

The junctions are:

- 3, 6, 7
- 9, 12, 13

The value of x is taken as zero at junction 9, 12, 13 and increases to seaward. The flow during an ebb tide is in the positive x direction.

The simulated equations of conservation and momentum, Equation 3 and Equation 5 are abbreviated by:

$$F(Q_i, Q_{i+1}, y_i, y_{i+1}) = 0 \dots \dots \dots (10)$$

$$G(Q_i, Q_{i+1}, y_i, y_{i+1}) = 0 \dots \dots \dots (11)$$

$Q_i, Q_{i+1}, y_i, y_{i+1}$ are values of discharge and stage at time $j+1$. Since all unknown quantities are at time $j+1$ that superscript has been omitted. Equations 10 and 11 can be written for each channel section as follows:

Section 1, 2, 3

$$F(Q_1, Q_2, y_1, y_2) = 0 \dots \dots \dots (12)$$

$$G(Q_1, Q_2, y_1, y_2) = 0 \dots \dots \dots (13)$$

$$F(Q_2, Q_3, y_2, y_3) = 0 \dots \dots \dots (14)$$

$$G(Q_2, Q_3, y_2, y_3) = 0 \dots \dots \dots (15)$$

Section 4, 5, 6

$$F(Q_4, Q_5, y_4, y_5) = 0 \dots \dots \dots (16)$$

$$G(Q_4, Q_5, y_4, y_5) = 0 \dots \dots \dots (17)$$

$$F(Q_5, Q_6, y_5, y_6) = 0 \dots \dots \dots (18)$$

$$G(Q_5, Q_6, y_5, y_6) = 0 \dots \dots \dots (19)$$

Section 7, 8, 9

$$F(Q_7, Q_8, y_7, y_8) = 0 \dots \dots \dots (20)$$

$$G(Q_7, Q_8, y_7, y_8) = 0 \dots \dots \dots (21)$$

$$F(Q_8, Q_9, y_8, y_9) = 0 \dots \dots \dots (22)$$

$$G(Q_8, Q_9, y_8, y_9) = 0 \dots \dots \dots (23)$$

Section 10, 11, 12

$$F(Q_{10}, Q_{11}, y_{10}, y_{11}) = 0 \dots \dots \dots (24)$$

$$G(Q_{10}, Q_{11}, y_{10}, y_{11}) = 0 \dots \dots \dots (25)$$

$$F(Q_{11}, Q_{12}, y_{11}, y_{12}) = 0 \dots \dots \dots (26)$$

$$G(Q_{11}, Q_{12}, y_{11}, y_{12}) = 0 \dots \dots \dots (27)$$

Section 13, 14

$$F(Q_{13}, Q_{14}, y_{13}, y_{14}) = 0 \dots \dots \dots (28)$$

$$G(Q_{13}, Q_{14}, y_{13}, y_{14}) = 0 \dots \dots \dots (29)$$

This system consists of 18 equations and 28 unknowns. To find a solution ten additional equations are required. They may be written based on the conditions existing at the boundaries.

At each junction the energy level is the same, so that the energy, represented as $y + z + \frac{v^2}{2g}$, can be equated for each section at a junction. Abbreviating the energy equation as

$$H(Q_i, Q_{i+1}, y_i, y_{i+1}) = 0 \dots \dots \dots (30)$$

the following four equations can be written:

Junction 3, 6, 7

$$H(Q_3, Q_7, y_3, y_7) = 0 \dots \dots \dots (31)$$

$$H(Q_6, Q_7, y_6, y_7) = 0 \dots \dots \dots (32)$$

Junction 9, 12, 13

$$H(Q_9, Q_{13}, y_9, y_{13}) = 0 \dots \dots \dots (33)$$

$$H(Q_{12}, Q_{13}, y_{12}, y_{13}) = 0 \dots \dots \dots (34)$$

The law of conservation of mass at each junction is used to obtain the following two equations:

Junction 3, 6, 7

$$F(Q_3, Q_6, Q_7) = 0 \dots \dots \dots (35)$$

Junction 9, 12, 13

$$F(Q_9, Q_{12}, Q_{13}) = 0 \dots \dots \dots (36)$$

The water surface elevations provided by the tide gauges provide boundary data for four more equations. They are represented

as
 $F(y_1) = 0 \dots \dots \dots (37)$

$$F(y_4) = 0 \dots \dots \dots (38)$$

$$F(y_{10}) = 0 \dots \dots \dots (39)$$

$$F(y_{14}) = 0 \dots \dots \dots (40)$$

The system of Equations 12 through 29 and 30 through 40 provides twenty eight equations and twenty eight unknowns which can be solved by several methods.

Flow Model Input Data

Boundary conditions, bathymetry data, friction coefficient and initial flow rates were used as model input data. The boundary conditions were expressed as water surface elevations as a function of time. The values are listed in Table 1. The channel section parameters of cross sectional area and wetted perimeter are represented by linear algebraic equations as a function of depth *y*, measured from mean low water. The equations are:

$$A = A_0 + A_1 y \dots \dots \dots (41)$$

$$P = P_0 + P_1 y \dots \dots \dots (42)$$

*Above Mean Low Water

The values of A_0 , A_1 , P_0 , P_1 are listed for each station in Table 2. The area coefficients were obtained from the fathometer profiles. Since the channels were wide with respect to their depth, the wetted perimeter was considered to be the channel width. The friction coefficient was estimated and then adjusted until the computed results matched the observed values. The initial flow rates were considered for time zero using the current velocities measured with the current meter. Time zero was the predicted time of low tide. The values are listed in Table 3.

Flow Model Output Data

The output of the model was average discharge and elevation at each station. The computed results for station 14 (See Figure 4) are plotted along with measured data in Figures 5 and 6.

Flow Channels

The bedforms on the offshore bar were analyzed to determine the pattern of flow across the offshore bar. Figure 7 illustrates the ebb flow patterns (larger arrows indicate higher velocities).

SEDIMENT MOVEMENT

Hypothesis of Sediment Bypassing System

Bedform analysis provided the majority of the data used in the formulation of the preliminary hypothesis. Several areas of the inlet were found to carry the majority of the flow as it moved across the offshore bar. The two major areas included an ebb channel, a few meters offshore of Holden Beach, and another minor channel, when compared to the main inlet gorge, near the grid point 2700 (See Figures 4 and 7). These two areas on the offshore bar were found from bedform analysis to carry the highest velocities of flow. A disordered pattern of flow near grid point 2700 was indicated by the observed orientation of the bedforms, but flow over a large portion of the offshore bar tended to move toward the Holden Beach ebb channel. Bedform analysis showed little tendency of the flow to move seaward except through these two previously indicated ebb channels.

Flow data used in the formulation of the preliminary hypothesis included a wave refraction analysis of the area, current velocity measurements, and bathymetry profiles. Wave refraction analysis provided an idea of the location of areas at which extensive erosion would likely occur. The analysis by the Corps of Engineers² found these areas to be the eastern tip of Holden Beach and the western tip of Long Beach. A typical wave from S 60° W and a period of 8 seconds was used in the analysis. The wave refraction analysis also provided the Corps of Engineers with data used to estimate the amount of energy transmitted to the beach zone. From this data, the Corps of Engineers was able to estimate a net annual littoral drift of 245,000 cubic meters/year (320,000 cubic yards/year) in an easterly direction. Current velocity measurements showed the maximum ebb velocity in the inlet gorge to be 1.2 meters/second (4 feet/second) but this velocity was significantly reduced to 0.77 meters/second (2.5 feet/second) in the inlet gorge off Long Beach. This velocity reduction was due to a combination of the widening of the inlet as well as the passing of large volumes of water over the offshore bar. Bathymetry profiles obtained during the period of study showed a maximum depth of 5 meters (17 feet) in the inlet gorge. A depth of 1.5 to 1.8 meters (5 to 6 feet) covered the offshore bar at the high tide. The depth of the water flowing through the ebb channel along Holden Beach reached a depth of 1.5 meters (5 feet) at high tide.

FIGURE 5. Comparison of Computed and Observed Values of Discharge at Station 14.

FIGURE 6. Comparison of Computed and Observed Values of Stage at Station 14.

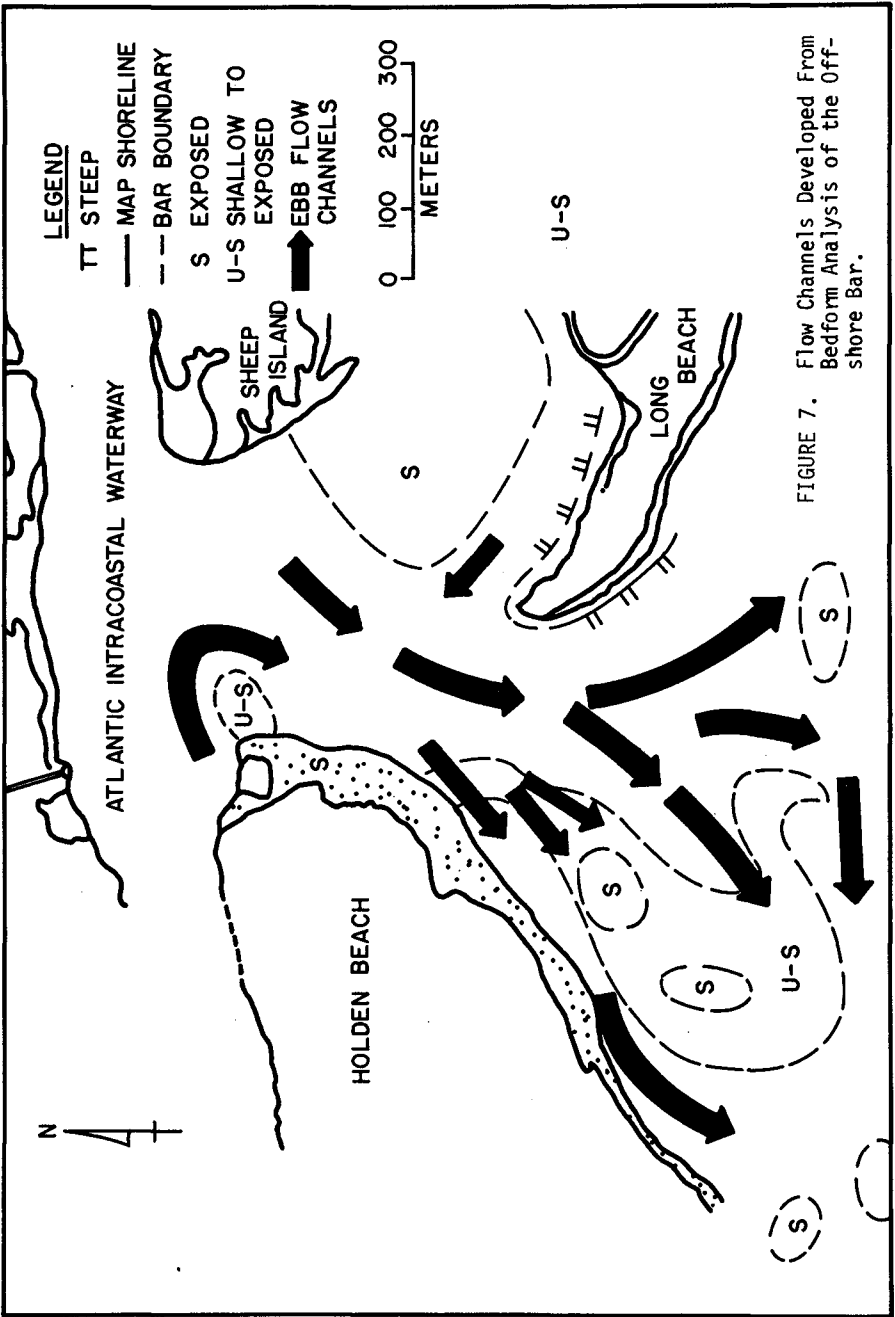

FIGURE 7. Flow Channels Developed From Bedform Analysis of the Off-shore Bar.

From an analysis of this data, a preliminary hypothesis of the bypassing system was developed. Sediment moved either toward the ebb channel near Holden Beach and was swept into the inlet gorge by the high tidal velocities, or else bypassed the inlet by moving across the offshore bar toward the 2700 grid point. This hypothesis was tested by introducing three different colored tracers onto the offshore bar along the 2000 grid line. Tracer tests were conducted during the ebb to flood cycle in an attempt to verify the pattern of movement indicated from the preliminary hypothesis.

Bar Bypassing Tests

The movement of the sediment across the bar was determined by introducing a fluorescent tracer onto the offshore bar in water soluble bags. The water soluble bags released the tracer onto the bar without allowing it to go into suspension in the water column. Signal green and fire orange were released on the offshore bar along grid line 2000. Blaze orange was raked into the beach between low and high tides along grid line 2000.

Core samples were taken during the tidal cycle. The samples were later analyzed by counting the number of tracer grains present in each sample under a long wave ultraviolet light. Samples containing 1-5 grains were considered to indicate a presence of tracer, while those with 6-10 grains indicated a low concentration; 11-20 grains indicated a medium concentration, and a sample containing more than 20 grains was considered to be highly concentrated. Eighty three core samples taken from the offshore bar were analyzed. Fifty percent of the core samples contained 5 or less grains. Six percent of the core samples did not contain any tracer sand, while twenty-two percent contained 20 or more grains.

Sediment Movement Tests

Ebb to Flood Tests. Two hundred twenty seven kilograms (500 lbs.) of signal green and fire orange tracer were released onto the offshore bar along grid line 2000. Blaze orange was raked onto the beach. The tracer sand entered the bar migration pattern. Samples were taken in the grid system between grid lines 2000 and 3000. Tracer was detected in high concentrations near the point of introduction. The tracer pattern was distinguishable along the shoreline of Holden Beach until it reached the Atlantic Intracoastal Waterway. Signal green tracer initially was stagnate at the end of the ebb channel. Within 24 hours the signal green tracer had established a pattern of movement across the bar. Fire orange tracer established two bypassing patterns; one similar to that which blaze orange initially followed, and the other a pattern of movement also across the offshore bar. Fire orange tracer traveled along the Holden Beach shoreline in an easterly direction until being influenced by the tidal currents of the gorge. From tracer analysis, fire orange tracer was found in detectable concentrations on Long Beach, possibly carried by the current of the inlet gorge. From tracer analysis, fire orange tracer was found in detectable concentrations on Long Beach after 24 hours. A second pattern across the offshore bar was established

as was the case with the blaze orange and signal green tracer. Two types of sediment bypassing were evident at the inlet. The first type tidal flow bypassing, was verified by the pattern of movement of fire orange tracer. The fire orange tracer moved across the offshore bar until being influenced by the tidal currents. The second type found at the inlet was bar bypassing, which from stability analysis was found to be the dominant type of bypassing in effect at the inlet.

Transport Rates Across The Offshore Bar

The transport rates were estimated from the tracer data. The actual transport rates were possible higher than the rates estimated. Blaze orange tracer was first detected at the 2600 grid line (considered to be the edge of the bar) 9 hours after its introduction onto the beach. The rate of transport across the offshore bar was estimated to be 1.8 cm.sec./ (0.059 ft./sec.). Neither signal green nor fire orange tracer was detected on the edge of the bar until 24 hours following introduction. The rate of transport for both tracers was computed to be 0.7 cm./sec.). (0.023 ft./sec.). A composite of the locations of the sediment tracer materials in the bar bypassing tests are shown in Figure 8.

CONCLUSIONS

The following conclusions were drawn from the study:

1. The numerical simulation model agreed reasonably well with the measured values for stage and discharge.
2. The sediment movement patterns in the inlet were related to tidal current patterns.
3. Sediment crossed the inlet from east to west.
4. The offshore bar will continue to grow as it traps and bypasses sand.
5. The inner shoal will continue to grow and encroach on the intracoastal waterway, thus necessitating periodic dredging.

CHAPTER 99

MEASUREMENT OF BED FRICTION IN TIDAL INLETS

by

A. J. Mehta¹, R. J. Byrne² and J. T. DeAlteris³

ABSTRACT

The flow characteristics and the stability of a tidal inlet are governed, among other factors, by the channel bed friction. In order to determine the bed shear stress regime and the frictional characteristics, near-bed velocity profiles were obtained at the throat sections of two inlets, John's Pass and Blind Pass, on the Gulf Coast of Florida. A specially designed steel cage with five current meters in a vertical array was used to obtain the profiles in the bottom one meter of the flow.

The profiles were found to be logarithmic but it is noted that, especially near the times of slack water, the effect of inertia becomes significant. However, during the major part of the flood or ebb flow period, frictional effects are dominant. In the fully rough regime of flow, the bed-shear stress - velocity relationship is found to follow the square law, with a constant, characteristic friction factor and Manning's n for each inlet. This friction factor is used in hydraulic formulas, based on uniform, steady open channel flow relationships, to obtain the tidal prism - throat cross-sectional area ratio, which is then compared with that obtained from flow discharge measurements. Agreements and discrepancies in the comparison are discussed. The relationship between the bed shear stress at incipient motion and the grain size at the bed is reviewed, and it is noted that the observed relationship at the two inlets does not agree with the well-known correlation of Shields for uniform sandy beds.

INTRODUCTION

The hydraulic and sedimentary regime of a tidal inlet depends strongly on the friction characteristics of the channel bed. These characteristics are most commonly defined in terms of a friction factor, a Chezy coefficient or a Manning's n . Standard texts on hydraulics give values of these coefficients, particularly Manning's n , for rivers and canals of various geometries and vegetative cover. However, for tidal inlets, information of this sort is limited and is only derived indirectly from measurements of tides and currents, rather

³ J. T. DeAlteris, Graduate Assistant, Virginia Institute of Marine Science, Gloucester Point, Virginia 23062.

than through direct near-bed measurements. Correspondingly, the variation of the bed shear stress with the tidal cycle and its relationship to the motion of the sediment over the bed is also established indirectly.

Experience and observation have established that the most characteristic morphologic feature of a tidal inlet is its throat section, and that flow measurements at this location yield important information on the hydraulics and the stability of an inlet. A significant part of the frictional resistance to the flow occurs at the throat, and the cross-sectional area of the throat, among other parameters, seems to correlate uniquely with the tidal prism through the inlet (O'Brien, 1969, 1976). Moreover, it has been shown that there appears to be a correspondence between this prism-area relationship for stable inlets and the regime equations for rivers and canals in non-silting, non-scouring equilibrium (Mason, 1973, Bruun, 1974), despite the fact that the flow in an inlet is primarily oscillatory. The question arises as to whether the direct measurement of near-bed velocity profiles at the throat can yield a friction factor, or a Manning's n , which may be considered to be characteristic for the inlet in a manner similar to that in a canal. Furthermore, inasmuch as the regime of sediment transport is dependent upon the bed shear stress, the determination of the latter as a function of the stage of tide should correlate with the bed sediment motion at the throat. These considerations led to the planning of the field experiments described in this paper, with the following specific objectives:

- (1) To measure the velocity distribution in the bottom one meter of the flow at the throat section of an inlet.
- (2) To simultaneously record the state of bed motion at the throat.
- (3) To determine characteristic friction coefficients from the measured data.
- (4) To obtain the tidal prism-throat cross-sectional area ratio based on hydraulic formulas involving the above coefficients, and to compare this ratio with that obtained from flow discharge measurements and a survey of the throat.
- (5) To establish the relationship between the critical shear stress for the bed grain motion and the grain size at the throat.

HYDRAULIC RELATIONSHIPS

The simplest method of analysing and testing inlet hydraulic data is that based on the generally accepted correspondence between inlet hydraulics and steady, uniform open channel flows. In the turbulent regime, the logarithmic profile for the flow velocity u is

$$\frac{u}{u^*} = B + \frac{1}{\kappa} \ln \frac{Z}{K} \quad (1)$$

where u^* = friction velocity, κ = Karman constant (= 0.40), $Z = zu^*/\nu$, $K = ku^*/\nu$ (wall Reynolds number), z = elevation above the theoretical bed, k = bed roughness and ν = kinematic viscosity of water. The depth-mean velocity \bar{u} can be

obtained from Eq. (1) for a depth of flow h (assuming $h \gg z_0$)

$$\bar{u} = 2.5u^* \left[\ln \left(\frac{h}{z_0} \right) - 1 \right] \quad (2)$$

and Manning's n and k from

$$n = \frac{1.49h^{1/6}}{g^{1/2}} \frac{u^*}{\bar{u}} \quad (3)^1$$

$$k = (31.6n)^6 \quad (4)^2$$

Finally

$$B = 2.5 \ln \left(\frac{k}{z_0} \right) \quad (5)$$

where z_0 is the value of z at $u = 0$.

It can be shown that the sensitivity of Manning's n to the depth h may be expressed as

$$\frac{\Delta n}{n} = \left[\frac{1}{6} - \frac{1}{\left\{ \ln \left(\frac{h}{z_0} \right) - 1 \right\}} \right] \frac{\Delta h}{h} \quad (6)$$

Here Δn and Δh are small changes in n and h , respectively. The purpose of introducing Eq. (6) is to test the effect of changes in depth due to the tide on the computation of Manning's n . If this variation is small, it would be acceptable to ignore the range of tide in the inlet for the purpose of the hydraulic computations.

The bed shear stress τ_0 ($=\rho u^{*2}$) is defined as

$$\tau_0 = \frac{f}{4} \rho \frac{\bar{u} |\bar{u}|}{2} \quad (7)$$

where, in the fully rough range of flow ($k > 70$), the friction factor f depends solely on the ratio of the bed roughness to the depth of flow (for a wide channel).

$$\frac{1}{\sqrt{f}} = 2.34 + 0.87 \ln \frac{h}{k} \quad (8)$$

The foregoing relationships are strictly applicable to steady, uniform wide open channels only, but Eqs. (1) through (8) should be applicable to tidal inlets with the following characteristics:

- (1) no significant density stratification, i.e. low fresh water discharge relative to the tidal prism

¹The foot-pound-second units are used in the computations throughout this paper; metric units have been used in data presentation only.

²Eq. (4) is also known as Strickler's equation.

- (2) low ratio of tidal amplitude divided by the mean depth of flow
- (3) relatively large width to depth ratio
- (4) negligible wave-induced turbulence
- (5) negligible effect of the inertia of the mass of water in relation to frictional dissipation at the bed.

PRISM-AREA RELATIONSHIP

The tidal P is by definition related to the cross-sectional mean maximum velocity \bar{u}_{max} in an inlet according to

$$P = \frac{\bar{u}_{max} A_c T}{\pi C_K} \quad (9)$$

where A_c = throat cross-sectional area below MWL, T = tidal period and C_K is a coefficient that accounts for the deviation from the sinusoidal variation of the velocity in the inlet (Keulegan, 1967). Keulegan and Hall (1950) found that $C_K = 0.86$ agrees well with most inlet data. In Eq. (7), at $\bar{u} = \bar{u}_{max}$, $\bar{\tau}_o = \bar{\tau}_{o,max}$, and eliminating \bar{u}_{max} with the help of Eq. (9) yields

$$\frac{P}{A_c} = \sqrt{\frac{g}{T\rho}} \sqrt{\bar{\tau}_{o,max}} \frac{T}{\pi C_K} \quad (10)$$

If f , $\bar{\tau}_{o,max}$ and T are measured, P/A_c can be calculated and compared with a corresponding ratio in which P is obtained directly from volumetric flow discharge measurement and A_c determined by a survey.

By assuming a depth as well as width averaged velocity as in an open channel, and a relatively small ratio of the tidal amplitude a_c at the throat divided by the cross-sectional mean depth \bar{h} , Krishnamurthy (1974) obtained

$$\frac{P}{A_c} = 1.25 u_{cr}^* T \left(1 + \frac{2a_c}{\pi h} \right) \left[\ln \left(\frac{10 \cdot 93 \bar{h}}{k} \right) \right] \quad (11)$$

Here it is also assumed that the inlet is in a state of non-silting, non-scouring equilibrium, and that in such an inlet, on the average, the friction velocity $u^* = u_{cr}^*$, corresponding to τ_{ocr} , the critical bed shear stress for the incipient motion of the grains on the bed.

An agreement between the measured P/A_c and that derived from the above two equations, particularly Eq. (10), would clearly point to the relevance of the measured value of the friction factor at the throat.

THE INLETS

Two inlets, John's Pass and Blind Pass, shown in Fig. 1, were selected for the purpose of the measurements. These inlets connect the Gulf of Mexico to Boca Ciega Bay, near Tampa, Florida. Despite their relative proximity, the two inlets have disparate morphological characteristics, as seen from Table 1.

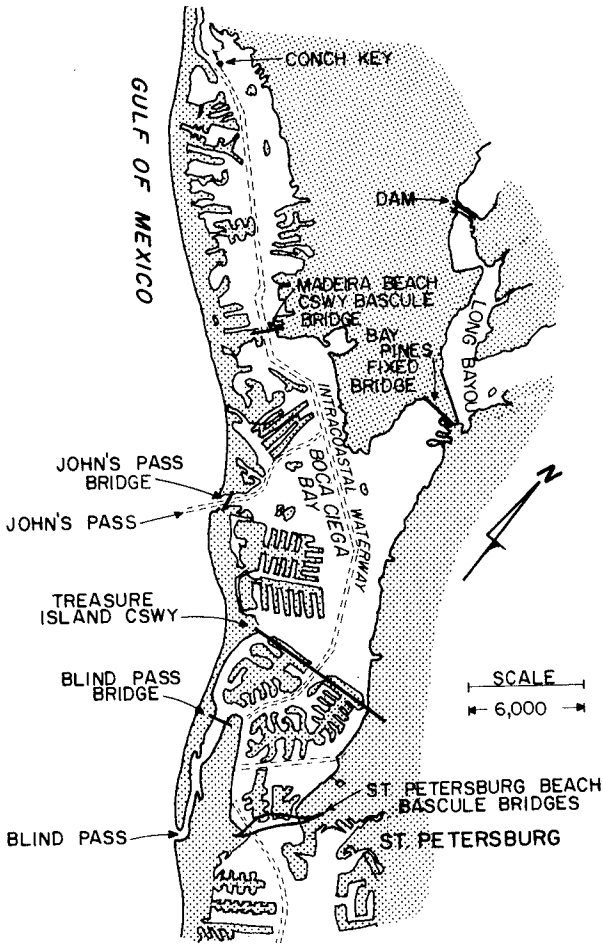

Fig. 1. John's Pass and Blind Pass Connect the Gulf of Mexico to Boca Ciega Bay. The City of Tampa (not shown) is due Northwest.

TABLE 1

Inlet	Mean Depth \bar{h} at the Throat below MWL (ft)	Throat Cross-section A_c below MWL (ft ²)	Length of the Channel (ft)	Jetties	Stability
John's Pass	16.0	9,500	2,200	one	Good
Blind Pass	5.2	440 ³	1,200	two	Intermediate

John's Pass is a stable inlet with no major problem of sedimentation. The 1,200 ft. long Blind Pass channel is followed by another 6,000 ft. long and relatively wider channel which enters Boca Ciega Bay. This second segment of the channel may, however, be considered to be a part of the bay itself, as currents in this channel are relatively low (Sanchez-Diaz, 1975). The inlet cross-section has been decreasing steadily during the past century (Mehta and Adams, in press), and there have been some shoaling problems near the entrance, but the inlet has remained open. Figs. 2 and 3 give a closer look at these inlets, and indicate the locations of the throat sections. The penetration of ocean waves at these sections is minimal. Currents and salinity profiles indicated that the fresh water outflow at these inlets is rather small and that density stratification is not significant. The bed at the throat of John's Pass is laden almost entirely with relatively large pieces of shell. At Blind Pass, shells are found in patches surrounded by relatively fine sand.

EQUIPMENT

The essential equipment consisted of a vertical array of five ducted impeller current meters fitted inside a steel cage which could be lowered at the desired location from a specially designed A-frame on a barge. The following is a brief description of the current meter and the cage.

The current meter (Fig. 2): This consisted of a 3 in. o.d. and 6 in. long stainless steel duct containing an axially mounted impeller with six epoxyglas blades. Two small magnets attached to the tip of two of the blades closed a reed switch mounted on the duct. The circuit was connected through a long insulated wire to a deck unit which could count the actuation caused through the rotation of the impeller. The counts were calibrated to yield the current speed (Byrne and Boon, 1973).

The cage (Fig. 2): This consisted of a framed cube, 4 ft. on the edge, constructed of 1 x 3/16 in. angle iron. For stability at the bottom of the inlet, the base of the cage was weighted with four 75 lb. lead weights fastened, one each, to the bottom corners of the frame. The vane assembly (which helped align the meters along the direction of flow) was fabricated from a 45 in. section of channel aluminum, modified to accept the mounting arms of five current meters, which were installed at 21.6, 36.2, 51.4, 75.6 and 103.6 cm above the base of the cage. Outputs from the current meters were monitored on a barge, anchored at a position close to the cage. A more detailed description of the equipment

³ Based on data obtained in 1974 prior to the construction of new jetties.

Fig. 2. John's Pass. The Inset Shows the Steel Cage with the Current Meters and the Vane Assembly.

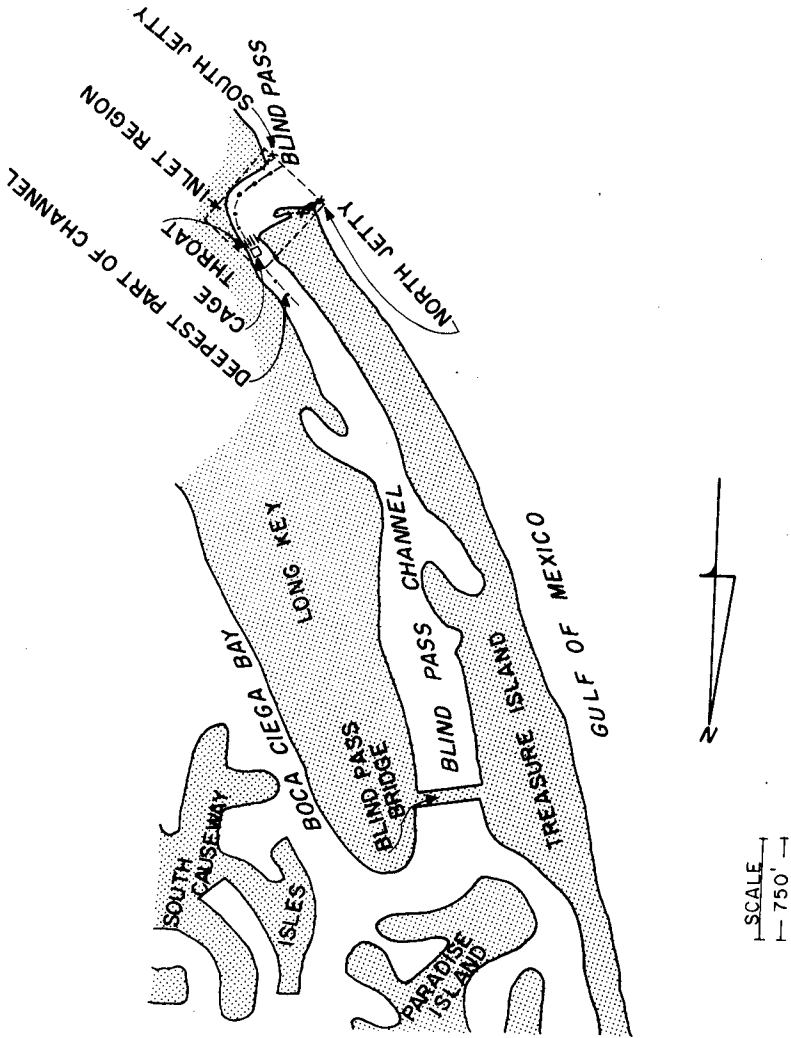

Fig. 3. Blind Pass. Note the Narrow Throat Section.

and its use may be found elsewhere (Mehta, Byrne and DeAlteris, 1975).

FIELD STUDY

The original plan was to obtain near-bed velocity profiles at a number of points across the throat by moving the cage from point to point, but time limitation and the presence of very heavy seaweed concentrations in the flow along certain parts of the channel at John's Pass permitted measurements at one location only, namely at the deepest part of the channel near the throat (Fig. 2). At Blind Pass, due to the narrow throat section, the measurements were also taken at one location only (Fig. 3) close to the deepest channel.

At John's Pass, data were collected on August 5, 6, 7, 8 and 9, 1974, and on August 14 at Blind Pass. On each day, counts corresponding to each of the five current meters were simultaneously recorded from the deck units on the barge every few minutes, for a total time period ranging from slack to slack (one-half tidal cycle). At John's Pass measurements were obtained over floodtides and at Blind Pass over an ebbside. The depth of water below MWL at the site of the cage was 25 ft. at John's Pass and 12 ft. at Blind Pass.

In addition to the near-bed profiles a single current meter at John's Pass obtained a few profiles over the entire depth. At Blind Pass, a current meter was installed near the throat to yield a continuous velocity measurement there. Tides were measured at both the inlets and a set of six stilling wells were installed at Blind Pass to measure the water surface slopes near the throat. Divers made observations on the state of sediment motion at the bed.

DATA ANALYSIS

Due to fouling by seaweed, divers had to clean the meters from time to time. For data analysis, any profile with less than four data points was considered unsuitable. As a result, for example, all the profiles obtained on August 6 had to be eliminated.

Fig. 4 shows examples of the velocity profiles obtained at John's Pass on August 9, and Fig. 5 shows profiles at Blind Pass on August 14. As in these examples, almost all the profiles were found to be logarithmic, according to Eq.(1). The ratios, a_c/h , of the average amplitude of tide to the depth of flow at the cage during the experiment were as follows: .

TABLE 2

Inlet	a_c (ft)	h (ft)	a_c/h (%)
John's Pass	0.76	25	3
Blind Pass	1.36	12	11

Thus at John's Pass, the tidal amplitude was 3% of the depth at the cage and at Blind Pass it was 11%. Using a typical value of $z_0 = 0.007$ ft., and these percent changes in depth, Eq.(6) gives the corresponding $\Delta n/n$ as less than 0.1% at John's Pass and less than 0.2% at Blind Pass. It can be shown likewise, that the percent changes in \bar{u}^2 corresponding to the above changes in depths are also negligible. Thus in Eqs.(3) and (7), the effects of tidal

Fig. 4. Typical Examples of Near-bed Velocity Profiles at John's Pass, August 9, 1974.

variation on the value of n and f , respectively, may be ignored. In all computations, therefore, only the depth below MWL at the site of the cage was used.

The question of the effect of inertia was dealt with by observing the behavior of the coefficient M

$$M = \frac{\frac{\partial \bar{u}}{\partial t}}{\frac{f}{8h} \bar{u} |\bar{u}|} \quad (12)$$

which is the ratio of the temporal acceleration term divided by the friction term in the momentum equation.⁴ In Fig. 6, \bar{u} and M are plotted for the floottide on August 9 at John's Pass. From slack to slack, the period of flood is 5 hr. 45 min. It is observed that at times of fluctuation in current speeds M becomes large, but its value is most significant close to times of slack water, where the inertia effect is clearly dominant. Consider for example the time period during which $|M|$ is equal to or greater than unity. Ignoring those times when this occurs for short intervals, and taking only the periods close to slack waters, the total time interval when $|M| \geq 1$ is 45 min., which is only 19% of the flood period. Measurements on other days at John's Pass yielded similar values, and at Blind Pass, on August 14, $|M| \geq 1$ only during 11% of the ebb. These observations tend to indicate that it is not unreasonable to use steady, uniform flow formulas for tidal inlet hydraulics although, clearly, phenomena close to slack water are likely to be strongly influenced by the effects of inertia.

In all calculations, \bar{u} , as computed from Eq. (1), was used instead of one which may be obtained from a measured velocity profile over the entire depth of flow. This is because only a few of the latter were obtained, and it was found that the average velocities obtained from these did not differ to any appreciable extent from those obtained from the near-bed profiles.

RESULTS

Fig. 7 is an example of the variation of the bed shear stress τ_o with time, on August 8, at John's Pass. From recorded diver observations on the state of bed motion, it is possible to determine the corresponding bed shear stress, as indicated on the figure.

In Fig. 8, τ_o is plotted against \bar{u} on logarithmic co-ordinates for all the data points from John's Pass. Of particular importance here is the observance of the square law according to Eq.(7), with a constant friction factor f . The straight line gives $f = 0.027$, Manning's $n = 0.026$ from Eq.(3) and bed roughness $k = 0.31$ ft. from Eq.(4). Fig. 9 shows similar data for Blind Pass, with $f = 0.021$, $n = 0.020$ and $k = 0.07$. A few bed shear stress values obtained from surface slopes at Blind Pass were found to be nearly twice as large as those obtained from the velocity profiles, as these included losses at the channel bend (Fig. 3) as well (Mehta et al., loc. cit.).

In both, Figs. 8 and 9, at low velocities, the data points begin to

⁴The temporal acceleration term is much more significant than the spatial acceleration term in the flow through the channel itself. The flow may therefore be considered to be uniform.

Fig. 6. Effect of Inertia Relative to Friction in Tidal Flood Flow through John's Pass, August 9, 1974.

Fig. 7. Time Variation of τ_0 at John's Pass, August 8, 1974.

Fig. 8. Relationship between τ_0 and \bar{u} , John's Pass.

Fig. 9. Relationship between τ_0 and \bar{u} , Blind Pass.

deviate systematically from the straight line, such that the measured shear stress is lower than that predicted by the line. This is, it can be shown, because these data points are in the transition range of flow, with $K < 70$ (Mehta, et al., loc. cit.). The friction factor f initially decreases in this range, as in an open channel, giving lower τ_o values.

At flow velocities near 4 fps and greater, another deviation from the straight line is observed in Figs. 10 and 11. This deviation is such that the measured friction factor f is greater than that predicted by the straight line, and is possibly due to a changing bed roughness associated with a re-orientation of the bed at these high velocities.

In Figs. 10 and 11, the coefficient B of Eq.(1) calculated from Eq.(5) has been plotted against K , for John's Pass and Blind Pass, respectively. A comparison with the well-known experimental relationship obtained by Nikuradse for beds of relatively uniform sand grain roughness shows that the B values from the two inlets are generally higher than those indicated by the curves. Furthermore, for high values of K , B indeed attains a constant value; $B = 8.65$ for John's Pass and 8.60 for Blind Pass, as opposed to 8.50 for the Nikuradse data. These higher values of B are most likely to be due to the non-uniformity of the bed material in the inlets (Yalin, 1972). Thus in the case of John's Pass, where the proportion of shell on the bed is greater than at Blind Pass, the B value is correspondingly larger. This fact is clearly reflected in the values of the bed roughness k as well.

Measured tidal prisms and the tide ranges at the two inlets are given in Table 3. The prism through John's Pass is an order of magnitude larger than that through Blind Pass. Indeed, the former inlet is primarily responsible for the flushing of the northern portion of Boca Ciega Bay.

BED MOVEMENT

The motion of sand and shell was observed by the divers and is summarized in Table 4.

TABLE 4

Observation	τ_o (approx. range) (psf)
No detectable motion	0.000 - 0.010
Incipient motion of individual sand grain	0.010 - 0.015
Creeping motion of sand and "small" shells	0.015 - 0.045
Movement of individual "large" shells	0.045 - 0.060
Movement of the entire shell bed	0.060 -

Ranges of bed shear stress τ_o were determined by matching the times of observation with τ_o in plots such as Fig. 7. Since the diver observations were somewhat subjective, and the sediments in the two inlets are similar (the median, shell free sand diameter is 0.22 mm. at both the inlets), the classification of bed movement in Table 4 ignores any differences in bed motion between the two inlets. In the table, "small" refers to shell pieces less than approximately 5 mm. in diameter, and "large" to pieces larger than 5 mm. in diameter.

Because of the relatively small quantities of fine sand and shell pieces in motion at low flow velocities, attempts to collect the sediment in bed-load traps were not successful. Also, at high velocities, the divers were unable to enter the waters, and therefore could not make observations on the sediment motion when the currents were maximum.

DISCUSSION

A way in which the relevance of the friction factors derived from measurements at the throat may be determined is by testing Eqs.(10) and (11) against P/A_c determined from discharge measurements. Table 5 summarizes the calculations.

TABLE 5

	P/A_c (ft)	
	John's Pass	Blind Pass
Eq. (10)	5.12×10^4	8.81×10^4
Eq. (11)	3.04×10^4	4.26×10^4
Measured	4.08×10^4	8.54×10^4

The ratio for John's Pass represents a four day average ($\tau_{o\max} = 0.16, 0.11, 0.10$ and 0.06 psf at John's Pass and 0.13 psf at Blind Pass). In the estimation of $\tau_{o\max}$, a smooth curve was fitted to each of the τ_o -time curves, and the maximum was selected. A correction to this maximum was applied according to

$$\bar{\tau}_{o\max} = (\bar{u}_{\max} / \bar{u}_{\max}^2) \tau_{o\max} \quad (13)$$

to account for the transverse velocity profile. Here, \bar{u}_{\max} and τ_{\max} are values at the location of the cage, $\bar{\tau}_{\max}$ and \bar{u}_{\max} are the corresponding cross-sectional averages. It was found that $\bar{u}_{\max}/u_{\max} = 0.90$ and 0.86 , at John's Pass and Blind Pass, respectively. Also, measurements gave $C_K = 1.0$ and 0.84 , respectively.

Table 4 indicates that Eq.(10) predicts a P/A_C which is larger than the measured value by 25% at John's Pass and 3% at Blind Pass. This implies that the appropriate value of the friction factor f in Eq.(10) should be 1.56 times the directly measured value (0.027) at John's Pass, but only 1.06 times the measured value (0.021) at Blind Pass.

It is interesting to note that, considering the assumptions involved, Eq.(11) (with $u_{Cr}^* = \sqrt{\tau_{ocr}/\rho} = 0.079$ fps) agrees reasonably with the measurements at John's Pass, but predicts a substantially lower P/A_C at Blind Pass. A possible explanation for this is that Blind Pass is not a very stable inlet. This is reflected by the rather large measured P/A_C value as well.

Another comparison can be made through Eq.(8). This equation gives $f = 0.026$ and 0.022 , which is in excellent agreement with the measurements. These values are obtained by using the local mean depth $h = 25$ ft. and 12 ft., respectively, at the two inlets. If the cross-sectional mean depths \bar{h} from Table 1 are used, $f = 0.030$ and 0.027 respectively, at John's Pass and Blind Pass.

It is worthwhile to compare the observed relationship between the critical stress at incipient motion and the grain size, with the well-known relationship obtained by Shields for channels with sand beds in the fully rough range of flow:

$$\tau_{ocr} = 0.056 (\gamma_s - \gamma) d_{50} \quad (14)$$

where γ_s is the unit weight of the sand grain ($=169$ lbs/ft³), $\gamma = \rho g = 64$ lb/ft³ and d_{50} is the median grain size. Using $d_{50} = 0.22$ mm $= 0.0007$ ft. gives $\tau_{ocr} = 0.004$ psf, whereas the observed value was close to 0.013 psf. It has been shown elsewhere (Mehta and Christensen, 1976) that this discrepancy is due to the presence of a rather large ratio of the bed roughness k to the diameter d_{50} , and also due to the differences in the velocity profiles from that in a channel with a uniform sand grain bed.

CONCLUSIONS

1. The velocity profiles in the bottom one meter of the flow near the deepest part of the channel throat section were found to be logarithmic at John's Pass and Blind Pass.
2. The effect of inertia was found to be important in relation to frictional dissipation near the times of slack water. Elsewhere, this effect may be considered to be relatively insignificant.
3. The bed shear stress and the depth-mean velocity derived from these profiles were found to be related by the square law in the fully rough range of flow, with a characteristic friction factor and a Manning's n for each inlet.
4. The velocity coefficient B was found to vary in a manner similar to that in a wide open channel, but B values were generally higher for the two inlets.

5. The tidal prism-throat cross-sectional area ratio, as determined from a hydraulic relationship, Eq.(10), agreed with the directly measured ratio at Blind Pass, but at John's Pass, there was a difference, indicating that f , as determined from the measurements, was 56% too low.
6. Shields' criterion for the incipient motion of sand grains predicted a critical shear stress which was about one-third of the observed value.

ACKNOWLEDGEMENT

Thanks are due to Dean O'Brien for his help in the planning and execution of the field operation. Dr. Wiseman of the Coastal Studies Institute, L.S.U., provided data on salinity measurements at John's Pass. The assistance of Chris Jones in the computations is acknowledged. The work described here was supported by funds from the Office of Naval Research, Geography Programs, Contract N00014-68-A-0020, Project NR-388-106.

CHAPTER 100

MORPHODYNAMICS OF A WAVE-DOMINATED RIVER MOUTH

L.D. Wright
Coastal Studies Unit, Dept. of Geography
University of Sydney
Sydney, N.S.W. 2006 Australia

Abstract

The mouth of the Shoalhaven River on the southeast coast of Australia is subject to direct attack by high energy waves and offers a general model of wave-dominated river-mouth deposition. During river floods seawater is completely flushed from the lower reaches of the channel and significant quantities of sandy bed load and suspended silts are debouched into the Tasman Sea. However, breaking waves cause intense mixing between the effluent and ambient waters while wave-induced mass transport and setup oppose and partially impound outflow. Unusually rapid deceleration and lateral effluent expansion result. Sediments accumulate in the form of a broad crescentic river-mouth bar with its crest situated about 2 channel widths seaward of the outlet and as broad shallow subaqueous levees capped by swash bars. Post-depositional shoreward return of sands by shoaling waves produces a constricted outlet. During low river stage wave setup enhances flood tidal currents and partially inhibits ebb tide outflow. This leads to a gradual shoreward migration of the river-mouth bar, a narrowing of the constricted outlet and to upstream migration of river-mouth sands into the lower reaches of the channel.

Introduction

Recent studies show that river mouth depositional patterns depend on the relative contribution from three primary processes which derive their energy directly from the river outflow and on modifications by marine processes. The three primary processes are: (1) turbulent diffusion, (2) turbulent bed friction; and (3) buoyant expansion. Major modifying processes include those induced by tides and waves. Depositional patterns at many river mouths may be explained largely in terms of one or more of the primary processes. The well-studied mouths of the Mississippi, for example, are dominated by buoyant expansion and experience minimal influence from tides and waves (Wright and Coleman, 1974). In contrast, many river mouths are attacked directly by high wave energy. Wave-current interactions cause pronounced modifications to effluent behavior while waves directly redistribute the river mouth sediments contemporaneously with their initial discharge. Some notable examples of wave-dominated river mouths include the mouths of the Senegal (West Africa); Sao Francisco and Jequitinhonha (Brazil); Magdalena (Columbia); Orange (South Africa); Burdekin (Queensland, Australia); and Shoalhaven (New South Wales, Australia). The process signatures and depositional morphologies of these river mouths show common attributes among themselves but differ markedly from those of river-dominated or tide-dominated river mouths. The high-energy southeast coast of Australia offers excellent examples of wave-dominated river mouths. This paper summarizes 18 months of observations at the mouth of the Shoalhaven River about 150 km south of Sydney, Australia.

Environment of the Study Area

The Shoalhaven River Delta and estuary (Fig.1) are situated near the township of Nowra, New South Wales on the east coast of Australia. By world standards the Shoalhaven is a small river although it is the largest on the south coast of New South Wales. The river's catchment has a total area of 7250 km² and receives an average rainfall of 760 mm. The mean discharge rate at the Nowra Bridge near the head of the delta is only 57.3 m³ sec⁻¹; however, flows of over 5,000 m³ sec⁻¹ occur at a return interval of 10 years. Flows in excess of this magnitude occurred in both 1974 and 1975. The bed load of the river consists of fine to medium sands of angular to rounded quartz, feldspar and rock fragments. During flood the river also transports high concentrations of suspended silts and clays.

The Shoalhaven has built a Recent deltaic plain 85 km² in area, extending from Nowra to the coast. At the present time the discharge of the Shoalhaven enters the sea via 2 outlets; the Crookhaven entrance which is situated in a relatively protected environment in the lee of Crookhaven Heads and the Shoalhaven entrance which is exposed to the full spectrum of wave conditions. The protected Crookhaven entrance provides a low energy "control" example for comparing the behavior of the wave-dominated Shoalhaven entrance. The river debouches into Shoalhaven Bight, a broad, arcuate embayment bordering the Tasman Sea. The nearshore bed, though flatter than that fronting neighboring coastal sectors, is relatively steep, with an average gradient of 0° 45' and a concave-upwards profile. Water depths of 20 metres occur within 1.5 km from the present shoreline.

The tides of the region are semidiurnal with a mean range of 1.2 metres and a spring range of 1.8 metres. The combined tidal prism of the Shoalhaven and Crookhaven estuaries is estimated to be about 23 x 10⁶ m³ during spring tides. This exceeds the base flow by 18 times but is only 1/5 the volume of extreme flood discharge. The river mouth and adjacent coastline are dominated by high energy waves. The region experiences a highly variable wind wave climate superimposed on persistent refracted long period southerly and southeasterly swell. Deepwater wave power averages 178 Watts per cm of crest width and exceeds 1250 Watts cm⁻¹ for 1% of the time. Significant deepwater wave height exceeds 1.5 metres 50% of the time, is greater than 3 metres for 5% of the time and has approached 10 metres several times over the past 2 years.

Field Techniques

This paper is based largely on direct field observations made over the period August 1974 to January 1976. Observations of outflow behavior, estuarine circulation, wave characteristics and resultant morphologic patterns were made over a wide range of hydrologic and marine energy conditions. Bathymetric surveys in the Shoalhaven estuary and offshore were conducted using a Ratheon model DE 731 echo sounder; positions were determined by theodolite and horizontal sextant angles. Autolab salinity-temperature meters were used for S-T profiling and Toho-Dentan direct-reading current meters were used for current profiling. Drogues and dye were employed to determine larger scale flow patterns. Continuous tidal and river stage height data were recorded by means of 5 Bristol recording tide gages maintained by the Shoalhaven Shire Council and by a Stephens water level recorder. Incident deepwater wave characteristics were measured by the Maritime Services Board of New South Wales' offshore wave rider located 5 km seaward of the entrance to Botany Bay (100 km north of the study region).

Figure 1: The Shoalhaven Delta

Flood-Stage Outflow

Significant transport and deposition of river-derived sediments at and immediately upstream from the mouth of the Shoalhaven takes place primarily during river flood when seawater is flushed from the estuary. During floods the beach which often seals the Shoalhaven Heads entrance is breached (or widened if the entrance has not been previously sealed) and sands are debouched through the outlet into Shoalhaven Bight. The Shoalhaven experienced extreme flood conditions in August 1974 and again in June 1975. The discharge rates associated with both floods substantially exceeded the 10 year discharge rates: peak discharge associated with the August 1974 and June 1975 floods were $7400 \text{ m}^3 \text{ sec}^{-1}$ and $6900 \text{ m}^3 \text{ sec}^{-1}$ respectively at the Nowra Bridge 13 km upstream from the entrance (Dept. Public Works, N.S.W., 1975). During the August 1974 flood observations were restricted logistically to field reconnaissance; however, field data were obtained during the June 1975 flood.

Figure 2 shows water surface elevation curves from Nowra Bridge and Shoalhaven Heads encompassing the period preceding, during and immediately following the flood (June 19-25, 1976). The portion of the curves for the period June 19-20 indicates the normal low-stage surface behavior and demonstrates the tidal dominance of the lower channel. It is apparent from this low-stage curve that tidal amplitude undergoes only slight attenuation and deformation over the distance from the entrance to Nowra. A tidal lag of about 1 hour 45 minutes is also evident. With the onset of the flood water levels rose abruptly at both the upstream and river mouth stations. A flood peak of 5.09 metres at Nowra (2130 hrs. on June 21) was accompanied by a peak of 2.15 at the Shoalhaven Heads entrance, thus resulting in a maximum water surface gradient of 23 cm km^{-1} in the lower estuary. Flood flow completely obliterated the effects of tidal rise and fall at the Nowra Bridge over the period June 21-26. However, at the mouth tidal influence persisted throughout the flood even though marine waters were completely flushed from both entrances.

Unfortunately it was logistically impossible to obtain direct current observations in the entrance during the flood peak; however, current, salinity-temperature and bathymetric data were obtained immediately following the peak during the period of subsiding stage. Figure 3 shows typical velocity profiles and water density structures in the Shoalhaven Heads entrance during ebbing and flooding tides on June 26-27. The flood-stage river-mouth bar profile is also shown. (In this figure and figures which follow, water density is expressed in units of σ_t which is related to density, ρ , by $\sigma_t = (\rho - 1) \cdot 1,000$ and is calculated from salinity and temperature data.) As the diagram indicates salt water was completely flushed from the entrance and flow was seaward at all depths during both phases of the tide. The influence of tides is strongly evident from a comparison of the ebbing versus flooding currents: outflow was accelerated during ebbing tide and inhibited during flooding tide. The ebb-tide outflow attained surface speeds of over $2 \text{ metres sec}^{-1}$ whereas surface outflow averaged only about $40\text{-}50 \text{ cm sec}^{-1}$ during flooding tide. Strong bed shear accompanied the flood stage outflow on both tidal phases and pronounced seaward transport of bed load was evidenced from the presence of seaward-migrating mega-ripples with amplitudes on the order of 50 to 100 cm.

Vertical density stratification in the entrance throat and over the river-mouth bar was negligible (Fig.3). It has been shown elsewhere that the effectiveness of buoyancy in suppressing effluent turbulence depends

To a large extent on F' , the densimetric Froude number at the outlet (Hazashi and Shuto, 1967, 1968; Wright and Coleman, 1971) where

$$F'_o = U / \sqrt{\gamma gh'}$$

where U is the mean outflow velocity, g is the acceleration of gravity, h' is the depth of the maximum density gradient and γ is the density ratio

$$\gamma = 1 - (\rho_f / \rho_s) \text{ where } \rho_f \text{ and } \rho_s \text{ are respectively the}$$

densities of fresh water and sea water. Throughout the high stage and falling stage period F' exceeded substantially the value of 16.1 regarded by Hayashi and Shuto (1967, 1968) as necessary for fully turbulent effluent diffusion.

Figure 2: Water Surface Elevation Curves for Shoalhaven Heads and Nowra Bridge, June 19-25, 1975

Figure 3: Current and Density Profiles at the Mouth of the Shoalhaven River on Ebbing and Flooding Tides, June 26-27, 1976

It is common on the southeast coast of Australia for increased stream-flow to coincide with the occurrence of powerful southeasterly waves. The floods of August 1974 and June 1975 were associated with lows situated over the coast which also generated high energy waves: the June 1975 flood was accompanied by a significant wave height of 7 metres. The dominant waves associated with the storm arrived from the southeast and had a peak period of 13 seconds. Owing to the direction of incidence of these waves the Crookhaven entrance was comparatively sheltered from extreme energy conditions; however, the Shoalhaven Heads entrance was fully exposed to direct wave attack.

The most conspicuous influences of high wave energy on flood-stage outflow were wave-induced setup and increased effluent diffusion and deceleration. The importance of wave setup on the Shoalhaven Heads entrance is apparent from Figure 4 which shows simultaneous flood-stage water level curves from Shoalhaven Heads and Greenwell Point (situated just upstream from the Crookhaven Heads entrance) together with the significant wave heights for the same period. From the graphs it can be seen that flood-stage water levels were substantially higher at the exposed Shoalhaven Heads entrance than at the more sheltered Crookhaven outlet. At the time of the peak wave height, which preceded the flood crest by about 15 hours, water level at Shoalhaven Heads exceeded that at Greenwell Point by 60 centimetres.

Figure 4: Simultaneous Curves of Significant Wave Height as Recorded by the Botany Bay Offshore Wave Rider and Water Surface Elevations at Shoalhaven Heads and Greenwell Point, June 19-25, 1975

The important role of waves in enhancing effluent mixing and deceleration was evident from a comparison of observations at the two outlets made on June 27 and 28 during falling stage as sea water reentered the extreme lower reaches of the distributaries. At the time of these observations river discharge had decreased to levels insufficient to flush completely the seawater from the channels but still significantly exceeded the tidal prism of the estuary. Conditions such as these have been observed elsewhere to favour strong vertical stratification and salt-wedge intrusion under normal conditions (e.g., Wright, 1971). At highly stratified river mouths such as the mouths of the Mississippi River the outlet densimetric Froude number tends to maintain values near unity and outflow expands largely as a buoyant plume which experiences only gradual deceleration (Wright and Coleman, 1971, 1974). Figure 5 shows the typical density (σ_t) structure and current profile observed at the Crookhaven outlet during falling stage. A close analogy to the Mississippi model is apparent: there was a steep pycnocline, the densimetric Froude number was slightly less than 1 and there was a flow reversal just beneath the pycnocline. Seaward of the outlet the Crookhaven effluent expanded in the shelter of Crookhaven Heads as a buoyant surface layer with minimal lateral and vertical mixing.

Figure 5: Density and Flow Structure in and Seaward of the Crookhaven Mouth During Falling Stage, June 27, 1975

Outflow patterns at the exposed Shoalhaven Heads entrance during the same period contrasted sharply with those of the Crookhaven. From Figure 6 it can be seen that denser brackish water had intruded a short distance into the Shoalhaven entrance by June 28, 1975. However, unlike the Crookhaven, flow through the Shoalhaven Heads outlet was seaward at all depths and the density structure indicated a vertically well-mixed condition owing to the action of breaking waves. Immediately seaward of the entrance throat breaking waves caused rapid mixing and momentum exchange between effluent and ambient water. In addition to intensified mixing, outflow was opposed by wave-induced shoreward transport of seawater which abruptly converged with the effluent immediately seaward of the seawardmost break point. The combined effect was to cause extremely rapid seaward deceleration of the outflow: maximum velocities decreased from 1.5 m sec^{-1} at the entrance throat to 20 cm sec^{-1} within a distance of 2 channel widths (250 m) seaward. This rate of deceleration was several times greater than that predictable from the theories or observations of fully turbulent or buoyant jets (e.g., Wright and Coleman, 1974) and must be attributable to wave effects.

Figure 6: Density and Flow Structure and Two-Dimensional River-Mouth Morphology at the Shoalhaven Heads Mouth During Falling Stage, June 28, 1975.

The plan-view surface outflow patterns associated with flood discharge are illustrated in Figure 7 together with the resultant depositional morphology. Flow patterns shown in this diagram were determined by drogue and dye tracking and from aerial observations. Waves which broke over the crescentic river-mouth bar impeding seaward flow caused the effluent to spread abruptly alongshore. Flow divergence landward of the bar crest was accompanied by shoreward transport and emergence of seawater over the seaward front of the bar. Lateral to the effluent centreline, velocity gradients were extremely steep causing abrupt deposition and shoaling in the form of subaqueous levees.

Figure 7: Horizontal Surface Outflow Patterns and Plan-View Morphology at the Shoalhaven Heads Mouth, June 28, 1975 (lengths of arrows not proportional to current speed)

Flood-Stage River-Mouth Morphology

The depoositional morphology produced by the flood stage outflow is shown in profile and plan in Figures 6 and 7. Rapid wave-induced deceleration caused abrupt depoosition of bed load resulting in a conspicuous river-mouth bar at a short distance from the inlet throat. The bar was wide and crescentic in plan-view and was situated at 2 channel widths seaward of the outlet (as compared with 4 to 6 channel widths at the mouth of the Mississippi: Wright and Coleman, 1974). Surveys immediately after the flood in June, 1975, in August, 1975, and in December, 1975 indicated that the bar consistently had 2 crests. The seawardmost bar crest was asymmetrical with a steeper landward face and appeared to be migrating shoreward under the influence of shoaling waves.

In plan, the distinguishing features of the river mouth were: (1) a crescentic and highly regular river-mouth bar; (2) a constricted outlet; and (3) broad subaqueous levees which widen to shoreward and are surmounted by swash bars. The wide subaqueous levees are apparently associated with the combination of steep lateral velocity gradients and post-depositional reworking of river-mouth sands by shoaling waves. These levees were the most extensive depositional unit at the river mouth in terms of both surface area and sand volume. Sediments returned shoreward by wave-induced swash bar migration over the levee/shoals accumulate adjacent to the entrance throat and constrict the mouth until a balance is achieved between the reconcentrated outflow and the waves. The crescentic bar and wide subaqueous levees of the flood-stage Shoalhaven mouth appeared to be analogous in form and function to the terminal lobe and ramp-margin shoals of ebb-tidal deltas (e.g., Hayea *et al.*, 1970; Oertel, 1972).

Low-Stage Outflow

As the river returns to normal or low flow, saltwater quickly intrudes into the lower reaches of the channel. Figure 8 shows the low stage density structure in the lower 15 km of the Shoalhaven estuary. Throughout most of its length the estuary is well mixed by tides. At and immediately upstream from the Shoalhaven Heads entrance marine salinities prevail; salinities decrease progressively upstream becoming fresh a short distance above the Nowra Bridge. Under low stage conditions flow is bidirectional through the two entrances which function essentially as tidal inlets. Tidal influence extends to well above the Nowra Bridge and there is minimal tidal attenuation in the lower 15 km of the channel.

Figure 9 shows a comparison of the low stage tide curves from the Shoalhaven Heads and Crookhaven entrances, and illustrates the continual effects of wave-induced setup on the Shoalhaven Heads outlet. This setup impedes ebb outflow and augments flood tide inflow through the Shoalhaven entrance. Under these low stage conditions waves breaking over the crest of the river-mouth bar impound ebb outflow, causing it to spread laterally along the inshore zone (Fig.10). Sediment-laden efflux trapped in this way ultimately escapes by way of rips which prevail on either side of the large transverse bar, created by the river-mouth bar.

A recent set of 25 hourly observations by C. Brown (Posford, Pavry, Sinclair and Knight Consulting Engineers, 1976) testified to the importance of wave setup in creating tidal transport asymmetry through the Shoalhaven entrance.

The results of these observations are summarized in Table I. The table demonstrates that at the time of the observations (March, 1976) low

stage inflow through Shoalhaven Heads exceeded the outflow by more than 2 times. The excess inflow through Shoalhaven Heads exits together with the base flow of the river by way of the more protected Crookhaven entrance.

Figure 8: Longitudinal Density Profile of the Lower Shoalhaven Estuary at Low Stage, August 11, 1975

	Main Channel Upstream from Canal	Shoalhaven Heads	Crookhaven Heads
Flood (inflow)	$9.6 \times 10^6 \text{ m}^3$	$11 \times 10^6 \text{ m}^3$	$12 \times 10^6 \text{ m}^3$
Ebb (outflow)	$13.6 \times 10^6 \text{ m}^3$	$5 \times 10^6 \text{ m}^3$	$22 \times 10^6 \text{ m}^3$

(Source: Posford, Pavry, Sinclair and Knight Consulting Engineers)

Figure 9: Simultaneous Tidal Curves for Shoalhaven Heads and Crookhaven Heads during Low Stage, August 3-6, 1975

Low-Stage Sediment Transport and Morphology

During prolonged low-discharge periods the combination of shoaling waves, flooding tides and setup results in a net shoreward return of sediment which ultimately reenters the lower reaches of the lower Shoalhaven estuary. Much of this sediment accumulates as a flood-tidal delta just upstream from the entrance throat along the flanks of the channel; however, a significant proportion of the sediment migrates over 5 kilometres upstream and accumulates on tidal point bars and mid-channel islands. Analyses of sediments from the river mouth and lower Shoalhaven channel indicate a mixture of well-rounded quartz typical of offshore and open coast environments and riverine sands consisting of angular rock fragments, feldspars and quartz. The percentage of riverine sand increases upstream from 30% to 50% at the river mouth to 100% at 13 km upstream.

Figure 11 shows the depositional morphology of the Shoalhaven Heads outlet as it appeared in January 1976 following a low-stage period of 5.5 months. By this stage large swash bars had migrated shoreward over the subaqueous levees and entered the mouth as a complex succession of recurved ridges which substantially reduced the width of the outlet. The crescentic river-mouth bar had migrated shoreward while the southern subaqueous levee had become extended across the outlet by dominant southeasterly waves,

causing outflow to be deflected to the north. In profile the double-crested bar form previously described was still apparent. However, both crests had migrated approximately 100 metres shoreward and the outer crest had become more pronounced and 1.5 metres shallower. In addition, the outer bar had increased in longshore width and had assumed a more regular form. Except for an outflow channel across the northeast quadrant the bar extended continuously shoreward to the beach on either side of the outlet. Where the river-mouth bar welded to the beach wide transverse bars surmounted by large emergent swash bars resulted. The transverse bars were flanked on either side by large rips by way of which the wave-impounded river effluent escaped seaward (Fig. 11).

Figure 10: The Mouth of the Shoalhaven During Low Stage, January, 1976
Note Turbid Effluent Water Trapped Inshore of Surf Zone

Figure 11: Low Stage Morphology and Outflow Patterns of the Mouth of the Shoalhaven, January, 1976

Inspection of aerial photographs reveals that when conditions of low river flow and wave dominance persist for a prolonged period, bar sands will continue to enter the mouth, narrowing the throat and choking the outlet. This causes discharge to be increasingly diverted through the Crookhaven entrance. Eventually shoreward migration of the bar completely seals off the Shoalhaven outlet. Once sealed, the mouth remains closed until it is breached by the next flood (Fig.12).

Figure 12:

The Mouth of the Shoalhaven as it Appears when Fully Closed Following Prolonged Low Discharge Periods

Summary and Conclusions

The depositional morphologic patterns observed at the mouth of the Shoalhaven contrast drastically with patterns observed at river mouths in low-wave energy environments but are analogous in major respects to those of other wave-dominated river mouths. It is inferred from this study that the distinguishing aspects of the morphology of the mouth of the Shoalhaven River are largely attributable to interactions between the river outflow and high-energy shoaling waves. Waves influence effluent behavior in at least two fundamental ways: (1) wave breaking and associated turbulence enhances mixing, obliterates vertical density gradients and causes more rapid deceleration; and (2) wave-induced mass transport and setup oppose the outflow, causing a local reduction in longitudinal hydrostatic gradient, "trapping" the issuing river water inshore and promoting abrupt lateral spreading of the outflow.

The major morphologic features produced by these wave-effluent interactions include: (1) a broad crescentic and highly regular river-mouth bar located at a short distance seaward of the outlet; (2) broad shallow sub-aqueous levees; and (3) a conspicuously constricted outlet.

Acknowledgments

This study was supported by the Australian Research Grants Committee (ARGC) and by a University of Sydney Research Grant (URG). Able assistance both in the field and the data analysis stage was provided by Mr. P. Cowell and Ms. D. Waddy. Valuable information and cooperation were provided by Mr. C. Brown of Posford, Pavry, Sinclair and Knight Consulting Engineers, and Mr. J. Downey, Shire Engineer, Shoalhaven Shire Council. Wave rider data were provided by Neil Lawson of the Maritime Services Board of N.S.W.

CHAPTER 101

RESULTS OF RIVER MOUTH TRAINING ON THE CLARENCE BAR, NEW SOUTH WALES, AUSTRALIA

Cyril D. Floyd, Late Principal Engineer, Harbours and Rivers,
Department of Public Works, N.S.W., Australia.

Bruce M. Druery, Department of Public Works, N.S.W., Australia

ABSTRACT

A case study is given of river training works at the mouth of the Clarence River. The study spans a period of ninety years. Extensive hydrographic data from the later part of this period is presented and examined in detail.

Prior to 1903 internal training walls had been constructed to stabilise the internal channel and stabilise the bar location at the mouth of the Clarence River. In 1956 construction started on entrance jetties with the aim of deepening the bar. The work was carried out over a period of 16 years. The slow rate of construction has allowed changes in bar depth to be compared with depths estimated by an empirical formula which relates bar depth to tidal flow and channel width. Results have shown that the empirical formula gives a reasonable estimate of bar depths and that bar depth is independent of jetty length.

Results have shown that the behaviour of the bar is strongly affected by floods. Some details of bar volume and movement are presented.

1. GENERAL

The Clarence River is the largest river reaching the coast of New South Wales. It is situated in the north of the state of New South Wales and the entrance lies on the southern fringe of the Australian cyclone area - see fig. 2.1. The Clarence has a catchment area of 8463 square miles (2190 km²).

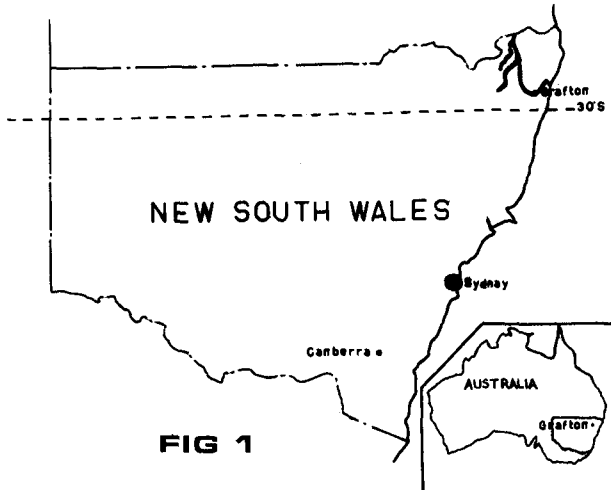

FIG 1

Flow from the catchment is extremely variable. At times the flow can be zero for long periods and in flood, flows of up to 600,000 cubic feet per second (16800 cubic metres per second) have been recorded at Grafton which is 40 miles (64 Km.) from the ocean. Normal fresh water flow is about 4000 cubic feet per second (113 m³/sec.).

Below Grafton a flood plain of about 127,000 acres (51,000 ha.) acts as storage for flood flows so that the maximum flow at the entrance is much reduced and prolonged. Flood flows at the entrance exceeding the normal tidal flow at extreme spring tides are rare.

The river is tidal for a distance of about 60 miles (96 Km.) from the ocean and the area of the tidal reaches is 34,000 acres (13,750 ha.). Tidal range in the ocean is 4.42 feet (1.34m.) for mean spring tides and extreme range is 6.58 feet (1.99m.).

Maximum tidal flow through the entrance for a mean spring tide (4.42 ft. ocean range) is 88,000 cubic feet per second (2.5×10^6 m³ per second) ebb tide and the total volume of flow is about 8×10^8 cubic feet/ (2.26×10^7 m³). The maximum flow occurs at low water with a tide level of about 1 foot above I.S.L.W.

The entrance and lower reaches are in tidal regime. Prevailing swell is from the south east and net annual littoral drift, from south to north, is considered to be of the order of 100,000 cubic yards.

2. HISTORICAL

The mouth of the river was first surveyed in 1845 but details other than the position of mean high water mark are not now available. A report several years later states that the mouth which was 6,800 feet (2060m.) wide consisted of a series of shallow tortuous channels which were not navigable. See fig. 2

In 1860 the entrance had narrowed to 750 feet (228m.) and at this time plans were prepared to construct training walls and jetties to stabilise the location of the channel and the bar crossing. Details of this proposal are shown in figure 3.

Following a series of floods in the years 1860 to 1880 the scheme was modified to that shown in figure 3 (Moriarty's proposals) but the work was abandoned in 1889 when a new scheme was approved as shown in figure 3. At that stage works constructed under the original proposal were as indicated in the same figure.

The internal training walls of the 1889 scheme were constructed but the entrance jetties were not. The work stopped in 1903 and apart from some additions and alterations to the internal walls no further work was carried out until 1956.

Although no effective work was carried out on the entrance jetties other than a short length on the southern one the internal walls resulted in a stable location and a bar which with frequent dredging served reasonably well for coastal shipping until this declined during the war years 1939/45.

3. WORK SINCE 1956

Following on from a Parliamentary decision to establish a port at the mouth of the river, plans were prepared for the construction of jetties to improve bar depths. It is not possible to ascertain with any certainty what bar depth it was hoped to obtain but it seems that a channel depth of 20 feet (6.1m.) below I.S.L.W. was the aim, with apparently a similar bar depth.

The works proposed are shown in figure 3 and consisted of two jetties of unequal length, the northern being the longer. The original plan was not adhered to and during construction the width between the jetties was reduced and the southern jetty lengthened.

Construction started in 1956 and continued until July, 1971 when work ceased. During this period the entrance channel, bar and nearby areas were surveyed at frequent intervals (usually every

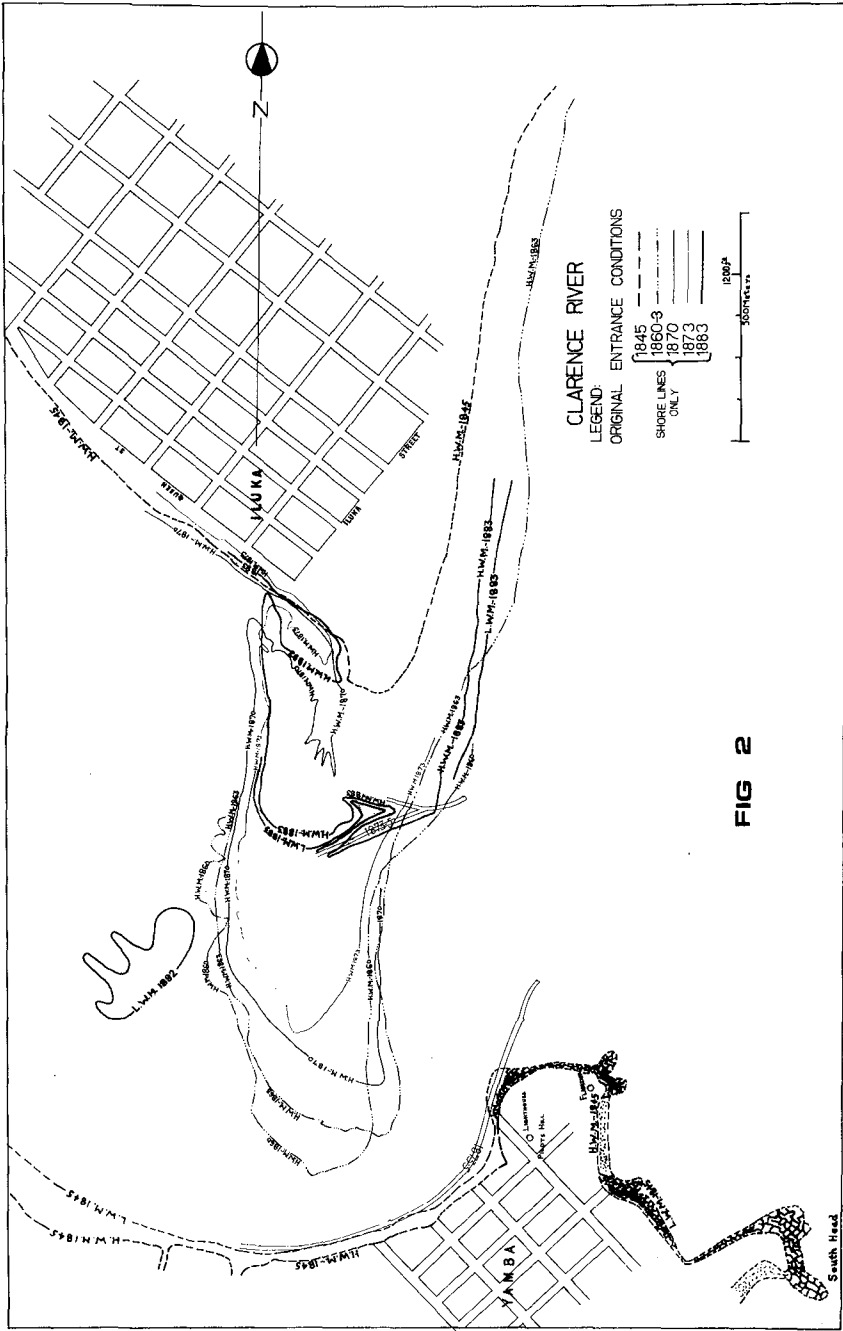

FIG 2

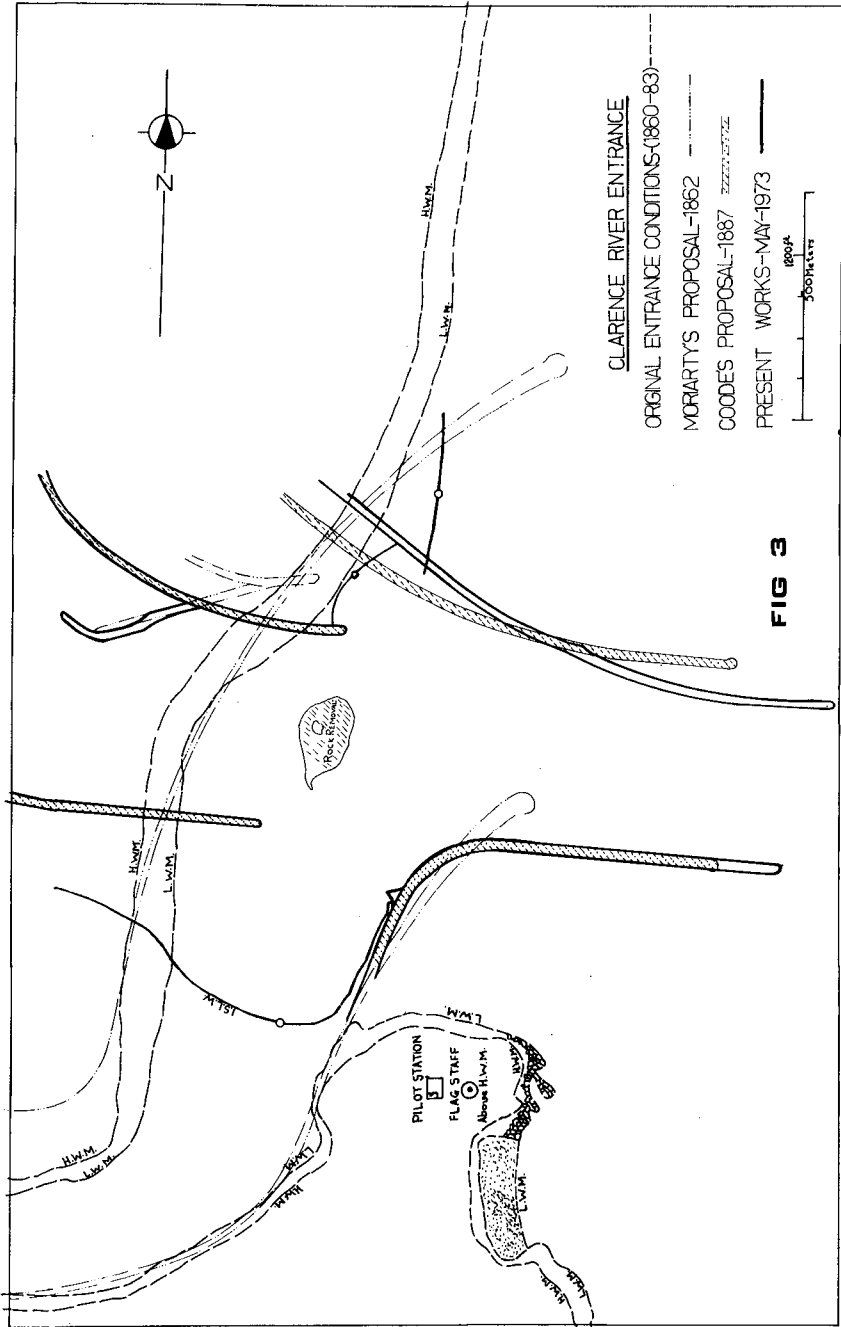

FIG 3

three to six months and quite often monthly).

A rock reef with depths varying from about 23 feet on the south to 8 feet on the north lies between the ends of the old internal training walls. This reef is irregular and causes considerable turbulence at flood and ebb tides as well as during floods. Removal to a depth of about 23 feet below I.S.L.W. over a width of about 500 feet was included in the authorized works but has not been done.

Construction started on the northern jetty and when it reached a distance of 2,150 feet seaward of the end of the old southern training wall (for convenience and also as an approximate indication of effective change in entrance geometry the end of the old southern training wall has been used as a reference point in this paper) work then transferred to the southern jetty which was constructed to an effective length of 2,750 by July, 1964. As this stage work again transferred to the northern jetty and it was extended to its final length of 3,950 feet seaward of the reference point by November, 1968. The final stage was the extension of the southern jetty to an effective length of 3,800 feet by July, 1971.

The old internal training walls had been constructed with centre lines 1450 feet apart at their seaward ends. The new jetties commenced in 1956 were to be 1450 feet apart.

In 1964 an assessment of tidal flow was first made. This indicated that the jetty spacing as authorized would not result in a channel depth of 20 feet below I.S.L.W. if tidal flow was distributed evenly between the jetties. A spacing of 1,200 feet centre to centre was then adopted as a compromise between navigation and flood needs.

4. RESULTS OF WORKS

(a) Bar Formation

Early surveys from 1860 to 1883 show bar depths of from 12 feet to 15 feet below a low water datum (exact definition not known). The alignment of the entrance was due north as shown in fig. 4. Internal channels had ruling depths of about 14 feet.

The original scheme did not progress sufficiently to draw any conclusions on its effects.

The works carried out under the 1889 proposal improved the internal channel depths and alignment and resulted in a stable mouth which was now aligned almost due east. A Symmetrical bar formed with a natural depth of 12 feet below I.S.L.W. see fig. 5. Flow patterns through the entrance were irregular, a result of the reef between the ends of the walls and of the alignment of the internal channels.

FIG 4

FIG 5

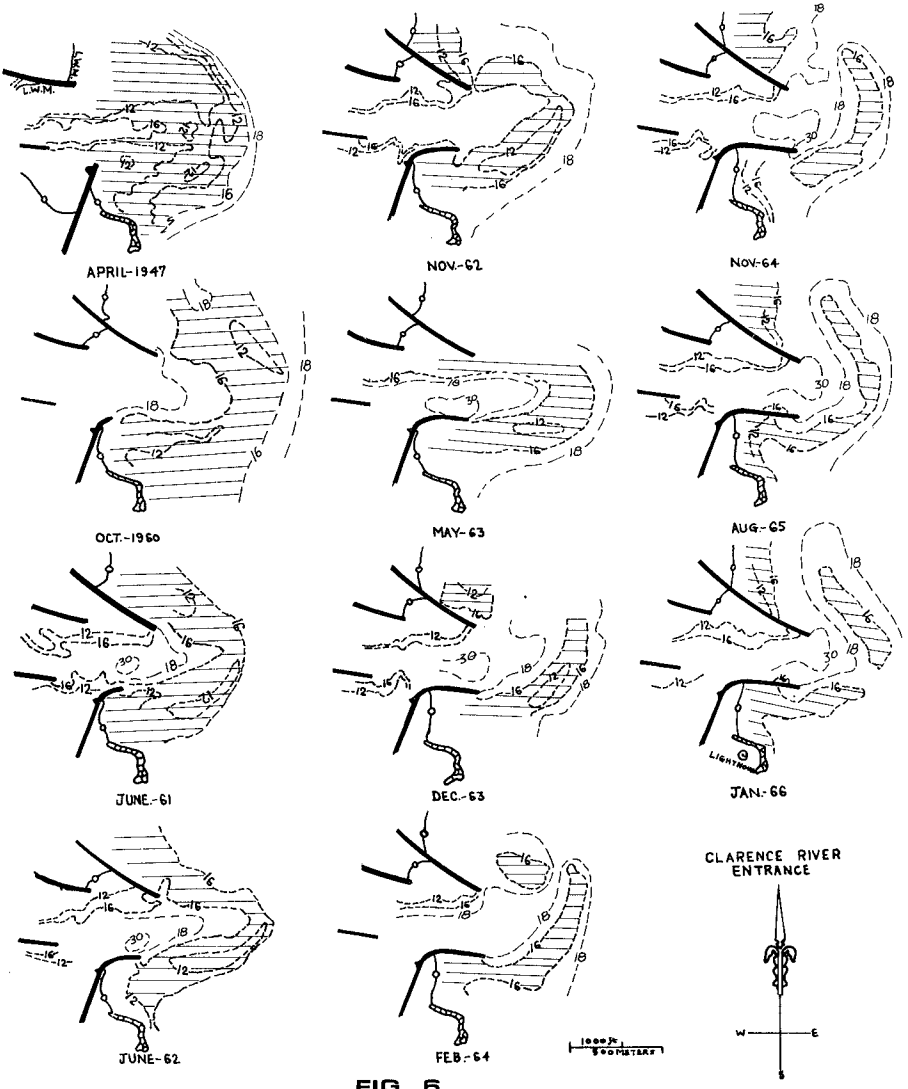

FIG 6

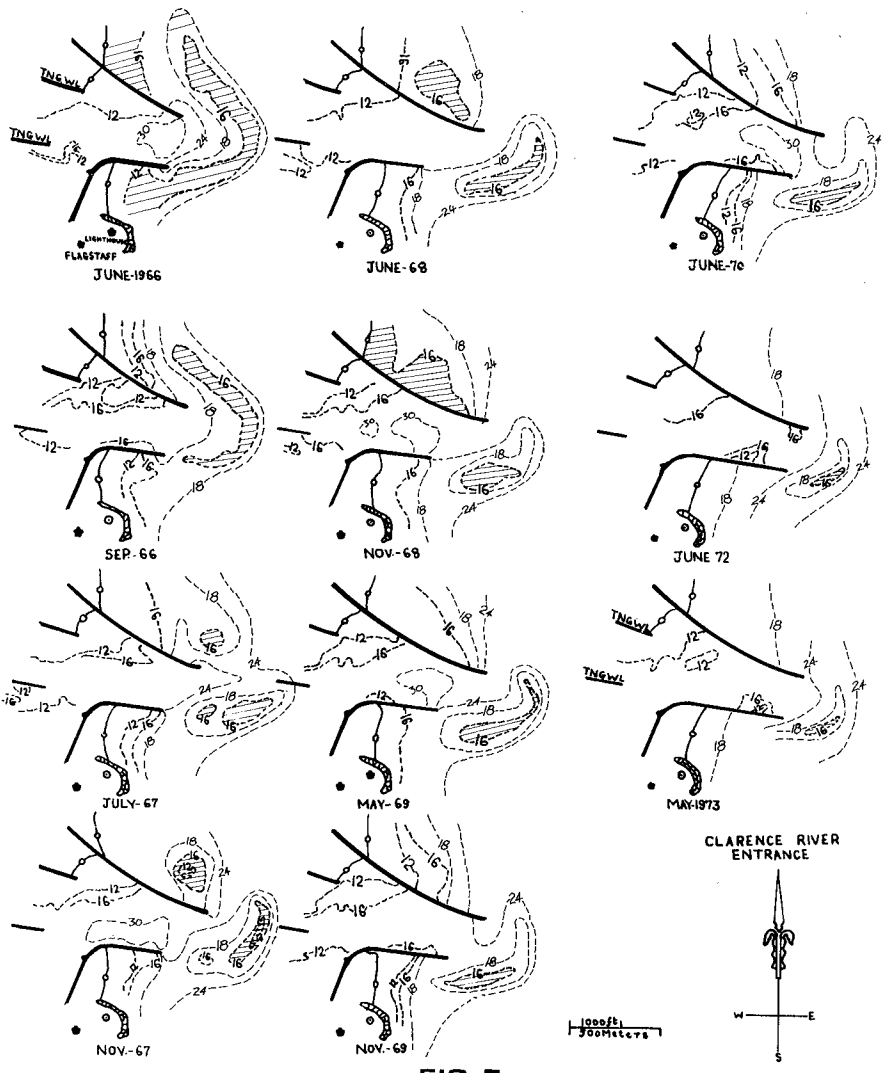

FIG 7

In the period 1956-1959 the northern jetty was built to a point of 2,150 feet seaward of the reference line referred to earlier. At this stage the bar depth was unchanged but the bar was in the form of an isolated shoal with deeper water between the shore and its two ends. The bed of the small bay between the entrance and Wooli Head had deepened by about 10 feet - see fig. 6.

From 1960 to 1965 the northern jetty length was unaltered and the southern one was constructed to 2,750 feet from base. The alignment of the inshore section of the south wall is such that it did not affect ebb flow through the entrance until mid-1961 when its effective length changed from nil to 1,400 feet in a few months. Shortly afterwards the bar became asymmetrical and could almost be considered a half bar (figure 6). This condition continued until mid-1964 when the two jetties projected equal distances and the bar again became symmetrical. The bar was again in the form of a crescent shoal with deeper water shoreward of each end.

With further extension of the northern jetty the bar remained symmetrical until the northern jetty was about 1,200 feet beyond the southern. The bar then again became asymmetrical. Further lengthening of the southern jetty did not alter this and the work ceased in 1970 with the northern jetty 3,950 feet and the southern jetty 3,800 feet seaward of the base line. The last survey in 1973 showed no marked change - see fig. 7.

(b) Bar Movement

Bar movement seems to have been strongly related to at least two factors :-

1. The seaward advance of the jetties
2. The occurrence of floods

Referring to fig. 8, the solid line is a plot of the distance from the end of the southern internal training wall to the seaward extremity of the outer 20 ft. contour of the bar. The broken line is a similar plot for the inner 20 ft. contour. The progress in construction of the entrance jetties is also shown from the same baseline.

On the whole it can be seen that the construction of the entrance jetties to a length of approx. 3900 ft. has caused the outer face of the bar to advance seawards by 1000 ft. and the inner face to advance seawards by 2600 ft. The result has been a progressive decrease in width across the bar.

The abrupt peaks on the graph correspond to the occurrence of

FIG 8

RECORD OF PROGRESSIVE BAR DEPTHS

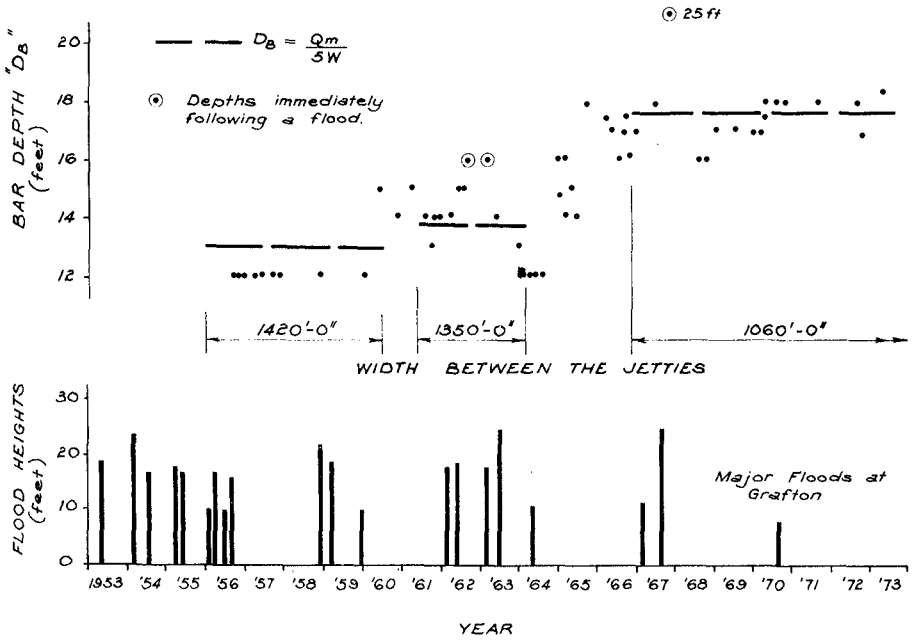

FIG 9

a major flood in the river. During each flood sand in quantities up to 0.6 million cubic yds. (N.B. volumes are discussed under (d)), were deposited on the seaward face of the bar thereby causing it to advance seawards as much as 700 ft. Scouring of the inner face of the bar occurred but the advance was seldom more than half that of the outer face.

During the 12 months immediately after each flood, the outer face of the bar retreated to a new equilibrium position compatible with the position of the advancing jetties. After this 12 month period of adjustment the outer face was very stable and showed very little tendency to move.

(c) Bar Depth

In a paper presented at the 1968 Coastal Engineering Conference (ref. 1) an empirical relationship for prediction of bar depths was derived from results of other river training works.

This was in the form :

$$D_B = \frac{Q_m}{5W}$$

where D_B = depth over bar saddle measured below the surface when maximum ebb flow occurs for a tide of mean spring range.

Q_m = Maximum ebb flow for that tide channel.

W = Surface width when Q_m occurs (all measurements in feet).

In figure 9, D_B is compared with measured bar depths (depths measured below water level for maximum flow during a tide of mean spring range, i.e. 1 foot above I.S.L.W.).

With a full semi-circular bar the depth is taken as the best depth over the bar saddle. With a "half" bar the depth is taken on the centre line of the ebb flow as indicated by bottom contours.

The correlation between bar depth and channel depth found on other entrances could not be checked here because of the turbulence resulting from the reef formation near the ends of internal walls. The bottom contours at all times were very irregular between the jetties.

During the first stage of construction whilst the northern jetty was being built to 2,150 feet the bar was consistently

at a depth of 12 feet or 1 foot less than calculated D_B . In the second stage whilst the southern jetty was being constructed to 2,750 feet bar depths fluctuated between 16 feet and 13 feet. It returned to a depth of 12 feet for a short period as further lengthening of the northern jetty was started. Calculated D_B was 13.75 feet at this time.

With further extension of the northern and southern jetties to their final length bar depths were generally between 0.6 and 1.6 feet less than the calculated value of D_B .

Since the work stopped bar depths have been consistently 0.4 feet deeper than calculated D_B .

The period when bar depths are less than predicted D_B are when the northern jetty projects beyond the southern.

Depths appreciably greater than predicted occur from the time the works first reduced the entrance width until the final width was established.

Such consistent increases in bar depths as occurred followed reductions in the effective width of the channel.

The comparatively small variation in bar depths from the predicted (- 1 3/4 ft. neglecting short term increases in depth due to local guttering by floods) is probably due to the slow rate of construction and the long pauses whilst jetties were brought up to equal lengths. Usually bar depths of as much as twice the predicted can be expected during construction.

(d) Sand Volume

Within the limitations of early surveys, it appears that the volume of sand in the bays to the south of the river mouth, the bar, and the adjacent beaches and dunes has not significantly altered between 1860 and 1960. That is to say the early training works simply re-distributed the entrance bar and shoal with very little change in overall sand volumes.

The results of detailed volume calculations for the period 1962-1972 are shown in fig. 10. The volumes were calculated within a control area bounded by a line joining the ends of the internal training walls, the 42ft. sounding line, 1600 ft. of Iluka Beach to the north and 800 ft. of Yamba Beach to the south.

It can be seen that floods have supplied sediment in quantities up to 0.6 million cubic yards during any one year of floods. The total supply of sediment during 62/72 period was 1.5 million cubic yards.

VOLUME CHANGES ON THE CLARENCE RIVER BAR

FIG 10

The rate of removal of sediment from the bar system by littoral agencies was greatest immediately following periods of deposition. The maximum loss occurred in 1964 when approx. one million cubic yards was removed from the control area. The gross removal of sediment during the 62/72 period was 3.0 million cubic yards.

There has been some accumulation of sand on Yamba Beach and on the new beach between Woolf Head and the southern jetty. This, however, has been accompanied by a compensatory deepening immediately seaward.

It appears, therefore, that the small littoral drift from the south is deflected by Yamba Head and either enters the bar exchange system to eventually pass to the north or even passes around the bar.

Volume calculations have not been sufficiently extensive to trace the path of the sediment removed from the bar. It is strongly suspected that the majority has moved northwards up the coast.

5. CONCLUSIONS

The results of entrance jetty constructions over a period of sixteen years on this river confirm that bar depth can be related to tidal flow and channel width and is independant of jetty length. It follows that entrance jetties should not be any longer than is necessary to move the bar outside the beach system so that it may be reasonably stable.

In this case jetties just long enough to transition smoothly to the required width would have produced the same bar depth. Possibly because of the sheltered position it might have been possible to obtain a satisfactory result with modification to the existing training walls.

Floods have been an important factor in the behaviour of the Clarence River bar. While the inner face of the bar responded to construction of the entrance jetties by progressively moving seawards, it was found that floods were the necessary catalyst to bring about movement of the seaward face. There is an inference here that if construction of the jetties had been carried out at a considerably greater rate, the bar would have been eliminated for a time until re-established by flood and littoral deposits.

The decrease in sand volume around the entrance would lead to the expectation that with a return of a period of more regular floods, the bar formation will cease to be that of a "half bar" and again assume a semi-circular shape.

CHAPTER 102

SEDIMENTATION PROBLEMS AT OFFSHORE DREDGED CHANNELS

by

A. A. Kadib

Coastal Engineering Specialist, Bechtel Inc.,
San Francisco, California U.S.A.

ABSTRACT

Estimating the rate of sediment deposition and annual maintenance dredging at offshore dredged channels have been two of the most challenging tasks confronting coastal engineers in the past 10 to 15 years. Because of the complexity of the mechanism of sediment-flow interaction and the lack of available practical methods for estimating the sediment transport rate under waves and current action, it is felt that a simple and rational method is needed for describing sediment behavior at offshore dredged channels and estimating accretion rates. It is hoped that this paper contributes to the answer of this problem.

The paper describes the mechanism of sediment deposition and presents a simple method for estimating the rate of annual maintenance dredging. The effect of using a submerged breakwater for relieving the sedimentation problem within the dredged channel is also presented.

INTRODUCTION

Along any reach of coastline where navigation works and other coastal structures exists or are contemplated, patterns and rates of long-term littoral and offshore sand movement and expected accretion are vital information for proper engineering, design and maintenance. Sediment movement along the breaker zone and at the offshore area is controlled mainly by the action of the prevailing waves and currents of these locations. When moving sediment loads encounter a partial obstruction such as a dredged channel, a condition is realized that is conducive to sediment deposition. There are at least three basic types of man-made works at the offshore area which function as sediment barriers (Figure 1). These consist of: (a) dredged navigation channels connecting super-tanker harbors with deep water offshore and up to 25 meter water depth; (b) dredged offshore channels for cooling water intakes for nuclear and liquefied natural gas plants; and (c) dredged offshore areas for open-sea loading and berthing terminals. In a recent study, the question

came up concerning the economical feasibility of such offshore dredging activities and their impact on the overall shoreline processes operative in the project area. In order to answer this question, estimates of the rate of sediment movement and the expected annual maintenance dredging are necessary preliminaries. Unfortunately, there is no proven prediction method of general validity for quantitative estimates of onshore-offshore and longshore sediment transport rates, and designers usually rely on limited field data of questionable accuracy to formulate some feeling for the problem under consideration. Because of the above difficulties and the fact that more accurate field data are usually expensive and difficult to get, it is felt that a simplified method is needed to estimate the rate of sediment movement for water depths of up to at least 20 meters.

The approach described here is based on available theoretical studies(2, 3, 4, 5, 6) and experiences gained with maintenance dredging at the Suez Canal offshore dredged channel, located at Port Said Harbor, Egypt(7, 8, 9). Items considered are: (a) factors contributing to sedimentation; (b) method of estimating deposition rate; (c) effect of using a submerged breakwater for relieving the sedimentation problem, and (d) optimum design for protection against accretion.

FACTORS CONTRIBUTING TO SEDIMENTATION

Consider any section along the offshore part of a dredged channel shown in Figure 2. Assume that both the current and wave climatology in the vicinity of the dredged channel are known. This could be considered either as (1) an average steady current characterized by a velocity U , a wave height H , and a wave period T , or (2) as a known number of storms with a given duration and direction. For the first case, the average currents and wave condition can be used to estimate the annual sediment effect, whereas for the second case, the effect of each storm can be evaluated separately and the annual effect can be obtained by integrating the effects of all expected storms within a given year. In either case the basic flow field is the same. This flow field (Figure 2-a) may be simplified as:

- Steady current with an average velocity U_1 at water depth d_1 . By continuity, this current will have velocity U_2 at depth d_2 .
- Maximum oscillatory current $U_{bed\ max}$ at the bed, due to wave action. This current may be expressed by the equation

$$U_{bed\ max} = \frac{\pi H}{T} \frac{1}{\sinh 2 \pi d/L} \quad (1)$$

where

H = wave height,
 T = wave period,
 L = wave length at water depth d.

It is believed that the above flow velocities are the most important factors contributing to sediment movement in the vicinity of the dredged channel and their contribution may be summarized as follows:

1. Bed Load (Q_b).

Einstein(5), Kalkanis(3) and Abou-Seida(2), proposed the use of a modified unidirectional bed load function, shown in Figure 3, for estimating the rate of bed load movement under wave action. In order to use Figure 3, one has to calculate flow intensity Ψ_* defined as

$$\Psi_* = \xi \frac{\gamma_s - \gamma_f}{\gamma_f} \frac{g D}{U_a^2} \quad (2)$$

where

ξ = "hiding factor" for small particles in a sediment mixture and may be assumed unity for uniform grains,
 γ_s = specific weight of sediment,
 γ_f = specific weight of water,
 g = acceleration of gravity,
 D = sediment size,
 U_a = wave particle velocity at 0.35 D from the boundary.

References (2), (3) and (5) show U_a is the most difficult factor to calculate in equation (2). Analysis of the data reported by Abou-Seida(2) show that U_a can be approximated by

$$U_a = 0.5 U_{bed \max} \quad (3)$$

Now with a known value of flow intensity Ψ_* , the oscillatory bed load intensity ϕ_* can be obtained from Figure 3. The oscillatory bed load rate q_b is given by the equation

$$q_b = \phi_* \gamma_s \left(\frac{\gamma_s - \gamma_f}{\gamma_f} \right)^{1/2} g^{1/2} D^{3/2} \quad (4)$$

The sediment concentration in the bed layer, C_a , is given by Abou-Seida(2) as

$$C_a = \frac{q_b}{2DU_a} \quad (5)$$

and the bed load rate Q_b is given by

$$Q_b = C_a a U_c \quad (6)$$

where

a = thickness of the bed layer, assumed in this study as equal to 2 cm,
 U_c = local current velocity near the bed and including mass transport velocity due to wave action.

2. Suspended Load Q_s

Theoretically speaking, wave motion, other than the breaking wave effect, lacks the existence of turbulence which is responsible for suspended sediment. On the other hand, it has been observed that considerable amounts of sediment move in suspension under the combined action of waves and currents^(4, 7, 11). Therefore, it was decided to attack the suspension problem by assuming that the steady current effect, only, is responsible for suspended sediment distribution within any cross section along the dredged channel.

If it is assumed that bed load takes place within a certain layer, the average concentration within this layer can be computed from equation (5). From this concentration, C_a , at height, a , above the bed, the concentration C_h at a height, h , above the bed can be expressed by the well known relationship (1)

$$\frac{C_h}{C_a} = \left[\frac{(d-h)a}{(d-a)h} \right]^Z \quad (7)$$

in which $Z = \frac{V_s}{0.4U_*}$ with V_s = fall velocity of the sediment grain, U_* = bed shear velocity; and d = the total water depth.

According to Einstein⁽¹⁾, the suspended load Q_s can be written as

$$Q_s = 11.6 U_* C_a a [P I_1 + I_2] \quad (8)$$

where

I_1 and I_2 can be obtained from reference 1.

P is determined from $P = 2.3 \frac{h}{h_o}$ in which

h_o = bed roughness.

From equation (8), the suspended sediment load to the updrift side of the dredged channel and inside the channel can be estimated.

METHOD OF ESTIMATING DEPOSITION RATE

When an offshore channel is dredged, both the flow and sediment patterns, approaching from the updrift side of the channel experience some changes as the flow crosses the dredged channel. This is shown in Figure 2. Consider Figure 2-a where the channel is dredged to depth d_2 below mean sea level, and the natural water depth to the updrift side of the channel is d_1 . Flow approaching the channel has a certain sediment load capacity which could be estimated using equations (6) and (8). As the flow approaches the dredged channel, two main mechanisms will take place:

- The dredged channel will act as a sand trap along most of its length and consequently most of the bed load Q_b approaching the channel will deposit within the channel.
- The suspended load, Q_s , on the updrift side of the channel will reduce to Q_{s2} across the channel. This reduction is caused by a decrease in the steady flow velocity within the dredged channel.

These considerations permit calculation of the rate of sediment deposition per channel unit width, Q_d , according to the following equation

$$Q_d = Q_{s1} - Q_{s2} + Q_b \quad (9)$$

where

Q_{s1} = rate of suspended load reaching the channel/
unit width,

Q_{s2} = rate of suspended load across the channel/
unit width,

Q_b = rate of bed load reaching the channel/unit
width.

Equation (9) can be used for various natural water depths, d_1 , along the channel thus permitting calculation of the total deposition rate along the channel.

As an example consider a dredged channel depth of 20 meters with a natural water depth of 10 meters. The annual rate of sediment deposition, Q_d , is estimated under the following assumed conditions:

average wave height (H) = 2.00 meters;
 average wave period T = 8 seconds;
 average bed material grain size D = 0.10 mm.

Results of the computations are summarized in Table 1.

TABLE 1

Example of Estimating Sediment
 Deposition Along a Dredged Channel Section

<u>Item</u>	<u>Sediment Rate m³/m/Year</u>
Q_b	340
Q_{s_1}	1700
$Q_{total} = Q_b + Q_{s_1}$	2040
Q_{s_2}	940
$Q_{deposition}$	1100

SUBMERGED BREAKWATER EFFECT

Submerged breakwaters have been used successfully for relieving and reducing the sediment deposition along offshore dredged channels. An example is the Suez Canal navigation channel which extends from the Port Said Harbor to natural water depth of about 15 meters. (The Suez Canal Authority is presently deepening the navigation channel to accommodate ships with drafts up to 22 m). Table 2 summarizes the annual maintenance dredging conditions along the offshore navigation channel during the period 1901 to 1966(7, 8).

TABLE 2

Variation of Annual Maintenance Dredging
Along the Suez Canal Navigation Channel
(Port-Said Harbor) During the Period 1901-1966

<u>Period (Years)</u>	<u>Average Depth of Navigation Channel (m)</u>	<u>Mean Annual Dredging (million m³)</u>	<u>Type of Protection Against Accretion (Updrift Side)</u>
1901-1906	9.5	0.65	Full breakwater to water depth of 7.00 meters
1911-1916	11.50	2.25	Full breakwater to water depth of 9.00 meters
1917-1920	12.00	0.35	Partial construction of a submerged breakwater about 4 meters high
1921-1923	12.00	1.25	
1939-1945	12.00	0.600	Submerged breakwater to water depth of 11.5 meters and about 4 meters high above bottom
1951-1955	13.00	1.4	Submerged breakwater to water depth of 11.5 meters
1961-1966	14.00	2.4	

Table 2 shows that: (1) increasing the depth of the navigation channel causes an increase in the annual maintenance dredging; and (2) construction of the submerged breakwater has considerable effect on reducing the annual maintenance dredging.

EFFECT OF SUBMERGED BREAKWATERS ON SEDIMENT AND FLOW PATTERN

Consider a submerged breakwater with average height h above the bed and located to the updrift side of the dredged channel (Figure 5). The use of such a breakwater would have the following principal effects on the sediment and flow conditions in the vicinity of the dredged channel:

- The submerged breakwater could cause the bed load to either go around it or settle to the updrift side of the breakwater.
- Portion of the suspended sediment load of relatively high concentration near the bed would also be partially prevented from reaching the dredged channel.
- The submerged breakwater will generate a longitudinal current along its entire length which will transport sediment in the offshore direction away from the dredged channel.

Quantitative analysis of the effect of submerged breakwaters in relieving the sedimentation problem along the dredged channel is rather difficult. It is believed that a reasonable answer to this problem is given by the rational method developed below.

1. Submerged Breakwater Efficiency η .

Consider a submerged breakwater with variable relative heights $\frac{h}{d}$, where h is the breakwater height above the natural bed and d is the water depth as shown in Figure 5. For any breakwater relative height $\frac{h}{d}$ the breakwater's sediment trapping efficiency, η , may be defined by the equation

$$\eta = \frac{Q_t(h/d)}{Q_d(h/d=0)} \quad (10)$$

where

$$\begin{aligned} Q_t(h/d) &= \text{rate of sediment trapped by the} \\ &\quad \text{breakwater for any relative height} \\ &\quad h/d, \\ Q_d(h/d=0) &= \text{rate of channel deposition without} \\ &\quad \text{the breakwater.} \end{aligned}$$

2. Sediment Risk Factor "R"

Figure 4 shows the definition of the sediment risk factor R . The physical meaning of R may be explained as follows:

- (a) For $h/d = 0$; $R = 1$ and the expected annual dredging to maintain the dredged channel is equal to the annual rate of sediment deposition Q_d .

- (b) For $h/d = 1$; $R = 0$ and expected annual dredging = 0.
- (c) For $h/d = \text{any ratio}$, the expected annual dredging can be approximated by the equation

$$Q_{\text{dredging}} = Q_d \times R \quad (11)$$

where

Q_{dredging} = annual maintenance dredging; and

Q_d = annual rate of channel deposition for $h/d = 0$.

Using the definition of R as shown in Figure 5,

i.e.,

$$R = \frac{\int_a^h \left[\frac{(d-h)a}{(d-a)h} \right] dh \frac{v_s}{0.4} U_*}{\int_a^d \left[\frac{(d-h)a}{(d-a)h} \right] dh \frac{v_s}{0.4} U_*} \quad (12)$$

and considering sediment particle grain size range from 0.075 mm to 0.2 mm and average steady flow velocities between 0.2 m/sec and 1.00 m/sec, the average values of the risk factor R for various h/d ratios are shown in Table 3.

TABLE 3

Average Values by Risk Factor R	
Breakwater Relative Height h/d	Average Value of R
0	1
0.2	0.36
0.3	0.25
0.5	0.125
1.00	0

Using the sediment risk factors obtained in Table 3 as a reduction in the deposition rate for $h/d = 0$ case, and equation (11), the annual rate of deposition for various breakwater relative height can be estimated. The breakwater sediment trapping efficiency, n , can be computed from equation (10).

Using the results of the example given in Table 1, the submerged breakwater efficiency and the estimated annual maintenance dredging is given in Table 4.

TABLE 4

Effect of h/d on % Annual Dredging and Breakwater Efficiency n

h/d	R	Q_d $m^3/year$	Q_t $m^3/year$	n %	% Annual Dredging w.r.t. $h/d = 0$
0	1	1100	0	0	100
0.2	0.36	400	700	64	36
0.3	0.25	275	825	75	25
0.5	0.125	140	960	87	13
1.00	0	0	1100	100	0

It can be observed from Table 4, that submerged breakwaters with relative heights, h/d , between 0.3 and 0.5 would have greater effect in reducing sedimentation problems inside the dredged channel. Figure 5 shows the relationship between h/d and percent annual dredging needed to maintain the dredged channel. The annual dredging is plotted as:

(a) percentage of the total sediment load ($Q = Q_s + Q_b$)

estimated to the updrift side of the breakwater, and (b) percentage of the expected channel deposition rate without the use

of a submerged breakwater ($\frac{h}{d} = 0$).

Examination of the data reported in Table 2 shows that the annual maintenance dredging for the Suez Canal navigation channel (Port Said Harbor) reached 2.25 million m^3 /year during the period 1911-1916. A submerged breakwater ($\frac{h}{d} = 0.4$) was constructed and completed during the period 1939-1945. After the submerged breakwater was completed, annual maintenance dredging reduced to 0.6 million m^3 /year which is

about 25% of the annual dredging without the submerged breakwater. To the writer's knowledge, this is the only field data available on the submerged breakwater effect which could be used to check the theoretical curve shown in Figure 5.

OPTIMUM DESIGN FOR OFFSHORE DREDGED
CHANNEL AND PRACTICAL APPLICATION

The results of studies reported in this paper are useful for feasibility and economical evaluation of offshore dredging projects. In practice the following steps are suggested:

- Step 1. Collect field data on waves and current climatology, and bed material characteristics.
- Step 2. For the proposed dredged channel geometry, estimate annual rate of deposition (which is equivalent to the expected rate of annual maintenance dredging). This can be obtained from equation (9).
- Step 3. Estimate the average annual cost of dredging the dredged channel without the use of any breakwater protection.
- Step 4. Consider submerged breakwater protection schemes with various $\frac{h}{d}$ ratios. For each $\frac{h}{d}$, estimate average annual cost for:
- Breakwater construction.
 - Expected annual maintenance dredging. The rate of maintenance dredging can be obtained from Figure 5.
 - Estimate average maintenance cost for the breakwater. It should be noted that submerged breakwater does not need frequent maintenance as compared with full breakwater.
- Step 5. From step 4, get the average annual cost for various submerged breakwater schemes and plot the data as shown in Figure 6.
- Step 6: From a plotting similar to that shown in Figure 6, one can usually find a design scheme which will minimize the average annual cost. This scheme will give the most economical design.

SUMMARY AND CONCLUSIONS

A rational method is presented to estimate annual maintenance dredging along offshore dredged channels. The method is based on available theoretical studies on the subject of mechanism of sediment transport under wave and current action.

The effect of protecting the dredged channel against accretion is discussed. Efficiency of using submerged breakwaters with various relative height for relieving the sediment deposition rate are analyzed; breakwaters with relative height 0.3 to 0.5 were found to have high efficiency in reducing sediment deposition within the dredged channel.

CHAPTER 103

STABILITY OF TIDAL CHANNELS DEPENDENT ON RIVER IMPROVEMENT

by

Volker Barthel *)

1. Abstract

Many authors have dealt with the migration of sand in front of the German coast of the North Sea. Especially the movement of sand-banks and deep channels in the Weser-estuary was subject-matter of several investigations with different results.

Thorough investigations of selected cross-sections point out, that the movement goes on in some regions. The important shipping channel however has obtained a certain stability during the last 30 - 40 years, because the migration of sand occurs otherwise than in former days.

This phenomenon coincides with the extensive and decisive river improvement measures in the inner part of the Weser-estuary.

Current measurements in the investigation area demonstrate, that concentrated tidal currents in the deep channels guarantee a sufficient clearance for shipping purpose.

It seems to be sure, that for the present no essential shifting of the main channel calls for important measures in the field of shipping, dredging and building of sea-marks.

2. Introduction

The estuaries of the navigable rivers in the Federal Republic of Germany flowing to the North Sea are deep cutting bights with fine sand bottoms.

*) Dipl.-Ing.

Wasser- und Schifffahrtsamt Bremerhaven
Am Radarturm 1, 2850 Bremerhaven, W.-Germany

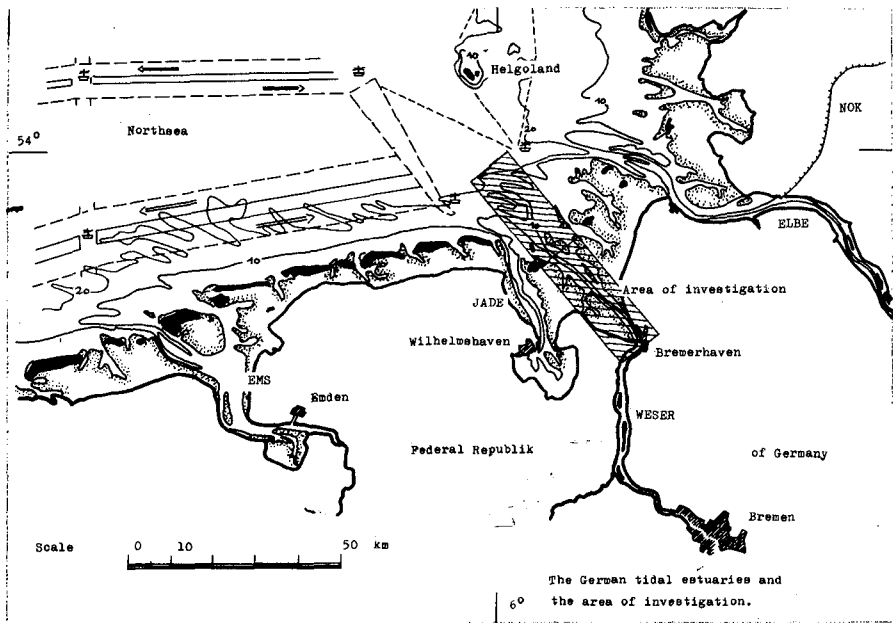

Fig. 1

On Fig. 1 one can see a part of the German bight with the large tidal rivers Ems, Jade, Weser and Elbe. The investigation area, which is to be spoken about, lies inside of the Weser-estuary. A few words of explanation to the situation:

The Outer Weser has a length of about 60 km, extending from the open sea til Bremerhaven, and important port of transshipment of ore, cars, fruit, mixed cargo an with a most important container terminal. About 65 km upstreams lies the city of Bremen with its also important harbour at the lower Weser.

Between Bremerhaven and Bremen the harbours of Nordenham and Brake are situated. Ships with a draught up to 45 feet can go to Bremerhaven, those with a draught up to 35 feet can go til Bremen.

The atlantic tidal wave penetrates in a wide-spread front into the North Sea and it has its largest tidal range on the right side, i.e. at the Scottish coast. The right branch proceeds very fast into southern direction whereas the left branch remains behind. Arriving at the German coast the tidal wave turns aside to the east and now follows the coast-line counter clockwise. The predominant tidal currents go in the same direction in the flood tide, the currents in the ebb-tide have a predominant direction from east to west. Caused by reflection and the deflecting power of the rotation of the earth there are some rotational tides in the North Sea which influence the directions of the tidal currents too. The tidal waves penetrate into the estuaries and are reflected, absorbed and deformed dependent on the morphology of the estuary. But those phenomenons are well known.

3. Morphological changes

The evident north-east directing migration of sand in front of the German coast effected by dominant waves and currents carries material from the North Sea Reservoir and eroded sand from the East Friesian Islands. This material crosses the estuaries and causes permanent shift of the channels and sand banks in the reef region.

On Fig. 2 one can see the migration of channels and sandbanks in two cross-sections in the Outer Weser from 1910 til 1975. The two important tidal and navigable channels with depths down to 20 sometimes 25 m are the "Neue Weser" and the "Alte Weser". The surrounding sand-banks come up to a height of 2.5 m beneath the water surface and the other less important channels are not directly connected with the river - bed of the Weser. The drawing shows the movement of the center or the axis of gravity of the most important banks and channels referring to a fixed line.

MIGRATION OF THE CHANNELS AND SAND-BANKS IN THE OUTER WESER 1910 - 1973

Fig. 2

The movement is also to be seen on a simplified graph in Fig. 3

MIGRATION OF THE 10m-CONTOUR
 IN THE "NEUE WESER" 1940-1975

Fig. 3

You see the contours of the 10 - m - line in the "Neue Weser" in the states of 1940, 1960 and 1975. The mean velocity of migration is

- on the west side: 20 m / year
- on the east side: ~ 60 m / year on an average.

Because of this provable migration the navigable channels, the buoys and the pertinent sea-marks (i.e. light houses, directional beacons etc.) had to be transferred or given up several times in the past.

The laws and regularities of this migration in the reef region have been discussed by several authors until now (Ref. 2,6,7). And there were different results of investigations:

Some of them discovered, that it takes a sand-bank 60 - 70 years to cover the distance to the next sand-bank. Plate (Ref. 6) writes about the "return of similar forms" in the reef region. Göhren (Ref. 2) presents an extensive classification of all these statements and points out a "return of similar states" every 110 - 120 years.

There are maps of the Outer Weser since 1859, which are sufficiently exact for an investigation of the migration in the reef region. Since 1910 the maps are so exact that you can follow the motion of single cross-sections. In an extensive research of the morphological changes from that time until now it was found out, that the migration of sand in the decisive regions happens otherwise today than in former days. This finding seems to be of an eminent importance for navigation, building of sea-marks and dredging.

In former days the penetration of flood in the reef region was delayed by a labyrinth of shallow channels and sandbanks, spread over the whole estuary. The sand migrating from west to east crossed the estuary in large sandbanks and underwater-dunes, the height of which was often only 2 - 3 m beneath the water surface. This undulatory motion seemed to lead to a recurrence of similar states in morphology in a period of 110 - 120 years. This regularity still required a development, which was undisturbed by all artificial influences.

After a thorough investigation of up to 8 cross-sections in the reef-region one can see, that the migration of large sand-banks nearly stops in parts of the cross-sections between 1920 and 1930. In Fig. 2 it is shown, that especially in the "Neue Weser" and in the "Alte Weser" this effect is evident. The increase of the graph of "Neue Weser" and "Alte Weser" comes to zero, while in the time between 1859 and 1920 it was nearly steady. The results of the other cross-sections, show the same trend.

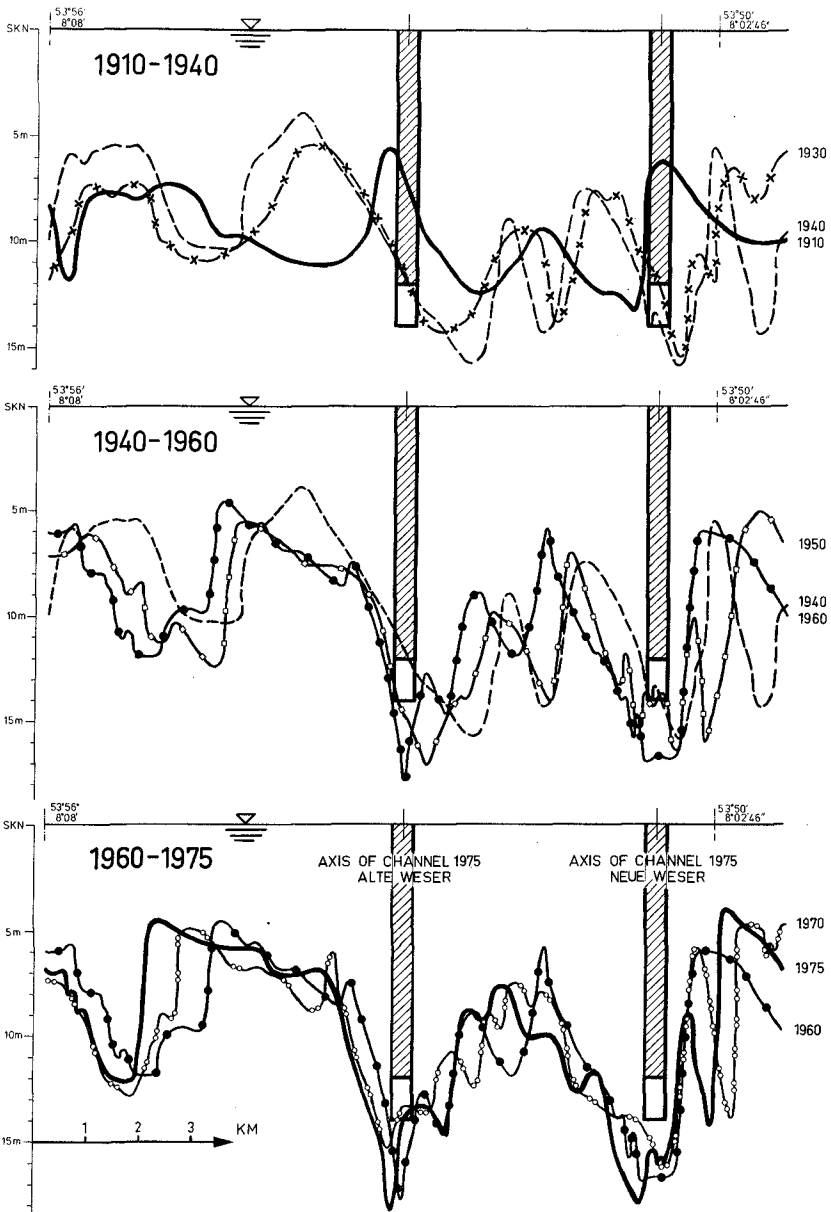

Fig. 4

Fig. 4 presents the development of the channel "Neue Weser" (NW). The left part indicates, that the proportional sectional area of the NW has been growing since 1930 from 21 % to 33 % on an average. The development of the maximum depth in the NW shows an increasing tendency with deviations. That ist not so obvious in the AW.

A careful study of the development of the cross sections in their chronological sequence gave the picture, which is to be explained in Fig. 5 in one cross-section, though it is to be found in nearly all of the analysed ones: Before 1920/30 the large sand-banks cross the estuary as a whole, leading to a permanent alteration of the navigable channels and the banks between them. But then there is a change in behaviour. The underwater - slopes moving from the west become steeper, a small underwater dune is

ALTERATION OF THE CROSS-SECTION KM 115 FROM 1910 - 1975

Fig. 5

separated from its origion bank and moves with increasing loss of size down to the bottom of the channel NW where it isn't to be found again.

Where does this behaviour come from?

Already in 1935 it could be proved, that the shift in the reef region had affected the conditions of the shipping channel of the inner part of the Outer Weser. Yet a mutual influence between inner and outer region could not be detected at that time.

Within the period of 1920 - 1930 the large and important improvement measures and dredgings in the middle section of the Outer Weser were carried out and influenced the hydraulic conditions in a good manner. Misplacing of the unfortunate shipping channel into a better position, building of a lot of groynes and training walls and dredging led to a more undelayed penetration of the tidal wave and affected the concentration of tidal currents in a positive way. The further morphological development in the Outer Weser showed, that the river structures in connexion with dredging operations had fully achieved their effect. An extensive study of these facts was carried out in 1970/1972 and was lectured on the 14th CEC in Kopenhagen 1974. It showed that most of these hydraulic and morphological developments began soon after those important improvement measures. (Ref. 5)

DEVELOPMENT OF THE PROPORTIONAL SECTIONAL AREAS F_0 OF THE CHANNELS "FEDDERWARDER ARM" (FA) "WURSTER ARM" (WA) AND "FEDDERWARDER PRIEL" (FP)

Fig. 6

The maximum current velocities grew in parts of the river with 30 %. The distribution of the quantity of flow in those parts of the river, which are divided into two branches, is of a great importance for the hydraulic behaviour. The development of this distribution was also satisfactory, as Fig. 6 shows in one example. Besides the whole river up to Bremen was deepened from 1890 til now (12 m beneath SKN* in the Outer Weser). The mean tidal range in the Lower Weser grew from 0.25 m to 3.5 m.

4. Current measurements

Though there was no opportunity to compare nowadays measurements with elder ones there were carried out a lot of measurements of current velocity and direction in the whole area to support the theory of nowadays behaviour of the reef region. The therefore required instruments are developed especially for an application in shallow water in Western Germany. All current meters were installed about 1,5 m over the bottom to record the currents near the bottom. The evaluation method for the measured values which are photographed by a camera is well - known (Ref. 3). During the interpretation great importance was attached to the ratio

$$\frac{V_e \max}{V_f \max} \quad \text{and} \quad \frac{SV_e}{SV_f}$$

and the maximum and resulting currents (Fig. 7,8)

$$SV_{e,f} = \text{amount of the vector } Fe_{,f}$$

$$V_{e,f} = \int_{K_e}^{K_f} v_i dt$$

The interpretation of all measured values gives the following characteristics of currents in the investigation area:

The maximum currents are situated in the deep channels, especially at the west side of the "Neue Weser". The intensity of the currents, i. e. the amount of velocity with regard to it's time of influence, has it's maximum values in the same region. The time of less transportation of sand ($v \leq 25 - 30$ cm/s) is very short here (1 hour) and is growing with decreasing distance to the east side of the investigation area. (3.5 hours)

* SKN = the German word "Seekartennull" = mean low water of a spring tide

Fig. 7

The directions of the currents, which are affected by wind and rotational tides demonstrate the possible transportation of sand.

The resulting current vector

$$V = \int_{K_e}^{K_e} v_i dt$$

shows the displacement of a water particle during one tide. One can recognize, that the directions of the resulting vectors only in the "Neue Weser" (Fig. 8) correspond with the direction of the channel axis. In the other regions, especially on the sand-banks, there is an enormous displacement to the North-East. The dependence of the resulting vectors' directions on wind-affected tides is very important.

The ratio $\frac{v_e \max}{v_f \max}$ and

$\frac{SV_e}{SV_f}$ finally shows, that there is a

predominance of flood currents in the "Neue Weser" and of ebb-currents in the "Alte Weser".

There is every reason to believe that the migration of sand on the sea-floor is proportional to the fourth power of the current velocities (Ref. 1,4). Therefore the evaluation method includes the computation of the values.

$$\sum_{D_f} \frac{(v_f - v_{gr}) \cdot v_f^3}{D_f} \quad \text{and} \quad \sum_{D_e} \frac{(v_e - v_{gr}) v_e^3}{D_e}$$

v_{gr} = limiting value of velocity for the start of sand-transportation (~ 25 cm/s)

$D_{f,e}$ = period of flood/ebb - current

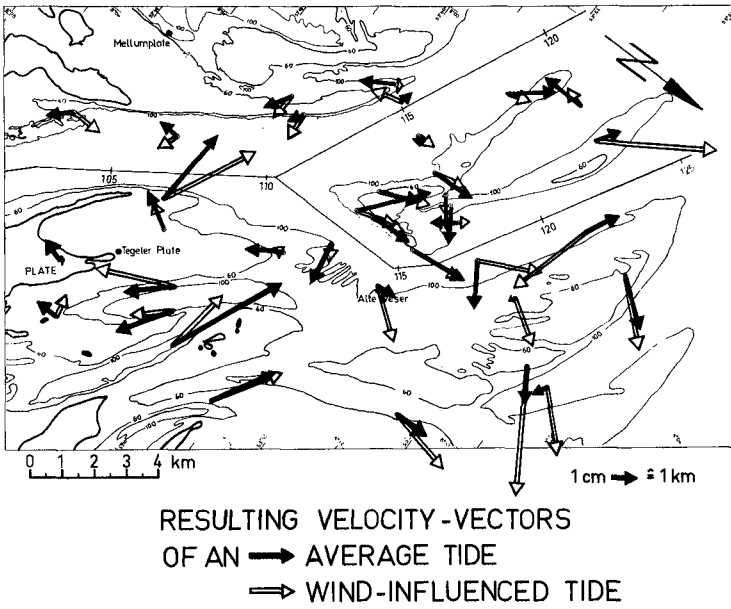

Fig. 8

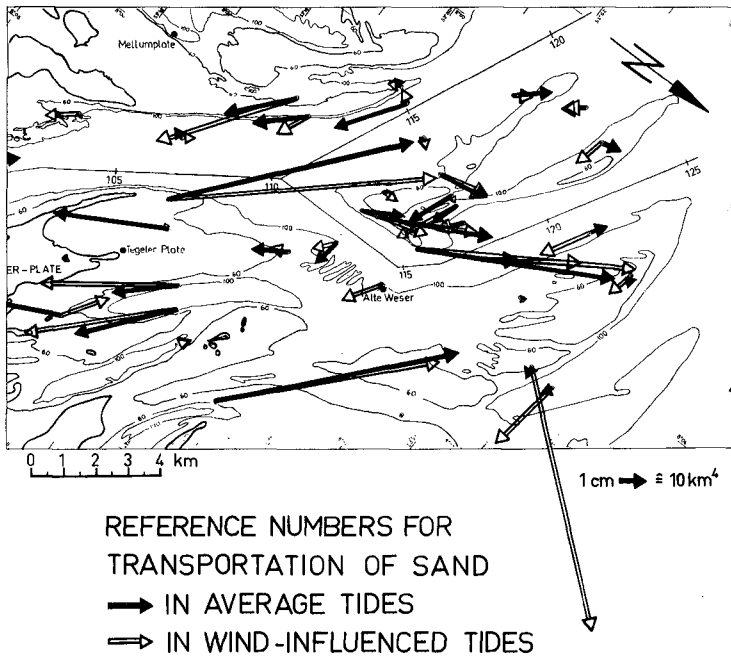

Fig. 9 shows the resulting reference numbers of sand-transportation which give another indication for the direction and amount of the movement of sand.

5. Conclusions

Comparing the results of the current measurements with the view of morphological changes you see the following proceedings in the reef area:

Effectuated by wave motion and tidal currents the sand is eroded at the steep underwater slopes of the NW and AW and crosses the deep channels as giant ripples, which seldom narrow down the required depth. On the back of the extended sand-banks the sand moves on zig-zag course with a resulting North-East direction. The migration in little ripples occurs there as well as the motion of larger underwater-dunes. At some places the underwater slopes come up to a speed of 60 m a year. The average speed is 20 to 30 m a year. Both of the deep channels are changing their form; the crucial deep channel for shipping-especially in the NW is nearly steady however. Beside the tidal currents wave motion has especially on the sand banks an essential part in migration of sand. Therefore the direction of migration depends on the respective wind direction too. It will be the task for the next years, to filter the quantitative part of wave motion in the interaction between waves and currents by measuring.

As a by-product of the investigations the cover-line of the same cross-section in different years (Fig. 5) gives a clue to the kind of material (sedimented or undisturbed) which can be found at dredging.

CHAPTER 104

CHANGES DUE TO JETTIES AT TILLAMOOK BAY, OREGON

Paul D. Komar¹ and Thomas A. Terich²

ABSTRACT

Bayocean Spit, separating Tillamook Bay from the Pacific Ocean on the north Oregon coast, underwent severe erosion following construction of a north jetty at the bay entrance in 1914-17. This erosion ultimately led to the complete breaching of the spit in 1952. Simultaneous to the spit erosion south of the entrance, the shoreline north of the north jetty advanced seaward by some 600 m (2000 ft). This pattern of erosion and deposition following jetty construction has generally been interpreted as the jetty blocking a large north to south net littoral drift in the area, estimated by a previous study at 620,000 m³/yr (800,000 yd³/yr). Our reexamination of the shoreline changes and patterns of erosion and deposition following jetty construction disagrees with this interpretation, and instead we conclude that all of the changes resulted from local rearrangements of the beach due to the disrupted equilibrium following jetty construction, but at the same time maintaining an overall condition of zero net littoral drift. This interpretation is supported by other evidence that indicates a near-zero net drift on this portion of the Oregon coast. Thus severe coastal erosion can result from jetty construction even in areas of zero net littoral drift.

A new south jetty has been recently completed (1974). The result has been further realignments of the shoreline with accretion and shoreline advance immediately south of the south jetty. This provides further confirmation that a zero net littoral drift exists in the area.

This study also demonstrates the effects of building only a single jetty rather than a pair of jetties. Following construction of the north jetty, the outer bar or ebb-tide delta at the Tillamook Bay inlet grew appreciably in size. Sand deposited there came from erosion of Bayocean

¹School of Oceanography, Oregon State University, Corvallis, Oregon 97331.

Spit further to the south. The shoal growth pushed the main channel at the entrance against the north jetty where it has remained since jetty completion. In the process, the channel became much deeper and narrower than the channel geometry prior to jetty construction.

INTRODUCTION

Bayocean Spit on the northern Oregon coast, about 80 km (50 miles) south of the Columbia River, separates Tillamook Bay from the Pacific Ocean (Figure 1). This spit has had a long history of development and

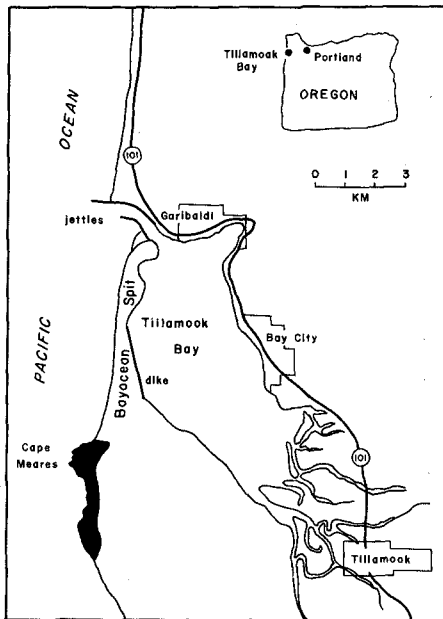

Figure 1: Tillamook Bay and Bayocean Spit.

erosion. The development and ultimate financial failure of Bayocean Park, a resort community built on the spit early in this century, has been discussed by Terich and Komar (1974). The final demise of the community resulted from erosion to the sand spit following construction of a north jetty at the Tillamook Bay entrance in 1914-17. Erosion over some

thirty-five years progressively narrowed the spit, and in 1952 it was breached at its narrowest point. This breach has been subsequently repaired by the construction of a dike, and recently a new south jetty has been constructed. The purpose of the present paper is to analyze the shoreline changes that resulted from the jetty construction and led to the erosion of Bayocean Spit. This example of shoreline erosion resulting from jetty construction is unusual in that, as will be shown, this area of the Oregon coast has a zero or near-zero net littoral drift along its beaches. Thus the shoreline changes and erosion are not the more familiar case of jetties blocking a net littoral drift, causing erosion in the downdrift direction. This study also demonstrates the results of constructing only a single jetty under such conditions, rather than a pair of jetties.

LITTORAL DRIFT ON THE OREGON COAST

With the exception of the section of coast near the mouth of the Columbia River, the Oregon coast is a series of long pocket beaches separated by pronounced rocky headlands. All evidence indicates that these areas are experiencing a seasonal reversal in the sand drift along the beaches, but with a zero or near-zero net littoral drift over a several years time span. This is best demonstrated by the effects of jetty construction on patterns of shoreline erosion and accretion. The study of Komar, et al. (1976) investigated these patterns for all jetty systems on the Oregon coast with the exception of the Columbia River jetties. Our study found that following jetty construction, sand would in general accumulate adjacent to the jetties, both to the north and south, filling in the pockets formed between the jetties and the pre-jetty shorelines which curved inward at the entrances. Our study showed that the amount of deposition adjacent to the jetties depended on the sizes of the pockets formed by the jetty construction. Deposition commonly occurred both north and south of the jetty systems, and the relative amounts of shoreline accretion on opposite sides of the jetties could in no way be taken as inferring a net littoral drift along the coast. Sand for this shoreline advance next to the jetties came from erosion of the coast at greater distances from the jetties.

The shoreline alterations following jetty construction continued until the shoreline became essentially straight and parallel to the prevailing wave crests, at which point zero net sand transport was again achieved and a new equilibrium reached. As will be shown in this paper, this pattern of deposition adjacent to the jetties and erosion at greater distances along the coast also explains the shoreline alterations at the Tillamook Bay entrance that led to the destruction of Bayocean Spit. The pattern of changes there, however, was complicated by the fact that only a north jetty was constructed initially, not a pair of jetties.

Deposition around jetties therefore indicates that, except near the Columbia River, the Oregon coast beaches have, as close as we can determine, a long term zero net littoral drift. This is also supported by observations that there is a seasonal reversal in the general transport directions due to the patterns of storm systems. During the summer months waves prevail from the northwest, causing a southerly sand transport along Oregon beaches. During the winter months the transport is to the north due to waves arriving mainly from the southwest. The wave data is inadequate, however, to actually carry out any calculations of littoral drift rates in an attempt to demonstrate a zero net drift.

Similar to the jetties, the rocky headlands show no indications of blockage of a net littoral drift, there being no accumulations of beach sand either to the north or south sides. What little study that has been done of heavy minerals in the beach sands also indicates that there is no bypassing of littoral sands around these headlands, which is reasonable considering their sizes and that they extend to considerable water depths. It is because of these barriers that the Oregon beaches can be described as pocket beaches of varying size. The only net littoral drift required within a pocket beach is the small amount necessary to redistribute the beach sand away from its sources to the complete stretch of beach. Previous studies (for example, Komar and Rea, 1976) have shown that sea cliff erosion is the primary source of beach sands in most areas, the river sands being trapped within the estuaries. Therefore even a net drift required for sand redistribution within the Oregon pocket beaches will be very small.

Because there is essentially a zero net drift of littoral sands

on the Oregon coast beaches, the erosion of Bayocean Spit following jetty construction clearly is not another example such as the Santa Barbara, California, breakwater, or the Port of Madras, India, where the coastal erosion resulted from blockage of a large net littoral drift by jetty construction.

SHORELINE CHANGES FOLLOWING CONSTRUCTION OF A NORTH JETTY

The principal sources of information on the shoreline changes utilized in this study are: (1) surveys undertaken by the Corps of Engineers, Portland District, before and after jetty construction; (2) aerial photographs from a variety of sources; (3) field studies of old shorelines and other features that are still visible; and (4) the writers' surveys in the case of the more recent construction of the south jetty at Tillamook Bay. In addition to the shoreline changes, once erosion became appreciable on Bayocean Spit, the Corps of Engineers, Portland District, monitored the rates of retreat of the dune bluffs and coastal property on the spit; this data has also been utilized. Since most of the shoreline changes and spit erosion occurred more than twenty-five years ago, we have had to rely primarily on historic data rather than on our own measurements. There is of course a certain amount of uncertainty in doing this.

A north jetty at the entrance to Tillamook Bay was begun in 1914 and completed in 1917. For economic reasons, an accompanying south jetty was not constructed at that time. The most apparent immediate response to the north jetty construction was a shoreline advance to the north of the jetty, documented in Figure 2. The buildout of the shoreline there nearly kept pace with the jetty extension. As in the cases of jetty construction elsewhere on the Oregon coast, and already discussed in this paper, this deposition adjacent to the north jetty occurred primarily so that the pocket formed between the jetty and the pre-jetty shoreline, which curved inward toward the bay entrance, would be filled. The shoreline built outward only until it became parallel to the prevailing wave crests, at which point long term changes ceased. The overall position of the shoreline has changed very little in the

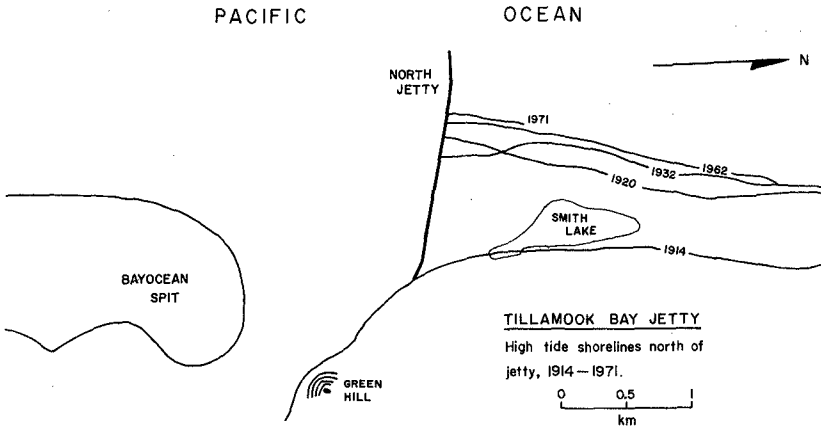

Figure 2: The shoreline advance north of the north jetty at the Tillamook Bay entrance after its completion in 1917. The 1914 shoreline gives a typical pre-jetty location.

past forty-some years, the only alterations being due to partial jetty degradation and reconstruction in the 1930's.

The sand accumulation north of the north jetty amounted to some $6,000,000 \text{ m}^3$ ($8 \times 10^6 \text{ yd}^3$). The second most apparent effect of the north jetty construction was the resulting erosion of Bayocean Spit to the immediate south. Based on this pattern of deposition to the north and erosion to the south, previous studies generally concluded that there must be an appreciable southerly net littoral drift. Based on accumulation rates north of the north jetty, this littoral drift was estimated at $600,000 \text{ m}^3/\text{yr}$ ($800,000 \text{ yd}^3/\text{yr}$) by the Corps of Engineers (1970), but placed at a lower estimate of $140,000 \text{ m}^3/\text{yr}$ ($180,000 \text{ yd}^3/\text{yr}$) by O'Brien (1930). We have already summarized the evidence that argues against such a net littoral drift on the Oregon coast. In the case of the Bayocean Spit and Tillamook Bay area, the pronounced headland Cape Meares exists to the immediate south (Figure 1). If such a large net drift did exist, this cape should also block the transport causing a buildout of the beach there to the north; there is no noticeable buildout, the beach in fact being principally gravel and cobbles; not sand as on the beach

to the north fronting the spit, and the cliffs near Cape Meares are undergoing extensive erosion. As already indicated, the deposition north of the north jetty following its construction can be better interpreted as changes resulting from local rearrangements of the beach due to the disrupted equilibrium caused by the jetty's presence but at the same time maintaining an overall condition of zero net drift.

It is difficult to determine when noticeable dune and property erosion began on the spit itself following construction of the north jetty in 1914-17. O'Brien (1930) indicated that there was considerable erosion at that time just to the north of Cape Meares (Figure 1), off the spit itself. He also mentioned, however, that the spit itself had suffered little change, "although the channel has moved northward against the jetty, probably due to the decreased sand pressure from the north." This channel migration following jetty construction and the growth of the shoal outside the bay entrance will be documented later. The sand deposition at the bay entrance came from erosion of the beach along the length of Bayocean Spit. From O'Brien's comment it would appear that there may have been some beach erosion at that time but the erosion had not yet reached the dunes nor threatened any property in Bayocean Park.

O'Brien (1930) also mentioned that the north jetty had weathered down appreciably. For this reason, the north jetty was reconstructed and lengthened in 1932-33. After this reconstruction erosion on the spit became very apparent. Even while reconstruction was in progress erosion began to undermine the sidewalk fronting the natatorium of Bayocean Park, built close to the beach, and by 1936 the structure's roof had collapsed (Figure 3). Erosion of the spit was progressive, although some winters were more severe than others and caused rapid dune and property retreat. For example, during January 1939 a storm broke a small gap along the narrow southern end of the spit, washing sand and gravel into the bay. The natatorium was finally completely destroyed by this storm (Figure 3). Maximum recession of the top of the dune bluff was 7.5 m (25 ft) with an average recession of 2 m (7 ft). In addition to the loss of the natatorium, four houses were undermined and lost, nine were immediately threatened,

Figure 3: Progressive erosion of the natatorium on Bayocean Spit.

and six had to be moved back for safety.

Washovers of the spit occurred during subsequent winter storms until on 13 November 1952 storm waves together with high tides entirely breached the spit's narrowest southern section, initially removing a 1200 m (4000 ft) long segment of spit. This breach progressively widened, becoming nearly a mile wide at high tide. The breach developed into the natural opening for the bay, the northern entrance with the jetty beginning to shoal and close (Figure 4; 1955 survey). Waves rolled through the breach producing swells within the bay, causing some erosion to farmlands on the bay's edge. For this reason it was decided to close the breach, so in 1956 work was begun on a rubblemound dike, set back within the bay. The construction of this dike and the difficulties in closure are discussed by Brown, et al. (1958). It was anticipated that the

Figure 4: Progressive erosion to Bayocean Spit leading to its breaching in 1952, necessitating the placement of a dike closing the breach.

pocket in the shoreline seaward of the dike would fill and re-establish a sand beach fronting the dike, which it did as can be seen in the 1971 survey of Figure 4.

SHOAL DEVELOPMENT AND CHANNEL CHANGES AT THE BAY ENTRANCE

Although erosion occurred along most of the length of Bayocean Spit following construction of the north jetty, there was some deposition to the immediate south of the jetty (as well as to the north, as already seen). This deposition to the jetty's south at the bay entrance was in the form of a substantial growth to the outer bar or ebb-tide delta. As will be discussed later, it is estimated that some $3.3 \times 10^6 \text{ m}^3$ ($4.3 \times 10^6 \text{ yd}^3$) of sand was added to this shoal following jetty construction.

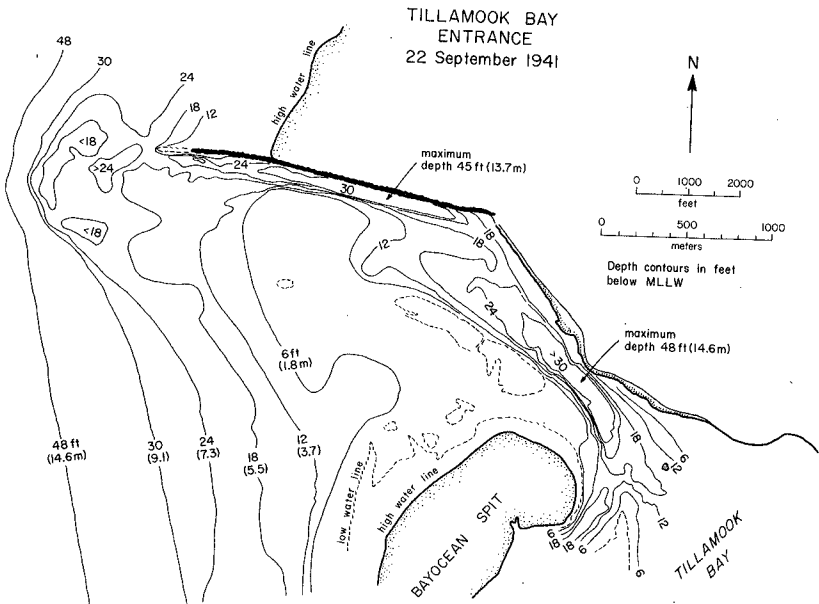

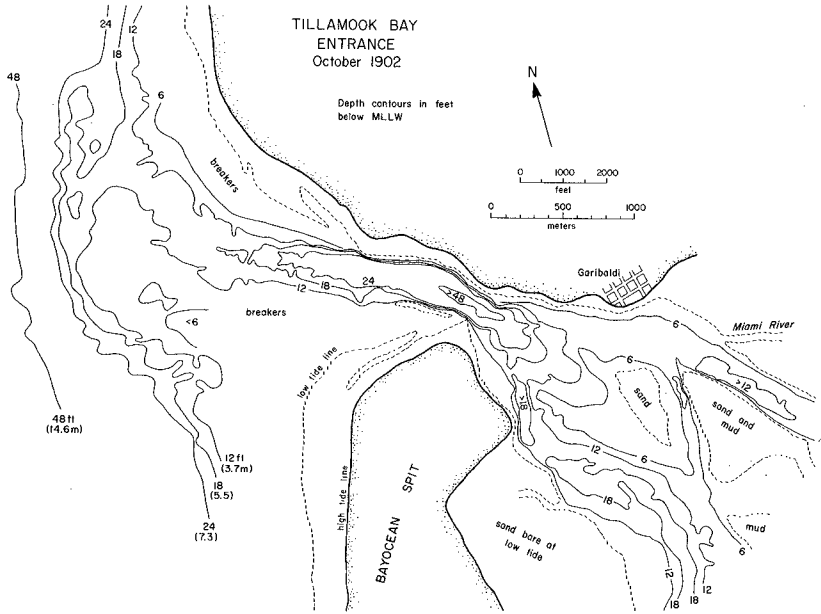

Figure 5: Tillamook Bay entrance before (upper) and after (lower) north Jetty construction in 1914-17.

The changes in the shoal and bay entrance are illustrated by Figure 5, the upper survey showing the entrance prior to jetty construction and the lower being typical of the entrance after construction. It is seen that there was an increase in the overall size of the outer bar shoal and a reduction in water depths. Under moderate to high wave conditions, this shoal became entirely covered by breaking waves and surf, making it a hazard to boats using the entrance.

Figure 5 also shows that the channel leading from the bay entrance was pushed northward against the jetty by the growth of the shoal. The channels at the entrances to the Umpqua and Coquille Rivers on the Oregon coast similarly migrated until they became adjacent to the single jetties that were initially built there (Komar, et al., 1976; Kieslich and Mason, 1976). Such a response to a single jetty rather than a pair of jetties has also been shown to occur on other coasts (Kieslich and Mason, 1976).

In addition to the growth of the outer bar and migration of the main channel following construction of the north jetty at Tillamook Bay, there were changes in the geometry of the channel outside the entrance. This is shown in Figure 6 which compares channel cross-sections before (June 1914) and after (June 1920) jetty construction. It is seen that after jetty development the channel became much deeper and narrower than existed prior to construction. These changes are presumably the response of the channel to the pressure from the south by the shoal growth. However changed in depths and widths, the channels before and after jetty construction did not differ significantly in cross-sectional areas. In addition, the changes in geometry did not extend inward along the channel into the entrance itself. Figure 7 shows a number of channel cross-sections immediately north of the spit at the entrance's narrowest point, some before and some after jetty completion. There are no noticeable effects there due to the addition of the north jetty. Despite the changes in channel geometry just outside the entrance and the growth of the shoal, the entrance itself remained relatively unchanged and bore the same relationship to the tidal prism within the bay according to O'Brien's (1931, 1939) relationship.

Although this study undertook no field investigations of the currents and waves in the area of the entrance, the changes in the channel position and geometry, and the growth of the outer bar shoal can be

Figure 6: Deepening and narrowing of the channel following construction of a north jetty.

understood in terms of the findings of previous studies of inlets. Processes in the vicinity of inlets are complex in that they are the combined results of tidal-currents, wave action, and possible effects of salinity and thermal stratification resulting in a net inward flow at the bottom of the channel. The main ebb flow currents generally act to carry sand from the bay and nearshore areas to the offshore where it is deposited in the form of a delta, sometimes called the "ebb-tide delta." If located on a coast with a zero net littoral drift, this delta would be symmetrical and arcuate in shape. The existence of a net littoral drift would produce an asymmetry. Although the main ebb flow is directed offshore, currents move inward toward the entrance in the nearshore, from both sides of the inlet. Two eddies or gyres may develop on flanks of the main ebb channel emanating from the inlet; one gyre would be a clockwise flow, the other

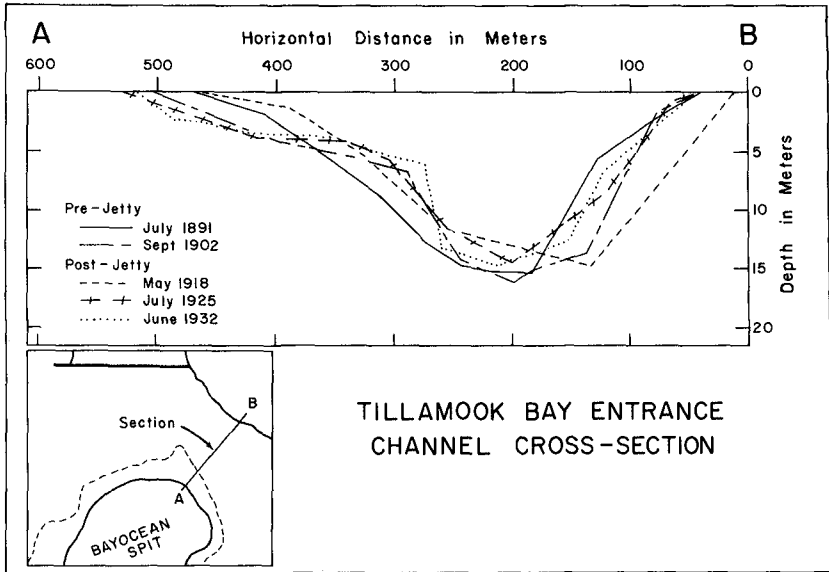

Figure 7: Cross-sections of the Tillamook Bay entrance before and after construction of the north jetty.

counter-clockwise, but both would produce currents directed toward the inlet on their shoreward sides. Lynch-Blosse and Kumar (1976) subscribe to such gyres being important at inlets, and discuss modifications where longshore currents are superimposed due to a general oblique wave approach to the coast. Dean and Walton (1975) point out that the ebb current can be viewed as a jet directed seaward, the high velocities in the central current of the jet transferring momentum outward and entraining adjacent waters, giving rise to the gyres described above. As a result, during ebb flow from the inlet there will be inward moving currents close to the shore, transporting sand toward the inlet and aiding the development of the flanking outer bars or shoals. During tidal flood flows the water converges toward the inlet from all sides, especially in flood channels to the flank of the deeper ebb channel. Thus the flood currents also aid in the development of flanking shoals.

Wave action generally acts to counter growth to the outer bar of the inlet. It does this by transporting sand back onshore to the beaches.

For this reason, on coasts of high wave conditions (like Oregon) the outer bars of inlets tend to be smaller than on coasts of small waves (Dean and Walton, 1975; Walton and Adams, this volume). However, wave refraction over the shoal can also aid in the development of the outer bar, and some studies have suggested that this process may be more important than the current gyres already discussed (Hayes, et al., 1971; Hubbard, this volume). Refraction of the waves around the outer bar causes a longshore current directed toward the inlet from both sides, thus working in concert with any ebb-tide gyres and flood-tide currents acting in the area. With an overall oblique wave approach to the inlet area, the longshore current may be inward toward the inlet on only the updrift side.

As seen in Figure 5 (upper), typical flanking outer bars existed at the Tillamook Bay entrance prior to jetty construction. There was a seaward offset of the northern shoreline which is sometimes taken to indicate a net littoral drift (Hayes, et al., 1971; Lynch-Blosse and Kumar, 1976), but there is no consistency as to whether the shoreline offset is updrift or downdrift of the inlet. The presence of an offset at the Tillamook Bay inlet in an area of zero net littoral drift casts doubts on offset direction as an indicator of net drift direction and on the theories of origin of the offset which rely on the presence of a net littoral drift.

The construction of the single north jetty at the Tillamook Bay inlet provided additional protection from the wave activity. This protection would allow for further growth of the south flanking shoal, the north flanking shoal becoming covered by the shoreline advance to the north of the north jetty. The growth of the south flanking shoal was presumably due to the continuation of an eddy gyre in this region during ebb tide, and perhaps due to wave refraction effects, both described above, but with a decrease in the wave activity that had acted to reduce the size of the shoal. This is partly verified by model studies conducted at the Waterways Experiment Station on the Masonboro Inlet, North Carolina, and reported in Dean and Walton (1975, page 137). Like the Tillamook Bay entrance, the Masonboro Inlet has only a single jetty. The model studies indicated that shoal growth resulted from (a) the jetty's sheltering of the shoal area, thereby creating a sand

trap, and (b) a large eddy or gyre carrying sand toward the inlet on both ebb and flood currents.

It is seen that all factors affected by the installation of a north jetty at Tillamook Bay would act to increase the growth of the south flanking shoal. The shoal growth pushed the channel northward against the jetty, and the pressure from the developing shoal also presumably accounts for the narrowing and deepening of the channel.

INTERPRETATION OF SHORELINE CHANGES AND THE BUDGET OF SEDIMENTS

As already indicated, a closer inspection of the changes following construction of the north jetty does not agree with the interpretation of a large net littoral drift identified by earlier studies (Corps of Engineers, 1970). The overall pattern of erosion and deposition is illustrated schematically in Figure B, and it is seen that the pattern is symmetrical north and south of the jetty, complicated by the fact that only a single jetty was installed. Although erosion occurred along most

Figure B: Patterns of erosion and deposition following construction of a north jetty but prior to the south jetty development.

of the length of Bayocean Spit, there was a net deposition just to the south of the jetty in the form of growth to the flanking outer bar. Following jetty construction, sand moved northward from most of the length of the spit and accumulated in this shoal growth. As will be shown shortly, the loss of sand from the spit erosion can be approximately balanced by the amount of sand deposited on the shoal plus that carried into the bay during the 1952-56 breach.

To the north of the jetty sand accumulated and the shoreline advanced (Figure 2). Deposition there probably derived its sand from beach erosion further to the north, symmetrical with the northward movement of sand on the spit to the inlet. This overall pattern of deposition adjacent to jetties and erosion at greater distances was shown to occur at other Oregon coast jetty systems (Komar, et al., 1976), and was reviewed earlier in this paper. Erosion to Bayocean Spit was much greater than erosion to the north of the jetty at Manhattan Beach and Rockaway Beach (Figure 8) because of the longer stretch of beach that exists to the north. Only a small amount of sand had to be eroded per unit length of shoreline to supply sand to the accretion area immediately north of the jetty. In contrast, Bayocean Spit is only a small segment between the jetty and Cape Meares on the south (Figure 8) so that a larger amount of sand had to be supplied by each unit length of spit shoreline erosion to support the shoal growth next to the inlet.

We have attempted to put sediment volumes on the patterns of erosion and deposition illustrated in Figure 8 by the development of a budget of sediments. This budget is for changes following the completion of the north jetty in 1917 but before the construction of the south jetty in 1969. Our estimates are given in Figure 9. Deposition to the north of the jetty amounted to some $6 \times 10^6 \text{ m}^3$, which agrees with previous estimates of the fill (Corps of Engineers, 1970). As already indicated, this sand deposition came from beach erosion further to the north; that erosion value is given in Figure 9 in parentheses because we have no actual measure of the erosion other than the supposition that it will balance the deposition north of the jetty. Of course any transfers of sand around the jetty during or after construction would alter this exact balance; unfortunately we have no way to evaluate such a

Figure 9: Budget of sediments for areas of erosion and deposition following construction of the north jetty at Tillamook Bay.

transfer around the north jetty, but believe it to be small, especially in comparison with the volume of sand deposited to the north of the jetty. This belief is in part supported by the continued existence of a shoreline offset north and south of the jetties, even after construction of a south jetty. This suggests that the jetties are an effective barrier to longshore movements of sand on the beaches; otherwise sand would presumably transfer from the north to the south beach until they have equal offshore extents.

We estimate that the flanking outer shoal to the south of the jetty increased in volume by $3.3 \times 10^6 \text{ m}^3$ following jetty construction. This estimate is based on comparisons of bathymetric surveys such as those of Figure 5, before and after jetty completion. Our estimate shows reasonable agreement with the results of Walton and Adams (this volume). They place the total volume of the outer bar of Tillamook Bay at $15 \times 10^6 \text{ m}^3$, so the measured growth volume is small in comparison. Of special interest is that Walton and Adams show that outer bars on

coasts with small wave energy are some 23% larger than bars on coasts with large wave energies. If we reason that the growth of the Tillamook inlet outer bar is due to the additional protection offered by the jetty from wave attack, and employ their 23% resulting growth factor, one obtains a volume increase of $3.5 \times 10^6 \text{ m}^3$, almost exactly the same as our measured increase ($3.3 \times 10^6 \text{ m}^3$).

Erosion of Bayocean Spit and the area to its immediate south up to Cape Meares amounted to some $5.7 \times 10^6 \text{ m}^3$ (Figure 9). This estimate is based on measured beach and dune bluff retreats and heights of the dune bluffs and sea cliffs.

The other large transfer of sand in the area was into the bay when the spit breached in 1952 and remained open until 1956. This volume of deposition and loss from the seaward side of the spit is estimated at $1.5 \times 10^6 \text{ m}^3$, and is based on the volume of spit removed by the breaching process (which gives a minimum transfer) and shoaling values within that portion of the bay. This estimated volume is considered to be much poorer than our estimates of spit erosion or deposition near the jetty.

There is also the possibility of some deposition on the inner shoal (flood-tide delta), within the bay at the jettied entrance. The surveys of the entrance area, before and after jetty construction, suggest that deposition within the bay in this area was small, but we could not make satisfactory measurements from the available data.

Altogether there is a reasonable accounting for the transfer of sand from erosion areas to deposition areas in the region of Bayocean Spit and Tillamook Bay following construction of the north jetty. The shoal growth and sand entering the bay through the breach together account for $4.8 \times 10^6 \text{ m}^3$ of deposition. This is close to the $5.7 \times 10^6 \text{ m}^3$ of estimated erosion from the spit. Considering the inaccuracies of these estimates, the results demonstrate that the patterns of erosion and deposition can be accounted for by local rearrangements of nearshore sands following construction of the north jetty, without blockage of an appreciable net littoral drift by the jetty.

CONSTRUCTION OF THE SOUTH JETTY

The hazardous channel conditions which developed due to the growth of the outer bar following construction of the north jetty prompted renewed considerations for construction of a south jetty. Construction of a south jetty was begun in April 1969 and completed in 1974 with a total length of 2000 m (6,500 ft).

Even as the south jetty was being constructed, sand accumulated between it and the curved pre-jetty shoreline, causing a shoreline advance to the south. This accumulation continued until the shoreline became straight and parallel to the prevailing wave crests, the same as described earlier for other jetty systems on the Oregon coast as well as for the earlier construction of the north jetty. This provides further proof for a zero or near-zero net littoral drift in the area.

SUMMARY OF CONCLUSIONS

(1) With the exception of the section of coast near the Columbia River, the Oregon coast is a series of pocket beaches separated by pronounced rocky headlands. There is a zero or near-zero net littoral drift within these pockets. Shoreline changes due to jetty construction are therefore not due to blockage of a net drift.

(2) Following completion of a single north jetty in 1917 at the Tillamook Bay entrance, the shoreline built outward to the immediate north. This accretion occurred to fill the embayment created between the jetty and the pre-jetty shoreline which curved inward toward the bay entrance. Deposition continued until the shoreline became straight and parallel to the prevailing wave crests, at which time a new equilibrium was achieved with a zero net littoral drift.

(3) Bayocean Spit to the south of the Tillamook Bay entrance suffered severe erosion following construction of the north jetty, culminating in its breaching in 1952. Initially, sand eroded from the spit moved northward and was deposited at the entrance in the form of growth to the outer bar (ebb-tide delta). Later when the spit breached, considerable quantities of littoral sediments were also carried into the bay.

(4) Growth of the outer inlet bar or shoal following construction

of a north jetty can be understood in terms of wave and current processes acting at inlets. The single jetty offered increased protection from the waves and perhaps augmented flanking currents flowing inward toward the inlet.

(5) Considerable coastal erosion can result from jetty construction even in coastal areas that are not experiencing a sizeable net littoral drift; blockage of a net drift by jetty construction is not a necessary prerequisite for erosion.

CHAPTER 105

CHANGES IN INLET OFFSET DUE TO STABILIZATION

ABSTRACT

Available evidence indicates southward littoral transport through the Merrimack Embayment. In apparent contradiction, the beach on the southern (Plum Island) side of the inlet has built seaward of the updrift beach. This phenomenon is related to a balance between storm and fair weather conditions. Wave observations under a variety of surf conditions show that during storms, sand is transported southward along the face of the nearshore bar fronting Plum Island. During calm periods sand is moved northward along the beach until it is trapped by the southern jetty and removed from the then active tidal current transfer system. Using discharge data and wave measurements from the Merrimack Inlet area, Bruun's bypassing coefficient ($r = Q_{1s}/Q_{max}$, where Q_{1s} is the longshore transport rate in M^3/yr and Q_{max} is the maximum inlet discharge in M^3/sec) was computed for storm and fair weather conditions. During storms, the bar bypassing observed in the field was clearly indicated. During calmer periods tidal current transfer was predicted. This relationship is considered only an approximation as it does not consider many important physical parameters (grain size, nearshore slope, wave type, etc.).

INTRODUCTION

The literature is replete with references concerning bypassing of sand around tidal inlets. Numerous researchers have considered the importance of this process to engineers (Angas, 1960; Bowman, 1960; Bruun and Gerritson, 1960; Caldwell and Lockett, 1965; Dean and Walton, 1975; Herron and Harris, 1967; Hodges, 1955; McDonald and Sturgeon, 1956; Watts, 1962). These studies have generally shown that the type and rate of bypassing that occurs are dependant upon the volume of sediment supplied to the inlet (littoral drift) and the ability of the inlet to flush this material from its throat (related principally to tidal prism). Furthermore, the nature of this relationship will be reflected in the morphology of an individual inlet and its associated sand bodies.

At Murrells Inlet, S. C., (Fig. 1) net longshore transport rate is small and sand tends to reside in the inlet system. The near balance between sand entering and leaving the inlet causes it to be choked with sand. In this case, bar bypassing dominates at the expense of local navigation. At Kiawah Inlet, S. C. (Fig. 2) another type of bypassing, channel abandonment, occurs. Over a period of 10 months, the sand that had accumulated on the updrift side of the inlet was bypassed as the main channel was closed and a path further updrift was initiated (Fig. 2).

Whatever the process responsible for bypassing, introduction of a large structure into the littoral zone (a jetty, for example) results in a significant

Figure 1. Low tide photograph of Murrells Inlet, S. C. Note the large shoal occupying the channel cross-section. This is a result of the near balance of sand moving in and out of the inlet.

Figure 2, Bypassing at Kiawah Inlet, S. C. These photographs show the configuration of the inlet in April, 1975 (A), November, 1975 (B) and February, 1976 (C). Note the abandonment of the main ebb channel between April and November, 1975 followed by swash bar development in February, 1976.

modification of the bypassing process. In most documented cases, the resultant pattern of erosion and deposition is similar to that shown in Figure 3; that is, accretion along the updrift beach at the expense of the eroding downdrift beach.

The Merrimack River Inlet is located in northeastern Massachusetts near the Massachusetts-New Hampshire border (Fig. 4). The inlet separates two active Holocene barriers, Salisbury Beach to the north and Plum Island to the south. A variety of coastal defense structures have been used to stabilize the inlet and retard the rate of erosion along adjacent beaches. Since their construction however, these structures have been responsible for many problems (Hubbard, 1974). The jetties, built in sections since 1912, have effectively stabilized the position of the inlet while causing localized erosion on the nearby beaches and river front. Despite the apparent effectiveness of the jetties as barriers to littoral transport, the downdrift side of the inlet does not show the serious erosion usually associated with structures of this type. In fact, the downdrift beach is presently undergoing rapid progradation. Both field observations and mathematical considerations are presented to explain this phenomenon.

The inset is a low tide aerial photograph looking northward over Plum Island (foreground) and Merrimack Inlet. Note the well developed nearshore bar system that extends past the inlet mouth.

Sediment Dispersal

Several lines of geomorphic evidence indicate a southward transport of littoral material through the Merrimack Embayment (Fig. 5). First, the seaward displacement of the 20 meter contour near the southern end of the embayment suggests that Ipswich Bay is a sink for material moving in that direction. Bothroyd (pers. comm.) has observed an accretionary beach at Castle Neck. Also, the southward migration of Plum Island by spit growth on its downdrift end (Farrell, 1969) indicates a sediment supply to the north. Finally, grain-size trends along Plum Island and Castle Neck beaches (Anan, 1971) and on the Merrimack ebb-tidal delta (Hubbard, 1975) also suggest southward littoral transport through the area (Fig. 5).

Morphology and Hydrodynamics

One would expect that under these conditions the beach on the northern side of Merrimack Inlet would be accreting while the southern beach eroded. To the contrary, the downdrift shoreline extends approximately 300 meters seaward of the northern beach. Furthermore, rapid accretion has been observed adjacent to the inlet since the 1967 rehabilitation of the south jetty.

If we consider that this offset is the result of some factor other than the jetties, then the downdrift offset inlet should have persisted when the jetties were absent. Analysis of existing charts of Merrimack Inlet show that although

the inlet was offset downdrift in 1741, by 1776 the inlet configuration had changed to that of an updrift offset (Fig. 6). 1809 saw the reestablishment of the downdrift offset. These and other reversals were probably related to the by-passing of sand around the inlet. Under natural conditions, the inlet therefore did not persist as a downdrift offset. The flip-flopping observed between 1741 and 1900 ceased abruptly however after the jetties were built in the early 1900's. A 1940 photograph from Chute and Nichols (1942) shows that the present configuration had already developed at that time (Fig. 7). It seems logical therefore, that the pattern of erosion and deposition observed at Merrimack Inlet is related to the presence of the jetties.

This pattern results from a balance between the dominant northeasterly storm waves and the prevailing southeasterly waves generated during fair weather conditions. It can be seen in Figure 8 that during storms the sediment moves uniformly southward except for a divergence in transport direction occurring immediately downdrift of the inlet. At this point a break in the nearshore bar occurs through which waves pass and break directly on the beach. Immediately updrift of the gap the bar reaches its highest elevation in response to the retardation of sand flow along the shoal. This adjustment of the waves to the topography of the nearshore bar results in northward sand transport during storms along the beach immediately downdrift of the jetty and the retention of sand in this part of the system.

Figure 7. Aerial photograph looking westward across Merrimack Inlet. Note the similarities between this photo and Figure 9. From Chute and Nichols (1942).

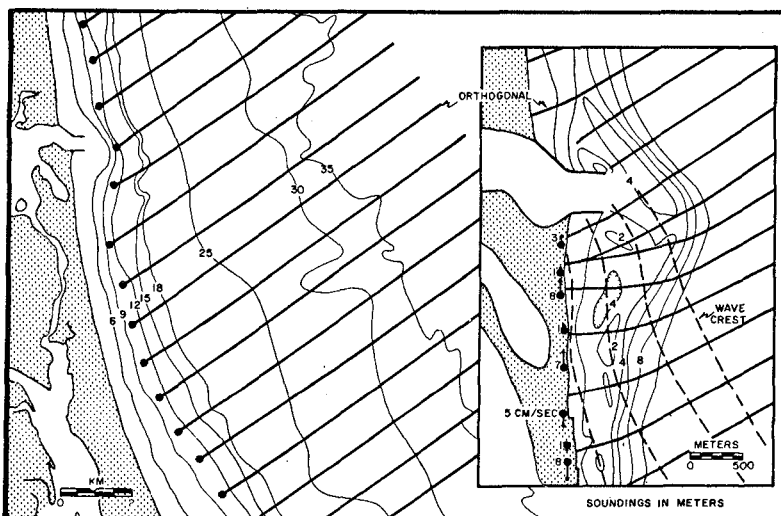

Figure 8. Wave refraction around the Merrimack ebb-tidal delta. The numbers in the inset are longshore current velocities measured during northeast wave approach.

During higher tidal stages, be they astronomical or meteorological, the entire beach comes under severe wave attack. Sand is removed from the beach and moved offshore toward the permanent nearshore bar and to the south (Fig. 9). The bar on the updrift side of the inlet extends nearly to the beach and provides a point of entry for sand into the by-passing system.

During fair weather, sand is moved landward and toward the north under the influence of the prevailing southeasterly waves (Fig. 9). On the south side of the inlet, this landward transport occurs through the migration of entire segments of the permanent nearshore bar onto the beach (Fig. 10). Once on the beach, this sand moves northward until it is trapped by the southern Merrimack jetty.

Bruun (1966) presented a formula to determine whether the movement of littoral material past an inlet would occur by the development of an inlet shoal or by tidal current transfer. Using a ratio between littoral drift (Q_{LS} in M^3/yr) and maximum inlet discharge (Q_{max} in M^3/sec) in twenty-eight inlets, he was able to determine whether tidal current transfer or bar bypassing would dominate in each case. Empirically, r values ($r = Q_{LS}/Q_{max}$) less than 10 - 20 indicated predominant tidal current transfer while values greater than 200 - 300 implied bar bypassing.

Using the maximum spring-tidal discharge of $2500 m^3/sec$ measured in the Merrimack Inlet, a value of $7.5 \times 10^4 M^3/yr$ was calculated as the volume of

Figure 9. A (above). Sand transport patterns observed during storm conditions. The X indicates the point of attachment of the nearshore bar on the northern side of the inlet.

longshore drift necessary to initiate bar by-passing. Using these data and formulas from the Shore Protection Manual (U.S. Army, 1973), longshore transport rates for the Merrimack Inlet area were computed. Using the relationships,

$$P_{1S} = 100.6 (H_b^3/T) \sin \alpha_0 \quad (1) \text{ and,}$$

$$Q = (7.5 \times 10^3) P_{1S} \quad (2)$$

where: P_{1S} = surf zone approximation for the longshore component of wave energy flux
 H_b = breaker height
 T = wave period
 α_0 = angle between deepwater wave crest and shoreline
 Q = longshore transport rate

it was determined that an 8 ft. (2.4 m) wave with a deepwater approach angle between 30° and 45° and a period between 6 and 9 seconds could initiate bar bypassing. Waves observed during northeasters are commonly above this height. Also due to the strong effect of local waves during storms, these periods and angles are representative.

Waves in excess of three meters were observed by Abele (1972) during a northeaster on 19 February 1972. According to the U. S. Army (1973) relationships,

$$Q = (7.5 \times 10^3) P_{1s} \quad (2) \text{ and,}$$

$$P_{1s} = 32.1 H_b^{5/2} \sin 2\alpha_b \quad (3)$$

where α_b = angle between crest of breaker and shoreline, breaking waves with a height of 10.7 ft (3.25 m) and an approach angle of ten degrees (values consistent with Abele's (1972) data) could transport volumes of 8.75×10^5 M³/yr. The corresponding r value of 350 is above the value needed to initiate bar bypassing. Prevailing southeasterly waves during fair weather periods average 1 ft (30 cm) in height and have characteristically small breaker angles. Equations 2 and 3 were used to determine longshore transport rates and subsequent r values for 30 cm waves approaching at various angles. The bypassing coefficient corresponding to a breaker angle of 45 degrees (most breakers approach at angles less than five degrees) was computed as 2.8. This is well below the value of $r = 20$ for tidal current transfer. It should be pointed out that because the nearshore bar is a permanent feature it is both the wave condition and littoral drift volume (which are admittedly related) that determine the mechanism of inlet bypassing in this case. Bruun's relationship is therefore an indication of what is going on rather than an explanation of the process itself.

CONCLUSIONS

- 1) Several lines of evidence indicate net southward littoral transport through the Merrimack Embayment.
- 2) Despite this, the beach south (downdrift) of Merrimack Inlet is presently accreting.
- 3) This phenomenon is the result of a balance between storm and fair weather conditions:
 - a) During storms, sand moves off the beach and southward along the permanent nearshore bar that extends past Merrimack Inlet.
 - b) During fair weather, sand moves landward and toward the north along the beach. Under these conditions, sand is trapped by the southern jetty.
- 4) Bruun's bypassing relationship can be used to at least partially explain this phenomenon. During storms the volume of drift is high enough to bypass the inlet along the nearshore bar face. Under calmer conditions, tidal current transfer which is blocked by the jetties occurs.

** Head of Marine Hydrodynamics Division

Port and Harbour Research Institute, Ministry of Transport

Nagase, Yokosuka, Japan

ABSTRACT

This paper presents some general properties on topographic change on the shore and sea bed in the vicinity of ports and harbours constructed on the sandy beach, mainly with the case study of Kashima Port. Following three characteristics of the topographic change due to prolongation of breakwaters are discussed; that is,

- i) The shoaling and the change of topography in the area surrounded by breakwaters and shoreline.
- ii) Topographic change of artificial beach in the updrift beach of breakwater having the long oblique part.
- iii) Erosion and accretion of downdrift beach due to the prolongation of the oblique part of breakwater.

INTRODUCTION

Port Kashima, the biggest new industrial port in Japan, has been constructed on the central part of a bow-shape sandy coast of 70 kilometers long facing the Pacific Ocean as shown in Fig. 1 and Fig. 2. Since 1961, before the start of the construction works, many kinds of field investigations and model experiments have been conducted by the Port Construction Office of Ministry of Transport and the Port Construction Office of Ibaragi Prefecture under the continuous co-operation of Port and Harbour Research Institute.

Authors had reported the some results of these investigations on the characteristics of this coast before the beginning of the construction works in the 10th Conference on Coastal Engineering (S. Sato and N. Tanaka, 1966). Furthermore, one of authors had already presented a paper on the topographic change during the early period of the construction works in the 12th Conference

Fig. 1 The location of Kashima Port and other harbours mentioned in this paper.

Fig. 2 Kashima Coast and the location of Kashima Port.

Fig. 3 The terminology in this paper.

on Coastal Engineering (S. Sato and I. Irie, 1970). Therefore, this paper composes a series with these other papers. The terminology employed in this paper is given in Fig. 3.

THE CHARACTERISTICS OF THE COAST AND THE LITTORAL DRIFT OF KASHIMA COAST

The northern portion of Kashima Coast has a narrow beach with the cliff of Kashima Plateau and the Naka River flows out to the sea at the northern end. The southern portion is a part of the alluvion formed by the Tone River and has wide beach with sand dunes. The influence of the discharged materials from these two rivers is restricted in the area near to their river mouth, and it is considered that the source of sand drifted in the central portion should be the coast itself.

The natural topography before the port construction was comparatively simple and stable. At the central portion where Kashima Port is located a sand dune of about 8 meters high above L. W. L. ran along the coast and the backshore was 50 to 80 meters wide and 3 to 4 meters high. There were along-shore bars at 100 to 300 meters seaward from the shoreline which were of 0.5 to 2 meters deep at the crest and of 1.5 to 3 meters deep at the trough. In the offshore area of those alongshore bars, the sea bed topography was very smooth and depth contour lines ran parallel each other until the water depth reaches to 20 meters. But, the area less than 40 meters beyond 20 meters in water depth is very gentle in the bottom slope and reaches to the seaward edge of the submerged terrace and depth contour lines make complex curves. The sea bed slope was about 1/10 to 1/30 in the forshore, about 1/50 to 1/60 in the inshore and about 1/100 to 1/120 in the area shallower than 20 meters depth in the offshore.

Waves approach almost perpendicularly to the coast from the direction of northeast to east-southeast, though the southerly waves exceed the northerly ones a little in summer and the oppsite takes place in winter. The annual predominant direction of waves depends on the frequency of tyoons approached to this coast; in the year when tyoons frequently attack this coast, the southerly waves prevail. The maximum significant wave observed in this coast has been about 6.5 meters in height and almost 10 to 13 seconds in period.

The mean diameter of bottom materials is about 0.15 millimeters in the offshore zone and 0.2 to 0.6 millimeters in the inshore zone. The alongshore littoral transport per year has been estimated to be the order of 600,000 cubic meters both in the southerly and northerly directions, though the southerly transport slightly exceeds the northerly one (S. Sato and N. Tanaka, 1966).

CONSTRUCTION WORKS OF PORT KASHIMA

The general plan of Port Kashima was set in 1962, but it was modified in 1968 according to an increase of ship sizes as shown in Fig. 4.

The construction works began at April 1963 with dumping of rubble stones for the south jetty of the working basin for small crafts. By April 1975, the north breakwater of 1050 meters long, the parallel breakwater of working

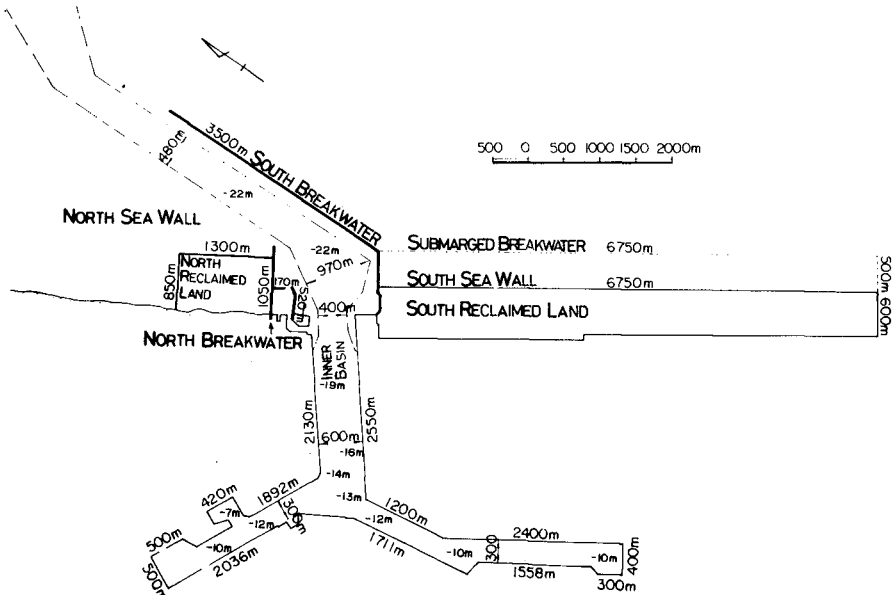

Fig. 4 The general plan of Kashima Port

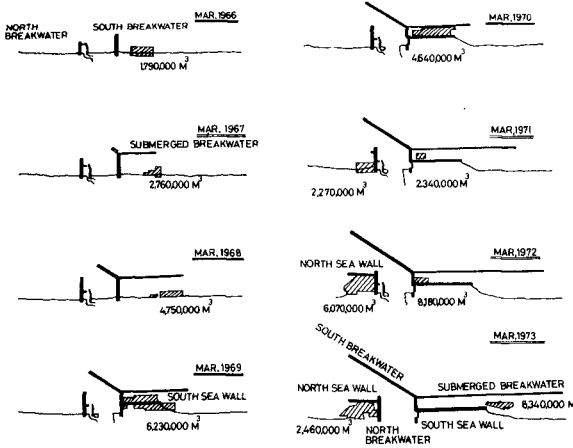

Fig. 5 The process of the construction works of structures and the discharge of dredged sand.

basin and the south breakwater of 4300 meters long have been completed.

In April 1965, the dredging works of the inner basin was begun without disturbing the shoreline in the outer basin by cutter-suction dredgers which entered into the inner basin through the beach of the working basin by cutting it. The shoreline in the outer basin was cut in September 1968 to connect the inner basin to the outer basin. The dredged sand has been dumped on the beaches of both sides of the harbour. In the period from April 1965 to April 1975, the amount of the sand dumped on the beach has reached to about 50 millions cubic meters.

In this period, the bulkheads were constructed for reclaimed land in the both side of the harbour and the submerged breakwater was also built in front of the south man-made beach. The processes of these works are shown in Fig. 5 and Fig. 6.

SHOALING OF THE OUTER BASIN OF HARBOUR FOLLOWING THE PROLONGATION OF BREAKWATERS.

Figure 7 shows sounding maps for each summer in the period from 1963 to 1968, during which the breakwaters were constructed but no dredging works were initiated in the outer basin. In this figure, solid lines indicate the constructed portions of breakwaters and dotted lines denote the portions where only the rubble mound base of caisson was constructed.

The comparison of the sounding maps of 1965 and 1966 indicates that the depth contour lines shallower than 5 meters moved landward at the middle of coast between the south and north breakwater and offshoreward near the both breakwaters, as the rectangular parts of those breakwaters were prolonged. This tendency became much clear with the prolongation of the oblique part of the south breakwater and the depth contour lines took more convex shape. Moreover, the mean direction of the beach in the outer basin became to take more oblique angle to the shoreline of former days, and the most receded point of shoreline was shifting northward with the prolongation of the oblique part of the south breakwater; this can be seen from the comparison of the sounding maps of 1967 to 1968.

On the other hand, the central portion of the outer basin was shoaled, the depth contour lines deeper than 7 meters becoming concave in shape as shown in the maps of 1966 to 1968.

Severe scouring were seen in the vicinity of the tip of the breakwaters when they were in the surf zone, as well as at the inside of the rubble mound. These characteristics of the sea bottom topography around breakwaters are commonly found in other harbours as reported by Sato and Irie (S. Sato and I. Irie, 1970).

Figure 8 indicates the volume change of sand in the outer basin in the same period as that of Fig. 7. Solid lines indicate the change of sand volume in each area shown in the note of this figure as well as that of the total area of the outer basin, while the dashed line is the volume change of the sand dumped on the south coast. In this four years, sand of about 2 millions cubic meters increased in the outer basin in total and the accretion of sand

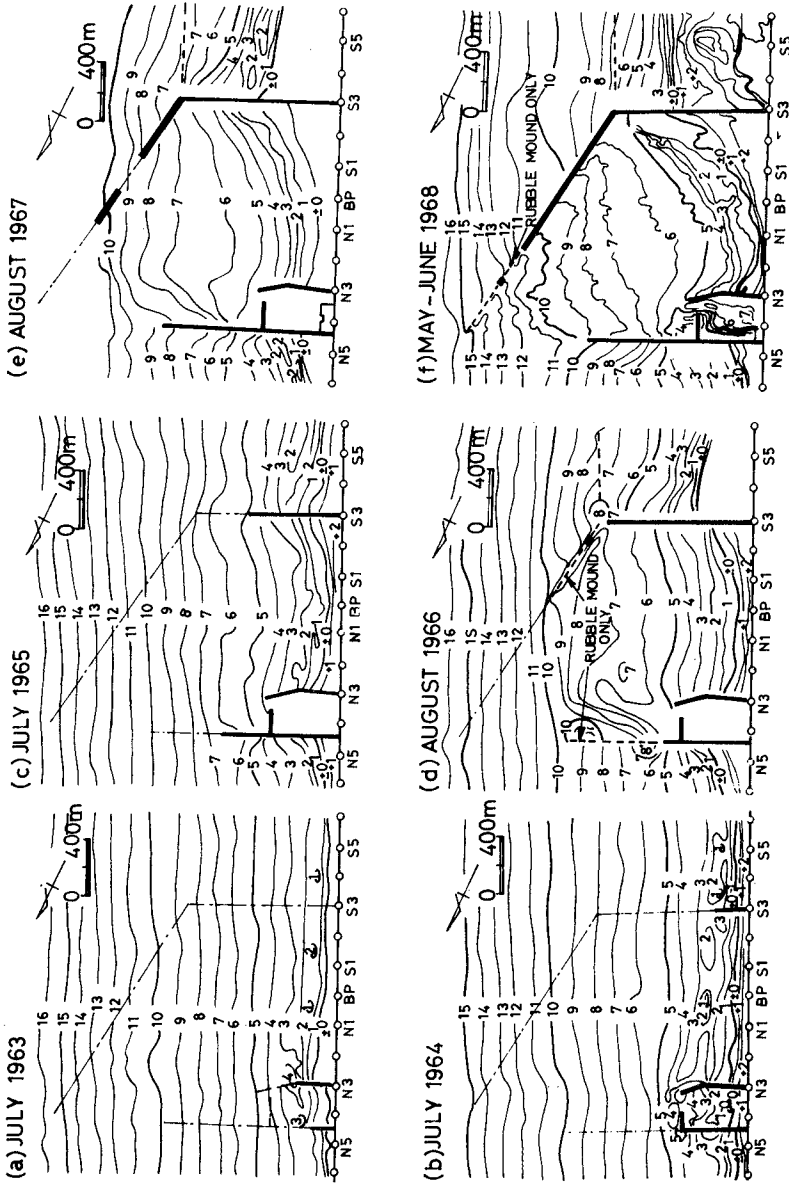

Fig. 7 Sounding maps for each summer from 1963 to 1968

took place in the area B, D and E which are located near the south breakwater. On the other hand, the area A and C were scoured gradually. These pattern of the volume change of sand is considered to be closely related to the diffraction of waves and formation of the counter-clockwise circulating currents in the outer basin as reported by authors (S. Sato and I. Irie, 1970 and N. Tanaka, 1974).

In Fig. 8, the change of the total volume of sand of the outer basin seems to have close correlation with the amount of sand dumped on the south coast. Figure 9 shows the distribution of fluorescent tracers injected in the offshore zone of the south coast on 12th of August, 1967. The result clearly indicates the movement of sands which move offshoreward along the south breakwater and enter into the outer basin going around the tip of the south breakwater.

TOPOGRAPHIC CHANGE OF ARTIFICIAL BEACH CONSTRUCTED USING THE DREDGED SAND

As mentioned above, since April 1965, dredged sands have been discharged onto the south coast and the amount of these sand reached to about 22 millions cubic meters until March 1971. The change of the shore line in this period is shown in Fig. 10. In this figure, the x, y and z axes indicate the alongshore distance from the south breakwater, the distance between the shoreline and the datum line, and the years of survey, respectively. Therefore, the thick solid lines represent the shape of the shoreline at a certain time and the thick dashed-dot lines indicate the change of the distance between the shoreline and the datum line.

The shoreline of the south coast began to advance seaward near the south breakwater due to the discharge of dredged sand, and the beach continued to extend seaward or southward until 1970. But, after the winter of 1970, although discharge of dredged sands was continued, the artificial beach began to be eroded from the neighbourhood of the south breakwater and this erosion was extended southward.

In pace with the change of the shoreline, the beach profiles also changes as shown in Fig. 11. The slope of sea bed in the part shallower than 10 meters deep became steeper gradually with the advancement of the shoreline, but after the beginning of the erosion, the slope returned toward the original one the reverse process of that mentioned above.

Figure 12 indicates the relationship between the advancement of the shoreline and the slope of the sea bed at each water depth. The slope of sea bed became steeper with the advancement of the shoreline and reached to a certain critical slope for the water depth of 10 meters and less. The average values of these critical slopes were as follows:

range of water depth	average value of the critical slope
0 to 2 meters	1/25
2 to 4 meters	1/50
4 to 6 meters	1/60
8 to 8 meters	1/65
8 to 10 meters	1/100

The difference between these critical slope and the natural one before fill is the largest in the area of 2 to 4 meters depth, and it becomes small in both the shallower or deeper area.

Fig. 10 The change of the shoreline in the south coast in the period from 1962 to 1972.

Fig. 11 The change of profiles of the south coast

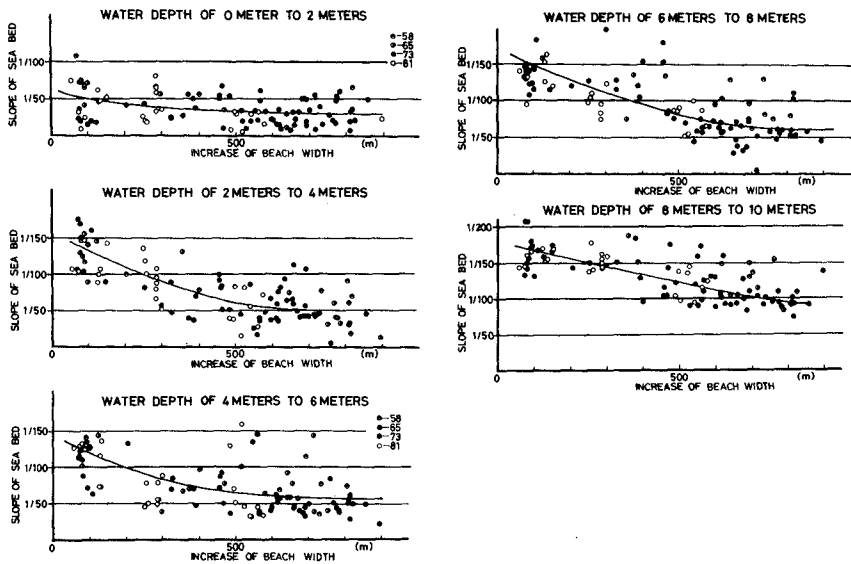

Fig. 12 The relationship between the advancement of the shoreline and the slope of sea-bed.

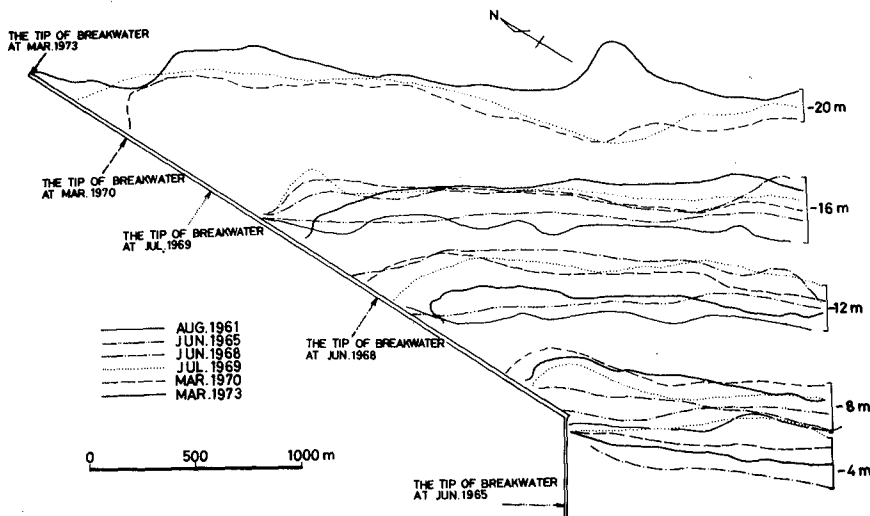

Fig. 13 The change of depth contour lines in the offshore side of the south breakwater.

Some amount of sand discharged onto the south coast was transported by waves and currents to the offshore side of the oblique part of the south breakwater forming a submarine bank along the breakwater. But, after the winter of 1970, this submarine bank was also rapidly scoured. The change of depth contour lines of 4, 8, 12, and 20 meters deep is shown in Fig. 13. In this figure, the attention is called for the fact that the contour lines of 16 and 20 meters deep moved offshoreward even after the beginning of scour of the submarine bank.

Figure 14 is the distribution of the difference of the water depth surveyed in the different years; i. e., the upper figure is the difference of depth in the period of the growth of the submarine bank from April 1965 to August 1970 while the lower one is the difference in the period of scouring of bank from August 1970 to March 1973. In the period of the growth of the submarine bank, the decrease of the water depth was the largest near the bending point of the south breakwater. The area of considerable shoaling extended from that point toward the tip of the breakwater forming a belt within the distance of about 200 meters from the breakwater. On the other hand, in the period of scouring, the scouring was found only around the bending point of the south breakwater, and the extent of scouring was the severest along the foot of the breakwater. The offshore area of this zone was continuously shoaled even after the beginning of the scouring of south coast.

Such the examples of the erosion at the updrift side of a long oblique breakwater are found in many other ports as in the cases of Sendai Harbour and Hachinohe Harbour shown in Fig. 15. These two harbours are located at the end of long sandy beaches facing the Pacific Ocean, where waves from the down drift side are sheltered by a headland. Although updrift side of these harbours are shoaled over the wide area, the erosion of the same pattern as Kashima Port is found near the breakwater of the updrift side.

Such erosion at the updrift side of a long oblique breakwater may be considered to be caused by the currents formed along the breakwater due to waves. Fig. 16 indicates examples of experimental results on the currents due to waves around the breakwater prolonged obliquely. The experiments were conducted using a fixed bed model having the bottom slope of 1/15 in the landward of the shoreline and 1/30 in the seaward of it. Model waves of 4 centimeters in height and 0.8 seconds in period were acted from the direction perpendicular to the shoreline. In this figure, thick solid lines indicate the breakwater, and the origin of the co-ordinate is taken at the point of intersection of the shoreline to the breakwater.

In every case, currents which flow updriftward along the breakwater and the shoreline are formed. These currents turn their direction offshoreward at a certain point, the position of which goes away from the breakwater with the increase of the length and obliquity of the breakwater. The velocities of these currents also increase with the length of breakwater, but the increase of the length in the offshore area of the surf zone is not so effective.

EROSION AND ACCRETION OF DOWNDRIFT BEACH BY THE PROLONGATION OF BREAKWATER.

Figure 17 shows the sounding maps for each winter in the period from 1970 to 1973 in which the oblique part of the south breakwater was prolonged beyond the tip of north breakwater. The dotted lines in each maps represent the

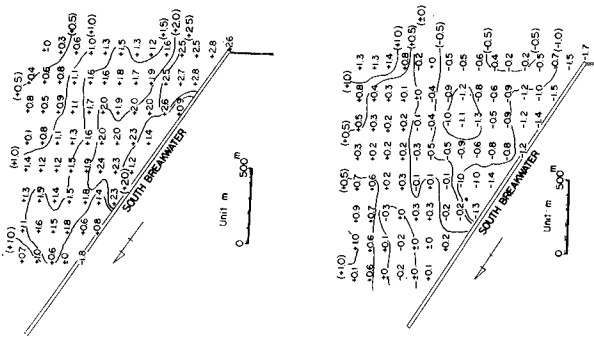

Fig. 14 The distribution of the differences of the water depth surveyed in the different year.

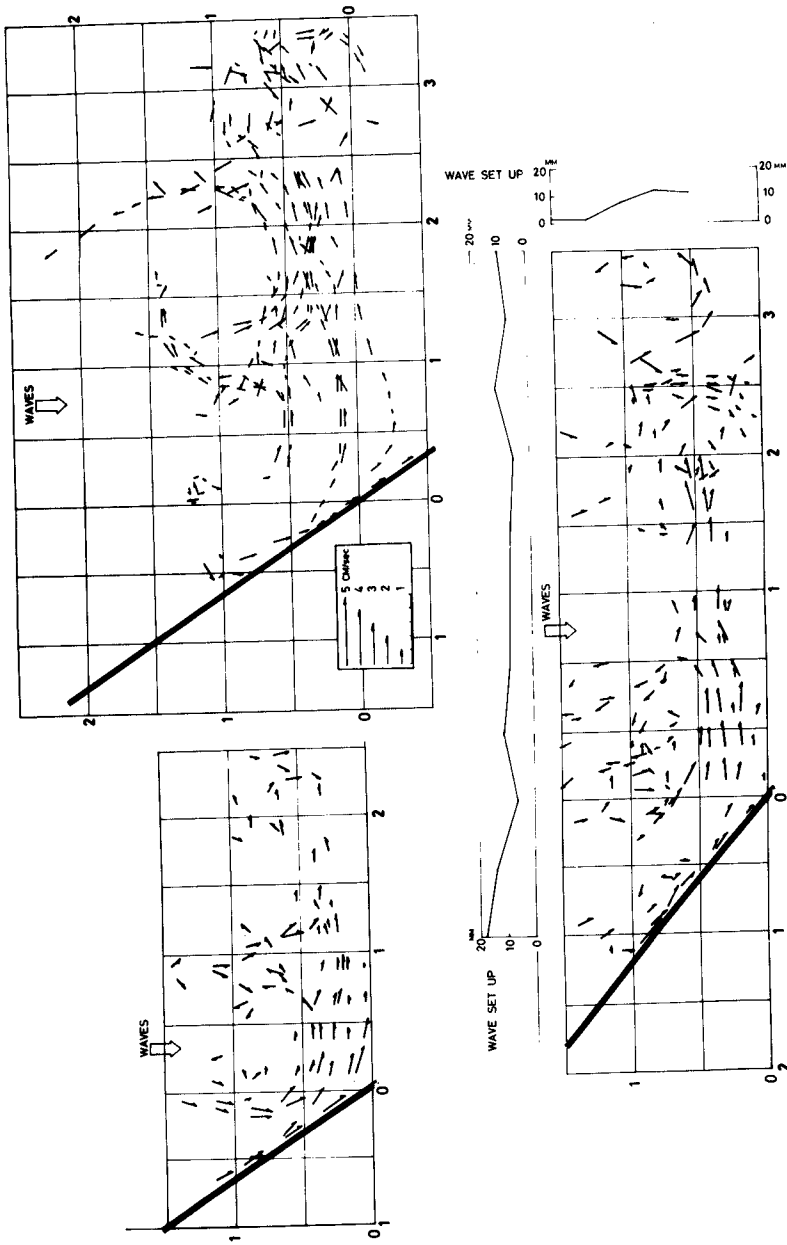

Fig. 16 Examples of results of the model experiment on the currents due to waves along the breakwaters prolonged obliquely (wave height= 4 cm, period= 0.8 sec.).

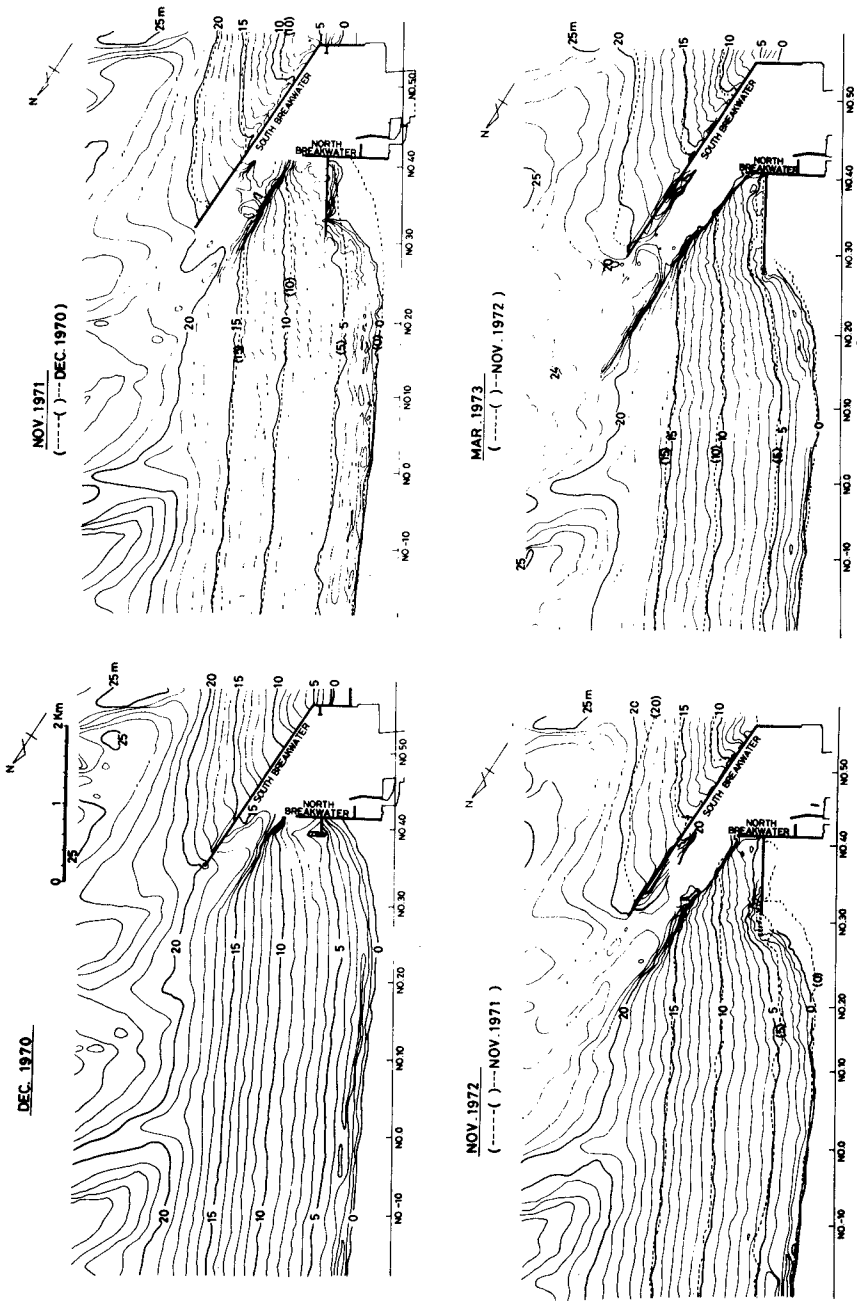

Fig. 17 Sounding maps for each winter in the period from 1970 to 1973.

depth contour lines of one year before.

In the area sheltered by the south breakwater at the outside of the north breakwater, the depth contour lines shallower than 15 meters moved seaward year by year. At the north side of these shoaled area, the zone shallower than 5 meters in depth was eroded. Moreover, these shoaling and erosion zone seem to extend to the north and the deeper area with the prolongation of the south breakwater.

Figure 18 indicates the change of the distance between the shoreline and the datum line measured along the fixed surveying lines in the north coast. At the line of No.27 to 39 located near the north breakwater, the shoreline advanced seaward gradually during the early years and after a certain years the advancement of shoreline was accelerated rapidly. At the lines of No.15 and 21, the shorelines moved seaward or landward slowly during the early years, but after a certain years the shorelines receded suddenly and then advanced again few years after. Furthermore, at the lines of No.3 to 9 located the most far away from the north breakwater, the shorelines were stable or erosive in the early years, but they were eroded rapidly after a certain years. The sudden change of shoreline movement occurred earlier at the line near to the north breakwater than the farther one. This fact means that the boundary between the shoaled area near the north breakwater and the eroded area of north side of it was shifted northward year by year.

Figure 19 indicates the relationship between the position of the tip of the south breakwater and the most eroded place or the north boundary of the accreted area near the north breakwater. In this Figure, dates written along the south breakwater and the shoreline indicate the times when the tip of the south breakwater, the most eroded place, and the boundary of the accreted area were located at respective positions. The thin solid lines and dashed-dot lines are the lines connecting the tip of the south breakwater to the most eroded place and the boundary of the accreted area at the same date, respectively.

In this figure, three solid lines run almost parallel each other, keeping the constant angle of 45 degrees with the predominant wave direction. Likewise, the three dashed-dot lines run parallel, keeping the angle of 30 degrees.

Figure 20 shows the distribution of differences of the water depth between the sounding maps of December 1970 and March 1973 as well as two lines which make the angle of 45 degrees and 30 degrees with the predominant direction of waves at the tip of the south breakwater. It is known from this figure that the area remarkably shoaled in the offshore area is also in the south side of the line of 30 degrees.

The above mentioned pattern of the change of the sea bed topography can be found frequently in other harbours as shown in Fig. 21, which indicates the changes of shorelines measured on aerial photographs. Harbours shown in this figure are located on the sandy beach facing the open sea. In these examples, the angles of the line connecting the tip of the main breakwater and the most eroded place measured from the wave direction are among 40 to 50 degrees. On the downdrift side boundary of accreted area, this angles are among 20 to 30 degrees.

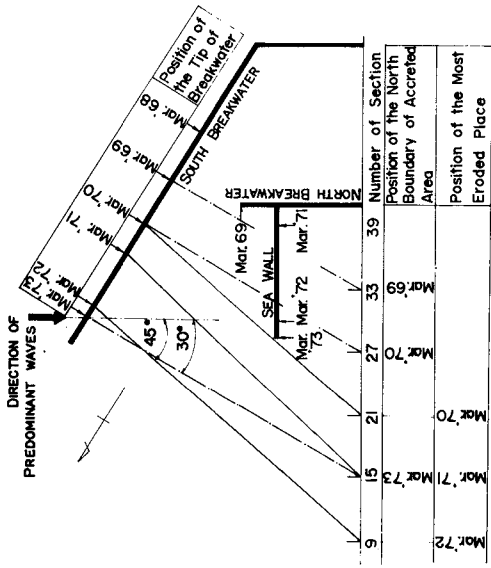

Fig. 19 The relationship between the position of the tip of the south breakwater and the most eroded place of the north boundary of the accreted area.

Fig. 18 The change of the distance between the shoreline and the datum line in the north coast.

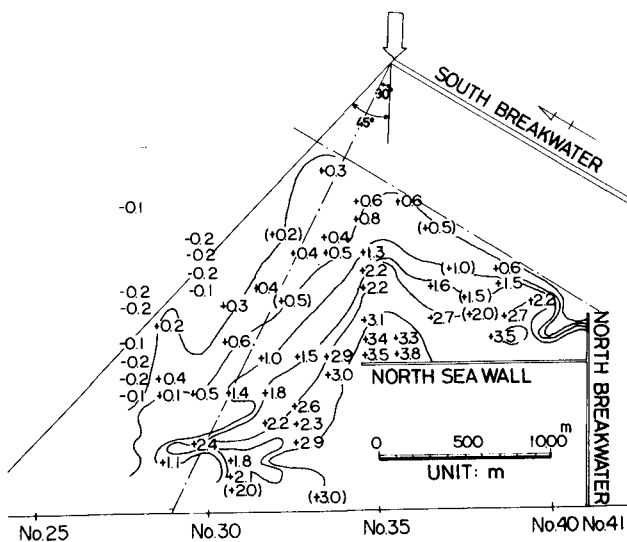

Fig. 20
The distribution of differences of the water depth between the sounding maps of Dec. 1970 and Mar. 1973.

Fig. 21 Examples of the topographic change at the downdrift side of harbours (Kashiwa-zaki Harbour, Oharai Harbour, Khochi Harbour and Hitachi Harbour).

As demonstrated in the example of a model experiment shown in Fig. 22, the cause of this kind of topographic change is considered to be the currents formed in the downdrift side of this harbour due to waves diffracted at the tip of the main breakwater. The experiment was performed in the same model in the former chapter under the same wave condition. Due to wave diffraction, the wave height becomes small behind the breakwater. As the result of this decrease of wave height, the wave set-up also decreases from the open portion toward the sheltered area behind the breakwater as shown in the upper graph of Fig. 22. This alongshore gradient of the wave set-up is considered as the main cause of the currents which transport bed materials toward the sheltered area behind the main breakwater.

CONCLUSION

The following points were made clear as the general properties on the change of the topography of sea bed caused by construction of new ports, that is:

- 1) When the oblique part of updrift side breakwater did not cover the tip of the downdrift side breakwater, the outer basin was shoaled remarkably. Almost all the materials entered into the outer basin were carried by the circulating currents and were deposited behind the updrift side breakwater of at the central portion of the outer basin. The central part of the beach in the outer basin was eroded due to these currents. As the result of these change, the shoreline in the outer basin took convex shape.
- 2) When the shoreline advanced due to the discharge of dredged sands, the profile became steeper gradually and reached to a critical one. But, in the erosion period, the slope of man made beach returned toward the original one taking the reverse process with one in the progressive period.
- 3) After the length of the oblique part of updrift side breakwater reached to about 2,000 meters, the updrift beach of this breakwater was severely eroded due to currents formed along the oblique part of updrift side breakwater.
- 4) Since the time when the oblique part of updrift side breakwater was prolonged beyond the tip of downdrift side breakwater, a certain place of the downdrift beach began to be eroded, and the harbour side of this eroded place was accreted. The position of this eroded place and the boundary of accreted area were shifted with the prolongation of the updrift side breakwater.
- 5) The line connecting the tip of updrift side breakwater with the most eroded place or the downdrift side boundary of the accreted area always kept a constant angle with the predominant wave direction. These angle were about 40 to 50 degrees for the most eroded place and 20 to 30 degrees for the boundary of the accreted area, respectively.
- 6) The cause of this change of sea bed topography is considered to be the currents formed in the downdrift side of the harbour due to waves diffracted at the tip of updrift side breakwater.

CHAPTER 107

IMPACT OF YACHTING MARINAS ON BEACHES

by

J.P. LEPETIT *

The development of tourism resulted in the construction of very many small yachting harbours along the French mediterranean shore during recent years. Some of them were constructed on the rocky foreland located at the end of sandy beaches. Such beaches being a priori stable, no particular sedimentation investigation was carried out. In several cases, the construction of a port led to rapid evolution of the beach, accretion occuring in the vicinity of the port and erosion elsewhere.

1 - NATURE OF THE PROBLEM

When a port is situated on a sandy shore experiencing significant littoral drift, many precautions are taken to ensure the continuity of sediment transit (by passing) or to remedy the consequences of its interruption.

It is not the same in the case of a sandy beach enclosed between two rocky forelands and apparently stable. Generally there is very little net sand movement from one beach to another past the headlands and the coastal line does not change significantly with time. This can be misleading giving the impression that there is little or no longshore transport of sediment : this however is not the case

* Chef de la Division Hydraulique Maritime - Laboratoire National d'Hydraulique de Chatou - Electricite de France - Chatou - France.

as the resultant littoral drift along a shore is usually a balance between sand movement due to swells from opposing directions which may individually transport very significant quantities of material. Even though the resultant sediment movement due to the two opposing swells produces zero drift on a stable beach between two rocky headlands, a change in only one of the terms can induce spectacular evolution.

To illustrate such a mechanism, let us consider the schematic case of a west-east oriented beach submitted to two swells, having different origins (north-west and north-east, as in fig. 1), but the same frequency. In the natural state, the north-west swell induces a littoral drift eastwards when the north-east swell does the same westwards. On average, they cancel each other out and the shore is stable during a long period of time ; it comes under the influence only of alternated evolutions, generally small, as the continuance of each swell is limited.

Now, let us build a port with an enveloping breakwater at the west end of the considered beach (fig. 2) ; this port will achieve a sheltered zone from the north-west swell, where the transit eastwards becomes zero and where the only transit westwards, due to the north-east swell subsists. The equilibrium is broken and a net littoral drift appears in the sheltered zone ; the sand accumulates at the port entrance and, to satisfy continuity, the rest of the beach erodes. The evolution so induced is therefore doubly harmful : the port access is endangered and the beach disappears.

This mechanism and the consequent beach evolution are very obvious and the explanation of the damage suffered is easy for the specialists in the subject. Unfortunately, the mechanism is less evident a priori and the engineers, having overcome their apprehension about the stability of the shore in its natural state, do not feel the need to get advice from these specialists before designing a project.

2 - AN EXAMPLE OF EVOLUTION VERIFIED IN SITU

A spectacular example is provided by Bormes-les-Mimosas port (fig. 3), which was constructed on a rocky foreland separating two beaches of very fine sand, the first at the north and the second at the south. This port includes a jetty constructed on the rocky foreland oblique to the shore and a breakwater parallel to the shore. The entrance to the port is open to the north beach. The beach experiences swells from the east which are almost parallel to the shore, and produce very little drift, swells from the south-east creating a south-north transport of sediment and north-east swells producing a contrary north-south movement. The port works considerably after the effect of the swells and result in a large zone on the south beach sheltered from the north-east swells and, on the north beach, a zone, as important as the first, sheltered from south-east swells. As a

consequence of the imbalance, more sand is transported along the north beach from north to south than formerly and similarly more sand is transported along the south beach from south to north, producing significant accretion in the vicinity of the port during the course of two or three years.

Figure 4 shows the evolution of the shoreline on each side of the marina during its construction.

On the upper part of the figure, only the south part of the breakwater is built, but it already creates a sheltered zone on the south beach where a beginning of accretion is clearly visible.

In the middle part, the accretion is increasing fastly and propagating to the north like a sand wave. The advancing of the breakwater to the north also induces an accretion on the north beach.

The last picture of figure 4 is a copy of a postcard showing the marina after completion. The accretion on both sides of marina is clearly visible.

Plan views of figure 5 show the initial configuration of the shoreline in 1968 and in 1973 after completion of the marina. There is a uniform recession of the north beach shoreline and it is quite evident that the sand trapped near the marina comes from this beach. But as the volume of sand trapped is greater than the volume lost by the beach, a part of it comes probably from offshore erosion which occurred in front of the breakwater.

Another erosion occurred on the south beach and a groyne was constructed to stop this erosion and its extension to the whole beach.

The advance of the shoreline at the south is more than 100 m, and on the side of the entry channel the accretion necessitates maintenance dredging.

3 - MEANS OF STUDY

For reasons of cost and time allowed, it is not possible to carry out a study on a movable bed model for each yacht-port to be built, but the noted evolutions may be anticipated thanks to simple studies on drawings. Such studies consist of the determination of the direction where the existing in situ swells come from, the establishment for these swells of wave refraction diagrams giving the propagation of swells as well as their angle of incidence with the shore and diffraction diagrams giving the effect of the port on the swells spreading. By reasoning from the results of these calculations or from the operation of a littoral drift mathematical model, it is possible to estimate both the effect on sand transport and the resulting evolution of the shoreline.

4 - POSSIBLE REMEDIAL MEASURES (fig. 6)

In order to avoid such a type of evolution, it is necessary to design ports that don't create sheltered zones from certain swells outside the structures. For that, the pegging out of the port along the shore shall correspond with a maximum possible accuracy to the extent of the zone where the spreading of various swells is disturbed by the presence of the port structures. The best way seems to design a port including two convergent breakwaters, the direction of each of them corresponding to the swells extreme origine. In the case of an asymmetrical port that includes only one breakwater starting from the shore, it seems necessary to build on the other side a groin long enough to allow the sands transit to stop just at the limit of the sheltered zone created by the port.

CONCLUSION

It should not be forgotten that a beach seeming stable is in fact in dynamic equilibrium under the action of various movements of sand that cancel each other out. Therefore, it is enough to change one of these to disturb the general equilibrium and provoke rapid evolution. The construction of a port, even of small importance, in the vicinity of sandy beaches must consequently be preceded by a minimum study by drawings, that will allow an assessment to be made of the future evolution resulting from port construction and the definition of a certain number of safeguards that will be used if the noted evolution is effectively as dangerous as the predicted one.

CHAPTER 108

HARBOUR INLETS ON TIDAL ESTUARIES

Hans Vollmers*

Two important points should be considered if a harbour mouth is planned on a river:

1. The traffic conditions especially the navigation must be considered (i.e. large width of the mouth)
2. The sedimentation should be small (i.e. small width of the mouth)

These conditions are contradictory. Harbour mouths are lateral enlargements. The current doesn't follow these enlargements, a separation sheet forms which is characterized by eddies. A more or less great mass of water is in movement in the enlargement. These rotating movements are called "vortices". One distinguishes "primary vortices", "secondary vortices" etc. depending on the initiating current (Fig. 1).

Fig. 1

The deposition of sediment in lateral enlargements depends on the characteristics of the vortices, because the exchange of liquid material has interacted with the exchange of transported material. Normally the coarse material deposits in area a and the fine material in area b (Fig. 1).

Generally one can define the reasons for sedimentation as follows (Fig. 2).

1. Current effect (vortex in the harbour mouth caused by energy exchange)
2. Tide effect (fill up of the harbour basin during the flood tide)
3. Density effect (density current caused by different salinity in the estuary and the harbour entrance)

* Dr.-Ing. Baudirektor, Bundesanstalt für Wasserbau
Hamburg, Germany

a. Current effect b. Tide effect c. Density effect

Fig. 2

The current effect is dominant for the sedimentation in harbour mouths situated on rivers with one-directional flow. If it is possible to influence the primary vortex the sedimentation will be smaller. Fig. 3 shows possible ways to displace or to diminish the primary vortex.

Fig. 3

There is the "vortex zone", the "vortex zone" restricted on the border current (core vortex zone), a so-called "disturbance opening" and a "disturbance step". These methods are based on an alteration of the downstream geometry of the harbour mouth.

It is possible to influence the separation zone i.e. the velocity gradient between the river flow and the vortex area with a so-called "partition flow". The "partition flow" is directly taken from the river flow, but only the upper layer with smaller sediment load.

The influence of the primary vortex with the "disturbance step" may be seen on Fig. 4. The practical use of a "vortex zone" is demonstrated on a harbour at the Rhine River. Above one can see the situation before the alteration of the mouth and below there is the new entrance. Now the deposition zone has been located downstream (Fig. 5).

Fig. 4

In estuaries it is very difficult to find a satisfying solution because the current direction changes rhythmically. Neglecting the density effect, the following happens (Fig.6): During the flood tide, the current effect and tide effect superpose mutually, i.e. the current intensity is very great starting on the stagnation point. During the ebb tide the two effects work against one another. Because vortices are movements with no much energy small currents can destroy the development of a vortex.

Fig. 5

These general considerations were used for a case study in the Ems-Estuary-Model at the Bundesanstalt für Wasserbau in Hamburg.

Fig. 6

The model includes the River Ems and has been built as a fixed bed model, with the possibility to also investigate sections with movable bed. The horizontal scale is 1:500, the vertical is 1:100. Since the Ems is a boundary river between the Netherlands and the Federal Republic of Germany a number of problems also arose for the Dutch authorities. The new entrance of the Delfzijl harbour was one of these problems (Fig. 7).

Fig. 7

The general situation of the Delfzijl harbour is shown in Fig. 8. 20 years ago the harbour was only the basin on the left, the bight of Watum was the access channel. Because the sedimentation in the bight of Watum increased, it was necessary to dredge a new access from the main channel Borkum - Emden. The industrial development and the sedimentation in the near field zone of the old entrance led to the enlargement of the basin and the construction of the new entrance. The old entrance will be closed later on. Contrary to usual harbours with vertical

development to the river the Delfzijl harbour is practically only a parallel channel under tidal influence. It could be expected that very bad current conditions would appear if the old entrance was closed. Therefore the model investigations were concentrated to improving the current situation in the new entrance.

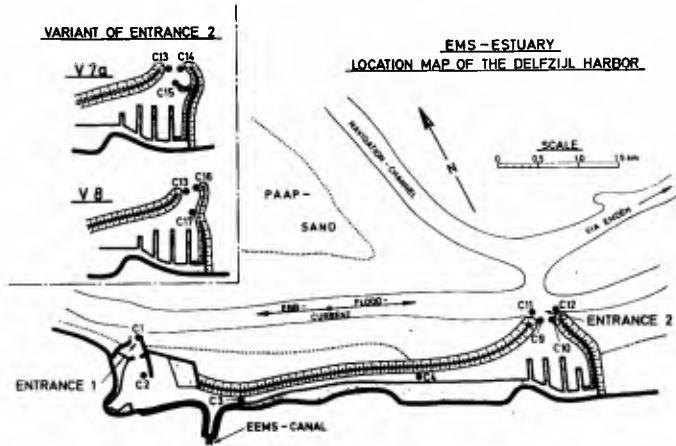

Fig. 8

The estimation of the different investigated variations has been carried out with the aid of the surface current visualised with photographed scraps of paper and with the aid of velocity measurements in a medium water depth at certain points.

Fig. 9

EBB

The current situation for V2 (new entrance open, old entrance closed) can be gathered from Fig. 9. During the flood tide there is a velocity concentration on the right jetty which produces a large vortex in the main basin. The current effect and tide effect are superposed upon one another. During the ebb tide the tide effect i.e. the outflow from the basin dominates the current effect. There is no rotating flow in the entrance zone. In this case the current effect is especially small caused by the diversion of the upstream jetty.

Fig. 10 shows clearly that using a "vortex zone" there is no possibility to avoid the primary vortex in the harbour mouth. Only in the first flood phase one can see a relatively good velocity distribution in the entrance cross section. Subsequently, large vortices appear.

Fig. 10

EBB

Geometrical alterations were not sufficient to suppress the overlapping of current and tide effect. Finally the only possibility was to renounce the closure of the sea-side entrance and to produce a stream against the tide and current effect in the new entrance. For this reason a systematic investigation has been started with different widths (100, 65, 50, 40 m) of the old entrance. The development of the surface current for an inlet width of 100, 65 and 40 m is demonstrated by the following photos. The results of the investigation with three various inlet width are

- a) 100 m(Fig. 11): The energy slope is sufficient to prevent the inflow on the upstream jetty. In the first flood phase there is practically no movement. Later, a uniform outflow appears in the harbour mouth. During

the ebb tide the current enters the harbours on the downstream jetty, a small vortex now turns in the large basin.

Fig. 11

- b) 65 m (Fig. 12): For an opening width of 65 m one can see nearly the same surface current distribution.

Fig. 12

c) 40 m (Fig. 13): This width is not sufficient to avoid the inflow on the upstream jetty in the first flood phases. Only in phase 4 an outflow occurs.

Fig. 13

During the ebb tide the current distribution is nearly the same for all opening widths.

To help confirm the observations of the surface currents, velocity measurements were carried out in medium water depth in certain points. Fig. 8 shows these measuring points. The velocity has been measured either in flood/ebb direction or vertically to it. Fig. 14 may help explain.

Fig. 14

At the velocities for V 7a und V 8, there are high inflow rates in C 14 and also in C 16. The oscillations in C 15 depend on the position of the current distribution in C 13 has the same characteristic for V 7a and V 8 (Fig. 15).

Fig. 15

Fig. 16 to Fig. 19 demonstrate the results of the test series V 10 in comparison with V 1 (old harbour without the new entrance) and V 2 (new harbour, old entrance closed). In C 1 one can see clearly the increase of velocity depending on the width of the old entrance. The decrease of velocity in C 2 in relation to the increased width depends on the situation of C 2 because this point is influenced by the jet-stream (Fig. 16 and Fig. 8).

In the harbour channel the velocity relationship is clear. With decreasing width the velocity also decreases. This clearly appears during the ebb tide in C 4 (Fig. 17).

Fig. 16b

Fig. 16a

Fig. 18

Fig. 17

The points C 11 and C 12 are situated in the main current in front of the new entrance. The distribution is typical for a tide flow. The smaller and oscillating ebb velocities in C 11 are influenced by the upstream jetty and the outflow from the harbour basin (Fig. 18).

In C 10 the difference of the current situation between closed and opened old entrance is clearly recognizable. There is a very high inflow during the flood tide and a small outflow in the ebb tide. In C 9, one can notice a permanent outflow during the whole tide. (flood: vortex in the harbour mouth; ebb: emptying of the harbour) (Fig. 19).

In the test series V 10 the graduation between as well flood and ebb as the width of the old entrance is very good. For V 10 an ebb inflow is not possible because for this test the old entrance has been closed during the ebb.

Following the model tests it was proposed not to close the old entrance and to observe the situation. After finishing the construction in nature a number of velocity measurements were made in the two entrances and in the harbour channel. Up to now the results are not completely analysed.

Fig. 19

In general one can say the following:

The model results are in a fair agreement with the nature. But concerning the vertical distribution of velocity there are phenomenon which need special investigations to explain it.

In contrariety to a vortex which is produced by an one-directional flow and which shows a good agreement between surface and bottom current, one observes different rotating systems in lateral enlargements under tidal influence.

Measurements in the entrance to the Kiel-Kanal may explain this phenomenon (Fig. 20). Certainly in this case the density effect is of great importance. In Fig. 21 and 22 the normal velocity distribution during the tide has been measured in the Elbe River in front of the entrance. One can recognize also the displacement of the slack-water. Fig. 21 shows the first flood phase. In the surface area there is a fillstream in the entrance and near the bottom the water flows out. During the ebb tide the distribution of surface and bottom current is also quite different, which is demonstrated by Fig. 22.

CHAPTER 109

SAND CIRCULATION PATTERN AT PRICE INLET, SOUTH CAROLINA

Duncan M. FitzGerald

ABSTRACT

A sand circulation pattern has been determined for Price Inlet, South Carolina, using wave refraction diagrams, littoral process measurements, bedform orientations and inlet hydraulic data. The dominant process acting on the ebb-tidal delta is wave swash which impedes the ebb-tidal currents and augments the flood-tidal currents. This produces a net landward transport of sand on the ebb-tidal delta as evidenced by the landward migrating swash bars. Bedform orientations and velocity measurements taken on the swash bars also support this conclusion.

Countering the general landward transport direction is the ebb dominance of the main channel. This dominance can be explained by higher inlet efficiency at low water than at high water. Consequently, bay tide phase lag is larger at high than at low water resulting in a longer flood duration. This causes higher mean ebb-tidal currents and a consequent larger potential net ebb transport of sand. This inlet characteristic explains why little sand is transported inside the inlet, why the throat remains scoured and why sand entering the main channel is carried seaward.

INTRODUCTION

Wave refraction diagrams, littoral process measurement, bedform orientations and inlet hydraulic data were used to determine the pattern of sand movement at Price Inlet, South Carolina. A knowledge of sand transport in the vicinity of inlets is important in understanding ebb-tidal delta morphology and how sand naturally bypasses tidal inlets. This study verified certain conclusions of previous investigations and generated a sand circulation model which is a further development of one proposed by Hine (1975).

Physical Setting

Price Inlet is located 15 km north of Charleston Harbor between two beach-ridge barrier islands of Holocene Age (Fig. 1). The inlet is backed by an extensive system of salt marsh and meandering tidal creeks and is connected to the Intracoastal Waterway. The inlet has no fresh water influx other than local precipitation. The mean tidal range is 1.5 m, and the mean tidal prism is 14 million cubic meters. During spring tides, these parameters may increase to 2.1 m and 20 million m³, respectively. The dominant annual onshore wave energy comes from a northeasterly direction, (FitzGerald, 1976).

Figure 1. Aerial view and location map of Price Inlet, South Carolina. Note the well-developed ebb-tidal delta.

Review of Previous Work

Detailed field investigations of sediment transport patterns in the vicinity of tidal inlets were initiated by Bruun and Gerritsen (1959). Based on studies at Eyerlandse Gat Inlet on the Dutch coast, they recognized the segregation of flood and ebb channels and the resultant sand transport. Oertel (1972; 1975), working on the Georgia coast, observed the importance of breaking waves on swash bars and the interaction between the wave bore and the ebb-tidal currents. He also recognized that ebb-deltas have separate regions of flood and ebb dominance. Dean and Walton (1975) traced the flow pattern during maximum current velocity through Redfish Pass, Florida, and concluded that the lateral transfer of the expanding ebb jet momentum caused entrainment of adjacent waters. Entrainment, in turn, would explain flood dominance of the marginal flood channels. They also stated that the seaward transport of sand was due to tidal currents; whereas, the landward movement of sand was probably due to wave forces. At the Chatham Harbor estuary, Massachusetts, Hine (1975) demonstrated the seaward transport of sand in the main ebb channel and recognized wave-induced landward migrating swash bars.

Ebb-Delta Morphology

The large intertidal and shallow subtidal accumulation of sand that fronts Price Inlet conforms well to the ebb-tidal delta model developed by Hayes (1975), (Fig. 2). The major components of this model are the following: a main ebb channel that ends at the terminal lobe, the seaward dipping lobe of sand; channel margin

linear bars which flank the main ebb channel; swash platforms, shallow sub-tidal sheets of sand located on either side of the main ebb channel; swash bars, intertidal sand bodies occurring on the swash platforms; and marginal flood channels, located between the swash platforms and the adjacent beaches. At Price Inlet, the northern channel margin linear bar is connected to a number of large coalescing swash bars. On the southern part of the ebb delta, the channel margin linear bar is attached to a series of elongate landward-migrating swash bars that parallel the shoreline of Capers Island for almost a kilometer. The main ebb channel and marginal flood channels are well developed at the inlet (Fig. 1).

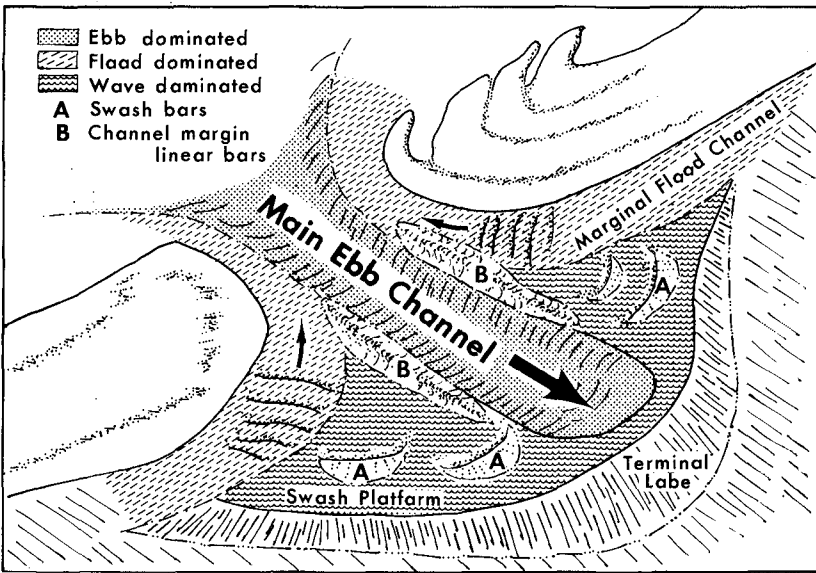

Figure 2. Typical ebb-tidal delta morphology (After Hayes, 1975). The ebb jet maintains a deep central trough, the main ebb channel, flanked by channel margin linear bars and wide arcuate swash platforms. Wave action on the swash platforms generate landward migrating swash bars. Marginal flood channels separate the channel margin linear bars from the adjacent beaches.

Different patterns indicate which areas are dominated by ebb currents, flood currents or waves.

SAND TRANSPORT PATTERNS

Transport to the Inlet

On the central South Carolina coast, there is dominant southward transport of coarse-grained littoral sediment although short term reversals in transport direction do occur. This is determined from wave observations, geomorphic evidence and trends of accretion and erosion (Finley, 1975; Stephens, et al., 1975). Sand enters the ebb-tidal delta complex by longshore transport from the north. Flood-tidal currents and wave bores carry the sand to the marginal flood channels and to the channel margin linear bars. The marginal flood channels constitute pathways for sand transport into the main ebb channel as demonstrated by the flood oriented sandwaves and megaripples which floor these channels. Current measurements in the marginal flood channels also reveal a dominant landward flow (Fig. 3). Wave bores and flood-tidal currents across the swash bar-channel margin linear bar complex probably deliver the bulk of sediment to the main ebb channel. At low tide, wave action transports a portion of the incoming sand in a southerly direction along the periphery of the swash platform.

Figure 3. Current velocity curves at Price Inlet, August 15, 1975. Note the dominance of landward currents in the marginal flood channels. Wave bores traveling across the swash bars cause a super-elevation of the water surface in the marginal flood channels, thus augmenting inlet-directed currents.

Transport in the Main Ebb Channel

From high resolution seismic studies of the channel bottom and monitoring of bedform migrations over many tidal cycles, it is evident that no significant amount of sand moves landward through the throat. Therefore, the main channel must be ebb dominated. Seismic profiles made with a 3000 hz EG&G uni-boom system, reveal a gently (3 deg.) seaward dipping surface of probably Pleistocene age (Colquhoun, 1976; pers. comm.) underlying the inlet. At the throat, the channel is scoured to this surface; further seaward, the Holocene ebb-tidal delta wedge gradually thickens to reach a maximum of 6 meters (Fig.4). SCUBA-diving has identified a 10-20 cm thick layer of coarse sand and shell fragments at the throat bed. Bottom traces of the main ebb channel made over a complete tidal cycle indicate that no bedforms migrate across the inlet throat. Also, sandwaves and megaripples which floor portions of the channel bottom remain ebb oriented.

Figure 4. Seismic trace and interpretation through the main ebb channel. The trace runs seaward from the inlet throat (left) where the channel is scoured down to the Pleistocene surface. The Holocene ebb-tidal delta, a wedge of coarse grained clastic sediments, overlies the Pleistocene horizon and reaches a maximum thickness of 6 meters.

It is here proposed that the ebb dominance of the inlet is a function of the hydraulic characteristic of the inlet-marsh system. Keulegan (1967) has defined a repletion coefficient as a measure of the impedance to flow through an inlet. The coefficient is proportional to the quantity A_C/A_B where A_C is cross-sectional area of the inlet throat and A_B is the surface area of the water in the bay. During flooding, A_B increases rapidly as the lower marsh and tidal flats are covered with water. On the other hand, steep banks of the inlet throat cause only minor changes in A_C during the tidal cycle. Consequently, flow through the inlet is much more efficient at low water than at high water, (Table 1).

Table I

Mean Tidal Range (1.52 m)	A_c	A_b	A_c/A_b
Average low water	1002	2,541,000	.00040
Average high water	1093	6,543,000	.00017
Spring Tidal Range (2.1 m)			
Average low water	994	2,347,000	.00042
Average high water	1110	7,563,000	.00015

Note: Areas in square meters
 A_c - inlet cross-sectional area
 A_b - bay area

At ocean high tide, there is a substantial landward surface slope through the inlet as a result of the high impedance. Thus, the inlet will flood during early ocean ebb. Inlet impedance is greatly reduced at low tide, and the lag between ocean and bay lows is insignificant (Fig. 5). This inlet characteristic results in a longer flood duration, an average of 44 minutes at Price Inlet. Boon (1975) and Byrne (1976), working at Wachapreague Inlet, Va., have also documented the same trend, and ascribe the cause to distortions of the tidal curve. Due to the diurnal inequality, successive ebb and flood tidal prisms are not necessarily equal, but the mean ebb prism equals the mean flood prism. Because the ebbing period is shorter than the flooding period, the mean ebb currents are stronger than the mean flood currents.

Figure 5. Hypothetical relationship between ocean and bay tides at Price Inlet. As the ocean reaches high water, inlet efficiency, A_c/A_b , the ratio of throat cross-sectional area to the surface area of the bay, is low and the water level inside the inlet lags that of the ocean. Therefore, the inlet floods even after the ocean has begun to ebb. At low tide, inlet efficiency is high, and the bay water level closely follows that of the ocean. This results in a longer flood duration than ebb duration. At Price Inlet, the average difference is 44 minutes.

Maddock (1969), using sedimentation flume data, established that total sediment transport rate is proportional to the cube of the current velocity. His transport equation for a velocity range of .1 to 2 m/sec and a mean grain size range of .3 to .7 mm is:

$$V = 4.03 (L/\rho)^{1/3}$$

where V is velocity, (m/sec), ρ is mass density of the fluid, (kg/m^3), and L is the total sediment load, $\text{kg/m}^2\text{-sec}$. Assuming the validity of the relationship for tidal inlets, Maddock's formula has been used to determine sand transport rates at Price Inlet. Using hydraulic data measured at the inlet, the weight of sand passing through the inlet throat has been calculated for ebb and flood tidal cycles of varying tidal ranges. It is seen in Figure 6 that a fairly close relationship exists between potential load and tidal range, and that ebb currents will transport far more sand than flood currents.

Figure 6. Potential load (tons/tidal cycle) has been determined at the throat section of the main ebb channel using Maddock's (1969) relationship where bedload transport is proportional to the cube of velocity. The individual values were computed from current velocity data measured at Price Inlet for varying tidal phases (neap to spring tides). Except for very low tidal ranges, potential ebb transport predominates.

Sediment transport calculations show a potential net ebb transport rate of 364,000 tons/year through the inlet throat at Price Inlet. A net longshore sand transport rate of 128,000 tons/year toward the inlet was estimated from wave parameters measured on Bull Island just north of the inlet (Kana, 1976).

Consequently, the potential net ebb discharge of sand through the inlet is more than capable of removing sand entering the inlet and keeping the channel scoured.

Effects of Wave Refraction

Sand in the main ebb channel is ultimately carried to the seaward portion of the ebb delta where the mean depth is typically 2 m. The dominant north-east waves breaking in this area at low tide generate a net southward sand transport. Due to wave refraction on the swash platform, a sediment transport reversal occurs just south of the delta. Figure 7 demonstrates a net transport of sediment toward the inlet north of point A regardless of deep water wave approach direction. Inside the swash bars, the transport of sand toward the inlet is augmented by flood-tidal currents. The transport reversal is partly responsible for reintroducing sand into the inlet and in building the beach directly south of the inlet. This mechanism is thought to cause downdrift offsets (Hayes, 1970).

Swash Bar Processes

Swash bar development and migration is a continuous process on the swash platform. Over the past four years, many swash bars have formed in these areas and migrated toward the inlet to form swash bar-channel margin linear bar complexes. Both of these bar complexes have recently increased in volume; the southern one has migrated landward; whereas, the one to the north has remained essentially stable with the bulk of its accretion on the seaward side. During an 8 month period from August 1975 to April 1976, the 1 to 2 m slipface which fronts the entire southern bar complex migrated approximately 100 m. Process measurements on the southern bar complex indicate that its landward migration is related to wave swash (Fig. 8). The bore created by waves breaking on the swash bars impedes the ebb tidal currents but augments the flood tidal currents, resulting in a net landward transport of sand. Bedform orientations, shell alignment and current lineations reflect this landward sand transport (Fig. 9). The most common large scale bedform on the bar complexes are linear and cusped megaripples. The migration of the bar complex will continue until it welds to the beach, causing an increased downdrift offset at the inlet. Aerial photographs document at least five episodes of bar welding at Price Inlet since 1941. A more complete description of ebb tidal delta morphology at Price Inlet and associated shoreline changes is discussed by FitzGerald (1976).

The momentum of the wave bore across the swash bars causes a water level set-up behind the southern bar system. This causes the water to exit through the southern flood channel even during a portion of the ebbing cycle (Fig. 3). This flood dominance was explained as jet entrainment by Dean and Walton (1975), a process which is believed to be minimal at Price Inlet. There is a smaller water level set-up in the northern flood channel due to the attitude of the bar with respect to the updrift beach and the incoming waves (Fig. 1).

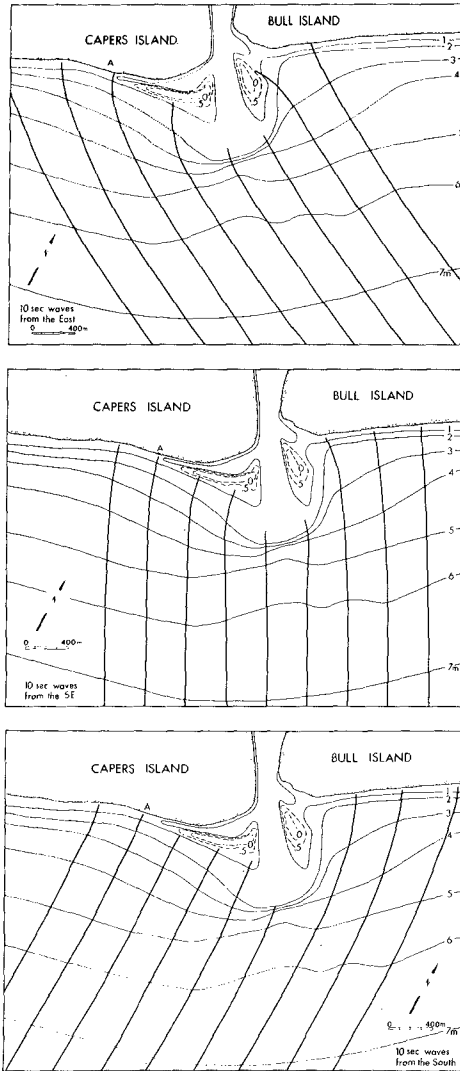

Figure 7. Wave refraction diagrams for 10 sec waves indicate that regardless of wave approach direction, wave refraction around the ebb-delta causes a sediment transport reversal just south of the delta at location A. This mechanism is partly responsible for reintroducing sand into the main channel and for accretion of the downdrift beach.

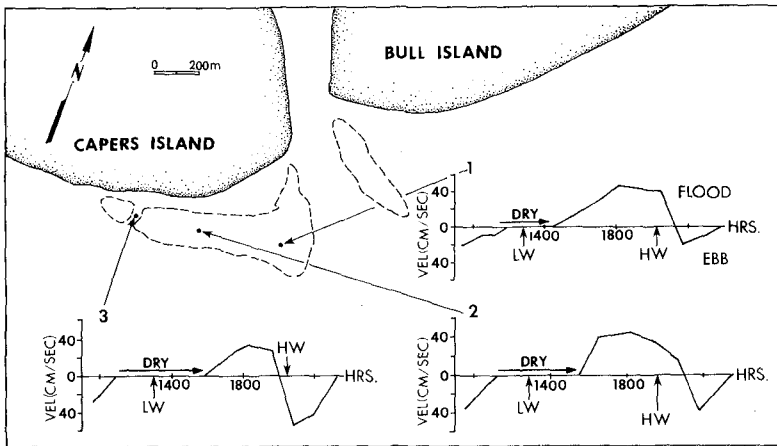

Figure 8. Velocity measurements on the southern swash bar-channel margin linear bar complex on August 20, 1975, show that landward currents predominate. The velocity asymmetry is a result of wave swash retarding the ebb currents and increasing the flood currents.

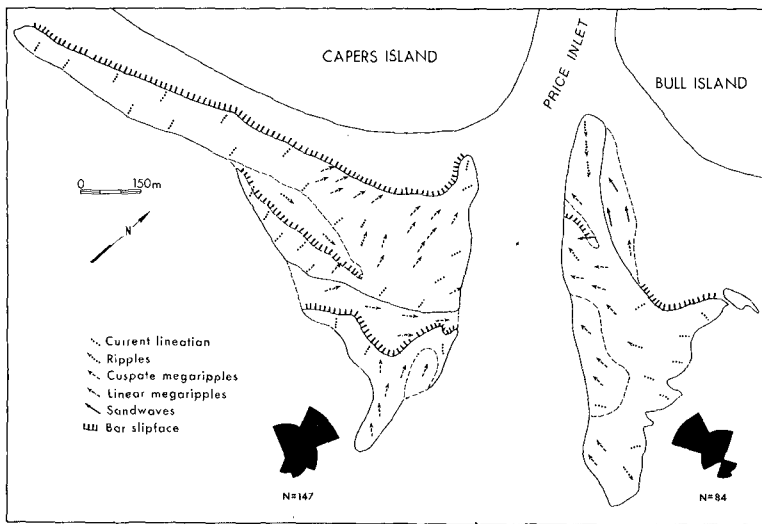

Figure 9. Bedform orientation map of the intertidal portion of the ebb-tidal delta at Price Inlet. Note from rose diagrams that the dominant bedform orientation on either side of the main ebb channel is toward the inlet, indicating landward sand transport.

CONCLUSIONS

1. The sand circulation pattern (Fig. 10) on the ebb-tidal delta of Price Inlet illustrates dominant landward transport except along the periphery of the swash platform where southward transport occurs. Countering this general landward transport pattern is the seaward transport of sand in the main ebb channel.

The ebb dominance of the main channel is explained as a result of greater inlet efficiency at low water than at high water. Landward currents generated by wave bores dominate the swash platform and the swash bar-channel margin linear bar complex. Wave set-up behind the southern bar system augments the inlet-directed currents in the southern marginal flood channel. This process occurs to a lesser extent in the northern flood channel.

Assuming that velocity cubed is proportional to total sediment transport, a potential net ebb transport of 364,000 tons per year was determined for the inlet throat. This value, compared with a net long-shore transport rate toward the inlet of 128,000 tons per year, indicates that all sand entering the main channel will be carried seaward and the throat will remain scoured.

Figure 10. Sand circulation pattern for Price Inlet determined from wave refraction diagrams, littoral process measurements, bedform orientation and inlet hydraulic data. Note the different wave effect at low and high tide, the seaward transport in the main channel due to the dominant ebb-tidal currents, and the landward transport on the ebb delta due to wave swash.

ACKNOWLEDGEMENTS

This study was supported by the U. S. Army Research Office Grant No. DAAG 29-76-G-0111 (Miles O. Hayes and Dag Nummedal Principal Investigators). Jeff Knoth, Ray Levey, Rob Clemens, and Stormy Attaway are gratefully thanked for field assistance. Mrs. Ethel Magwood is thanked for her hospitality in her home at Price Inlet.

CHAPTER 110

BEACH HAVEN AND LITTLE EGG INLETS, A CASE STUDY

Joseph DeAlteris¹, Thomas McKinney², and James Roney³

ABSTRACT

A comprehensive investigation of coastal processes active within and in the vicinity of Beach Haven and Little Egg Inlets was completed as part of the Coastal Processes Investigation for the proposed Atlantic Generating Station. The suspected complex nature of this dual natural inlet system was documented and a process-response model is presented to relate the more significant physical forcing functions to observed morphologic and hydraulic changes. A rising sea level, a net littoral drift from the north and the sediment scouring power of the flow in the two main channels serving the tidal basins are the principal factors related to the geographic and hydraulic stability of the system. The results of the study can be used to evaluate the potential impact, if any, of the proposed Atlantic Generating Station on the adjacent coastal environment.

INTRODUCTION

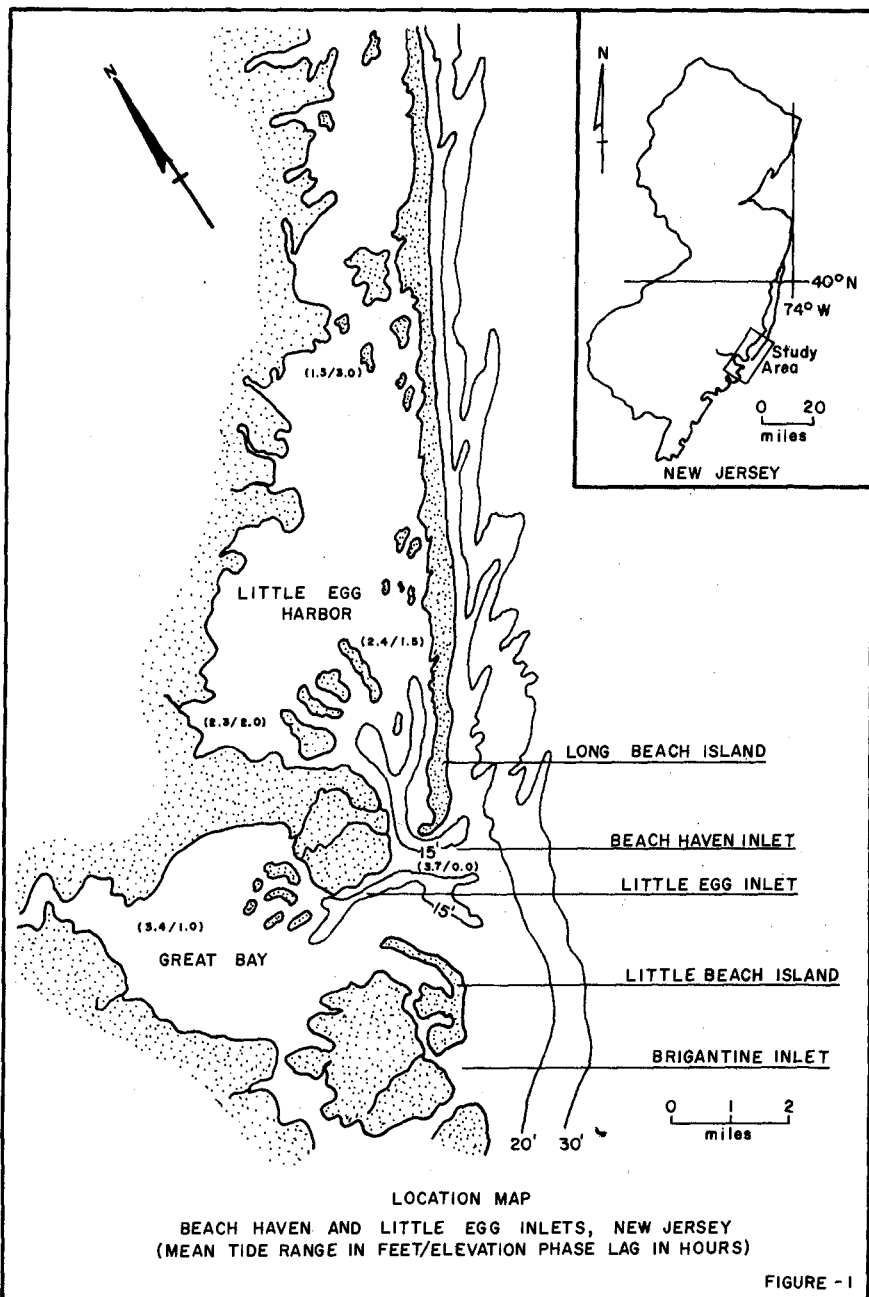

Beach Haven and Little Egg Inlets are juxtaposed natural tidal inlets located midway along the New Jersey Coast, U.S.A. (Figure 1). As part of the Coastal Processes Investigation, for the proposed Atlantic Generating Station, a study was made of these inlets and their adjacent beaches to obtain baseline data on the dynamic nature of this complex natural system. The necessity for a study of this type was noted by the Atomic Energy Commission (1973) in their report on the Workshop for Offshore Nuclear Power Siting. The inlet study included the following task investigations:

1. A study of the recent geomorphic history of the inlet complex using historical shoreline and bathymetric charts dating from 1840 to 1974, site aerial photographs dating from 1933 to 1974, and the biweekly monitoring of beach profiles in the vicinity of the inlet channels.

1 Pandullo Quirk Associates, Wayne, N.J. 07470

2 Dames and Moore, Cranford, N.J. 07016

3 Franklin Institute, Philadelphia, PA 19103

2. A study of the hydraulic characteristics of the inlet complex including analyses of short-term and long-term changes in the cross-sectional areas of the inlet throats, of the storage basin characteristics for each of the inlets, and tide and velocity measurements at the inlet throats.

The purpose of this paper is to present the methodology and results of these individual task studies and a process-response model for the long and short-term evolution of the inlet complex.

Previous studies in this area include the contributions of Shepard and Wanless (1971) which provides a general discussion of the coastal geological features and Charlesworth (1968) which discusses marine sedimentation processes in the inlets. Caldwell (1966) estimates the net littoral drift in this area to be approximately 500,000 cubic yards per year to the south. Fair weather waves in the study area are generally from the SE, are less than 3 feet in height, and have periods of 5 to 6 seconds, (Darling, 1968). Storm generated waves are generally from the NE, are greater than 3 feet in height, and have periods greater than 7 seconds. The mean ocean tide range at Atlantic City Steel Pier (10 miles to the south) is 4.1 feet; the spring tide range is 5.0 feet. The tides are semi-diurnal in nature. The Beach Haven-Little Egg Inlet system is located at a sharp boundary between two distinctly different sediment regimes in the New Jersey coastal sector (McMaster, 1954). The beaches to the north of the inlet system are characterized by medium to coarse sand with an opaque heavy mineral assemblage while the beaches to the south are characterized by fine sands with a hornblende heavy mineral assemblage. DeAlteris and Vespucci (1975) describe the quarternary stratigraphic sequence of the inlet complex based on the results of borings along the transmission line route (Figure 2).

The general limits of the study area included Beach Haven and Little Egg Inlets, their respective storage basins and the beaches adjacent to the inlet (Figures 1 and 2). The Beach Haven Inlet throat channel is located between the southern terminus of Long Beach Island and Sheepshead Marsh. The channel presently reaches a maximum depth of 48 feet (Referenced to MLW). The storage basin served by Beach Haven Inlet includes Little Egg Harbor and Manahawkin Bay. The overall dimensions of these bays are 15 miles long by 3 miles wide. The bays are flanked on the landward side by fringing upland marsh. The average depth of bays is 3 feet (Referenced to MLW). Within this storage basin, there are significant reductions in tidal amplitude and phase lags in the tide curve. Beach Haven Inlet channel is about 2 miles long and has large ebb and flood tidal deltas at each end.

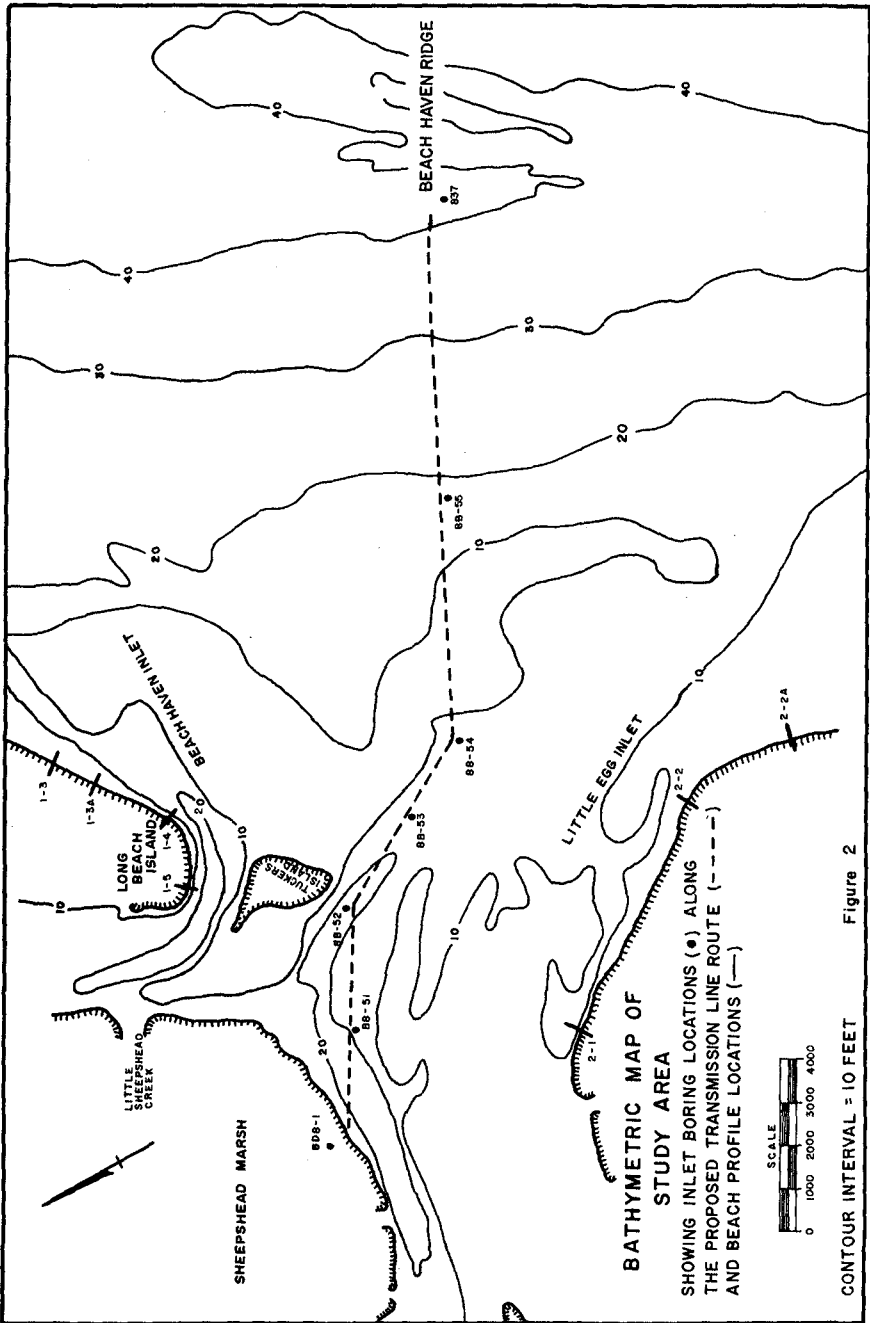

Figure 2

The Little Egg Inlet throat channel is located between the northern flank of Little Beach Island and Sheepshead Marsh. The channel presently reaches a maximum depth of 52 feet (Referenced to MLW). The storage basin served by Little Egg Inlet consists of Great Bay and the lower reaches of the Mullica River. Great Bay is a large open bay, approximately 4 miles in diameter, with an average depth of 6 feet (Referenced to MLW). There are no significant reductions of the tidal amplitude or phase lags in the tide curve within Great Bay. Great Bay is surrounded by fringing salt marsh that periodically floods on spring tides. The lower portion of the Mullica River is tidal in nature and is therefore included in the storage area. The mean annual discharge of the Mullica River is about 0.1% of the mean tidal discharge of the inlet and therefore has not been considered in the tidal hydraulic analysis. The Mullica River is flanked by fringing upland marsh. The outer inlet channels of Beach Haven and Little Egg Inlets are presently separated by Tuckers Island Shoal.

GEOMORPHIC HISTORY OF THE INLET COMPLEX

Using copies of the original hydrographic survey boat sheets available from the National Ocean Survey for the period 1840 through 1954 and the results of a bathymetric survey conducted in 1972 by E G & G, the history of the inlet channels and adjacent beaches was investigated. The individual charts were adjusted to a common scale and grid for comparison purposes and the results of these efforts are summarized in Figure 3.

In 1840, two inlets were present, separated by a large island called Tuckers Island. The primary channel was Little Egg Inlet between Little Beach and Tuckers Islands. The maximum depth of the channel was 59 feet. Some flow also passed between Tuckers and Long Beach Islands, but data are not available on the channel dimensions. Between 1840 and 1873, accretion on the southern end of Long Beach Island caused it to extend southward, overlapping Tuckers Island. Long Beach Island had grown almost 13,000 feet south of its 1840 location. Tuckers Island decreased from about 12,000 feet in length to less than 5,000 feet.

The closure of Beach Haven Inlet's outer channel in the 1870's, had a pronounced effect on the northern limb of the channel at Little Egg Inlet. Tidal flow from Little Egg Harbor was routed through the narrow passage between Tuckers Island and the peninsula to the west. Deep scour occurred over an area extending far into Little Egg Harbor. Depths to 50 feet were present in several places, showing the effect of increased constriction of the channel. By 1903, Long Beach Island had grown more than 7,000 feet and completely absorbed Tuckers Island. At this point, conditions seemed to reach a state of quasi-stability with a

BEACH HAVEN AND LITTLE EGG INLETS
1840 - 1972

Figure 3

single inlet (Little Egg Inlet) relieving both Great Bay and Little Egg Harbor and with Beach Haven Inlet outer channel temporarily non-existent. With a single channel serving the two basins, tidal velocities were apparently sufficiently high to prevent further deposition or constriction of the channel. This semi-stable condition continued until 1920, with the maximum southerly extent of Long Beach Island occurring in 1915. The effect of the constriction was most apparent in the channel, which was now 3 miles long and had depths in excess of 60 feet.

In 1920, equilibrium was upset and Long Beach Island was breached at a point 20,000 feet north of the 1972 position of Little Egg Inlet. The new inlet established itself rapidly, eroding into Long Beach Island to form a major topographic feature. The previous cycle of southerly migration, closure of the northerly inlet, and subsequent growth to a semi-stable single inlet condition had been completed and the cycle begun anew. The survey of 1935 indicated that Long Beach Island had grown southward several thousand feet, while Tuckers Island had eroded considerably. This survey showed increased scour in the northern portions of Beach Haven Inlet. The inlet was narrower and the channel apparently deepened. Little Egg Inlet to the south, showed signs of shoaling. A deep gorge was maintained, but it was reduced to a very narrow breadth. The northern branch of the channel which lead into Little Egg Harbor had been completely buried. By 1954, Tuckers Island was reduced to an intertidal shoal, and the axes of the two channels were separated by about 7,000 feet at their closest point. By 1972, the separation had reduced to little more than 3,000 feet with Little Egg Inlet remaining in a stationary position. All movement can therefore be attributed to the southerly migration of Beach Haven Inlet.

Using aerial photographs dating from 1933 to the present, a more detailed study of the recent evolution of the inlet complex was accomplished. The most interesting result of this study is shown in Figure 4 and suggests a correlation between the rate of migration of Beach Haven Inlet and fluctuations in the rate of sea level rise and storm action. The sea level curve is taken from Hicks (1973) and the distance of inlet migration was determined by measuring on the aerial photographs from a fixed reference point on the barrier to the inlet channel. The periods of rapid southerly inlet migration correlate with periods of rapid sea level rise; while periods of minimal southerly inlet migration and short-term reversals correlate with periods of minimal sea level rise and lowering of sea level.

Figure 4

In order to provide data on short-term changes on the beaches adjacent to the inlets, a beach profiling program was initiated in the summer of 1973, and continued for a period of 18 months. Using a horizon leveling method adapted from Emery (1961), the beach profiles were measured on a bi-weekly schedule. The area under each profile was represented as cubic feet of sand per linear foot of beach. This was plotted as a time series and a first order regression line calculated for each profile to represent the trend, (Goldsmith and others, 1975). The results of the profiling program (Figures 5 and 6) indicate that the profiles which show the most dramatic trends of erosion and/or accretion are located in and adjacent to the inlets. The profiles located at the distal portions of both prograding spits on Long Beach and Little Beach Islands, (1-3, 1-3A, 1-4, 1-5, 2-1) show accretional or relatively stable trends, suggesting continued inlet-directed drift along these beaches. Seaward of these segments, zones of significant erosional trends are noted on both Long Beach and Little Beach Islands. The exact mechanism of the erosional trend at Profile No. 2-2 on Little Beach Island spit is not clear, but the refraction pattern for waves from the northeast suggest that in addition to the suspected interaction of Little Egg Inlet flow, wave energy concentrations into this zone may also be an important factor. Most of the remaining ocean-facing portions of Little Beach Island show a slight erosional trend during the measuring period. Profile No. 2-2A on the north end of Little Beach shows a high accretional trend. This is also suggested by the shoal in the nearshore area as outlined by the 10 foot contour line (Figure 2). The shoal is elongated parallel to the trend of the outer channel of Little Egg Inlet. The details of the processes controlling this accretional nodal point are also lacking. However, it may represent the confluence of the northerly directed littoral drift derived from the eroding beaches to the south on Little Beach and the tidal ebb flow of Little Egg Inlet. The proximity to the dominantly erosional segment at Profile No. 2-2 also suggests a transport contribution from that source, perhaps aided as well by the tidal flow from Little Egg Inlet. In contrast to these inlet influenced beach profiles, the beach profiles facing the Atlantic Ocean are more subdued in both their short-term changes and long-term accretion/erosion trends. This is attributed to the more uniform wave energy distribution along this section of shoreline.

HYDRAULIC CHARACTERISTICS OF THE INLET COMPLEX

The tidal prism represents the volume of water entering the storage basin in a given tidal cycle. If the basin surface remains horizontal throughout the bay as the tide rises and falls, then:

$$P = \text{Tidal Prism} = H \times A_B \quad (1)$$

Figure 5

Figure 6

where A_p is the basin area and H is the average difference between high and low tide elevations in the bay. In practice, however, there may be considerable differences in tide range within the bay accompanied by phase lags of several hours. Computation of tidal prism is then considerably more complex and a straightforward prism analysis is possible only by making discharge measurements at the inlet throat.

The tidal prisms for Beach Haven and Little Egg Inlets were first calculated from Equation 1 using average values for mean and spring tide ranges. For Little Egg Harbor, the basin was subdivided into eight sections for which the range was relatively constant and the total prism was taken as the summation of the sectional prisms. The result of this calculation is given in Table 1 for mean and spring tides. It is emphasized that this calculation is only a crude first approximation. There is a significant phase lag in surface elevation within Little Egg Harbor because of the time involved for the tidal wave to proceed up the shallow bay. For Great Bay, the phase lag is on the order of one hour, therefore the volumetric calculation of tidal prism should be reasonable (Table 1). However, for Little Egg Harbor, the phase lag between high water in the inlet and in the upper bay is about three hours and therefore the calculation of tidal prism simply based on storage basin area and tide range may be subject to considerable error.

Analyses of inlet throat discharges were made, based on measured velocity profiles and tide varying channel cross-sectional areas. Velocity data taken at hourly intervals at the surface, mid-depth and near bottom over an entire tidal cycle were obtained from the Corps of Engineers, Waterways Experimental Station. Cross-sectional areas for each section were evaluated from Alpine Geophysical's 1974 bathymetry. The raw current data from each station were plotted as a function of time and smoothed by fitting a sinusoidal type curve to the data. From the velocity data and the channel cross-sections, the channel discharges were calculated. These values were then adjusted to be representative of a spring tide range and are shown in Table 1.

To a good approximation, the hydraulic stability of a "sandy" inlet may be characterized by a unique relationship between the cross-sectional area at the entrance and the spring tidal prism. Based on a wealth of empirical data, O'Brien (1969) postulated,

$$A = (2 \times 10^{-5}) P \text{ spring} \quad (2)$$

	<u>Little Egg Inlet</u>	<u>Beach Haven Inlet</u>
Mean Tidal Prism (Volumetric)	3.1 (10) ⁹ ft ³	1.9 (10) ⁹ ft ³
Spring Tidal Prism (Volumetric)	3.8 (10) ⁹ ft ³	2.3 (10) ⁹ ft ³
Spring Tidal Prism (adjusted discharge)	3.7 (10) ⁹ ft ³	2.4 (10) ⁹ ft ³
Throat Cross Sectional Area, 1974 (Ref MSL)	7.0 (10) ⁴ ft ²	4.3 (10) ⁴ ft ²
Equilibrium Flow Area Based on O'Briens Relationship (Ref MSL)	7.4 (10) ⁴ ft ²	4.8 (10) ⁴ ft ²

HYDRAULIC CHARACTERISTICSTABLE 1

where A = Cross-sectional area at the throat at MSL (ft^2), $P_{3\text{spring}}$ = Volume of tidal prism at spring tide (ft^3).

The implication is that tidal prism or "tidal power" is the forcing mechanism which maintains and determines the entrance channel. The term "stability" does not imply that the inlet will not change over time but rather that the system is in a state of dynamic equilibrium. A "stable" inlet implies a long-term balance between scour capability of tidal currents and depositional potential from littoral drift. Dramatic or permanent changes in storage basin characteristics of a tidal inlet system will then be manifested by a change of the entrance channel cross-sectional area. One such mechanism might be a geomorphic alteration of the storage basin which would change the tidal prism. A stable inlet will adjust to such changes with a new entrance channel which again permits a state of equilibrium.

Many inlets are not in fact totally "sandy". In a given inlet, one might expect to find a wide range of sediments, ranging from cohesive silts and clays on the channel flanks to shells and gravels on the channel bottom. Given some sand, however, it appears that the adjusting mechanism is generally sand transport as sands are most easily eroded (DeAlteris and Byrne, 1973). This explains, in part, why a unique maximum velocity (about 3.5 fps) is approximated in many inlets and a wide range of inlets may be characterized by Equation (2), (O'Brien, 1969). In particular, Little Egg and Beach Haven Inlets are at least partially sandy so that O'Brien's relationship should be a valid interpretation of their "stability".

Given the present spring tidal prism (adjusted discharge, Table 1), the equilibrium cross-sectional areas were computed from Equation (2). These results are shown in Table 1 and are compared with actual sections given by recent bathymetry. The results indicate that the measured cross-sections at Beach Haven and Little Egg Inlets are approximately equal to the "equilibrium cross-sections".

Within the accuracy of O'Brien's relationship and combined with the inaccuracies of the present analysis, one may conclude that Little Egg and Beach Haven Inlets are at present hydraulically in equilibrium or stable type inlets.

Historical changes in the bathymetry of Little Egg and Beach Haven Inlets were studied to gain some insight into the long-term stability or variability of the area. Hydrographic boat sheets showing both inlet channels, were available for 1903 and 1935 and Alpine Geophysical Associates' data for 1972 and 1974. A "throat" was identified for each inlet and the cross-sectional area was computed from the chart bathymetry. The cross-sectional areas of these sections are given in Table 2. Note that while a particular inlet may change drastically (even disappear), changes in the combined inlet area are relatively minor. For 1903 and 1935, the total Beach Haven and Little Egg cross-sectional areas were nearly identical at about 73,000 ft.², compared with recent cross-sections which average about 97,000 ft.². Adjacent geomorphic changes must therefore also be considered. Great Bay was formerly serviced by an additional inlet slightly north of Brigantine Inlet, commonly called Wreck Inlet. Since 1933, Wreck Inlet has migrated some 1,400 feet southward until merging with Brigantine Inlet in 1963. Wreck Inlet serviced Great Bay by means of Great Thoroughfare which is still present, but in a very reduced state. Simultaneously, Brigantine Inlet was narrowed from 3,000 feet in 1940 to its present width of 700 feet. One may conclude, therefore, that at one time, significant quantities of tidal flow were interchanged between the Wreck Inlet-Brigantine Inlet system and the southern portions of Great Bay. Great Thoroughfare is no longer an avenue for significant flow so that Great Bay is almost exclusively serviced by Little Egg Inlet. In view of the previous discussion of hydraulic stability, the changes in total entrance area from 1903-1935 era to present, seems at least qualitatively reasonable. The effective tidal prism for Little Egg Inlet is now considerably larger, encompassing all of Great Bay. As the storage basin area and tidal prism have increased during the last 30 years, the inlet cross-sectional area has increased to preserve hydraulic stability.

Short-term changes of the inlet channel cross-sections were also investigated by periodic bathymetric measurements along five transects across the Beach Haven and Little Egg Inlet channels. The measurements were made using a small boat, a precision fathometer and an electronic range finding device. The raw profiles were corrected to MSL with local tide data. Channel cross-sectional areas were computed using a limited baseline length that included the central channel and its flanks only, not the wide peripheral shoal areas. During the monitoring period, the area changes were minimal (less than 10 per cent of the average area). In all cases, the actual morphologic changes occurred on the seaward

YEAR	AREA AT BEACH HAVEN INLET (ft ²)	AREA AT LITTLE EGG INLET (ft ²)	COMBINED TOTAL (ft ²)
1903 (1)	-----	-----	72,480
1935 (1)	35,860	37,090	72,960
1972 (2)	35,650	58,900	94,550
1974 (2)	36,680	60,800	99,480

HISTORICAL INLET CHANNEL CROSS SECTIONAL AREAS

TABLE 2

flank opposite the marsh. This is due to the geology of channel cross-section, that is, sands occur on the seaward or updrift flank while cohesive sediments are found on the channel bottom and on the channel flank adjacent to the marsh.

SUMMARY AND CONCLUSIONS

The results of these inlet studies were directed toward assessments of the geomorphic and hydraulic stability of the inlet channels. Beach Haven Inlet is geographically unstable due to the steady southwestward elongation of Long Beach Island. During the last 20 years, Beach Haven Inlet has migrated southwest at a mean rate of 160 feet per year. Fluctuations in this rate along with mean shoreline recession rate, correspond well to fluctuations in the local rate of relative sea level rise. During the next 50 years, it is speculated that Beach Haven Inlet will merge with Little Egg Inlet forming a single entrance to the sea, after which a new break-thru inlet will form on the northern portion of Long Beach Island. This sequence occurred under identical circumstances between 1873 and 1923. This speculation presumes that there will be no attempt to stabilize this natural system. Hydraulically, Beach Haven Inlet appears stable. That is, during the last 75 years, the cross-sectional area of the inlet throat has remained relatively constant at approximately 36,000 square feet. The measured tidal prism for Beach Haven Inlet when plotted against the throat cross-sectional area, lies reasonably close to O'Brien's curve. Little Egg Harbor, the storage basin for Beach Haven Inlet, is long, narrow and shallow. Within this storage basin, there are significant reductions in tide range and phase lags in the tide curve. In contrast to Beach Haven Inlet, Little Egg Inlet is geographically stable; only the outer inlet channel thru the ebb tidal delta has migrated in the recent past. Little Egg Inlet appears hydraulically stable, that is, the inlet throat cross-sectional area has remained relatively constant. Both the calculated and measured tidal prisms when plotted versus the channel throat cross-sectional area, lie reasonably close to O'Brien's curve. Between the surveys dated 1936 and 1973, the inlet throat cross-sectional area increased from 37,000 square feet to its present size of 59,000 square feet. This increase in cross-sectional area can be related to an increase in tidal prism served by the inlet due to the closure of Wreck Inlet, a former inlet on the south side of Little Beach Island. Hydraulically, Little Egg Inlet is distinctly different from Beach Haven Inlet. There are no significant reductions of the tidal amplitude or phase lags in the tide curve within Great Bay.

CHAPTER 111

OFFSHORE SEDIMENTARY PROCESSES AND RESPONSES NEAR BEACH HAVEN-LITTLE EGG INLETS, NEW JERSEY

Cranford, New Jersey

INTRODUCTION

The offshore region in the vicinity of the Beach Haven and Little Egg Inlets of New Jersey is the site of the proposed Atlantic Generating Station, a floating nuclear power plant to be constructed 2.8 n. mi. offshore by Public Service Electric and Gas Company (Figure 1A). In order to assess the impact of this proposed project on the region, a comprehensive study of the nearshore and offshore region was conducted. A complete synopsis of this study is available in PSE&G (1976). This paper presents the results of the investigations into the sedimentary processes operative in the offshore region. The dynamics and coastal evolution of the nearshore region is summarized in DeAlteris et al., (1976; this conference).

The proposed Atlantic Generating Station (AGS) is located offshore of the complex and transient tidal inlet system of Beach Haven and Little Egg Inlets. These inlets are the major hydraulic connections between the Atlantic Ocean and the Great Bay and Little Egg Harbor estuaries. A large, roughly triangular ebb-tidal delta is present at the mouths of and between the two inlet channels. The major offshore bathymetric feature is a broad linear sand ridge, the Beach Haven Ridge, which trends northeast and reaches a maximum elevation of -28 feet (NLW) (Figure 1A). The AGS site is located on the landward flank of the ridge and partially in the adjacent trough in about 40 feet of water. Landward of the wide, northward-deepening trough, the ocean bottom slopes gently up towards the ebb-tidal delta of Beach Haven and Little Egg Inlets. The offshore zone adjacent to the proposed AGS is separated from an extensive tidal marsh lagoon system by a broken chain of barrier islands, from Long Beach Island on the north to Little Beach and Brigantine Islands on the south.

The Beach Haven Ridge is one of a system of sand ridges which occur on the shelf surface. In recent years the origin of these features has been the subject of a number of studies. Duane et al., (1972) studied the sand shoals on the inner portions of the eastern continental shelf of the United States. Swift et al., (1973) review the question of the ridge and trough topography of the Middle Atlantic Bight. A detailed description of the geomorphic elements of the inner New Jersey continental shelf for this region is presented in PSE&G (1975). Duane et al., (1972) suggested that the shoreface-connected ridges originated in a shallow nearshore environment in response to the interaction of south-trending, shore-parallel, wind-driven currents and waves during winter storms. They suggest that as sea level rises, and the shoreface retreats, the shoals are abandoned and isolated as "relict" features on the shelf surface. This concept was proposed in part by Moody (1964) from studies of the ridge system at Bethany Beach, Delaware.

Duane et al., (1972) recognized two categories of shoreface-connected ridges based on their orientation to the shoreline and their inferred response to the coastal hydraulic regime:

¹Pandullo Quirk Associates, Wayne, New Jersey

²Rutgers University, New Brunswick, New Jersey

³Franklin Institute, Philadelphia, Pennsylvania

Type I Ridges - Ridges with wide angle to the shoreline (over 30°)

Type II Ridges - Ridges with low angle to the shoreline (less than 30°).

Type I ridges are oriented transverse to the wind-driven storm currents and essentially parallel to the direction of wave attack. The Type II ridges would be oriented nearly parallel to the storm-generated currents and normal to the wave attack. During the initial stages of development, the low angle ridges (II) have the morphologic responses of wave-built bars (Duane *et al*, 1972; McHone, 1972). Wide angle ridges, such as those studied by Moody (1964), are more responsive to the coast-parallel storm currents and may migrate to the south. Moody's data showed that for a 42-year period, migration rates were about 10 feet per year. These cases of ridge migration were noted for the shallow segments of the shoreface-connected ridges.

Moody (1964) also suggested that considerations of wave refraction indicated that the wave orthogonals tended to converge over crests, producing nearbottom residual wave currents which would converge obliquely shoreward toward the crests. The wave refraction patterns may also be an important generating mechanism for the shoal topography (Moody, 1964; Goldsmith and Colonell, 1970). Thus, ridges oriented parallel to the prevailing storm wave attack, would produce consistent patterns of wave convergence on the north side of their connections with the shoreline, causing erosion in this area. The ridges would tend to perpetuate themselves by a feedback mechanism during the retreat of the coastline.

The Beach Haven Ridge cannot be classified as a typical shoreface-connected ridge. Duane *et al*, (1972) define the shoreface-connected ridges as those ridges outlined by, but landward of the isobath that defines the shoreface (usually the 30 ft isobath). In the study area, the nearshore profile is dominated by the sedimentary buldge of the tidal delta from the double inlet system (Figure 1B). The Beach Haven Ridge is located adjacent to the basal segments of this progradational feature which has been deposited over the shoreward edge of the ridge system (Figure 1B). Thus, the position of the ridge is comparable to the isolated, "relict" linear shoals elsewhere on the inner shelf and its location adjacent to the rising nearshore profile (shoreface) is due to its proximity to the large inlet system. The Beach Haven Ridge forms a low angle with the shoreline and would be comparable to Type II ridge of the shoreface-connected ridges, suggesting a response comparable to a longitudinal bedform in relation to the inferred controlling processes. Thus, its position beyond the upper shoreface and its orientation, parallel to the storm currents (Type II), both suggest a degree of stability of position and a lower sedimentary transport climate. The studies conducted in the offshore zone tend to substantiate these inferences.

GEOLOGIC FRAMEWORK

The geologic studies carried out in conjunction with soil investigations of the AGS site are presented in detail elsewhere (Stahl *et al*, 1972; PSE&G, 1972). These investigations support previous findings which indicate that the ridges on the inner shelf were formed by nearshore dynamic processes subsequent to the Holocene transgression of the shoreline (Field and Duane, 1976).

In addition, the AGS studies indicate that a backbarrier sand unit is differentially preserved below the sand ridge and that the underlying Holocene lagoonal clay unit below this is locally exposed in the landward trough. The subsurface data thus suggests that during shoreface retreat, the backbarrier unit was differentially eroded from the trough and its residue was deposited in the adjacent ridge (Figure 1B). The preservation of the backbarrier facies below the ridge suggests that, once the ridge formed, it did not migrate substantially and thus protected the underlying backbarrier sandy units from further erosion in this earlier upper shoreface setting. This pattern of long-term stability, suggested from the geologic data, is consistent with the historical analysis of the ridge stability, the studies of short-term stability of the ridge in response to major dynamic events and the assessment of the sediment transport from the monitoring of the hydraulic regime.

SURFICIAL SEDIMENTS

The nearshore area in the vicinity of the AGS site was sampled during the summer of 1974. The location of bottom samples is indicated in Figure 1A. Grain size analysis was conducted on the samples using calibrated 1/4 Phi sieves and where appropriate, hydrometer analysis.

Sieving was conducted on 8-inch diameter sieves using standard techniques as outlined by Folk (1968). Sieves were calibrated with respect to effective openings by using sets of standard glass spheres from the U.S. Bureau of Standards. Calculation of statistical movement measures following Friedman (1961) and plotting of frequency, and cumulative frequency curves was carried out using a computer program.

The grain size parameters which were found most useful in defining the patterns of sediment distribution and dispersal in the nearshore zone were the modal grain size and the percentage of fines (greater than 62 microns). The distribution of these parameters are presented in Figure 2A and Figure 2B.

Previous detailed grain size studies have revealed that in sandy sediments, a central sub-population can be recognized (Moss, 1962, 1963, and 1972; Visher, 1967). This central population is the main component of most sands and appears to represent a saltation population of framework building grains. This central population is a near Phi - normal distribution and is

represented by a central parabola when the frequency distribution is plotted on logarithmic scale (Hald, 1954; McKinney and Friedman, 1970). The parabola-like aspects of the distribution can be seen in the frequency plots listed in Figure 3 and 5B. The modal size was determined as the central grain size of this parabola. From Figures 2A and 2B the distribution of sediment patterns can be delineated.

Figure 3 presents the sequence of frequency curves on logarithmic scale across sampling Profile I to illustrate the nature of the systematic variation and traceability of distinct modal entities and their relationship to the morphologic elements in the nearshore zone.

The modal size shows systematic variation which enables this parameter to be contoured and related to apparent dispersal trends which reflect the transport and depositional processes which resulted in accumulation of these sediments (Figure 2A). The modal size distribution map of primary modes has been constructed using a contour interval of 0.4 Phi units. The following sediment classes of modal sizes have been shaded for additional emphases: a) Modal sizes coarser than 1.0 Phi (includes coarser and very coarse sands). b) Modal sizes 1.0 Phi to 1.8 Phi (medium sand). c) Modal sizes 1.8 Phi to 3.0 Phi (fine sands). d) Modal sizes 3.0 to 3.4 Phi (very fine sands). Note that the boundaries between B and C listed above is not the boundary between medium and fine sands as defined in the Wentworth (1928) classification of grain sizes, but for the purposes of discussion in the context of the contouring of modal sizes discussed above, these subdivisions will be referred to as medium sands and fine sands, respectively. The contoured pattern of modal sizes reveals and outlines three major sedimentary facies:

1. Tidal sand deposits - these sediments are defined by the alternating patterns of fine and medium sand reflecting the onshore-offshore pattern of tidal ebb and flood flow from the double inlet system.
2. The shoreface very fine (and silty) sands.
3. The shelf sand sheet - with modal sizes ranging from coarse to fine sands.

Tidal Sand Facies - Tidal sand facies as mapped by the contours of modal shows a very close relationship to the tidal channel and inlet morphology. Fine sands are deposited on shoal areas between active tidal channels which are characterized by medium sands. Locally, coarse sands characterize the deeper portions of the inlet channels as in the Beach Haven channel system to the north. A general asymmetry to the sizes can be noted within the inlet system with the northern half of the inlet system being characterized by a predominance of medium sand modal sizes, while the southern portion has a greater abundance of fine sand sizes. Charlesworth's (1968) study of sediments and hydraulics of this double inlet system reveal a similar southerly decrease in grain size as defined by trend surface

analysis of mean grain sizes of inlet samples. The variation in modal size also shows a systemic pattern of decreasing sizes down the axis of the inlet channels in an offshore direction. This pattern terminates in bulges in the modal size contours of the fine sand lobes on the upper shoreface. This would seem to indicate and reflect the decreasing sediment transport capacity associated with the flow in the tidal channels offshore and the associated deposition. Fine sand seems also to have accumulated in the shadow zone of the ebb flow seaward of Tucker's Island.

The distal portions of the complex ebb delta system is marked by a slope increase illustrated by the 10- to 15-foot contours. Locally, a flattening is noted on the upper segments on this outer delta front, seaward of the Beach Haven Inlet as outlined by the 5-foot contour. These outer flattened margins of the delta complex are characterized by coarser grain sizes. The flat area off of the Beach Haven delta is characterized by modal sizes of 1.2 to 1.3 Phi. The outer edge of the delta front to the south is characterized by an increase of modal sizes to 1.5 Phi above the surrounding suite of modal sizes which range from 1.8 to 2.1 Phi. These patterns apparently reflect the storm-wave reworking of the outer distal portions of the ebb tidal delta.

Most of the tidal sands within this area are characterized by very low percentage of fine material. In general, there is an increase in the percentage of fine materials at the distal edge of the tidal sand facies corresponding with the sediments in the upper portions of the shoreface zone, where percentages of fines increased to 0.5 to 1 percent of the total sediment (Figure 2B). Locally, a few sampels within the tidal sand facies contain percentages of fines greater than 1 percent as is indicated in Figure 2B.

Shoreface Facies - The modal size distribution reflects a systematic decrease in grain size from the sediments which characterize the outer segments of the tidal sand facies as described above, into the sedimentary suite defined as the shoreface sand. These sands are characterized by a definitive pattern of modal grain sizes which occur within the upper portions of the shoreface morphology as defined by the approximate position of the 15-foot contour.

The sediments within the shoreface zone are characterized by a very uniform pattern of modal sizes over the wide area of this zone which range from 2.9 Phi in the upper portions of the shoreface to 3.2 Phi in the lower portions (Figure 2A and 3). In general, this area is characterized by sizes within the very fine sand modal class.

The distribution of these very fine modal sands is best developed in the central and southern portions of the study area. The shoreface area seaward of Long Beach in the northern segment of the study area does not appear to be characterized by a continuous suite of very fine sands. In this region, corresponding with the location of small-scale ridge and swale morphology, the bottom sediments are characterized by coarser grain sizes

ranging from fine to medium to coarse sands. The distribution in the occurrence of the very fine modal sand class as outlined in Figure 2A also corresponds with those areas characterized by percentage of fine material which are greater than 1 as indicated in Figure 2B.

Thus, the shoreface sands are located within a definitive morphological setting and are characterized by the well-defined and narrow range of modal sizes and increased percentages of fine silty material. The percentage of fine materials increases locally on the lower portions of the shoreface zone to values in the 30 to 40 percent range (Figure 2B).

The shoreface sands have been identified from textural analysis of samples within cores from subsurface material across this zone. Cores through the shoreface suite are characterized by similar modal sizes of very fine sand and similar percentages of fine silty material. Sedimentary structures within the cores are locally characterized by thin laminations of this very fine silty sand material. Except for the occurrence of one sample in the landward trough of the offshore sand facies to be described below, this distinctive modal suite is present only within the narrowly defined limits of the shoreface zone.

Shelf Sand Facies - Beyond the thin distal edge of the shoreface very fine silty sand facies described above, lies the shelf sand sediments. This facies is characterized by predominance of coarse and medium sands. The contour patterns of modal grain sizes for this offshore suite is characterized by a distinctive coast-parallel orientation in contrast with the coast-perpendicular patterns of contours in the tidal sands and shoreface facies.

The northern portions of the shelf sand facies is characterized by very coarse modal sizes, apparently representing the southern distal edge of the reworked fluvial gravel deposits of Schlee and Platt (1970). Frank and Friedman (1971), also identified these coarse sands in similar depth position immediately to the north of the present study area.

The boundary between the offshore distal edge of the shoreface sand and the shelf sand facies is, in general, a very sharp one as indicated by the contours of modal size (Figure 2A), with modal sizes varying from very fine sands to coarse to medium sands within very short distances. In addition, sediments of the shelf sand facies located adjacent to the distal edge of the shoreface sands are characterized by secondary modes of the very fine sand mode of the shoreface suite (Figure 3).

As with the other facies within the study area, there appears to be a regional fining of the grain sizes within the shelf sand facies from coarse on the north to predominantly finer sizes on the south.

The more detailed variations in the distribution of modal sizes can be described within the context of the ridge and swale topography as outlined in the bathymetric chart of the Atlantic Generating Station area

(Figure 1A). The landward trough of the Beach Haven Ridge is characterized by an underlying framework of medium and coarse sand sizes. This suite forms a thin cover over the Holocene lagoonal clay unit as described in corings and borings (Figure 1B). Locally, the clay is exposed at the surface. In addition, during the sampling period, isolated samples of fine sand and one sample of very fine modal sand were present within the landward trough. The medium and coarse sands above the Holocene clay show the presence of secondary modes of fine and very fine sands as admixtures (Figure 3). Locally, higher values of fine material (Figure 2B) correspond with the presence of the very fine sand admixtures in the landward trough.

Thus, the landward trough is characterized by a thin sedimentary cover which represents an admixture of predominantly coarse and medium modal sizes and local admixtures of suspended fine material and secondary modes of fine and very fine sand which locally represent the predominant modal size. Thus, the sorting within these sediments is relatively poor compared to adjacent areas (Figure 3).

The Beach Haven Ridge itself is characterized by the predominance of medium sand sizes along its axial portions. A decrease of modal sizes occurs from the central axial portions of the ridge down the northward sloping axial portions of the ridge from grain sizes of 1.2 Phi to 1.3 Phi to 1.4 Phi in a northerly direction. A central zone of coarse sand is located along the axial portions of the ridge where the lineation aspect of the ridge is clearly defined. The location of this coarse sand zone along the axis of the ridge correlates with the crossing of caustic rays as indicated in the wave refraction diagrams for storm waves from the northeast (PSE&G, 1975). Further to the south of this area, along the continuation of the ridge trend, grain sizes within the ridge proper decrease. In this region, the ridge morphology is not clearly defined and flattens out with a general southward merging with the shoreface morphology.

This flattening of the ridge crest to the south is outlined by the nature of the 30- to 35- foot contours in this area (Figure 1A). Also noted in the ridge morphology in this region, is a broad delta-like fan which occurs on the upper portions of the seaward flank. This is indicated by the outline of the 35- and 40- foot contours. This feature, which occurs opposite a lower area, or swale in the crestal portions of the ridge, is very similar to the fan-like features mapped and discussed by McHone (1972) for a shallow shoreface-connected ridge on the south Virginia coast. The Virginia features are associated with erosional saddles in the ridge crest and have been ascribed to the breaching of the ridge during storms and the deposition of fine sediments in the adjacent sediment lobes on the seaward flanks.

A careful examination of the modal sizes in the area of this fan-like bulge shows that it corresponds to a comparable lobe of finer bottom sizes as indicated by the seaward convexity in the isopleths of modal size that become finer down the axis of the fan. At the base of the fan, immediately seaward of the 35-foot contour, a depocenter of fine sand (modal size 2.2 Phi) is noted.

Superimposed on the general pattern of coarse and medium sands, is the distribution of fine sands in selected areas in the offshore sand facies. A distinctive aerial distribution of such fine sands is encountered on the seaward flank of the Beach Haven Ridge and incorporates the fan-like feature described above.

The modal sizes of the outer shelf fine sands are characterized by a narrow range of modal sizes (2.0 to 2.3 Phi). This is in contrast to the wide range of fine modal sizes noted for the sands of the tidal facies which can be related to the systematic dispersal of sediment from the tidal inlets. The surficial zone of fine sand (2.0 to 2.3 Phi) noted on the seaward flank of Beach Haven Ridge has also been identified from analysis of cores in this area. The core data indicates that the fine sands are 1 to 2 feet thick and overlie medium sands which characterize the core of the ridge. Another ridge-parallel zone of fine sand occurs further seaward of the ridge flank but it is not as clearly defined as the former. To the south, both fine sand units appear to merge to form a broadening zone of fine sand which characterizes the southern inner segments of the shelf sand facies.

The occurrence of the fine sand deposit on the seaward portion of the Beach Haven Ridge also corresponds to a general increase in the percentage of fine material in this area of the offshore facies. Locally, values of percent of fines are greater than 1 and in a few cases very high portions of fine material occur in isolated patches on the outer segments of shelf sand facies (Figure 2B).

BOTTOM STABILITY

An analysis of bathymetric data from 1677, but in detail from 1935 to 1972, reveals the Beach Haven Ridge has maintained its general position for almost 300 years and its overall orientation and shape for at least 35 years, the period when detailed maps were available. Moderate variation in the sea floor over this period are, however, evident.

The landward trough has been the site of alternating periods of infilling and erosion. The periods of infilling can be related to greater influx of sediment from the adjacent inlet system. The correlation of such an event with the passage of Hurricane Agnes in June 1972 suggests that sediment was pumped out of the inlets by the reflux of storm surge that accompanied this event and was deposited at the distal edge of the shoreface. Subsequent remobilization of this fine silty sand during storm events, resulted in the removal of a few feet of this material from the trough surface. At no time, however, did erosion proceed down to and involve the Holocene clay unit which underlies the trough. The overall trend was one characterized by a general erosion of the lower shoreface and the south-trending headward segments of the trough.

The erosive resistance of the Holocene clay which underlies the trough is further documented by a laboratory analysis of the critical shear stress of erosion of this unit that was carried out at the University of

California, Davis (Krone, 1974), samples of cohesive sediment from 20 diver-collected cores were kept moist and shipped immediately to Davis. Testing was accomplished using a rotating cylinder apparatus, modified after Moore and Masch (1962), using both sea water and distilled water. The critical shear stress for surface erosion was found to exceed the capacity of the apparatus, 82 dynes/cm². Occasionally, the presence of small sand lenses and concentrations of shell material, resulted in the falling off of "chunks", even though the rest of the surface did not erode.

Accompanying the patterns observed in the landward trough, were the observations of slight depositional trends ranging to a few feet on the seaward flank of the ridge. Subsequent sediment analysis from cores and surface samples indicate that this depositional trend was also characterized by fine sands. Thus, the differential mobility of the fine sands appears to correlate to the minor variations in the ridge and trough morphology over the measuring period.

A program to evaluate short-term changes in and around the ridge was conducted from the summer of 1973 to the summer of 1974. Bottom elevations were measured by divers on a bi-monthly schedule. Measurements were made with reference to a series of stakes at each field (Figure 4A). The results indicate that there was no significant scour or accumulation at any of the stake fields at any time during the measuring period. Variations noted were on the order of magnitude of the wave ripple heights.

In addition to bottom elevation measurements, the stake field study enabled divers to collect bottom samples over the monitoring period for an analysis of the temporal variations in bottom sediment texture. The statistical parameters for a particular stake field were remarkably consistent during the measuring period. This consistency is reflected in the plots of the size distributions which fall into tight envelopes as plotted on the Phi-probability scale (Figure 4B). The small variations noted may easily reflect the variations expected due to the combined sampling, splitting and analysis operations and/or the variations related to position on a ripple crest or trough. Stake field 5 samples showed the most variability within the stake field and with time for a particular stake. The slight variability at stake field 5 occurs in the fine sand portion of the distributions.

Storm Hydraulics and Effects of December, 1974 Storm - The long-term cumulative effects of erosion and deposition are intergrated and reflected by the changes in the historical bathymetry. Such patterns are responses to the coastal circulation system.

The dynamic aspects of the coastal circulation at the AGS site have been monitored for over two years (E.G.&G. 1974, 1975). This area is characterized by the interaction of tidal current outflow from the inlets and the general pattern of coast-parallel, coastal current circulation. Like other segments of the Middle Atlantic Bight, this coastal region displays a geostrophic coastal current which is driven by the density patterns associated with lighter nearshore waters due to the freshening influence of river runoff and results in a general net south-westerly drift, measured at the site as 5 cm/sec. Although the net and predominant drift is to the south, during

winter months, due to the low runoff and extreme cooling for the inner shelf waters, the density gradients are reversed and the drift can be reversed, to a northeasterly direction. Superimposed on this coastal drift, is a weak (1.5 cm/sec.) quasi-estuarine onshore-offshore circulation; offshore in the surface waters and onshore along the bottom.

The dominant process operative in the offshore area with the potential for differential sediment transport, is the wind-driven circulation associated with major storms. The intensity and directional aspect of the bottom flow regime is directly related to the wind intensity and direction; reversals in the wind direction are accompanied by reversals in the bottom current circulation patterns. The wind patterns associated with storm events generally resulted in coast-parallel circulation particularly to the southwest or downcoast direction in response to "Northeaster" storms which characterize this area. Currents in this direction tended to be characterized by somewhat greater values and were of slightly longer duration than the upcoast bottom currents associated with continental storms. This can be related to the superposition of the downcoast wind-driven circulation with the southwesterly geostrophic drift which characterizes the coastal circulation. However, the data indicates that upcoast storm-driven bottom circulation does occur in response to continental storms and must be considered in the evaluation of the sedimentary processes for the offshore area. This upcoast transport is increasingly important for winter months when the tendency for a northeasterly drift is increased.

The current data (obtained from Savonius Rotor instruments) as summarized for the year 1972, shows that the percentage of occurrence of current values with a potential for bottom transport (velocities greater than 40 cm/sec. near the bottom) was about 3 percent and was associated with the wind-driven circulation from these storm events, mostly in a downcoast direction.

On December 1 and 2nd, 1974, a major northeaster storm passed the site, resulting in strong winds out of the east with unlimited fetch. A maximum observed wave height of 5.6 meters and a maximum significant height of 4.4 meters, recorded on December 1st were the most severe to be encountered during the two year measuring period. This storm was the most damaging coastal storm for the eastern seaboard since the major storm of 1962. Peak flow in the lower meters had an hourly average speed of 62 cm/sec, while the upper flow speeds reached 85 and 95 cm/sec, directed in the downcoast direction. In order to assess the impact of this storm on the bottom configuration and sediment texture of the ridge, a series of bathymetric profiles across the ridge system were measured shortly after the storm (Figure 4A). In addition, stake fields 2 and 5 were measured and bottom sediment samples were collected to compare with earlier data. Comparisons of the pre- and post-storm profiles are presented in Figure 5A. The results indicate that the ridge system was essentially unchanged by the storm. Measurements at stake fields 2 and 5 were unchanged also from the previous measuring period. The post-storm bathymetric profiles do indicate that one to two feet of sediment was eroded from the lower portion of the shoreface and some from the landward trough. There is also the suggestion of a slight zone of accretion

on the seaward flank of the ridge in places. The sediment analysis of the post-storm samples did show an interesting variation at stake field 5; stake field 2 sediments were unchanged. The comparison between a representative size distribution for stake field 5 sediments prior to the December, 1974 storm and the post-storm sediment distribution is presented in Figure 5B. The storm resulted in the addition or admixture of a distinct very fine sand modal component to the earlier sediment distribution. The very fine sand population apparently is derived from the erosion and remobilization of the very fine silty sands of the lower shoreface and landward trough. The storm transport has apparently moved this material from the lower shoreface and trough up onto the landward flank as a thin textural admixture. The process has also enabled the separation of the silty fraction from the shoreface sands as the very fine sand moved offshore as bottom sediment while the fines (< 62 microns) were suspended and apparently travelled further downcoast.

DISCUSSION AND CONCLUSIONS

The distribution of the sediments in the study area and the aerial variations in their compositional and their textural parameters provide insight into the nature and degree of sediment transport processes that have been operative in this region. The modern active processes of sediment transport and deposition are most active in the double-inlet system in the nearshore zones. Here, tidal currents are largely responsible for the sediment patterns observed. The decreasing pattern of grain sizes and increased proportion of fine suspension material of the shoreface zone, represents the distal portions of the modern zone of nearshore sedimentation. The origin of the basic coarse pattern of the sediment distribution and character of the offshore shelf sands cannot be attributed to modern processes. Their general pattern can be related to the reworking of fluvial deposits to the north and the differential erosion of backbarrier Holocene sediments by coast-parallel processes at lower sea levels.

The nature and degree of modern sediment transport in and around the offshore ridge system can be closely related to the distribution of fine sand and suspended material as primary and secondary modal entities in the offshore sands. The landward trough is the distal depo-center for modern very fine sand and silt derived from the nearshore zone. When the influx of this fine silty sand material is high, as perhaps during major storm events which produce a flushing of the inlet system, the trough floor is covered with these fine silty sands over the thin coarser sands which cap the Holocene clay within the trough. Subsequent coast-parallel storm transport, especially by northeasters, may flush out the fine sands from the trough. This appears to reflect the ongoing balance of accretion from, and progradation of, the distal portions of the shoreface zone and the subsequent reworking of these loose silty sands by storms.

The remobilization of the fine sands in this setting at the headward portions of the trough, may thus pass to the south and over the flattened crestal parts of the ridge. Such migration of the mobile fine sand fraction would explain deposition of the fine sands which characterize the gentle seaward flank of the ridge. This sand has accumulated here in the "lee"

of the ridge as a thin coating and relates to data from the historical bathymetry analysis which indicates accretional events in these seaward flanks over various measuring periods.

The base level of the landward trough reworking is clearly the erosion-resistant Holocene clay foundation and its coarse sand capping.

It is the coming and going of the fine silty sands which have characterized the modern sediment transport in and around the ridge system. Elsewhere, away from the main source of this modern fine material, the coarser sediments of the offshore shelf facies only display this finer material as subordinate bimodal admixtures.

The well sorted and unimodal medium to coarse sands of the Beach Haven Ridge crestal zone are an exception. Here storm-wave agitation has apparently kept these transient fine fraction admixtures from accumulating within the crestal ridge sands.

The suggestion that the only significant transport of sediment in the offshore zone, is the fine sands which form the thin and disconnected admixtures into the coarse sands of the offshore shelf facies, is substantiated by sediment analysis of the stake fields. In particular, the post-storm (December, 1974) sediment comparisons for stake field 5 clearly indicated that it is this fine sand only, which has been differentially moved and deposited on the ridge's landward flank.

It is concluded that the Beach Haven Ridge, originated during an earlier sea level stand by an active differential erosion on the upper shoreface. Due to sea level rise, the ridge system is now located out of the zone of active shoreface erosion and within the zone of nearshore deposition. The outflux of sediment in the nearshore zone from the double inlet system is of considerable magnitude and has been capable of covering the shelf sand facies (Figure 1B). This depositional zone thins to a distal edge over the shelf sands to the north, apparently due to the net effect of the transport of the shoreface sands to the southwest in response to the net coastal currents in that direction.

A differential battle at the offshore distal edge of the shoreface depositional zone, between the progradation of this edge, due to the greater sediment influx into this zone, and the regression of the distal edge by the reworking currents and low sediment supply to the offshore zone, appears to characterize the sediment regime in the offshore area. In this battle, fine sands are transported over the ridge system out onto the shelf in a step-like fashion, as a thin coating over the older coarser shelf sediments. The long range pattern, if sea level continues to rise, would be one of the translation of the nearshore shoreface depo-center shoreward, further isolating the ridge system as the distal edge as the shoreface migrates landward.

ACKNOWLEDGEMENTS

This work was performed for Public Service Electric and Gas Co. and we would like to acknowledge the assistance and guidance of Mr. Doug Briggs during this effort.

CHAPTER 112

CAPACITY OF INLET OUTER BARS TO STORE SAND

Todd L. Walton, Jr.¹ and William D. Adams²

ABSTRACT

Inlets act as large sand sinks for sand derived from adjacent beaches. An attempt to quantify the amount of sand in an outer bar is made with the major governing parameter of inlet hydraulics, tidal prism. In areas of high wave activity there appears to be a well defined limiting relationship to the amount of sand stored in the offshore bar as a function of tidal prism. In areas where inlets are exposed to lower wave activity, more scatter is noted in this correlation.

Relationships for estimating the equilibrium storage volume of sand in the outer bar/shoal of newly cut inlets on highly exposed, moderately exposed, and mildly exposed coasts (where degree of exposure relates to wave action offshore) are proposed for use in estimating quantities of sand which will eventually be lost to adjacent beaches.

A conclusion of the study is that more sand is stored in the outer bar of a low energy coast than in the outer bar of a high energy coast. An upper limit to outer bar storage in low energy zones may be a function of additional parameters other than tidal prism such as longshore energy flux at the inlet site and inlet history.

INTRODUCTION

A commonly recurring problem of importance to coastal engineers is evaluating the number of inlets which a given length of shoreline can maintain in terms of inlet stability, and the degradation which a given inlet will cause to the surrounding shoreline. A considerable amount of research effort has been placed on the hydraulic aspects of inlet design and is discussed in References (1,2,3,4,5, and 6). Little research though has been done on the effects of inlets on adjacent shorelines (7). It is apparent that these effects are considerable when a correlation of shoreline erosion rates and locations of tidal inlets are made. In Florida, shoreline recession rates in the near vicinity of inlets are one to two orders of magnitude higher (10-70 feet per year) than average shoreline recession rates away from the influence of inlets (1-3 feet per year) (8). It is apparent that these inlets act as sand sinks in their capacity to absorb tremendous quantities of sand in both their outer bars and their inner shoal areas. Unfortunately this sand is derived from adjacent beaches and causes a consequential degradation to those beaches. An idea as to the magnitude of the inner shoal volumes of

¹Assistant Professor - Marine Advisory Program - Coastal and Oceanographic Engineering Laboratory

²Graduate Assistant - Coastal and Oceanographic Engineering Laboratory

sand trapped by an inlet is given in Table 1. The data in this Table are calculated from comparative surveys of the inlets over the period of years noted. It appears that the inner shoals of inlet systems may reach an equilibrium shoaling volume (Reference (10)) after a given period of time, therefore decreasing the erosional influence on adjacent shorelines (assuming no dredging of inner shoals takes place).

It seems reasonable to assume at first that such a process might occur on outer shoal/bars of inlets also. If an inlet is to be cut in a barrier island system, it is desirable to have an estimate of this sand volume which will eventually be lost from the surrounding beaches to the outer bar/shoals and to the inner shoals of the inlet. The present paper discusses a correlation between the amount of sand stored in the outer bar of an inlet and the inlet tidal prism or the inlet channel cross section. Assuming one can properly estimate the inlet hydraulics and equilibrium cross-sectional area which an inlet will take, this correlation should allow a coastal engineer to obtain a rough approximation of the final consequences which the opening of an inlet will have on adjacent shorelines.

METHODOLOGY

Calculation of Sand in Outer Bar/Shoals

The procedure followed in calculating the volumes of sand residing in the outer bar/shoals of inlets is covered in depth in Reference (7). A summary of the methodology follows.

The parallel contour lines upcoast and downcoast of an inlet away from the influence of the inlet, were assumed as the natural topography of the coast without the inlet. This idealized "no-inlet" hydrography was then superimposed on a chart of the actual hydrography for the inlet. Depth differences between the actual existing bathymetry and the idealized "no-inlet" bathymetry were then calculated at the intersections of a grid system and averaged for each grid square and summed to give a volume of sand in the outer bar. The procedure for calculation is summarized in Figure 1 from Reference (7). As the procedure is somewhat subjective, the total difference in sand volume between the idealized "no-inlet" shoreline and the existing inlet shoreline was calculated two or more times for each inlet system with acceptable answers showing less than 10% deviation in the bar/shoal sand storage volumes calculated. Volumes of sand in outer bar/shoals of inlets on the lower East Coast of Florida were very hard to estimate in this manner due to complicated offshore reef structures in the nearshore zone and in all but one case were eliminated from further consideration. Volumes of sand stored in the outer bar/shoals of 44 inlets around the sandy portion of the United States coastline were calculated in the above manner and are presented in Table 2.

As an indication of how extensive some inlet outer bar/shoal systems are, Figure 2 shows an inlet outer bar/shoal system for St. Mary's River Entrance. St. Mary's River Entrance on the Florida-Georgia border has shoals extending over five nautical miles offshore (from the updrift coastline). This inlet has one of the largest offshore bar/shoal systems

Table 1. Volumes of Material Deposited in Inlet Bay Shoals

<u>Inlet</u>	<u>Calculated Volume of Shoaled Material in Bay Shoals (cubic yards)</u>	<u>Period of Survey</u>	<u>Inlet History</u>
Redfish Pass, Florida	3.75×10^6 (130,000/year)	1879 - 1956	Inlet opened in hurricane in 1926
Fort Pierce Inlet, Fla.	7.49×10^6 (160,000/year)	1879 - 1930	Inlet opened by man in 1921
St. Lucie Inlet, Fla.	7.46×10^6 (210,000/year)	1882 - 1930	Inlet opened by man in 1892
Sebastian Inlet, Fla.	2.58×10^6 (180,000/year)	1882 - 1938	Inlet opened by man in 1924 - has had a history of natural closure
Clearwater Pass Entr., Fla.	5.09×10^6	to - 1950	Inlet historically open
Carolina Beach Inlet, N.C.	4.00×10^6 (235,000/year)	1952 - 1969	Inlet opened in 1952 Reference (9)

Procedure

1. Construct Idealized No-Inlet Contour Lines
2. Impose 1000 foot square grid system on chart and calculate differences between actual depth and idealized no-inlet depth at grid line intersections (see example block)
3. Average depth differences at intersections and record in center of block (see example block)
4. Compute volume of sand in outer shoal by summing averaged block depth differences and multiply by 10^6 feet²

Figure 1. Steps in Calculation of Accumulated Volume of Sand in the Outer Bar. Procedure Illustrated for Idealized Inlet. From Reference (7).

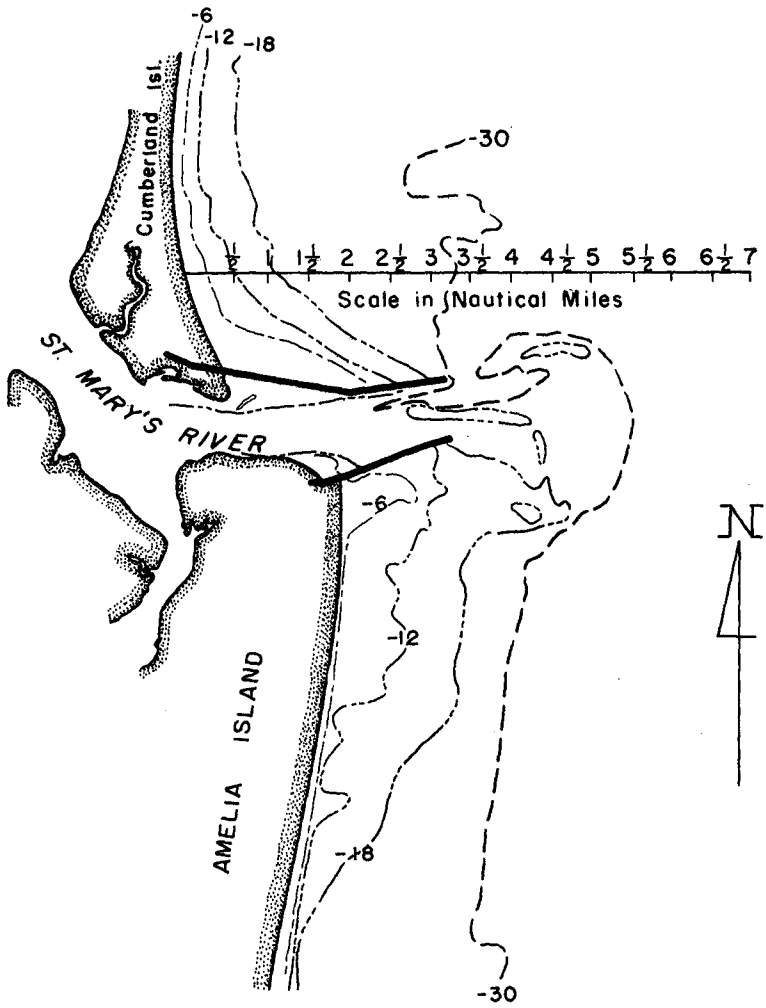

Figure 2. St. Mary's River Entrance.

of inlets investigated in Florida with over 136 million cubic yards of sand stored in it. The heavily developed area to the south of this inlet has historically suffered from erosion.

Tidal Prisms

Tidal prism measurements came from References (11,12,13,14, and 15). In most all of the cases the tidal prisms were either measured from current data taken at the throat of the inlet or by the "cubature method". Jarrett (14) discusses the cubature method in detail. In most all cases the date when the prism was measured corresponded to the survey date from which the estimate of outer bar sand volume was made.

Tidal prisms for the 44 inlets in which sand volumes have been calculated are presented in Table 2.

Channel Cross Section Areas

Channel cross section areas came from References (11,12,13,14, and 15) and from some additional measurements by the authors. In most all cases the cross section used was that at the throat area as defined in Reference (11), and were taken from the same survey as the inlet outer bar. Channel cross sectional areas are presented in Table 2.

Coastal Energy Regime

To suitably classify the data on inlets into some organizational scheme with regard to wave energy acting on the outer shoals of the inlets it was necessary to use some type of coastline parameters which gives a rough quantitative description of the energy potential available to modify the outer shoals of inlets. The parameters chosen were wave height, wave period, and nearshore continental shelf slope. Wave heights and wave periods available were average wave heights from wave gages in the nearshore zone (15 to 20 feet below MLW) from the Coastal Engineering Research Center wave gage program. As these wave heights already have the measure of continental shelf slope implicit in them (energy has been dissipated over the shelf up to the wave gage depth), the basic measure of wave energy used to separate energy environments was the parameter H^2T^2 (wave height² x wave period²). On mildly exposed, moderately exposed, and highly exposed coastlines, this parameter was arbitrarily chosen to range from 0-30, 30-300, >300 respectively. This classification lumps the South Carolina, Texas, and lower Gulf Coast of Florida inlets into the mildly exposed coast range; the East Coast, and Panhandle of Florida (Gulf Coast) inlets into the moderately exposed coast range; and the Pacific Coast coasts into the highly exposed coast range. The (wave energy) parameter H^2T^2 , and the offshore distance to the 5 and 10 fathom depth curves are given for various coastal segments in Table 3.

RESULTS

The data used in the correlations of tidal prisms with outer bar/shoal sand storage volumes are given in Table 2. Correlations were made for three coastal energy level groupings and for all inlets combined using

an equation:

$$V = aP^b \quad (1)$$

where

V = volume of sand stored in the outer bar/shoal of the inlet
(in cubic yards of immersed sand),

P = tidal prism of inlet (in cubic feet),

a, b = correlation coefficients.

Linear regression was used to obtain the coefficient b for the case of highly, moderately, and mildly exposed inlets and for the case of all 44 inlets combined. For these four cases the coefficient b equals:

Highly Exposed Inlets	$b = 1.23$
Moderately Exposed Inlets	$b = 1.08$
Mildly Exposed Inlets	$b = 1.24$
All Inlets	$b = 1.26$

As there was no significant difference in the exponential correlation coefficients, the value $b = 1.23$ corresponding to high energy coast (Highly exposed) inlets was used for the correlations with all inlet groupings. The justification for this somewhat arbitrary fixing of parameters was that a minimum of scatter existed in the correlation of the Pacific Coast Inlets (Figure 3). The minimum scatter in this plot over two orders of magnitude is somewhat surprising in view of the many parameters which should be of importance in inlet outer bar shoaling such as inlet history, available longshore energy flux, and physiography of the inlet-coastal location. The reasons for this minimum scatter in the Pacific Coast inlets studies may be more apparent upon considering the variables causing sand shoaling in outer bars.

The mechanism whereby sand is fed to the outer bar is twofold. Ebb tide flows tend to drive the material offshore which is being fed to the inlet by longshore currents, and wave activity on the outer bar tends to drive the material back to shore while at the same time feeding sand to the inlet in adjacent longshore current systems. The inlet outer bar/shoal is self perpetuating in the sense that longshore currents feed sand to the inlet system which causes the outer bar to grow which in turn causes wave refraction and sheltering effects at the inlet promoting a continued flux of sand toward the inlet over an increasing area (16).

Inlet history is important too. Should the inlet close or the tidal prism be reduced drastically (due to modifications of the inlet inner bay system) much of this material would be driven back to the beaches. The principal author has noted this occurrence in two locations on both the East Coast and Gulf Coast of Florida. In the case of the Pacific Coast inlets studies, all of the inlets have been open over recorded history.

Physiography must play an important part also. The authors have

FIGURE 3. Tidal Prism-Outer Bar Storage Relationship for Highly Exposed Coasts.

FIGURE 4. Tidal Prism-Outer Bar Storage Relationship for Inlets on Sandy Coasts.

FIGURE 5 . Tidal Prism-Outer Bar Storage Relationship for Moderately Exposed Coasts.

FIGURE 6 . Tidal Prism-Outer Bar Storage Relationship for Mildly Exposed Coasts.

noted that inlets which are estuarine (i.e., estuaries), have significantly smaller inner shoals most likely due to the predominance of ebb flow during landward flooding periods. The Pacific Coast inlets used for the highly exposed coast correlation are alike in that they are estuary systems.

Thus, the Pacific Coast inlets are physiographically similar, historically open, and have similar (in a gross sense) longshore energy flux levels; and, therefore, should experience less scatter.

Using the exponential correlation coefficient $b = 1.23$, analysis was made to determine the correlation coefficient a and the corresponding volume - prism relationship for the three groupings of inlets and for the 44 inlets combined. The corresponding equations are shown below:

Highly exposed coasts (7 inlets)	$\Psi = 8.7 \times 10^{-5} P^{1.23}$	(2)
Moderately exposed coasts (18 inlets)	$\Psi = 10.5 \times 10^{-5} P^{1.23}$	(3)
Mildly exposed coasts (16 inlets)	$\Psi = 13.8 \times 10^{-5} P^{1.23}$	(4)
All inlets (44 inlets)	$\Psi = 10.7 \times 10^{-5} P^{1.23}$	(5)

The plots of the prism-outer bar storage volume for the various inlet groupings are given in Figures 3, 4, 5, and 6. Three inlets were not used in any of the inlet groupings although they were used in the "all inlet" correlation. These inlets and the reasons for non-inclusion in the groupings are shown below:

1. Baker's Haulover Inlet - The inlet was created in 1923 with very short jetties which were destroyed in the hurricane of 1926 along with the occurrence of major modifications on the inlet. The inlet was rebuilt in 1928 shortly before the survey data in Table 2 was taken, therefore the outer bar would be expected to be far below any equilibrium value.
2. Clearwater Pass (formerly Little Pass) see below
3. Dunedin Pass (formerly Big Pass) Major modifications have occurred in the Clearwater Harbor area, drastically changing the inlet hydraulics of Clearwater Pass and Dunedin Pass to the North. The outer bars have responded to the tidal prism changes accordingly but may not as yet have reached an equilibrium for the new tidal prisms of the inlets as changes in the sedimentary structure of an inlet lag changes in tidal hydraulics.

As inlet channel cross-sectional area shows a definite correlation with tidal prism (11, 12) and is an easier quantity to measure than tidal prism, a correlation was also made with the available data for bar volume—~~channel cross-sectional area~~ relationships. Correlations were made for the three coastal energy level groupings and for all inlets combined using an equation:

$$\Psi = a'A^{b'} \quad (6)$$

where

V = volume of sand stored in outer bar/shoal (as before),
 A = inlet channel cross-section area at throat (in square feet),
 a', b' = correlation coefficients

Linear regression was again used to obtain the coefficient b' for all cases and is tabulated below:

Highly Exposed Inlets	$b' = 1.28$
Moderately Exposed Inlets	$b' = 1.23$
Mildly Exposed Inlets	$b' = 1.28$

The value $b' = 1.28$ corresponding to the highly exposed and mildly exposed inlets was used for the correlations with all inlet groupings, and analysis was made for the coefficient a' . The corresponding equations for all inlet groupings are shown below:

$$\text{Highly exposed coasts (7 inlets)} \quad V = 33.1A^{1.28} \quad (7)$$

$$\text{Moderately exposed coasts (18 inlets)} \quad V = 40.7A^{1.28} \quad (8)$$

$$\text{Mildly exposed coasts (16 inlets)} \quad V = 45.7A^{1.28} \quad (9)$$

The plots of the cross sectional area-outer bar storage volume for the various groupings are not shown, but prove to have considerably less scatter than the tidal prism - outer bar storage volume plots. Under a given set of conditions either tidal prism measurements or inlet cross-sectional measurements could be considerably unrepresentative of the "equilibrium" conditions, hence, both the volume - prism and volume-cross section relationships should be considered when obtaining an estimate of the sand storage capacity of an outer bar system.

CONCLUSIONS

The volume of sand stored in the outer bar/shoals of inlets shows a strong correlation with the tidal prism, and also, as would be predicted by the pioneering work of O'Brien (11,12), a strong correlation with cross sectional inlet throat area also.

Although a great deal of scatter exists in the data, the trend of increasing outer bar/shoal storage with increasing tidal prism exists over two orders of magnitude as shown by the included inlet data.

A correlation was made of these parameters and it was found that more material was stored in the outer bar/shoals of low (wave) energy coasts than high (wave) energy coasts. This is because there is more available (wave) energy to drive the sand back to shore in high energy environments after being deposited as a shoal.

A number of parameters other than tidal prism (or cross-sectional area) and wave energy also play a large role in sand trapping on outer bar/shoals. Two important parameters which have not been explicitly considered in the present analysis are longshore energy flux which moves the sand to the inlet where the ebb tidal current can deposit it on the outer bar, and size distribution of littoral material which limits the

ability of the material to movement away from the surf zone. Further research is needed to better define how these parameters control the influence of outer bar sand storage.

Further work is also needed on the inner bay or lagoon shoal storage volumes and on the potential of any given inlet to trap sand in its interior shoal system.

CHAPTER 113

INLET CHANGES OF THE EASTFRISIAN ISLANDS

by

Günter Luck

Research Station for

Island- and Coast-Protection,

Norderney, West-Germany

ABSTRACT

The seven sandy islands of the Eastfrisian group would appear to be initially formed and now continually supplied with sand from the Westfrisian group and the mainland to the west. The inlets between these islands are in dynamic equilibrium with the strong tidal currents of the near 2,5 m range in the area. Hydrographic information dating back to 1650 permits the development of a hypothetical model which explains the historic changes and might predict future trends. The installation of coastal defence structures on the eroding western extremities of some islands in the mid 19th century has greatly influenced the bars by which sand is transported from island to island in an easterly direction.

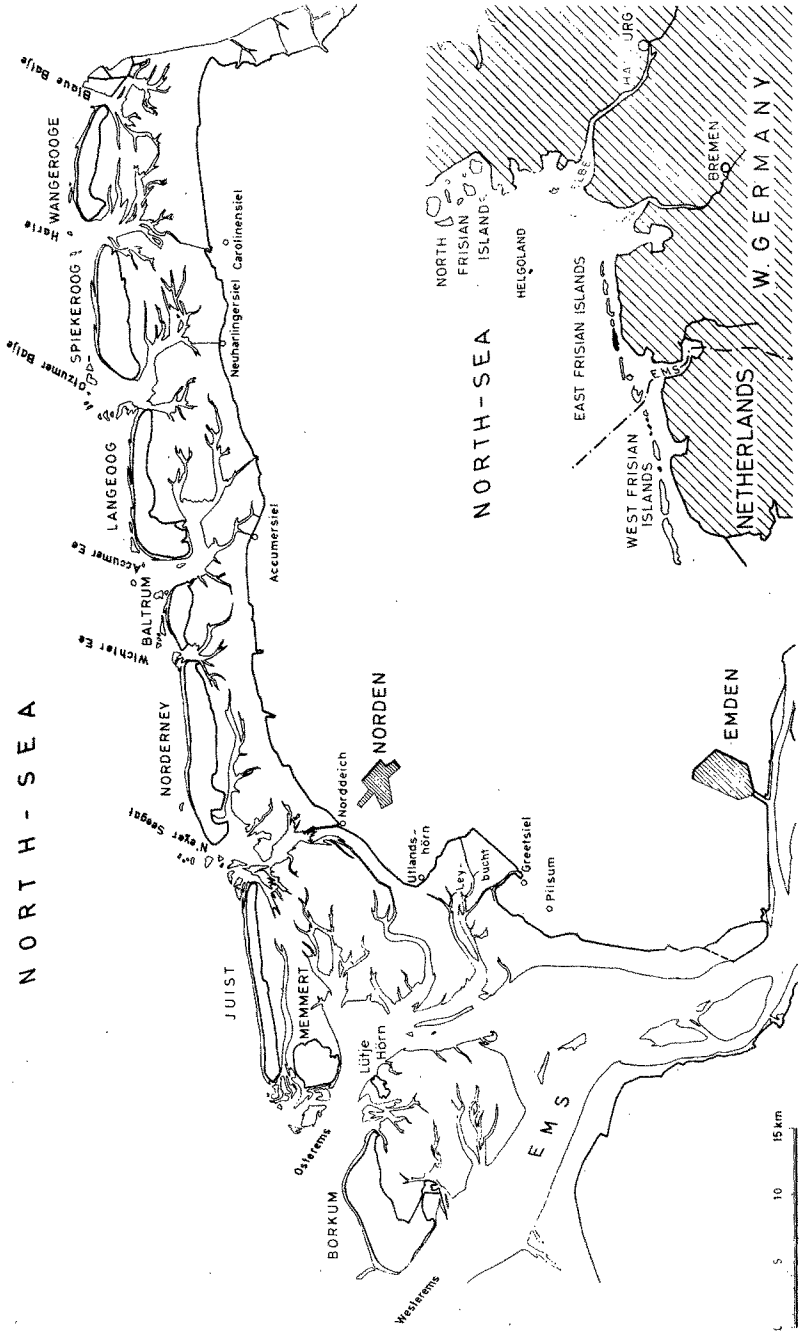

GEOGRAPHY

In front of the southern German North Sea coast between the estuaries of the Jade and Ems Rivers the Eastfrisian Islands are situated; from west to east they are: Borkum, Juist, Norderney, Baltrum, Langeoog, Spiekeroog and Wangerooge (fig. 1). These islands are separated by the tidal inlets Osterems, Norderney inlet, Wichter Ee, Accumer Ee, Otzumer Balje and Harle. Southward, to the coast of the mainland, extend vast tidal flats with sand, silt or mixed soil. The mean tidal range increases from west to east as follows: 2,2 m at Borkum, 2,4 m at Norderney, 2,6 m at Baltrum, 2,7 m at Spiekeroog and 2,9 m at Wangerooge/east.

FORMATION AND AGE OF THE ISLANDS

The islands are completely built of sand and only along their southern borders are more-or-less extensive marsh areas, which have developed by natural siltation. For a long time there have been only very vague notions concerning formation and age of the islands. It was supposed that they were remainders of the former mainland, separated at some stage by storm tides. According to another theory they once belonged to an extended spit of land, which was pierced during a storm tide at several points. However, by the aid of rationalizations, facts and latest findings of the morphological/hydrological processes in the Eastfrisian tidal flats it can be shown, that the islands were formed by the coincidence of current, surf and wind (LÜDERS, 1953).

Fig. 1: EAST FRISIAN ISLANDS

The west to east directed flood current, which is stronger than the ebb current, shifts the sands necessary for the formation of the islands from the Belgian/Dutch coastal area.

Even today the origin of the sands has not been definitely resolved. Mineral explorations prove some sediments are from the big rivers, but also there is erosion material from the British cliffs. More distant sands of the bottom of the North Sea are traceable. These sediments, transported by the tidal currents, are formed into longshore bars by wind and waves and finally the surface is elevated above the high-water-level and is stabilized by vegetation. The influence of plants on the blown sand is to increase the height of the bars until they become dune islands. The constant supply of new sea sands provides the nutrients necessary for a strong and healthy vegetation.

The distance between the mainland and the islands is determined by the tidal range. At little or no tidal range the longshore bars and finally the dune islands are formed closer to the coast.

So far it is not possible to determine the exact age of the islands. However, there are references from Greek sailors which permit the hypothesis, that the islands already existed in 300 B.C. As the Atlantic transgression, which led to the formation of the North Sea, commenced about 10.000 B.C. and was interrupted by several phases

of regression, a geological determination of the age of the shifting sands cannot be performed and therefore a definite estimate of the age of the islands is not possible.

As the sands are powerless against the forces of current, surf and wind, the islands in the past underwent frequent changes of shape, with long-term developments being overshadowed by short-term events. The tidal flats, tidal inlets and islands are in a state of dynamic equilibrium (WALTHER, 1971) and therefore the changes in the islands and tidal inlets affect also the tidal flats. Only by the construction of the protection works on the islands in the middle of the last century was this process interrupted.

ANCIENT REPORTS

The coast and the adjoining tidal flats were first described by the Roman geographers PLINIUS and STRABO at about the birth of Christ. But the first time the islands were named was in 1398. However, the document did not give further details. Since the 16th century the islands are mentioned more frequently in nautical manuals, and recorded in coastal views for navigation purposes. The first comprehensive descriptions of the islands date from the years 1650 and 1657 (cited in THILO, 1953). For the first time the height and location of the dunes were related to sea level. Narrow beach sections and dune erosion were fully described and measurements were recorded. Following upon these

observations inquiries were made as to whether the natural sand supply was sufficient or if there was a necessity to protect beach and dunes by artificial means.

These reports are valuable since. With their aid, supplemented by other ancient reports, it is possible to record the island contours relatively well. They provide also the basis for the Historical Map 1 : 50.000 of the Research Station for Island- and Coast-Protection, Norderney (HOMETIER, LUCK, 1969).

The most remarkable phenomenon of the long-term development of the islands, traceable since about 1650, is the fact that at their western ends they underwent a considerable loss of beach and dunes, whilst they built up in the east. This phenomenon, being interrupted by the construction of the protection works, often has been called the "west-east-migration" of the Eastfrisian Islands. The west to east directed "migration" results from the preponderantly eastward directed forces of wind, tide and surf current. With the aid of numerous investigations in the area of the Eastfrisian Islands the mechanism of this west-east-shift could be interpreted.

THE MAP OF GUITET OF 1708

The first map recording the area of the Eastfrisian Islands well enough to be interpreted was drawn by the Dutch Admiral Mathurin GUITET in 1708 (fig. 2). The then existing contours of tidal flat, islands and tidal inlets are preserved in

Fig. 2: Wad en buyten-kaart, M. GUITET, Amsterdam 1708/10

Fig. 3: Eastfrisian coast and islands, A. PAPEN, 1843

this map. However, the length of the islands, width of the tidal inlets etc. cannot be measured due to the map's lack of accuracy in scale. For the coastal research the most remarkable phenomenon at that time was the division of the tidal inlets between the islands into two deep narrow channels, which were separated by middle-sands. The first map of accurate scale from the year 1860 (fig. 3), however, shows tidal inlets with only one deep narrow channel. Consequently in most tidal inlets there must have been an alteration from double to single channel profile.

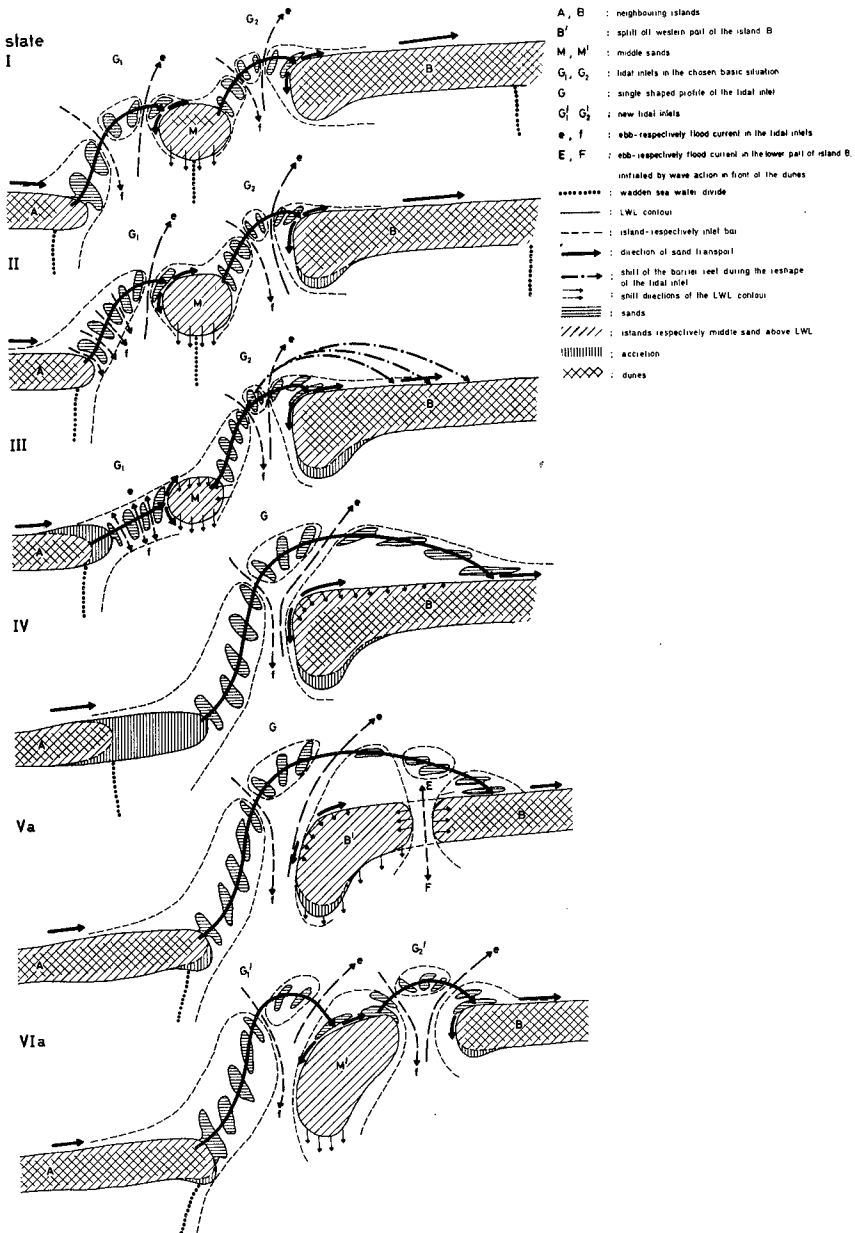

The map of GUITET shows the remains of the once large island Buise, which obviously extended into the present offshore area north of Juist Island. The final phase of the disappearance of this island is recorded relatively well in contemporary maps, discussions, sailing-instructions etc. (LANG, 1955). The well substantiated events in the Norderney inlet, the reduction of the island Buise to a middle-sand and it's final merging at the eastern end of Juist Island, plus the change of the tidal inlet from a double to a single channel profile, made it possible to rationalize these processes on the basis of the findings of modern hydrodynamics. Though the existing information for the other inlets is less comprehensive it is sufficient to prove the applicability of these basic findings.

MODIFICATION OF THE TIDAL INLETS

Though the events in the tidal inlets did not all proceed at the same time, the modifying processes are uniform and can be reproduced in hypothetical models. These explanations can be divided into separate successive stages (fig. 4):

Stage I: The middle-sand M between the islands A and B lies above high-water-level and is being shifted to the south. This southward displacement of M is substantiated by contemporary reports. The tidal inlets G_1 and G_2 , which seem to have been hydraulically equal, are located on both sides of the middle-sand. Each one, G_1 and G_2 , has it's own intake area separated by the topographical water-divide of the middle-sand M. Northward of the tidal inlets are sands, the spatial order of which evoke the optical impression of a bow, for which reason they are called "sand-reef-bow" or simply "reef-bow". The west-east sand transport within the region of the tidal inlets takes place within these reef-bows. Since their widths correlate more-or-less to the dimensions of the adjoining Wadden-Sea intake areas (WALTHER, 1934) (i.e. small intake area = small reef-bow and visa versa) these reef-bows are relatively flat and reach from A to M and from there to B. As M is small and the sand, coming from A, does not find enough room to spread or build dunes, these sand-supplies do not take hold and M undergoes a loss of material. The

Fig. 4: model of longterm reshape of a tidal inlet
(without scale)

north-western end of B, however, is well provided with sand and correspondingly resistant to erosion.

Stage II: Due to the continuing southern movement of M and the east-directed growth of A the reef-bow of G_1 shortens. As the total sand-supply remains constant over a longer period of time the shoals are moved closer together and consequently the water-exchange in G_1 is reduced. These processes are complementary. Although the water-exchange is now increased in G_2 , due to the reduction in G_1 , the arc of the reef-bow is still unchanged and the northwestern end of the island B is still well supplied with sand. At the same time the topographical water-divide of M, still effective in Stage I, is gradually reverted and the formerly two separate catchment areas gradually become one.

Stage III: The processes of Stage II continue and M has now become part of the reef-bow of G_1 . As the entire intake area between the water-divides of the islands A and B remains constant, changing only minimally over a long period of time, the water-exchange shifts increasingly to G_2 . Thus the reef-bow of G_2 is displaced further north and the attachment area of the sands on B is shifted eastward. This produces a sand deficiency on the western end of island B.

Stage IV: The development of the tidal inlet from a double to a single channel profile has been completed. The reef-bow of G has found it's new shape and in the west of island B, which is no longer receiving natural sand-supply, the dunes begin to recede under the influence of the surf. On Norderney Island for instance this state was reached around 1800.

With the Eastfrisian Islands the natural development has not gone beyond Stage IV. The beach and dune erosion, which occurs after termination of Stage IV, was prevented by seawalls and groynes. An uninterrupted development would have allowed the inlets to further change their shape as described in Stage V and Stage VI. In one case, namely on Wangerooge Island, this process has already begun with the formation of a new deep channel (FÜHRBÖTER, LUCK, LÜDERS, 1973).

Stage V: The dunes of island B are eroded by surf and wind; they recede up to the area of sufficient sand-supply (attachment area) and there remains only a beach B'. At elevated high-water-levels the surf erodes a channel close to the dune base, which gradually becomes deep enough to overflow even at normal tides. With this the preconditions for the formation of a new tidal inlet are fulfilled. On Wangerooge Island, the eastern most Eastfrisian Island, such a development started about 1900. The final development of a new channel was

prevented by the construction of a long and heavy groyne (LÜDERS, 1952).

Stage VI: The channel in front of the dune base of island B has developed into a new tidal inlet. The duneless west-beach of the island B is cut off and has become a new middle-sand M'. By this stage a configuration has been reached, which approximates that of Stage I.

The developments, described in this hypothetical model, apply to the islands Juist to Wangerooge. Borkum Island, due to its location in the Ems estuary, is influenced by other parameters, which do not allow a transfer of the concepts to the Ems and Easter-Ems inlets.

The investigations, involving developments since 1650, prove that the transitions of the tidal inlets tend to proceed in cycles from double to single channel profile and back to the double version. An unrestricted extrapolation of these phenomena into the future, however, is not possible without consideration of the secular water rise. Over a longer period of time the secular water rise effected a southward shift of the islands, which will continue. At the moment the possibilities are being studied for including the secular water rise into the present models.

DEVELOPMENT OF LENGTH AND WIDTH OF THE ISLANDS
AND TIDAL INLETS

Since 1650 the total length of the island chain from Juist to Wangerooge remained constant at about 68 to 69 km, provided that the beach accretions of Juist/west and Wangerooge/east (about 3,5 km) are deducted. However, within the row of islands changes on a large scale took place (see Table I).

Table I: Development of the tidal inlets and islands
between the MHW-lines [m]

Year	1650	1750	1860	1960

Harle Inlet	5800	5670	4810	2000
Wangerooge Island	7300	7400	7950	8320
Total	69200	70180	71750	72680

All tidal inlets narrowed and the islands, except Baltrum Island, became longer. The shortening of Baltrum Island of about 3 km since 1650 was effected by a simultaneous strong eastward growth of Norderney Island. This development was prevented by the construction of protection works on Baltrum Island, which stopped a further transformation of the tidal inlet Wichter Ee and with this the on-going eastward growth of Norderney Island. Without it's strong protection works Baltrum Island finally would have been completely destroyed, similar to Buise Island, and the last remains would have merged into the eastern end of Norderney Island.

Figures 5 and 6 also illustrate the relations between the transformation process in the row of islands and the events in the tidal inlets. Figure 5 shows the curves of the total length of the islands (without tidal inlets) between the low and high water lines, of the dunes, of the total surface and of the total circumference.

Altogether a growth of the islands can be recognized.

Of special interest are the curves of the lengths, which increase slowly in the beginning and then quickly after 1750. At first the construction of the protection works 1860 through 1870 had little effect on the lengths between the high water lines, because the protection works in the beginning were only effective within the reach of the dunes. Therefore at first the MHW lines

F_I : Total surface above MHW
 L_H : Total length between the MHW-lines
 L_N : Total length between the MLW-lines
 U : Total extent
 L_D : Total length of dunes

Fig. 5: Development of the row of islands

Fig. 6: Development of the width of the tidal inlets km
 B_H : Total width between the MHW-lines; B_N : Total width between the MLW-lines;
 B_S : Width of the beach between MHW and MLW

had still space to shift backward. The curve of the lengths between the MLW lines, however, falls significantly after the construction of the protection works. These reductions in length occurred at the western ends of Juist Island and Wangerooge Island, the latter being displaced southward since the storm tides of 1854/55.

The curves of the total widths of the tidal inlets (fig. 6) show a complementary development. The more the total lengths of the islands increased, the more the tidal inlets became narrow. Here in the beginning the construction of the protection works had no influence on the curve either, as the MHW and the MLW lines first still had enough space to shift. The rise of the MLW curve after 1860 has to be referred to the southward displacement of the duneless westbeach of Wangerooge Island, which has already been mentioned. The seawalls and groynes, constructed after 1874, served as immediate dune protection and left the large westbeach to the forces of waves and current (LÜDERS, WILLECKE, 1951).

CONCLUSIONS

Under natural conditions (i.e. without protective works) the Eastfrisian Islands tend to shift eastward. On the basis of well substantiated long-term events in the Norderney inlet this tendency could be traced back to

morphological events in the tidal inlets and systemized in a hypothetical model. The application of the concepts, gained for the Norderney inlet, to the tidal inlets between Juist Island and Wangerooge Island can be proved by means of old maps, descriptions etc. as well as by consistent reasoning, facts and findings of modern hydrodynamics.

The ancient "west-east-migration" or shift of the Eastfrisian Islands has been effected by the active processes in the tidal inlets, followed passively by the islands. The seawalls and groynes have produced a static condition, which if not present would have been temporary in nature.

CHAPTER 114

BARRIER ISLAND DYNAMICS: OVERWASH PROCESSES AND EOLIAN TRANSPORT

Stephen P. Leatherman¹

Abstract

The northern 5 miles of shoreline at Assateague Island, Maryland are presently being eroded. During storms, swash surges are able to overtop the most landward (storm) berm as overwash with deposition occurring on the barren flats. Where primary barrier dunes still exist, sediment-charged surges are funneled through breaches in the dune field for deposition of the entrained material on the washover fan.

Sediment budget computations show that there has been a small net loss of material at each washover area, in spite of 7 discrete overwash events during a 26 month time interval. The predominant north-west winds effectively eroded the overwash material, transporting the majority of the sand back to the beach. This analysis indicates that there exists a balance between overwash and eolian processes with wind transport being slightly dominant.

Introduction

The impetus that spurred this research was the sharp debate among coastal investigators concerning the importance of overwash in terms of the sediment budget of a barrier island. Dolan (1972) maintained that construction of large barrier dunes in the 1930's along the Outer Banks of North Carolina has had a significant adverse impact on this shoreline's stability. By preventing overwash, material that would have been deposited on the backdune area will either be lost offshore or carried alongshore. The viewpoint of the Corps of Engineers (Shore Protection Manual, 1974) is that island maintenance by overwash is probably only significant within the context of a geologic time frame. The mechanics of barrier island migration by the overwash process have not been previously established by quantitative studies.

Assistant Professor, Department of Geology, Boston University,
Boston, Massachusetts 02215

This investigation was designed to address the question of the short-term sedimentary dynamics of a washover area on Assateague Island.

The concept of a sediment budget was adopted to monitor the amount of sediment transport. The sediment budget is defined for the control volume which includes the washover fan/flats and adjacent barrier dunes, vegetated barrier flats and marsh. The beach is excluded from the control volume since only net changes can be recorded, not the actual quantities and directions of sediment removal, transportation and deposition. Sediment budget calculations should permit determination of the relative importance of overwash as a process shaping the barrier island.

During the past 26 months (February 1973 - April 1975) of continuous study, 7 discrete overwash events were monitored at Assateague Island, Maryland. Field surveying prior to and after an overwash enabled calculation of the total subaerial sediment transport along selected sections of the island. Monthly surveys allowed for the detection of subsequent post-storm reworking and transport of sand on the backdune zone.

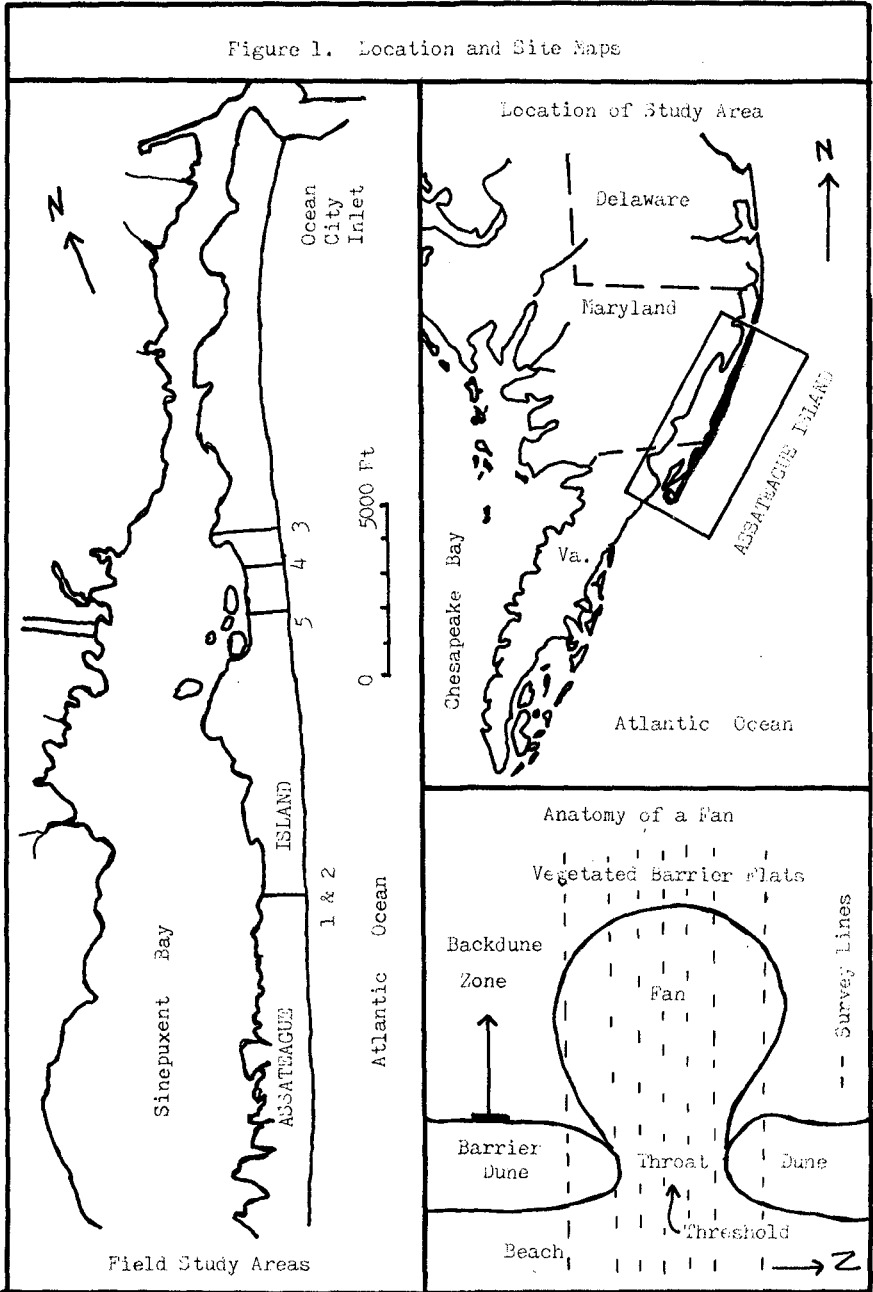

A single washover fan (Site 1) was selected for the initiation of this study (Fig. 1). The dunes are eroded during major storms, and gaps between the dunes force overwash sediments into discrete units enabling study of individual deposits. Site 2 was established in the fan adjacent to that of Site 1 for volumetric comparison on an annual basis. For the final year of field work, 3 additional sites were chosen based on their position along the island and on their physiographic features. Sites 3 and 4 are located in a region of broad washover flats where barrier dunes no longer exist. Site 5 is similar to the primary site (Site 1), except that the dimensions of the fan are much larger.

Previous Research

Overwash has been reported to be a significant process along the Gulf and East Coasts of North America, but little quantitative data is available on its transport potential. In fact, there is a scarcity of data correlating "storm intensity" to the expected amount of shoreline erosion. This type of data has direct application to engineering considerations, but it is difficult to obtain due to the unpredictability of occurrence and magnitude of coastal storms.

Caldwell (1959) compiled data concerning the amount of beach erosion for various storms along the New Jersey shoreline. Everts (1973) and Everts *et al.* (1974) also used surveying programs to determine the amount of erosion associated with single storms for New Jersey and New York beaches. These data sets, along with original field data on beach erosion and overwash deposition from the North Carolina coast, have been summarized by Schwartz (1975).

Figure 1. Location and Site Maps

Overwash Sediment Transport

Storm parameters and overwash deposition for each event monitored by this investigator as well as Schwartz's (1975) data are given in Table 1. Relative measures of storm surges at Assateague Island were obtained by subtracting the predicted tide (U.S. Dept. of Commerce, NOAA Tide Tables) from the recorded tide (NOAA-NOS) for the Indian River Inlet (Bridge) tide gage, located approximately 20 miles north of Ocean City, Md. Significant deep water wave hindcasts were based on the Bretschneider technique. Surf observations of breaker height and wave period were obtained from the CERC Beach Evaluation Program.

The amount of sediment transport for the first two storms re-recorded during this study were reported by Fisher, Leatherman and Perry (1974), and these results will not be reviewed. The March and November 1974 northeasters were sedimentologically insignificant. Field observations for both storms showed that overwash surges represented only a small portion of the total swash, as only the leading edge of water was able to traverse the beach face. The April 1975 northeaster also represented a threshold occurrence. Since none of these storms resulted in any appreciable amount of beach erosion or overwash, no further discussion is warranted.

The December 1, 1974 northeaster was the largest storm to attack these shores during the survey interval, and data is available for all survey sites along the island. Figure 2 shows the transect across Site 1 washover fan from the beach to the barrier flats. The fan gained 217 ft^3 of sediment per foot while the first 60 feet of beach seaward of the dune line was eroded 110 ft^3 per foot for a net gain of $107 \text{ ft}^3/\text{ft}$. The sand plug level indicated that erosion by the overwash surges was confined to the seaward-most (throat) portion of the fan. The total volume of material transported into this single fan was $9,840 \text{ ft}^3$ which corresponded to an effective transport of 221 ft^3 per foot of throat width.

Sites 3, 4 and 5 were also surveyed so that the amount of beach erosion and overwash deposition along these transverse slices of the island would be available for comparison. At Site 3, the lower beach was apparently not eroded by the December northeaster while the storm berm on the backshore was carved away (Fig. 3). The quantity of sand eroded from the storm berm approximately equaled the amount of overwash, except for a small total line loss of $-29 \text{ ft}^3/\text{ft}$. The overwash penetration distance was 800 feet, equal to one-half of the island's width at this location, but only $91 \text{ ft}^3/\text{ft}$ of material was deposited on the flats as overwash.

Site 4, the other line extending across the broad, nonvegetated washover flats, experienced a totally different pattern of sediment redistribution (Fig. 4). The upper beach profile migrated over 80 feet landward with a loss of $64 \text{ ft}^3/\text{ft}$ for the 80 feet of beach surveyed. The major lens of sedimentation occurred from 200 feet to 600 feet landward of the beach for 153 ft^3 of overwash deposition per

foot of beach. Absence of material seaward of this zone of accumulation must be related to the hydraulics of the overwash surges. The overwash surges carried sediment to within 220 feet of the bay where it was deposited as delta foreset beds. Calculations indicate a net gain of sediment across the profile line ($89 \text{ ft}^3/\text{ft}$), but only 80 feet of beach was included in the survey.

The final survey site (Site 5) experienced the greatest amount of deposition. Approximately $300 \text{ ft}^3/\text{ft}$ of new material was deposited along this line as overwash (Fig. 5). As in the previous cases, only the upper backshore of the beach could be surveyed due to high water so that the total amount of beach erosion could not be ascertained. The deposit abruptly terminated at a distance of 250 feet from the bay. The dunes were severely scaped and eroded, but volumetric determinations were not possible at this site.

During the March 1975 northeaster, an electromagnetic current meter was successfully used to measure the overwash surge velocities during the storm event. The mean of the maximum instantaneous velocities was $5.2 \text{ ft}/\text{sec}$ at 1.5 inches off the bottom, while the flow depths averaged 6 inches. During the 4 hour and 40 minute time period bracketing high tide, 121 overwash surges were recorded by the magnetic tape data logger. A comparison of profiles taken hours before the storm and on the following day showed that an average of 29 ft^3 of overwash material was deposited per foot of breach. There was actually a small amount of beach accretion ($9 \text{ ft}^3/\text{ft}$), indicating a net onshore movement of bottom sediment. The barrier dunes were not eroded since the storm tide was quite low (Table 1).

Sediment Budget

Sediment budget calculations indicated the net changes for the washover areas. Overwash was the only significant mechanism of sediment transport to the backdune zone as documented by monthly surveys. Eolian processes were largely ineffective in westward transport, but the strong winter northwest winds resulted in severe deflation of the washover fan/flats between storms.

The net 2 year change at Site 1 has been erosion (Table 2). Survey lines that experienced greatest erosion were the least vegetated along their lengths. Figure 6 shows the net 26 month change along the centerline at this site. The fan elevation has been lowered several feet while the vegetation contact, which appears as a bulge in the survey line, has actually moved seaward during this time interval. The total change for the washover fan and adjacent environs at Site 1 has been a small net loss of material from the fan surface. Slightly over 1000 ft^3 of sand has been lost from the area bounded by the survey grid, not including seaside dune and beach erosion.

The trend for the adjacent washover fan (Site 2) was weighted heavily toward erosion for a net loss of $6,000 \text{ ft}^3$ during this time interval. This fan, however, was sparsely vegetated with an active

Figure 6. Site 1, Centerline, Net 26 Month Change

blowout on the north dune which flanked the fan. In the absence of any stabilizing agent, the newly-deposited overwash sand was very susceptible to reworking by the predominant northwest winds, resulting in loss of material from the fan surface.

Sites 3, 4 and 5 had similar response patterns during the 1974-75 storm season. In each case there was a zone of eolian action where wind was able to strip away large quantities of sand as shown at Site 4 (Fig. 7) and Table 2. Below an elevation of 4.7 feet, there has been net accretion on all three lines. Sand deposited below this critical elevation will not be reworked. Field observations indicated that this elevation coincided with watertable or semi-saturated conditions.

Discussion

A limiting criterion for the generation of an overwash event can be related to a significant wave hindcast by the Bretschneider method. Deep water waves with heights of 10 to 11 feet represent the minimum conditions necessary for overwash. This condition is generally satisfied by a small northeaster, which generates 24 knot winds for 20 hours or more. For larger events, the deep water wave hindcast is certainly an important index in terms of assessing a storm's impact on the shoreline, but is perhaps not the most important factor.

For this discussion of storm size versus amount of overwash, refer to Table 1. Data for the February 9-11, 1973 northeaster at Cape Hatteras is from Schwartz (1975), and this storm was hindcasted by this investigator for comparative purposes. Unfortunately, other storm parameters, such as amount of surge, are now known. Examination of Table 1 reveals that there is not a clearly definable correlation between storm size, as given by deep water wave height, and amount of deposition. A far more important parameter may be storm surge, in-as-much as the December 1, 1974 northeaster resulted in the largest amount of deposition per breach width, but had the third highest hindcasted deep water wave height. This analysis does not argue against waves as a controlling parameter for overwash but asserts that storm surge may be more important. Large waves and high surge are somewhat coupled systems since both are dependent on some of the same meteorological parameters. Based on this data set, it is suggested that storm surge is the single most important factor in determining the magnitude of an overwash. Since only certain size waves are allowed to reach the shore based on breaking criterion, it is the height of the storm tide that allows the dunes to be directly attacked by storm waves and swash surges to overtop the barrier threshold as overwash.

In attempting to determine if there is a differential amount of sedimentation along the island, only the December 1, 1974 overwash data is available for all survey sites. Sites 3, 4 and 5 showed the greatest amount of variance in deposition (Table 2), but are all con-

Figure 7. Site 4, Net 1 Year Change

tained within a one-half mile stretch of coast. This differential amount of sedimentation may be linked to local constraints, such as sand availability.

As previously mentioned, overwash deposition at Site 3 almost perfectly matched the amount of storm berm lost plus a small amount of beach erosion. At Site 4, there has been a much greater amount of overwash deposition, and, as reflected by before and after profiles (Fig. 4), probably a greater amount of beach erosion. The length of beach surveyed (80 ft in this case) was a severe limitation in exactly defining this relationship. At Site 5, there was 300 ft³/ft of overwash deposition, which is over three and almost two times greater than that recorded at Sites 3 and 4, respectively. The corresponding amount of beach erosion at Site 5 was quite small in comparison to the large amount of deposition. It should be noted that Site 5 washover fan is bounded by large dunes on each side of the throat which may act as a source of sand. Post-storm field inspection indicated a large amount of seaside dune face erosion associated with its scarping and landward retreat. This analysis indicates that the chief source of material for the overwash surges is the beach backshore and dunes.

A rough calculation of the amount of overwash as compared to beach and dune erosion can be made by using the December 1974 data set at Site 1. The average amount of beach erosion for the first 60 feet seaward of the dune line was 118 ft³/ft. Dune erosion rates were quite variable as recorded by the north and south dune profile lines, so an average value of 52 ft³/ft was used for calculation purposes. The third dimension of the control volume can be defined as half the shoreline distance between fans on each side of the fan monitored. For Site 1 this distance corresponded to 145 feet of dune and 187 feet of beach length as source area or a total of 29,600 ft³ available for net displacement. Total volume calculations for Site 1 showed that 9,300 ft³ of material was effectively transported across the threshold which represented 31 percent of that available in this specified zone of change. The majority of sand removed from this zone was probably transported a short distance offshore to become incorporated into the large storm bar. Undefined amounts of sand are permanently lost offshore, and an imbalance in the longshore transport at any particular point along the shoreline necessitates net erosion or accretion of material.

Conclusions

In spite of contributions from 7 discrete overwash events, there has actually been a small net loss of material from the fan/flats. Sand transport by wind was seen to be of the same order of magnitude as hydraulic transport by overwash. This analysis indicated that there is a balance between overwash and eolian processes with wind transport being slightly dominant. As a result of these two processes, there is a tendency for sediments from different environments of deposition to become homogenized. Since the backshore beach, dune

and overwash sand are almost of the same mean grain size (1.70 ϕ) and standard deviation (0.30 ϕ), there is only a small loss of material associated with their transport and redeposition. Sand from each area can act equally as a source for the other. This interpretation agrees with the long-held concept that dunes serve as sources of sediment (to the beach) in times of need (during storms).

The above indicates that non-vegetated washover fan/flats serve merely as temporary reservoirs for the eventual redistribution of the sand. Wind reworks the deposit with the bulk of the sand being blown back onto the beach face. The result of this sediment exchange process is dune erosion due to seaside scarping, no change on the fan, flats and marsh, and a stable or eroding beach consistent with upstream littoral drift conditions.

CHAPTER 115

PROCESS AND MORPHOLOGY CHARACTERISTICS OF TWO BARRIER BEACHES IN THE MAGDALEN ISLANDS, GULF OF ST. LAWRENCE, CANADA

by

E. H. Owens

Coastal Studies Institute, Louisiana State University,
Baton Rouge, Louisiana 70803

ABSTRACT

Detailed field investigations of barrier beach morphology and processes at adjacent sites in the Magdalen Islands, Gulf of St. Lawrence, show that the two beaches are in distinctly different morphodynamic environments. The differences are expressed in terms of wave energy levels, sediment dispersal patterns, and nearshore, littoral, and dune geomorphology. The exposed west-facing coast has a steeper offshore gradient, is a zone of sediment bypassing, and has a complex sequence of three nearshore bars. Wave energy levels are lower on the sheltered east coast, and this is a zone of sediment redistribution and deposition with a single, linear nearshore bar. The different morphological characteristics of the two barriers are attributed to the spatial variation in energy levels and to the differences in offshore gradients on the two coasts. Computed wave energy values, derived from data monitored during two study periods (August and November, 1974), indicate that the mean wave energy levels were greater on the west coast as compared to the east coast by factors of 2.25 in summer and 2.95 in winter. This is due primarily to the dominance of winds out of the westerly quadrant throughout the year.

INTRODUCTION

The Magdalen Islands consist of a series of barrier beaches that are oriented northeast-southwest to connect small bedrock outcrops on the shallow central shelf of the southern Gulf of St. Lawrence (Owens, 1975) (Figure 1). This is a microtidal environment (mean tidal range less than 1.0 m) and, as the Gulf is an enclosed sea, the wave climate is dominated by locally-generated wind waves. Winds are dominantly from between southwest and northwest throughout the year, with a higher frequency of storm winds in winter months (Table 1). Limiting factors for wave action on the beach are maximum fetch distances on the order of 300 km and the presence of sea or beach-fast ice for periods up to four months each winter. Littoral processes are dominated by wind waves associated with the west to east passage of low-pressure systems across Atlantic Canada (Table 2). On the west coast of the Magdalen Islands the shoreline is exposed to the dominant and prevailing winds out of the northwest. Maximum wave and breaker height values on the west beach occur at times of maximum wind velocities, independent of wind direction. On the east-facing coast wave characteristics are closely associated with the onshore wind component (Owens, 1977).

	>90 km/h	Duration >3 hours	Duration >6 hours	>115 km/h	Duration >3 hours
NW-NNE	6.4/yr	1.7/yr	0.9/yr	2 in 5 yr	1 in 13 yr
NE-ESE	1.5/yr	1 in 3 yr	1 in 13 yr	--	--
SE-SSW	3.1/yr	2 in 5 yr	1 in 8 yr	1 in 20 yr	--
SW-WNW	3.0/yr	2 in 5 yr	1 in 4 yr	1 in 5 yr	1 in 40 yr

Mean and maximum wave height values are greater on the west coast in all seasons due to the prevailing onshore winds. A distinct difference in wave energy levels exists between the two study sites (Figure 2). Comparison of computed wave energy values (Table 3), derived from time-series data monitored during two study periods (August and November, 1974), shows that the mean values are greater on the west coast by factors of 2.25 and 2.95 for the summer and winter phases of the study. The same comparison for the computed longshore sediment transport rates (Table 4) shows that the combined hourly rates are greater on the west coast by 2.7 and 2.0 for the summer and winter study periods. The estimated annual gross volume of longshore sediment transport is approximately four times greater on the west-facing barrier.

Figure 2. Seasonal variations in (1) estimated wave energy on the east and west barriers, (2) mean monthly wind velocity, and (3) storm frequency. The period of sea-ice cover or beach-fast ice is indicated by the shaded area. Wave energy values are extrapolated. Storm frequency (*) is the number of periods in each month when wind velocities exceed 55 km/h, based on data over a 40-year period.

Table 3. Computed Wave Energy Values (ergs/cm)

		Mean	Minimum	Maximum
Summer	West	2.52×10^{11}	2.12×10^9	1.65×10^{13}
	East	1.12×10^{11}	2.12×10^9	1.10×10^{13}
Winter	West	2.51×10^{12}	1.68×10^{11}	7.38×10^{13}
	East	8.51×10^{11}	3.04×10^{10}	5.89×10^{13}

Table 4. Summary of Computed Longshore Sediment Transport Rates

		West Coast	East Coast
Average Hourly Rate (m^3/h)	Summer	149 to N	53 to N
		95 to S	39 to S
	Winter	631 to N	265 to N
		519 to S	315 to S
Net Daily Rate (m^3/day)	Summer	428 to N	201 to N
	Winter	1,261 to N	962 to S
Estimated Annual (m^3/yr)	Gross	2,059,030	550,943
	Net	233,931 to N	104,112 to S

Owens (1977) has shown that in addition to this spatial variation there is also a distinct temporal variation in energy levels between the two sites that is reflected in littoral zone morphology. On the west coast there is a seasonal variation in wave energy levels that produces a "summer-winter" beach cycle. On the sheltered east coast variations in energy levels due to the passage of low-pressure systems across the region are more important than the seasonal variations. This produces beach cycles of erosion during storms and deposition during the post-storm recovery period (Table 5).

Table 5. Characteristic Differences between the Coastal Environments of the East and West Barriers—Magdalen Islands

	West	East

	b. Marked seasonal variation in wave energy levels	b. Large short-term variations due to storm-wave activity
Littoral zone morphology	a. "Summer-winter" beach cycle	a. Storm/post-storm beach cycle
	b. Relatively stable morphology in plan and profile	b. Large short-term variations in morphology
Offshore Slope	0°10'	0°05'
Nearshore Slope	0°33'	0°53'

OFFSHORE ZONE

On the shallow shelf adjacent to the west coast of the Magdalen Islands, sediment is being transported landward by present-day processes (Owens, 1975). This is an area of coarse and medium sands (Table 6) and is a non-depositional sedimentary environment, with local reworking and the formation of lag deposits (Loring and Nota, 1973). Sediment that is transported toward the Islands is moved rapidly alongshore in shallow water toward and around the extremities of the barriers. The shelf adjacent to the east coast is sheltered from waves out of the west and is a depositional area of fine-grained sediments (Table 7) (Loring and Nota, 1973).

The nature of the sedimentary environments on the Magdalen Shelf is controlled in part by differences in the wave climate to the west and to the east of the islands that result from the dominance of wind-generated waves out of the west. In the zone of sediment reworking and transportation on the shelf to the west of the Islands the sandstone bedrock is overlain by a thin, discontinuous layer of sand and gravel. In the depositional area to the east of the Islands the bedrock is buried by a continuous cover of well-sorted

Table 6. Sedimentary Environments--Magdalen Islands

	West	East
Offshore	Coarse/medium sands	Fine sands
Nearshore (<5 m)	Medium sand (1.31 ϕ)	Medium sand (1.81 ϕ)
Beach	Medium sand (1.67 ϕ)	Medium sand (1.87 ϕ)
Dunes	Medium sand (1.67 ϕ)	Medium/fine sand (1.95 ϕ)

Table 7. Energy-Morphology Characteristics--Magdalen Islands

		West	East
Sediment dispersal	Offshore	Toward east	Zone of deposition
	Nearshore	Rapid longshore movement	Zone at redistribution and deposition
Subaqueous profile		Relatively steep (1:300)	Relatively flat (1:625)
Frictional attenuation of waves		Low	High
Amount of energy reaching shoreline		High	Low

sands (Loring and Nota, 1973). The gradients of the subaqueous slope off the west- and east-facing barriers are therefore partially controlled by the sediment dispersal pattern that results from the local wave climate.

Wright and Coleman (1972) note that nearshore wave power is a function of the subaqueous slope, due to the effects of frictional attenuation, and that as water depth decreases frictional attenuation rates increase. The offshore profiles adjacent to the two barriers are very different (Figure 3), particularly between the 15-m and 40-m depth contours. The broad, shallow shelf off the east coast has an average gradient of $0^{\circ}05'$ (1:626) from the shoreline to the 20-m contour, approximately half the gradient of the shelf off the west coast ($0^{\circ}11'$, 1:312). Wave periods are usually less than

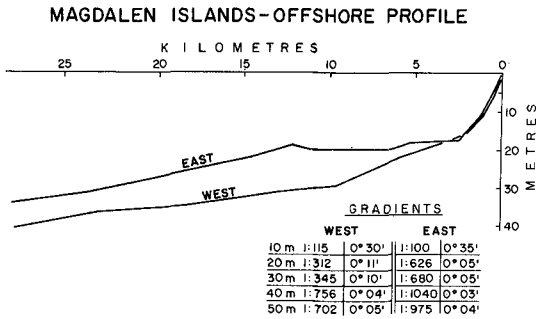

Figure 3. Offshore profiles and gradients--taken on lines perpendicular to the shoreline at the two study sites.

8 seconds in the Gulf, so that although some longer period waves would feel bottom in water depths up to 50 m, the frictional attenuation rates would probably be highest in depths between 30 m and 10 m.

Due to the shallower depths on the east coast the loss of energy by frictional attenuation is much greater than on the west coast. In addition, as the dominant and prevailing winds are out of the west, and locally-generated waves dominate the wave climate, the east coast is a protected environment in which wave heights are lower than on the west-facing barrier (Owens, 1977). The net effect is that (1) more energy is available on the western barriers (Table 3) and (2) a higher proportion of that energy reaches the nearshore zone as compared to the east-facing barrier.

NEARSHORE ZONE

The effects of the difference in the wave energy levels on the two coasts are clearly reflected in the nearshore zones. Surveys on the west study site show a large crescentic bar system that shoals to 5-6 m at 800 m from the beach, a smaller middle crescentic bar, and an intermittent inner bar (Figure 4). Comparison of field surveys in 1974-75 with aerial photographs taken in 1970 indicates that the plan form of the outer bar appears to be constant through time. Small longshore movements of the outer crescentic bar system result in occasional overlapping of the bars in the vicinity

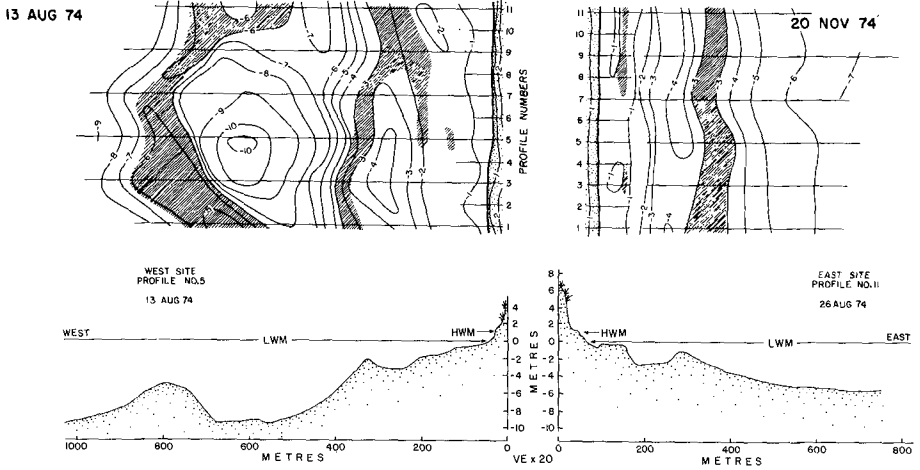

Figure 4. Nearshore profiles and morphology at the west and east coast study sites. The nearshore profiles are spaced at 100-m intervals and shaded areas on the maps indicate the location of subaqueous bars.

of the horns of the crescents. Also, it was found that the apex of the outer bar oscillated perpendicular to the shoreline between 700 and 900 m from the beach (Figure 5). These variations resulted in modification of the crescentic bar form but surveys showed that the basic location and shape of the outer bar did not change over a 9-month period. More variation was observed in the plan form of the two inner bar systems, particularly following periods of storm-generated waves.

By contrast the east-facing barrier is characterized by a single asymmetrical linear nearshore bar that shoals to 1.5-2.5 m at 250 m from the beach (Figure 4). The trough depth on the landward side of the bar varied between 3 and 5 m. Migratory bars were also recorded inshore on the shallow low-tide terrace adjacent to the beach. Although the nearshore bar had a low amplitude rhythmic plan shape following storm-wave activity, the basic linear form of the bar did not change significantly over the 9-month period of the surveys. The plan form of the bars on the low-tide terrace varied considerably, and this has been related to differences in the direction of wave

Figure 5. Composite of nearshore profiles surveyed on line 5 on the west study site. The profile is located on Figure 4 (from Owens, 1977).

approach during summer months and to storm-wave activity during the winter season (Owens, 1977).

Although the large differences in wave energy levels on these two barriers clearly affect the character of the nearshore zone, the actual variations in the size and the morphology of the nearshore bar systems could be explained in several ways. If it is assumed that breaking waves control bar formation, then the fact that the bars on the western barrier are farther offshore, in deeper water, and larger than the bar on the east coast would be due simply to higher wave heights on the west coast. But, as the two sets differ so radically in plan form it is difficult to accept that bar formation could result from a simple variation in wave height between the two coasts. On the other hand, it is possible that the variation in the size and spacing of the bars, perpendicular to the shore, could be due to the effects of standing waves generated by the reflection of incident waves from the beach (Bowen and Inman, 1971; Suhayda, 1974). Bowen and Inman suggest that the alongshore plan form of crescentic bars results from the sediment dispersal patterns associated with the formation of edge waves in the surf zone. The absence of a well-defined crescentic bar on the eastern barrier probably results from the consistently oblique wave approach and high breaker angles that generate strong longshore currents, thus preventing the development of rhythmic morphology on the outer bar.

INTERTIDAL ZONE (BEACH)

Sediment size (Table 6) and tidal range are constant between the beaches of the two study sites, so that variability in beach morphology results from differences in wave energy levels or in nearshore topography modifying the incoming incident waves. The beaches of the western barrier are generally narrow (20-30 m) (Photograph 1) with a relatively steep beach-face slope (approximately 1:4) (Figure 6). These beaches are characterized by an overall lowering of beach elevation in winter months, due to increased levels of wave activity during this season. This produces a "summer-winter" beach cycle (Figure 7).

The beaches of the eastern barrier are wider (40-50 m) (Photograph 2) and have a flatter beach-face slope (approximately 1:8) (Figure 6). The dominance of storm-wave activity over seasonal variations in wave energy levels on this coast produces beach cycles that are related to erosion during storms and recovery during post-storm conditions. Although the beach elevation is lower in winter months, as compared to the summer (Figure 7), the short-term variability related to storm-wave activity is more significant (Owens, 1977).

The difference in slope of the beach face at the two sites is a reflection of the different effects of nearshore topography on breaking waves. Waves reaching the beach face on the west coast were predominantly plunging breakers, during both study periods, whereas those on the east coast were predominantly spilling breakers. This difference in breaker type results from the different gradients immediately seaward of the intertidal zone. Water depths and gradients are greater at the west study site (Figure 4) due primarily to the presence of a wide low-tide terrace on the east-facing barrier.

Figure 6. Representative beach profiles for the two study areas.

Photograph 1. West study site beach (May 1975).

Photograph 2. East study site beach (August 1974).

Figure 7. Sweep zone profiles for summer and winter beach profiles at selected locations for the two study sites (after Owens, 1977).

The berm crest was slightly higher on the western beach (Figure 6) as a result of higher wave heights on this coast that lead to a build-up of sand to greater elevations on the berm during high tide periods. Bascom (1954) pointed out that, although storm waves tend to erode the berm, they also create a berm at a greater elevation due to increased wave heights and that they may leave a high, narrow berm that will survive until a larger storm erodes it.

SUBAERIAL ZONE (DUNES)

The dunes on the western barrier are up to 15 m in height, and erosion during major storms produces irregular scarps in the backshore dunes (Photograph 3). During post-storm recovery a new foredune ridge develops adjacent to the beach, leaving an abandoned scarp that is subsequently modified by eolian processes. This pattern of irregular erosion in the backshore, followed by infilling to maintain a regular shoreline, has produced a complex dune topography. The concentration of wave energy at particular locations along the dune barrier is probably a reflection of the effects of the complex nearshore morphology on storm waves.

Photograph 3. Aerial view of dunes at the west study site (August 1974).

The dunes of the east study site are part of a progradational dune-ridge complex (Photograph 4) with a series of parallel ridges that reach 10 m in height adjacent to the beach (Owens and McCann, in preparation). Erosion during storms is relatively constant along this section of barrier, and there is no evidence that the ridges have been breached at any time. This dune-ridge complex is not characteristic of all the east-facing barriers of the Magdalen Islands (Figure 8). Elsewhere dune heights are rarely greater than 5 m and storm-wave erosion causes the development of washover channels that breach the dunes and the development of fan deposits on the lagoonal side of the barrier (Photograph 5).

SUMMARY

The high energy west-facing barriers of the Magdalen Islands are primarily a zone of sediment bypassing. Material that is fed into the nearshore-littoral system is transported rapidly alongshore toward the northeastern and southern extremities. The barriers are relatively stable, with washover deposits occurring only in the updrift sections adjacent to bedrock outcrops

or, in the case of the southern tombolo, where there is a movement of sediment away from the central section of the barrier (Figure 8). The sheltered, lower energy eastern barriers are both lower and, except for the two beach-ridge complexes, are frequently overwashed. This environment is primarily one of sediment redistribution and deposition, with a net nearshore-littoral transport from northeast to southwest.

These basic mesoscale differences between the two barrier systems are reflected in the morphology and process characteristics of each coast. Spatial variations in offshore, nearshore, beach, and dune morphology can be directly related to the amounts and variability of wave energy levels on the two coasts. The pattern of sediment dispersal in the offshore and nearshore zones is controlled by the dominance of wind-generated waves out of the west (controlling the overall energy levels) and the resulting differences in subaqueous slope gradients (which affect the nearshore wave energy levels).

ACKNOWLEDGMENTS

The research program on the Magdalen Islands was part of a study carried out at the Atlantic Geoscience Centre, Bedford Institute of Oceanography, Dartmouth, Nova Scotia (Geological Survey of Canada Project 740009). Salary support since January 1976 has been provided under a contract with the Geography Programs, Office of Naval Research, Arlington, Virginia 22217. The illustrations were prepared by the Drafting and Illustrations Section of the Bedford Institute and by Mrs. G. Dunn of the Coastal Studies Institute.

CHAPTER 116

GEOMORPHOLOGY OF THE SOUTHERN COAST OF ALASKA

Miles O. Hayes

ABSTRACT

The shoreline of southern Alaska is a narrow coastal plain dominated by large glaciers, periodic earthquake activity, and strong extratropical cyclones. Studies on the coastal geomorphology and sediments carried out in 1969-71 and in the summer of 1975 were directed at defining geological hazards with respect to developing shore facilities for OCS oil exploration activities. Most of the shoreline was found to undergo rapid changes and experience a variety of serious environmental hazards. The safest potential port areas are located inside Icy Bay and Yakutat Bay. The coastal areas in the vicinity of the Malaspina Glacier and the Copper River delta are examples of the two principal shoreline types (glacial outwash plain and deltaic).

The coastal area surrounding the Malaspina Glacier, the largest piedmont glacier in the world, was classified into 5 categories on the basis of its geomorphology, sediments, and local glacial history:

1. Regional retreating coast: This area, which is located at the mouth of Icy Bay, is eroding rapidly (approximately 1.5 km since 1900) as a result of retreat of a glacier (up the bay) a distance of over 40 km since 1900. Consequently, it should not be developed.
2. Prograding spits: Sandy spits that have built into either side of Icy Bay since the retreat of the glacier are also unstable because of the general recession of the shoreline as a result of erosion at the mouth of the bay.
3. Abandoned glacial coasts: These areas, located on the inner eastern shores of Icy Bay and Yakutat Bay, are coastlines of relatively low wave energy composed of abandoned glacial tills, kame terraces, and outwash sediments. These are the most stable and least hazardous areas on the southern Alaska coast.
4. Actively eroding glacial margins: This area, located at Sitkagi Bluffs on the southernmost terminus of the Malaspina Glacier, is an eroding scarp of glacial till jutting into the Gulf of Alaska.
5. Glacial outwash coasts: These shorelines are highly variable and are usually dominated by prograding spits composed of sand and gravel.

The shoreline of the Copper River delta is made up of a complex of six fine-grained mesotidal barrier islands separated by tidal inlets that increase in size in a westerly direction. The islands have undergone major readjustments since the Good Friday earthquake of 1964, which raised the area 3 m. For example,

Egg Island has increased significantly in size; shoreline accretion of 400 m between February 1970 and May 1975 was measured at a site on the updrift end of the island. The patterns of erosion and deposition on the islands conform to those of the barrier island drumstick model developed during studies of the South Carolina coast.

INTRODUCTION

The southern coast of Alaska (Fig. 1) is an exceptionally dynamic area. Intense tectonic activity, large waves, strong tidal currents, highly variable winds, and active glaciation interact to produce one of the most rugged and variable coastlines in the world. The Chugach and St. Elias mountains, an extension of the Cordilleran Mountain system, control the gross orientation of the coastline. Fronting these mountains is a narrow coastal plain consisting of glacial and fluvial deposits undergoing active modification by tectonic, aeolian, and marine processes. Rapid advance and retreat of the numerous glaciers that border the coastal plain has caused sudden and dramatic shifts in loci of erosion and deposition along the beaches.

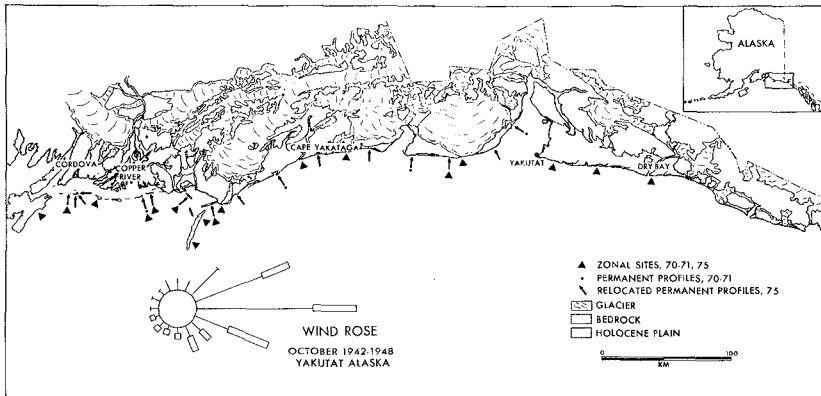

Figure 1. Study area. Note distribution of Holocene coastal plain (max. width = 35 km). Wind rose for Yakutat shows a dominance of easterly winds.

The coastal mountains, formed in response to subduction of the Pacific plate along this collision-type coast, are undergoing rapid uplift. Frequent earthquakes result in large ground displacements. During a single earthquake in 1899, the head of Yakutat Bay was uplifted 15 m. The entire coastal zone of southern Alaska has been subject to modifications resulting from this rapid tectonic activity.

The morphology and sediments of the coastal plain shoreline of southern Alaska were studied on a reconnaissance basis in 1969-71. Fifteen permanent beach profiles were established, 18 detailed specific site studies (zonal studies) were carried out (Fig. 1), and sediment samples were collected at 90 stations,

using a 4 km spacing. The area was revisited in the summer of 1975, during which time the permanent profiles were remeasured, and 99 beach profiling stations were occupied in the central portion of the study area (in the vicinity of the Malaspina Glacier). Using a 15 cm coring tube, sediment samples were taken at 3 stations at each of the 99 profile locations. The samples were then analyzed for grain size with a settling tube. Approximately 10,000 ground and aerial photos were taken. They have been analyzed and compared to photos taken during the 1969-71 studies and also compared with vertical aerial photos from various sources.

Extratropical cyclones that generate southeasterly winds dominate the coastal processes. Wind frequency diagrams for the entire Gulf of Alaska area are shown in Figure 2 (from Nummedal and Stephen, 1976). These winds create wave energy flux patterns that trend from east to west in the study area (Fig. 3), and, consequently, generate a dominant east to west littoral sediment transport pattern (Fig. 4).

Figure 2. Wind frequency distributions for coastal data squares in the Gulf of Alaska. The diagrams are based on wind observations presented in Summary of Synoptic Meteorological Observations (U.S. Naval Weather Service Command, 1970). The dominant and prevailing winds are generally aligned parallel to the shoreline because of the temperature-induced pressure gradient along the coastal mountains. On the northeast coast of the Gulf, the dominant winds blow toward the northwest; on the northwest coast, they blow toward the east and northeast. (From Nummedal and Stephen, 1976; Fig. 13)

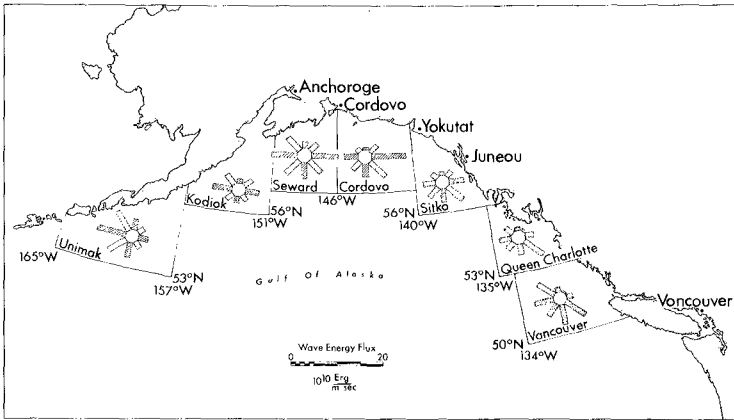

Figure 3. Wave energy flux distributions for the coastal areas of the Gulf of Alaska. The computations are based on deep water wave observations presented in Summary of Synoptic Meteorological Observations (U. S. Naval Weather Service Command, 1970). The wave energy flux is highest out of the southeast for the Vancouver, Queen Charlotte, and Sitka data squares, out of the east at Cordova, and out of the west at Seward, Kodiak, and Unimak. This pattern corresponds closely to that of the winds (Fig. 2). (From Nummedal and Stephen, 1976; Fig. 18)

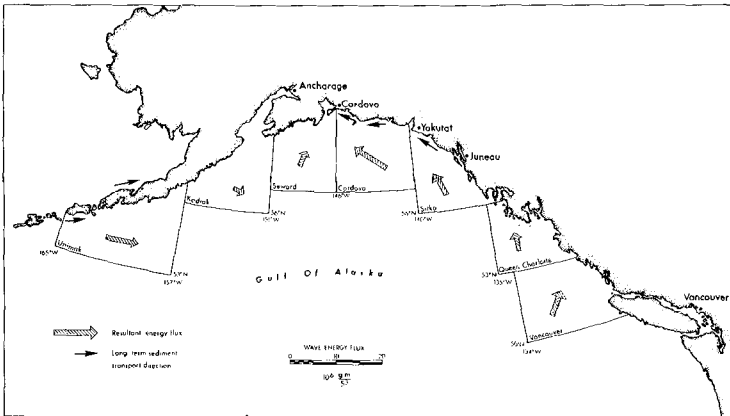

Figure 4. Direction of longshore sediment transportation based on large scale coastal geomorphic features and resultant wave energy flux distribution for the coastal areas of the Gulf of Alaska. Large scale coastal features used in establishing long-term transport directions include spits, inlet offsets, and crescentic embayments. The resultant wave energy flux is determined by vectorial addition of the distributions presented in Figure 3. Note the convergence of wave energy flux toward Prince William Sound. (From Nummedal and Stephen, 1976; Fig. 19)

The coastal morphology consists of (1) an outwash plain shoreline, which is a complex of outwash streams with downdrift beach-ridge plains, and (2) the delta of the Copper River, which has a seaward margin made up of mesotidal barrier islands. It is unusual to find a depositional shoreline of this magnitude (Fig. 1) on a collision coast. It owes its origin to the huge sediment output of glaciers that drain the largest ice field in North America, and to the sediments of the Copper River, which has a mean annual load of $100 \pm \times 10^6$ metric tons (Reimnitz, 1966; see Table 1).

TABLE 1. Annual Sediment Load of the Copper River (Reimnitz, 1966)

WOOD CANYON	Suspended Load: 66.0×10^6 metric tons
	Bed Load: <u>9.9×10^6 metric tons</u>
	Total: 75.9×10^6 metric tons
DELTA	Total Load: $100 \pm \times 10^6$ metric tons
<u>Comparisons:</u>	
COPPER RIVER (at delta)	$100 \pm \times 10^6$ metric tons
MISSISSIPPI RIVER	450×10^6 metric tons
AMAZON RIVER	347×10^6 metric tons

Figure 5 compares the beach sediments of the outwash plain depositional system with the beach sediments of the barrier islands of the Copper River delta. The outwash plain beaches are both texturally and mineralogically immature. All of the samples have very low percentages of quartz, being classified as litharenites (using scheme of Folk, 1974). The samples show a wide range of values of sorting and mean grain size (Fig. 5).

Figure 5. A. Composition of outwash plain and Copper River delta barrier island sediments. All samples are litharenites, with the barrier island sands being more quartz rich. B. Mean grain size (M_z ; Folk, 1974) vs. sorting (σ_T). Copper River delta beaches are moderately sorted medium to fine sand; whereas the outwash plain sediments show a wide range in size and sorting.

MALASPINA AREA

Introduction

Study during the summer of 1975 was focused in the vicinity of the Malaspina Glacier (Fig. 6). The project was designed to provide process information and to continue our study of the coastal morphology and sedimentation. Beach profiles were measured at 3 km intervals over the entire study area (Fig. 6) in order to assess regional trends in beach morphology. The results of these studies allow the subdivision of the coast into five principal geomorphic type areas which are closely related to the local glacial history.

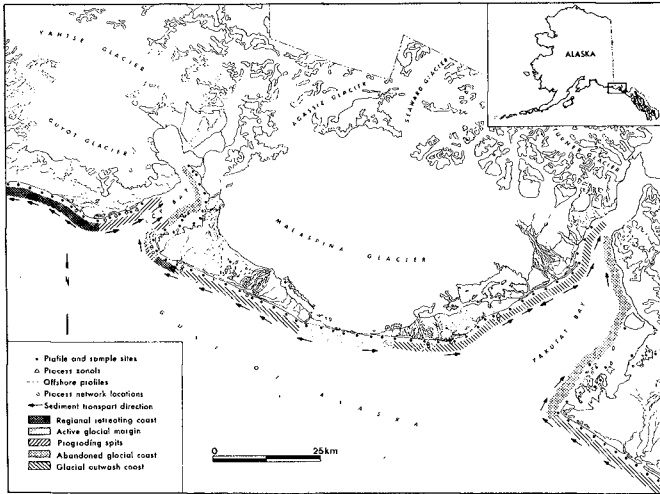

Figure 6. Location of area studied in summer of 1975. Arrows indicate dominant longshore sediment transport direction on the basis of combined morphological and process data. The different classes of shoreline types and location of study sites are also indicated.

Regional retreating coast

This area is located at the mouth of and downdrift of Icy Bay (Fig. 6). The recent retreat of the Guyot Glacier up into Icy Bay resulted in a loss of sediment to this coastal section, causing widespread erosion (approximately 1.5 km since 1900). Beach profiles are generally flat with concave-upward upper beach faces backed by eroding scarps at the spring high-tide swash line (Fig. 7). Sediments are mixed sand and gravel. Heavily forested beach ridges, glacial outwash plains, and till areas on either side of Icy Bay are being cut back severely. Broad overwash terraces are advancing over low-lying areas. This area should be omitted from all considerations for shoreline development.

Figure 7. Regional retreating coast. A. Beach profile and sketch for station DBC-79, which is located approximately 5 km west of the entrance to Icy Bay (Fig. 6). Note the concave upward shape of the profile, the erosional scarp, and the developing washover terrace. LTT = low-tide terrace; A, B, C = sediment sampling localities. B. Station DBC-79 on 14 June 1975.

Figure 8. A. Riou Spit, a prograding sand spit at the eastern entrance to Icy Bay. Photo taken on 4 August 1975. B. Example of abandoned glacial shoreline, eastern margin of Yakutat Bay (Knight Island). Photo taken on 21 August 1975.

Prograding spits

On either side of Icy Bay, sandy spits are prograding into deeper water as the shoreline around the mouth of the bay erodes. The largest, Riou Spit, is located on the east, or updrift, side of the Bay (Fig. 8A). Riou Spit is migrating both alongshore and landward because of recession of the shoreline adjacent to the bay. The beach profiles on the spits are relatively flat with broad berm-top overwash areas. These spit areas are considered to be quite unstable for development purposes because of their rapid rates of change and their exposure to open ocean waves.

Abandoned glacial coasts

These areas, located on the inner eastern shores of Icy Bay and Yakutat Bay, are characterized by deposits of unconsolidated tills, kame terraces, and outwash sediments which supply abundant gravel to the beaches. An example is shown in Figure 8B. Profiles are very steep, short, and often have well-developed multiple cusped berms. High vegetated storm berms indicate infrequent but violent storms. Sediments are predominantly well-sorted and rounded gravel. Sand and gravel spits occur downdrift of till islands in Yakutat Bay. Because of their protected nature and slow rates of erosion and deposition, these are the most favorable areas available for the development of shore facilities.

Actively eroding glacial margins

This area, located at Sitkagi Bluffs, on the southernmost terminus of the Malaspina Glacier, is an eroding scarp of glacial till on the shoreline of the Gulf of Alaska. Beach profiles in front of the Bluffs are extremely short and steep, backed by eroding till scarps (Fig. 9A). Beach material ranges from sand and angular gravels to large erratics left behind as the scarps retreat (Fig. 9B). These retreating scarps, and their adjacent boulder beaches, are virtually inaccessible for any kind of human activity at high tide.

Glacial outwash coasts

These beaches are generally prograding, with abundant mixed sand and gravel spits trailing toward the west, except inside Yakutat Bay, where a major transport reversal occurs. Beach-ridge plains often develop downdrift of the major river mouths. Beach profiles are relatively flat with abundant ridge-and-runnel systems, resulting in a shoreline with a characteristic rhythmic topography. Typical examples of glacial outwash coasts are illustrated in Figure 10. When glacial sources are distant, sediments tend to have a high sand to gravel content. The beaches in these areas are relatively stable and are considered to be the second most desirable areas for shoreline development in southern Alaska.

Process data

Process observations were obtained at two levels during July-August, 1975:

A) Process Network (Fig. 6). Regional process variability was determined by multiple observations during stable meteorological conditions.

B) Six Process Zonals (Fig. 6). Continuous 48-hour monitoring of meteorological, wave, littoral, and morphological variability was maintained at single sites selected as representative of shoreline segments.

Regional process parameters document littoral transport in directions that correlate with regional morphology. Dominant south and southeast waves yielded sediment transport toward the west away from eroding till cliffs and from the mouths of outwash streams.

Process zonal measurements allowed documentation of the passage of a complete storm cycle. Commonly, two distinct wave trains were monitored. Under such conditions, drift directions and velocities were erratic and strong rip currents were prevalent. Dominant wave approach was a function of the path of low pressure systems moving through the Gulf of Alaska. Southerly waves were characteristic of calm conditions, and southeasterly waves were characteristic of storm conditions.

Breaker heights averaged 1.5 to 2.0 m, with a maximum measured height of 4 m recorded during a storm. Suspended sediment concentrations taken from the bore of plunging waves were as high as 150 gms/liter. Measured beach profiles revealed up to 15 cm of accretion to the beach face during one tidal cycle.

COPPER RIVER DELTA AREA

Introduction

The barrier island shoreline of the Copper River delta was uplifted 3 m by the Good Friday earthquake of March 1964 (Fig. 11). This has brought about many adjustments of the morphology of the islands in response to changes in the level of wave erosion and deposition. The sands of the barrier islands are mineralogically immature, averaging about 50% quartz and 50% metamorphic rock fragments (Fig. 5). They are moderately sorted, medium- and fine-grained sands.

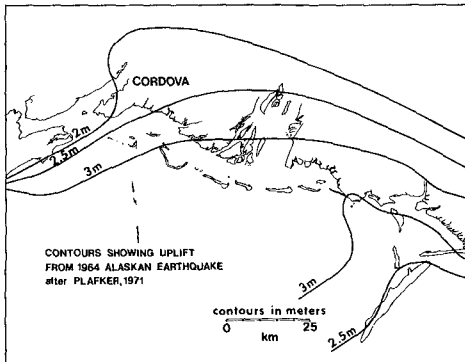

Figure 11. Uplift (in meters) of the Copper River delta area during the Good Friday earthquake of 1964.

Mesotidal barrier islands

A tidal range of 3-4 m places the Copper River delta in the mesotidal class of Davies (1964). As has been pointed out elsewhere (Hayes et al., 1973; Hayes and Kana, 1976), mesotidal barrier islands have two distinctive morphological characteristics:

1. In coastal areas with dominant waves that approach the shoreline at an oblique angle, the tidal inlets commonly show downdrift offsets; that is, the barrier beach downdrift of the inlet protrudes further seaward than the one on the updrift side (Hayes et al., 1970). The tidal inlets of New Jersey, the Delmarva Peninsula, and South Carolina are good examples. The present downdrift offset at Price Inlet, S. C., which has changed from downdrift offset to updrift offset and back to downdrift offset again since 1941, is discussed in detail by FitzGerald (1976).
2. Many mesotidal barrier islands have a drumstick shape, with the bulbous part of the drumstick being located on the updrift side of the barrier (Fig. 12A). Drumstick-shaped mesotidal barrier islands from Alaska, the Netherlands, South Carolina, and Georgia are outlined in Figure 12B.

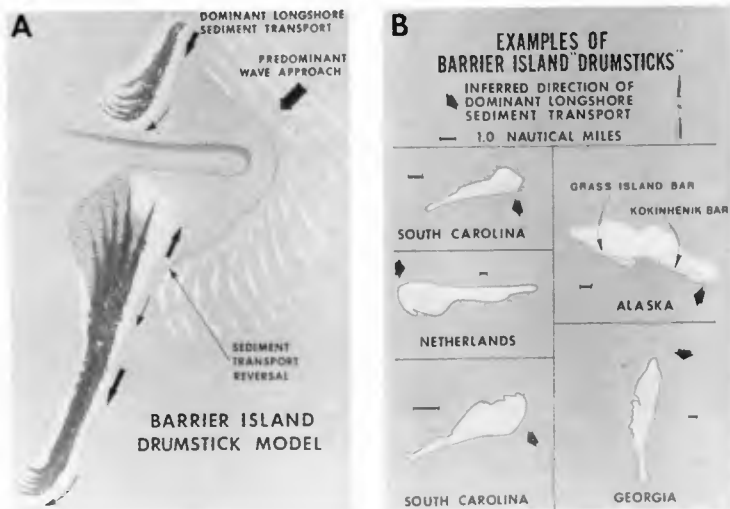

Figure 12. A. Barrier island drumstick model. B. Examples of barrier island "drumsticks" from South Carolina, Georgia, the Netherlands, and Alaska.

Barrier islands of the Copper River delta

The mesotidal barrier islands of the Copper River delta conform well to the drumstick model discussed above. Four systematic east to west changes in the barrier island system are apparent (Fig. 13):

- (1) The downdrift offset increases in an east to west direction, except at the westernmost spit, which is anchored to bedrock;
- (2) The size of the ebb-tidal delta increases from east to west;
- (3) Inlet width increases from east to west; and
- (4) The drumstick shape of the barriers becomes more pronounced in a westerly direction.

These changes are thought to be brought about by two interrelated factors. The river is rapidly filling in the eastern portion of the estuarine system; hence, smaller tidal prisms and smaller ebb-tidal deltas are developed on the east side of the delta. A 20 km long island, Kayak Island (see Fig. 1), is located to the east of the delta, which partially protects the eastern end of the delta from the dominant southeasterly waves. It is, thus, the western part of the delta that is more strongly affected by the oblique wave approach of the dominant waves. Therefore, the effect of wave refraction around the ebb-tidal deltas is greater on the west side of the delta. The drumstick shape of the barriers becomes more accentuated as the wave refraction increases.

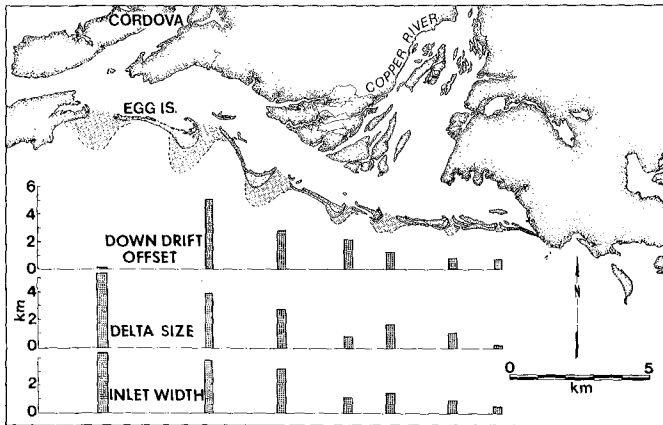

Figure 13. Barrier islands of the Copper River delta.

These barrier islands have undergone some remarkable changes in the past twelve years. They have largely prograded since they were uplifted by the March 1964 earthquake. Data for Egg Island (Figs. 14 and 15) illustrate these changes. A wave-cut scarp on a permanent profile at the east end of the island (EG-1; Fig. 14) eroded 56 m between February 1970 and May 1975. On the other hand, station EG-4, which is located at the widest point of the updrift bulge of the island, prograded 400 m during that same time. This process of overall aggradation of the barrier just downdrift of the inlet accentuated the drumstick shape of the barrier. This process of downdrift accretion is illustrated by the photographs in Figure 15.

Figure 14. Changes of Egg Island, Copper River delta, Alaska, after the March 1964 earthquake, which raised the delta 3 m. Note continual accentuation of the drumstick shape of the island through time.

Figure 15. Egg Island, Alaska. A. Low-tide view taken in June, 1971. B. Low-tide view of east end of Egg Island taken in May 1975. Arrow points to same sand bar as the one indicated by the arrow in A. This beach accreted 400 m between February 1970 and May 1975 (see Fig. 14; profile EG-4). C. Multiple intertidal ridges welding on the beach at station EG-4. Photograph taken in the summer of 1969.

These remarkable changes, plus the occurrence of severe storms that overwash the islands, make the barrier islands of the Copper River delta an undesirable place to develop. On the other hand, Cordova, which has a sheltered harbor on Price William Sound, shows considerable promise.

CONCLUSIONS

1. In the Malaspina Glacier area, the most desirable shorelines for coastal development are the stable, sheltered abandoned glacial coasts inside Icy Bay and Yakutat Bay. The least desirable area is the regional retreating coast at the mouth of Icy Bay, which is eroding rapidly.

2. Southeasterly storms (extratropical cyclones) play a primary role in shaping the morphology of the coastal zone.

3. Combination of wave hindcast data, field process measurements, and studies of coastal geomorphology indicate a dominant littoral sediment transport from east to west.

4. The mesotidal barrier islands of the Copper River delta area show characteristics typical of other mesotidal shorelines (downdrift offsets and drumstick shapes).

5. Major changes in the barrier islands have occurred since the area was uplifted during an earthquake in 1964. Changes continue to accentuate the drumstick shape of the islands.

ACKNOWLEDGEMENTS

The earlier phases of this project (1969-71) were supported by the Geography Programs of the Office of Naval Research (Contract No. N00014-67-A-0230-0001, Miles O. Hayes, principal investigator), and the later phases were supported under contract with the National Oceanic and Atmospheric Administration (Contract No. 03-5-022-82; Miles O. Hayes, principal investigator).

CHAPTER 117

TRACING ESTUARINE SEDIMENTS BY NEUTRON ACTIVATION

by

Richard M. Ecker,^{1/} John F. Sustar^{1/} and Cpt. William T. Harvey^{1/}

ABSTRACT

Tracing the movement of dredged sediments in north San Francisco Bay was accomplished jointly by the San Francisco District of the U.S. Army Corps of Engineers, Explosive Excavation Research Laboratory (now the Explosive Effects Division of the Weapon Effects Laboratory, U.S. Army Waterways Experiment Station), and the Stanford Research Institute. The study involved developing a technique which would permit the long-term tracing of fine sediments dredged from Mare Island Strait after disposal at the Carquinez Strait disposal site; application of the tracer; disposal of the tagged sediment for the February-March 1974 dredging of Mare Island Strait; sampling bottom sediments throughout the study area for a 10-month period; and, quantitative analysis of the collected samples.

INTRODUCTION

The continuous maintenance of navigable waterways in a dynamic sediment system such as San Francisco Bay opens many questions regarding the economics of the dredging operation and the sphere of influence that the operation has on the marine environment. Annual maintenance dredging for Federal, local and private facilities in San Francisco Bay is about 10 million cubic yards. The annual sediment inflow into the Bay is also about 10 million cubic yards. Previous studies to determine the dispersion of dredged sediments have been short-term studies, showing the initial distribution of dredged sediments only. Thus, a study was initiated to investigate the long-term dispersion and circulation of dredged sediments disposed of in a portion of San Francisco Bay.

The technique used for tracing dredged sediments was originally developed to trace tagged material emplaced in an underground explosive charge and subsequently released to the atmosphere by detonation of the explosive. The application of the tracing technique involved the fixing of a tracer element onto quantities of dredged sediments, introduction of this tagged material into dredge hoppers prior to disposal, sampling bottom sediments throughout the study area for a 10-month period, and quantitative analysis of the collected samples.

^{1/} Navigation and Coastal Planning Section, U.S. Army Engineer District, San Francisco, California.

STUDY AREA

The study area was located in the northern portion of San Francisco Bay including Suisun Bay, Carquinez Strait, Mare Island Strait and San Pablo Bay shown in Figure 1. Ninety percent of sediment inflow to the Bay comes through Carquinez Strait, the outlet of flows from the Central Valley of California.

The major portion of dredging in this area is the maintenance of the Mare Island Strait channel to a depth of 30 feet mean lower low water, an annual quantity of about 2.5 million cubic yards. Disposal occurs at a designated site in Carquinez Strait, west of the entrance to Mare Island Strait. Other dredging operations are conducted across San Pablo Bay, at oil terminal facilities and in small marinas throughout the area. With exception of San Pablo Bay (Pinole Shoal), dredged sediments are silty-clay with clay contents ranging from fifty to sixty percent.

TRACING TECHNIQUE

The method used for tracing the movement of dredged sediments in the study area was neutron activation. Radioactivity is not involved in this method until after the samples are collected and the tracer element is used at low concentrations. Certain chemical elements, when exposed to thermal neutrons in a nuclear reactor, become radioactive by capturing the neutrons. The radioactive atoms (radionuclides) of the element decay by releasing energy in the form of an electron (beta particle) and one or more gamma rays. The period of time required for the radionuclide to lose 50 percent of its activity is known as its "half-life." If the decay process is accompanied by one or more gamma rays, the gamma rays have a characteristic energy level which is associated with the atomic mass and chemical species of the decaying radionuclide. The neutron-activable elements can be identified by measuring the gamma-ray energies emitted by an activated sample. The quantity of each of the elements in the sample can be calculated if the gamma-ray emission rate and neutron exposure of the sample are known.

In using the neutron activation technique to trace sediment movement, a small amount of a trace material, in very low abundance in the prototype system (at least a factor of five less than that being added), is fixed to a quantity of sediment and introduced at a known concentration into the dredge hopper. The dredged material and tagged material are then released into the study area at the disposal site. After a period of time, bottom sediment samples are taken, processed, neutron activated, and the amount of trace element in the sample determined. Knowing the concentration of trace element fixed to the original sediments and the amount of the tagged sediments added to each hopper load allows the calculation of the percentage of dredged material present in a bottom sample.

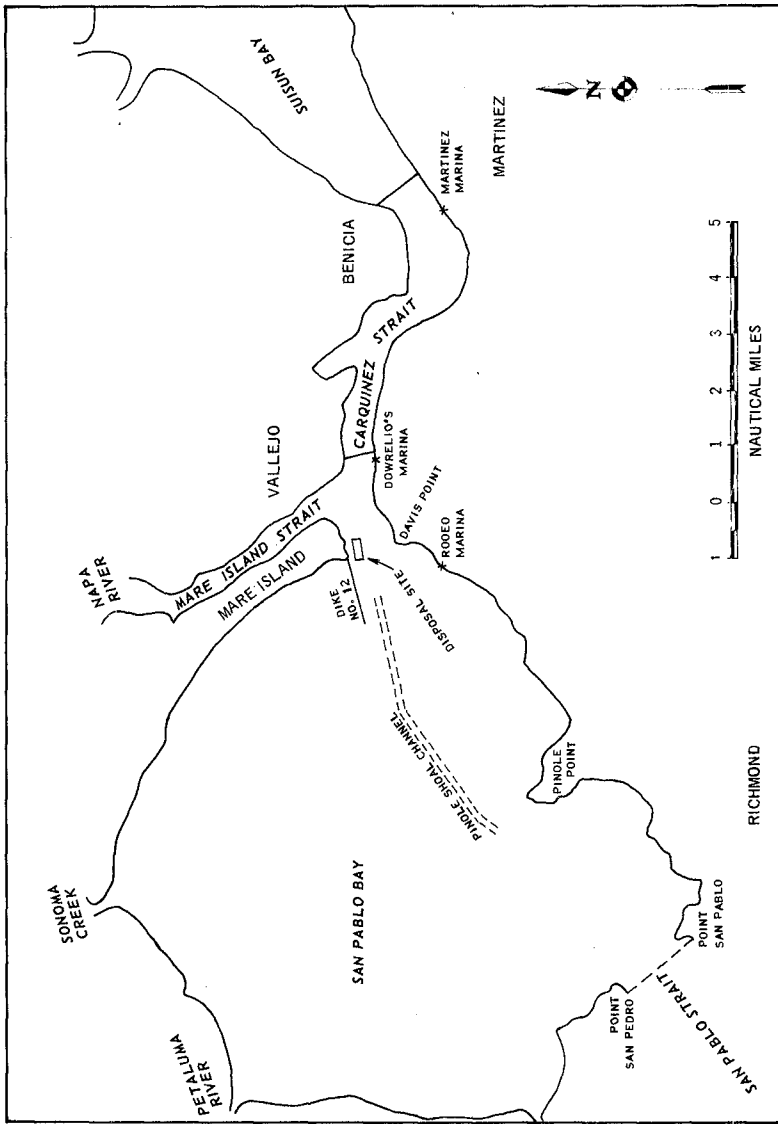

FIGURE 1

STUDY AREA FOR MATERIAL RELEASE INVESTIGATION.

The selection of a trace element to be used with the Mare Island Strait sediments was based on an extensive investigation of chemical element concentrations in sediments from Mare Island Strait and San Pablo Bay and an evaluation of detection limits. Estimates of total sediment movement over a one-year period within the study area ranged from ten to twenty million cubic yards of sediment, which included the quantity dredged, sediment inflow to the study area, and the mixing of sediments in San Pablo Bay, Mare Island and Carquinez Straits, and Suisun Bay.

After an investigation of numerous candidate trace elements, including gold, rhenium, and iridium, it was determined that iridium would be the best tracer element for the following reasons:

a. "The amount of iridium minimizes the mass that must be added to the traced sediment and therefore would least affect particle settling characteristics."

b. "The limit of detection for iridium is a factor of two lower than that for rhenium."

c. "The 74.37 day half-life permits examination of neutron activated samples at significantly long post-irradiation time without significant reduction in signal due to radioactive decay."

The concentration of iridium determined to occur naturally in the study area is 5×10^{-10} grams of iridium per gram of dry sediment.

SEDIMENT TAGGING AND DISPOSAL

The iridium, approximately 22 lbs. (9.9 kg), to be used in the tracing operation was initially purchased in the form of a metal powder and subsequently converted to a soluble iridium salt. The soluble salt was then surface adsorbed to 21,729 lbs. (9.86×10^6 grams) of sediments previously dredged from Mare Island Strait by the Navy and deposited in a landfill site. The resulting concentration of iridium in the tagged sediments was approximately 1.01×10^{-3} gram of iridium per gram of dry sediment.

The chemical and physical properties of the material from the landfill site were investigated and found to be essentially the same as those of sediments taken from dredge hoppers during a previous dredging of Mare Island Strait.

A total of 8,169 gal (30.9 m^3) of tagged material in 5 gal paint cans and 55 gal drums was placed aboard the Corps dredge, CHESTER HARDING, prior to dredging in February 1974. The HARDING is a dual suction dredge having port and starboard variable-depth trailing suction arms and two bottom-dumping hoppers located forward and aft of the mid-ship superstructure.

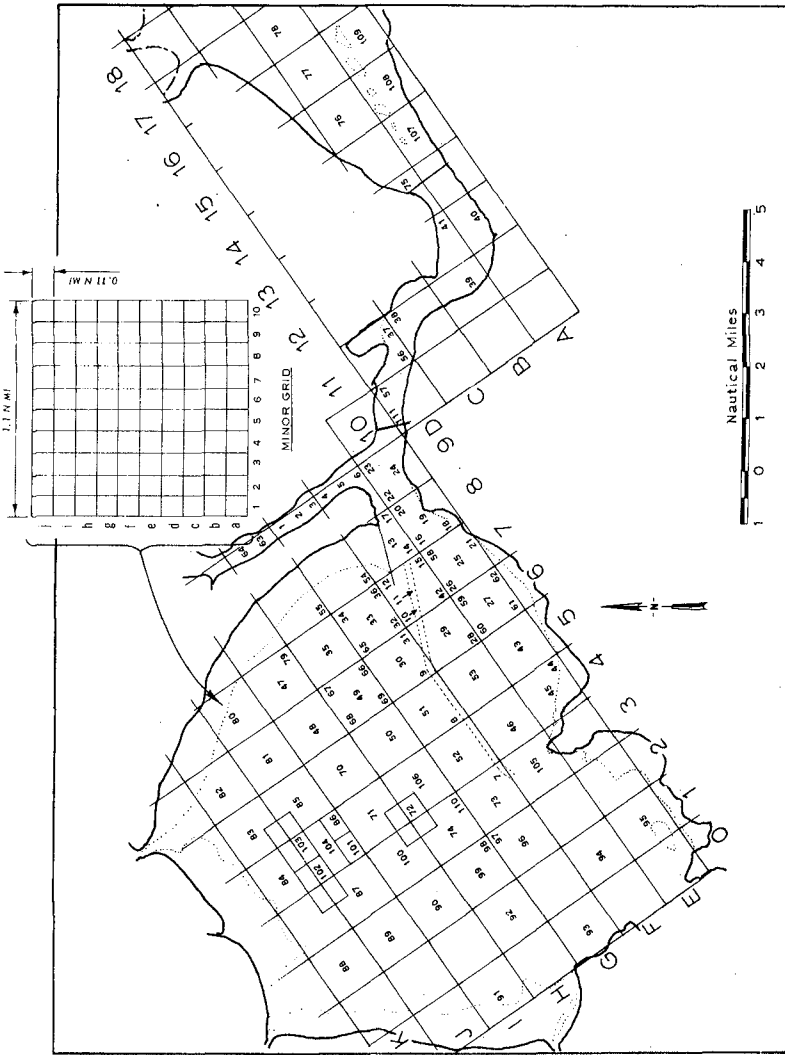

The dredging of Mare Island Strait began on 19 February 1974 and continued until 30 March 1974. Dredging of the Strait was continuous for 12 consecutive days, followed by a 2-day break. A total of 706 trips between the dredging area and the Carquinez disposal area were made during the 35 dredging days. Tagged sediments were introduced into the hoppers on each of these 706 trips. The volume of dredged sediment carried in the dredge hoppers was 2,300 cubic yards per load. A total of 1,624,000 cubic yards of sediment were dredged and disposed of at the Carquinez disposal site during the 35 dredging days. The concentration of iridium in the dredged sediments was 1.95×10^{-8} grams of iridium per gram of dry sediment.

Addition of the tagged sediments to the dredge hoppers was always accomplished after leaving the channel to avoid contamination by hopper overflow. The tagged sediments were added to the dredged material via standpipes located in each hopper.

SEDIMENT SAMPLING

To quantify the deposition and circulation of dredged material, a high percentage of tagged sediment must be accounted for during each of the sampling periods. For this reason, a sampling area encompassing the maximum limits of circulation of the tagged dredged material was desirable. Prior studies indicated that the majority of the dredged sediment released at the Carquinez Strait disposal site during a one-year period will remain in an area encompassed by San Pablo Bay, Carquinez Strait, Mare Island Strait and Suisun Bay.

A grid sampling system was established for the tracer study. Figure 2 shows the grid system established for the study area. The basic grid system consists of grids 1.1 nautical miles square and is oriented 58 degrees East of North. Each basic grid was further subdivided into a minor grid (shown in Figure 2) with 0.11 nautical mile square grids. Samples were taken at the midpoint of each designated grid once per sampling period. A total of 111 sampling locations (shown in Figure 2) were established in the study area. Sampling locations were located in the deep waters of Carquinez Strait; however, due to an inability to penetrate the hard bottom at several locations with the sampling equipment, limited sampling was conducted. This is a good indication that dredged material deposited in the deep channel areas of the Strait probably did not stay there very long. Sampling periods were designated monthly due to the ability of the sampling boat to sample approximately five locations per day. The first sampling period, March 1974, was divided into two periods by sampling approximately 50 locations twice during the month. The remaining sampling periods occurred monthly from April-December 1974 and included sampling of approximately 100 locations per month. In addition to the samples taken at regular intervals in the study area, other sediment samples were taken in an attempt to further define the dredged material circulation. These additional samples were taken from the hoppers of the dredge during the February-March 1974 and October-November 1975 dredging cycles, from selected shoaling areas in Central and South Bays (Figure 3), and from 10 cross sections of the Mare Island Strait shown in Figure 4).

Tracer Program Grid

FIGURE 3

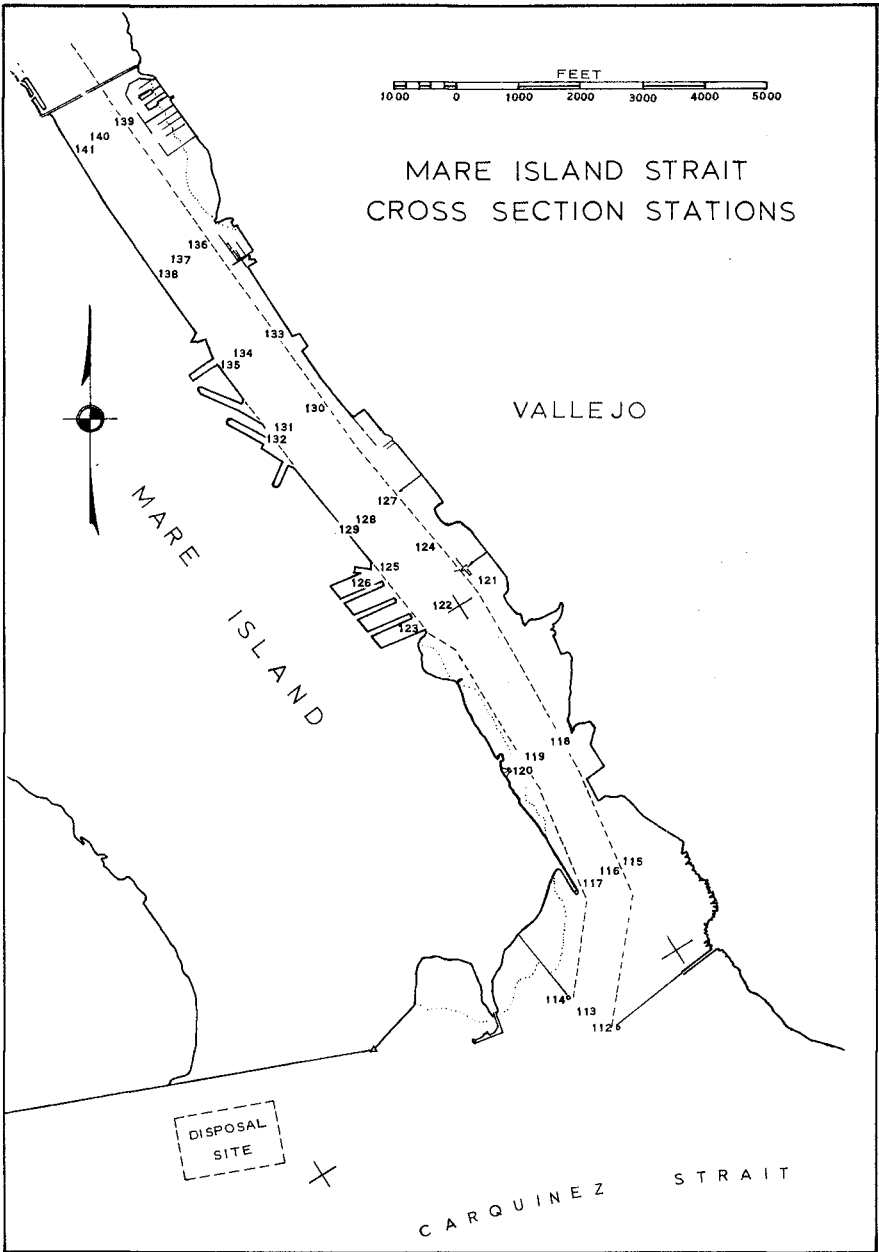

FIGURE 3

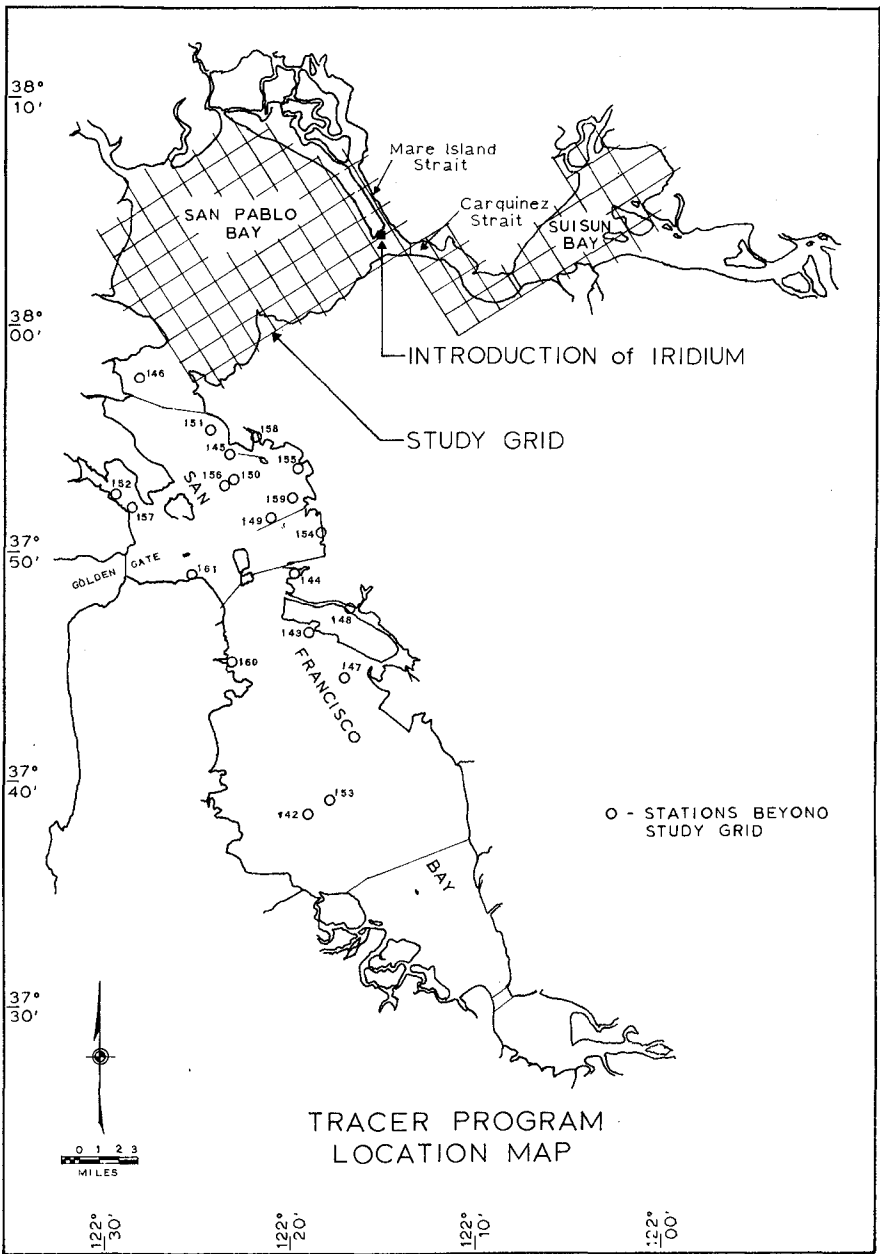

FIGURE 4

The purpose of taking samples along cross sections in Mare Island Strait (Figure 4) was to attempt to determine the extent of movement of dredged material back into the Strait prior to the fall dredging of the Strait from 20 September - 30 October 1974. In late August 1974, 30 core samples were taken along 10 cross sections in the Strait.

The purpose of taking hopper samples was to determine if the dredge was rehandling sediments that were previously dredged and to estimate the return of tagged sediments to the dredged channel. The hopper samples taken during the February-March 1974 dredging were collected on every tenth dredging cycle and prior to the introduction of iridium into the hoppers. The samples were taken by dipping a plastic container into the sediments in the hopper. The samples were subsequently placed in plastic containers. All samples were carefully taken to avoid iridium contamination.

The purpose of sampling shoaling areas in Central and South Bays was to determine if the dredged material disposed in Carquinez Strait contributed significantly to shoaling in these areas. Samples were taken at 20 locations (Figure 3) from September to December 1974.

Horizontal control for the sampling program was provided by three-point sextant triangulation and radar; and, where the water was shallow, sampling locations were marked by stakes. The depth of the top of the samples was referenced to mean lower low water datum by staff gages located at various points in the study area close to the sampling locations.

The sampling program was conducted using a modified World War II landing craft medium (LCM). The cargo deck of the LCM was modified with a well through the deck and hull. A double "A" frame was positioned above the well for raising and lowering of the sampling equipment through the well.

Push-tube vertical core sampling was used for bottom sampling. This method uses a 4-inch pipe casing in which a 2-1/8-inch ID steel push-tube barrel is inserted. The pipe casing was lowered to the bottom from the surface and provided a readily available elevation reference and reentry into the same hole. The push-tube barrel with acrylic liner was then inserted into the pipe casing and pushed into the sediment to obtain a core sample. Core samples up to 30 inches in length could be taken; however, 20-inch samples were normally taken to insure inclusion of the top layer of sediment. Five core samples were normally taken at each sampling location. Each sample was logged and labeled and stored for subsequent processing.

SAMPLE PROCESSING

The daily collection of samples was taken to the Stanford Research Institute facilities at Camp Parks, California, for processing.

The top one inch of sediment from each of the five tubes from a particular location was removed, dried, and the weight of dry sediment recorded. The remaining sediments in one of the five tubes was then selected for further processing, and the sediments were carefully removed in 4-inch increments. Each of these 4-inch increments was also dried and the weight recorded. The remaining four tubes were stored for possible future use.

The five 1-inch increments were combined into one sample and ground and passed through a 20-mesh sieve. These increments were combined to produce a sample large enough to extract a 50-gram aliquot. The 4-inch increments were also ground and passed through the mesh.

A 50-gram aliquot was selected from each incremental layer for determination of iridium content. The iridium content of each aliquot was determined using a fire assay process. Fire assay is a process used in the assay of ores for noble metals. In this process, finely divided ore is mixed with lead oxide, a reducing agent, and fluxing materials. The mixture is heated until it melts, and, upon melting, separates into two liquid phases. The ore stays on top in a slag phase, and the noble metals and a few other elements in the heavy metallic phase go to the bottom. When the mixture cools, the slag and the noble metals are separated and the slag is discarded. The noble metals were then formed into a right cylinder and sealed in an aluminum tube for neutron activation.

The irradiation of the encapsulated metals was performed at the General Atomic TRIGA Mark III reactor at the University of California, Berkeley. After an adequate decay period, the irradiated samples were taken to SRI's Camp Parks facility for gamma ray counting and determination of iridium content.

RESULTS

The large number of samples taken in the study area and processed presented a rather massive problem in data display for analysis purposes. The solution to the data presentation problem was the creation of computer-prepared graphical displays of the percent dredged material data. The graphical displays were produced using the AUTOMAP II computer mapping program developed by the Environmental Systems Research Institute of Redlands, California. The program comprises a computer graphics system written in Fortran IV language, which can produce various types of maps displaying qualitative and quantitative information. The initial work in keypunching the data for use with the AUTOMAP II program and the computer graphics for the study area was accomplished by the Corps of Engineers, Hydrologic Engineering Center in Davis, California.

Graphic displays were produced for each sampling period. However, for the purposes of this paper only certain months will be shown and these will be a composite (weighted average) of samples taken in the first 9 inches of sediment. The displays illustrate the distribution

of percent dredged material over the study area. Table 1 is a legend to go along with the displays, showing the maximum value of percent dredged material, the range of percent dredged material for each map symbol, the frequency of occurrence of percent dredged material for sampled locations, and the percent of the study area covered by the specified map symbols. The graphical displays have been designed such that, upon visual inspection, the darker areas represent greater percentages of dredged material.

April 1974 (Figure 5)

The April sampling period was conducted shortly after cessation of dredging and disposal operations.

As shown in Figure 5, dredged material was dispersed throughout most of San Pablo Bay, Carquinez Strait, Suisun Bay and Mare Island Strait. Localized areas of high percentages of dredged material were found in the northwestern shallows of San Pablo Bay, off Pinole Point and in the southeastern shallows of San Pablo Bay. These areas, representing about eight percent of the total surface areas, had percentages of dredged material ranging from 8 to 40 percent. Twenty-five percent of the total surface area had percentages of dredged material of 4 to 8 percent. These intermediately high areas were found in the southern shallows of San Pablo Bay between Pinole Point and Point San Pablo, the northern shallows of San Pablo Bay, Mare Island Strait, Benicia and Martinez, and the west end of Suisun Bay. Forty-eight percent of the total surface area had percentages of dredged material ranging from 0.5 to 4 percent. About eighteen percent of the total surface areas had percentages of dredged material ranging from 0 to 0.5 percent.

August 1974 (Figure 6)

By the end of August, five months after completion of dredging in Mare Island Strait, very little dredge material was found over the entire 100 square mile study area. The highest percentages of dredge material ranged from 0.5 to 2 percent and was found over approximately fifteen percent of the total surface area. These low percentages were found primarily in the northern shallows of San Pablo Bay, and small areas of Carquinez Strait. Eighty-five percent of the total surface area had percentages of dredge material between 0 and 0.5 percent.

October 1974 (Figure 7)

During the months of September and October the percent dredged material throughout the 100-square-mile area increased. The second dredging cycle in Mare Island Strait took place between 20 September and 30 October 1974. None of the dredge sediment from the second dredging cycle was tagged with the tracer element. All sampling in the month of September was completed before the dredging operations commenced so the increase in dredge material during September cannot be attributed to redredging of sediment that was released in February-March. However,

the increased percentages in October were substantially greater than in September leading one to believe that previously tagged dredged material from the first dredging cycle had found its way back into the Mare Island Strait Channel after disposal at the Carquinez disposal site and was being redredged during the second dredging cycle. However, as the percent dredge material increased in September prior to redredging, the drastic increase in October cannot be solely attributed to the redredging of Mare Island Strait. The increase is a combination of redredging and wind-wave resuspension and deposition of sediments.

Twelve percent of the total surface area during the month of October had percentages of dredged material ranging from 8 to 40 percent. These high percent dredged material areas were found primarily in the eastern southern shallows between Pinole Point and Carquinez Strait and the eastern northern shallows. Isolated areas of higher percentages of dredge material were also found in the natural channel leading to San Pablo Strait and Central Bay and near Martinez in Carquinez Strait. Intermediately high areas, between four and eight percent dredged material, were located around the fringes of the high percentage areas, in the extreme southern end of San Pablo Bay, and along the eastern shore of Suisun Bay. Seventy percent of the total surface area had percentages of dredge material less than two percent. These low percent dredge material areas were found in the northern San Pablo Bay shallows, Carquinez Strait and Suisun Bay.

December 1974 (Figure 8)

By December much of the dredged material that had reappeared in September and October had again disappeared from the top 9 inches. Ninety percent of the total surface area had percentages of dredge material less than two percent. Six percent of the area had percentages of dredged material between two and four percent, and three percent of the area had percentages of dredged material greater than four percent.

CONCLUSIONS

Dispersion of dredged material after disposal at the Carquinez disposal site was very rapid. During the dredging operation dredged sediments make up a large percent of the total sediment in and around the disposal site, including dredged material that had re-entered the dredged channel. After the completion of dredging operations at Mare Island Strait, dredged material was found dispersed in April over a 100-square-mile area including San Pablo Bay, Carquinez Strait and Suisun Bay. Localized areas were found in San Pablo Bay of high percentages of dredged material. By August, five months after completion of dredging, little evidence of dredged material was present in the top 9 inches of sampled sediments over the study area. However, in September tagged dredged material reappeared in the sampled sediments. In October dredged material in the study area increased significantly over that found in September. This increase has been attributed primarily to the estuarine processes which resuspend, circulate, and deposit sediments within the study area. The primary cause of the increase was not attributed to redredging of tagged sediments, although this certainly accounted for some of the increase. By December, two months after the second dredging cycle of Mare Island Strait, most of the dredged material had again disappeared from the top 9 inches of the study area.

The initial movement of dredged material back into Mare Island Strait was estimated to be 10 percent of the total volume dredged, and the long-term movement into the Strait estimated to be no more than 15 percent. These estimates generally agree with those made by other investigators. Limited amounts of tagged sediments were also detected in shoal areas of Central and South Bays indicating that dredged material was leaving the study area and moving seaward. Limited amounts of tagged sediments were also found at depths of approximately 2.5 feet below Bay bottom, indicating that sediments are being mixed either during or after deposition.

ACKNOWLEDGEMENT

The material in this paper is based on observations by the authors during studies by the San Francisco District of the U.S. Army Corps of Engineers of dredged material disposed in San Francisco Bay. Publication of this paper has been approved by the Corps of Engineers but any views, interpretations or conclusions developed are those of the writers only.

CHAPTER 118

SAND MOVEMENT INVESTIGATIONS BY MEANS OF RADIOACTIVE TRACERS IN A HYDRAULIC MODEL AND IN THE FIELD

by

Hans Rohde*)

The Lower and the Outer Elbe constitute the sea-going navigation channel which has the heaviest shipping traffic in the Federal Republic of Germany. In order to obtain and maintain the fairway depth necessary for shipping, river construction works and dredging are applied to an equal extent (5). In order to investigate the practicability of these measures in detail, large hydraulic models of the River Elbe Estuary are available at the Coastal Department of the Federal Institute for Hydraulic Engineering (Außenstelle Küste der Bundesanstalt für Wasserbau) at Hamburg. The problems which result from the displacement of the sands and the fairways, as well as those of sediment transportation, are especially investigated in a model with a moveable bed consisting of granulated polystyrol (5). Details concerning the construction, instrumentation, and questions concerning the scale ratios of this model were given by VOLLMERS during the 13th International Conference on Coastal Engineering 1972 in Vancouver (7). Fig. 1 shows the River Elbe Estuary and the outer boundaries of the model, the length scale of which is 1 : 800 and the depth scale 1 : 100. Fig. 2 shows a view of the model in the direction of the ebb current.

Fig. 2: The Elbe model with moveable bed

In 1973 an investigation was first undertaken to measure direct, with the aid of radioactive isotopes, the spreading of the moveable bed material. The aim was to find ideal situations in the River Elbe Estuary where dredged spoil taken from the fairway could be deposited without danger of the material being retransported - owing to the current - to positions where it could again hinder shipping. The hydraulic fill-fields must be accessible to deep-drawing hopper dredgers. In order to investigate the retransportation of the dredger spoil deposited, a small amount of the models bed material was labelled with the isotope Bromine 82 (Br 82 , half-life value 36 hours). From time to time, 25 g with an activity of 10 Mikrocuries (μCi) were placed at different positions in the model, one after the other; and the distribution of the material after a period of 150 tides in each was investigated and then compared with current conditions prevailing at the time. An evaluation for the various dredge spoil hydraulic fill-fields was obtained from that data. Fig. 3 shows the

Fig. 3: Measurement equipment for the investigation of the spreading of radioactive material in the model

the measurement by scintillation counter of the spreading of the radioactive material in the model. The counting equipment hangs on a boom which can be moved transverse to the direction of movement of the mobile measurement bridge which spans the whole of the model. Thereby, every point of the model's surface can be reached by the counting equipment. On the left of the picture, one can see the printer with which the measurement values are registered. VOLLMERS provided details of the model investigations during the 15th IAHR Congress in Istanbul (8).

As yet, the comparison between the isotope measurements in the hydraulic model and corresponding measurements in the field were still not available. For such a comparison two positions were chosen. The position I was situated in the Lower Elbe between Brunsbüttel and Cuxhaven, and II in the Outer Elbe, northeastwards from the Island of Scharhörn (see Fig. 1). This manuscript is intended to provide information concerning those investigations. Nearly 50 similar investigations using radioactive tracers have been carried out in the coastal areas of the North Sea, since 1960, by the Coastal Department of the Federal

Institute for Hydraulic Engineering at Hamburg. The methods of labelling applied thereby, the introduction onto the sea bottom or the river bottom as well as the measurement of the radioactivity and its spreading over the bottom, is comprehensively reported in (1), (3), and (6).

In the case of all hitherto existing investigations, the main point was merely to qualitatively comprehend the sand movements; therefore, to gain evidence about the main direction of movement of the sand. At the present time, there are investigations in operation that will enable quantitative statements to be made in the future; therefore, evidence about the amounts of radioactive materials transported in the various directions. A method for that has been given by MUNDSCHENK (4). For this method, a new, particularly heavy measurement sledge has been constructed by the Coastal Department of the Federal Institute for Hydraulic Engineering. This sledge is illustrated in Figs. 4 and 5. Fig. 4 is a side elevation of the sledge, which - during measurement operations - is dragged over the bed of the waterway behind a tow-boat.

Fig. 4: The new measurement sledge, lateral view

Fig. 5 : The measurement sledge from below

Fig. 5 shows the underside of the sledge, and - at the same time - provides a clear impression of its size. The measuring probe can be seen at the rear end. This measurement sledge has proved itself to be very good. It is extraordinarily stable, and will reriht itself alone if it has tipped over. The distance of the probe from the bottom remains practically always constant, which is of special significance for the comparatability of the measurement values, especially in the case of quantitative investigations. The registration of the measurement values is carried out on board of the towing ship by means of a tape printer. This measurement sledge was also used in the investigations (described in this manuscript) which were carried out in the Lower and the Outer Elbe, although the

spreading of the radioactive sand was to be only qualitatively recorded.

The investigation area I lies westwards of the Neufelder Sand (see Fig. 1). The Medemrinne (Medem Channel), a subsidiary channel of the Lower Elbe, has sufficient depths to be able to be negotiated by deep-draught hopper dredgers. The Channel is separated from the actual navigational channel by a sand ridge. Current measurements gave a rather larger flood stream velocity when compared with that of the ebb stream velocity: on the other hand, the ebb stream duration was larger than that of the flood stream. Fig. 6 shows the tidal curve and the graph of the current velocity at the eastern end of the Medem Channel, as it was measured in the model experiment. On the basis of the current, velocities, nothing can be definitely concluded as to how the sand movements take place. In the model, at the two positions (Point A) at the eastern end of the Medem Channel and 3 km to the East of that (Point B); each time, in succession, 25 g of radioactive bed material was deposited and the spreading was measured after 150 model tides. In Fig. 7, the areas in which radioactive material could be identified are shown as being darker. From this, it could be seen that there was a clear movement in the direction of the extensive sand plate which lies in the direction of the flood - the Neufelder Sand. A sand transportation in the navigational channel was not observed.

In spring 1973, in the immediate vicinity of the model deposition Point A, an amount of 10 kg of sand was introduced on the river bed in the field. This sand was labelled with 3 Curie Scandium 46 (Sc 46, half-life value 84 days). The stratification of the isotope on the surface of the sand grains direct took place by a chemical method (2) without preliminary preparation of the sand with waterglass (Na_2SiO_3). The spreading of the material was measured by

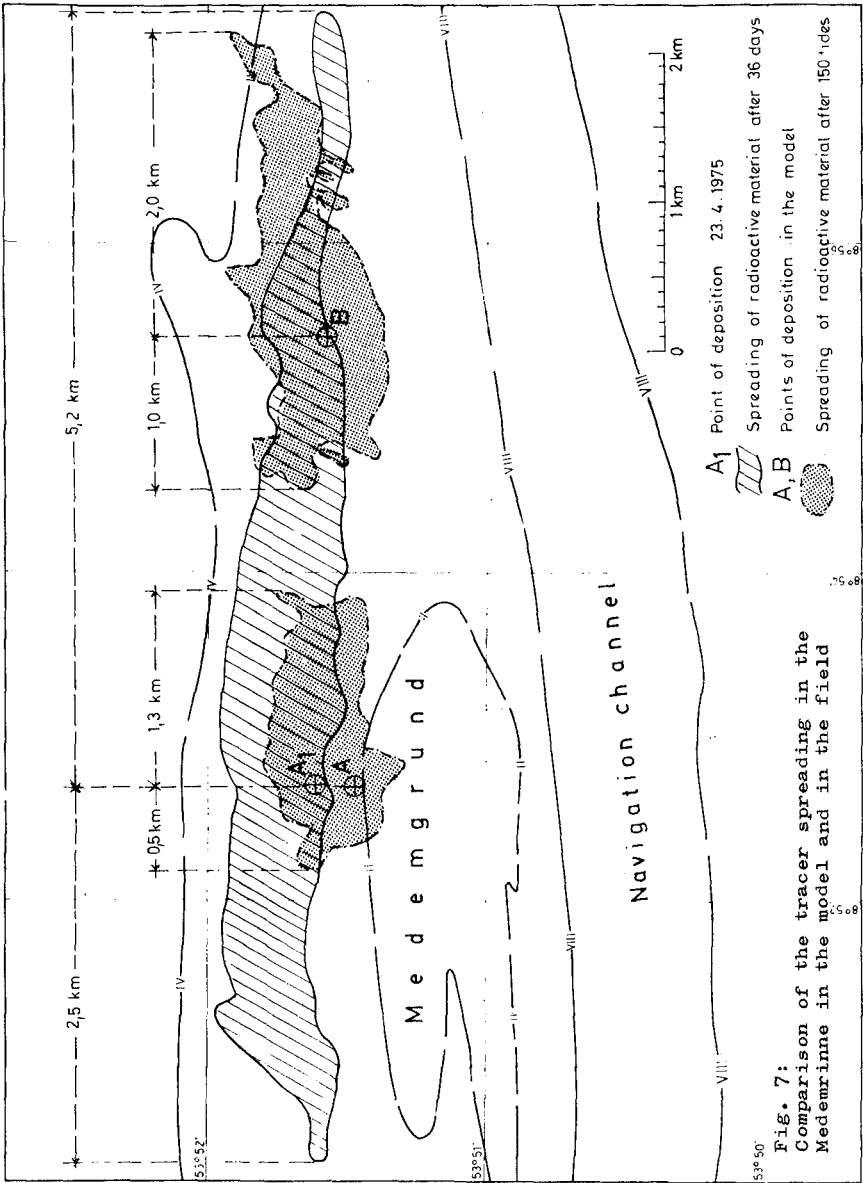

Fig. 6: Tidal curve and graph of the current velocity in the dumping area of the Medemrinne (Model measurements)

means of a scintillation counter. The counting equipment was built into the heavy measurement sledge (shown in Figs. 4 and 5) which was towed by the ship over the bottom. Furthermore, for control and for precise demarcation of the area in which radioactive sand was detectable, extensive bottom samples were taken and were γ -spectrometrically investigated by means of a multi-channel analyzer. The area in which radioactive sand in the field could be detected within 36 days is shown cross-hatched in Fig. 7.

The investigations revealed a good harmony between the spreading direction of the radioactive tracer in the model and in the field. Not only in the field, but also in the model, a predominating transportation in the direction of the flood stream took place in the direction of the Neufelder Sand. No radioactive material was found in the navigational channel. During the whole of the investigation period of 36 days, the activity in the close proximity of the introduction point remained the highest. In comparison, considerable differences in the spreading period in the model and of that in the field could be recognized. To begin with, if one considers the introduction points A and A1: in the model the largest spreading in the flood stream direction measured after 150 tides was 1.3 km; in the ebb stream direction only 0.5 km. The spreading stretch, therefore, was 2.6 times larger in the flood stream direction than that in the ebb stream direction. In the field experiment, the introduction point lay 250 m more northwards. Already, after 36 days or 72 tides, radioactive material was found at a distance of 5.2 km in the flood stream direction and 2.5 km in the ebb stream direction. Therefore, the spreading in the flood stream direction was 2.1 times greater than that in the ebb stream direction.

The model introduction point B was at the eastern end of the spreading area detected in the field. The material deposited here, therefore, spread out in the flood stream

direction double so far as in the ebb stream direction (2.0 km and 1.0 km). The spreading direction was also in good conformity with that established in the field experiment.

Fig. 8 shows the radioactivity as measured in the field (after 3 and 4 weeks) in the longitudinal reach of the spreading. The points are the measurement values calculated on the day of the introduction. The dashed line evens out these values and provides a picture of the distribution of the radioactivity. The logarithmical scale, which is based upon this illustration, is shown on the left of Fig. 8, the dimension is Nanocurie (nCi). The staged curve shows the distribution of the radioactivity in the model experiment, the scale is given on the right of the figure, the dimension is Impulses per Minute. Nanocurie and Impulses per Minute are not to be compared direct, it is intended only to present the form of both distribution curves vis-à-vis to one another in Fig. 8. One can quite clearly recognise that, in both cases, the rise on the left (that is, to the West of the introduction point) is very steep. The maximum is somewhat displaced towards the right. The main body of the radioactive bed material, in the model experiment, had obviously shifted intensely towards the right (East), and a second maximum had built itself up. The more intense shift towards the East, in the direction of the flood current, was also produced by the distribution curve in the field.

The comparison of the experiments revealed that the spreading took place in the field substantially quicker than in the model experiment. The relationship between the extents of the spreading in both the ebb and flood stream directions, indeed, were about the same size both in the model and in the field. However, it was positive that in about half the number of tides in the field the distance from the introduction point in which radioactive

Fig. 8: Spreading of the tracer in the Medemrinne in the model and in the field (Distribution of the radioactivity in the main spreading direction)

material could still be detected was four times greater in the flood stream direction and five times greater in the ebb stream direction, than those in the model experiment. Thereby, one must still bear in mind that, in the so-called morphological Model Time Scale, a model tide represents a larger span of time than a tide in the field. These great differences in the spreading velocity are to be traced back, primarily, to differences between the transportation behaviour of the model bed material and that of the natural sand in the field. The model bed material is transported predominantly as bedload; on the other hand, a larger part of the sand in the field - in suspension. In particular, the radioactive amounts of sand furthest away from the introduction points and which were found only at individual positions, would seem to have reached their deposition location in suspension. Only in a part of the stretch where the sand could be detected as enclosed strips, could the radioactive sand have been transported as bedload, during the relatively short period of observation.

A further investigation in the Outer Elbe was carried out in autumn 1975. The investigation area II lay at the westerly end of the Norderrinne (Northern Channel) which is separated by the Neuen Leuchter Grund from the Mittelrinne (Central Channel) which serves as the main navigational channel (see Fig. 1). Thereby, the deposition point was situated in the vicinity of the introduction point 1 (which is described in (8)) in the model with a moveable bed. In this investigation, the isotope Chromium 51 (Cr 51, half-life value 28 days) was used, and the enrichment was made after previous preparation of the sand with water-glass (1). 100 kg of sand with an activity of 20 Curie was used. Chromium 51 is not so ideally suited for investigations of this type as is Scandium 46, because Chromium 51 has a shorter half-life value and a less energy-rich γ -radiation. As Fig. 9 shows, the ebb stream velocity predominated quite obviously in the vicinity of the introduction

Fig. 9: Tidal curve and graph of the current velocity in the dumping area of the Northern Channel (Model measurements)

point. Correspondingly, a predominant transportation of the sand in the direction of the ebb stream was also to be expected. The spreading of the radioactive bed material, which was measured after 150 model tides, is illustrated in Fig. 10 as dark area. The area where radioactive sand could be detected already five days or ten tides after the introduction in the field, is shown as cross-hatching. Here, also the transportation directions show good harmony, practically no transportation occurred in the flood stream direction. It is particularly interesting that, three weeks after the introduction, a limited spot with heavily increased radioactivity at the edge of the main navigation channel was to be found at 8 km distance from the introduction point. This position is shown in double-hatching in Fig. 10. Sand deposits build up abundantly at this position. The investigations in the Northern Channel of the Outer Elbe confirm the results which were obtained during the investigations in the Medem Channel. Here, also, the spreading in the field occurred very much more quickly than in the model experiment, which is to be traced back to transportation in suspension. The radioactive material which was found at 8 km distance away, must have been transported exclusively in suspension.

The investigations have shown that experiments using radioactive tracers in a model with a moveable bed can give valuable indications concerning the sediment transportation to be expected in the field. In particular, it permits the determination of the direction of main movement. In the field, however, larger transportation distances are attained in a shorter time, because, in part, the transportation takes place in suspension. In the model experiments, the deposition of the whole of the amount of the radioactive material introduced could be recorded exactly. To date, that is not yet possible in investigations carried out in the field. As, in the only qualitative field investigations, however, the same main transportation directions resulted

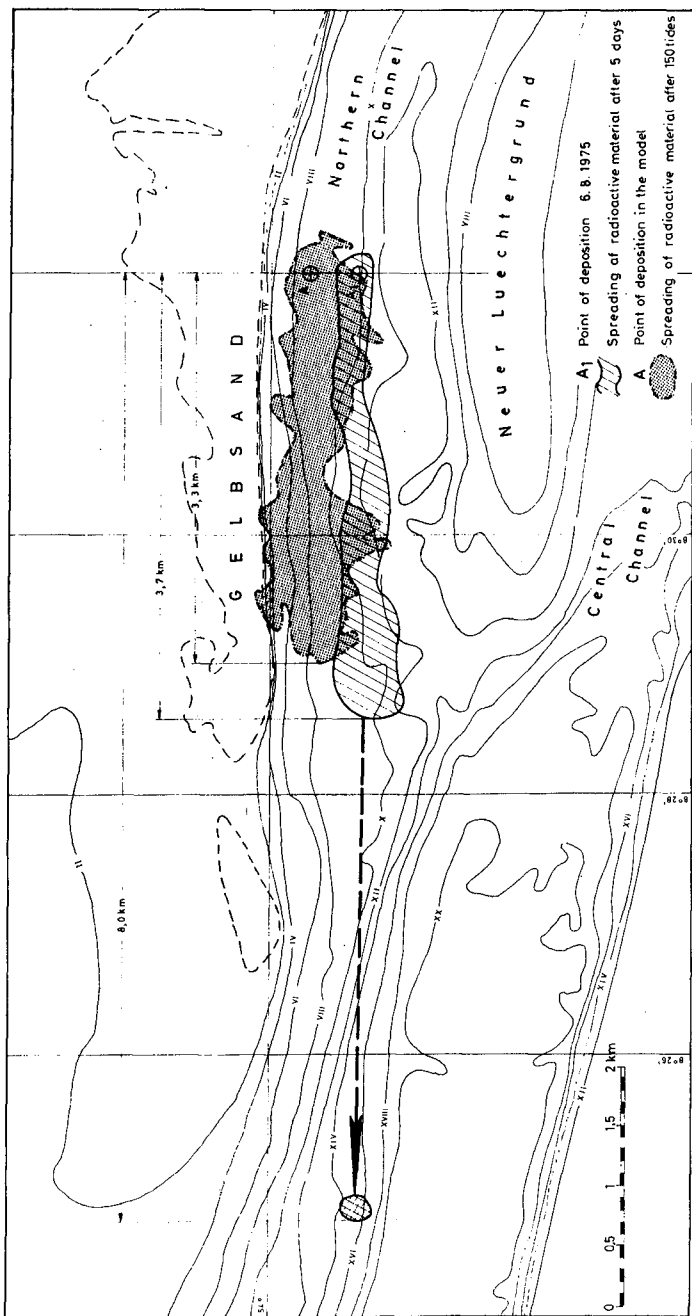

Fig. 10: Comparison of the tracer spreading in the Northern Channel in the model and in the field

as in the model experiment, and as the shape of the distribution curves was also similar, it is to be supposed that thereby an indication is given about the amount transported. In the area in which the higher radioactivity was measured in the field, in spite of the greater possibilities of a mixing and over-enrichment with inactive sands, the heaviest sand transportation is to be expected.

Further comparisons between model experiments and investigations in the field must yet clarify details, especially also the different transportation of the radioactive sand in the field, not only quantitatively but also qualitatively. Such investigations are planned for the future.

CHAPTER 119

MEASUREMENT OF SUSPENDED SEDIMENT IN THE SURF ZONE

F.A. Kilner *

1. Introduction

The sea is an important source of water for cooling and other industrial purposes. From practical considerations, the water is usually drawn from a zone close to the shore, perhaps within one or two kilometres of the shore line through an intake structure such as a tunnel, pipeline or harbour or some combination of these. If the coast is exposed to strong wave action and the local sea bed is of a sandy nature, sediment will be lifted into suspension by the oscillatory motion induced by the waves, and thus any sea water transported to the shore will contain a sediment load.

This sediment content may have an adverse effect on the operation of the intake structure in various ways. If the water velocity is maintained at a high enough value throughout to avoid deposition, then the sand water mixture will tend to abrade the surface with which it is in contact. If however the water velocity is permitted to fall below the deposition value, sediment accumulation will occur which may be intentional as in a settling basin (requiring regular dredging or other removal) or inadvertent as in a pipe conduit (leading to partial blockage of the pipe).

The writer has been associated with two sea water intake schemes, one on the western coast of South Africa, being a cooling water supply for a nuclear power station with a water consumption of about $100 \text{ m}^3/\text{s}$; the other an intake for the recovery plant of a mining company in Namibia, water capacity about $1 \text{ m}^3/\text{s}$. In both cases, information was needed concerning the variation of sediment concentration with distance above the sea bed, this distribution being measured at selected distances from the shore line. This led to a review of available techniques for determining the sediment content of sea water, and thence to development of new procedures and instruments. The details of these developments are presented in this paper.

2. Laboratory measurements of sediment concentration

There are established methods of measuring sediment concentrations in laboratory channels, either directly by withdrawing a sample of water under conditions of minimum disturbance of the local flow, (with subsequent analysis of the withdrawn sample) or indirectly by measuring the optical, electrical or acoustic properties of a localised water volume, the changes in these properties being related to sediment concentration by calibration.

* Associate Professor, Department of Civil Engineering, University of Cape Town, Rondebosch, South Africa.

For example the electro-optical sediment concentration meter, which senses electrically the loss of light transmission due to the presence of sediments, was first described by Hom-ma and his associates in the period 1962 to 1965 [3, 4 and 5] and subsequently further refined and developed by Kennedy and co-workers in the period 1969 to date, [7, 8, 9 and 15]. In 1969 Hattori [6] introduced a sensor system in which the electrical conductivity of a sediment laden zone enabled the number of grains to be effectively counted. Basinski and Lewandowski [13] introduced a radiation sensor which made use of the principle that the concentration of suspended sediment in water is related to the absorption of gamma radiation. Wenzel [14] described acoustic methods of sediment concentration determination in which either the change in acoustic velocity or the extent of sound absorption could be related to the quantity of solids present.

Such inferential methods for assessing the sediment concentration imply that the instrument is sensitive only to the mass of the sediment in the zone explored. However in most cases it appears that other factors may influence the measurement obtained, for example the size and translucency of the particles and even the speed with which they are moving, thus a series of calibrations may be required.

In uni-directional flow, much attention is paid to the withdrawal of sediment laden water at the rate appropriate to the local flow velocity of the water. However, in wave action, where the velocity vector varies in magnitude and direction, it seems practically impossible to synchronise the rate of water withdrawal with the local velocity. In a laboratory of course, there is at least no difficulty in locating the instrument in the desired sampling position.

3. Field measurement of sediment concentration

There are surprisingly few field measurements of this type, although it is here necessary to distinguish between comparative samplers, such as bamboo tubes which give relative concentrations only [2], and quantitative samplers which give an absolute measurement of sand content in (say) ppm (parts per million by mass). In this latter category Watts [1] made a major contribution by measuring sand concentration at a site on the California coast, using a pump-filter-meter system all components of which appeared to be submersible. His measurements were taken at six stations between 100 and 300 m from the shore line (largely in the surf zone) and sampled mainly within 1 m of the sea bed. These tests identified the concentrations as being of the order hundreds to thousands ppm, and as the sand content was retained in the instrument, size distributions of the sediment could be obtained. The field tests were preceded by laboratory experiments to identify the optimum conditions for water withdrawal which appeared to be a vertical nozzle drawing at a high water speed (about 5 m/s); the resulting quantity of water withdrawn was about 200 litres, over about 5 minutes. The equipment required a

power supply, made use of a convenient pier, and the paper concluded with the comment that "no satisfactory operational procedure has been developed for this sampler which would facilitate the procurement of samples other than from a fixed structure".

Fairchild [10] made use of a similar pier mounted sampler, but modified the system in that only the nozzle was submerged, the pump and receiving tank being tractor mounted to make the system more manoeuvrable. He also used a slightly higher intake velocity, greater than 6 m/s, which could have caused some entrainment with the nozzle positioned at its lowest position of 75 mm from the sea bed.

Hom-ma and Horikawa [3] make reference to an instantaneous horizontal sampler (Fujiki type) as used on tests on the coast of Japan, but give no details of how the sampler operated or was positioned.

Jensen and Sorensen [12] described measurements made in the entrance channel to the port of Karachi in water 11 m deep. They used a steel tripod frame resting on the sea bed, with nozzles attached at various elevations, and water samples were lifted by suction to an anchored surface vessel for subsequent concentration determination. The samples appeared small (2 litres at a time) and as the wave heights were less than 3 m, the zone explored was outside the breaker line.

4. Design criteria

The literature review led to tentative specifications for a versatile sediment sampler for determination of offshore concentrations as follows:-

- a) Indirect sampling methods were rejected for use in the sea on the grounds that organic content and small marine organisms could give spurious information. In addition, the calibration of indirect instruments may be affected by the nature of the sediment as distinct from its mass. Direct sampling implies positive withdrawal of a water sediment mixture.
- b) The water volume sampled should be as large as possible (minimum 100 litres) in order to handle as large a sediment quantity as possible (for example 100 litres of water yields only about 10 g of sediment at 100 ppm concentration). This sampling will take several minutes.
- c) Following from (b) above, the sediment must be extracted and the water rejected (returned to the sea) otherwise the storage capacity required for the instrument would be excessive. This procedure has the added advantage that the sediment load may be examined in detail.

- d) As far as possible, a field test should not involve personnel in or on the sea, otherwise zones of particular interest, such as a breaker line, and occasions of particular interest, such as a period of unusually strong wave action, may in themselves inhibit sampling activity.

5. Pneumatic samplers

From the outset, it was decided to use pneumatic power for any sampler design, based on the ready availability of portable vacuum and compressor equipment.

An elementary form of sampler was used initially, employing commercially available preserving jars, of 2 litre capacity, which are able to withstand a total internal vacuum. When equipped with a modified screw lid, containing a quick release manual valve, it could be used as a hand held sampler, suitable for relatively high concentrations in wading depths. Auxiliary equipment consisted of a portable generator and vacuum pump, which enabled as many bottles as desired to be vacuumised on the beach: when opened under water, a pressure head of about 10 metres is available immediately to fill the bottle, a process which takes about 2 seconds. Although only accurate when concentrations are of the order thousands of ppm, this procedure remains convenient for work close inshore.

For deeper water two compressed air samplers have been designed to fulfill the criteria outlined in paragraph 4, both using conventional 7 litre, 200 atmosphere compressed air cylinders for power supply. Sampler I has been in use for some months, and has proved effective, but requires a helicopter to insert and retrieve it. Sampler II is under development, and attempts to avoid a support vehicle entirely, rather making use of an offshore anchor.

The basic operational component of both these samplers consists of a compressed air cylinder connected to an air motor through a trigger valve. In sampler I this valve is actuated by water inflow into a compartment when the sampler is resting on the sea bed. The air motor has a common shaft with a centrifugal pump which draws sea water through an inlet tube positioned at the desired sampling height above the sea bed. The pump drives the water sample through a water filter and meter and back to the sea. The air cylinder capacity is such that the quantity of water sampled is about 100 litres and takes about 5 minutes to flow through the instrument, although the quantity could be increased easily by using higher pressure cylinders. The complete unit is weighted by a base plate, which also has three radial support arms to permit the sampler to remain stably on the sea bed under wave action. The function of the helicopter is restricted to lifting the prepared sampler off the beach, transporting it to the desired offshore station, lowering it into the water until slack rope indicates the device is on the sea bed, and

then hovering until the sampling is complete, when the sampler is lifted clear of the water and returned to the beach. Once onshore, the empty cylinder is replaced, the water meter reading is taken as a measure of sample size, the nylon mesh filter is removed and replaced, and the process repeated. If desired, the position of the inlet pipe may also be changed. The cycle time for one reading is of the order of 15 minutes, but the strain on the helicopter pilot is considerable, and in practice not more than eight readings have been taken in one day.

Sampler II is designed to avoid the use of the helicopter, which is replaced in effect by an endless rope between the shore line and a heavy offshore anchor, the sampler being attached to the rope and in this way moved into desired station. In this development the sampler is basically buoyant, but when in position an air chamber is flooded by radio signal from the shore, causing the sampler to sink into position and initiate the sample pumping as described above. By means of time switches the air chamber is blown free of water at the end of sampling, the device surfaces and is pulled back to shore again.

The figures and photographs on following pages show the two compressed air samplers in outline and under operating conditions.

6. Conclusion

Subject to the successful operation of sampler II, surf zone sampling may now be accomplished by a shore-based party subject only to the retention of an offshore anchor buoy and sheave to accommodate an endless rope link to the shore. This permits sampling under any conditions of wave action. For isolated samples required from different areas, the helicopter may still be useful for sampler positioning.

Measurements of sediment concentration have been obtained inside and just outside the surf zone under local wave heights up to about 6 metres. Viewed from a helicopter under these conditions, the magnitude of vorticity about a vertical axis occurring naturally appears to outweigh the local vorticity generated by the presence of the instrument, thus it is assumed that the sediment measurement is not being exaggerated by the presence of the device. Further support for this view is not possible, as it is believed that this is the first time sampling has been achieved at all under these wave conditions, and thus comparative measurements are not available. However, very broadly the concentration magnitudes obtained in the present series of tests seem rather low when compared with tests conducted from fixed pier platforms.

7. Acknowledgements

The author is indebted to Mr Neil Heidstra, a postgraduate student, who contributed significantly to the development and field trials of the instruments described in the paper. Generous financial support for this research programme was received from the Electricity Supply Commission of South Africa for which the author expresses appreciation.

CHAPTER 120

IOWA SEDIMENT CONCENTRATION MEASURING SYSTEM

by

Tatsuaki Nakato⁽¹⁾, Frederick A. Locher⁽²⁾,
John R. Glover⁽¹⁾, and John F. Kennedy⁽³⁾,

I. INTRODUCTION

The Iowa Sediment Concentration Measuring System (ISCMS) is an electro-optical instrument developed in 1969 (Glover, Bhattacharya, and Kennedy 1969) for measurement of suspended solid concentrations in unsteady solid-liquid flows. It has been used extensively in laboratory investigations to determine spatial and temporal variations of sediment concentration in a variety of steady, unsteady, uniform, and nonuniform flows (Bhattacharya 1971; Danushkodi 1974). Concurrent measurements of concentration and velocity fluctuations have been used together to obtain estimates of mass transfers in unsteady sediment-laden flows, with the goal of improving the understanding of the underlying mechanisms responsible for sediment entrainment and suspension (Nakato 1974). Interpretation of the data gathered in these experiments pointed out the need for a more thorough understanding of how the optical and electronic components of the ISCMS respond to the passage of individual sediment particles through the optical field of the transducer (Locher *et al.* 1974). An investigation was undertaken to determine the sensitivity of the ISCMS output to the position of a particle in the transducer field; the role of particle velocity in determining the ISCMS output; the effects of particle translucency and size on the output of the system; and the dependency of mean concentration estimates on integration time.

II. THE ISCMS PROBE FIELD

The transducer consists of a 1.55-mm diameter light source (P-N gallium arsenide, type TIL 24) and sensor (NPN planar silicon phototransistor, type TIL 604) separated by a distance of about 3.2 mm with their optical axes co-aligned, as shown in figure 1. Light from the source is attenuated by particles in the probe's optical field and the modulated light signal is transduced to an output voltage by the sensor and electronic circuits. Calculation of the average number of particles present in the transducer field in some wave-induced sediment entrainment studies at The University of Iowa demonstrated that often only one or two particles are present in the field, and highlighted the importance of knowing the effects of particle position and residence time in the space between the source and sensor on the system output.

Figure 1. The ISCMS probe.

To investigate the ISCMS sensitivity to particle position, "artificial particles" were made by spattering India ink on a glass slide and then selecting several ink spots with the desired size and shape for detailed investigation. This approach was adopted because there is no means of supporting single glass bead or sand particle within the probe field without introducing additional refraction of the light. The slide with simulated particles was mounted on a microscope traversing mechanism, the ink spots were positioned at various locations along the optical axis of the source-sensor pair, and the corresponding ISCMS outputs were monitored. The results of tests with circular spots with diameters of 0.38, 0.25, and 0.12 mm are summarized in figure 2, in which the system output voltage normalized by the voltage obtained with the particle adjacent to the sensor is plotted versus spot distance from the sensor. It is seen that the ISCMS output voltage initially rises sharply with increasing distance, obtains a peak value at about 1.0 mm from the sensor, and then trails off monotonically until the spot is adjacent to the source where the output is only 50-60 percent as great as when it is adjacent to the sensor. In other words, the ISCMS response is strongly dependent on the position of the particle when traversed on the optical axis within the transducer field.

Tests also were conducted to ascertain the effect of the radial position of a "particle" in the probe field on the system response. These were realized by traversing a spot radially across the probe field in planes that were perpendicular to the optical axes and located at various distances from the sensor. The typical set of results shown in figure 3 depicts the variation in the ISCMS response as the 0.38 mm spot was traversed radially at several sections between the source and sensor. Note that the ISCMS output voltage for each location was normalized with the reading obtained with the particle adjacent to the sensor. These results show that the ISCMS output voltage varies continuously as the particle is moved radially through the optical field. It was found that the diameters of circular cylinders within which the normalized voltage is larger than approximately 0.5 are 0.6 and 1.0 mm for the 0.25 and 0.38 mm particles, respectively. The physical diameter of the source and sensor is 1.55 mm; therefore a substantial portion of the cross-sectional area of the probe field is not highly effective in sensing the particle.

Figure 2. Variation of the ISCMS output for three "artificial particles" traversed along the optical axis of the transducer.

Figure 3. Variation of the ISCMS output along the radial axis of the transducer for the 0.38 mm "artificial particle".

The effects of particle velocity on the ISCMS response were investigated by passing a field of simulated particles through the transducer's sensing volume at different speeds. The "particle field" consisted of 120 0.127-mm diameter drilled holes equally spaced around the periphery of an 8.89-cm diameter circle on a lucite disk. The disk was rotated at various angular speeds about the center of the particle circle, with the simulated particles crossing the optical axis of the source-sensor pair. The rms of the ISCMS output voltage was recorded for several different angular speeds of the disk. The rms output voltages were normalized by the rms voltage obtained at a frequency of 100 particles per second or less; the results from several repetitions are plotted on figure 4. It is seen that there is no attenuation of the amplitude of the ISCMS voltage for frequencies under 100 Hz, but at higher speeds the signal is progressively diminished. This indicates that the upper limit of particle speed for which the instrument is able to measure the concentration corresponding to the passage of an individual particle through the transducer's field is approximately 23 cm/s. However, at a particle speed of 46 cm/s, the normalized rms voltage of the ISCMS output was reduced by only about 8 percent.

III. EVALUATION OF MEAN CONCENTRATION OF SUSPENDED SEDIMENT

To evaluate the effects of particle translucency on the ISCMS output, mean sediment concentrations were measured in suspensions of three different sediments: two quartz sands and crushed walnut shells with median diameters of 0.14, 0.25, and 0.20 mm, respectively. The specific weights of the two materials were 2.65 and 1.33 g/cm³. These tests were conducted in a turbulence jar, in which each sediment was held in suspension in water by means of vertically oscillating grids. During calibrations, samples were withdrawn to obtain reference values of concentration, and the ISCMS output was recorded with the probe at several different elevations. The test results are plotted in figure 5 with $\Delta V/V_0$ presented as a function of $\bar{C}/\gamma D$, where ΔV is the net ISCMS output voltage; V_0 is the output voltage with the light sensor shielded from the source light (approximately 12 volts); \bar{C} is the measured mean concentration in ppm; D is the median diameter of the sediment; and γ is the specific weight of the sediment. It is seen in figure 5 that the calibration curves for the three samples are linear, and the data from the two quartz sands plot almost congruently. However, the slope of the calibration curve for the walnut shells is much larger than that for the quartz sands. This difference was attributed to variations in the opaqueness of the two materials. The walnut shells are less translucent than the quartz sand, and therefore produce stronger attenuation of the transmitted light and larger ISCMS output voltages. During the calibration, photographs of the ISCMS signals for each sample were obtained and their signal characteristics were compared. The results showed that there are far more voltage readings below the zero reference for the quartz sands than for the walnut shells. This effect is the results of light being reflected off the surface of the quartz particles into the sensor as the particle enters or leaves the probe field. The crushed walnut-shell surface does not reflect light as well as the quartz sand, and therefore drops below the reference voltage level were not so prominent. These negative voltages indicate light intensities above the ambient light

Figure 4. Attenuation of rms voltage as a function of particle frequency (rotating disk test).

Figure 5. Calibration curve expressing $\Delta V/V_0$ as a function of $\bar{C}/\gamma D$ for quartz sand and walnut shells.

level with no particle in the probe field; therefore these negative voltages have to be discarded through a single polarity integrator in the instrument. The principal conclusion from this phase of the investigation was that the ISCMS must be calibrated for each different sediment material.

Tests to ascertain the sensitivity of the ISCMS to particle diameter also were conducted in the turbulence jar using four different glass beads with median diameters of 0.029, 0.062, 0.100, and 0.200 mm. Calibration data for the four samples are plotted in figure 6. The calibration curves are seen to be linear over the range of concentrations tested: 400 to 16,000 ppm. However, the slopes of the calibration curves are dependent on the diameter, with values of 3.62, 4.87, 7.96, and 12.35 ppm/mV, for the 0.029, 0.062, 0.100, and 0.200 mm beads, respectively. This dependency of calibration-curve slope on particle diameter can be explained as follows. For a fixed concentration, the number of particle present in the sensing volume of the probe increases with reduction in particle diameter. In the case of the finer sediments, some particles hide in the shadows of others, and are not detected by the light sensor. Therefore, at high concentrations the actual particle concentration in the probe field is higher than that indicated by the output.

Tests also were conducted in the turbulence jar to determine the effect of integration time on the measured estimate of mean sediment concentration for the two quartz sands and the walnut shells described above. A series of 200 sequential 10-sec averages of the ISCMS output voltage were obtained for each of these sediments at low, medium, and high mean concentrations ranging from 360 to 11,000 ppm. Successive 10-sec averages were combined to form sets of 20-sec and 50-sec averages, and the effects of averaging time of the confidence intervals of the mean concentration estimates were examined. It was found that increasing the averaging time above 10-sec does not have an appreciable effect on the confidence interval of the mean-concentration estimates. Similar tests also were made in the Iowa Oscillatory-Flow Water Tunnel (Nakato 1974; Locher *et al.* 1974). In these tests a signal-averaging technique (Trimble 1968) was employed to decompose the analog concentration signal into its mean, periodic, and random components. Although the ISCMS response is dependent on the position of the sediment particle in the probe's sensing volume, for a completely random sediment motion the trajectories along which the particles traverse the field tend to be uniformly distributed over the sensing volume. Therefore, the effect of particle position on probe response described above averages out over time, and the signal-averaged measurements of $\bar{C} + C_p$, where \bar{C} and C_p are respectively, the mean and periodic components of the sediment concentration, were judged to be accurate. The period of the oscillatory fluid motion, T , over the 0.14 mm quartz sand bed was 1.8 sec, and the piston stroke was 15.2 cm. The ripples produced on the bed had a mean wavelength of 8.5 cm and a mean height of 1.2 cm. With the probe over the ripple crest, data from 200 wave cycles were obtained, with a sampling interval of 18 milliseconds, and analyzed in groups of 20, 50, and 100 wave cycles. The value of \bar{C} for the data from 200 wave cycles was 3,094 ppm, while the mean concentrations for the data from the first and second 100 cycles were 3,096 and 3,092 ppm, respectively. The values of $\bar{C} + C_p$

Figure 6. Calibration curve expressing $\Delta V/V_0$ as a function of \bar{C}/D for glass beads.

Figure 7. Comparison of estimates of $\bar{C} + C_p$ with 100- and 200-cycle wave data.

calculated from the set of 200-cycle data and the first 100-cycle data are plotted in figure 7. It is seen that there is not much difference in the estimates of $\bar{C} + C_p$ between two sets of data. However, the mean concentrations as well as the periodic components C_p obtained from the sets of 50- and 20-cycle data varied somewhat from that yielded by the 100-cycle data sets. The variations in the \bar{C} estimates were found to be between 2,867 ppm and 3,317 ppm, and 2,746 ppm and 3,521 ppm for the 50- and 20-cycle data, respectively. The plots of \bar{C} and C_p values from the 50- and 20-cycle data also were found to scatter much more widely than those of 100-cycle data. It was concluded, therefore, that at least 100 wave cycles of data are necessary to obtain meaningful estimates of the mean and periodic components of sediment concentration in the suspended sediment field produced by oscillatory motion over a rippled sand bed investigated in this study.

IV. SUMMARY OF RESULTS

The principal results of this investigation may be summarized as follows:

1. The ISCMS response to the single particle depends strongly on the particle position within the probe field. Therefore, the instantaneous output voltage of the ISCMS cannot be correlated with the instantaneous suspended sediment concentration within the probe position.
2. The frequency response of the instrument limits the use of the ISCMS to flows with mean velocities less than approximately 23 cm/s. At a particle velocity of 46 cm/s the rms output is down approximately 8 percent.
3. The ISCMS output voltage varies linearly with mean sediment concentration. However a separate calibration must be obtained for each sediment.
4. An integration time of at least 10 seconds is necessary to obtain reliable estimates of mean sediment concentration when calibrating the ISCMS probe in a turbulent jar. This appears to be a reasonable lower time limit also when the ISCMS is used in steady uniform flows.
5. Approximately 100-cycle wave data are sufficient to obtain quantitative estimates of $\bar{C} + C_p$ in the oscillatory flume used in the present study.

CHAPTER 121

FACTORS INFLUENCING ESTUARY SEDIMENT DISTRIBUTION

by
Mary P. Kendrick¹ and B. V. Derbyshire²

Introduction

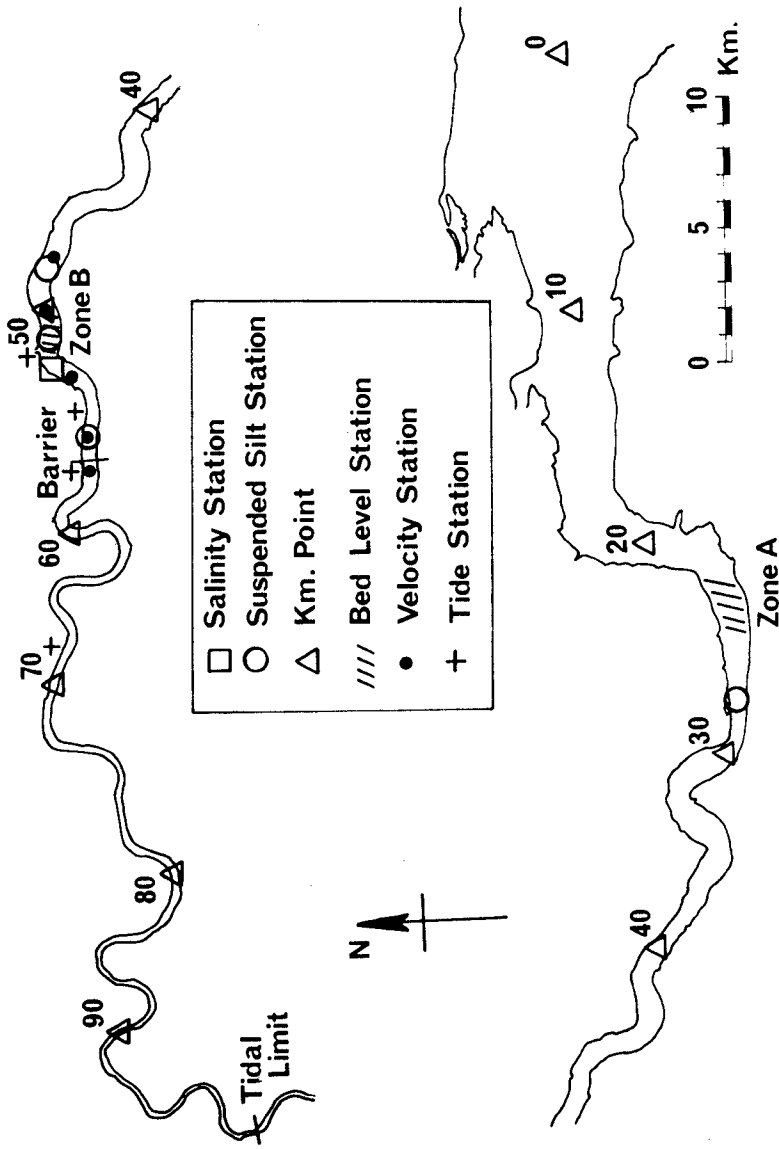

Many factors combine to determine the way in which sediments are distributed throughout an estuary.

Most fundamental are those which produce the natural rhythm of diurnal (or semi-diurnal), bi-monthly and seasonal fluctuations due to predictable variations in tide and weather. This group includes tidal discharge, fresh river flow and the resultant distribution of saline water. When considered together with such factors as the availability and properties of sediments within and beyond the landward and seaward limits of an estuary, they determine how the available material shall be eroded, transported and deposited during the course of the natural cycle.

Superimposed on these regular fluctuations are the effects of other factors which may or may not be predictable, are not necessarily regular in occurrence and may be either natural or man-made.

These include secular trends, such as long-term adjustments in land/sea levels or climatic conditions, which have a small but continuing effect on some of the factors in the first group. They also include sudden, short-term events like earthquakes or hurricanes which impose a shock to the system that may involve the movement of large quantities of material during the subsequent period of readjustment. Sometimes the influence of this group

Oxon, England.

KEY PLAN OF ESTUARY

Fig. 1.

of factors on sediment movement is indirect in that they necessitate the implementation of civil engineering works which, in turn, lead to a redistribution of sediment.

Finally, and most familiar to the coastal engineer, are those factors which create the recurring practical problems confronting him as estuaries are developed more and more intensively to meet the demands of modern industrial society - the construction of new jetties and container berths, channel dredging and training for navigation, sand and gravel winning for industry, the commissioning of water-cooled power stations, the discharge of sewage and industrial effluents, the control of water supply and tidal discharge by hydraulic structures, etc. Such developments usually affect the prevailing distribution of sediment in some way.

The tidal Thames in England (Fig 1) exemplifies a relatively well-documented estuary which for many years has been studied in the field, on physical and mathematical models and through laboratory tests on sediment. Using some of the results of these studies, the authors attempt to demonstrate how the above-mentioned factors interact: (a) in the short-term throughout a single tide, (b) during the slightly longer course of the bi-monthly spring-to-neap cycle, (c) as a result of annual seasonal variations and (d) in the longer term over a period of 30 years or more. Finally the paper illustrates the impact that civil engineering works can have on an estuary whose prevailing sediment distribution is already the result of the combined effect of the factors previously discussed.

Diurnal (or semi-diurnal) effects

Fig 2 depicts events on one (semi-diurnal) spring tide over an 8 km stretch of estuary (Fig 1).

The tidal range, which was 5.53 m at km point 0 (the mouth) about 50 km away, is amplified to 6 m (a), the

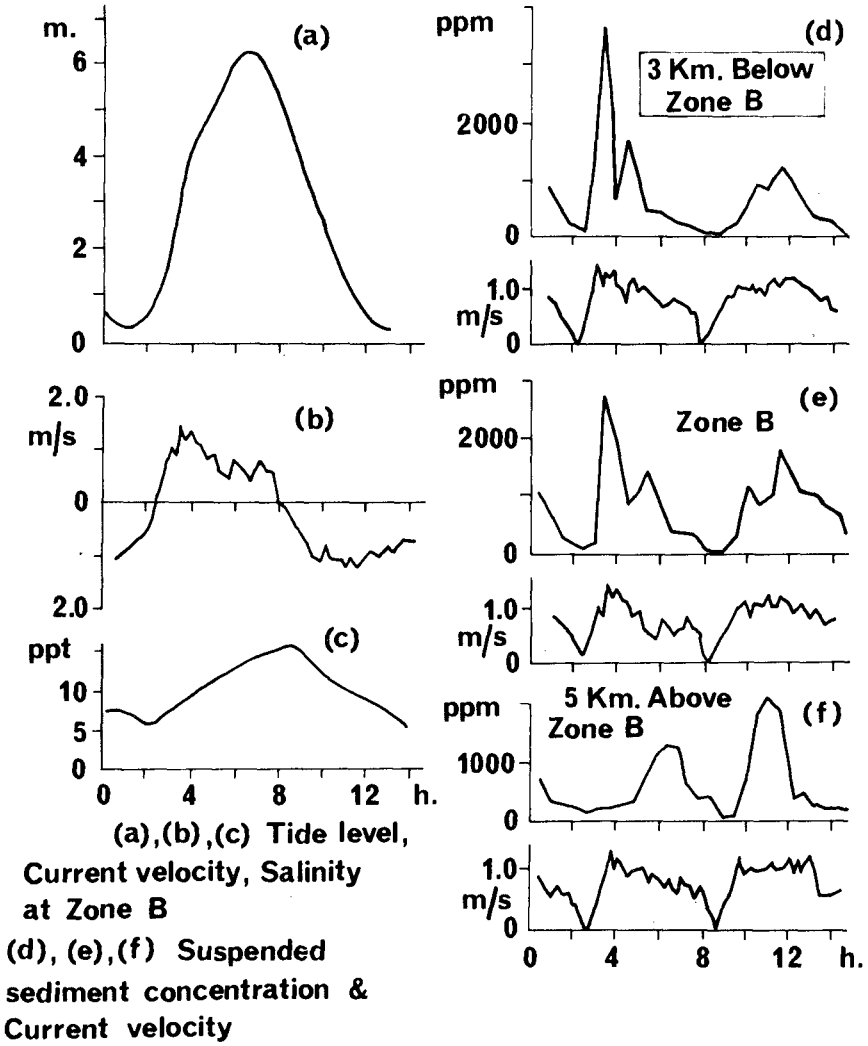

Fig. 2. SEMI-DIURNAL FLUCTUATION IN FACTORS AFFECTING SEDIMENT DISTRIBUTION

slightly shorter flood period giving marginally higher maximum current velocities on the flood than on the ebb (b). The vertically well-mixed conditions produce a rise in salinity of 10 parts per thousand at all depths from slack low tide to slack high tide (c). Because of the difficulties inherent in attempting direct measurement of changes in the level of the surface of a silty bed throughout a tide, measurements of variations in both the concentration of suspended sediment and current velocity at a number of depths at selected stations are used to infer how material is eroded, transported and deposited in a given reach of the estuary.

The records shown on (d), (e) and (f), 1.5 m above the bed, typify the pattern of changes occurring throughout the lower 3 m of flow.

On the flood tide, material at the station 3 km seawards of Zone B (d) is entrained as soon as the critical shear for erosion is reached. The fact that the subsequent sharp decline in sediment concentration is not accompanied by a significant decrease in current velocity suggests that the material passes from the site up the estuary. Some of it deposits before arriving at Zone B, probably in the lee of bends, where flow is slow. If this were not the case, the concentration-time curve at Zone B would provide evidence of its arrival there. Instead, graph (e) shows that conditions at this site are similar to those shown on graph (d), sediment entrainment occurring early on the flood tide followed by a reduction in concentration as material moves away up-estuary.

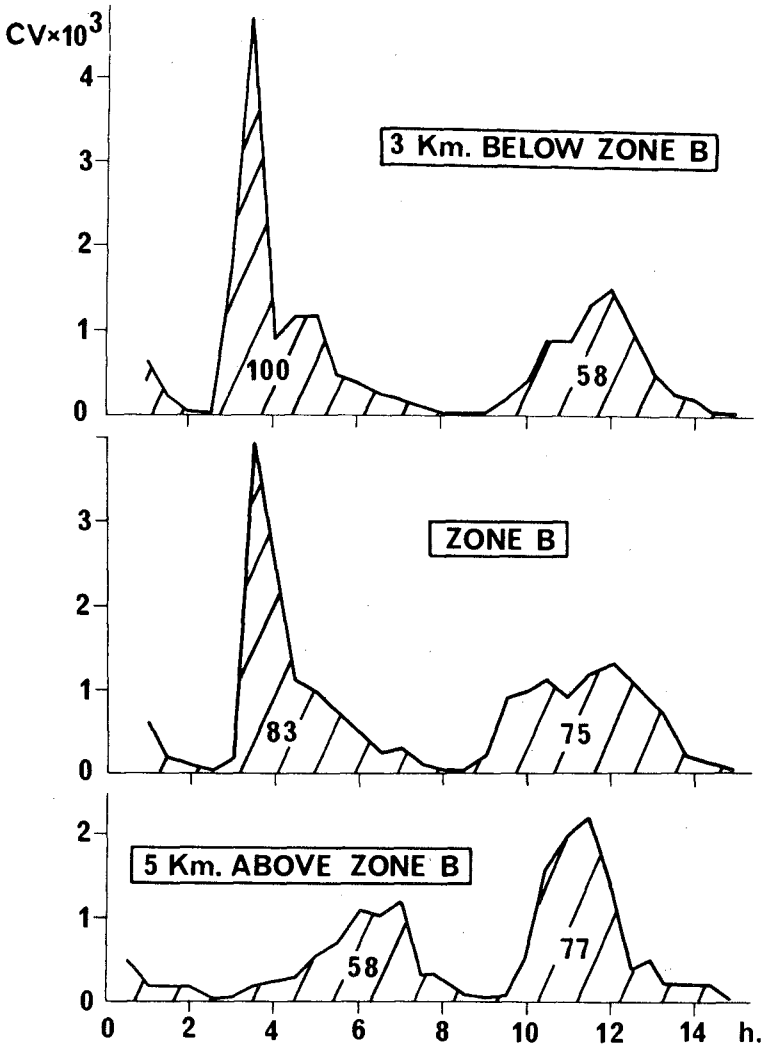

A second, smaller concentration peak occurs at both stations and, assuming that suspended sediment travels at the speed of the water transporting it, the evidence suggests that this material was eroded from the bed at a position more than 3 km below Zone B, passed through the lower

silt station, deposited some of its load on the bed between there and the second station and passed on up the estuary.

At the third station, 5 km above Zone B (f), events are quite different. The suspended sediment concentration remains low even when the current velocity has exceeded 1 m/s, indicating little or no erosion of the bed locally. It is not until between 3 and 4 hours after low water that material arrives from further down the estuary, and the timing suggests that this could have originated at, and upstream of, Zone B. Some of this sediment passes on for a short distance before settling on the bed, the remainder deposits at the station due to the decrease in current velocity associated with the arrival of slack high tide.

On the ebb, concentrations at this station soon exceed 2000 ppm as the deposited sediment is re-entrained, and clearly more sediment passes down the estuary at this point than passed up on the preceding flood tide. The velocity-time curve shows that the sediment is transported seawards, concentrations remaining low for the rest of the ebb tide. At Zone B, conditions at the start of the ebb are similar, material being eroded from the bed as soon as the critical shear is reached. This moves away down-estuary, but halfway through the ebb tide the concentration-time curve (e), peaks suddenly, and this rise coincides with the arrival time of the suspended sediment which created the concentration peak at the station 5 km up-estuary. From this point until slack low water, the concentration at Zone B falls as current velocity falls, material depositing at and below the site.

At the third station 3 km seaward, sediment concentration rises and falls gradually as ebb current velocity increases and decreases (d), reaching only half the maximum value recorded at the other two stations - a further indication of deposition on the bed between here and Zone B.

C = Concentration (ppm) V = Velocity (m/s)

Fig. 3. SEMI-DIURNAL FLUCTUATION IN SEDIMENT FLUX

The data in (d), (e) and (f) are re-plotted on Fig 3 as sediment-flux curves for each of the three stations. These graphs illustrate more clearly the longitudinal sediment redistribution in the study area already inferred from the raw data on Fig 2 since the areas under the curves represent the quantity of sediment per unit area passing each station on each half tide.

To facilitate comparison, the flood tide sediment flux at the seaward station is regarded as 100 units. With this as the reference, Fig 3 demonstrates that within the 8 km of estuary used in the example, the amount of sediment deposited on the bed during the flood tide is more than twice that deposited on the ebb. Furthermore, whereas flood tide deposition is distributed relatively evenly both above and below Zone B, most of the ebb tide deposition occurs at Zone B and seawards. (Clearly the greater the number of measuring points per river section, the more reliable will be the result.)

Bi-monthly (spring-to-neap) effects

Figs 2 and 3 shew how sediment can be redistributed during the course of a single tide under a condition of low river flow. Fig 4 demonstrates the slightly longer-term variations that can occur during the bi-monthly spring-to-neap cycle, employing data collected near to Zone A and Zone B (Fig 1), two areas respectively 25 km and 50 km above the estuary mouth. The data are plotted both for summer (low river flow) and winter (high river flow) conditions. Graph (a) shews the cyclic variation in tidal range and indicates that tidal currents in both summer and winter must be similar since tidal ranges are similar. (River flow has negligible effect on currents at the monitoring stations.) (b) shews the steady, low summer river flow and the fluctuating, higher winter river flow. (c) and (d) shew the bi-monthly variation in mean suspended sediment concentration on both flood and ebb tides.

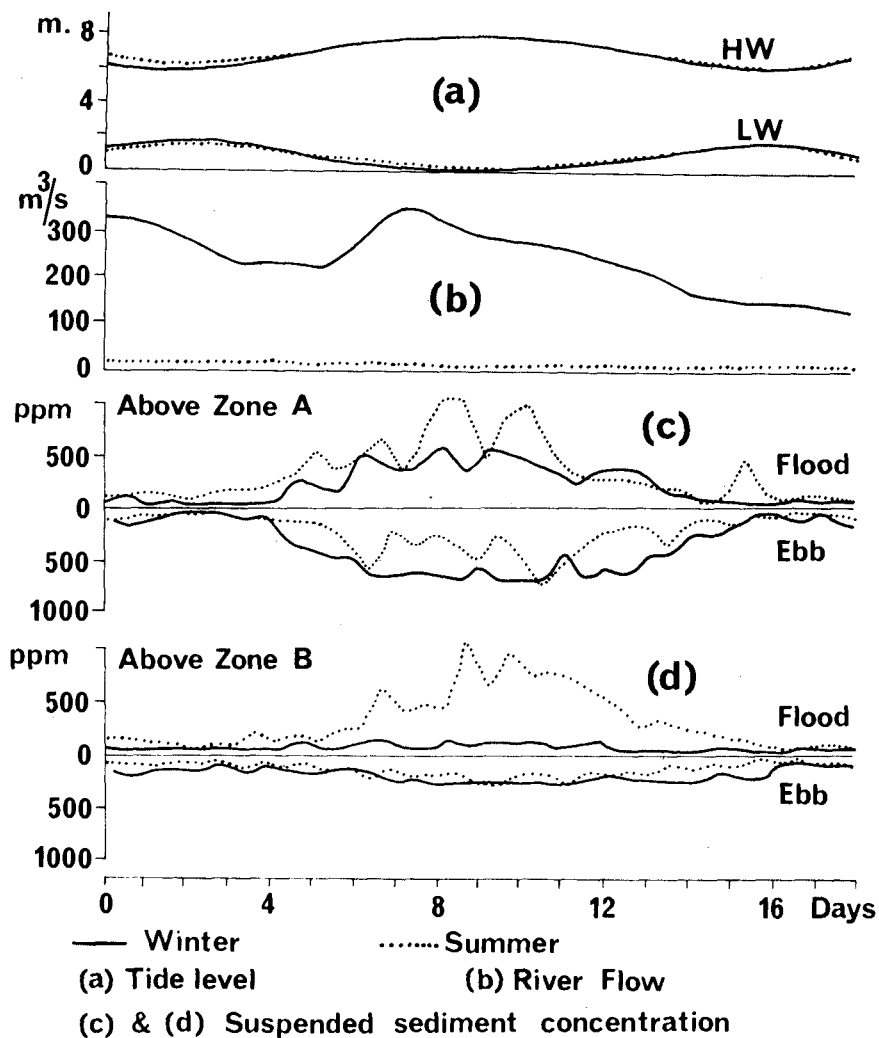

Fig. 4. BI-MONTHLY FLUCTUATION IN FACTORS AFFECTING SEDIMENT DISTRIBUTION

The most significant fact to emerge is that sediment concentration increases and decreases with tidal range, remaining low throughout the period of neap tides and increasing as the range exceeds the mean value. Significant sediment movement is therefore largely confined to spring tides.

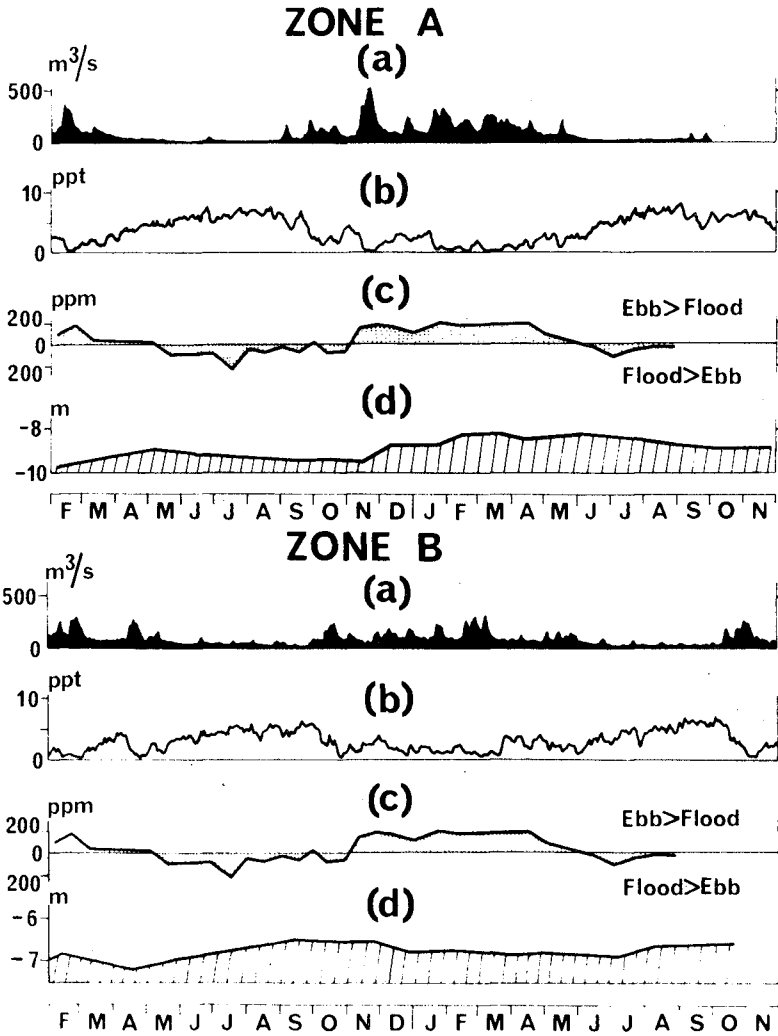

In the summer, spring tide concentrations are higher on the flood than on the ebb at the 2 stations just above Zone A and Zone B, suggesting a net landward movement of material up the estuary during this period. However, flood tide values are similar at the 2 stations indicating no net accretion of the bed between the sites. The transported material must therefore deposit further up the estuary. On the ebb, values are higher near Zone A than near Zone B indicating erosion of the bed between the stations.

In the winter the converse is true. Spring tide concentrations are higher on the ebb than on the flood at both stations, implying net deposition seaward of the lower station (from bed level data this in fact occurs at Zone A). However, at this time of the year both flood and ebb values are much greater near Zone A than Zone B, indicating considerable sediment movement, with deposition occurring between the two sites on the flood and erosion occurring on the ebb.

Annual seasonal effects

Continuing the study by extending the time-scale of cyclic variations from 2 weeks to 2 years, Fig 5 shows the relationship between fresh river flow, water salinity, concentration of suspended sediment and river bed level at Zone A and Zone B. The location of study zones and monitoring stations is given on Fig 1.

The significant feature is that for a given 2-year pattern of variations in river flow, salinity and suspended sediment concentration, bed levels in the two areas react in diametrically opposite ways.

(a) River flow (b) Salinity (c) Suspended sediment concentration (d) Bed level relative to Chart Datum

Fig. 5. SEASONAL FLUCTUATION IN FACTORS AFFECTING SEDIMENT DISTRIBUTION

High river flow (October-April), the consequent low salinity and the subsequent ebb-predominant, suspended sediment concentration result in accretion of the bed at Zone A. On the other hand, a similar combination of factors produces erosion of the bed at Zone B. Low river flow (May-September), the consequent high salinity and the subsequent flood-predominant, suspended sediment concentration result in erosion of the bed at Zone A whilst at Zone B, the result is accretion.

Clearly, material is redistributed seasonally along the estuary, the reduction in salinity associated with a prolonged period of high river flow leading to the release (through a reduction in cation bonding) of deposits at Zone B for transportation down-estuary. Conversely, during the period of low river discharge, the prevailing net landward movement of water and sediment in the lower layers of flow in the seaward reaches results in the gradual up-river transport of sediment.

Effects of secular trends

So far, the paper has described only those regular, largely predictable variations in natural phenomena which affect estuary sediment distribution. It now considers other, less regular, less predictable factors whose continuing effects, though small, can be of considerable significance when superimposed on existing regular fluctuations. The long-term land/sea level adjustment taking place in the southern North Sea provides a useful example.

Following an examination of 50 years of daily records of tide level, salinity and river flow, the authors confirm earlier findings (Ref 1, Ref 2) that mean tide level at the mouth of the Thames and tidal amplitude 70 km up-estuary have risen significantly during this century. In addition they shew this to be accompanied by a rising trend in saline penetration and a falling trend in river flow. Fig 6

Fig. 6. SECULAR TREND IN FACTORS AFFECTING SEDIMENT DISTRIBUTION

Fig. 7. RESPONSE OF BED LEVELS TO SECULAR TRENDS

illustrates this in the form of 15-year running means for all three parameters for the period 1920-1950.

The relative dependence of saline penetration on tidal range and river flow is currently being investigated. However, for present purposes, the significant fact is that for a period of at least 30 years, the main hydraulic factors controlling sediment movement themselves underwent a gradual change in a constant direction. The net effect on sediment distribution was to increase the thickness of the deposits on the estuary bed in the reaches immediately landward of the major deposition zone of the estuary - Zone B. Civil engineering works, including continuous channel maintenance dredging, masked this effect to some extent during the major part of the period, but when dredging was reduced, the readjustment of the estuary sediment distribution to the changing situation was rapid.

This effect is demonstrated by Fig 7, which shows changes in mean bed level (derived from soundings at approximately 30-m intervals on sections 175 m apart) between 1923 and 1971 for a 4-km - long reach located 3 km above Zone B. Annual dredging during the period of continuous channel maintenance is taken to be 100 units.

Effects of civil engineering works

Up to this point, the paper has been largely confined to a consideration of the interaction of those factors which affect estuary sediment distribution before they have been modified in any way by man's intervention. The authors now go a step further and examine what can happen to the sediment distribution when development schemes are carried out which modify the influence of those factors.

Two examples are cited - one familiar, the other perhaps less so. The first, jetty construction, usually affects only the local area but can be costly in terms of economic efficiency if badly located and ill-designed, as

Fig. 8. EFFECT OF JETTY CONSTRUCTION ON SEDIMENT DISTRIBUTION

was often the case in the past and unfortunately still happens today.

Fig 8 demonstrates the response of bed levels in the Thames to the construction and extension of jetties about 35 km above the mouth. The bankside accretion which occurred between 1873 and 1957 following the building of the first jetty (Section A-A') amounted to a riverward movement of the low tide mark of about 80 m. This was relatively local in effect, not extending as far down-estuary as Section B-B' where the bankline had remained as before. However, once a jetty was built at B-B' and associated front face dredging carried out, bankside deposition began there also, and in 2 years (1966-1968) the bankline advanced about 50 m. Meanwhile, back at A-A', an extension into deeper water had been added in 1959 and dredging also undertaken along the front face. Deposition continued - at a reducing rate behind the original 1873 construction, but at a higher rate between it and the new extension.

Why did this deposition occur? Prior to jetty construction sediment was carried into the area on the flood tide, deposited round about slack high water, re-entrained on the ebb and transported seawards. A long-term balance was therefore maintained and bed levels near the side of the estuary changed very little from year to year. Jetty construction had the effect of marginally reducing current velocities near the bank and thus providing a longer period for deposition at high water. Furthermore the ebb current was less efficient in re-entraining sediment and so the former balance between deposition and scour was no longer maintained.

The civil engineering undertaking used as the second example of how such works modify the influence of the hydraulic factors responsible for estuary sediment distribution is tide control (Ref 3). It is more ambitious than

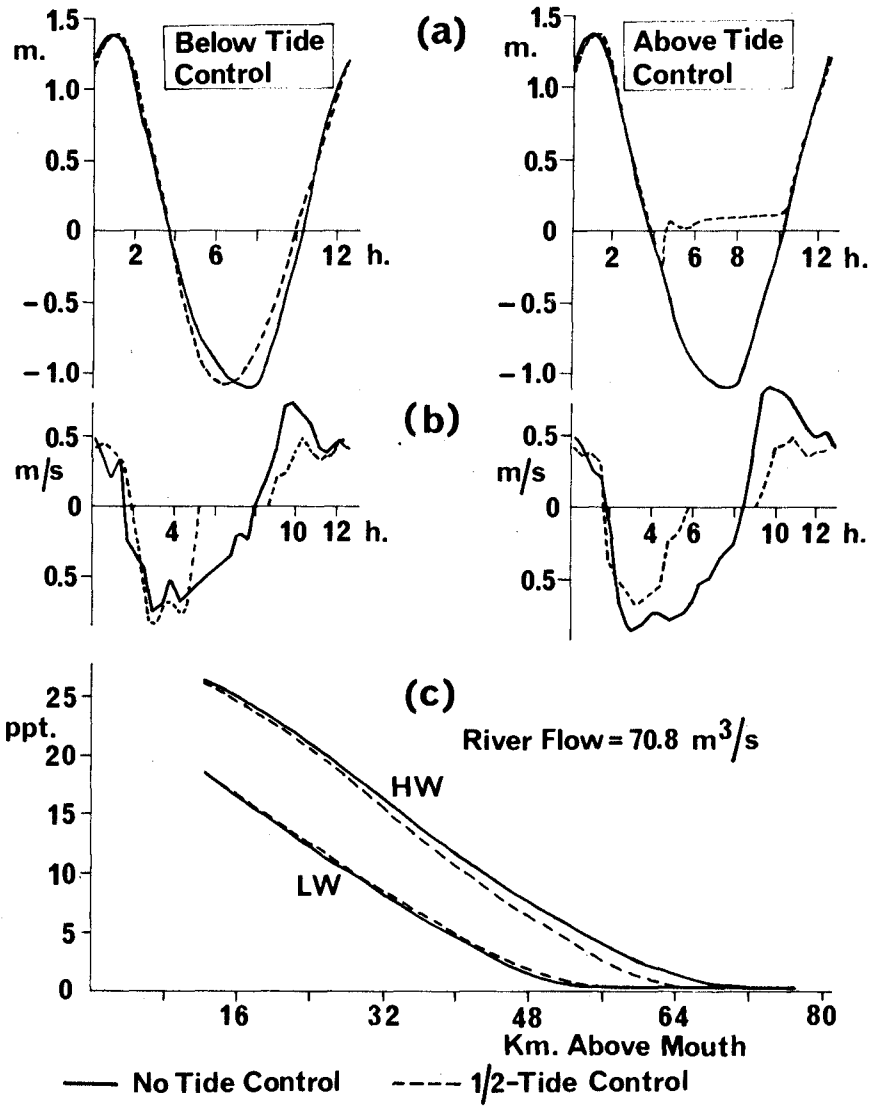

Fig. 9. EFFECT OF TIDE CONTROL ON WATER MOVEMENT

jetty construction, has more far-reaching effects and is therefore much less likely to be carried out without prior investigation into its likely impact on the estuary environment.

Physical and mathematical model studies of various forms of tide control have been made at Wallingford. Using physical model results, Fig 9 shows the effect on water movement of one form - half-tide control by a gated barrier located 55 km above the estuary mouth. The way the system operates is for the gates to be shut halfway through every ebb tide, remain closed throughout the low water period, be re-opened halfway through the following flood tide when water levels on either side of the structure are the same, and remain open throughout the high water period.

The effect is demonstrated by comparing tide levels (a), current velocities (b) and salinity (c) with and without half-tide control at stations above and below the structure. Below the structure, the response to tide control is for the ebb period to be shorter, the flood period correspondingly longer, maximum flood current velocities lower and maximum ebb current velocities higher. Above the structure, once the initial fall in flood tide level following gate closure has occurred, levels increase slowly with incoming river flow until the gates are re-opened: current velocities on both flood and ebb tides are lower. The main effect of half-tide control on the longitudinal salinity distribution is to move the upstream limit of saline penetration about 5 km seawards (Ref 4).

Fig 10 demonstrates how these changes in water movement within the estuary affect the sediment distribution on the bed according to both the physical model (upper diagram) and the mathematical model (lower diagram).

The results take different forms. Those from the physical model are presented in the form of deposition/erosion

Fig 10. EFFECT OF TIDE CONTROL ON SEDIMENT DISTRIBUTION

charts which compare the negligible change in sediment distribution following construction but before operation of the tide control structure, with the considerable sediment redistribution resulting from continuous half-tide control. The mathematical model results illustrate longitudinal changes in the location of zones of erosion and deposition, indicating that tide control has the opposite effect to that of the rising trend in tidal range in that it produces a seaward migration of the major deposition zone.

CHAPTER 122

SEDIMENT TRANSPORTATION AND DEPOSITION MODELS FOR MOBILE BAY, ALABAMA

by

Gary C. April¹
Samuel Ng²
C. Everett Brett³

ABSTRACT

The objective of this study is the application of hydrodynamic and material transport mathematical models for Mobile Bay in predicting sediment transport and deposition profiles within the bay system. Of particular importance are the seasonal variations of sediment distribution which are critically influenced by current patterns within the estuary. Both point and non-point sources of sediment will be included in the analysis.

Results will be presented in two ways. The first or long term variations in sediment distribution will be assessed by correlation with tidal cycle average velocities at various locations within the bay. Calculated distribution patterns will be compared with observed bathymetric data over the past century. The net effect of the construction of the Mobile ship channel on deposition patterns within the bay will also be evaluated. Secondly, short term variations in sediment transport and deposition resulting from man-made and natural disturbances will be analysed using a sediment transport model. This model will include deposition, bulk fluid transport and resuspension characteristics and will be capable of predicting localized, short term sediment patterns from maintenance dredging operations within the bay. Model trend results will be compared with field data collected during recent dredging activities and high altitude photographic data obtained for the bay area.

INTRODUCTION

There is a growing awareness that the natural resources of the world are limited. This fact gives credence and a sense of immediacy to those who are trying to better understand and describe those processes which affect the amount and the quality of these resources. One of the most abundant and most taken-for-granted natural gifts is water. The waters adjacent to coastal regions are some of the most often studied because of their importance to man.

The coastal environment is a vital part of man's daily activity - providing food, recreation, jobs and habitats. Thus the already complex, dynamic natural processes which maintain a balance between fresh water and saline water is further confounded by man-made impacts. To minimize adverse events on these areas, a clear understanding of the properties and behavior of these systems must be established. Plans formulated with technically sound data are far more likely to produce results which are both environmentally and economically sound.

In recent years, studies have been accelerated to better characterize the coastal waters and to better describe the processes which take place in these areas. Studies have included models - both mathematical and physical - as well as the more traditional investigations involving data acquisition - both field oriented and remotely sensed. The interaction of these methods provide techniques for the rapid prediction of changes in the system and the impact that these changes have on water quality and behavior.

This paper summarizes some of the interactive methods used to characterize sediment transport patterns within the Mobile Bay estuary along the coastline of the northeastern Gulf of Mexico. The methods described are part of a continuing effort to develop compatibility between model, ground truth and remotely sensed information for the rapid estimation of estuarine behavior as governed by man-made and natural events.

MOBILE BAY SYSTEM

Mobile Bay receives the discharge of the fourth largest river system in the United States (Figure 1). An average of 5×10^9 kilograms of suspended sediment are transported into the estuary each year. Circulation patterns within the bay are governed by these river discharges, tidal influence from the Gulf of Mexico, wind influence and bay geometry. Seasonal variations due to meteorologic conditions, and shorter term variations due to the diurnal tidal state, result in hydrodynamic and material transport behavior which is complex.

The bay experiences seasonal variations in rainfall, runoff and sediment loading which can be broadly classified as low, medium and high in the following way (Table 1).

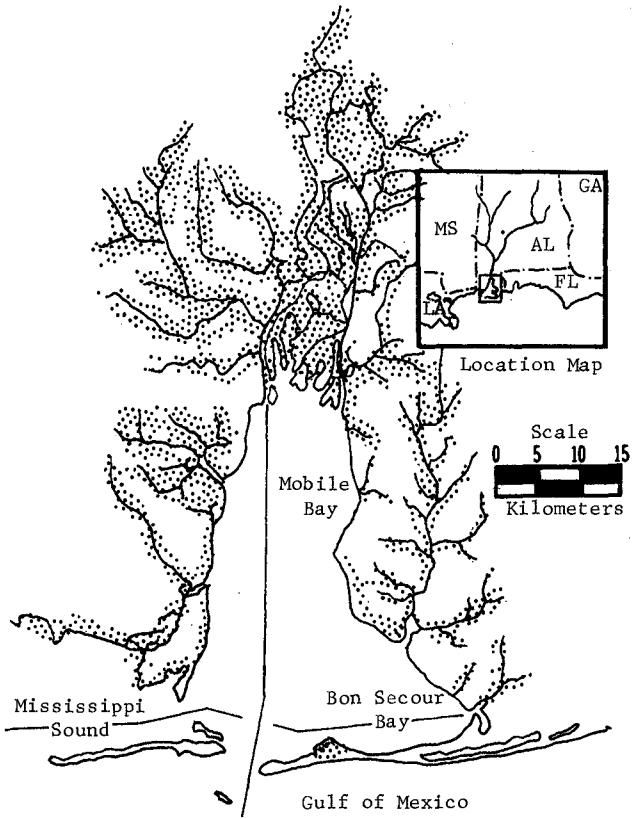

Figure 1.--Mobile Bay Estuarine System.

Table 1. -- Seasonal Average River Flow Rates and Sediment Load for the Mobile Bay System; 1952-1963 (U.S. Corps of Engineers, 1974).

River Flow Rate Classification	Period Covered	Average	Flow Rate	Average Sedi-	Sediment
		Flow Rate m ³ /sec	(Range) m ³ /sec	ment Load Kilograms x 10 ⁻⁶	Load (Range) Kilograms x 10 ⁻⁶
Low	August-November	531	447-700	68	50-107
Medium	May-July	1090	801-1609	215	145-353
High	December-April	2978	1609-3849	673	343-937
	Annual Averages	1609		357	

During the heavy runoff period the bay receiving waters are dominated by the high river flows to the extent that salinity intrusion within the bay is suppressed to the mid and lower sections of the estuary. This condition also results in the most pronounced transportation of sediment within the bay. Conversely, during periods of reduced river flow and sediment loading, bay currents are dominated by the tidal influence. This results in a greater potential to deposit sediment although the total volume is significantly reduced because of the decrease in solids loading during these periods.

Shoaling in the bay has averaged about 0.6m per century. However, there are portions of the bay which are highly stable and other regions which have rates of nearly 3.0m per century. These wide variations are a result of the complex, natural circulation patterns and man-made influences such as channel construction and maintenance dredging activities which exist in the bay (Ryan, 1969). Nearly 1.6×10^9 kilograms of suspended sediment bypass the bay annually. This material discharges into the Gulf through two natural passes in the southwestern area of the estuary. During tidal dominant periods (especially during flood tide cycles) solids can be introduced into the bay from the Gulf. These materials are transported to the bay mouth by the predominantly east to west littoral current which occurs in the northeastern Gulf of Mexico.

The influence of these variations in sediment transport and deposition patterns is analysed in this paper by considering the hydrodynamic behavior of the bay using mathematical modeling methods (Hill and April, 1974; Liu and April, 1975).

MODEL DESCRIPTION

Several mathematical models based on the laws of conservation of mass and momentum have been formulated for Mobile Bay (Table 2). These include two dimensional (depth averaged) models describing the hydrodynamic, conservative and non-conservative species transport behavior within the bay. Solution of the model equations is achieved using finite difference methods on a UNIVAC 1110 digital computer. These models have been used to study the influence of river discharge rate, wind direction and speed and tidal conditions on bay circulation and material transportation. Utilization of these models to investigate long term and short term trends resulting from natural and man-made disturbances on the system is part of an on-going research effort.

MODEL APPLICATION

Examples of methods used to assess sediment behavior are presented for a series of different conditions as dictated by the time frame over which information is being sought. These periods are broadly classified into long range or seasonal events and short range or within tidal cycle events for convenience. Each type will be discussed separately in subsequent sections.

The Effect of Seasonal Variations on Sediment Transport in Mobile Bay

Just as there are settling and scouring events within tidal cycles, there also exist seasonal variations which influence the sediment transportation and deposition characteristics within the bay. The effect of these seasonal events are studied by considering the hydrodynamic behavior of the bay using mathematical modeling methods. In particular, for the purpose of this paper, correlation of the hydrodynamic and sediment transport behavior is made using a tidal cycle average current generated for seasonal average flow conditions. This technique is a convenient method of lumping variables which are difficult to interpret and impossible to obtain over long term periods. The method provides a rapid assessment of those regions more susceptible to high transport and/or deposition of sediment. For Mobile Bay, a value of 0.06 m/sec correlates well with observed long term sediment transportation and deposition trends (i.e. a value < 0.06 m/sec indicates a region of low transportation; a value > 0.06 m/sec indicates a region of high transportation). Areas which have a high transportation potential regardless of river flow rate are indicated by the closed regions (Figure 2). These include the Bay areas adjacent to passes and waters near the Mobile and Tensaw Rivers in the north.

Table 2.--Mathematical Representation and Operational Modes of the Mobile Bay Models (Hill and April, 1974; Liu and April, 1975).

Name	Equation Form	Results	Modes
Continuity	$\frac{\partial Q_x}{\partial x} + \frac{\partial Q_y}{\partial y} + \frac{\partial H}{\partial t} = -(R + E)$	Tidal Height	Tidal Cycle Daily Avg Monthly Avg Seasonal
Momentum x-Component	$\frac{\partial Q_x}{\partial t} + gD \frac{\partial H}{\partial x} = KV^2 \cos \psi - fQQ_x D^{-2} + Q_x (2Ws \sin \phi)$	x-Component of Surface Current	Tidal Cycle Daily Avg Monthly Avg Seasonal
y-Component	$\frac{\partial Q_y}{\partial t} + gD \frac{\partial H}{\partial y} = KV^2 \sin \psi - fQQ_y D^{-2} + Q_y (2Ws \sin \phi)$	y-Component of Surface Current	Tidal Cycle Daily Avg Monthly Avg Seasonal
Species Continuity	$\frac{\partial C}{\partial t} + v_x \frac{\partial C}{\partial x} + v_y \frac{\partial C}{\partial y} = E \left(\frac{\partial^2 C}{\partial x^2} + \frac{\partial^2 C}{\partial y^2} \right) + \frac{E}{D} \left(\frac{\partial C}{\partial z} (z_s) - \frac{\partial C}{\partial z} (z_b) \right) - \frac{1}{D} (Cv_z (z_s) - Cv_z (z_b)) + R_o$	Concentration of Species	
Salinity	$R_o = 0$	Salinity Concentration	Daily Avg Seasonal
Coliform	$R_o = KC$; where $K = f(\theta)$	Coliform Bacteria Concentration	Monthly Avg Seasonal
Sediment	$R_o = K_1 f(v_s) + K_2 f(E) - K_3 f(v_r)$	Suspended Sediment Concentration	Seasonal Tidal Cycle

Note: f in the last equation is a functional representation for those terms listed. For example a modified form of Stokes' Law might be represented by the term $f(v_s)$.

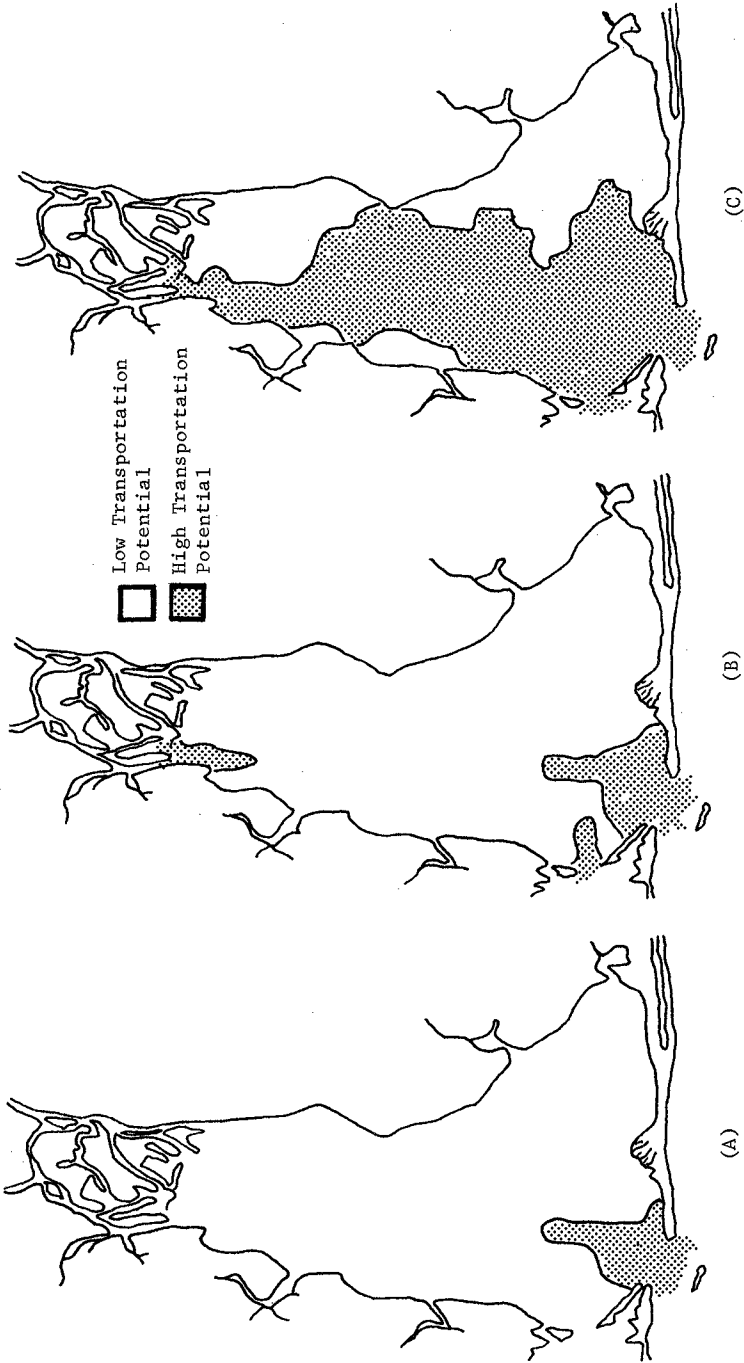

Figure 2.--Schematic Diagram Illustrating the Areas of High Transportation Potential at (A) Low, (B) Medium, and (C) High River Flow Conditions.

The open areas represent regions of low sediment transportation. These areas include the head waters between the Mobile and Tensaw Rivers, the Bon Secour Bay area and regions along the western shoreline. The seasonal variations can be observed by following the progression of the high transportation potential areas from high to low river flow conditions. It is likely that materials deposited during low river flow conditions become re-suspended during high river flow periods. This phenomenon can be traced using the hydrodynamic and material transport model for the bay. Included in this method of analysis are allowances for turbulence as estimated by local dispersion coefficients.

The Impact of Channelization on Long Term Sediment Transport in the Bay

In order to assess the possible long term impact that the Mobile ship channel has had on bay circulation and sediment transportation patterns, the hydrodynamic model was run under two conditions. The first set of conditions was derived from the 1847-1851 bay contour diagram from which bay depths were used as input to the model (Ryan, 1969). The second set of conditions were those including the ship channel in which bay depths and model parameters were adjusted to simulate this modification to the natural system. Both cases were run for a river flow rate of $3510 \text{ m}^3/\text{s}$. Transportation patterns were again determined using the tidal cycle average velocity criteria discussed earlier (Figure 3). A more even transportation pattern is observed over the lower two-thirds of the bay for conditions in which the ship channel is excluded. This condition can be explained by the higher volumetric throughput that occurs as a result of channelization along the west-central bay. A comparison of these results with deposition maps for the periods 1852-1920 and 1920-1973 prepared from bathymetric data supports the general patterns projected by the hydrodynamic model (Figure 4).

Within Tidal Cycle Variations in Mobile Bay Sediment Transport

Short term variations in sediment transportation patterns within the bay are of two varieties; man-made sediment disturbances resulting from maintenance dredging activities, and, naturally occurring sediment disturbances caused by high river flow rates, runoff and wind conditions. The latter cases are of particular interest in that it provides a means of interacting the hydrodynamic model with satellite and high altitude photographic data (remotely sensed) obtained during high sediment load conditions.

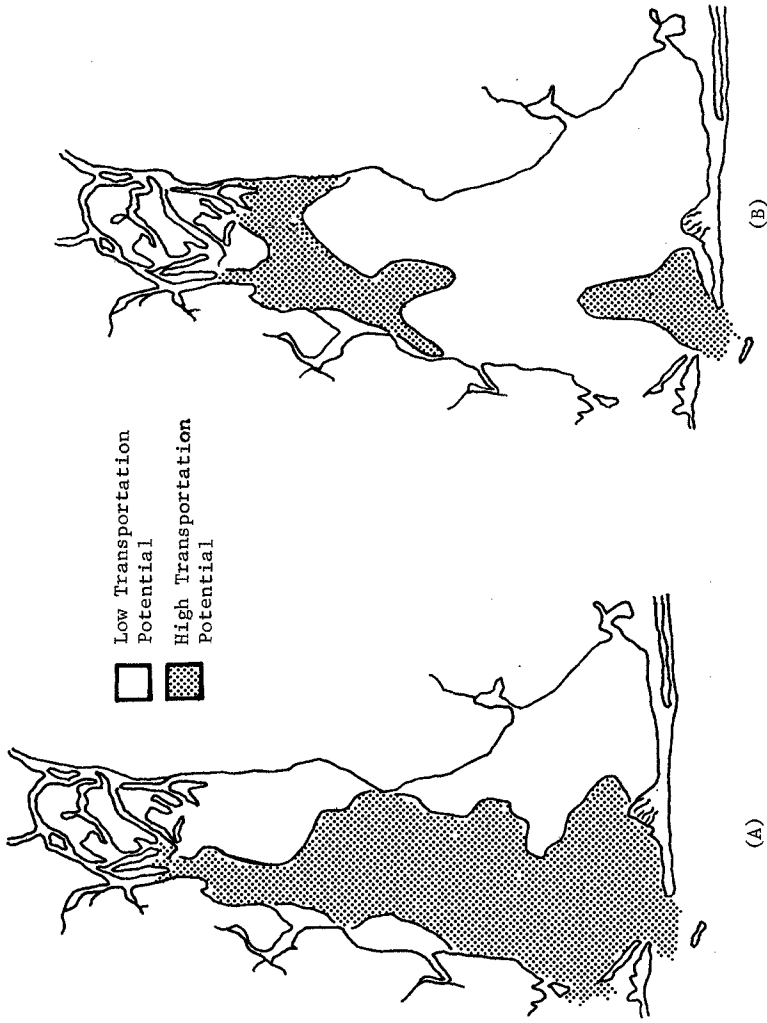

Figure 3.--Schematic Diagram Illustrating the Impact of Channel Construction on Bay Transportation Potential at High River Flow Conditions; (A) No Channel, (B) Channel.

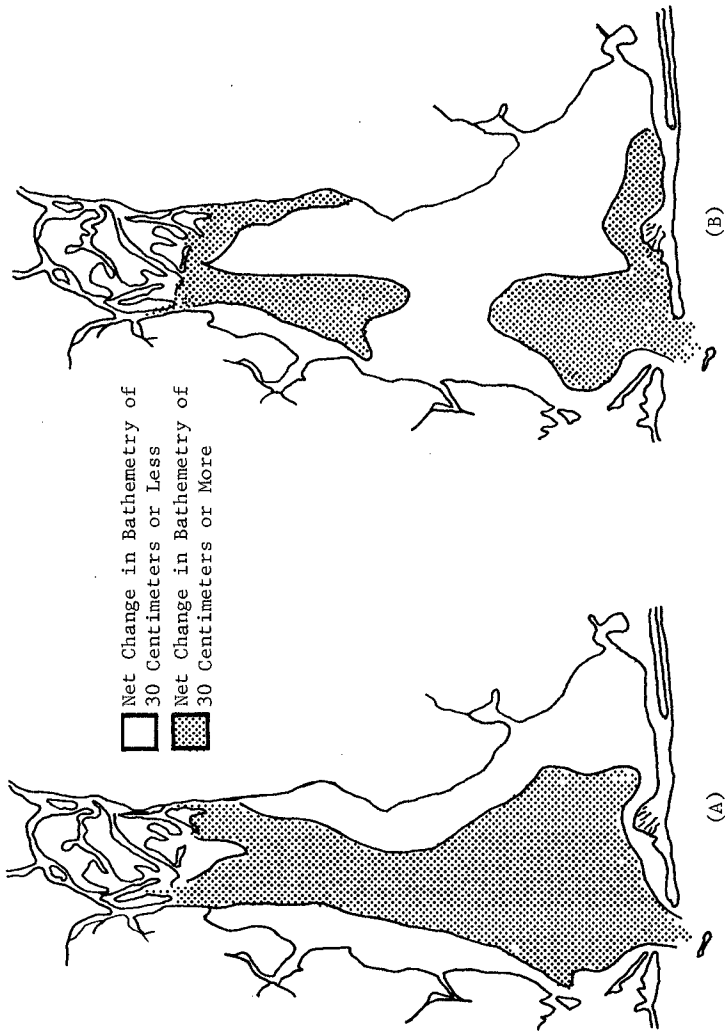

Figure 4.--Sediment Deposition Trends as Reflected by Bay Bathymetric Data for the Periods (A) 1852-1920 and (B) 1920-1973 (Sapp, 1975).

Sediment Transportation Resulting from Maintenance Dredging

Disturbances to the bay system resulting from maintenance dredging activities in areas adjacent to the Mobile ship channel account for the relocation of approximately 7.6×10^6 cubic meters of sediment. Hence, it becomes important to assess the impact that these dredged materials have on bay sediment transport and resettling behavior and the areas affected.

Such an analysis was made using the hydrodynamic model of the bay as a source of current direction and speed, and dispersion coefficient data as a function of tidal state. Subsequently, the material transport model was used for a subsystem (i.e. cell grid dimensions of 0.5 km; reduced from the two km hydrodynamic grid size) defined by the location affected by the dredging operation.

Field data collected in an independent study (Brett, 1975) were used to verify the model results. The field data were collected in May 1972 for the purpose of measuring the extent of sediment transport and deposition adjacent to a dredge discharge line. The dredge location was in the central bay (Figure 5). Comparison of suspended sediment concentrations as a function of distance from the dredge discharge indicates good agreement between the model predicted results and actual field data (Figure 6). There was no noticeable level of sediment in the water column beyond station 5; a distance of 1525 meters from the dredge discharge in a north-northeasterly direction. This is attributed to a change in the bay current pattern from near flood tide to near high water slack in which current velocities decrease rapidly to levels less than 0.06 m/sec. Similar conclusions can be derived by considering the thickness of deposited material along the north-south sampling transect (Figure 6).

As the tide enters high water slack, the sediment transport was shifted from a north-northeasterly direction to a more easterly direction. Similar patterns were observed as those discussed during the flood tide condition. However, because of the low current velocities, the dredging discharge rate becomes an important source of energy for transportation during this period. Thus the nature of the deposition patterns was such that this material was deposited over a shorter distance (Figure 6). These observations are consistent with the lower velocities and shorter period of time that occur during the slack water condition.

Similar patterns to those experienced during flood tide and high water slack conditions were postulated for ebb tide and low water slack. More material will be transported over a longer distance as a consequence of the longer period of high current velocities in the ebb flow direction. During seasonal periods when river flow rates are smaller than the value investigated in this study, a smaller area will be affected as a result of the more uniform ebb/flood tidal relationship. Because of the river inputs, the ebb tide condition is always greater than the flood conditions except during unusual periods.

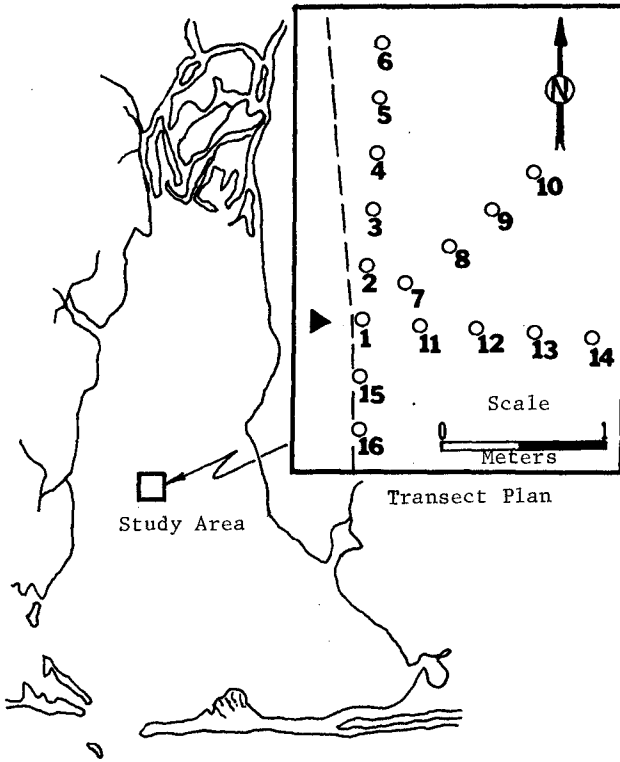

Figure 5.--Location Map and Transect Plan for Maintenance Dredging Program (Brett, 1975).

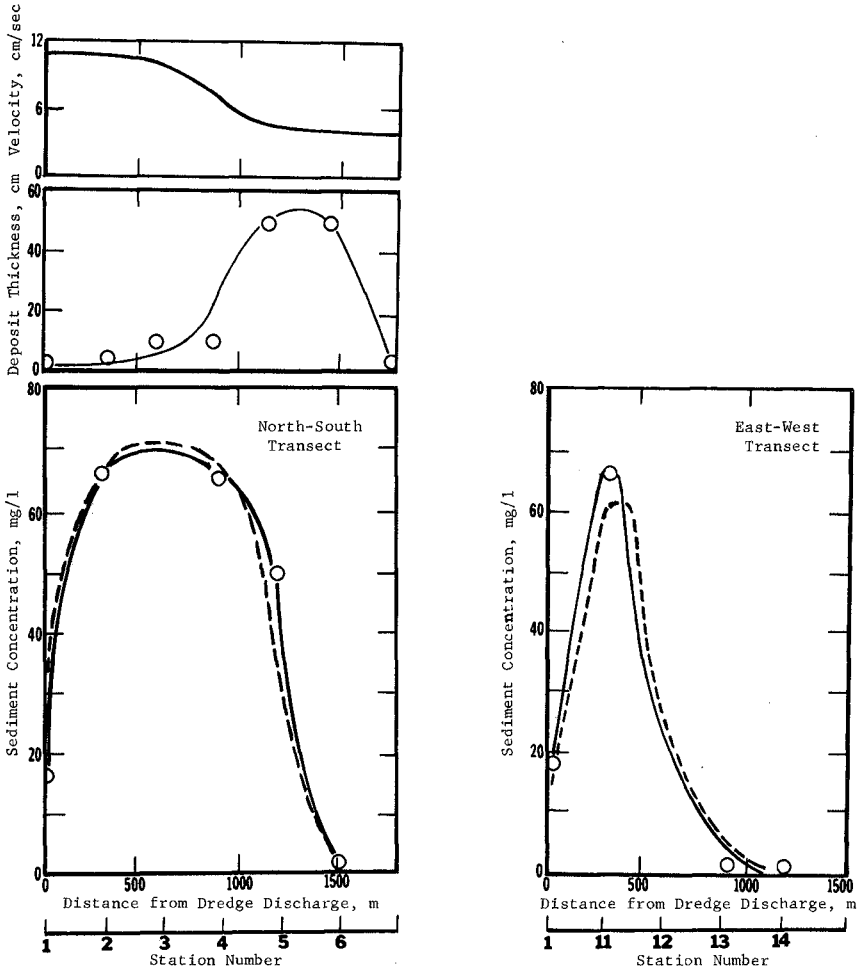

Figure 6.--Comparison of Model Calculated (Dash) and Field Measured (Solid) Results for Maintenance Dredging Program (Brett, 1975).

Naturally Occurring Sediment Transportation Events

The relationship of sediment transportation patterns to the hydrodynamic properties of Mobile Bay is shown by comparing model predicted velocity profiles with satellite photographs (Figure 7). In the case shown the hydrodynamic model was run at the local conditions observed during the photographic mission over the bay. The resulting velocity vectors were then reduced by a density slicing method where the following criteria were applied:

Category	1	2	3	4	5
Velocity Range m/sec	0-0.13	0.13-0.25	0.25-0.45	0.45-0.90	0.90-1.25

It should be noted that this method is highly acceptable when there is high sediment loads within the bay in which hydrodynamic factors constitute the primary driving force. Studies are in progress to better identify and account for those conditions which produce wind and/or bay bottom sediment disturbances.

The comparison shown indicates a first attempt at using remotely sensed data to complement mathematical modeling efforts. It also provides better coverage of bay behavior than what is currently available by either sporadic field data programs and photographic missions, the success of which is dependent on good meteorological conditions.

CONCLUSIONS

The above discussion of ongoing work related to the characterization of natural and man-made disturbances and the impact that they have on bay behavior is intended as a review of methods currently used. Because of the interrelationship of material transport (sediment) and hydrodynamic behavior (current), the use of mathematical modeling methods to predict change and assess impacts on the bay quality and material transport can be made. As seen the techniques can be rather crude such as those long range variations in sediment depositional potential or more refined analyses involving local, within tidal distribution of dredge materials. In either case, the dependency on data to calibrate and verify the results forms the critical step in the method. Once calibrated, however, the model results can be used to supplement data collection programs and provide a broader, more complete coverage than what is currently available. Some success has been shown for high sediment load conditions which are river oriented. Continued efforts to predict disturbances which are wind driven or which result from local bay bottom scouring is important to complete this area of investigation.

(A) (B)
Figure 7.--Comparison of Sediment Transportation Patterns Predicted by the Hydrodynamic Model (A) and Skylab IV photograph taken January 21, 1974 (B).

The knowledge gained from these studies have allowed, in many cases, quantification of results previously considered only in a qualitative sense. Although far from analytical in all cases, these methods provides a basis for assessing trends in behavior caused by natural and man-made disturbances. These methods also point out the need for continued investigations aimed at better descriptions of these complex systems which are vital to man's future.

ACKNOWLEDGEMENT

The authors would like to acknowledgement the support of the National Aeronautics and Space Administration, Marshall Space Flight Center and the United States Corps of Engineers, Mobile District, during certain phases of this study and other related investigations. The University of Alabama, Marine Science Program, is also thanked for their support during the developmental stages of the Mobile Bay modeling projects.

CHAPTER 123

WAVE-FORMED RIPPLES IN NEARSHORE SANDS

John R. Dingle¹
Douglas L. Inman²

ABSTRACT

Ripples are generated and modified by wind-generated waves and their profiles are controlled by the nature of the near-bottom wave motion and by the size of the bed material. Wave-formed ripples develop under a definable set of conditions called the ripple regime. The ripple regime is bounded by those conditions that initiate grain motion, low-wave intensity, and by those that cause the disappearance of ripples, onset of sheet flow. Sheet flow occurs when intense wave motion causes several grain layers to be in motion. Three distinct ripple types occur in nearshore areas of fine sand - relict ripples, vortex ripples, and transition ripples. Vortex and transition ripples lie within the active ripple regime, whereas relict ripples do not.

Ripples in fine sand were studied in the field at La Jolla, California, where profiles were obtained using a newly developed high-resolution sonar capable of vertical resolution of the order of one millimeter. Simultaneous profile and wave-pressure measurements permit correlation of the ripple profiles with individual waves and with the wave spectrum. The sonar, with its rapid scan capability (\sim one meter per second), gives instantaneous measurement of the actively changing bed features in nearshore waters. The combination of bottom scans and wave-pressure measurements extends previous wave-ripple studies to include all of the nearshore ripple regime.

The relation between the wave and ripple data from this study is best shown by plotting ripple steepness η/λ against the wave form of the Shields relative stress criterion θ . Vortex ripples ($\eta/\lambda \sim 0.15$) occur for θ values less than 40 but greater than the minimum value which is determined by the onset of grain motion.

The transition from vortex ripples to sheet flow commences at a θ value around 40 and ends at $\theta_c \sim 240$, where θ_c is the critical value for the onset of sheet flow. With transition ripples, the decrease in steepness is caused by a decrease in ripple height, since the ripple wavelength remains essentially constant. Beds that become planar as a result of intense wave conditions ($\theta > 240$) re-ripple in a few wave cycles once the intensity decreases. For this reason, bottom scans taken before equilibrium is reestablished show ripples that have a low steepness.

-
1. U. S. Geological Survey, Menlo Park, CA 94025
 2. Scripps Institution of Oceanography, La Jolla, CA 92093

During some experiments where no sheet flow occurred between scans, migration of transition ripples was measured and found to range between zero and four centimeters per minute, increasing with increasing values of the theoretical bottom wave-drift current. Whenever migration was observed, it was in the direction of wave propagation, i.e., onshore.

Ripple symmetry is the ratio of the horizontal crest-to-trough distance β (in the direction of wave travel) to the ripple wavelength λ . A β/λ value of 0.50 indicates a symmetric ripple. Measured values of β/λ ranged from 0.36 to 0.61 with 74% of the values in the range 0.45 - 0.55, and 55% in the range 0.47 - 0.53.

INTRODUCTION

When progressive surface gravity waves shoal, interactions occur between the oscillating fluid and the bottom sediment. When these interactions become sufficiently intense, ripples develop on bottoms composed of sand. The oscillatory nature of the flow produces ripples that are generally symmetric in cross section, a geometry that is discernible from the distinctly asymmetric ripples formed by unidirectional flows. If the wave conditions remain constant for a long enough period of time, the ripples reach an equilibrium state with constant values of height and wavelength. The equilibrium ripple geometry is a function of the sand size and the character of the wave action above the bottom.

As shoaling progresses the near-bottom orbital velocities become more intense. This produces a ripple regime within which ripple sizes change systematically and within which each ripple is in equilibrium with the waves over it. For time periods of the order of a wave period, the movement of a ripple is characterized by an onshore-to-offshore oscillation of the ripple crest as first the wave crest and then the wave trough pass over the ripple. Any net movement of the ripple over longer time periods is related to differences in the crest and trough orbital velocities that occur in shallow water.

Flow conditions commensurate with the ripple regime occur over much of the nearshore, and the profile of the ripples varies within this region (Figure 1). In deeper water, where the wave action is generally too weak to move the sand, the bed generally contains relict ripples which formed under earlier, more intense wave action and which are gradually reworked by organisms. Ripples form once the wave action is of sufficient strength to move sand. Although the ripple height η and wavelength λ change as the wave intensity increases, the ripple steepness η/λ remains relatively constant (vortex ripples) until the bottom is subjected to the very strong flows that normally occur in relatively shallow water. As the flow strength increases beyond the conditions where vortex ripples occur, the ripples become less steep (transition ripples) until finally the ripples disappear as several grain layers are in motion (sheet flow regime). In deeper water the ripples tend to be relatively short crested, giving the bed a three-dimensional appearance (Inman, 1957). By the time transition ripples develop, ripple crests are quite long and the bed has become markedly two-dimensional in appearance.

Previous Work

Hunt (1882) and Darwin (1883), using laboratory wave tanks, were among the first to show that symmetrical ripples could be produced by oscillatory water motions. The work of Bagnold (1946) quantified the relation between ripple size and flow conditions. Bagnold's work has been extended by subsequent investigators, and now many aspects of oscillation ripples can be predicted with some degree of accuracy.

Bagnold's classic experiments on oscillation ripples demonstrated the relation between orbital diameter and ripple wavelength when flow conditions are near the threshold of grain motion (Figure 2). Once grains begin moving, ripples form and their wavelength is approximately equal to the orbital diameter. Increases in orbital diameter cause an increase in wavelength until a limiting value is reached, and the limiting value is grain size dependent. Over the range of orbital diameters studied by Bagnold, the wavelength was not a function of the period of oscillation. Bagnold did not extend the experiments to more intense flow conditions to determine whether the wavelength remained constant until sheet flow occurred.

Inman (1957), in a comprehensive field study of wave-formed ripples, obtained the ripple wavelengths by marking with grease pencil on clear plastic laid on top of the ripples. The near-bottom orbital displacements were measured in situ, while the wave period was obtained from the record of a fathometer mounted on a small boat. The results of Inman's work are shown in Figure 3. Except for a few points, ripple wavelength generally decreases with increasing orbital diameter. The Inman field data was produced under larger orbital diameters than the Bagnold laboratory data. Combining the two data sets reinforces Bagnold's observation that the ripple wavelength can only increase to a certain point with increasing orbital diameter. Then, rather than remain constant, as might be inferred from Bagnold's data, the wavelength actually decreases again. These aspects of ripple wavelength are integrated into a conceptual model of sedimentary structures by Clifton (1976).

Inman's rough estimates of ripple height gave a steepness value on the order of 0.15 except in the more intense flow regimes where the steepness began to decrease. Carstens, and his coworkers (1969), looking at oscillation ripples on sand beds using a pulsating water tunnel, also observed that the ripple steepness decreased from 0.15 under the most intense flows.

Most nearshore sands are composed of material with density similar to that of quartz (density of 2.65 gm/cm^3). It is important, however, that the variation of ripple form with grain density be studied for application to heavy mineral environments and to movable bed modeling. Mogridge and Kamphuis (1972) showed that variations in ripple height and wavelength can be significant, but that the ripple steepness is only weakly affected by grain density since the height and wavelength variations tend to cancel out. They further state that the importance of grain density diminishes as the wave period increases since fluid accelerations become less important at the longer periods.

Present Study

Previous studies show that the equilibrium ripple wavelength is a function of the grain size of the sediment and of the near-bottom orbital diameter of the oscillating fluid. Some of the earlier studies also suggest that the ripple steepness decreases systematically prior to sheet flow (it is zero at the onset of sheet flow). This study, undertaken as part of a doctoral program at the Scripps Institution of Oceanography (Dingler, 1974), establishes criteria for the limits of the ripple regime and describes the ripple geometry in the transition zone between constant steepness ripples and sheet flow. The lower limit of the ripple regime (onset of grain motion) was studied in a large wind-wave channel using oceanic wave periods and heights (Dingler, 1974). The upper limit (onset of sheet flow) and the ripple profile in the transition zone were determined by field measurement using a newly developed profiler. Most of the experiments were performed in the vicinity of the Scripps pier where the sediment is a well-sorted fine quartz sand.

THEORETICAL CONSIDERATIONS

Wave Relations

The wave and ripple parameters used in this study are sketched in Figure 4. The near-bottom orbital velocity u at any point is related to the maximum velocity u_m and the phase of the wave by

$$u = u_m \cos(\sigma t)$$

where t is time, $\sigma = 2\pi/T$ is the angular frequency of oscillation and T is the wave period (linear wave theory; Airy, [1845]). The maximum velocity, which occurs during crest and trough passage, is given by

$$u_m = \frac{\pi d_o}{T} = \frac{\sigma H}{2 \sinh(kh)} \quad (1)$$

where d_o is the orbital diameter, h is the water depth, H is the wave height, $k = 2\pi/L$ is the wave number and L is the wave length at the point of interest. The value of kh is obtained for a given depth and period by iterative solution of the wave dispersion relation

$$\left(\frac{2\pi}{T}\right)^2 \frac{h}{g} = kh \tanh(kh)$$

where g is the acceleration of gravity. In shallow water ($h/L < 1/20$) deviations from linear theory become significant with the exception that the near-bottom velocities are still reasonably predictable from linear theory (LeMehuate, et al., 1969; May, 1975).

When the wave train consists of waves of varying amplitudes and frequencies, Fourier analysis techniques are used to analyze the time series of the wave record. The technique used in this study follows the procedure of Cooley and Tukey (1965) with the final output being a plot of the mean-square elevation of the water surface $\langle \eta^2 \rangle$ per fre-

quency band Δf . Since the mean energy per unit area of water surface E is related to $\langle \eta^2 \rangle$ by

$$E = \rho g \langle \eta^2 \rangle = 1/8 \rho g H_{rms}^2$$

where H_{rms} is the root-mean-square wave height, $\langle \eta^2 \rangle$ is proportional to the available wave energy given that the fluid weight per unit volume ρg remains essentially constant for sea water. Then, u_m is related to $\langle \eta^2 \rangle$ by

$$u_m = \frac{\sigma (2 \langle \eta^2 \rangle)^{1/2}}{\sinh(kh)}$$

Another commonly used parameter, the significant wave height $H_{1/3}$, is assumed to be given by

$$H_{1/3} = \sqrt{2} H_{rms}$$

Dimensional Analysis

The ripple steepness η/λ is a function of seven independent variables. These seven variables are (1) fluid related: the fluid viscosity μ and density ρ ; (2) sediment related: the grain density ρ_s and grain size D ; and (3) flow related: the near-bottom orbital diameter d_o , the period of oscillation T , and the acceleration due to gravity g (note that grain-shape factors are not included in this analysis, although a completely general analysis would include shape and packing). Since u_m , d_o and T are related in linear theory (Equation 1), only two of these three variables are required to specify the wave conditions. As the immersed weight of the sediment depends on a density difference, the factor converting volume to immersed weight γ_s ,

$$\gamma_s = (\rho_s - \rho)g$$

replaces gravity as an independent variable. The complete dimensional functional relation is given by

$$\eta/\lambda = f(\rho, \mu, \rho_s, D, d_o, T, \gamma_s)$$

and this is non-dimensionalized to give the functional relation

$$\eta/\lambda = \phi \left[\frac{\rho \gamma_s D^3}{\mu^2}, \frac{\gamma_s T^2}{\rho D}, \frac{d_o}{D}, \frac{\rho_s}{\rho} \right]. \quad (2)$$

Equation (2) will be represented in shorthand notation by

$$\eta/\lambda = \phi (X_1, X_2, X_3, X_4).$$

A fifth dimensionless variable, the wave form of the Shields relative stress criterion θ , is obtained by combining X_2 and X_3 .

$$\theta = \pi^2 X_3^2 / X_2 = \rho u_m^2 / \gamma_s D.$$

The dimensionless variable X_1 is equal to Re^2/θ , where $Re = \rho u_m D/\mu$ is a Reynolds number. Although Re and θ include flow parameters, X_1 is formed by the fluid and granular properties only. It therefore reflects the influence of viscosity independent of the stage of the fluid-granular motion, and remains constant throughout the stages of the flow. The dimensionless variable X_2 indicates the influence of wave period. The dimensionless variable X_3 indicates the importance of the drag force F_D to the inertial force F_I in an oscillatory system. Thus,

$$F_D \sim D^2 u^2$$

and

$$F_I \sim D^3 (du/dt).$$

For oscillatory flow

$$du/dt = u_m \sigma \sin(kx - \sigma t).$$

Then

$$\frac{F_D}{F_I} \sim \frac{D^2 [u_m \cos(kx - \sigma t)]^2}{D^3 u_m \sigma \sin(kx - \sigma t)}.$$

Comparing maximum values, even though they are 90° out of phase, yields

$$\frac{F_D}{F_I} \sim \frac{u_m}{D} = \frac{d_o}{2D} = \frac{X_3}{2}.$$

The dimensionless variable X_4 is the "specific mass" and indicates the influence of the mass of grains ρ_s relative to that of fluid ρ . Since ρ_s is associated with inertial forces of the grains, its nondimensional form X_4 may be significant whenever grains are subjected to non-gravitational accelerations.

EXPERIMENTAL PROCEDURE AND DATA ANALYSIS

The results of this study are based primarily on field data as bed forms in the large wind-wave channel at Scripps were influenced by the channel boundaries during intense flow conditions. Most of the study was conducted in the high-energy nearshore environment at La Jolla, California, where flow conditions were sufficient to produce both ripples and a flat bed (Figure 5).

Ripple Profiling

Oscillation ripples on beds of fine sand tend to have elevations of the order of a centimeter and lengths of the order of a decimeter.

Ripple wavelengths can be measured rather accurately in situ with a meter stick, but ripple heights are almost impossible to measure manually because the weight of the meter stick flattens the crests and because constant water motion from the waves disrupts the measurement. To overcome this difficulty, a sediment surface profiler using high frequency sound waves (4.5 MHz) was developed (Dingler, et al., unpublished manuscript). The vertical resolution of the sonar was ascertained to be at least 1 mm. The sonar head was mounted in an open aluminum framework that sat about 25 cm above the bottom (Figure 6). The frame was easily transported and relatively scour free. Visual observations during field experiments under various flow conditions indicated that the flow disturbance caused by the sonar frame did not reach the sand bed.

Procedure

Most of the experiments were undertaken in the vicinity of the Scripps pier. Two Scuba divers entered the water at the end of the pier and the sonar frame with attached pressure sensor was lowered to the divers. The divers carried the sonar away from the pier in order to eliminate effects of the pier on the flow field and oriented the frame on the bottom normal to the ripple crests (Figure 6). A surface sample of sand was collected from each site.

Each experiment lasted at least 8.5 minutes. The procedure was repeated as many as three times at stations spaced about 70 m apart (on-offshore). Often wave intensities were such that sheet-flow conditions extended far enough offshore to permit only one experiment.

Sonar scans occurred about once a minute and each scan required from three to six seconds to complete. Generally, the scans were made to coincide with lulls in wave activity in order to minimize profile errors caused by crest movement during the passage of moderate to large waves. Also, under intense flow conditions, there was sufficient sand in suspension just above the bottom that the sonar responded to the suspended load rather than to the bed forms.

Data Reduction and Analysis

All the data was cabled to a shelf station where it was transmitted to the laboratory via the Shore Process Laboratory SAS system (Lowe, et al., 1972). The data was first digitized at a sample rate of 125 times per second with a 10 bit resolution. Then it was recorded on both strip chart and on magnetic tape. Each ripple profile was plotted from tape on graph paper and the data on the plots reduced by hand. Averages and standard deviations were obtained for ripple height, wavelength and asymmetry, and the averages were used in subsequent calculations. Finally, by following individual ripple crests from profile to profile an estimate of the migration rate for the ripples was obtained.

In some experiments the bed was smoothed by intense flows and subsequently re-rippled. In these cases the use of spectral wave parameters would be inappropriate. Instead, the analog pressure record was

directly analyzed and the wave parameters calculated from a few large waves that occurred before the scan of interest.

RESULTS AND DISCUSSION

Oscillation ripples occur over a range of definable flow conditions. The lower limit is the onset of grain motion and the upper limit is the occurrence of sheet flow. Within these limits the ripples have a cross-sectional geometry that is predictable when the flow intensity and grain size are known. Based on steepness, two types of ripples are found: vortex ripples (ripple steepness ~ 0.15) and transition ripples (ripple steepness < 0.15).

Ripple Geometry

Two data reduction procedures were used on the wave data in this study. In the first procedure the flow parameters were calculated from the wave spectrum and represent the root-mean-square values as recorded over an interval of 8.5 minutes. In the second procedure the near-bottom flow parameters were calculated from a short section of the wave record preceding the sonar scan and represent the "instantaneous" conditions prior to the measurement. In subsequent discussions the latter procedure will be referred to as the "single wave" procedure. It was employed only when flat bed conditions had been observed at some time during the experiment.

The nature of field experimentation generally precludes systematic variation of one dimensionless variable while holding the others constant as can be done in the laboratory. In the dimensionless functional relation

$$\eta/\lambda = \Phi(X_1, X_2, X_3, X_4)$$

the dimensionless variables X_1 and X_4 are independent of the flow conditions. By selecting field locations where the sediment is material of quartz density and where the grain-size variations are small, the effect of the variables X_2 and X_3 can be analyzed independent of X_1 and X_4 . When the data for fine sand is plotted as

$$\eta/\lambda = \Phi_1(X_2^a X_3^b)$$

on log-log paper, values of $a = -1$, $b = 2$ produce a coherent trend to the data. This is not surprising as this combination of the two dimensionless groups is proportional to the relative stress Θ (Equation 3) which is an important variable in many fluid-granular interactions.

Ripple steepness is plotted as a function of relative stress in Figure 7. Although the data shows a consistent trend when plotted in this manner, the steepness values begin to decrease at a lower value of the relative stress than in the studies of Inman and Carstens, et al. This occurs because there is a fundamental difference in analysis procedures. Bed forms for fine sand respond rapidly (i.e., in one or two wave periods) to changes in wave characteristics. The "single wave" procedure, which emphasizes instantaneous conditions, is thus similar to

the constant wave conditions of the laboratory. The spectral analysis procedure, on the other hand, considers waves of varying height and period occurring over a time period of 8.5 minutes. To emphasize the importance of larger waves on the ripple geometry, Inman used an orbital diameter parameter based on the significant wave rather than the root-mean-square wave. When Figure 7 is modified to emphasize the importance of the larger waves on the ripples (Figure 8), correlation is significantly improved for those conditions where the data sets overlap.

Figure 9 is a five minute record of the second experiment of 26 October 1972 at a water depth of 3.4 meters. The top trace is the wave record as measured at the pressure sensor. The second trace shows the output of the sonar head as it sat at the onshore end of the track. The third trace gives time relative to the start of the experiment. The times of the scans are indicated by arrows and the scans are shown in the bottom four traces. At the time of scan 1 the bed was rippled and the steepness value fell on the equilibrium curve of Figure 8. Subsequently, a set of large waves produced sheet flow and a flat bed (scan 2). Following the passage of several smaller waves the bed again was rippled, although the steepness had not yet reached an equilibrium value (scan 3). Before equilibrium was reached a set of two large waves almost re-leveled the bed (scan 4). This series of bed profiles shows that in fine sand the bed responds rapidly to intense flow and a bed can be flattened and re-rippled in a time equivalent to a few wave periods.

The transformation of a fine sand bottom from transition ripples to a flat bed occurs over one or two wave periods. Assume that the bottom is subjected to waves of variable height and of sufficient intensity that transition ripples occur following the passage of intermediate height waves, while the largest waves produce sheet flow and a flat bottom. Once the flat bottom occurs, it persists during periods of the smallest waves because they are not of sufficient intensity to move the sand. As the wave conditions intensify, sediment begins to move and vortex ripples start to form. If these wave conditions were to persist for a sufficient time (minutes), the ripples would eventually reach an equilibrium configuration with a steepness of about 0.15. This wave pattern does not persist for more than a few wave cycles in such a variable system and only transition ripples form.

Transition ripples occur for relative stresses greater than 40, but less than the critical value for sheet flow. The decrease in steepness of the transition ripples is attributable to decrease in ripple height since the experiments show that the ripple wavelength itself remains constant for these flow conditions (Figure 10). At a critical relative stress value of 240 sheet flow prevails and a flat bed again forms. The growth of the ripples from a flat bed to transition ripples is schematized by dashed lines in Figure 8.

The effect on ripple steepness of the dimensionless variable $X_1 = \rho \gamma_s D^3 / \mu^2$ was not determined conclusively because of a lack of good study sites with coarse sand. The only usable information on the importance of larger grain sizes came from some preliminary laboratory experiments and from a few field experiments. All of the laboratory and all

but two of the field data points were for vortex ripples (Figures 7 and 8). The two transition ripple values fall with the fine sand values, which suggests that ripple steepness does not strongly depend on the dimensionless variable X_1 . This is consistent with the findings of Mogridge and Kamphuis (1973).

Because the grain density remained constant for the field experiments, X_4 was not evaluated. Mogridge and Kamphuis state that this variable is not important with respect to the ripple steepness although X_4 does have a significant effect on the ripple height and wavelength.

The criterion for the onset of grain motion under progressive waves has been shown to be

$$\frac{\gamma_s T^2}{\rho D} = 240 \left[\frac{d_o}{D} \right]^{\frac{4}{3}} \left[\frac{\rho \gamma_s D^3}{\mu^2} \right]^{-\frac{1}{9}}$$

when the grain diameter is less than the (theoretical) thickness of the wave-formed boundary layer (Dingler, 1974). Rearrangement of this relationship in terms of the threshold relative stress θ_t gives

$$\theta_t = 0.0027 (\gamma_s^2 / \rho \mu)^{\frac{1}{3}} T. \quad (4)$$

For the case of material of quartz density ($\rho_s = 2.65 \text{ gm/cm}^3$) in a typical nearshore environment ($\rho = 1.0 \text{ gm/cm}^3$, $\mu = 1.1 \text{ centipoise}$), equation (4) reduces to

$$\theta_t = (1.7 \text{ sec}^{-1}) T.$$

In Figure 8 this relation has been superimposed upon the curve for the equilibrium ripple steepness to indicate the lower limit of the ripple regime for various wave periods.

Ripple Migration

Ripple migration under oscillatory flow conditions might be expected to occur when a net fluid flow is superimposed on the oscillations. The bottom wave-drift current has been shown to produce an onshore ripple migration in the laboratory (Inman and Bowen, 1963). Ripple migration is a critical aspect of sediment transport over the shelf since the rate of grain migration is inherently related to the burial and exposure of the grains by the moving ripple form (Inman and Bagnold, 1963). Study of ripple migration for transition ripples is complicated by the occasional destruction or near destruction of the ripples and by the associated high sediment concentrations in sheet flow. The migration rate of the sand thus involves both movement of the ripple form and movement by sheet flow.

The intermittent scanning of the bottom prevented ripple migration measurements for every experiment. Yet in several experiments, the position of individual ripple crests could be traced from scan to scan and the migration rates of these ripples showed a positive correlation

with the theoretical bottom wave-drift current u_0 (Table 1).

$$u_0 = 5/4 u_m^2 T/L. \quad (5)$$

A better understanding of the nature of the bottom wave-drift current over rippled beds is necessary before a more detailed study of ripple migration rates can be attempted.

Table 1

Ripple migration rates obtained from repeated sonar scans. The bottom wave-drift current u_0 is calculated from Equation 5 using rms values from the wave spectral analysis.

Experiment	u_0 , cm/sec	Migration rate cm/min
1	4.7	4.2
6	3.2	1.2
11	2.8	0.5
9	1.2	0.0

Ripple Shape and Variability

Analysis of the ripple profiles included the measurement of the horizontal distance from crest to onshore trough β , which when divided by the wavelength λ , is indicative of the symmetry of the ripple form. The ripple symmetry factor β/λ is 0.50 for a symmetrical ripple, less than 0.50 when the ripple has a steep onshore facing crest, and greater than 0.50 for a steep offshore facing crest. The measured values of β/λ ranged from 0.36 to 0.61 with 74% of the values in the range 0.45 - 0.55, and 55% in the range 0.47 - 0.53. There was no correlation between the symmetry value and the relative stress for the spectrally related ripples, but this can be attributed to the fact that the ripple scans followed specific waves while the relative stress was based on 8.5 minutes of wave record. Even though the ripple height and length do not change with every wave for non-sheet flow conditions, a large wave crest or trough could slightly modify the steepness factor by a slight onshore or offshore movement of the ripple crest. Some uncertainty in the measurement of β due to the flat nature of ripple troughs also contributed to the range of symmetry values. The β/λ values for the "single wave" ripples showed some correlation with the relative stress such that a β/λ value of 0.42 corresponded to the lowest relative stress value and β/λ increased to 0.48 with increasing relative stress.

Standard deviations were calculated for the ripple parameters η , β , and λ . For comparative purposes these values were expressed as the coefficient of variation that is defined as the ratio of the standard deviation to the mean value. For all the data, the values of the coefficient of variation for η and β were generally between 0.10 and 0.25 while for λ they were often less than 0.10. Some of the variation in the ripple elevation is probably due to the fact that the elevations were generally so small that their measurement has a lower relative accuracy than that of the other parameters. The β measurements were

more variable than the λ measurements because of the greater difficulty in determining the exact location of the lowest part of the trough.

CONCLUSIONS

From this study of wave-formed ripples in a high-energy nearshore sand environment these conclusions are drawn:

1. Once ripples form, their steepness is controlled by the relative stress. The steepness remains constant until the relative stress reaches a value of 40, then decreases to zero (flat bed) for sheet flow.
2. Sheet flow, which produces flat beds, commences at a value of the relative stress of 240.
3. Relative stresses greater than 240 cause ripples in fine sand to disappear and the bed to become flat after the passage of one or two large waves. A rippled bed reappears after the passage of a few smaller waves.
4. Ripple migration rates in fine sand range from zero to 4.2 cm per minute. The migration is always onshore and can be correlated with the theoretical bottom wave-drift current.
5. Grain size appears to have negligible effect on steepness of vortex or transition ripples. It should be noted however, that the maximum ripple wavelength and height are grain size dependent.
6. Ripple symmetry ranged from 0.36 to 0.61 with 55% of the values falling in the range 0.47 - 0.53 and 74% in the range 0.45 - 0.55.
7. A sonic bed profiler operating at 4.5 MHz is capable of resolving the ripple elevation to at least 1 mm and works well in both the laboratory and the field.

CHAPTER 124

ORIGIN OF SUBMARINE DUNES

by

M.S. Yalin¹

ABSTRACT

The turbulent bursting process is outlined and attention is drawn to the fact that the "coherence distance" of the regenerating macroturbulent eddies is of a magnitude that is much the same as the length of dunes. Consequently it is postulated that the length of dunes is merely the "imprint" of the coherence distance on the deformable surface of a movable bed and the origin of dunes is explained accordingly. It is shown that the frequently observed similarity between tidal and unidirectional dunes is due to the similarity of the tidal transport and the transport corresponding to an intermittent unidirectional flow. The explanations presented herein are expected to be valid for dunes caused by both unidirectional flows and tidal currents.

INTRODUCTION

Measurements carried out in the field indicate that the large scale bed features (dunes, megadunes) produced by tidal currents approximate rather closely to the dunes produced by the equivalent unidirectional flows. Thus in Ref [1] H. Ozasa states that "the dimensions of submarine sand waves (dunes) formed by tidal currents in the Bisan Strait at the Seto inland sea in Japan are approximately equal to the values calculated by Yalin's formula". Similarly, in Ref [2] Per Bruun points out that the dunes on the bottom of the Cook Inlet in Alaska are much the same as those on the bottom of the Mississippi river (where the flow conditions are comparable with those of the Cook Inlet). The data obtained from some parts of the British coast also appear to indicate the resemblance between the two types of dunes (W.A. Price, Hydraulics Research Station, Wallingford - private communication).

The approximate equality of unidirectional and tidal dunes can be explained by the similarity of the mechanisms of their production. Indeed if a tidal current is present then the cyclic velocity and shear stress diagrams (corresponding to a location) can no longer be symmetrical. It will be assumed in the following that the positive part of the τ_0 diagram is higher than its negative part (Fig 1) and that

¹ Professor of Hydraulics, Queen's University, Kingston, Canada.

$$|(\tau_o)_{\max}^+| > (\tau_o)_{cr} \quad \text{while} \quad |(\tau_o)_{\max}^-| < (\tau_o)_{cr} \quad (1)$$

In this case the transport will be present, and dunes will form, only during the time interval θ^+ when the tidal flow is virtually a unidirectional flow. One can say that if (1) is valid, then the dunes are formed by the tidal flow in the same manner as if they were formed by an intermittent unidirectional flow. It should be remembered that the duration (\mathcal{C}) of the development of large size dunes is of the order of several months. Thus \mathcal{C} is much larger than the tidal period T which justifies the expression "intermittent unidirectional flow". Clearly in some cases $|(\tau_o)_{\max}^-|$ can also be larger than $(\tau_o)_{cr}$. This, however, can hardly invalidate the above description in principle, as the presence of the less effective opposite transport during θ^- will merely reduce the efficiency of the "build up" during θ^+ . The reduction of "efficiency" will, of course, lead to the extension of the development duration \mathcal{C} , but this has no bearing on the argument.

FIG. 1

No dunes have been observed in laminar flows, and the prevailing view is that they are due to turbulence. The author is of the same view. The present paper is his attempt to explain the occurrence of dunes in the light of the new information gained in the field of turbulence research.

Much has changed with regard to the understanding of turbulent flows in the past few years. Recent research (Refs [3] to [8]) has revealed that "turbulence is not as chaotic and random as has been assumed previously", (J. Laufer, Ref [3]). It has been found that turbulence contains in its structure "a certain order" which manifests in the form of an "observable chain of events", even if the elements forming this "chain" exhibit some substantial stochastic deviations from their (definable) average values. The total chain of the events mentioned is referred to as the "bursting process". In the following, first outline information on the bursting process is given, then, using this information, an attempt is made to explain the origin of dunes (i.e., of the sand waves which have the size proportional to the external dimensions of flow). This explanation appears to be clearer than previous ones (Ref [9]).

The descriptions and considerations that follow refer to unidirectional flows. However, as it can be inferred from the earlier part of this Introduction, they should be applicable also to tidal flows (during the time intervals θ^+).

BURSTING PROCESS

1. Consider a developed macroturbulent eddy E transported in the direction of the flow (Fig 2.1). The current formed by the (adverse) velocities of its lower part is referred to as the "sweep". The arrival of a sweep at a location of the flow boundary (bed) slows down the flow contacting the bed at that location. The reduction of the flow velocities leads to a local conversion of turbulent flow contacting the bed into a retarded viscous flow. Since the eddy E is usually three-dimensional (e.g., spheroidal rather than cylindrical) the sweep and consequently the retarded local viscous flow layer, shortly the "low-speed streak", are also three-dimensional (i.e., they have a limited width).
2. The passage of the eddy E further downstream causes appropriate conditions for the "separation" (or the "lift-up") of the low-speed streak (Fig 2.2), and consequently for the formation of a "recirculation cell" C. The separated low-speed streak ("ejected fluid") and the recirculation cell C constitute together the "lifting module" which moves away from the bed and which is transported downstream (by the time average flow).
3. The removal of the lifting module causes the replacement fluid to move instead ("cleansing sweep"). Thus the motion of the lifting module inevitably generates a flow field as shown schematically in Fig 2.3. Note that the recirculation cell C and the cleansing sweep adjacent to its downstream side form a "new" eddy E' which progressively grows in its size when the elevation of the lifting module increases. One can say that the progress of the lift-up is equivalent to the growth of a "newly born" macroturbulent eddy (E').

FIG. 2

FIG. 3

4. The lifting module E' moves downstream immediately behind the "parent" module E . Since much of the energy of the parent module E was spent for the birth of E' , the module E is in a "weak" state, and therefore the adverse velocity fields of E' and E (Fig 2.4) are likely to destroy the module E by disintegrating it into a multitude of smaller eddies ("break-up phase"). The scattered multitude of smaller eddies manifests itself in the form of high frequency fluctuations (microturbulence) superimposed on the low frequency ones (macroturbulence).

Although the study of the quasi-cyclic events is still only at its beginning, the researchers in the field seem to be in agreement that the bursting process is regenerative, i.e., that the "birth" of one module is associated with the "death" of another, and thus that the path of a module (E) should end at the location where the path of the next module (E') begins (Fig 3). Let L be the average value (expectation) of the possible path lengths L_i . It is clear that the length L , which can be called the average

"coherence length", is yet another linear characteristic determining the internal structure of a turbulent flow (in addition to the eddy sizes ℓ). Since a macroturbulent eddy carried by the flow downstream can maintain its identity or coherence only along a distance L_i comparable with L , a

"signal" transmitted by an eddy, on average, cannot travel farther than L . One can say that the length L signifies the average extent of the longest disturbances that can occur in the longitudinal direction (x) of a turbulent flow. How big are the coherence lengths L_i of macroturbulent eddies? The measurements of M.A. Badri Narayanan and his co-workers (Ref [5]), carried out for a boundary-layer flow, indicate that the distances L_i are "of the order of several boundary-layer thicknesses δ ". Indeed, as can be seen from their plot (Fig 9 (middle) in Ref [5]), the majority of the experimental points are scattered within the interval

$$\approx 4 \delta < L_i < \approx 7 \delta \quad (2)$$

which includes the value $L_i = 2 \pi \delta$. In the case of a two-dimensional flow in an open channel, h must figurate instead of δ and one would expect that the average coherence distance should be close to $2 \pi h$ which is a "standard" for the orientative prediction of the length of dunes. A more detailed prediction of the dune length Λ can be carried out with the aid of Fig 7.28 in Ref [9] which is the graph of the function

$$\Lambda = \phi(X, Z) \cdot h \quad (3)$$

where $\phi(X, Z) \approx 2 \pi$ if $X > \approx 40$ and/or $Z > \approx 10^4$.

If (as is often postulated) the large scale formations on the flow bed (dunes) are caused by the large scale longitudinal disturbances that occur in the velocity field (u) of a turbulent flow, then the effective spectral density function $S(\omega)$ of the stochastic process $u = f(x)$ (which reflects the fluctuations along the flow direction x at a given instant) must be regarded as defined over a "narrow band" which includes the lowest spacial frequencies $\omega = 1/L_i$ only (Fig 4). The frequency $1/L$ is in the midst of the "band", corresponding autocorrelation function being

$$R_x = e^{-\alpha x} \cdot \cos \left(2 \pi \frac{x}{L} \right) \quad (4)$$

As is clear from the (trigonometric) nature of this function, shown schematically in Fig 4, any disturbance of the field u at a section $x = 0$, say, must be accompanied by similar kinds of disturbances (along x) with the intervals L . For example, if the disturbance in the field u at $x = 0$ (e.g., due to an imperfection or discontinuity on the bed surface) is as to produce an "accretion" (+), then the tendency for an accretion will also be present at the sections $x = L, 2L \dots$ etc. (though with a lesser intensity, due to the "damping factor" $e^{-\alpha x}$); at the sections $x = L/2, 3L/2 \dots$ etc., the tendency for an "erosion" (-) will be present. The sequence of alternate accretions and erosions will inevitably deform the flat initial bed surface into a wavy one, the wave length Λ being the same as L .

When concluding this paper it should be mentioned that the average coherence length L of macroturbulent eddies is, in fact, proportional to their maximum size ℓ_{\max} . Since in the case of a unidirectional flow the size of the largest eddies is the same as the thickness of the flow (δ or h) the proportionalities such as $L \sim \delta$ or $L \sim h$ (introduced above) are justifiable. In general, however, $L \sim \ell_{\max}$, and $\Lambda \approx L$ should be regarded as given by

$$\Lambda \approx 2 \pi \cdot \ell_{\max} \quad (5)$$

(if $X > \approx 40$ and/or $Z > \approx 10^4$)

In some cases of a tidal flow the time average value of ℓ_{\max} (during θ^+) may be less than the average flow depth h , and therefore it would be more prudent to consider the length Λ of the tidal dunes as a quantity which "cannot exceed $2 \pi h$ " (if $X > \approx 40$ and/or $Z > \approx 10^4$) rather than as that which is "equal to $2 \pi h$ ".

LIST OF SYMBOLS

t	time
x	direction parallel to the flow
y	direction perpendicular to flow
ρ	fluid density
ν	kinematic viscosity
h	flow depth
δ	boundary layer thickness
u	local flow velocity
τ	local shear stress
τ_0	shear stress acting on the bed
$(\tau_0)_{cr}$	critical value of τ_0 (corresponding to the beginning of sediment transport)
$v_* = \sqrt{\tau_0/\rho}$	shear velocity
D	representative grain size (usually D_{50}) of bed material
$X = v_* D/\nu$	grain size Reynolds number
$Z = h/D$	relative flow depth
Λ	dune length
$\overline{\tau_0}$	duration of the dune development
T	tidal period
θ	part of the tidal period where $\tau_0 > (\tau_0)_{cr}$
L_i	"coherence distance" of an eddy (i)
L	average value (expectation) of the distances L_i

CHAPTER 125

TRANSPORT MECHANISM IN TIDAL DUNES

by Horst Nasner^x

I. Preliminary Remarks

An interesting question arising within the scope of the further development of the German tidal rivers Elbe and Weser, is whether tidal dunes or sand waves will be formed after the navigation channel deepenings and that the success of the development measures will thus be partially or fully undone. In order to be able to better assess the formation and regeneration of these large patterns after dredging, heightened knowledge of the sand transport in a tidal dune field is necessary. A possibility of investigating the sand transport in a tidal river with pronounced tidal dunes in the field, can be realized by measurements with luminaries or tracers. The advantage of investigations in the field is, that all laboratory required scale effects are eliminated. The more difficult measuring comprehension of the course of the test in prototype must be solved through purposefully planned investigation programs.

Subsequent to observations of many years standing, on behavior of four tidal dune areas in the navigation channel of the Weser River estuary (6), investigations were carried out with luminaries above reach 1 (Fig. 1) from September till November 1974. The aim was, to obtain information on the transport mechanism for tidal dunes and heightened knowledge on the causes of regeneration after dredging.

II. Execution of the Investigations in the Field

A. The Investigation Area

The sand wave stretch in the straight section of the lower Weser River between km 27.5 and km 28.0 was fixed for the luminary measurements. As shown by earlier investigations, the large dunes in this area are approximately two-dimensional. Their crests and troughs run perpendicular to the flow direction in the navigation channel (6). The longitudinal profile was determined by the navigation line. In order to be able to undertake the locality determination for the longitudinal soundings required for the waterway survey, double markers have been erected by the Waterways Administration at intervals of about 500 meters on both shores of the Weser. The profile of the Weser bottom in the axis of the navigation channel in the investigation area after various soundings in 1974,

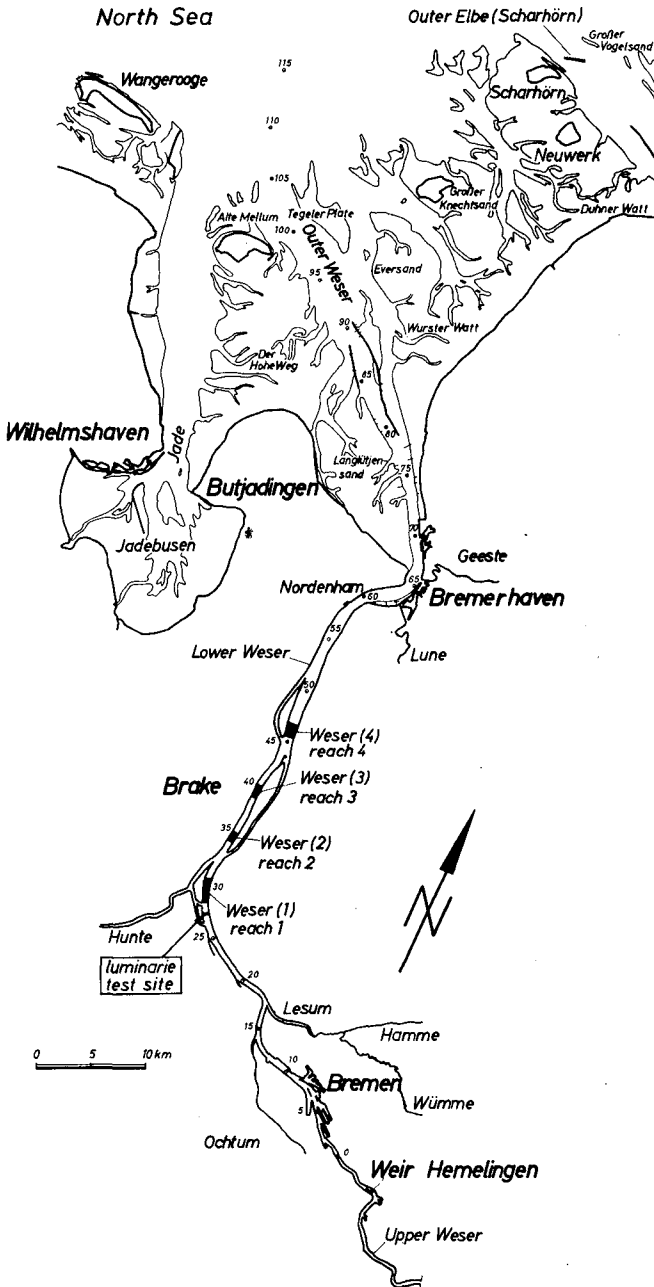

Fig. 1 Weser River with Luminarie Test Site

Fig. 2 Echograph Recordings of the Weser River Bottom

A to B: Grain curve strip of care sample 12

C: Grain distribution curve of the test material

Fig. 3 Grain Distribution Curves

is depicted in Fig. 2. In order to facilitate the locating of the sand waves for the measurements, the position of five sand wave crests and six sand wave troughs was additionally fixed by double markers on the shore of the Weser River on 29th August 1974. As the large dunes change their form only insignificantly in the tidal current rhythm and migrate over a long period of time very slowly in ebb current direction, contingent on the fresh water discharge Q_0 of the Weser (the greater Q_0 is, the higher is the transport velocity u (6)), the additional reference markers were of valuable assistance in carrying out the planned soundings.

B. The Investigation Program

On 29th August 1974, about 1 m^3 of sand was taken from the crest zone of sand wave c (Fig. 2) and subsequently prepared for the investigations. A grain distribution curve for the dyed sand has been depicted in Fig. 3. A very uniform sand ($d_{50} = 0.65 \text{ mm}$, $d_{90}/d_{10} = 2.44$) is concerned here. The test material was dyed two different colors (yellow and orange) and packed into sacks of water-soluble material.

On 18th September 1974, the dyed sand was deposited into a grabber on an anchored ship and quickly placed on the luff slopes of sand wave b (orange) and about 40 m below at c (yellow) in the crest zones, in mid-navigation channel (Fig. 4).

As a result of the packing, it was ensured that none of the sand material would enter a state of suspension before reaching the bottom. On the following days (19/9 and 20/9/74), two and four tides later, the first 9 core extractions were carried out from an anchored vessel with a Senkowitsch probe. The core diameter was 7 cm.

In order to disturb the river bed as little as possible in the area of the sand placing points (at b and c) the core samples were taken at sand waves d and e (Fig. 4). The crest of sand wave d was about 40 m from the location where the yellow dyed sand had been placed and about 90 m distant from sand wave crest b (orange). The crest of sand wave e lay a further 50 meters below d.

In order to create as little danger as possible for ship traffic, the soundings at d and e on the 19th and 20th September 1974 were taken up to 8 m beyond the navigation line. On 22nd and 23rd October 1974, 8 further core extractions were executed at sand waves e and d up to about 15 m beyond the navigation line. The taken bed material was investigated sectionwise (5 cm and 10 cm) for the grain composition and luminaries present.

Fig. 4 Location of the placed luminaries and the Core Sampling Points

In a further operation with a soil grabber on 4th November 1974 in a limited investigation area, upstream to Weser-km 25.5 and downstream to Weser-km 30.0, samples were taken in the navigation line from the surface of the Weser bottom. Subsequently, it was ascertained whether and how many luminaries were present in the soil samples.

III. Investigation Results

A. Tidal and Fresh Water Conditions in the Investigation Period

No storm tides occurred during the investigation period. The mean range of tide in the test area is app. 3.35 m, the mean water depth about 10 m and the mean ebb current velocity app. 100 cm/s.

All measuring operations were executed at low tide.

The mean fresh water \bar{Q}_O between the measurings is compiled in the following:

29/8/1974	Taking of the test material
18/9/1974	Start of the investigations
19/20/9/1974	Core sampling (CS 1 to CS 9)
	\bar{Q}_O (29/8 to 18/9/1974) = 131 m ³ /s
22/23/10/1974	Core sampling (CS 10 to CS 17)
	\bar{Q}_O (19/9 to 21/10/1974) = 144 m ³ /s
4/11/1974	Taking of soil samples
	\bar{Q}_O (22/10 to 3/11/1974) = 429 m ³ /s

According to earlier investigations, at such low fresh water as was the case at the end of October 1974, the sand waves migrate in ebb current direction only very slowly (up to about 20 cm/day) (6). The mean migration velocity of the large tidal dunes in the investigation area was about 50 to 70 cm/day for $\bar{Q}_O = 429$ m³/s from 22/10 to 3/11/1974.

Dredging was not carried out in the test field in the period between 29/8/1974 and 4/11/1974.

B. Core Extractions

1. Luminaries

A total of 63 luminaries were found in the up to app. two meter long core extractions (CS 1 to CS 9, Fig. 4), of 19th and 20th September 1974, of which 36 (57 %) were yellow and 27 (43 %) orange. This result was not surprising, as the placing point of the yellow material lay a

sand wave length closer to the extraction position. According to the evaluation of the samples taken on 19th and 20th September 1974, luminaries were found at sand wave d down to a depth of 0.30 m, and 50 m below at sand wave e, to a depth of 0.10 m.

Soundings of the Weser River bottom on 25/9/1972 during a full tidal current period and at a spring tide range of 405 cm, showed a displacement of the sand wave crests of an average 2.0 m in the tide current direction for the Weser area of km 28.4 to km 30.9. The average sand wave height at the time of the turning of the high tide K_f was 11 cm higher in the mean, than at the turning of the low tide K_e . In contrast to laboratory tests (1), the geometry of the tidal dunes in the field remains unchanged during alternating tidal currents (8). The explanation for the height increase of the sand waves in the Weser is, that the steeper lee slope is levelled off by the flood current and the thereby eroded material is deposited on the luff side. The local redistribution of the sand waves during the tidal movement clears up the question, why the luminaries were found in the extracted cores up to 0.3 m below the sand wave surface, one and two days after they had been placed.

The core samples taken on 22nd and 23rd October 1974 were intended to give information on the long-term resultant redistribution of the bed material in ebb current direction. A total of 138 were found in the 8 core samples (CS 10 to CS 17, Fig. 4), of which 80 (58 %) were yellow and 58 (42 %) orange. The number of luminaries found in the samples of only 7 cm diameter is of minor significance as compared to the fact, that the investigation material was found at greater depths in six of eight cores. Luminaries were present in core sample CS 12 down to 1.80 m below the surface of the sand wave. The only explanation for this is, that in the resulting wandering of the sand wave in ebb current direction, the dyed sand was deposited on the lee side. A similar result was brought about by theoretical considerations for directionally steady current (2,3,4), according to which the sand transport is effected in a sand wave field through erosion of the luff slopes and alluvium on the lee side in short distance transport. In Fig. 5, the distribution of the luminaries found at 10 cm intervals in the core sample CS 12 taken from sand wave e, is depicted. The luminaries are spread over the entire length of the core, as was also the case with the other samples. The number of luminaries present in the 10 cm long cylinder pieces, fluctuates between 2 and 8. Conclusions can be drawn only with reservations and without claim to general acceptance, because of the low number. It is therefore conceivable for example, that the section-wise alternating quantity of luminaries, is traceable to differing tidal and current conditions in the time from 18/9/1974 (placing of the material)

Fig. 5 Luminaries found in a Core Sample taken from Dune Crest app. four Weeks after Start of Tests

Fig. 6 Luminaries found on the River Bottom app. six Weeks after Start of Tests

up to 22/10/1974 (taking of CS 12). An increased ebb tide current on several days could have led to a stronger alluvium in the lee area of the sand wave and thus to a higher concentration of luminaries in certain extraction depths. The explanation for the presence of the luminaries from the upper surface down to 1.80 m boring depth is, that the material which had been deposited during the ebb tide phase in the lee area, was transported upstream again in part during the following flood tide phase.

As a result of the luminaries at greater depth below the upper surface of the sand waves, the fact is confirmed that the sand transport at tidal sand waves takes place essentially through local redistribution of the bed material.

The extent to which the luminaries had spread on the upper surface in the investigation area about six weeks after their placing on the Weser bottom, was determined by taking soil samples in the axis of the navigation channel between Weser km 25.5 and Weser km 30.0, and in the crest and trough areas of sand waves a to e. No luminaries were found upstream from km 27.5 and downstream from km 28.0. The luminaries found in a limited investigation area have been depicted in Fig. 6. With the exception of the sample in section No. 9 with a total weight of about 220 g, all other soil samples had a total weight of about 1000 g and thus easy to compare.

The result given in Fig. 6 shows clearly, that the investigation material was transported only insignificantly in ebb current direction, even 6 weeks after the start of the field test.

In comparison to the resultant current route in the test reach, the ebb current orientated sand transport in the sand wave field is smaller by decimal powers, as shown by the following. Cross section referred flood and ebb routes " s_f " and " s_e " were determined according to a calculation with mean tide by the Wasser- und Schiffahrtsdirektion Bremen (Waterway and Navigation Authority Bremen) (9). The mean ebb (flood) current velocities v_{em} (v_{fm}) in the discharge cross section result from the integral of the current velocities between the turn of tide points K, divided by the current duration D_f (D_e).

$$v_{fm} = \frac{\int_{K_e}^{K_f} v_f(t) dt}{D_f} ; \quad v_{em} = \frac{\int_{K_f}^{K_e} v_e(t) dt}{D_e}$$

The cross section referred flood (ebb) routes are determined with:

$$"s_f" = \int_{K_e}^{K_f} v_f(t) dt \quad ; \quad "s_e" = \int_{K_f}^{K_e} v_e(t) dt$$

The residual current results from $s_r = "s_e" - "s_f"$. The following values for s_r result for two Weser reaches below the investigation area are of interest here

Weser	Q_0 m ³ /s	s_r km/Tide
km 28.4 to 30.9 reach 1, Fig. 1	100 282 600	3.9 7.1 12.3
km 34.5 to 35.5 reach 2, Fig. 1	100 282 600	3.9 6.9 11.4

At a fresh water discharge of only 100 m³/s, the residual current is already app. 4 km/tide in ebb current direction. The fresh water discharge was $Q_0 = 224$ m³/s in the mean from the beginning of the investigations (18/9/1974) up to the day of the taking of the soil samples (4/11/1974). The short travel distance of the bed material on the surface shows how stable the sand wave covered river bottom is. The investigations with luminaries have shown in total, that the bed material in a sand wave field is transported through local redistribution with the resultant travel velocity of the tidal dunes.

2. The Bed Material

The section-wise executed sieve analyses of the core samples have shown, that the bed material in the interior of the sand waves is not uniform. In Fig. 3, the enveloping grain distribution curves of the analyses of the core samples CS 12 have been depicted (curves A and B). The earlier determined grain distributions of sand wave reaches in the Weser and Elbe Rivers (6), all lie in the medium sand range between enveloping curves A and B.

The tendency is, that the grain distribution curves of the other core samples are similar to those shown in Fig. 3.

The evaluation of the bed material in the soil samples, showed in general with increasing depth, a reduction of the finer components as compared to the coarser material, as also shown by the example of core sample CS 12 (Fig. 7). This result also coincides with earlier investigations on river banks and sand waves, according to which, coarser material is present in the trough areas (5,6,8).

The inconstant distribution in the core samples shows how the transport of fine and coarse bed material, contingent on the time, proceeds over the luff slope of a sand wave to the neighbouring lee slope, as a result of which, the stratification recognizable in Fig. 7 occurs. This time-contingent transport of differing bed material can likewise be responsible, that the number of found luminaries fluctuates in the core sample sections. In order to be able to obtain further information thereon, the grain diameter of the luminaries must also be determined in future measurings.

It must yet be mentioned at this point, that model tests at the Franzius Institute with bed material from sand wave c, have confirmed the alternating stratification of coarser and finer bed material in the interior of the sand wave, despite the changed geometric and hydraulic conditions in the laboratory at stationary current (10).

The fact emerged during the core extractions at sand waves d and e, that beginning at drilling depths which correspond to the elevation of the troughs, a firm clay layer was found. Accordingly, the sand banks in the area under consideration here, migrate over a non-erodable soil, from which no sand waves are formed. This result shows, what importance is attached to objectively executed soundings, before the deepening of a river bottom. It can only then be stated, whether sand wave formation must be figured on after the work is completed, when it is known what type of bed material will be encountered during deepening dredging. If for example, there is a layer of clay present at the trough level of a sand wave reach and a subgrade is created during a deepening through stripping the sand wave, sand waves could only then form after the development measures, if sandy material from outside can penetrate into the deepened river stretch.

Fig. 7 Core Sample taken from a Dune Crest

IV. Conclusions

The investigations with luminaries in a sand wave reach of the lower Weser River, in good concurrence with theoretical considerations (2,3,4), have shown that the sand transport is effected essentially through local redistribution of the bed material. The resultant sand transport in ebb current direction corresponds to about the migration velocity of the tidal dunes. It emerges from the result, that the regeneration of the sand waves after dredgings and the minimum depths resulting therefrom, are likewise caused by short distance transport. Separate investigations on the regeneration of tidal dunes after dredgings have shown, that the troughs are very stable and that the sedimentation takes place chiefly in the crest area (7). As undesirable water depths are repeatedly encountered also in sand wave reaches of several kilometers length, and the sand transport proceeds only very slowly, the bed material required for the growth of the banks must enter the navigation channel in transverse transport from the embankments and shores. If it could be managed to prevent the continued feeding of bed material from the sides through shore and embankment revetments, it should be possible to considerably lengthen the regeneration time of the tidal dunes solely herefrom.

V. Acknowledgement

The investigations were carried out at the request of the Deutsche Forschungsgemeinschaft (German Research Association) in cooperation with the City of Brake Waterways and Navigation Authority, the Bundesanstalt für Wasserbau (Federal Institute of Hydraulic Engineering) Küste field office in Kiel and the Franzius-Institute of the Technical University of Hanover.

CHAPTER 126

SEDIMENTATION STUDIES ON THE NIGER RIVER DELTA

Ramiro Mayor-Mora, D. Eng. (1)
Preben Mortensen, M.Sc. (2)
Jorgen Fredsoe, M.Sc. (2)

1. Introduction

An area of the Niger River Delta was studied from October 1974 to October 1975 in connection with feasibility studies and preliminary design for the development of a deep draught port in the Western portion of the Delta. The provision of a 100-kilometer, 8 or 10 m navigation channel through one of the entrances from the sea, up to new port facilities at Warri required comprehensive hydraulic, hydrographic and sedimentation surveys over such period.

Figure 1. Location Map

- (1) SNC Inc. (Consultants), Montréal, Canada
- (2) Danish Hydraulic Institute, (DHI), Copenhagen, Denmark

The sedimentation studies dealt primarily with the conditions at the entrances. The main entrance to the existing ports of the Western Niger Delta used today by ships of up to 6 m draught is the partly protected entrance of Escravos. At such entrance, two moles were constructed around 1960 following intensive hydraulic studies that included testing on physical models.

However, the sedimentation is concluded to be in the order of 2 million cubic meters per year in the lee of the breakwaters. This sedimentation has been explained and possible solutions discussed.

An unprotected channel through the Forcados Entrance was considered as an alternative to improvement of the Escravos Entrance. Such a channel would be dredged through sand and the sedimentation due to combined current and wave actions was studied.

A theory for sedimentation of suspended load in an unprotected dredged channel in non-cohesive material was developed in connection with the study of Forcados Entrance. This theory is presented herein as an appendix.

2. Escravos Entrance

2.1 Background

The present entrance to the ports of the Western Niger Delta for ships drawing less than 4 to 5 m was chosen following hydrographic and hydraulic studies in the period 1953-1955. The minimum natural depth of Escravos bar was about 4.0 m and those studies concluded that a dredged 6 m deep channel through Escravos Entrance was required and that it had to be protected from sedimentation.

Based on hydraulic model tests, it was decided to construct a breakwater system consisting of a main breakwater (length 9 km) on the southern side of the channel and a detached breakwater (length 1 km) on the northern side of the channel, as illustrated on Figure 2 below.

Figure 2. Present Escravos Entrance Protection

The purpose of the breakwater protection was

- to protect the navigation channel from deposition of material coming from the south due to the northgoing littoral drift.
- to guide the main part of the ebb current over the Escravos Bar creating current velocities sufficient for natural maintenance of the dredged channel.

The model studies concluded that the flow had to be concentrated further by means of an island breakwater, whereas the last 2 to 3 km of the dredged channel beyond the tip of the main breakwater were suggested to be left unprotected.

2.2 Monitoring of Sedimentation

One of the main objectives of the study was to investigate and explain the heavy siltation that was known to take place in lee of the breakwaters.

After a maintenance dredging carried out in November-December, 1974, a field investigation program including frequent soundings on the bar was initiated and continued until August, 1975. The monitoring yielded definitive answers to the important questions of where and when sedimentation occurs and which kind of material is depositing in the channel.

It was calculated that if the dredged channel had been constantly maintained with a navigation depth of 6.0 m, the annual maintenance dredging would be in the order of 2.0 million cubic meters depending on the assumptions made (frequency of dredging, over-dredging, etc.).

Apparently, sedimentation in the channel in the lee of the breakwater takes place throughout the year. It is difficult to calculate any seasonal variation of the sedimentation based on the results of the monitoring, since a depth close to the natural depth was achieved about half a year after completion of the dredging. But it is assumed that the sedimentation rate is constant throughout the year, since no significant change is found from the period December to March (when the fresh water season ends) to the period April to May (when the rough-wave season starts).

The sediments deposited in the dredged channel were found to consist of extremely fine, silty materials.

2.3 Sedimentation Mechanism

An explanation to the heavy siltation in the channel in the lee of the mole is found through a study of the current patterns through the Escravos Entrance, which are strongly dominated by the tides.

During the ebb current, the flow is concentrated at the mouth of the Escravos River. At some distance seawards from the mouth, the depth in the main channel decreases, the current velocities increase slightly and a flow out of the channel into the shallow area north of the channel is found.

Figure 3. Sedimentation and Ebb Discharges in the Lee of the Breakwater

It is evident that a major part of the flow turns north before reaching the tip of the breakwater, especially in the area between the breakers and the island breakwater. The resulting effect is a decrease in current velocity east of the tip of the breakwater.

Figure 3 shows a characteristic ebb discharge across a section along the navigation channel in percentage of the total water discharge leaving the mouth of the Escravos River. It can be seen that only about 10% of the total discharge passes over the sedimentation area.

It is therefore concluded that the breakwaters do not create the desired effect, except for a local increase in current velocities between the breakwaters which does occur. The region of heavy siltation is found in the lee of the main breakwater, where current velocities decrease.

It should be emphasized that the clay and silt depositing in the channel do not necessarily originate directly in the Escravos River. North of the channel the bed consists of silt and clay exposed directly to wave action, the magnitude of sediment concentrations at the river mouth being very close for either the rough or the mild wave seasons. Therefore, considerable quantities of suspended silt and clay are being brought into the Escravos River during the flood current and out again during ebb current. The sedimentation in the channel may therefore be considered a transport from one area of the Escravos Entrance to another due to the difference in the current patterns during flood and ebb.

2.4 Possible Improvements

The most straightforward way to reduce sedimentation would be to construct a northern breakwater which should run more or less parallel to the existing main breakwater and be connected to the coast north of the Escravos Entrance as shown on Figure 4. This new arrangement would reduce the quantity of fine material being brought into the system from the north and at the same time, because of the flow concentration, create a scouring effect between and beyond the breakwaters.

By confining the navigation channel between two breakwaters the flow conditions between them would be similar to those at the mouth of the Escravos River in the present situation:

Figure 4. Escravos Entrance Improvement

During ebbing the flow acts as a jet and during flooding its behaviour is similar to that characteristic of a drain. Hence, in order to avoid sedimentation or significantly reduce it in the new navigation channel, the tip of the new breakwater should necessarily be placed at such a distance from the coast that the erosion zone beyond the new mouth extends across the whole of the present bar region in order to obtain sufficient natural depths throughout that shallow region.

The difference in flow pattern between ebb and flood currents would, along with other mechanisms, be able to generate erosion of the bed to a new natural depth similar to the present depth at the mouth of Escravos River (11 m).

3. Forcados Entrance

3.1 Proposed Navigation Channel

A navigation channel through the Forcados Entrance was studied because a route through Forcados to Burutu and to Warri would be much shorter and involve much less capital dredging within the estuary than a waterway to the same ports through the Escravos Entrance (see Figure 1).

Figure 5. Navigation Channel through the Forcados Entrance

The outermost part of the channel has a direction perpendicular to the depth contours in order to minimize capital dredging.

3.2 Present Conditions

At the Forcados Entrance the present natural depth of the bar at the threshold is about 4.8 m according to soundings made in September 1975. The depth of 4.8 m is about equal to the natural depth on the Escravos Bar before construction of the breakwaters.

The main difference between the entrances of Escravos and Forcados is the vast breaker zone south of the Forcados entrance channel that creates an asymmetrical configuration of the entrance.

The breaker zone, reaching more than 10 km into the sea, is exposed to direct wave attack.

The ebb currents concentrate along the area north of the breaker zone with typical velocities of about 1.0 m/sec. at the mouth of the river. The current velocities have been found to decrease only slightly before reaching the Forcados Bar.

While flooding, the Forcados Entrance acts like a drain. The incoming currents just north of the breaker zone are very weak compared to the outgoing currents. Most of the tidal volume going in through the Entrance while flooding passes through the breaker zone.

In general, the bottom configuration in the Forcados Entrance area is found to be rather stable, charts covering a period of 100 years showing little change in the same configuration. But the vast southern area directly exposed to wave action and the interaction between northgoing and westgoing sand transports results in fluctuations of the bottom configuration around the breaker zone.

3.3 Sedimentation Mechanisms

On Figure 5, the navigation channel has been divided into two sections which, from a sedimentation point of view, are different since the principal mechanisms causing sedimentation are different.

Section 1 of the channel runs from the mouth of the Forcados River to the eastern side of threshold of Forcados Bar. Within section 1, the main sedimentation mechanism will then be flattening of the channel sides due to currents parallel to the channel alignment.

Section 2 of the channel is exposed to direct wave action, and the predominant current directions are perpendicular to the channel alignment.

In the channel where the bed consists of fine sand the concentration of suspended sediments is determined by the waves and the currents. Concentrations a few centimeters from the bottom are determined by the wave action (wave height and wave period) while the distribution of the concentration from the thin bottom layer to the surface is determined by the current.

The bottom concentration determined by the waves will, in general, decrease as the depth increases.

As the current passes over the side slope of the dredged channel, the concentration profile determined by the waves and the current will change, and in principle a quantity of suspended sediment corresponding to the difference in concentration profiles will settle in the dredged channel.

This sedimentation mechanism is dominating in section 2 of the navigation channel through Forcados Entrance. However, the mechanisms described for section 1 have also some effect although in a modified manner.

3.4 Calculated Sedimentation Rates

In section 1 of the entrance, the future sedimentation rates are calculated on the basis of the theory developed in Ref. 1 Levelling of Side Slopes in River Navigation Channels.

Figure 6.

The depositing volume per meter of channel (deposition area A shown on Figure 6 above) is found as the difference between the profile $h(x)$ at the time $t = t_2 > t_1$ and the profile at the time $t = t_1$:

$$A = a \frac{\sqrt{v}}{\sqrt{\pi}} \cdot (\sqrt{t+t_1} - \sqrt{t_1})$$

This general solution to the problem of instability of a transverse slope in an unidirectional flow yields the deposition volume at the bottom of the slope as a function of the time t after a certain start condition at time t_1 .

v is a function of the longitudinal bed-load transport rate.

In section 1 of the channel sedimentation rates of about 50 cubic meters per meter channel per year were found.

In section 2 of the channel the main sedimentation process is the one described in the Appendix, Changes in the Profile of Concentrations Due to Changes in Water Depth.

The general expression for the sedimentation rate in the dredged channel is:

$$q_r = \left\{ q_{10} \left(1 - \exp \frac{-W}{\epsilon} \frac{W}{V_b} \frac{D_1}{D_2} \frac{B}{\cos \alpha} \right) - q_{20} \left(1 - \exp \frac{-W}{\epsilon} \frac{W}{V_b} \frac{B}{\cos \alpha} \right) \right\} \cos \alpha.$$

where

- q_{10} = transport of suspended sediments, equilibrium conditions at depth D_1
- q_{20} = transport of suspended sediments, equilibrium conditions at depth D_2
- W = settling velocity of the sand grains
- ϵ = current eddy viscosity
- V_b = "slip" velocity
- B = total channel width
- α = angle between current direction and the perpendicular to the channel alignment
- D_1 = present depth
- D_2 = dredged depth

From the expression above, it is seen that the relative rate of sedimentation (the expression inside the main bracket) increases as the width of the channel B and the current angle α increase, and that the rate decreases as the current velocity V increases.

In the present case it was found that more than 95% of the material, corresponding to the difference in equilibrium transport at water depth D_1 and equilibrium transport at water depth D_2 would settle in the channel.

For the calculation of the equilibrium transport the concentration of suspended load in a reference level 5 cm above the bottom, C_a , was determined from experiments in an oscillating flume.

The sedimentation rates in section 2 of the channel were calculated to be in the order of 1000 cubic meters per meter channel per year (conservative estimate).

APPENDIX

Changes in the Profile of Concentrations of Suspended Material
Due to Changes in Water Depth.

A1 Introduction

In the following discussion a flow over the side slope of a dredged channel is considered. The bed beyond the slope is assumed horizontal and the width of the horizontal channel bottom is assumed to be of infinite length, as shown in the sketch below.

As the flow passes the side of the channel, its velocity changes and therefore the total sediment load, carried as bed load and suspended load, changes accordingly.

While the bed load is able to respond very quickly to changes in the flow, changes in the suspended load take place over a period of time due to the finite settling velocity of the suspended grains.

The purpose of this appendix is to describe how the concentrations of suspended material respond to the change in depth conditions. The theory is developed in two steps:

- In the first step the equilibrium concentration profile is determined by the bottom concentration only. The latter decreases as the depth increases, but the shape of the upper part of the concentration profile does not change.
- The shape of the concentration profile changes as the depth increases. The profile is stretched due to the divergence of the stream lines as the flow passes over the channel side.

A2 The Calculation Model

The calculation model is based on the "slip-velocity" method, described in Refs. 2 and 3. The basic idea behind this calculation method is to assume that the current eddy viscosity ϵ is constant over the depth (rather than decreasing to zero at the bottom). This method (or approximation) makes it necessary to introduce a finite velocity at the bottom, the so-called "slip-velocity".

In the following introduction to the basic equations, x_1 is the horizontal coordinate and x_2 is the vertical coordinate. The vertical distribution of concentration is considered in two situations.

In the steady, uniform condition the vertical distribution of the concentration c_0 is determined by the equilibrium between settling and diffusion.

$$Wc_o + \epsilon \frac{dc_o}{dx_2} = 0 \quad (A2.1)$$

where W is the settling velocity of the grains.

The solution to equation A2.1 is

$$c_o = c_{bo} \cdot e^{\left(-\frac{W}{\epsilon}x_2\right)} \quad (A2.2)$$

where c_{bo} is a nominal bottom concentration and ϵ is the current eddy viscosity.

In the non-uniform situation the distribution of concentration of suspended material is determined by an equilibrium between settling, diffusion and convection:

$$\frac{dc}{dt} = W \frac{\partial c}{\partial x_2} + \epsilon \nabla^2 c \quad (A2.3)$$

As mentioned above the theory will be developed in two steps. In both steps the approximation is made that the current field is steady and uniform, while the distribution of concentrations of suspended sediments is steady but non-uniform in the x_1 -direction. Using this approximation equation A2.3 may be written

$$v \frac{\partial c}{\partial x_1} = W \frac{\partial c}{\partial x_2} + \epsilon \left(\frac{\partial^2 c}{\partial x_1^2} + \frac{\partial^2 c}{\partial x_2^2} \right) \quad (A2.4)$$

Introducing the "slip-velocity" method the variation in the velocity v over the depth may be neglected, the velocity is constant, equal to the "slip-velocity", v_b .

A3 General Solution to the Problem

a) First Step

On the horizontal bed before reaching the side of the channel ($x_1 = 0$), the concentrations are considered to be stationary and uniform, and accordingly the concentration profile is given by equation A2.2. As the depth increases on the side of the channel the bottom concentration changes and equation A2.2 has to be modified in order to satisfy the non-uniform condition.

In order to find a general solution to equation A2.4 the distribution of concentrations is written as

$$c = c_1 \cdot e^{-\frac{W}{\epsilon}x_2} + f(x_2) e^{-\lambda x_1} \quad (A3.1)$$

where c_1 and λ are constants and $f(x_2)$ an unknown function of x_2 .

Substituting c in equation A2.4 for the expression for c in equation A3.1 we find:

$$\frac{d^2 f}{dx_2^2} + W \frac{df}{dx_2} + (\epsilon \lambda^2 + V \lambda) f = 0 \quad (A3.2)$$

The solution for equation A3.2 is

$$f(x_2) = \alpha_1 \cdot e^{(-\frac{W}{\epsilon} + \frac{\epsilon}{W}(\lambda^2 + \frac{\lambda V}{\epsilon}))x_2} + \alpha_2 e^{-\frac{\epsilon}{W}(\lambda^2 + \frac{\lambda V}{\epsilon})x_2} \quad (A3.3)$$

The constants α_1 , α_2 and λ are determined from the boundary conditions as follows:

On the horizontal bed on top of the slope ($x_1 = 0$) the boundary condition is determined by equation A2.2.

$$c = c_{b1} e^{-\frac{W}{\epsilon}x_2} \quad \text{for } x_1 = 0$$

At an indefinite distance from $x_1 = 0$ a new uniform solution, corresponding to equation A2.2 but with a different bottom concentration, is found:

$$c = c_{b2} e^{-\frac{W}{\epsilon}x_2} \quad \text{for } x_1 = \infty$$

The only set of equations that satisfies the first boundary condition is:

$$\frac{W}{\epsilon} = \frac{\epsilon}{W} (\lambda^2 + \frac{\lambda V}{\epsilon})$$

$$\alpha_1 = 0$$

$$c_{b1} = c_1 + \alpha_2$$

The second boundary condition is satisfied by

$$c_1 = c_{b2}$$

From these four equations the unknown constants in the solution to equation A3.1 are found:

$$\alpha_1 = 0, \alpha_2 = c_{b1} - c_{b2}, \lambda = \frac{W^2}{\epsilon v}$$

yielding the solution

$$c = c_{b2} e^{-\frac{W}{\epsilon}x_2} + (c_{b1} - c_{b2})e^{-\frac{W}{\epsilon}x_2} \cdot e^{-\frac{W^2}{\epsilon v}x_1} \quad (\text{A3.4})$$

when W^2/v^2 tend to zero, that is $W \ll v$.

b) Second Step

In the previous step the calculation was made under the assumption that the concentration profile was in equilibrium with a certain bottom concentration changing as the depth increased but the "shape" of the profile was unchanged.

In the second step it is assumed that the concentration profile is stretched due to the divergence of the streamlines as the flow passes over the channel side.

A simple exact solution to the problem of this step is not possible but the effects of the stretched profile may be described by changing the boundary conditions.

If the first boundary condition is given by the equation

$$c = c_{b1} e^{-\frac{W}{\epsilon}(1-\alpha)x_2} \quad x_1 = 0,$$

this condition will be fulfilled by equation A3.3, if

$\alpha_1 = 0$, $\alpha_2 = c_{b1}$ and $\lambda = (1-\alpha)\frac{W^2}{\epsilon v}$, considering $W \ll v$.

That is, for $c = c_{b1} e^{-\frac{W}{\epsilon}(1+\alpha)x_2} \cdot e^{-(1+\alpha)\frac{W^2}{v}x_1}$ (A3.5)

To this solution, a solution

$c_2 = f(x_1) e^{-\frac{W}{\epsilon}x_2}$ (A3.6)

to equation A3.4 that satisfies the boundary conditions

$c_2 = c_{b2} d^{-\frac{W}{\epsilon}x_2}$ for $x_1 = \infty$

$c_2 = 0$ for $x_1 = 0$

has to be added. This solution is

$c_2 = c_{b2} e^{-\frac{W}{\epsilon}x_2} (1 - e^{-\frac{W^2}{\epsilon v}x_1})$ (A3.7)

Therefore the total solution to the problem presented in the two steps is

$c = c_{b1} e^{-\frac{W}{\epsilon}(1+\alpha)x_2} \cdot e^{-\frac{W^2}{\epsilon v}(1-\alpha)x_1} + c_{b2} e^{-\frac{W}{\epsilon}x_2} (1 - e^{-\frac{W^2}{\epsilon v}x_1})$ (A3.8)

A4 Application of the General Solution

For the present application of the theory developed above, a situation determined by a combination of waves and a moderate current is considered.

The undredged depth is called D_1 , and the corresponding current velocity V_1 . The depth in the channel is called D_2 and the corresponding current velocity V_2 .

The concentration of suspended material in a bottom layer a few centimeters thick (bottom concentration) is determined by the wave action, as the bed shear stress due to the wave action is much greater than the current shear stress, whereas the vertical distribution of the concentrations from the bottom to the surface is governed by the currents.

The bottom concentration on the horizontal bed beyond the side slope is called c_{b1} and the vertical distribution of concentration is described by

$$c_{b1} \cdot e^{-\frac{W}{\epsilon} x_2} \tag{A4.1}$$

At the toe of the side slope of the channel the approximation is made that the bottom concentration is unchanged, but the concentration profile is stretched with the same ratio as the depth is changed, i.e. $\frac{D_1}{D_2}$. Therefore the concentration is given by

$$c_{b1} \cdot e^{-\frac{W}{\epsilon} \frac{D_1}{D_2} x_2} \tag{A4.2}$$

At an indefinite distance from the channel side a new equilibrium profile is reached. The bottom concentration is given by c_{b2} and the concentration profile is accordingly given by

$$c_{b2} \cdot e^{-\frac{W}{\epsilon} x_2} \tag{A4.3}$$

Keeping in mind that the eddy viscosity is assumed to be constant and that the current velocity in the applied calculation model may be replaced by the constant "slip-velocity", the transport of suspended material q may be easily calculated as

$$\int_0^D (c \cdot v) dx_2 \tag{A4.4}$$

At the un-dredged depth D_1 , the sediment transport q_{10} is

$$q_{10} = \int_0^{D_1} c_{b1} e^{-\frac{W}{\epsilon} x_2} \cdot v dx_2 \approx v_{b1} \cdot \frac{\epsilon}{W} c_{b1} \cdot (1 - e^{-\frac{W}{\epsilon} D_1}) \tag{A4.5}$$

In the case of sand particles (high W),

$$q_{10} = v_{b1} \cdot \frac{\epsilon}{W} c_{b1} \tag{A4.6}$$

At an infinite distance from the side slope ($x_1 = \infty$), the sediment transport is given by

$$q_{20} = \int_0^{D_2} c_{b2} \cdot e^{-\frac{W}{\epsilon} x_2} \cdot v dx_2 \approx v_{b2} \frac{\epsilon}{W} c_{b2} \tag{A4.7}$$

The sediment transport $q_2(x_1)$ between the two boundaries is given by an integration of equation A4.4

$$\begin{aligned} q_{20} &= \int_0^{D_2} \left\{ c_{b1} \cdot e^{-\frac{W}{\epsilon} \frac{D_1}{D_2} x_2} e^{-\frac{W}{\epsilon} \frac{W}{v} \frac{D_1}{D_2} x_1} - c_{b2} e^{-\frac{W}{\epsilon} x_2} \right. \\ &\quad \left. \cdot (1 - e^{-\frac{W}{\epsilon} \frac{W}{v} x_1}) \right\} \cdot v \frac{D_1}{D_2} dx_2 = \\ q_{10} \cdot e^{-\frac{W}{\epsilon} \frac{W}{v} \frac{D_1}{D_2} x_1} - q_{20} (1 - e^{-\frac{W}{\epsilon} \frac{W}{v} x_1}) \end{aligned} \tag{A4.8}$$

The overall aim of the above calculation is to evaluate the rate of sedimentation between the two boundary conditions corresponding to the two equilibrium situations at $x_1 = 0$ and $x_1 = \infty$. The rate of sedimentation as well as the distribution of sedimentation is found by subtracting the sediment transport $q_2 = q_2(x_1)$ from the sediment transport at $x_1 = 0$. The rate of sedimentation $q_Y(x_1)$ is given by

$$q_{10} - q_2 = q_Y(x_1) = q_{10} \left(1 - e^{-\frac{W}{\epsilon} \frac{W}{v} \frac{D_1}{D_2} x_1}\right) - q_{20} \left(1 - e^{-\frac{W}{\epsilon} \frac{W}{v} x_1}\right) \quad (\text{A.4.9})$$

If the current crosses the channel at an arbitrary angle α , the following sedimentation rate q_x per meter of navigation channel length is found:

$$q_x = \left\{ q_{10} \left(1 - e^{-\frac{W}{\epsilon} \frac{W}{v} \frac{D_1}{D_2} \frac{B}{\cos \alpha}}\right) - q_{20} \left(1 - e^{-\frac{W}{\epsilon} \frac{W}{v} \frac{B}{\cos \alpha}}\right) \right\} \cos \alpha \quad (\text{A4.10})$$

This general expression has been developed for application to sand bed material (non-cohesive materials only).

CHAPTER 127

GENERATION OF TROUGHS BY DENSITY CURRENTS

Hans Speekenbrink *

Abstract

Along the northern bank of the so-called "Maasgeul" scour has occurred, causing a trough. It is concluded from field measurements that the trough development is induced by density currents along the slope of the bank. The stratified flow system is dealt with mathematically. The calculated results are compared with the field measurements and agree fairly well. Trough development can be avoided by flattening the slope or by a bottomprotection.

Introduction

Since early 1970 scour has occurred along the northern boundary of the so called "Maasgeul", the dredged shipping route to the "Europoort" and Rotterdam harbours (see fig. 1), over a distance of about two miles. By this scour a trough has developed (see fig. 2 and 3) with a depth of 5 to 10 m below the bed of the navigation channel (M.S.L. - 24 m) with slopes of about 1 : 3 (see fig. 4). The surrounding sea bed has a depth of M.S.L. -16 m at the eastern- and of M.S.L. -19 m at the western end of the trough.

The material eroded from within the trough sedimentates south of it in the channel, from where it has to be removed right away in order to keep the guaranteed navigational depth at all times.

Widening of the trough in easterly direction possibly can endanger the stability of the end of the northern harbour mole.

*Rijkswaterstaat, Department for Coastal and Sea Research,
The Netherlands

Investigations have now been carried out into :

- a. The mechanism, that causes the generation of the trough
- b. The future equilibrium profile of the trough
- c. Possible measures to avoid or reduce trough development.

Trough development

Scouring has occurred along the northern bank of the "Maasgeul" from about 300 m west of the end of the northern harbour mole to about 4 km west of this mole. This section of the "Maasgeul" may be considered as a transition zone between open sea and the mouth of the river Rhine, which discharges its water via the "Rotterdam Waterway".

In January 1970 scouring started about 500 m west of the end of the mole over a distance of about 50 m and widened to the east (150 m) and to the west (200 m) in 4 months time. Some months later scouring was observed about 2 - 3 km west of the first trough over a distance of 1000 m. This trough widened in easterly direction to join the first trough although a small ridge remained between the two trough sections (see fig. 3).

Trough developments were first observed by routine echo soundings made to guard the navigational depth. In August 1974 with scour still continuing it was decided to carry out echo soundings more frequently. Every month, if possible in respect of weather conditions, echo soundings were carried out in lanes perpendicular to the trough axis at distances of 250 m. Until now scouring still continues almost linear in time (see fig.5), although it seems that scouring in summer is slightly greater than in wintertime.

The slopes of the northern bank steepened from about 1:10-15 to 1:3 in the first two years of trough development (see fig. 6). This slope has been rather stable since, although periodically slopes up to 1:1 were observed. The slopes of the southern bank have steepened to a value of about 1:4.

The northern bank remained very stationary but the southern bank moved in a southerly direction over an average distance

of about 15 m in two years time.

No significant widening of the trough in easterly nor in westerly direction could be distinguished during the last two years of observations.

The mechanism, causing trough generation

To find an explanation for the generation of the trough, surveys were carried out into the vertical distribution of the current velocities and directions and of the salt concentrations and temperatures. The measurements were related to the vertical tidal movement in Hook of Holland. The situations of the measuring points are indicated on fig. 2.

All measurements showed stratification during low tide. Differences in current direction up to 90° were found in upper and lower layer. In the upper layer the less saline water, discharged from the "Rotterdam Waterway" flows in a westerly direction, parallel to the channel axis (see fig. 7). Velocities reach values of 0.5 - 0.8 m/s at this tidal stage. The flow in the lower region shows a more southerly direction, almost perpendicular to the channel axis, corresponding to the direction of the tidal stream along the Dutch Coast at low tide. The velocities in this layer are about 0.5 - 0.6 m/s at the measuring point north of the trough, 0.8 - 1.0 m/s at the trough and about 0.5 - 0.6 south of it.

From these measurements of current velocities and density distributions it was concluded that density currents occur at low tide. A sketch of the stratified flow system is given in fig. 8.

The heavier underflow accelerates beneath the discharged, less saline river water, becoming critical at the upper edge of the bank of the trough and supercritical further down along the slope due to the steepness thereof.

Supercritical flow occurs at internal Froude-numbers F_i greater than 1.

$$F_i = \sqrt{\frac{u_i}{\epsilon g a_i}} \quad i = 1, 2 \quad (1)$$

in which u =velocity; $\epsilon = (\rho_2 - \rho_1) / \rho_2$; ρ =density;
 g =gravitation acceleration; a =layer depth; and subscripts 1 and
 2 = upper and lower layer respectively.

The increasing velocities will cause erosion and thus steepening of the bank. In this bank there is a clay layer with a thickness of about 3m. The top of this layer is found at a depth of about M.S.L. - 18 m at the eastern end of the trough and about M.S.L. - 20 m at the other end. The clay is very stiff and is resistant to scour, thus limiting erosion to the foot of the bank. When the slope steepens more than the natural slope of the bed material, the clay layer is undermined causing a slide down and thus an intermittent shift of the bank in a northerly direction. Although this shift can not be determined from the echo soundings it may be derived from core samples taken at the trough in 1974 that a local slide down of the clay layer occurred.

This clay layer may also be responsible for the fact that scouring did not start before 1970 and only after deepening the navigation channel to a level below this layer.

The foot of the bank may be regarded as a so called plunge-pool from which also sediment is removed.

The current measurements show that the flow is supercritical at the trough in the navigation channel. The conversion will take place via an internal hydraulic jump at the southern bank of the trough. Downstream this jump the current velocities will be too low for erosion and even sedimentation occurs, causing a ridge along the trough.

Mathematical model for two-layer stratified flow

A mathematical model may be derived for the flow across the trough. The following assumptions were made: (1) the flow is steady; (2) the flow in each layer is one dimensional i.e. there is a constant velocity and density at each cross section in each layer; (3) stratification is stable; there is a sharp interface between the layers and there is no entrainment across

the interface; therefore the density is also constant longitudinally in each layer; (4) shear stresses are acting along the bottom and the interface and are proportional to the velocity differences across the boundaries.

North of the trough the bottom has a gentle slope and the water surface and the interface are assumed to have gentle slopes too. The vertical accelerations may be neglected so the water pressure can be considered hydrostatic. The following equations, as given by Schijf and Schonfeld [1] may be applied.

The equations of motion for the upper and lower layers can be written as :

$$\frac{da_1}{dx} + \frac{da_2}{dx} + \frac{u_1}{g} \frac{du_1}{dx} + \frac{f_i |u_1 - u_2| (u_1 - u_2)}{ga_1} + S_b = 0 \quad (2)$$

and

$$(1-\epsilon) \frac{da_1}{dx} + \frac{da_2}{dx} + \frac{u_2}{g} \frac{du_2}{dx} - \frac{f_i |u_1 - u_2| (u_1 - u_2)}{ga_2} + \frac{f_b |u_2| u_2}{ga_2} + S_b = 0 \quad (3)$$

respectively, in which x = longitudinal coordinate taken as positive from north to south; f_i = friction factor at the interface; f_b = friction factor at the bed; S_b = bottom slope.

The continuity equations read :

$$\frac{dq_i}{dx} = 0 \quad i = 1, 2 \quad (4)$$

in which q = au = discharge per unit width.

Substituting the continuity equations in the equations of motion to eliminate du_i/dx and da_i/dx and neglecting u_i^2 in relation to $a_i g$ according to the field measurements, the resulting equation may be written as :

$$\frac{da_2}{dx} = \frac{(u_1^2 - \epsilon g a_1) a_2 S_b + (1 - \epsilon) f_i (a_1 + a_2) |u_1 - u_2| (u_1 - u_2) - f_b a_1 |u_2| u_2}{u_2^2 a_1 + u_1^2 a_2 - \epsilon g a_1 a_2} = 0 \quad (5)$$

$$\begin{aligned} \frac{da_2}{dx} = & \frac{q_1^2 - \epsilon g a_2^3 S_b + (1 - \epsilon) f_i (a_1 + a_2) (a_2 q_1 - a_1 q_2) |a_2 q_1 - a_1 q_2|}{(q_2^2 a_1^3 + q_1^2 a_2^3 - \epsilon g a_1^3 a_2^3)} + \\ & + \frac{-f_b a_1^3 |q_2| q_2}{(q_2^2 a_1^3 + q_1^2 a_2^3 - \epsilon g a_1^3 a_2^3)} \end{aligned}$$

At the upper edge of the northern bank of the trough critical flow will occur if the denominator equals zero :

$$q_2^2 a_1^3 + q_1^2 a_2^3 - \epsilon g a_1^3 a_2^3 = 0 \quad (6)$$

Deriving the total depth at the edge from echo soundings and vertical tide measurements, the discharges from flow measurements and ϵ from salinity and temperature measurements the depth of the interface at the edge may be computed from equation (6). With this depth as boundary condition the flow north of the trough may be calculated from the upper edge of the bank in negative x-direction using equation (5).

The northern bank has a steep slope and the flow in the lower layer will accelerate. It is assumed that the shear stresses in the lower layer are negligible and the energy equations are applied.

The energy equations for the lower and the upper layer may be written as

$$H = \frac{\rho_1}{\rho_2} a_{1x} + a_{2x} + a_{3x} + \frac{1}{2g} u_{2x}^2 \quad (7)$$

and

$$H_u = a_{1x} + a_{2x} + a_{3x} + \frac{1}{2g} u_{1x}^2 + h_x \quad (8)$$

respectively, in which H = energy head elevation relative to the trough floor; a_3 = bed surface elevation relative to the trough floor; index x refers to the distance along the bank; index u refers to the upper edge and h_x = inertia losses.

Assuming that the inertia losses h_x equal the drop in velocity head of the upper layer, thus

$$h_x = \frac{u_{1u}^2}{2g} - \frac{u_{1x}^2}{2g} \quad (9)$$

and substituting equation (9) in equation (8) yields

$$a_1 + a_2 + a_3 = \text{constant} \quad (10)$$

Differentiating equation (7) and using equation (4) and (10) the resulting equation may be written as

$$\epsilon S_b + \left(\frac{\epsilon g a_2^3 - q_2^2}{g a_2^3} \right) \frac{da_2}{dx} = 0 \quad (11)$$

Now the flow on the northern bank can be calculated from the upper edge of the bank in positive x -direction using equations (6) and (11).

The calculations may be simplified by assuming constant friction factors and constant slopes at both sides of the upper edge of the bank.

Calculations were carried out, taking $f_i = 0.001$ and $f_b = 0.004$. The boundary conditions q_2 , q_1 , ϵ and the slopes at both sides of the edge were derived from field measurements. As an example a calculated interface depth is given in figure 10 as well as the measured depth. As may be seen there is a fair agreement. The discharges used as boundary conditions in this example were derived from the velocity measurements in figure 7. The density profiles were derived from salinity and

temperature measurement at the same time (see fig. 11).

At the southern bank an internal hydraulic jump will occur. The flow system in this section is very complicated and has to be investigated by means of hydraulic model tests, which have not been made so far.

Future equilibrium profile

Erosion of the trough floor probably will continue until the hydraulic jump will be submerged. At what depth of trough this will occur has to be investigated in a hydraulic model.

A further widening of the trough is not expected. The longitudinal stability of the trough may be explained at the eastern end by the presence of a bottom protection around the toe of the northern harbour mole. At the western end the density difference decreases due to longitudinal mixing. Besides the steepness of the bank slope is much less (about 1 : 40) as well as the difference in depth between the channel and the surrounding sea bed. Due to these reasons the velocities along the bank are less too.

Measures to be taken to reduce or avoid trough development

To restrain the erosion a bottom protection on the trough floor and the banks may be considered. On the northern bank drag forces and gravity act in the same direction. The critical velocity for stability of loose grained material, as for instance shingle, on slopes can be compared with the critical velocity on a horizontal bed according to

$$u_{cr,s} = \sqrt{\cos S_b} \sqrt{1 - \frac{\tan S_b}{\tan \theta}} u_{cr,h} \quad (12)$$

in which u_{cr} = critical velocity for initiation of movement of bed material; θ = natural slope of the bed material; and subscripts s and h referring to slope and horizontal bed respectively. Using the Shields diagram and taking $\theta = 45^\circ$ it can be calculated that the minimum required grain diameter for the trough bank protection is about 3 cm. At the trough floor the

minimum grain diameter may be even more due to the strongly curved flows here.

Another possible measure to restrain the erosion is reducing the high current velocities and avoiding supercritical flow on the bank by flattening the slope. The flow in the lower layer will not accelerate when $da_2/dx \geq 0$. Using equation (5) and taking $da_2/dx = 0$, the equation for the critical slope, $S_{b,cr}$, may be written as

$$S_{b,cr} = \frac{f_b a_1^3 q_2^2 + (1-\epsilon) f_i (a_1 + a_2) (a_2 q_1 - a_1 q_2)^2}{a_2^3 (q_1^2 - \epsilon g a_1^3)} \quad (13)$$

Assuming $q_1 = 0$ and critical flow on the bank (equation (6)) the equation may be rewritten as

$$S_{b,cr} = f_b - (1-c) f_i \left(\frac{a_1 + a_2}{a_1} \right) \quad (14)$$

From this equation it may be derived that the critical slope is about 1 : 150. Due to possible variations in the main parameters, the friction factors, the critical slope must be considered of the order of 1 : 100 to 1 : 250. These flat slopes involve more than about $4 \cdot 10^6 \text{ m}^3$ to be dredged.

By flattening the slope the upper edge of the bank is shifted in a northerly direction and may become situated outside the surface front of the discharged less saline water. Due to this the flow in the lower layer will stay subcritical.

Because sand is needed in the near future for beach nourishment immediately north of the northern harbour mole, it is considered now to flatten the northern wall of the trough to a slope of about 1 : 50. For this measure a quantity of about $1.600.000 \text{ m}^3$ has to be dredged. Plans are being worked out now and dredging activities will probably be carried out in autumn 1976. The outcoming clay (about 600.000 m^3) will be dumped in the trough as refillment. The effect of this measure will be closely watched by making echo soundings every month, if possible in respect of weather conditions.

Summary and conclusions

Along the northern bank of the "Maasgeul" scour has occurred due to density currents induced by density differences between the discharged river water and the heavier sea water. Stratified flow occur at low tide.

The flow accelerations along the slope, causing trough generation, may be dealt with mathematically. The results of the mathematical model agree fairly well with field data.

The trough development, increasing the amount of maintenance dredging and endangering the stability of the northern harbour mole may be reduced by a bottom protection or by flattening the slope. The latter possibility will be carried out in the near future.

CHAPTER 128

CONCEPT OF MINIMUM SPECIFIC ENERGY AND ITS RELATION TO NATURAL FORMS

by

Gordon R. McKay^{*}, B.Eng., Ph.D. (Liverpool)

and

Ahad K. Kazemipour^{**}, B.Eng.(Tehran), M.Eng.Sc.(NSW)

It is proposed to show in this paper that there is a solution to the problem of non-uniform flow and this solution not only explains in detail many land forms which occur naturally, but thereby, yields a definition of 'form' loss.

If a channel, in which the transverse distribution of specific energy is uniform, converges and/or diverges, and the bed changes so that the flow will be critical at all cross-sections at the same time, the channel appears to be close to being hydraulically smooth.

Many natural forms, particularly estuaries, are readily explicable in this way. The most obvious one is the bar at the mouth of a river. It follows, if the river enters the sea with reasonable uniform grade, which most rivers do, the bed must rise as the flow loses the restricting influence of the banks (i.e. the width increases) if constant specific energy is to be maintained.

It is possible to calculate with considerable accuracy the dimensions of useful structures based on this concept. A large number of full size but nevertheless experimental structures have been built making use of the resultant benefits which develop:- low turbulence, accurate differential water levels and a clearly defined flow pattern, allowing very considerable savings to be made by eliminating expensive protective works.

INTRODUCTION

For more than two centuries, the calculation of open channel flow, steady or unsteady, uniform or non-uniform, has been based on the concept of a long uniform channel in which the boundary shear in some way determines the total head loss. Euler-Bernoulli principle (1700-1782), Chezy's (1718-1798), Poiseuille's (1799-1869), Darcy-Weisbach's (1803-1871), Bazin's (1829-1917) and Manning's (1816-1897) formulas, all of which are in regular use today, are based on the concept of such a long uniform channel. Adaptation of the relatively modern Karman-Prandtle's (1930-32) theory of boundary layer and velocity distribution to open channels is also based on the concept of the long uniform channel.

This assumption was reasonable in the past for artificial channels since most of the channel works (sewers and storm drains) were constructed so that the cross-section of the channel was often semi-circular and therefore the distribution of the shear stress around the boundary could be considered more or less uniform.

There is strong evidence in the literature^{1*} that the studies of energy losses in open channels have been closely related to the phenomena of the boundary layer. For fully developed flow in a uniform channel of any size, the boundary layer will occupy all of the channel, but in partly developed turbulent flow, the energy loss due to frictional resistance is related to the stage of the development of the boundary layer. Again, past research on boundary layer has been concentrated on flow through circular pipes and past flat plates parallel to the stream.

The practising engineer may rightly question the above philosophies and assumptions, but what alternative has been possible? From Report of Task Force on Friction Factors in Open Channels¹ - "*At least, it could be hoped there would be made available something similar to the resistance diagrams now used for steady flow in uniform pipes and for frictional resistance of ships. It should be stated at the beginning that these hopes cannot be realised at this time. Principle obstacles are the wide range of surface roughness sizes and types encountered in practical channels (from smooth concrete linings to boulder-stream canyons), the effect of bed movement in unlined channels, and the numerous bends and structures that prevent the attainment of steady, uniform, fully developed flow*".

In order to allow a solution to the apparently simple problem of determining the flow capacity of a bridge opening or culvert, the U.S. Bureau of Public Roads² publishes a manual of 90 pages of tabulated data. If the bridge type and flow pattern can be reasonably compared with one of those in the manual, a solution can be assessed. Such techniques do little to validate the basic principle.

* Numbers refer to the references in the Appendix.

In deriving and applying the basic formulae and principles of uniform flow to open channels, a quantity 'hydraulic radius', R , representing the channel geometry, is used. Diameter of the pipe, D , is replaced by $4R$. This substitution carries with it the assumption that the distribution of shear stress around the boundary of the channel is uniform. It is well known now that in open channels, especially with non-circular cross-sections, such uniformity of shear stress is a false assumption. This fact clearly points out the failure of hydraulic radius to be the sole geometric quantity representative of the channel cross-section. The effect of cross-sectional shape must be taken into account in the analysis and prediction of the energy losses in open channels. Such studies have been made by some investigators in recent years, among whom are F. Engelund (1964)³, H. Rouse (1965)⁴, E.O. Macagno (1965)⁵, C.C. Shih and N.S. Grigg (1967)⁶, E. Marchi (1967)⁷, N. Narayana Pillai (1970)⁸ and C.L. Yen and D.E. Overton (1973)⁹. The results of these investigations are yet inconclusive. According to H. Rouse⁴, "*the effect of change in shape upon the resistance function is actually twofold. On the one hand, it produces a change in the wetted perimeter, P , per unit cross-sectional area, A , the reciprocal of which is designated by the hydraulic radius, R . On the other hand, it produces a change in the distribution of velocity and shear; as a result, the shear will generally vary from point to point of the perimeter. Both effects are thus involved in the equilibrium relationship between the gravitational motive force and the surface resistance which the flow entails*". He supports the validity of the hydraulic radius concept, but concludes that the effect of cross-sectional shape is related to the variation in the hydraulic radius and two coefficients of a semi-logarithmic resistance function. He also refers to the importance of the aspect ratio in the analysis in relation to the effect of cross-sectional shape.

The junior author in another work* has proposed other parameters as being more representative of the cross-sectional shape on flow resistance in smooth channels. This method offers a far more rational solution than methods previously proposed by others.

If the flow takes place in a natural stream with erodible bed and banks, the calculations which are at all possible do little to determine the proportions of any change which is likely to occur and in fact hardly assist in allowing predictions of even the general form of the change. Because of the ever varying shape and size of the channel cross-section and unavoidable irregularities in channel alignment, the flow is rarely uniform in natural streams.

It should be appreciated that open channel formulae based on observations of pipe experiments or from small scale physical models of channels and canals or rivers, cannot and do not represent natural situations because :

* Under preparation for publication.

- (i) The dimensions and proportions of natural rivers are completely different from those of the pipes for which energy losses have been determined experimentally. In practice the pipes are almost invariably round, ranging in diameter from 1cm to about 10m. The cross-sectional shape of a natural watercourse is quite indeterminate; the width can vary from a few centimetres to many kilometres, while the depth varies from a few millimetres to a very limited amount compared with the width.
- (ii) It is quite impossible to represent all the detailed features and irregularities of a river on the model. We cannot truly conform to the laws of similarity.

Any researcher using large area landscape type models soon appreciates that such models are far too smooth although boundary shear relationships say they should be far too rough.

In small scale models, losses due to boundary shear will always be relatively large because of the effect of scale on both the size and velocity in Reynolds number. However, to assume these losses represent the total energy loss must lead to serious error.

All energy losses will be represented as turbulence. Eddy size is largely a function of the size of the solid boundary generating the eddy. The velocity will determine the number of eddies. Eddies from boundary shear are small and because of their size, dissipate quickly. In contrast eddies generated by channel irregularities and changes in cross-section will be large and will persist downstream adding considerably to the apparent roughness. The reaction of movable boundaries in natural streams to locally generated turbulence cannot be joined with the overall average conditions.

Often the energy losses due to boundary roughness, cross-sectional shape and the boundary irregularities have been confused with one another. For example, H.A. Einstein and N.L. Barbarossa (1951)¹⁰ separated the total energy loss of the natural flow into frictional losses and form losses. Frictional losses were defined as those due to grain roughness and form losses those due to size, shape and spacing of the individual irregularities and presence of sand ripples and dunes. L. Bajorunas¹¹, in the discussion of the same paper states that: the roughness factor that reflects the channel irregularities decreases and approaches zero with increasing flow. On the other hand in V.A. Vanoni and Li San Hwang's (1967)¹² results, the bed roughness due to form of the ripples and dunes is the major part of the total roughness and does not approach zero with increasing flow. In the discussion of Einstein and Barbarossa's paper, Sir. C. Inglis¹³ categorises the total losses into (i) those due to textural roughness; (ii) those due to ripple roughness; and (iii) those caused by form drag resulting from the major irregularities of the banks, bed, islands and sandbanks. Inglis does not believe in combining groups (ii) and (iii) because of a different time scale by which they change.

The question is, what constitutes the total energy loss in natural rivers and how much of the total loss is due to boundary shear and how much is due to form?

CONDITION FOR NO FORM LOSS

It is proposed to show in this paper that there is a solution to the problem of non-uniform flow and this solution not only explains precisely many land forms which occur naturally, but thereby yields a definition of 'form' loss.

The only channel which gives truly no 'form' loss is of rectangular section. In any other channel the specific energy must vary across the channel. This would generate turbulence not associated with boundary shear. The elements of flow across the section can be shown to respond in different ways to an overall change in section shape.

B.A. Bakhmeteff (1932)¹⁴ showed that if the flow in a channel is tranquil and the channel converges slowly, the surface will fall, the velocity will increase and, if the channel then diverges slowly to its original width, the flow will return virtually without extra loss, to its original uniform flow pattern; i.e. the 'form' loss is zero. If, however, the convergence continues, the flow will ultimately become critical (i.e., the depth y_c will be $2/3(y_o + v_o^2/2g)$ when y_o and v_o are the depth and velocity in the initial channel, g is the acceleration due to gravity and y_c is the critical depth). Any further convergence will lead to a rise in level upstream of the constriction and a corresponding head loss through it.

Similarly, it was shown that if in a uniform rectangular channel a smooth hump is introduced, the water surface level falls, the velocity increases and the depth decreases. The height of the hump for no 'form' loss is limited to that which creates critical conditions at the hump; i.e.

$$y_c = 2/3 \left[(y_o + v_o^2/2g) - \Delta z \right]$$

Δz being the height of the hump. If the height of the hump is increased beyond this limit, the upstream level will rise and a 'form' loss occurs at the restriction.

There is, however, in addition to these particular cases, a condition which offers a wide range of cross-section proportions which will offer no 'form' loss.

If $v_c^2/2g + y_c = H_o + \Delta z$ everywhere, and the transition is as before reasonably slow, there will be no 'form' loss.

H_0 is the initial specific energy = $v_0^2 / 2g + y_0$

Δz is now the change in level of the bed

v_c is the critical velocity

both H_0 and Δz have the same sign and for convenience are measured positively down from the total energy line.

In many natural channels the 'form' loss is the major portion of the total head loss. It is then possible, by building a non-uniformity to this concept to create useful structures which cause no afflux. Any increase in boundary shear loss due to increased velocities can be offset by a reduction in 'form' loss.

The proposition was not determined initially as a result of a theoretical or laboratory research. It arose from the successful solution of a number of ad hoc problems.

DESIGNED SMOOTH TRANSITION STRUCTURES

The City of Redcliffe is a satellite town of Brisbane, the capital of Queensland. It has extensive if quite beaches on Moreton Bay and is the nearest seaside holiday resort to Brisbane. The road pattern is just about 45° to the natural drainage lines. One of these drainage lines - Humpy Bong Creek - literally splits the centre of the town in two. In 1958 the sole crossing of this creek was a narrow wooden bridge joining the shopping centre to the south, with the municipal buildings to the north. The shopping centre was along the beach promenade. There were just about enough parking places for the shop assistants' cars. Shopping on any Saturday in the holiday season was quite an adventure.

FIG.1. GENERAL VIEW OF REDCLIFFE AND PROPOSED IMPROVEMENT ON THE CREEK

The flow in the creek was largely sullage water. The banks were steep, ragged and overgrown. Altogether it was a smelly, unpleasant area. It was therefore proposed that a multipurpose improvement be made. (Fig. 1).

- (i) Build a weir to raise the fresh water level in the creek to cover the ragged steep banks and allow the area to be dressed, grassed and easily maintained as a park. At the same time the weir would exclude the tide and eliminate the smell of rotting vegetation.
- (ii) Culvert the creek to remove access problems and create an extensive car park on and adjacent to the culvert. The car park would serve the shops and public offices by day and in addition the proposed Civic Centre and R.S.L. Hall by night.
- (iii) To alleviate flooding of the shops and adjacent area.

An admirable proposal, but how to do it? - particularly at a price the town could afford. The catchment of the creek was rapidly urbanizing and the estimated maximum flow was 910 cusecs ($25.8 \text{ m}^3/\text{sec}$). The general level of the land adjoining, and hence flood level, at the creek mouth was R.L. 8.0 ft (2.440m) L.W.O.S.T. This would preferably also be the level of the car park. High tide was R.L. 4.5 ft (1.370m) L.W.O.S.T. and experience had shown that any outlet with an invert below high tide became stuffed with sand in the dry winter season. It was also necessary that the standing water level in the lake should not be less than R.L. 5.25 ft (1.600m) L.W.O.S.T. to cover all the trash growth on the vertical banks and allow easy maintenance. At that time the whole area flooded at least once every two years and by traditional hydraulics the problem appeared to be unsolvable as the length of the culvert was some 600 ft (180m).

The Department of Civil Engineering, University of Queensland, suggested the solution illustrated in Fig. 2. The logic of this solution was :- The discharge is 910 cusecs ($25.8 \text{ m}^3/\text{sec}$) flowing upstream of the weir at a level of R.L. 8.0 ft (2.440m). If we neglect the velocity head we can take R.L. 8.0 ft (2.440m) as the level of the total energy line at the weir. The weir level was set at R.L. 5.25 ft (1.600m) to give satisfactory pondage conditions. The maximum available specific energy at the weir is 2.75 ft (838mm). Thus the critical depth is $\frac{2}{3} \times 2.75 = 1.83 \text{ ft}$ (558mm). The maximum flow per foot width of weir is thus 14.2 cusecs ($1.327 \text{ m}^3/\text{sec}/\text{m}$ width), so the minimum width of the weir is 64 ft (19.5 m). The culvert barrel was 18.0 ft (5.480m) wide, a Queensland Main Roads' Department standard width. The flow per ft width must be 50.51 cusecs ($4.7 \text{ m}^3/\text{sec}/\text{m}$) so the minimum (critical) depth is 4.30 ft (1.304m). The corresponding velocity head is 2.15 ft (652mm), so total specific energy is 6.45 ft (1.956m). Therefore the level of the culvert invert at entrance is R.L. 8.0 ft, less boundary shear fall, less 6.45 = approximately R.L. 1.43 ft (440mm).

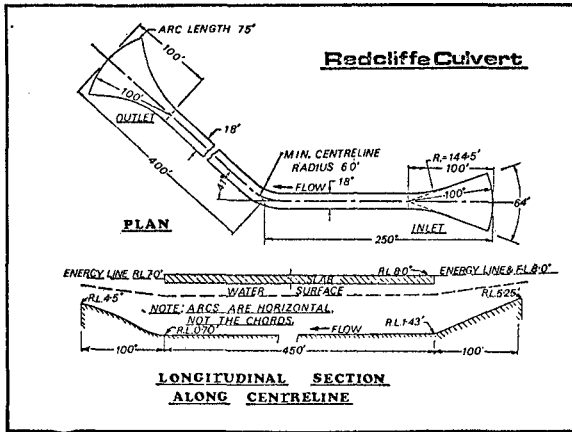

FIG.2. DETAILS OF REDCLIFFE CULVERT

An arbitrary assumption was made that there would be 1.0 ft (305mm) of head loss due to boundary shear so the level of the energy line at the outlet is R.L. 7.0 ft (2.130m). The high tide level is R.L. 4.5 ft (1.370m) L.W.O.S.T. so the available specific energy is $7.0 - 4.5 = 2.5$ ft (762mm). The minimum depth is $\frac{2}{3} \times 2.5 = 1.67$ ft (509mm) and the maximum flow per ft width at outlet is 12.25 cusecs ($1.139 \text{ m}^3/\text{sec/m}$) so minimum outlet width is 74.3 ft (22.620m).

In plan the inlet weir was joined to the culvert with an arbitrary shape and the culvert to the outlet weir likewise. The inlet and outlet floors were designed so that everywhere we had critical flow. The culvert slab fitted very conveniently between R.L. 8.0 ft (2.440m) and the water surface to give ample freeboard. Despite much critical comment the Department was commissioned to build a model. A very big model $1'' = 1 \text{ ft}$ (1:12) was built. Very quickly we learned that the inlet and outlet had to be part of flow nets. With this single modification the model performed perfectly. There was an amazing correlation between the calculated and model water levels, everywhere within 0.01 ft (3mm on the model). There was apparently no difficulty in imposing this flow system.

The culvert was built. No flow measurements have been taken but no flooding whatsoever has occurred since, although there have been at least three occasions when the design flow has probably been exceeded. This includes 1974 when Brisbane suffered devastating flooding, both from the local creeks and the Brisbane River.

Some years later we were asked to investigate the augmentation of the water supply for a small town, Clermont, in Central Queensland. With this request was attached a very odd condition - that any weir in the river must not cause flooding at a lesser flow than at present nor at more frequent intervals. There was good reason for this condition. Clermont lies in the junction of two streams, the Belyando River and Rocky Creek. Typical of western Queensland the highest land for some miles around is the river bank. Once the flood breaks out it spreads through the town and over the adjacent

country. In 1916 a major flood peaked on a Saturday night and nearly one hundred people were drowned. Naturally Clermont is now a little sensitive to flooding.

There is always a minimum storage below which storage has little purpose. This minimum storage determines the minimum weir height and, in this case, the required weir was relatively high compared to the banks of the river. The whole region is alluvium and consequently maintaining the weir in the river was also an equally difficult problem. Having tried a whole array of strange shapes and arrangements, we failed to satisfy these conditions and reported accordingly.

However, reflecting on the Redcliffe outfall, there were second thoughts. If this culvert were cut in two and placed end to end, it gave a system of weir without afflux. The bank full flow could be taken as the design flow, Q . The slope of the water surface at this stage is known. The velocity, V , is Q/A when A is the cross-sectional area at 'bank full'. The energy line will then be $V^2/2g$ above and parallel to the bank full-flow surface. The height of the weir crest; i.e. Storage Level, is already determined. The difference between storage level and the energy line level is the specific head. Forthwith the critical depth, the maximum flow per unit width and the minimum length (width) of the crest can be calculated. This crest width was very much wider than the river itself. By choosing an arbitrary plan shape, the height at any other transverse section of the weir can be readily calculated and the longitudinal profile determined; alternatively a profile of the weir can be chosen and the widths calculated.

The Clermont Weir (Fig. 3) was 20 ft (6m) high, 350 ft (106.8 m) wide along the crest. The bank slopes were, of necessity, flat to obtain a smooth transition. The problem now was not the adequacy of the design but how to build it. The only possible solution for such a big volume structure was somehow to build the bulk of it in earth.

FIG.3. PHOTOGRAPH OF CLERMONT WEIR

This was done (not without incident) and the earth protected by a filtered concrete slab. No other protection to bed and banks was found

necessary. Again no measurements have been made but there have been many flows over the weir and at least there have been no complaints in the twelve years of its existence. A much larger but similar weir has since been built. This second weir (Fig. 4) is at Chinchilla, South-West Queensland. It is 40 ft (12.2 m) high and has a crest of 750 ft (228.300m). It stores 7,500 acre feet ($3 \times 10^6 \text{ m}^3$) and the crest is actually level with the adjacent bank contour. A bank six feet high ties the end of the weir to higher ground some distance away. When the flow starts to overtop this bank; i.e. when flooding commences upstream, the flow is some 35,000 cusecs ($1000 \text{ m}^3/\text{sec}$) and the measured afflux was 4.0 inches (100 mm). Below the design flow the excess energy is dissipated in a single roller on the face of the weir. No other protective works are provided. Above the design flow, all trace of the weir disappears.

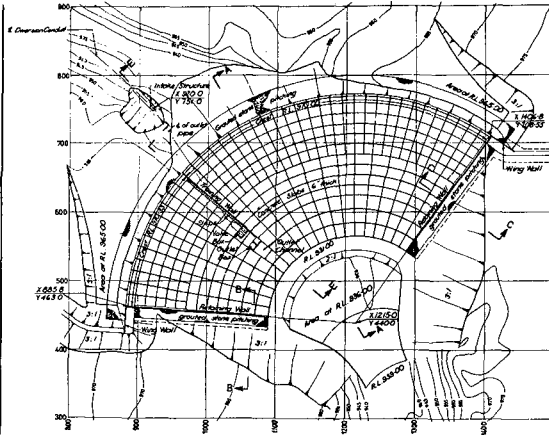

FIG.4. PLAN OF CHINCHILLA WEIR

The strangely smooth turbulent free flow over these weirs posed the question, was the concrete protection necessary? Eventually the opportunity arose to build an earth weir protected only by grass. It was designed to have no effect at a level at which the flow would cause flooding or nuisance if exceeded - not the maximum flow. It has been completely successful. The earth formation was completed on the 5th November, 1967. The bank was sown with Greenleaf Sudan - a fast growing sorghum and sprigged with Kikuyu. The first flow over it occurred exactly five weeks later. In January, 1968, two months after completion, the weir was submerged completely early on a Saturday evening and remained completely submerged until Tuesday mid-day. The photo (Fig. 5) was taken on the Wednesday. The growth was adequate protection and the weir has survived ever since. In order to secure these weirs in the early vulnerable period before the grass is established they have been reinforced with a cheap plastic mesh.

As grass had proved completely adequate as protection in these smooth flow structures, they became far more attractive cost-wise, despite the strange shape, than more traditional designs. A number of smaller but identical weirs have been built and protected by grass only. The cost is \$50-\$100 per million gallons stored ($500-1000 \text{ m}^3$ per dollar). This type

FIG.5. PHOTOGRAPH OF YULEBA WEIR

of weir makes possible extensive storage at sites which have previously been discarded. The optimum site is the *widest, shallowest*, and hence highest part of the river bed.

The farm dams were not high, averaging 5 ft (1.5 m); the highest has been nine feet (2.74 m). At small overflows the bank is subjected to velocities close to \sqrt{gh} when h is the height of the dam. Even at a height of five feet, this amounts to over 12 ft/sec (4m/sec). There was never suspicion of scour.

The calculations associated with these designs are indeed simple. The accuracy of the calculations is very good and the performance completely predictable. The confidence gained from these successes enabled much more exotic structures to be designed and built to achieve solutions not previously possible, in particular culverts and bridges without afflux but discharging at high velocities so that the span is minimized.

Typical is the Nudgee Road Bridge over the Kedron Brook in Brisbane. At the point of the crossing the natural stream channel had completely degenerated having left its well defined steep watercourse and entered the coastal swamp. Long since the area had been drained by a small canal-like waterway to a well defined tidal inlet some miles away. This channel could not even carry the annual flow. The design flood of 30,000 cusecs (850 m³/sec) spread over a width of 1320 ft (404m) increasing downstream. The road crossed the swamp on a low embankment rising to a short timber bridge over the canal, and the floods rose over the embankment and cut the traffic.

A major shopping complex had been built upstream of the crossing but still within the swamp zone. The council had required a considerable portion of their area to be retained as a flood relief channel and the remainder had had to be filled to a considerable depth. The area had continued to develop and Nudgee Road became a major traffic route and at this point the timber bridge failed. The situation required the immediate construction of a new two-lane all-weather crossing (subsequently to be four-lane). There could be no raising of the flood level for fear of damage in the shopping complex; the 1967 flood having risen to within 1 ft (300 mm) of the floor levels. The difference in cost of embankment

to bridge structure was \$1000 per ft length.

The constant energy design gave certainty of calculation and the absolute minimum span. The ground (bed) level was determined by the lowest level at which it was possible to grow grass - the area being tidal. This was taken at R.L. 7.5 ft (2.280m) L.W.O.S.T. The design flood (30,000 cusecs) level was R.L. 15.6 ft (4.750m); the existing ground level was R.L. 10.0 ft (3.047m). The slope is surface fall only and in flood, amounts to less than 1 foot per mile. The approach, being so wide, was considered rectangular.

Approach velocity = $30,000 / (1320 \times 5.6) = 4.0$ ft/sec (1.22m/sec)

R.L. Energy line is 15.85 ft (4.830m)

For ground level at R.L. 10.0 ft (3m), $y_c = 3.9$ ft (1.19m) and critical unit flow $q_c = 43$ cusecs ($4m^3/sec/m$), so flow can be restricted to 688 ft (210m) width only. Under bridge the available specific head $H_s = 8.1$ ft (2.470m), $y_c = 5.4$ ft (1.645m) and $q_c = 71$ cusecs/ft ($6.6 m^3/sec/m$), therefore the minimum width is 423 ft (129m). The bridge was built with 9 x 50 ft (9 x 15.26m) spans with round piers.

The lip of inlet fan was 400 ft (122m) above the bridge. The shape of the fan is shown in Fig. 6. A model scale 1:48 gave results which agreed with the computed results to within 0.2 ft (61mm). These models must be truly three-dimensional as it is no longer possible to study a 'representative' longitudinal section. The model showed that if the approaches were not depressed with the 450 ft (137m) wide opening, the

FIG. 6. NUDGEE ROAD BRIDGE INLET

flood level rose above R.L. 18.5 ft (5.650m), the minimum road embankment level, and overtopping occurred. The minimum span to pass the flood at ground level R.L. 10.0ft (3m) was 688 ft (210m). The model again showed the remarkably smooth turbulent free flow and as a result grass only was used as protection on the inlet and outlet fans even though the velocity exceeds 13 ft/sec (3.96 m/sec). The outlet fan was an exact image of the inlet fan.

The cost of the earthworks in the fans was \$10,000, the saving on the bridge about \$240,000.

The design procedure was used in different circumstances in Stawell, Victoria, Australia, by N. Cottmann, Shire Engineer. A bridge on the Stawell-Newington road had a capacity of 800 cusecs (22.62 m³/sec) before the road overtopped - which happened in every flood. The bridge approaches were redesigned so that the same bridge could carry 5,000 cusecs. Fig. 7 shows the bridge carrying 4,300 cusecs (122 m³/sec) in February, 1975. Although the water level under the bridge was well below the approach level it recovered the level and passed through virtually without afflux. Again, despite 15 ft/sec (4.57 m/sec) velocity and minimal protection, no scour occurred.

FIG.7. STAWELL BRIDGE CARRYING 4300 CUSECS (122 m³/sec) IN 1975

The concept lends itself to use in dual or multipurpose structures, in particular the combination of flood alleviation with stream crossings. The South East Freeway out of Brisbane was deliberately routed through the valley of the Norman Creek in order to minimize the number of houses it was necessary to resume. But the valley was free of houses because the area was subject to severe short floods from the adjoining urban areas. Retardation basins in the form of playing fields had been established along much of the length of the creek. The freeway not only crossed the creek on numerous occasions but the embankment occupied a significant portion of the available retardation basin area.

Because of the certainty of the calculation, minimum energy culverts were used throughout. The inlet fan to each culvert was so arranged as to act as a minimum energy weir and to discharge a particular flood at a particular level; i.e. the highest possible. (Fig. 8). The flow through one culvert is not affected by the backwater of the culvert/weir

FIG.8. PHOTOGRAPH OF CULVERT ENTRANCE

downstream. The loss of detention area was amply compensated by the increased depth made available.

A different version of this same theme, flood alleviation and a stream crossing, is that at Settlement Shores, Macquarie, N.S.W. This is a very popular holiday area conveniently situated north of Sydney. The Hasting River flows out of the ranges and meanders in a large loop through the coastal swamps. Even in small floods the area presented was flooded and is unsuitable for development.

A large channel will be built to short circuit the loop but at the lower end a minimum energy weir is to be built high enough to prevent egress of the tide. At the same time the weir allows the free discharge of the flood water virtually without head loss at a lower level and thus frees the area from danger of inundation. Immediately below the weir a very rapid convergence allows economic convenient bridging as access to

FIG.9. SETTLEMENT SHORES - HEAD-DISCHARGE RELATIONSHIP

the area. Fig. 9 shows the relationship between the calculated and measured head water/tail water on the model. From our experience, the prototype losses will be relatively far less.

NATURAL SMOOTH TRANSITIONS

It became increasingly clear that each of these structures had counterparts in nature. The Redcliffe tidal outfall is surely an idealized and miniaturized river bar formation. If a river enters the sea with reasonably uniform energy, then as the river loses the constricting influence of the banks, the bed must rise to maintain constant energy. If the divergence of the banks is uniform the bar is in fact curved. If the banks are curved the bar is straight. In the days of sail, it was always said that 'ships sailed up-hill over the bar', and how true this could be. Equally it is claimed, again with some truth, that it is always choppy over the bar.

It makes no difference whether the tide is ebbing or flooding, the same shape is demanded by the concept of constant energy. It is not surprising that C.D. Floyd (1968)¹⁵ reports on river mouth training in New South Wales, Australia to the Public Works Department. *"A summary is given of the results of training sixteen rivers in an endeavour to increase bar depths. The bars are of simple crescent formation fed by littoral drift.*

Whilst the training works have improved conditions for navigation, they have not resulted in any appreciable increase in bar depths.

Despite the complex mechanisms involved in bar formation a consistent simple relationship is found to exist between channel and bar depths. This correlation seems to apply to all rivers and inlets with simple bar systems and extends over a range from a bar depth of two feet to 60 feet!

The majority of the work (the training) was carried out in the period 1880 to 1910 with minor changes and additions in the period 1910 to 1930. Commencing in the 1950's, a major training scheme was started on the Clarence River and also a programme of development of small river entrances for fishing craft."

The inlet and outlet features of the culverts are surely the corresponding scour so often appended by nature to man-made structures. A perfect fan completely formed naturally is given in Fig. 10. This is below a small portal bridge over a gravel bed stream after a short sharp fresh flow. The complete culvert form is the shape which always develops between the tidal lagoon and the ocean. This is so well illustrated by Per Bruun (1966)¹⁶. He writes of 'the gorge' and the 'shoals' and illustrates it profusely when he is searching for a relationship for the stability of this strange shape which is deeper in its middle than at either end. (Fig. 11). The entrance to San Francisco Bay, both inside and out, is a perfect major example of this form (Fig. 12).

That this complete culvert shape is a not uncommon geological feature, many arch dam builders have found to their cost. The Gordon River in Tasmania, Australia, is typical. The gorge narrows to provide the perfect abutments but the solid floor is a long way below that at the entrance to the gorge. Of world renown because it is so well advertised, is that mysterious gorge on the River Aare in Switzerland. At places

FIG.10 FAN AT BLYTH CREEK - ROMA

FIG.11. TIDAL LAGOON - (FROM REF. 16)

The Golden Gate and its Ocean Shoals (U.S. Corps of Engineers Annual Report, San Francisco District, 1952).

FIG.12. SAN FRANCISCO BAY - (FROM REF. 16)

this is little more than a meter wide and its depth is a hundred metres below the river bed at each end.

"The Gorge of the Aare near Meiringen (by Professor Dr. P. Arbenz (Berne)). Half an hour beyond Meiringen the Haslital is blocked in the whole of its breadth by a barrier, on the steep walls of which grey chalk is everywhere to be seen. It is not the result of a landslip, nor is it a moraine, but rather a crossbar of rock, a small mountain range in the valley, abounding in small peaks and valleys and a labyrinth of wooded indentures and defiles. The river Aare pierces through this rocky obstacle in the famous Gorge of the Aare. It has eaten its way through the rock at so great a depth, that the fall on its way through the gorge is but slight. A level path leads to Innertkirchen on the other side of this rocky crossbar."

How else could a 'blind' channel be formed across half tide sand banks in an estuary?

The earth weirs arise in the central reaches of many rivers where a well formed channel suffers a change of grade, widens and shoals quite

severely to form pools in low flow periods - the silt banks of Australian streams - below which the stream will converge again to a well-defined channel. These are the sites to be chosen for farm dams and far from scouring, many of the grassed weirs are actually growing.

A very good example of accidental minimum energy culvert must surely be the old London Bridge (Fig. 13). As little as 25% of stream area was available to the tide passing through the bridge. The tidal range is high but up to high tide the plan shape is ideal and the Thames mud was no doubt duly scoured to give the correct profile. This bridge survived from 1209 to 1825 A.D. For five centuries it was the only bridge.

FIG.13. OLD LONDON BRIDGE

Obviously if a form persists there must be some mechanism by which it becomes self sustaining and able to resist any destructive forces. The concept of minimum energy is just such a mechanism. Minimum energy introduces critical velocities; i.e. the maximum velocity which can exist at that energy condition or for that flow per unit width. It is wrong to assume that critical velocities are high, they can be so small that they are unable to move even sand particles. The concept allows the velocity to diminish without reducing the total discharge. Thus the natural fan shape at both inlet and outlet becomes quite stable and self sustaining.

As the velocity of the flow in the connecting deeper channel is always greater than the approaching flow, any bed load is carried through the deeper section. Any floating material will move much easier in the deeper channel so anything which is carried in will be carried out. If the total flow increases for some reason, the inlet fan will erode back to a higher, longer lip. The central section will either become deeper or wider and the eroded material will be carried up the outlet fan to deposit there again to form a higher, longer lip.

The concept does not restrict a river, alluvial or otherwise, to one particular shape so much sought by many researchers - G. Lacey (1930)¹⁷, T. Blench (1957)¹⁸, F.M. Henderson (1963)¹⁹, D.B. Simons and M.L. Albertson (1960)²⁰. Any rectangular shape is acceptable. Provided there is everywhere

the right relationship between width and depth the energy grade will be uniform. The river can become narrower if it deepens or can become wider provided it shallows. The actual cross-sectional shape is a function of the material of the bed and banks. If you add the hypothesis of L.B. Leopold and W.B. Langbein (1966)²¹, that meanders are curves of minimum energy in bending (and there are any number of suitable curves for any situation), then a river has almost complete choice of cross-section and position and can still satisfy the overall concept.

CONCLUSIONS

- 1 - There is no doubt that the concept of minimum and constant energy unfolded here does allow the quantitative determination of smooth transitions in open channels and these transitions can have useful applications.
- 2 - It was shown that in addition to the previously known applications of specific energy, there is a condition which offers a wide range of cross-section proportions without additional 'form' loss. This condition is the reduction of ground (bed) level to satisfy a further convergence of the flow; i.e. to reduce span or to drop the water surface to increase headroom.
- 3 - A solution was offered to the problem of non-uniform flow and an explanation was given for the occurrence of many land forms in nature, such as formation of a river bar and estuaries.
- 4 - The transition shapes are essentially self sustaining. They are 'smooth' with no 'form' loss. There is no energy change and there is no turbulence, hence no scour. As any other shape would require more energy to convey the flow, there is also no deposition.
- 5 - To impose an unacceptable change on such a system is courting disaster as is evidenced by the many vain attempts to change estuarine conditions which are essential to the estuary's very survival. Equally futile is to attempt to rid rivers of the 'bar'. We can learn much by studying the natural shapes.
- 6 - By simply using constant energy rather than constant discharge, we can accurately predetermine the dimensions of the appropriate shape and this shape will be without 'form' loss. Structures can be built to other forms but they will have to be defended, to retain their form, by solid protection or continual maintenance.
- 7 - Always the shape is the same - a strange fan shape. The shape of a scour hole below a culvert. The shape of the old London Bridge. The shape of a tidal inlet to a lagoon. The shape outside San Francisco Bay; of a channel very much deeper than the lakes it connects or the channel through a sandy estuary. All these shapes are, we are sure, conforming to the concept of $v_c^2/2g + y_c = H_0 + \Delta z$.

CHAPTER 129

CONCEPTS IN DESIGN OF COASTAL STRUCTURES

Casimir J. Kray*

Timber Structures

Certain design of the existing and proposed coastal structures for lateral loading in the United States is presently based upon the use of timber which is structurally inefficient in the elastic range. Figure 1, for example, indicates the plan of timber pile structure. This is a low-capacity dolphin composed of 19 piles, where piles in line of load carry two times axial load and three times larger shear than next piles in line of load.

A relatively small load will be conducive to yield in the tension or compression members. Repetitive loading will gradually cause collapse of such structure.

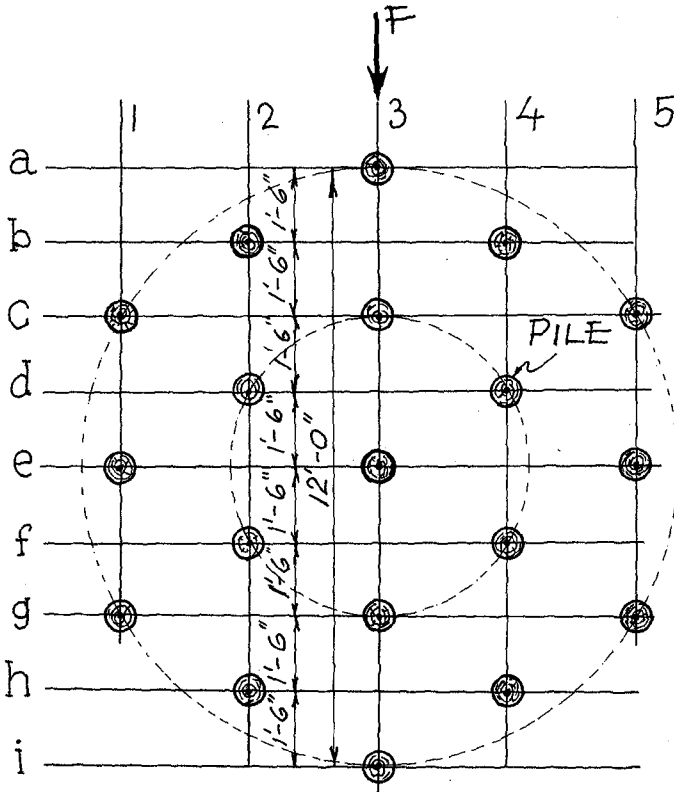

Being inefficient in the elastic range, timber structures may nevertheless, be adequate to provide safety for condition of shallow water, moderate wind pressures, moderate tides, and for moderate cross and reversing currents. However, such factors as: traffic safety, the possibility of marine borer attack, the location of structures in greater water depths, where they are exposed to waves, currents, tides, winds, and floating objects, indicate a need for larger capacity, more reliable and functional coastal structures consistent with the growing requirements.

Alternate Materials and Structural Considerations

The other type of coastal, rigid type structures, using reinforced concrete or structural steel with extensive bracing or with batter piles, are expensive and unyielding. This stiffness may be a reason for inflicted damages to the vessels and to structures themselves upon contact. These rigid structures are also prone to catastrophic failures during earthquakes.

*Consultant, Waterfront Structures, Naval Facilities Engineering Command, Alexandria, VA

By reason of the foregoing shortcomings of timber structures in general and rigidity of reinforced concrete, there is a trend in the Navy to high strength steel tubular sections, to be used singularly, or in groups for resilient type structures, see fig. 2.

PILES 2-3 & i-3 CARRY TWICE LARGER LOAD & THREETIMES LARGER SHEARS THAN PILES C-3 & g-3, REF 1.

K - " " " " " " " " " " " " " " " " K/FT^2

FIG 3 - CAPACITIES OF VARIOUS SIZE ROUND TUBE STEEL PILES

Such steel piles will provide:

- a. Improved pile to soil transfer of forces.
- b. More efficient sharing of centric and eccentric forces by all piles; also better resistance to torsional forces, and better mobilization of torsional strains, to enable high energy storage.
- c. Possibilities of larger deflections, for high energy absorption in bending, because the flexural elastic strain energy for steel is very high. Grade of steel can be varied in each pile, during the fabrication process.
- d. Far greater efficiency in torsion, remarkably more than that in bending.

This is because the torsional shear stress is the same around the circumference of the pile and along its length. That advantage should be distinguished from bending stresses, which vary from zero at neutral axis, to a maximum at extreme fibers of the cross section; and from zero at the top of the pile to the maximum at the bottom.

FIG 4 - ULTIMATE LOAD CONDITIONS FOR A PILE

Some assumptions made for design of resilient structures with tubular, round steel piles are:

- a. Slope changes at upper ends of group of two piles (or more) should not be constrained, which is particularly important in weak soils.

FIG 6 - VARYING RESPONSE SAFETY STRUCTURES

- b. 50% of yield point in piles is used for mooring and for berthing forces.
- c. 75% of yield point is used for energy absorption.
- d. 1/8" wall thickness is provided additionally, for effects of corrosion.

FIG 7 - PILE-SOIL INTERACTION

FIG 8 - ALTERNATE USE OF SLEEVE - VERTICAL SECTION
 PILE TO SLEEVE FORCE TRANSFER, REF. 2.

For illustration, figure 3 lists static force and energy absorbing capacities of various size tubular steel piles in cohesionless subgrade soil for forces applied at 50 ft from the bottom of the sea.

In consideration of the above-described items, there might be circumstances in which it would be desirable to transfer lateral forces acting on coastal structures into the soil through piles in bending, without the severe constraints to such bending which are imposed by soil behavior.

Regarding soil pile interaction, see figure 4 for the ultimate load capacity of a pile in cohesionless soil. It is assumed in figure 4, that the pile reaches its ultimate load condition, when a yield hinge develops at a certain depth. This is a commonly used approximation for interaction with cohesionless subgrade soil. In such a case, passive soil pressure counteracts the horizontal force action. Yield moment in the pile resists bending moment, caused by the horizontal forces.

FIG 10 - LOCATIONS OF PILE IN THE SLEEVE - PLAN

After deciding on the kind of piles most suitable for field conditions, next it will be the intent of the designer to optimize the structure-to-ground interface, for improved structural response to lateral loading.

Design Concepts in Development

Such structures which resist lateral load by pile bending, rather than by axial forces in piles, batter piles, or in the bracing; can absorb large amounts of energy, a major consideration in case of contact with floating objects propelled by wind, current, tides, and wave action. In the exploitation of this advantageous characteristic of piles in bending for coastal structures, it would be desirable to use structural steel- round tubular piles, preferably of high-yield strength.

FIG 12 - SLIP JOINTED PILES' CLUSTER ELEVATION

Figure 5 shows structures composed of single, two pile and three pile dolphins, for protection of other vulnerable coastal installations or vessels from damage upon contact. Also, often they supplement lateral resistance of piers, wharves or quay walls, themselves not capable of supporting larger lateral loads. Figure 6 is an arrangement in plan of piles for various response, used for the single, double, and multiple pile action.

However, piles of such structures develop large shear and bending moment at the seabed elevation and imply lateral soil pressures which may well be above the elastic capability of many soils.

The loading, moments and forces are concentrated at the upper end of embeddings where the soil is least resistant, see figure 7.

Therefore, certain improvisations are possible in order to provide for greater efficiency and safety in the applications of structural steel piles in coastal structures. For examples, the following could be done:

NOTE: IN A PILE CLUSTER
PROVISION FOR TORSION
MAY BE NEEDED FOR ONE
OR TWO PILES ONLY.

*After joint closure there is substantial additional force capacity (†modest additional energy capacity) as the pile pull-out capacity is mobilized.

FIG 14 - PERFORMANCE OF PILES' CLUSTER

The Sleeve Concept

In case of large shear and bending moment together with poor soil condition, the desired flexibility can be achieved by isolating the upper portion of the embedded section of pile from the soil contact by driving it through a pipe sleeve of larger diameter, see figure 8, which sketches three arrangements for transfer of forces from pile to sleeves. Mud-line force F and moment M react through load transfer diaphragms in the sleeve, as concentrated forces, at depths where soil resistance is greater. The sleeve of larger diameter than the pile delivers in turn the load to the soil.

Figure 9 depicts the comparison of moments, soil pressures and deflections for pile without sleeve, and for the sleeve action. Obvious smaller moments and better distribution of soil pressures as well as deflections result. Figure 10 illustrates two alternate relations between the pile and the sleeve as to location: concentric or eccentric. Figure 11 indicates two possible eccentric locations of the pile in the sleeve in vertical sections: with parallel axes of the pile and sleeve or skewed pile axis with respect to vertical sleeve. One case A is with constant eccentricity throughout the depth of embedment, the second case B with varying eccentricity, respectively.

FIG 15 - TORSION ACTION PLAN

TO BE MORE EFFECTIVE, RATIO OF BRACKET ARM LENGTH TO WATER DEPTH MUST BE SUBSTANTIAL

FIG 16 - TORSION BRACKETS - PLAN

This concept has also utilization potential in columns for alleviating earthquake distress or permit thermal expansion of horizontal overhead members carried by such columns.

The Elongation of Tension Piles

To introduce in the outer piles of structure slip joints which would preclude pile axial tension forces until the prepositioned joint stops are engaged; see figure 12. This figure shows seven parallel piles supporting rigid deck platform with slip joints in piles, permitting their elongation without inducing moments at the connection with platform, until stop lag is engaged by the bottom of top pile.

Such slip joints in piles are relatively simple, and capable to transmit pile torsion, as well as, pile bending moment. See also figure 13 for slip joints in cluster of piles. At the bottom in section C-C and on the top section D-D, detail of slip joints are shown. At the right is a pile at rest and at the left in fully extended position. Outer piles are permitted to lengthen under loading without inducing moments in piles until stops in piles are engaged. Then axial forces are induced and moment, thus augmenting load carrying capacity of the structure. Figure 14 represents an example of such a structure performance.

**FIG 17 - TETRAPOD - GRAVITY BALANCED
ELEVATION**

Torsion - Mode Piles

This concept utilizes vertical tubular piles fitted with torque arms on which the outside forces act, causing torsional and bending stresses in the piles. This increases their deflection and energy absorption, see figure 15, which indicates plan of torsion action induced in piles by loading the projecting arms rigidly connected to piles.

Max hor. force on one support is twice the dolphin capacity, F, tabulated above.

FIG 18 - PERFORMANCE OF A GRAVITY BALANCED TETRAPOD

Figure 16 depicts the other arrangement of torsion brackets for loads acting on either side of structure, as the case may be. Fender shields rotate on vertical pins thus being able to accept loads coming at an angle to the structure.

Tetrapod Concept

The idea utilizes a gravity-balanced tetrapod principle for a structure, consisting of a single-vertical pile, rigidly connected to three horizontal round steel tubular members in the seabed area.

Figure 17 is an example of tetrapod action in exaggeration. Lift of one of the legs on the side of the load is indicated.

The collision energy from floating objects is absorbed by bending of tubular elements. At large loads there is a lift-off at one of the three support points, rarely of two, and energy is absorbed by overcoming weight of steel members and sandfill in tubes - until stop is engaged for extra large load, see figure 17.

Figure 18 gives an example of tetrapod structures with tubular legs filled with sand in 60 ft and 70 ft of water depth for 36" and 48" diameter piles.

Acknowledgement

The above-discussed concepts suggest a number of design innovations which promise greater efficiency and performance for coastal structures. These ideas are in the experimental or development stage, currently being studied and investigated, by the Naval Facilities Engineering Command, with assistance from Hansen, Holley and Biggs Structural Engineers.

CHAPTER 130

WAVE ACTION ON LARGE OFF-SHORE STRUCTURES

C.J. Apelt (1) and A. Macknight (2)

SYNOPSIS

The paper describes investigations carried out in order to design for the wave action, both wave force and scour, on large off-shore berthing structures sited approximately 1.3 miles (2.1 km) off-shore near Hay Point, North Queensland, in 56 feet (17 m) of water at low tide, the tidal range being 20 feet (6 m). The region is a cyclone area and the structures must be capable of withstanding attack from maximum predicted waves with period of 8.25 seconds and amplitude of 24 feet (7.3 m).

The main units in the berthing structures are concrete caissons sunk on to the ocean bed and the largest of these have plan dimensions of approximately 150 feet (46.7 m) by 135 feet (41.4 m) with four columns approximately 40 feet (12.2 m) square projecting through the water surface. No theoretical method available at the time of the investigation was capable of accurate calculation of wave forces on these structures. A scale model was tested to obtain wave forces and the paper compares results from the model with those of numerical methods and discusses the application of the results to the design functions. Scour effects were also modelled and the results used as the basis for design of scour protection.

1. INTRODUCTION

Hay Point is an exposed rocky headland on the northern Queensland coast approximately 750 miles north of Brisbane. The Great Barrier Reef offers a degree of protection but fetch distances within the Barrier still allow the development of large wave heights during cyclonic disturbances. The port at Hay Point consists of two berths to cater for 100,000 dwt bulk carriers exporting coal to Japan; the annual throughput being some 20 million tons per annum (mtpa). The berths are sited 1.3 miles (2.1 km) offshore where 56 feet (17 m) of water is provided at low tide. The first berth, a conventional piled structure, was commissioned in 1971 and has a throughput capacity of approximately 10 mtpa. Studies of ship turn round times, tidal restriction and other factors showed that upgrading of the first berth, even with the provision of 2 shiploaders, would still leave it incapable of handling the output from the one or two additional mines proposed. Accordingly the decision was made to construct a second berth.

Once the location and alignment of the second berth had been chosen, several types of construction were considered. In the event, concrete caissons which could be constructed at a remote site, floated to and grounded at Hay Point were selected since they provided, inter alia, the following advantages:-

- * the maximum of work could be carried out in the sheltered conditions of the construction site, leaving a minimum to be completed at the exposed site.
- * minimisation of risk to shipping and of disruption of port operations during the construction period.

(1) Reader in Civil Engineering, University of Queensland.

(2) Partner, Rendel & Partners, Brisbane, Australia.

Figure 1 illustrates the site and the alignment of the two berths. The layout and structures of the new berth are illustrated in Figure 2, which also indicates the scour protection. The cross sections of a concrete berth caisson and of the large columns penetrating the water surface are shown in Figure 3, which also provides details of the scour protection system and of the foundation preparation adopted. Figure 4 shows a completed berth caisson grounded at Hay Point.

2. WAVE CLIMATE

Hay Point is located on latitude 21°S and is subject to cyclonic activity concentrating primarily through the months of December to April. The Great Barrier Reef is located to the East and is an effective barrier to storm waves originating in the Coral Sea. The longest uninterrupted fetch lies to the East with water depths varying between 6 and 30 fathoms. To the North, East and S.E. of Hay Point, fetch distances are largely broken up by islands and by shallow water.

Characteristically the wave climate predominates from the S.E., being influenced largely by storm activity in the Tasman Sea, but interposed with random and irregular cyclonic activity usually generated in the Coral Sea. Refraction of waves arriving from S.E. tends to concentrate long period waves from an East and E.S.E. direction, periods of at least 20 seconds having been recorded from the East. Extensive investigations into the wave climate were conducted and these are summarised in Figure 5. Figure 5 is a plot of measured data on wave height, and from this the following probabilities for deep water waves were obtained:-

Occurrence interval (years)	1	10	100
Significant wave height (feet)	10.5	13.5	17.5

The steepness of the waves is such that breaking conditions would not be expected. Directional distributions showed that most waves approached the site from the S.E. quadrant, the directions E.S.E. and S.E. being particularly dominant.

A special examination of potential cyclone activity was undertaken using hindcast techniques and 4 possible cyclones were simulated. Potential deep water waves of greater than 20 ft were generated with periods of the order of 8 seconds. The determination of the probability of such a cyclone occurring is quite difficult and even more so at a given location. However, at Hay Point the probability was considered to be of the order of 1 in 300 to 1 in 500 years and for the waves generated to occur at high water the probability is 1 in 600 to 1 in 1000 years. In general, most of the higher waves consistent with a prediction of a significant wave height of 20 feet would either be unstable because of large steepness or would have shoaled and, therefore, only a few could be expected to reach the structure in a 6 hour period and, then, only at high tide. The probability of a cyclone occurring with a maximum wave of 24 feet generated is estimated as approximately 1 in 50 years and, at high tide, 1 in 100 years. It was estimated that such waves could be expected to reach the structure 40 to 60 times in any 6 hour period of wave persistence. It was considered reasonable therefore to adopt a maximum design wave of 24 feet with a period of 8.25 seconds from which to determine the forces on the structure due to waves, the forces being subject to load factors as discussed below.

FIG. 5 DEEP WATER SIGNIFICANT WAVE HEIGHT.

3. PRINCIPAL DESIGN REQUIREMENTS

The size of an individual column on one of the caissons is approximately 40 feet (12.2 m) square, the theoretical wave length of the design wave is approximately 350 feet (107 m) and for the more frequent waves the wave length is about 200 feet (61 m). Thus, methods of calculating wave forces such as those developed by Morrison (Ref. 1) or by Sainflou (Ref. 2) are inappropriate since they are based on the assumption that the characteristic structure dimension is either very small or very large (i.e. a bluff body) compared to the incident wave length. In the first instance, therefore, a numerical method based on linear diffraction theory (Ref. 3) was used to give estimates of wave forces to allow the design process to commence and proceed. Simultaneously, measurements of wave pressures were made with a physical model of a complete caisson with its four columns, to include interaction effects from adjacent columns, the influence of a porous foundation and of the geometry of the bottom of the caissons which formed a cruciform gap under the central part of the base.

It was the intention that the caissons should be a gravity design and that they should be stable when grounded without additional securing or ballast. Therefore, an accurate picture of variations with time of wave forces on the columns and on the overall structure was

essential. In addition to the overall stability requirements, the value of the moment at the base of the column together with the positive and negative pressure history on a column during the passage of a wave were required to ensure the competence of the structural elements forming the columns.

In the case of scour protection the quantitative assessment of requirements could be achieved only by model analysis. The two principal types of caissons, the large berth caissons and the smaller approach caissons, both required modelling. The chief problem in the case of the berth caisson was to derive a suitable weight for the type of protection considered the most suitable from a construction viewpoint. In the case of the approach caissons it was not clear at the design stage whether or not the foundation should be recessed below the level of the surrounding sea bed or whether the foundation could be constructed directly on it and, so, both these arrangements were modelled.

4. WAVE FORCE ANALYSIS

The numerical calculations of wave forces were carried out by Dr. C.J. Garrison (Ref. 3). Since the dimensions of the structures are not small compared to the wave length, linear diffraction theory was used. All the cases analysed with this numerical model were for incident waves of height 23.6 feet (7.2 m) and period 8.25 seconds at high tide. Wave forces on the exposed surfaces of a main berth caisson of plan dimensions 150 feet (46.7 m) by 135 feet (41.4 m) were computed for incident wave directions normal to the longer and to the shorter faces, in a mean water depth of 78 feet (23.7 m). Wave forces were also computed for a single approach caisson in mean water depth of 70 feet (21.3 m), for a wave direction normal to one face. The total forces and moments on the exposed surfaces of the main berth caisson calculated for the case of waves approaching in the direction normal to the longer face are shown in Figure 6. Some results from the physical model are included for comparison. These are discussed in Section 6.

The wave forces calculated by linear diffraction theory gave estimates which enabled design to commence and proceed. However, the theoretical model is not accurately applicable in this case since it implies that all motions are very small, which is not a good approximation for the large waves involved, for which the ratio of wave height to water depth is approximately 1:3. Further, the theoretical calculations do not take into account effects due to separation of flow past the vertical columns nor can they predict the pressure fluctuations on the underside of the caisson. These limitations of the numerical model made it necessary to conduct extensive measurements of wave effects on a scale model.

5. WAVE FORCE MODEL

Transient pressures on the surfaces of a scale model of a berth caisson were measured under the action of both "cyclone" waves and of "design waves" at High Water and at Low Water. The incident wave characteristics adopted for the model tests on the basis of the data available on wave climate were as follows:-

Cyclone Wave:- Height (H_{max}), 24 feet (7.3 m); Period, 8.25 secs.
Design Wave:- Height ($H_{1/3}$), 12 feet (3.7 m); Period, 6.0 secs.

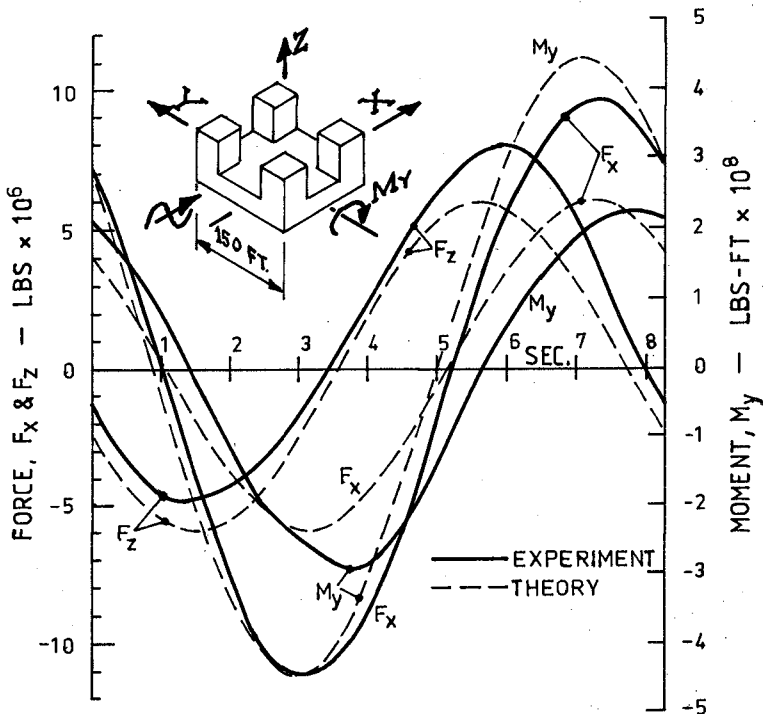

FIG. 6 WAVE FORCES FROM EXPERIMENT AND THEORY.

Wave roses obtained at the site indicated that the dominant direction for incident waves is from ESE, but that waves could be expected from virtually any direction within the range SE to NW. The compressed time period in which the model studies had to be carried out made it impossible to conduct tests for all possible directions of incident wave. Consequently, the tests were limited to the study of waves approaching normally to the berth line (wave crests parallel to the longer side of the caissons) and of waves approaching from the dominant ESE direction (wave crests at an angle of $52\frac{1}{2}^\circ$ to the longer side of the caissons). The tide levels adopted gave water depths above the foundation level of the caisson of 76 feet (23 m) at High Water and of 56 feet (17 m) at Low Water.

The berth caissons are founded on four pads, one at each corner, 40 feet x 40 feet in plan. The foundation pads are set on prepared base material, as shown in Figure 3, and it is considered that the water pressures applied to the under side of the foundation pads will be those corresponding to the current tide level without any significant effect from wave action. However, the cruciform area on the under side of the caisson between the foundation pads will be subjected to pressure variations caused by wave action because it communicates directly to the sea through the gaps between the foundation pads along each side of the caisson. The effects of wave pressures on this region

of the underside of the caisson were found to be very significant in the overall stability of the caisson. Consequently, wave pressures on the underside of the caisson were measured for two conditions, viz:- (i) the gaps along each side of the base were unobstructed, (ii) 90 percent of each gap was closed, the remaining 10 percent of opening being distributed uniformly over the length of the gap.

5.1 Experimental details

Wave Basin: All of the tests were carried out in a wave basin 10 feet (3 m) wide and 48 feet (15 m) long at the University of Queensland. The wave generator was of paddle type, the throw at top and bottom of the paddle being capable of independent adjustment. A spending beach of crushed rock at a slope of 1 in 10 was placed at the opposite end of the basin from the wave generator in order to eliminate wave reflection. The models were located approximately half way along the basin. The incident waves from the wave generator, as measured at this location, were free of any significant higher harmonics and there was no significant reflection off the spending beach.

Model: The model of the main berth caisson was constructed to a scale of 1:60 from clear perspex (lucite) sheet. It can be seen in Figure 7. A total of 135 pressure tapping points was built into the model for measurement of pressures on all external surfaces, including the under-side of the caisson. This large number of tapping points was dictated by the need to measure the pressure distribution in sufficient detail for the purposes of structural design. The pressure tappings were 0.062 inch (1.57 mm) in diameter and they were connected to the pressure recording system through rigid nylon tubing of 0.127 inch (3.22 mm) internal diameter. It was not possible to locate the available pressure transducers inside the model; instead it was necessary to connect the pressure tappings to the externally located transducers by carrying the connecting tubing out from the model through the tops of the four columns and it was physically impossible to fit more tubes into the columns. Because of this restraint, only one column was fitted with tappings, ten in each vertical face. For tests in which the waves were approaching normally to the structure, it was possible to measure the complete pressure distribution over the base caisson in one set-up, since measurements were needed over only one half of the base on account of symmetry. For this same set-up the pressures were measured on the one instrumented column in the front position and then the model was rotated through 180 degrees so that pressures could be measured on the column in the rear position. For tests in which the waves approached the caisson other than normally, it was necessary to set the model in four orientations in order to obtain the complete pressure distribution over the base caisson and over the four columns.

Pressure Measurement: The pressure tappings at the surface of the model were connected through rigid nylon tubing to pressure transducers with a range ± 10 inches (254 mm) of water. These consist essentially of a metal bellows which deflects under pressure and displaces an armature. The movement of the armature induces strain in unbonded strain gauge elements which form the arms of a Wheatstone bridge. The voltage output from the Wheatstone bridge was amplified by carrier amplifiers and the amplified signal was recorded on a pen recorder. The model wave periods were 0.775 sec. and 1.065 sec. for the Design

FIG. 7 Model Berth Caisson and instrumentation

wave and Cyclone wave respectively. The natural frequency of the pressure transducers (dry) is in excess of 300 Hz and the response of the pen recorders is flat up to 40 Hz. The pressure transducers were of differential type and the case reference pressure used was the ambient atmospheric pressure in order to prevent the occurrence of zero shift, which would otherwise be caused by changes in atmospheric conditions. In order to achieve consistent, repeatable performance over long periods of time, it was found necessary to ensure that the air in the cases of the transducers was completely dry. All of the elements of the instrumentation system can be seen in Figure 7. Full details are given by Apelt (Ref. 4).

Wave Profile Measurement: The wave profile was recorded by means of a capacitance type wave probe, the electrical output from the probe being recorded on the pen recorder.

Experimental Procedure: The instrumentation available for the tests comprised three pressure transducers and associated carrier amplifier systems, one wave recorder and two twin channel pen recorders. One recorder channel was used always to register the incident wave profile and the other three channels were used to record the outputs from the three pressure transducers which were connected to pressure tapping points in groups of three until all had been monitored. Synchronisation of the four separate signals was achieved by activation of the event marker pen on each recorder with a signal generated from a relay on the wave generator. The signal was pulsed once for each period of the wave generator and this provided an accurate time base as well as synchronisation. The pressure history at each tapping point was recorded for at least three successive wave periods in order

to average out the effects of any small variations in the incident waves. Provision was made in the circuitry to permit purging of the tubing under pressure in order to clear any air or blockage from the tubes at the beginning of each test and at any other time, if the need arose. The pressure transducers were also connected to a calibrating chamber so that static calibrations of the total pressure recording system could be carried out at the beginning and end of each measurement session.

Dynamic Calibration of Pressure Recording System: The inertia of the large volume of water in the tube connecting to the pressure transducer greatly modified the frequency response of the pressure measuring system. A preliminary series of tests established that it was necessary to adjust the length of the connecting tube to achieve satisfactory response characteristics at the different wave periods. For a wave period of 0.775 seconds the optimum length of the connecting tube was found to be 9 feet and for a wave period of 1.065 seconds it was found to be 15 feet. Even with this arrangement it was not possible to achieve a response which was completely free of amplitude modulation. Consequently, the pressure recording system was calibrated dynamically at the frequencies corresponding to the design wave and to the cyclone wave so that the appropriate conversion factor could be applied to the static calibrations carried out regularly throughout the programme of measurement. Details of the procedure used for dynamic calibration are given by Apelt (Ref. 4). At a wave period of 1.065 seconds the dynamic response was found to be amplified 1.13 times compared to the static response and at a wave period of 0.775 seconds the dynamic response was found to be attenuated by a factor of 0.80 compared to the static response.

6.0 RESULTS OF WAVE PRESSURE MEASUREMENTS

Only selected results which are thought to have some general interest beyond the specific design study are presented here. The full set of wave pressures and of wave forces are given in Apelt (Ref. 4). Forces and moments on elements of the caisson and on the caisson as a whole due to wave action were computed by numerical integration of the measured wave-induced pressures. The coordinate and sign conventions used are the standard conventions of calculus, as illustrated in Figure 6. The origin of coordinates is located at the centre of the caisson base at foundation level and moments have generally been computed with reference to this origin. However, moments on the columns have been computed about axes in the base of the column at the level of the upper surface of the caisson base.

In some tests the gaps along the lower edges of the Caisson base were left unobstructed, and this condition is referred to as "FULL OPENINGS", while for cases in which these gaps were closed for 90 percent of their length, the condition is referred to as "TEN PERCENT OPENINGS". In all of the model tests, water was allowed to enter the space inside each column through two holes, located one in each inward-facing side of the column. Scaled to prototype dimensions, each hole was 0.75 feet in diameter and was located 5 feet above the top surface of the Caisson base, on the centre-line of the face of the column. The depths of water inside the columns were inferred from the pressures recorded at the tapings inside the columns in the top surface of the Caisson base, and the water surface inside each column varied

significantly from the still water level throughout the wave period. The contributions to vertical components of forces and to moments due to these variations in water levels within the columns are included in all of the results, except where otherwise noted. Since it should be possible to achieve a virtually constant water level within the columns, corresponding to still water level, by reduction of the size of the openings through the sides of the columns, the effects of such a modification on maxima of forces and moments have been computed. Quantities calculated for the conditions when the water level inside each column is constant at still water level are indicated by a prime, i.e., $\Sigma Fz'$ and $\Sigma My'$.

6.1 Maximum forces and moments due to waves approaching in direction normal to berthline: The maximum forces and moments on the Berth Caisson due to waves approaching in the direction normal to the berthline are set out in Table 1. The largest horizontal and vertical forces are caused by 24 feet waves at High Water but the largest moments, in most cases, are caused by 12 feet high waves at Low Water. For the latter case the vertical forces are relatively small and the maximum variations in foundation stresses, both positive and negative, are caused by 24 feet high waves at High Water.

The effects produced by maintaining the water level inside the columns constant at still water level can be assessed from the data in Table 1. For example, this modification causes reductions in vertical forces but increases in moments for the case of 24 feet high waves at High Water, both for FULL OPENINGS and for TEN PERCENT OPENINGS.

The benefits derived from restriction of the openings along the bottom edges of the Caisson are clear from the data in Table 1. For three of the four test conditions the case of TEN PERCENT OPENINGS has smaller maxima for all forces and moments than does the case of FULL OPENINGS UNDER.

6.2 High Water: 24 feet high waves approaching in direction normal to berthline: The details of forces and moments experienced by a Berth Caisson and by components of it, for the case of 24 feet waves approaching normally to the longer face at High Water are shown in Figures 8a to 8d. The total forces and moments for the whole Caisson are shown in Figure 8a and the separate contributions of the base and columns to horizontal and vertical components of force are shown in Figures 8b and 8c respectively. The significant effects on vertical forces caused by partial closure of the gaps along the bottom edges of the Caisson are evident in Figures 8a and 8c. The columns contribute the largest component to the horizontal force on the Caisson, as can be seen from Figure 8b.

The details of moments experienced by the columns are shown in Figure 8d; it can be seen that the columns are subjected to very large moments and, in fact, the columns make the largest contribution to the moments experienced by the Caisson as a whole.

The time histories of forces and moments in Figures 8a to 8d display marked departures from symmetry which are due to a number of effects, including the large wave height (the ratio of wave height to water depth is approximately 1:3), separation of flow past the columns and interactions between the columns. It is of interest to note that, whereas the maximum total horizontal force is larger than the maximum

of any partial contribution to it, the maximum of total moment is less than the maximum contribution from the columns, a result of the complex phase relationships between the several contributions to the total effect. The maximum of total vertical force is approximately the same as that on the top surface alone for the case of FULL OPENINGS, but is smaller for the case of TEN PERCENT OPENINGS.

6.3 Low Water: 12 feet high waves approaching in direction normal to berthline: The total forces and moments experienced by a Berth Caisson under these conditions are shown in Figure 9. This case is included for comparison with the results for the 24 feet wave at High Water and it can be seen that the maximum moments in Figure 9 are larger than those in Figure 8a. The large total moments in Figure 9 are almost entirely the consequence of large moments on the base of the Caisson which, in turn, result from the fact that the contributions from the top and underneath surfaces of the Caisson are nearly in phase. In contrast, the large total moments in Figure 8a arise from the very large moments experienced by the columns.

6.4 Effects of Wave direction on Column Moments: The tests with waves approaching in the direction normal to the berthline showed that the columns would be subjected to very large forces and moments under the

FIG. 8 WAVE FORCES ON BERTH CAISSON; 24 FT WAVES AT H.W.

action of 24 feet high waves at High Water. A series of tests was completed to determine the forces and moments experienced by the columns for the same wave and tide conditions except that the waves were approaching from the dominant ESE direction. It was found that the maximum bending stresses due to moment under these conditions will be developed in the rear leading column in the presence of neighbouring caissons. This also proved to be the worst of all cases tested, giving bending stresses 22 percent higher than for the worst case for waves approaching normal to the berthline. The moments experienced by the rear leading column in these angled waves are shown in Figure 10, which includes results obtained with and without neighbouring caissons. It can be seen that the presence of neighbouring caissons causes the maximum moments on the column to be increased almost twofold. The presence of neighbouring caissons also resulted in increases of approximately 25 percent in the maxima of moments on the front leading column. However, in the case of both "down-wave" columns the presence of neighbouring caissons had only small effects on the maxima of the moments.

7. COMPARISON BETWEEN EXPERIMENT AND THEORY

The forces and moments produced by calculations of Garrison (Ref.3) based on linear diffraction theory, are compared with the results derived from experimental pressure measurements in Figure 6. The conditions for which the comparison is possible are those of High Water with cyclone waves approaching in the direction normal to the longer side of the Berth Caisson and, although the conditions used for theoretical calculations and experimental studies are very closely similar, they are not identical. The depth of water in the experimental studies was 76 feet (23 m) and the wave height was 24 feet (7.3 m). The corresponding values in the theoretical calculations were 78 feet (23.7 m) and 23.6 feet (7.2 m) respectively. The wave period was 8.25 seconds in each case.

The quantities compared in Figure 6 are total Moment, Horizontal and Vertical forces due to wave action on the exposed surfaces of the Caisson. The effects of wave induced pressure variations on the underside of the Caisson and inside the columns are not included in the comparison. The results obtained from the two approaches display significant differences. Whereas all three curves derived from linear diffraction theory are nearly symmetrical, all curves obtained from measured pressure distributions display large departures from symmetry. These departures from symmetry are considered to be due to the significant non-linearity of the incident wave and to the effects of flow separation about the vertical columns. The lack of symmetry in the curves derived from experimental results shows most clearly in the different magnitudes for positive and negative peak values. The two sets of results also show significant and complex differences in the phase relationships between the three quantities, F_x , F_z and M_y . The ratios of the peak values of the three quantities are given in Table 2.

TABLE 2 - RATIOS OF EXPERIMENTAL MAXIMA TO THEORETICAL MAXIMA

F_x		F_z		M_y	
+ve	-ve	+ve	-ve	+ve	-ve
1.60	1.85	1.36	0.81	0.50	0.64

The differences are least for vertical forces, F_z . The experimental

FIG.9 WAVE FORCES ON BERTH CAISSON; 12FT WAVES AT L.W.

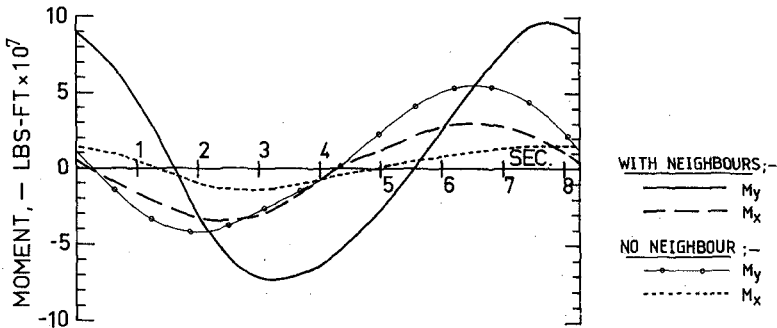

FIG.10 COLUMN MOMENTS; 24FT WAVES AT H.W. FROM E.S.E.

values of horizontal force F_x are much larger than those predicted by linear diffraction theory but, in spite of this, the experimental values of moments are only approximately one half those predicted by the theory. The explanation of the latter result is that the total moment is the summation of contributions from the four columns, from the vertical faces of the base of the caisson and from its top surface; the combination is considerably smaller in magnitude than some of the individual contributions and the phase relationships between the individual contributions are of very great significance in determining whether effects are additive or whether they cancel each other.

8. APPLICATION OF RESULTS

Pressure readings derived from the model study were converted directly to the equivalent head of water acting on the surface. The maximum loading condition on the column faces for the passage of waves was extracted from the readings and applied directly as a loading to the column for bending moment and shear force calculation on the column as a whole.

The exterior walls of the columns were designed for two methods of behaviour, viz:- as two dimensional panels and as horizontally spanning

beams of unit width. In the latter case it was necessary to analyse the entire circumference of the column as a continuous member and to apply the instantaneous pressure loading on the circumference. This loading varied from a maximum positive pressure of 25 feet of water to a maximum negative pressure of 15 feet. The method used ensured that the axial loading in the walls from the pressure distribution was also determined. The water level inside the columns was tidal and found to vary during the passage of the waves. The loading on the walls could vary from positive (inwards) to negative (outwards) as the water level rose and fell above tide level. This introduced a reversing load of compression and tension into the interior walls. The walls were designed for the worst case of tension and compression combined with bending moment induced by uneven external wall loading together with fatigue conditions.

The overall stability criteria were established prior to the present formal recommendations of Federation Internationale de la Precontrainte and Det Norske Veritas and were as follows:

(i) For loadings derived from numerical analysis

- * horizontal and vertical wave loads - load factor 1.4
- * wind loads load factor 1.4
- * dead loads load factor 1.0

In this case the worse combination of horizontal and vertical wave loads was adopted.

(ii) For loadings derived from physical modelling, the same load factors were used and, in this case, the combination of vertical and horizontal loads used was that conforming with the observed phase difference.

The somewhat unusual feature of taking the dead load factor as 1.0 in lieu of 0.9 is justified since the caissons, in floating, were effectively weighed to within 1 percent.

Stability criteria of 1.0 on overturning and 0.7 on sliding were adopted for both these load factors. In the event, the stability criteria adopted conformed to both Federation Internationale de la Precontrainte and Det Norske Veritas requirements.

9. STUDY OF SCOUR NEAR CAISSONS DUE TO WAVE ACTION

The ocean bed at the site of the berth is covered with fine sand. The berth area is dredged to a general depth of 56 feet below low water and the berth caissons are founded on an area of crushed rock, consisting of sizes passing a 4 inch screen, which has been levelled off to R.L. -56 feet (See Fig. 3). Scour tests were carried out at a linear scale of 1:60 in order to safeguard the structures against erosion resulting from wave action. The model of the main berth caisson which was used for pressure measurements was also used in the scour tests. At a scale of 1:60 the corresponding maximum size of foundation material for the model is 0.07 inch. The material used to represent the prototype foundation material in the scour studies was prepared from finely crushed rock, by rejection of all sizes not passing a No. 7 sieve and by washing from the remainder the sizes passing a No. 25 sieve.

Interaction between the incident waves and the berth structures will produce significant velocities in the vicinity of the caissons and

these induced velocities provide the most important mechanism for erosion of the foundation material. It is very difficult to assess the relative importance of viscous action in the complex phenomena involved in generation of the currents by interaction between incident waves and structures and in movement of the foundation material by these currents. However, the induced velocities are of the same order as the maximum orbital velocities in the incident wave and the Reynolds number based on bed material size is of order 1000 in the model. It is considered that this Reynolds number is large enough to ensure that scale effects in the model will not be so large as to invalidate the general results of the scour studies. The results of the scour studies are considered to be qualitatively correct but no estimate can be made concerning quantitative accuracy.

9.1 Wave scour near main berth caisson: For studies of wave scour near the main berth caisson, the model of the caisson was mounted on a 2 inch thick layer of the crushed rock fines. All wave scour tests were run continuously for one hour, which corresponds to 7.75 hours of prototype time reckoned according to Froude number scaling. However, as noted above, the uncertainty associated with different viscous effects in model and prototype makes scaling between elapsed times for the model and prototype approximate only. Further, the tide level varies continuously so that a continuous test at low water imposes conditions which are equivalent to a much longer interval of elapsed time with regard to scour development in the prototype.

No Protection: The first studies were carried out with no scour protection in place in order to determine the extent of the problem. The worst scour developed under the action of 24 feet high waves at Low Water. Deep scour and undermining developed along each edge of the caisson for waves approaching normally to the berthline; deep scour holes developed at each corner of the caisson for waves approaching from E.S.E. The scour hole developed at one of the "side" corners in this latter test is shown in Figure 11. Similar scour patterns were observed for 24 feet high waves at High Water and, although they were not as deep or extensive as those observed at Low Water, they were still quite significant. Waves 12 feet high caused some small localised scour when approaching normally to the berthline at Low Water but not otherwise.

Scour Protection: The protection developed during the model tests consisted of a skirt of woven plastic fabric, fixed to the bottom edges of the caisson and extending horizontally for a distance of 15 feet to provide a barrier between the erosive water currents and the foundation material. The fabric was to be held in place by concrete slabs, 7'6" square and having a net weight under water of 50-60 pounds per square foot. The slabs were to cover the fabric completely, and it was planned that they would be linked together at their edges by simple hinged connections. The protective fabric was to be of sufficiently open weave to permit rapid equalization of pressures above and below it, but the weave was to be close enough to prevent loss of any but the finest rock particles through it. In the tests on the model of the main berth caisson, an open weave soft plastic fabric was used to simulate the protective fabric and the slabs were simulated with square sheets of aluminium, 1.5 inch x 1.5 inch x 0.1 inch thick. The weight under water of the corresponding full size slabs is 56.8 lbs per sq.ft and,

if concrete slabs, the required thickness is 8.25 inches. This small discrepancy in thickness of the slabs is of no significance in the context of these studies. In the model studies the model slabs were not linked together so that any tendencies for the slabs to be moved about would be shown up more readily.

The series of tests with the scour protection in place showed that it was completely satisfactory for protection against 12 feet high waves. Waves 24 feet high caused varying amounts of movement of the protective slabs. The greatest movements of slabs were observed when these large waves approached from E.S.E. at low water and they occurred at the "side" corners of the caisson. The conditions at the same side corner as shown in Figure 11 after one hour of testing at these most severe conditions can be seen in Figure 12. Pumping action through the woven fabric resulted in some slight displacement of the foundation material.

9.2 Wave Scour at Approach Caisson: The approach structures linking berth to shore are supported on caissons which are 55 feet (17 m) square in plan. Two possible treatments of the foundations for the approach caissons were considered. In the "lowered" foundation a hole 90 feet (28 m) square is dredged to a depth approximately 5 feet (1.5 m) below the general bed level and partly back-filled with a layer of crushed rock, approximately 2 feet (0.6 m) thick. In the "raised" foundation the layer of crushed rock is placed directly on the sea-bed and the caisson founded on this raised layer. The same scour protection as had been developed for the main berth caissons was proposed for the approach caissons.

The scour studies on the approach caisson demonstrated clearly that the "lowered" foundation is very much to be preferred over the "raised" foundation. In the tests on the "raised" foundation, the wave-induced currents were so strong near the base of the caisson that the scour protection was attacked violently and its effectiveness was completely destroyed. On the other hand, in the case of the "lowered" foundation, the scour protection was found to be satisfactory even under the worst conditions but only if the cruciform-shaped gap under the caisson between its foundation pads is closed off. When this gap was left open a very strong pumping action with significant scour capacity developed beneath the caisson under wave action.

The conditions after one hour of testing on the "lowered" foundation with the gaps closed, under attack from 24 feet high waves at Low Water can be seen in Figure 13. The foundations of the caisson have been protected satisfactorily. The general erosion of the sea-bed down-wave from the caisson is caused by a strong streaming motion in this region which results from the interaction between the incident waves and the caisson.

10. CHOSEN METHOD OF SCOUR PROTECTION

The simulated scour protection devised for the tests was later considered too involved for actual construction and a form of flexible matting was devised as indicated on Figures 2 and 3. This consisted of a mat of concrete blocks approximately 15 feet square, each block being approximately 1'7" square in plan and 1'3" thick and cast on wire ropes running in two directions which allow flexibility and ready handling. The gaps between the blocks were maintained at 1½" to act as a filter

FIG. 11 Scour near Berth Caisson - 24 ft Waves from E.S.E. at L.W.

FIG. 12 Scour protection - 24 ft Waves from E.S.E. at L.W.

FIG. 13 Scour near Approach Caisson - 24 ft Waves at Low Water.

to prevent the removal of foundation rock during periods of intense wave action. The weight of the matting chosen was equivalent to 90 lbs/sq ft under water, which is nearly twice the model weight, but it was considered that the remedial work that might be required after severe scour could be very serious and therefore a conservative approach was adopted. Figure 14 illustrates the operation of laying 'scour mats and shows their inherent flexibility. Laying of the units was controlled by divers.

11. PERFORMANCE OF PROTOTYPE

The prototype has been in operation since July 1975 and the Queensland coast experienced 8 cyclones in the 1975-6 cyclone season. A wave-rider buoy has recently been installed by the Department of Harbours and Marine, approximately 19 miles (30 km) to the N.E. of Hay Point in 84 feet (26 m) of water, and a maximum wave height of 14.5 feet (4.4 m) was recorded during the most severe of these cyclones. Only one cyclone passed near Hay Point. This cyclone (code name David) necessitated full emergency precautions at the berth. When operations were closed down, the sea had risen to about 12 feet waves. Recording devices have not yet been placed on the structure and no further observations were possible. Examination of the structure and of the foundation after the cyclone revealed no signs of damage.

12. ACKNOWLEDGEMENT

The authors thank Utah Development Company, owner of the Berth, for permission to publish this paper.

CHAPTER 131

TSUNAMI HAZARD AND DESIGN OF COASTAL STRUCTURES

George Pararas-Carayannis

Director, International Tsunami Information Center

P. O. Box 3650

Honolulu, Hawaii 96811

Abstract

Damage of coastal structures by tsunamis results by the direct and indirect action of hydrostatic and dynamic pressures, foundation failures, overtopping and flooding. Reliable assessment of the potential tsunami hazard at a coastal site and adequate engineering design of critical structures require analysis and understanding of all aspects of a tsunami system leading to its terminal behavior. Description of the space-time history of tsunami waves generated by impulsive disturbances require consideration of events and processes in the following regimes: (a) generation; (b) propagation and dispersion; and (c) termination. Processes and events in each regime during the development of a tsunami are under their own unique hydrodynamic constraints but are dependent on what has preceded. In predicting tsunami wave characteristics at some distance from the generating source, the error structure may be pyramidal. Essential to any method of tsunami prediction at a distant or a nearby coast will be the full consideration and study of tsunami generative mechanisms. If the tsunami generation mechanics cannot be deduced with a reasonable degree of accuracy, it is not likely that the tsunami terminal aspects will be reliably predicted. Prediction of tsunami height at a distant or at a nearby coast requires knowledge of the magnitude and type of ground displacements in the tsunami generating area and of the characteristics of the surface waves resulting from such action. Although all mechanisms involved during tsunami generation are not fully understood, it is possible to obtain a suitable tsunami initiating function through the use of experimental data, historical data, and established empirical relationships, for each type of generating mechanism. Reliable computation of the tsunami propagation effects over and across the ocean can be obtained with proper modeling to provide an adequate description of the tsunami energy flow through the use of physical and numerical studies. Similarly, the terminal aspects and nearshore modification of the tsunami wave system can be approximated to provide the engineering criteria necessary for the assessment of the potential tsunami hazard at a coastal site.

Introduction

Increasing pressure for the construction of large coastal installations, such as power plants, and superport terminals, and the increasing residential development of coastal zones, have emphasized recently the need for more accurate estimates of the terminal effects of tsunamis. Questions that most often arise deal with such subjects as the frequency of catastrophic tsunamis at a given coastline; the maximum expected runup from a tsunami for a given site; the dynamic forces that can be expected; and finally how to design structures to withstand the forces and effects of a possible tsunami.

The answers are not simple. Attempts to solve these problems may become involved in numerous complex mathematical solutions which require numerous approximations and simplifications, to the point that the accuracy of these solutions becomes doubtful. In addition, theoretical and analytical solutions often assume a smooth transmission of tsunamis to the coast without taking into account the effects of obstacles (islands, seamounts, reefs, etc.) which complicate the phenomenon. At the mouths of rivers, in estuaries, and generally in bays or other irregular coastlines, tsunamis undergo such alterations and changes of their characteristics, that theoretical appraisal of tsunami height, runup, velocities, or forces on coastal structures often are invalid. In such instances, historical and statistical data, visual observations, and other empirically-derived data become the sole guide in evaluating the maximum possible height, runup, and effect of tsunami waves on coastal structures.

Unfortunately, historical and statistical data on tsunamis is non-existent for certain coasts, or the historic record may be of very short duration to permit a suitable analysis. Therefore, there is always the danger in designing coastal structures that potential tsunami effects may be either ignored, underestimated, or overestimated. If the tsunami potential danger is underestimated or ignored, the design of the coastal structure will not be adequate. If the tsunami potential danger is overestimated, overdesign of the coastal structure results, causing excessive financial expenditure for the project. In spite of all these difficulties, a combination of historical observations, laboratory experiments, and theoretical studies, provide assurances of a more accurate evaluation of a probable maximum tsunami at the coast. Such studies require time and expenditures which cannot be reasonably justified unless the coastal structures are important and will serve a critical function (i.e., protection of nuclear power plant).

Interaction of Tsunamis with Coastal Structures: Damage of coastal structures by tsunamis may be by the direct action of hydrostatic and dynamic pressures on the face of a structure, resulting in foundation failure due to erosion, or overtopping and flooding. The forces on the face of the structure are caused by the rapid water motion in the form of gravity waves or in the form of irregular violent motions. The hydrostatic and dynamic pressures of gravity waves on structures depend basically on the height, direction, period, and velocity of the waves, the design of the coastal structure, and a number of other factors.

The most adverse interaction of tsunamis with a coastal structure exists when the directional approach of the waves is perpendicular to the longitudinal axis of the structure because the pressure is exercised in the direction of least resistance of the structure. However, this is true if we consider only the water pressures on the structure and not other direct or indirect effects of a tsunami, which could be of greater danger, regardless of direction, or height. For example, there could be instances when the direction of water movement may not be perpendicular to the longitudinal axis of the structure and yet the water motion may result in strong currents which may undermine the structure by eroding the material near its foundation with subsequent failure.

The period of the tsunami is another factor which could influence the effect of these waves on a coastal structure. This may affect degree of flooding and permissible overtopping. Tsunami period is usually of 15-30 minute duration. Therefore, it is expected that when a tsunami arrives at an open harbor, it floods progressively both the outer and inner sides of coastal protective works of the harbor, without causing significant pressure differentials on opposite sides of structures. A small pressure differential on the two sides of a coastal protective structure may occur at the arrival of the tsunami waves due to the dynamic momentum of the moving water. This pressure effect is a function of the velocity of the tsunami and will be more pronounced if the harbor has a narrow entrance, if the tsunami approaches at high speeds, or if a bore is formed.

Hydrodynamic Pressures of Local Earthquakes on Coastal Structures: The design of coastal structures usually requires consideration of different loads which include those caused by wind waves, the weight of the structure itself, the seismic forces acting on the structure, and the permanent or moving loads resting or interacting with the structure. Although the seismic effects are often adequately considered, the hydrodynamic forces which could develop in the water from an earthquake and which interact with the structures, are often ignored.

Seismically-generated hydrodynamic pressures acting with a sloping breakwater, for example, are directly related to seismic accelerations, the depth of the water in front of the structure, and the slope of the structure's face. During a local earthquake, the hydrodynamic pressure on the structure ranges alternately from zero to a maximum value on both sides of the structure. It has an alternating direction in phase always with the direction of the seismic ground accelerations. It can be concluded that considerable hydrodynamic pressures can develop on the faces of coastal structures during a local earthquake and such forces should be considered in the design. These forces will be particularly critical in the design of high breakwaters, or of structures with a vertical face, if these structures will be constructed in areas where large and frequent earthquakes occur. A local earthquake may result also in oscillations of the waters of a bay or a harbor which could excite the natural mode of oscillation of a basin resulting in greater runup and damage to coastal structures within that basin. Such resonance effects are not always adequately considered in designing coastal protective works.

Engineering Guidelines

Runup height, terminal velocity and periodicity are the three most important terminal parameters of a tsunami of concern to engineers in designing coastal structures. Tsunami runup height and terminal velocity are the most difficult to estimate without knowledge of what has preceded. For a complete understanding of the problem and for the development of the spacetime history of tsunami waves generated by impulsive disturbances, consideration should be given to events and processes in the regimes of generation, propagation and termination. Processes and events in each regime during the development of a tsunami are under their own unique hydrodynamic constraints but are dependent on what has preceded.

Tsunami Generation: Prediction of tsunami height at a given coastal site requires knowledge of the magnitude and type of ground displacements in the tsunami generating area and of the characteristics of the surface water waves resulting from such action. Understanding of the disturbances responsible for tsunami generation is limited. Very little work has been done in relating tectonic or other impulsive disturbances to ocean surface effects. Most of the laboratory studies completed to date have investigated tsunamis resulting from simplified displacements under restrictions of analytical conditions which bear limited resemblance to processes in nature.

Although all mechanisms involved during tsunami generation are not fully understood, it is possible to obtain a suitable tsunami initiating function through the use of experimental data, historical data, and established empirical relationships for each type of tsunami generating mechanism. For example, the type and extent of crustal displacements associated with tsunamigenic earthquakes can be approximated. These displacements will depend on earthquake magnitude, depth of focus, epicenter location, geologic trends in the area, length of rupture, orientation, and type of ground motions.

In evaluating the runup at a specific coastal site, or the safety of a critical coastal structure (i.e. a nuclear power plant) for a tsunami generated from a distant or a local earthquake, consideration should be given to the nature, characteristics, and mechanism of the largest possible seismic event that can give rise to a maximum tsunami. It is proposed that the term of Maximum Probable Tsunami (MPT) be adopted in designating such a source event, and that criteria be developed to describe such design tsunami.

In planning or designing important coastal structures teleseismic and potentially tsunamigenic source areas should be identified geographically in relation to the site of interest. Tectonic structures and trends of each region should be identified. Historic information should be provided on depth, frequency, density, distribution, and magnitude of earthquakes, together with records of tsunami generating activity for each potentially tsunamigenic region. Following preliminary assessment of such data, a tsunamigenic source should be selected which would be most critical to the site of interest. Conservative values of seismic parameters should be assigned

to a hypothetical earthquake which can produce the maximum initial tsunami function. For example, a magnitude of 8.5 on the Richter Scale may be assigned to a hypothetical, shallow-focus earthquake, having a rupture of 1,000 km, a total displacement area of 150,000 square kms, involving vertical displacements along the rupture of at least 3 meters, and having a critical orientation towards the proposed site.

Using critical seismic parameters of the source, empirical relationships, current theories, and other historic or experimental data, an initial tsunami function should be reasonably developed which should be consistent with ground displacements, coupling mechanisms, and source dimensions.

Tsunami Propagation: The initial tsunami wave and subsequent waves should be propagated from the source taking into consideration interactions, resonances, and boundary modifications, in order to obtain the maximum possible tsunami runup at site of interest.

Finite difference numerical computer programs have been developed for the propagation of tsunami waves across the deep ocean to the edge of the continental shelf and have been used for verification using data of historical tsunamis (Wilson and Torum, 1964; Hwang and Divoky, 1970; Hwang, Butler and Divoky, 1972; Houston and Garcia, 1974). Such computer programs take into consideration the sphericity of the earth in solving the linearized long wave equation of motion and continuity. The finite difference methods permit uplift deformation of the water surface at the selected tsunami source to be used as an initial condition. A time history of water surface information conforming to the bathymetric features of the ocean, is propagated away from the source and a transfer function is provided at the edge of the continental shelf. To propagate a tsunami across the continental shelf, other analytical solutions of the linearized long wave equation have been developed. Although numerical models exist which can propagate tsunami wave across the shelf, the necessity for large systems and the computer storage and routine requirements are great and make such solutions expensive. Often simple two dimensional analytic solutions are used to propagate standing waves over the Continental shelf, based on theoretical solutions for tides in canals. These studies do not necessarily produce very correct results, but they are better than no studies at all.

Tsunami Termination: The probable maximum height of tsunamis at a coastline is difficult to estimate. There is no simple or exact method or numerical model which can be used for estimating tsunami runup. Most of the coastlines where tsunami runup estimates are required are irregular. Interactions of tsunami waves with an irregular coastline may result in the trapping and resonance of tsunami wave energy and may result in higher-than-expected runup. As mentioned earlier, large bays and harbors may have resonant periods which may coincide with the peak of the tsunami spectrum and such resonance could result in an increase of wave height and runup. Tsunami runup calculations for such irregular coastlines must first take into consideration the increase of wave height by resonance, then use this estimate as input in calculating total runup. Also, ambient conditions and cumulative effects should be considered. Numerical models applicable to

runup estimates of long waves have been developed which can be valid for waves of the tsunami frequency. In using these models, care should be exercised in selecting the proper boundary conditions.

The water velocity of the tsunamis that flow into a coastal area is difficult to estimate because it depends on many such factors, as the topography, the direction of approach, and the length of the waves. Because of the complexity of flow conditions, the velocity of the water can only be roughly approximated. An erroneous assumption often used in estimating terminal velocity is treating the tsunami as a bore -- something which in reality does not occur frequently.

Finally, since all the factors which contribute to tsunami runup are not fully understood, tsunami inundation cannot be computed entirely from theoretical analysis. For coastlines where historical information on runup is available, a statistical approach can be used to predict future events. This method does not require a complete understanding of the hydrodynamic considerations involved, but examines the magnitude and frequency of occurrence of historical tsunami runup. Such frequency analysis has been commonly used for the study of rainfall and stream flow records (Foster, 1935). Gumbel, (1941, 1942) applied an extreme value probability distribution to flood flows. Similar frequency studies of extreme events have been made ranging from rainfall to floods, to drought, to water quality and to ocean wave studies. In general, frequency analysis is a useful analytic tool for the study of randomly occurring events, such as large tsunamis.

CHAPTER 132

NUMERICAL CALCULATION OF WAVE FORCES ON STRUCTURES*

B. D. Nichols and C. W. Hirt**

I. INTRODUCTION

A finite-difference technique for solving the Navier-Stokes equations for an incompressible fluid is used to calculate transient wave forces experienced by fixed and moving bodies. The numerical technique is based on the Marker-and-Cell (MAC) method developed by Harlow and Welch (1965). This new technique uses an especially simple solution algorithm that is designed for persons with little or no experience in numerical fluid dynamics. Originally conceived as an instructional tool, it has proven to be an extremely useful and versatile calculational method. Many useful calculations are possible with the publicly available code, SOLA-SURF, which is briefly described in Sec. II; however, the outstanding feature of this numerical scheme is the ease with which it can be modified to handle more complex problems. Reported here, in Sec. III, are examples to illustrate the utility of this new calculational tool for investigating the dynamic interactions between ocean waves and coastal structures.

II. THE NUMERICAL TECHNIQUE

The solution algorithm contained in SOLA-SURF solves the Navier-Stokes equations for an incompressible fluid. A stationary network of rectangular cells is used to divide the calculational region into a finite number of elements with which the fluid variables are associated. The primary field variables are the velocity components and the pressure. Each of the velocity components is specified at the center of the cell face to which it is normal and the pressure is specified at the cell center.

*This work was performed jointly under the auspices of the United States Energy Research and Development Administration and the Office of Naval Research, ONR Task #NR 062-455.

**The authors are members of the Fluid Dynamics Group (T-3), Theoretical Division, Los Alamos Scientific Laboratory, Los Alamos, NM 87545.

The fluid motion is numerically determined by advancing the fluid configuration through a series of small time increments. During each time step the solution to the momentum equation is obtained in two phases. First, the velocities and pressures from the previous time step are used to determine the fluid velocities in each cell, with the initial conditions used for the first time step. This explicit calculation does not necessarily ensure incompressibility; therefore, in the second phase the tentative velocity field is adjusted through changes in the pressure field. The pressure in each mesh cell is adjusted to drive to zero the velocity divergence in that cell. The pressure and velocity distributions must be obtained by iteratively adjusting these velocities in each cell in the mesh. This solution algorithm and other features of the technique are described in detail in a report by Hirt et al. (1975).

Free or curved rigid surfaces are permitted across the top and bottom of the computational mesh. The surfaces are defined by single valued functions of the height above the bottom of the computational mesh and are specified at the center of each vertical column of cells. The change in the free surface elevation is determined kinematically by the local fluid velocities, i.e., by the vertical component of the fluid motion plus the horizontal convection of the surface elevation from adjacent cell columns.

The free surface boundary conditions require that the normal and tangential velocities immediately outside the surface be chosen to ensure a zero transfer of momentum through the surface. A good approximation to these conditions is to set the velocities normal to the surface to satisfy the incompressibility condition in the cells in which the free surface is located and to set the tangential velocities in the cells immediately outside the fluid equal to the adjacent interior velocities. The pressure in surface cells is determined by a linear interpolation or extrapolation between the pressure in the fluid cell immediately below the surface cell and a specified pressure at the surface.

The pressure in each cell in which a rigid surface is located is derived under the constraint that the velocity normal to the surface be zero. This requires a variation in the Newton-Raphson type solution method used to obtain pressures for interior fluid cells. The velocity boundary conditions for these rigid boundaries are free-slip, i.e., the normal velocity and tangential velocity gradient are zero at the boundary, which makes them identical to the free surface boundary conditions. In addition, these rigid surface boundary conditions can be easily inserted in SOLA-SURF to create rigid, curved bodies at any location in the computational mesh. A special boundary condition section has been designated in the code to facilitate these types of modifications.

A copy of the SOLA-SURF code is available from the Argonne Code Center. The address is Argonne Code Center, Argonne National Laboratory, 9700 South Cass Avenue, Argonne, Illinois 60439.

III. THE CALCULATION OF WAVE FORCES ON STRUCTURES

We present four brief studies to illustrate the areas in which the ocean engineer may find SOLA-SURF to be a useful tool. The first two calculations, i.e., solitary wave run-up on a vertical wall and on a sloped beach, are good examples of what can be done with the relatively simple SOLA-SURF code without modification. The remaining calculations require the addition of special boundary conditions to create stationary or moving interior structures.

1. Reflection of a Solitary Wave

In this first example, a solitary wave travels over a fluid of constant depth, runs up a vertical wall, and reflects from the wall. The calculational region was resolved by 75 horizontal by 10 vertical cells, with cell dimensions of 0.5 horizontally and 0.2 vertically, and a time step of 0.1 was used. (The units in this calculation were non-dimensional.) All the wall boundaries were specified to be rigid, free-slip boundaries and the fluid is nearly inviscid. Laitone's second order approximation was used to initially define the free surface profile and velocity field of the solitary wave, as presented by Weigel (1964). The pressure field was initially set to hydrostatic pressure. Figure 1 shows the free surface profile and the velocity field, represented by velocity vectors drawn from cell centers, at times 13, 18, 20, and 26. The integrity of the wave profile and the velocity field remains excellent as the wave propagates down the channel and reflects from the wall.

To compare with the experiment of Camfield and Street (1967), the numerical calculation was repeated several times with initial wave heights ranging from 0.1 to 0.6, and with an undisturbed fluid depth of 1.0. A comparison of the computed maximum wave run-up with the experimental results is shown in Fig. 2. The abscissa is the ratio of the initial wave height, H_0 , to the undisturbed fluid depth, d , and the ordinate is the ratio of the maximum wave run-up on the vertical wall, R , to d . As the plot shows, the SOLA-SURF calculated data are in excellent agreement with these experimental data for a wide range of initial wave heights.

2. Solitary Wave on a Sloping Beach

Solitary waves are often used as the initial wave shape to simulate shoaling, breaking, and run-up of large, long waves on a beach. SOLA-SURF cannot handle breaking waves because of the restriction that the free surface slope be less than the mesh cell diagonal. This restriction can be removed by using the more complicated surface marker particle treatment as described, for example, by Nichols and Hirt (1971). However, we have calculated the solitary wave running up a sloped beach and measured the variation in maximum amplitude with depth. The rigid bottom slope was $1/20$, with the ratio of wave height to fluid depth of 0.1.

Fig. 1. Free surface profiles and velocity vector plots of solitary wave run-up on a vertical wall at times 13, 18, 20, and 26.

Fig. 2. A comparison of the computed maximum wave run-up, R , with experimental values for many initial wave heights, H_o .

Again, Laitone's second order approximation was used to initially define the solitary wave. Free-slip boundary conditions were specified for all rigid boundaries. A mesh of 90 horizontal by 18 vertical cells was used with cell dimensions of 0.5 horizontally and 0.1 vertically. The mesh length was chosen to accommodate the solitary wave totally over the horizontal section of the mesh bottom. SOLA-SURF does not have provisions to treat the intersection of the variable top and bottom boundaries in a cell. To allow the solitary wave to run farther up the beach without reflecting from the vertical wall, a shelf two and one-half cells beneath the undisturbed fluid surface was incorporated into the bottom boundary configuration. This is shown in Fig. 3, along with the free surface profile and the velocity field at times 0, 9, 22, and 28. At the later times, steepening of the wave front and growth of the wave height is obvious. Indeed, the calculated variation in maximum amplitude with depth compares very well with previous calculations, as shown in Fig. 4. In this plot, we compare the computed variation in maximum wave amplitude at different fluid depths with the theories of Peregrine (1967) and Madsen and Mei (1969). The numerical calculation of Chan and Street (1970) are virtually the same as the SOLA-SURF results. Peregrine derived equations of motion for long waves in water of varying depth that are extensions of the Boussinesq equations and that include nonlinear terms and a term to account for the effects of the vertical acceleration of the water on pressure. These equations were solved numerically for a solitary wave on a beach of uniform slope. Madsen and Mei treated the same problem with slightly different, but equivalent, equations. One difference, however, between the calculations is that Peregrine located the crest of the solitary wave immediately above the toe of the slope. The effect of this is seen in the comparison plot. Peregrine's calculation starts with $H/H_0 = 1.0$ at $d/d_0 = 1.0$, where H is the wave amplitude, H_0 is the initial wave amplitude, d is the undisturbed fluid depth at the horizontal location corresponding to the wave crest, and d_0 is the undisturbed fluid depth over the horizontal section of the bottom surface. The Madsen and Mei and SOLA-SURF calculations, which start with the wave initially over the flat bottom, show the ratio of the wave height at the toe of the slope to the initial wave height is greater than 1.0. The SOLA-SURF calculations are in good agreement with the other calculations. The effect of the shelf in our calculation is evident. The wave height does not continue to grow as the wave front reaches the shelf and, consequently, the value of H/H_0 falls slightly below values calculated without the shelf at low values of d/d_0 .

3. Forces on Submerged Structure

The determination of forces on submerged structures in the presence of gravity waves is of practical engineering importance. The SOLA-SURF code was used to calculate the horizontal and vertical forces on a submerged, rectangular structure resulting from a train of regular surface waves. This rectangular structure was created midway between the free surface and the mesh bottom by setting to zero the velocities on all faces of cells that make up the structure. These are set in the special boundary condition section of the code. The horizontal and vertical forces on the structure were determined by integrating the pressures acting on the surfaces of the structure. The dimensions of the submerged structure were chosen to compare with the experimental data of Brater et al. (1958).

Fig. 3. Free surface profiles and velocity vector plots of solitary wave run-up on a 1/20 sloped beach at times 0, 9, 22, and 28.

Fig. 4. A comparison of the computed variation in maximum wave amplitude, H , at different fluid depths, d , with other calculations.

The surface wave train was generated at the boundary of the computational mesh by setting the time dependent wave height and velocity components in the fictitious column of cells at the left side of the mesh. The mesh was 120 horizontal by 16 vertical cells, and the obstacle was 2 by 5 cells. Figure 5 shows the computer generated free surface profile, velocity field, and obstacle at times 0, 1.50, 3.25, and 4.25. The wave form is not perfectly sinusoidal; however, this is expected because an approximate shallow water expression was used to generate the wave form and, of course, the leading wave is distorted as it travels into still water. The exact form of the waves used in the experiment is not known.

Our computed data are compared with the experimental data in Fig. 6. The wave forces, normalized by wave height, are plotted as the vertical coordinate and the location of the center of the structure ($Y_b + d_o$), normalized by d_o , is plotted as the horizontal coordinate, where Y_b is zero at the free surface and d_o is the undisturbed fluid depth. The computed horizontal forces are in very good agreement with the experimentally determined forces of Brater et al. (1958). However, the

Fig. 5. Free surface profiles and velocity vector plots resulting from the propagation of a sinusoidal wave over a submerged structure at times 0, 1.50, 3.25, and 4.25.

Fig. 6. A comparison of computed forces on a submerged structure with experimental data.

vertical forces calculated are about 20% larger than the experimental data. The accuracy of the numerical calculation was tested by increasing the temporal and spatial resolution and tightening the pressure iteration convergence criterion. These tests confirmed the originally calculated results, indicating that numerical accuracy is not the source of disagreement. Since the vertical force is very sensitive to the wave form, we may not be correctly modeling the experimental waves.

4. Forces on Floating Bodies

Hydrodynamic forces exerted on partially submerged, floating bodies are of interest to naval architects and ocean engineers. Different types of fluid motion may be generated to study these forces. Here we report on calculations for bodies undergoing forced harmonic oscillations in an otherwise quiescent fluid. In particular, we have studied heave forces on two-dimensional cylinders with rectangular and triangular cross sections and sway forces on a triangular or wedge shaped cylinder.

Pure heaving motions produce only vertical forces, which, for low amplitude motions, may be described by their amplitude and phase relative to the forced harmonic motion. These forces are due to buoyancy, inertial (added mass), and energy dissipation (wave generation) effects. In this study added mass and damping coefficients are computed and compared with the experimental work of Vugts (1968).

These calculations used mesh sizes that varied from 100 to 250 cells in the horizontal direction, depending on the period of motion, and 20 to 30 cells in the vertical direction. Typical calculation times on the CDC-7600 were 0.20 ms/cycle/cell. For the rectangular body, the mesh cell size was 0.1 horizontally and 0.2 vertically. Five cells were used to resolve the half-width of the body, which was located at a plane of symmetry at the left mesh boundary. Figure 7 shows the location of the rectangular body and the velocity field after approximately 2.5 periods of oscillation. To model the harmonic motion of the rectangular cylinder, special boundary conditions had to be added to the SOLA-SURF code. At the rigid bottom boundary of the rectangular body, the cell pressure is derived under the constraint that the normal fluid velocity be equal to that of the body. Because the SOLA-SURF boundary conditions restrict the surface slope to be less than that of a cell diagonal, we had to eliminate this restraint at the vertical side of the cylinder by aligning the side with a cell boundary line. Then boundary conditions were added to set zero velocities normal to the side of the cylinder.

The added mass coefficient, μ , and the damping coefficient, λ , are given by

$$\mu = \frac{\gamma \cos \beta}{\omega^2 a}$$

Fig. 7. Velocity vector plot of the fluid in which a rectangular cylinder is in forced heave at the left mesh boundary after 2.5 periods.

and

$$\lambda = \frac{\gamma \sin \beta}{\omega a} ,$$

where a is the amplitude of motion, ω is the frequency of motion, and γ is the amplitude of the assumed harmonic pressure force on the body. The phase shift β was obtained by comparing plots of the body displacement and pressure force acting on the rectangular body as functions of time and measuring the shift in phase. A detailed description of the determination of these coefficients is given by Nichols and Hirt (1975). These calculated added mass and damping coefficients are compared with experimental data in Fig. 8. The coefficients are normalized by ρA and $\sqrt{B/2}g$, where ρ is the fluid density, A is the mean submerged area, B is the rectangular body beam, and g is the acceleration of gravity. The calculations were for $B/T = 2.0$, where T is the rectangular body draft at its mean location. The amplitudes of motion, normalized by B , were 0.025 and 0.05. Vugts' experiments were conducted in fluid depths, normalized by B , varying from 4.50 to 5.625. The normalized depth was 4.0 for the calculated results. The calculated data generally agrees very well with the experimental data. The discrepancy in the calculated damping coefficient at the normalized frequency of 1.25 is probably due

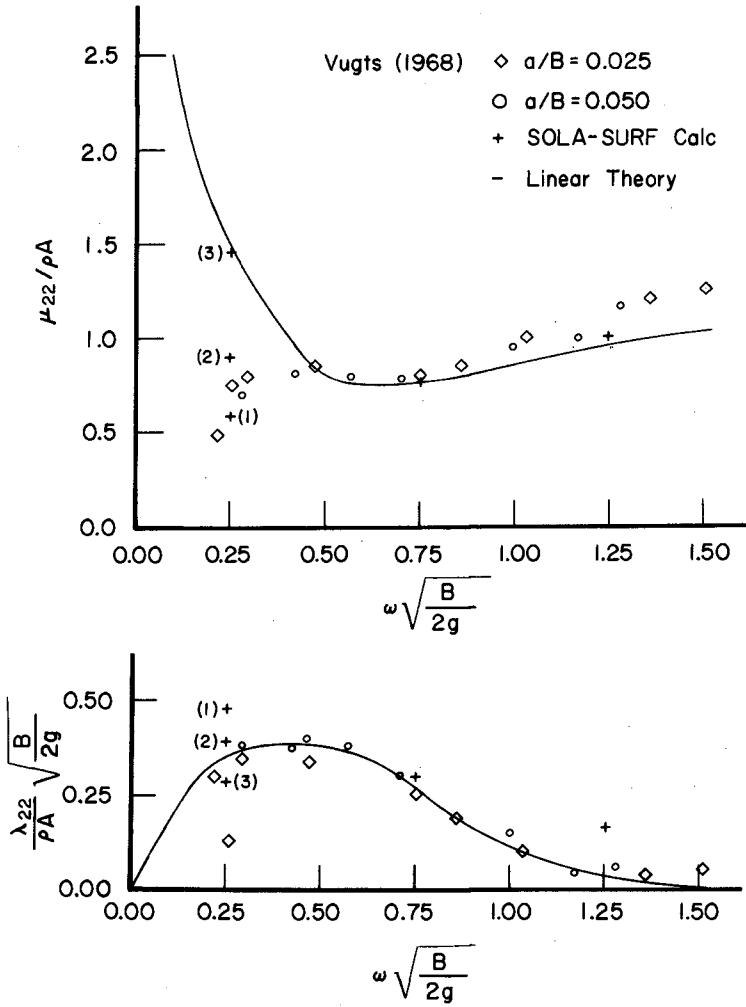

Fig. 8. A comparison of numerically computed and experimental values of added mass (top) and damping (bottom) coefficients from a rectangular cylinder in forced heave for $B/T = 2.0$.

to inaccuracies in determining the phase shift β , since it is very small at this beam width and frequency. To check this, another calculation was made, which is not plotted in Fig. 8, for $B/T = 8$ and $\omega\sqrt{B}/2g = 1.25$. In this case the phase shift is much larger, and the added mass coefficient agrees closely with the experimental data. The calculated damping coefficient in this case is very close to the experimental data, lying between the linear theory and the experimental data.

There is a discrepancy between the experimental data and linear theory for the added mass coefficient at normalized frequencies below 0.5. Vugts explains this as being caused by experimental inaccuracies. With a normalized fluid depth of 4.0, the calculated coefficient at a frequency of 0.25 is slightly higher than that of the experiments. (This is the middle point marked (2) in Fig. 8 at this frequency.) However, calculations with a fluid depth of 2.0, marked (1), and a fluid depth of 8.0, marked (3), show clearly that the finite depth is the cause of the disagreement with the linear theory. The added mass coefficient for the shallower fluid depth is slightly less than the experimental data, but with the normalized depth of 8.0 the calculated coefficient agrees with the linear theory, which assumes an infinite depth.

We next extended this capability to calculate the added mass and damping coefficients of a 60° wedge in sway. The coefficients, normalized as described above, were calculated for normalized frequencies ranging from 0.5 to 1.25 and with $B/T = 1.155$. An amplitude of motion, normalized by B , of 0.05773 was used. As shown in Fig. 9, the numerical data is in very good agreement with linear theory, but agrees less well with the experimental data. Expecting closer agreement with experimental data, we were concerned about possible numerical inaccuracies and tested for these in various ways. We tightened up the convergence criterion, increased by a factor of two the spatial and temporal resolution, used a new second order differencing scheme, and made various tests on the wedge interface boundary conditions. In addition, the calculations were performed in a moving reference frame attached to the body, as well as in the laboratory frame. However, all calculations were consistent to within a few per cent, thus, we believe the calculations are accurate.

Nonlinear effects were expected to have a greater influence. For example, secondary flow formed at the wedge tip is expected to increase the damping coefficient somewhat. This secondary vortex is shown in Fig. 10, which shows the velocity field and free surface configurations at times 0.50, 2.25, and 4.50. It should be noted that Vugts concluded that the generated eddy hardly disturbs the pressure distribution over the wedge surface. He explained the disagreement of his results with the linear theory as "a small systematic error at the higher frequencies of motion, where high demands are imposed on the structural set-up." We have shown that Vugts' tentative conclusions were correct and that linear theory does accurately predict the added mass and damping coefficients for the wedge in sway at this amplitude. Of course, at higher amplitudes for the forced sway, nonlinear effects must eventually enter.

CHAPTER 133

WAVE FORCES ON SQUARE CAISSONS

by

G.R. Mogridge* and W.W. Jamieson*

ABSTRACT

The forces and overturning moments exerted by waves on large vertical square-section caissons have been measured in the laboratory. Each model caisson extended from the bottom of a wave flume through the water surface and was oriented either with one side perpendicular to the direction of wave propagation or turned through an angle of forty-five degrees to this position. For a given orientation, each model was tested for a range of wave heights (up to the point of breaking) for various wave periods and water depths. A digital computer was used for the acquisition, processing, plotting and storage of the experimental data.

In addition to the experimental work, an approximate theoretical method is presented which allows the wave loadings on a square caisson to be estimated by means of a simple desk calculation. The experimental data shows that this simple method of calculation is reasonably accurate over a wide range of wave conditions and caisson sizes.

INTRODUCTION

In recent years, considerable research has been carried out to estimate the wave loads on various shapes of monolithic offshore structures; however, very little information is available in the literature concerning wave loadings on large vertical square-section caissons resting on the ocean bottom and extending through the water surface. Hogben and Standing (3) describe a numerical method which can be used for the solution of wave loads on large bodies including square caissons. The same method was previously used by Garrison and Chow (2), Milgram and Halkyard (7), and numerous others. Although numerical methods can be used for shapes

* Assistant Research Officers, Hydraulics Laboratory, National Research Council of Canada, Ottawa, Ontario, Canada, K1A 0R6.

for which closed form solutions do not exist, programming is time consuming and computation costs can be high. Hogben and Standing presented a few results of wave loads measured on a model of a square caisson. The experimental data was compared with the numerical solution (4) and also an approximate solution (3) based on the diffraction theory of MacCamy and Fuchs (6). For most of the range of relative caisson sizes tested, the results fitted both solutions reasonably well. Ijima, Chou and Yumura (5) have presented a numerical method for calculation of wave scattering by isolated breakwaters of arbitrary shape. Wave height distributions about rectangular breakwaters were calculated and were found to compare favourably with distributions measured in the laboratory. Although wave forces were not measured on the model breakwaters, they were calculated using the known velocity potentials at the boundaries of the breakwaters.

In this presentation it is assumed that in general terms, the wave forces on a square caisson or cylinder occur in a similar manner to the wave forces on a circular cylinder. That is, if the size of the square cylinder is small relative to the wave length, the cylinder does not deform the incident wave and the wave force on the cylinder consists of the sum of the inertial and viscous forces. However, if the size of the cylinder or caisson is large relative to the incident wave length, it causes reflection and diffraction of the incident waves and the viscous drag forces are negligible in comparison to the inertial forces.

This paper presents an approximate theory which can be used to estimate the wave forces and moments on large vertical square caissons. The theory, based on the linear diffraction theory of MacCamy and Fuchs (6), has been simplified so that only three graphs need be used to obtain the complete solution. Force and moment measurements on models of square caissons show that the approximate theory gives a satisfactory solution over a large range of caisson sizes and wave conditions.

THEORETICAL METHOD

It is assumed that the wave force on a large square-section cylinder or caisson can be expressed as an inertial force if the coefficient of mass used includes the effects of wave reflection and diffraction. Thus the horizontal force per unit length of the caisson is expressed as

$$f_x = C_{ms} \rho b^2 du/dt \quad (1)$$

where C_{ms} is the coefficient of mass for the square-section caisson, ρ is the mass density of the fluid, b is the side length of the caisson and du/dt is the horizontal component

of the water particle acceleration. Substituting into Eq. 1 the expression for du/dt from linear wave theory gives

$$f_x = C_{ms} \frac{2\pi^2 \rho b^2 H}{T^2} \frac{\cosh k(y+d)}{\sinh kd} \cos(kx - \sigma t) \quad (2)$$

where H is the incident wave height, T is the wave period, d is the water depth, σ is the wave frequency, $\sigma = 2\pi/T$, k is the wave number, $k = 2\pi/L$, L is the wave length and t is the time. The coordinates are chosen so that x is positive in the direction of wave propagation and y is positive in the upward direction. The origin of these coordinates is at the still water level where the water surface elevation plotted against x has a maximum negative slope (Fig. 4). By equating the inertial force per unit length on a square caisson to that on a circular caisson of diameter D_e ,

$$C_{ms} \rho b^2 du/dt = 0.25 C_m \rho \pi D_e^2 du/dt \quad (3)$$

it is found that the diameter of an equivalent circular cylinder is

$$D_e = 2b (C_{ms}/\pi C_m)^{\frac{1}{2}} \quad (4)$$

If it is assumed that $C_{ms} = C_m$, then,

$$D_e = 2b/\pi^{\frac{1}{2}} \quad (5)$$

The force per unit length on the equivalent circular cylinder is obtained using the diffraction theory of MacCamy and Fuchs (6):

$$f_x = \frac{2\rho gH}{k} \frac{\cosh k(y+d)}{\cosh kd} A(ka_e) \cos(\sigma t - \alpha) \quad (6)$$

where $A(ka_e) = \left[J_1'^2(ka_e) + Y_1'^2(ka_e) \right]^{-\frac{1}{2}}$

and $\alpha = \tan^{-1} \left[\frac{J_1'(ka_e)}{Y_1'(ka_e)} \right]$

g is the acceleration due to gravity, a_e is the radius of the equivalent circular cylinder, and J_1 and Y_1 are Bessel functions of the first and second kind respectively, both of the first order. Eq. 6 is equated to Eq. 2 for $x = 0$ to give the expression for the coefficient of mass C_{ms} for a square caisson:

$$C_{ms} = \frac{L^2}{\pi^2 b^2} A(ka_e) \frac{\cos(\sigma t - \alpha)}{\cos \sigma t} \quad (7)$$

A modified coefficient of mass C_{ms}^* is defined as

$$C_{ms}^* = \frac{L^2}{\pi^2 b^2} A(ka_e) \quad (8)$$

such that,

$$C_{ms} = C_{ms}^* \frac{\cos(\sigma t - \alpha)}{\cos \sigma t} \quad (9)$$

The coefficient of mass C_{ms} is a function of time and varies through a wave cycle while C_{ms}^* is only a function of b/L (Fig. 3). C_{ms} is equal to C_{ms}^* when α is approximately zero, that is, for b/L approaching zero or equal to 0.52. The phase angle α plotted as a function of b/L is shown in Fig. 4.

The total force in the x direction is obtained by integrating the force per unit length as given by Eq. 2 for $x = 0$, through the depth of water from the bottom to the still water level:

$$F(t) = C_{ms} \frac{\rho \pi b^2 H L}{T^2} \cos \sigma t \quad (10)$$

Substituting the expression for C_{ms} given by Eq. 9 into Eq. 10 gives

$$F(t) = C_{ms}^* \frac{\rho \pi b^2 H L}{T^2} \cos(\sigma t - \alpha) \quad (11)$$

The maximum force occurs when $\sigma t = \alpha$:

$$F_{\max} = C_{ms}^* \frac{\rho \pi b^2 H L}{T^2} \quad (12)$$

The overturning moment about the base of the cylinder is

$$M(t) = \int_{-d}^0 f_x(y + d) dy \quad (13)$$

Substituting the expression for f_x from Eq. 2 and C_{ms} from Eq. 9 and carrying out the integration gives

$$M(t) = C_{ms}^* \frac{\rho g b^2 H L}{4\pi} [kd \tanh kd + \operatorname{sech} kd - 1] \cos(\sigma t - \alpha) \quad (14)$$

The maximum overturning moment occurs when $\sigma t = \alpha$:

$$M_{\max} = C_{ms}^* \frac{\rho g b^2 H L}{4\pi} [kd \tanh kd + \operatorname{sech} kd - 1] \quad (15)$$

Figs. 3, 4 and 5 give the solutions to the above equations. Fig. 3 gives C_{ms}^* by the solution of Eq. 8 so that the maximum horizontal force may be calculated by Eq. 12. The maximum overturning moment can then be obtained directly from Fig. 5 since C_{ms}^* is known. The phase angle α is plotted in Fig. 4 and allows the determination of $F(t)$ and $M(t)$ as given by Eqs. 11 and 14.

EXPERIMENTAL METHOD

The square caisson (Fig. 1) used in the experiments was 12 in. by 12 in. in cross section and was constructed of 1/4 in. thick plexiglass. It was supported 1/8 in. above the flume bottom by a rigid 3 in. diameter steel tube clamped to a steel frame above the wave flume. A force meter was contained within the caisson and consisted of two 3/4 in. diameter stainless steel strain rods 12 in. long. The wave force on the caisson was transferred to the top strain rod through a horizontal steel bar and to the bottom strain rod through a steel base plate (Fig. 1). Foil strain gauges glued on the strain rods were aligned so that total horizontal forces could be measured in the direction of wave propagation and normal to the wave direction to give longitudinal and transverse forces, respectively. The photograph in Fig. 1 shows two brass bushings on the strain rods which make the fixed connection to the supporting 3 in. diameter steel tube. The steel plate connects the free end of the bottom strain rod to the caisson, and the steel bar which passes through apertures in the supporting tube connects the free end of the upper strain rod to the caisson. Using the two bridge outputs from the strain rods, it was possible to measure total forces and to calculate the corresponding total overturning moments. A more detailed description of the wave force meter and its calibration is given by Pratte et al. (9). From the calibration curves of the force meter, its error band was estimated to be less than $\pm 2\%$ over the range of forces measured. The natural frequency of vibration of the caisson in the maximum depth of water was approximately 11 Hz.

Wave profiles in the flume were measured using a non-contacting capacitive wave transducer suspended above the water surface midway between the cylinder and the flume wall. The wave flume was approximately 6 ft. wide, 4.5 ft. deep and 220 ft. long.

A limited number of tests were conducted using a square caisson 2 ft. by 2 ft. in cross section to obtain force and moment data for larger values of the relative size b/L . The model caisson was suspended from a force meter in a wave flume 12 ft. wide, 4.5 ft. deep and 162 ft. long. The force meter (Fig. 2) consisted of three aluminum strain members 3 in. in diameter. The strains in these members caused by wave loads were measured using semiconductor strain gauges forming six Wheatstone bridges. Three bridges measured strain due to bending and gave outputs proportional to longitudinal, transverse and vertical forces. Three bridges measured strain due to torque and gave outputs proportional to the moments about the three coordinate axes. A detailed description of this force meter is given by Funke (1).

Preliminary tests in the 12 ft. wave flume were carried out with a 12 in. square-section caisson (Fig. 2) to confirm experiments already conducted in the 6 ft. flume.

Wave heights were measured using a capacitive rod wave gauge at the location of the model but without the model in the flume. Thus, a different method of measuring incident wave heights was an additional check on the 6 ft. flume results.

Monochromatic waves were generated in five water depths ranging from 9.7 to 29.0 in. and nine wave periods were tested from 0.77 to 2.58 sec. For each water depth and period tested, a number of wave heights were generated ranging from small amplitude waves to those that were on the point of breaking. Each model caisson was tested with two faces parallel to the incident wave fronts ($\beta = 0^\circ$) and also at 45° to this position ($\beta = 45^\circ$). A digital computer was used for the acquisition, processing, plotting and storage of data. Sampling of the data was commenced after the waves passing the model reached steady state conditions. For each test, the wave profile and the corresponding wave forces were sampled every one hundredth of a second for a total of six seconds. Total forces and overturning moments were computed and automatically plotted along with the measured wave profile. Experimental results were also printed and data was stored on magnetic tape. Although it has not been possible to include all the experimental data in this paper, the results presented are representative of the complete testing program. A comprehensive presentation of the experimental results may be found in Mogridge and Jamieson (8).

EXPERIMENTAL RESULTS

The number of waves in each test record varied depending on the wave period because of the fixed sampling time of six seconds. Any test with a variation in wave height or maximum force measurement within the record of more than 5% was discarded. From the test records, total forces and overturning moments were taken as average absolute maximum values of positive and negative measurements, for which the variation was normally less than 5%. The forces and corresponding moments measured in the transverse direction were negligible and are not included in the presentation of experimental results.

Using the measured absolute maximum forces with known values of wave height, length, period and caisson size, C_{ms} was calculated for varying values of b/L and then plotted on the theoretical curve in Fig. 3. Dimensionless moments were also calculated using the known values of C_{ms} and were plotted on the theoretical curve in Fig. 5. The experimental data shows good agreement with the theory for b/L between 0.092 and 0.399 and also for d/L between 0.063 and 0.786. The results shown for b/L and d/L greater than 0.09 were obtained by averaging all the test results with wave steepnesses less than 0.09. For b/L and d/L less than 0.09, only data for wave steepnesses of less than 0.01 were used. Even with this restriction on the data used, there is still some

deviation of the C_{ms} data in Fig. 3, but the moment data in Fig. 5 shows good agreement. It is concluded that the approximate theory can be used for situations where b/L and d/L are both greater than approximately 0.09. Although there is no data presented in this paper defining the d/L limit, experiments were conducted for d/L approximately equal to 0.09 and b/L greater than 0.09 for which the experimental data agreed with the linear theory. Additional data for d/L equal to 0.08 and b/L greater than 0.09, did not fit the theoretical curve, thus defining d/L of approximately 0.09 as the limit for the theory.

To examine the variation of the forces and moments with wave steepness, they have been expressed non-dimensionally and plotted against H/L in Figs. 6 to 8. The experimental results for b/L and d/L greater than 0.09 (Figs. 6 and 7) show reasonable agreement with the theoretical curves for wave steepness up to 0.09. Fig. 8 shows data for which there is a reasonable comparison with the theoretical curves only for very low wave steepness because b/L is less than 0.09. For close agreement at high wave steepness, it is necessary for both b/L and d/L to be greater than 0.09. The largest deviation between the theory and the experimental results is approximately 85% and occurs for the moment measurement for $\beta = 45^\circ$, $b/L = 0.047$ and $H/L = 0.032$. The large differences from the linear theory for b/L and d/L less than 0.09 and large H/L are believed to be due to non-linearity of the waves and the effect of viscosity introducing drag forces of considerable magnitude. For b/L and d/L larger than 0.09, these effects are apparently negligible although at values of d/L approaching 0.09, the waves were obviously non-linear and there was flow separation at the corners of the caisson under all wave conditions.

There are two factors which are evident in the experimental results from which the data in Fig. 8 has been obtained. Firstly, the absolute values of positive and negative wave loads are no longer approximately equal. They differ from their average values by as much as 30% for the data in Fig. 8 for which $b/L = 0.047$ and $\beta = 45^\circ$. Secondly, the phase angles between wave load records and wave profiles do not correspond to the theoretical values for α given by Eq. 6. To illustrate this, results which compare well with the theory have been plotted in Fig. 9 and results for b/L equal to 0.047 which do not compare well with the theory have been plotted in Fig. 10. In Fig. 9, positive and negative forces are approximately equal and for all wave steepnesses the measured phase difference between the force records and the wave profiles are approximately equal to the theoretical value of $\alpha = 8.8^\circ$. Although the theoretical phase difference for the results in Fig. 10 is $\alpha = 1.3^\circ$, the measured phase difference increases to almost 50° with increasing wave steepness. This is characteristic of an increasing drag force. However, the increasing phase angle

can also be due to the non-linearity of the waves because the maximum acceleration of the fluid no longer occurs at the still water level.

Although most of the experimental results described above were obtained in a 6 ft. wide flume, some experiments were conducted in a 12 ft. flume using different equipment and techniques. Since the results are intermixed, it is necessary to show how the measurements in the two wave flumes compared. The comparison is made by repeating the same tests in each wave flume using 12 in. square caissons. The first comparison shown in Fig. 11 is for $b/L = 0.184$, $d/L = 0.445$ and $\beta = 0^\circ$. The second comparison (Fig. 11) is for a series of tests where there are large deviations from the theory, that is, for $b/L = 0.047$, $d/L = 0.115$ and $\beta = 0^\circ$. In both cases the data obtained in the two flumes agree closely, giving an added degree of confidence to the experimental results.

CONCLUSIONS

An approximate method (Figs. 3, 4 and 5) based on the diffraction theory of MacCamy and Fuchs (6) has been developed to give the solution for the wave loads on a square caisson piercing the water surface. The method has been found to be satisfactory for relative caisson sizes of b/L from 0.09 to 0.40, for relative water depths of d/L from 0.09 to 0.79 and wave steepnesses up to 0.09. For b/L and d/L less than 0.09, the theoretical method cannot be used except for waves of very low steepness, because viscous drag forces and non-linearity of the waves become important. The above limits of applicability for the theory are the same whether the alignment of the square caisson is beam on to the waves, $\beta = 0^\circ$, or turned through an angle of 45° to this position.

CHAPTER 134

WAVE PRESSURES ON LARGE CIRCULAR CYLINDRICAL STRUCTURE

by Hiroshi Nakamura
Civil Engineering Laboratory, Central Research Institute
of Electric Power Industry, Chiba, Japan

ABSTRACT

The field observations on wave pressures on large circular cylindrical structures are performed at the cooling water intake structure for Hamaoka nuclear power plant, which is located at the coast of Pacific Ocean. In this report, the results of the field observation on wave pressures are compared with the results of the calculation by small amplitude wave theory considering wave diffraction around the cylinder.

1. Introduction

There are many researches on wave forces on circular cylinder. If the diameter of circular cylinder is small in comparison with wave length, we can neglect the deformation of wave by cylinder and express wave forces as the sum of drag force and inertial force in accordance with Morison's formula. But if the diameter of circular cylinder is large, Morison's formula become invalid, and we must consider deformation of wave around the cylinder.

Wave forces on large circular cylinder are studied by Laird,¹⁾ McCamy and Fuchs,²⁾ Bonnefille,³⁾ Nagai and others,⁴⁾ Chakrabatri,⁵⁾ Watanabe and Horikawa,⁶⁾ Yamaguchi and Tsuchiya⁷⁾ and so on. Most of these studies are theoretically or experimentally in the laboratory. Field observations on wave forces or pressures on large circular cylindrical structure are very rare.

Though it is not easy to measure all factors governing the phenomena in field observation, we can confirm the results of theoretical calculations and experiments in laboratory.

In this paper, the results of the field observations on wave pressures acting on large circular cylindrical structure are compared with the results of the calculation.

Observations were performed at the cooling water intake structure for Hamaoka nuclear power plant. It is sited at the coast of Pacific Ocean in Japan (See Fig. 1)

Cooling water intake structure is 600 m from shoreline. The water depth at this site is about 9 m and bottom slope is 1/100. The diameter of the

structure is 16 m, and its height above the bottom is 11.2 m. (See Fig. 2)

Since the diameter of this structure is large, the inertial force is rather predominant than the drag force in all wave condition if we assume that $C_M = 2.0$ and $C_D = 1.0$. So it is possible to calculate the wave pressures on the structure by McCamy and Fuchs's formula.

Intake structure has six intakes, and there is a circular projection below the intakes, and there are fenders above the still water level. So it is not simple circular cylinder. And its height above the still water level is low in order to avoid breaking wave forces. But here it is assumed that the structure is circular cylinder, and the effect of wave overtopping is neglected. Thus we compared measured pressures with calculated pressures. Of course measured pressures are due to irregular waves, and calculated pressures are due to replaced regular waves.

2. Theory

(1) Wave pressures by small amplitude wave theory.

Wave pressures around the large circular cylinder is expressed as Eg. 1., if we consider the cylindrical co-ordinate shown in Fig. 3.2)

$$\frac{P}{wH} = - \frac{1}{\pi^2 \left(\frac{D}{L}\right)} \frac{\cosh kh \left(1 + \frac{Z}{h}\right)}{\cosh kh} \cdot f\left(\theta, \frac{D}{L}\right) e^{i\sigma t} \dots (1)$$

$$f\left(\theta, \frac{D}{L}\right) = \frac{1}{H_0^2 \left(\frac{\pi D}{L}\right)} + 2 \sum_{n=1}^{\infty} (i)^n \frac{\cos n\theta}{H_n^{(2)} \left(\frac{\pi D}{L}\right)} \dots (2)$$

in which w is unit weight of water, p is wave pressure, H is height of progressive wave, L is wave length, k is wave number, σ is wave angular frequency, h is water depth, D is diameter of cylinder, $H_n^{(2)}$ is derivative of Hankel function of the second kind of orders n , n is positive integer.

(2) Dimensional analysis of wave pressure on large circular cylinder.

It is known a priori that wave pressure acting on large circular cylinder depends on the next parameters, if the roughness of structure surface is neglected,

$$\frac{P}{wH} = f_1 \left(\frac{D}{L}, \frac{h}{H}, \frac{H}{D}, \frac{\nu}{D\sqrt{gD}}, \frac{Z}{h}, \theta \right) \dots (3)$$

in which ν is coefficient of kinetic viscosity, g is acceleration of gravity.

The fourth parameter on the right-hand side of Eg. 3 may be considered to represent the ratio of the Froude number to Reynolds number. It may be disregarded as it seems to be small.

Thus the dimensionless wave pressure acting on the side of circular cylinder could be written as

$$\frac{P}{wH} = f_2 \left(\frac{L}{D}, \frac{h}{H}, \frac{H}{D} \right) \dots (4)$$

In analysis of the results of field observation, the effects of parameters in right-hand side of Eg. 4 on the value of P/wH are investigated.

3. Outline of observation

Field observations have been performed for about two years from September in 1972. (See Fig. 4)

Eight pressure gauges were attached to the side of intake structure shown in Fig. 5. Pressure gauges are strain-gauge type ones, and their range is from 0 to 2 kg/cm^2 .

Wave gauge is set up in the offing. Its distance from the shoreline is 950 m, and water depth at the wave gauge site is about 13 m. Wave heights and pressures were often observed simultaneously, and about 170 data on the vertical and horizontal pressure distributions were recorded.

Each datum was recorded for twenty minutes and we obtained highest pressures, significant pressures and so on from the records for twenty minutes.

The analysis of the results of the observations is performed on the data that the highest wave height is more than 1 m. The range of the values of the highest wave height H_{max} , wave period T_{max} , water depth h , and dimensionless parameters shown in right-hand side in Eg. 4 are as follows:

H_{max}	: 1.0 - 8.9 m	D/L_{max}	: 0.11 - 0.34
T_{max}	: 6.0 - 16.0 sec	h/H_{max}	: 1.1 - 16
h	: 8.4 - 10.0 m	H_{max}/D	: 0.06 - 0.56

in which L_{max} is a wave length of highest wave as small amplitude wave.

4. Results

In order to compare the observed values with calculated values by Eg. 1, it is assumed that the highest pressure P_{max} acting on the structure depend on the highest wave height, and the relations between dimensionless wave pressures and the dimensionless numbers shown in the right-hand side of Eg. 4 are investigated.

In obtaining above-mentioned dimensionless numbers from field data, we assume as follows :

- a. The incident waves come shown in Figure 4. In other words, point No. 2 and 4 are at $\theta = 0$.
- b. Progressive wave height at the site of intake structure equals to wave height obtained by wave gauge.
- c. Water depth at the site equals to one obtained from the tide curve at the Omaezaki Harbour, where is 8 km from the power station.

(1) Relations between D/L_{max} and $P_{\text{max}}/wH_{\text{max}}$

Relations between D/L_{max} and $P_{\text{max}}/wH_{\text{max}}$ are investigated from the field data at all pressure measured points. The relations at the point No. 2 and No. 4 are shown in Fig. 6. The curves in Fig. 6 are calculated

from Eg. 1. Upper curve corresponds to the case of observed minimum water depth, and lower curve corresponds to the case of observed maximum water depth.

The results of comparison of observed dimensionless pressures with calculated ones are as follows:

- a. Most of observed values are smaller than calculated ones at the deep part, but there are many observed values larger than calculated ones near the still water level.
 - b. In case of small values of D/L_{max} , observed values of P_{max}/wH_{max} are scattered above and below the calculated values. But in case of large values of D/L_{max} , most of observed values of P_{max}/wH_{max} are smaller than the calculated values.
- (2) Relations between h/H_{max} and P_{max}/wH_{max}

Relations between h/H_{max} and P_{max}/wH_{max} in case of $D/L_{max} \neq 0.15$ (0.14 - 0.16) and 0.20 (0.19 - 0.21) at the point No. 2 and No. 4 are shown in Fig. 7. In this figure, calculated values of P_{max}/wH_{max} are shown as solid line.

In case of small values of h/H_{max} , observed values of P_{max}/wH_{max} are smaller than calculated values. This is due to nonlinearity of wave, as pointed out by Yamaguchi and Tsuchiya.⁷⁾

In case of large values of h/H_{max} , observed values are larger than calculated ones. This reason is not clear. But it is considered that the observational error is large if the wave height is small, and that the fenders near the still water level have influence to the observed wave pressures.

- (3) Relations between H_{max}/D and P_{max}/wH_{max}

Relations between H_{max}/D and P_{max}/wH_{max} in case of $D/L_{max} \neq 0.15$ and 0.20 at the point No. 2 and No. 4 are shown in Fig. 8. In this figure, calculated values of P_{max}/wH_{max} are shown as solid line. The observed values of P_{max}/wH_{max} become smaller, as the value of H_{max}/D become larger, and in case of small values of H_{max}/D , observed values of P_{max}/wH_{max} are larger than calculated values.

- (4) Vertical and horizontal distributions of wave pressures

In case of $D/L_{max} \neq 0.15$ and 0.20, vertical distributions of observed and calculated wave pressures at $\theta = 0$ are shown in Fig. 9. Horizontal distributions of observed and calculated maximum wave pressures at the slightly lower points than still water level are shown in Fig. 10. As shown in these figures, the observed values coincide fairly well with the calculated values, or the formers are smaller than the latters in case of $h/H_{max} < 4$.

Fig. 11 shows the horizontal distributions of observed and calculated wave pressures as maximum pressures occur at $\theta = 0$. In this figure the observed values are larger than calculated values at the rear side of structure. This reason is not clear. But it is perhaps due to the waves passing through the intakes.

(5) Applicable range of Eg. 1

From the applicable point of view, it is necessary to know the applicable range of Eg. 1. Comparing all field data with the results of theoretical calculation, the applicable range is investigated. Broken lines in Fig. 7 and 8 show the upper limit of observed values of $P_{max}/\eta H_{max}$. Such limits are obtained at the another measuring points, and applicable range of Eg. 1 shown in Fig. 12 is obtained.

(6) Wave pressures on very large circular cylinder

Calculations of wave pressures on large circular cylinder by small amplitude wave theory are not so precise, as it is described already. Recently calculations of wave pressures by finite amplitude wave theory are presented, but these calculations are very complicated. So if we can use Eg. 1, it is very convenient.

The results of the calculation by Eg. 1 for the side of circular island, which has a very large diameter, are shown in Fig. 13.

CHAPTER 135

FORCES ON ROUGH-WALLED CIRCULAR CYLINDERS

IN HARMONIC FLOW

by

Turgut Sarpkaya

Distinguished Professor of Mechanical Engineering
Naval Postgraduate School, Monterey, California

ABSTRACT

This paper presents the results of an extensive experimental investigation of the in-line and transverse forces acting on sand-roughened circular cylinders placed in oscillatory flow at Reynolds numbers up to 1,500,000, Keulegan-Carpenter numbers up to 100, and relative roughnesses from 1/800 to 1/50. The drag and inertia coefficients have been determined through the use of the Fourier analysis and the least squares method. The transverse force (lift) has been analysed in terms of its maximum and root-mean-square values. In addition, the frequency of vortex shedding and the Strouhal number have been determined.

The results have shown that all of the coefficients cited above are functions of the Reynolds number, Keulegan-Carpenter number, and the relative roughness height. The results have also shown that the effect of roughness is quite profound and that the drag coefficients obtained from tests in steady flow are not applicable to harmonic flows even when the loading is predominantly drag.

INTRODUCTION

The prediction of the forces generated by waves and currents remains as a basic problem in marine hydrodynamics. The complexity of the problem stems partly from the difficulty of accurately defining the kinematics of the flow field, partly from the difficulty of accounting properly for the effects of time-dependent separation and vortex shedding, and partly from the difficulty in extrapolating the laboratory findings to various conditions of the marine environment where three-dimensional effects and reduced spanwise coherence play important roles.

The methods based on diffraction theory and classical hydrodynamics are applicable only to relatively simple cases, irrespective of the size and shape of the structure, where separation does not play an appreciable

role. It is a well-known fact that the shear-layer instability and the non-linear interaction between the shear layers lead to vortex shedding in steady flow past bluff bodies. The general characteristics of this shedding mechanism are fairly well understood through measurements, flow visualization, and numerical experiments for various bluff bodies, in particular for a circular cylinder held normal to the ambient flow. Any effect, such as the periodicity of flow, which interferes with the production of vorticity, position of the separation points, shear-layer instability, and the feedback mechanism causes additional time and history dependent non-linear interactions. The net effect of these interactions is to change the vortex shedding and hence the vortex-induced oscillations in both the forces and structure in both the in-line and transverse directions. The problem is not yet amenable to mathematical analysis and requires experiments of high intrinsic quality for at least a partial understanding of its many perplexing aspects.

Much of the present knowledge on separated harmonic flows has been obtained by means of model tests at Reynolds numbers generally two to three orders of magnitude smaller than prototype Reynolds numbers. These model tests have relied heavily on the so-called Morison formula for expressing the force as the sum of a drag and inertia force. The values of the drag and inertia coefficients to be used in the Morison equation became the subject of many experimental studies in the last twenty years. The correlation of these coefficients with the relative amplitude of the waves (or the Keulegan-Carpenter number, hereafter referred to as K) has been generally inconclusive [1]. Furthermore, lift forces which are associated with vortex shedding have received relatively little attention. It thus became clear that much is to be gained by considering plane oscillatory flow about cylinders at high Reynolds numbers in order to isolate the influence of individual factors such as relative amplitude, Reynolds number, relative roughness, spanwise correlation, wall-proximity, etc. on vortex shedding and resistance. It is with this realization that a broad research program was undertaken to study the characteristics of periodic flow about bluff bodies.

The results obtained with smooth cylinders in two U-shaped water tunnels have been previously reported by Sarpkaya [2-6]. The preliminary results obtained with rough-walled cylinders for one particular value of K , ($K = 50$), through the use of various types of distributed roughness elements (sand, sand paper, and polystyrene beads) have also been reported in [3] and [4].

The present paper deals with in-line and transverse forces acting on sand-roughened circular cylinders in harmonic flow in the range of Reynolds numbers from 10,000 to 1,500,000; K values from about 4 to 100; and relative sand roughnesses from 1/800 to 1/50.

BACKGROUND ON THE EFFECTS OF ROUGHNESS

Of the scores of papers dealing with fluid loading on offshore structures (see the reviews by Grace [7] and Hogben [8]), none seems to have treated the effect of roughness on the force-transfer coefficients. Yet it is a fact that the structures in the marine environment become gradually covered with rigid as well as soft excrescences. Thus, the fluid loading due to identical ambient flow conditions may be significantly different from that experienced when the structure was clean partly because of the 'roughness effect' of the excrescences on the flow and partly because of the increase of the 'effective diameter' of the elements of the structure.

In the absence of any data appropriate to the harmonic or wavy flows, it has been assumed that "the drag coefficients obtained from tests in steady flow" over artificially - or marine-roughened cylinders "are applicable to wave flows at least when the loading is predominantly drag" [9].

It is not generally appreciated that the consequences of all "nearly steady flows" are not always identical to those of "steady flows." The case in point is the harmonic flow under consideration. Even for large amplitudes of oscillations, there is only a finite vortex street comprised of vortices of nearly equal strength due to the "nearly steady" nature of the flow. As the flow reverses, the situation is not that of a uniform flow (with or without free stream turbulence) approaching a roughened cylinder but rather that of a finite vortex street approaching a rough-walled cylinder. Such a flow cannot be regarded identical to steady flow with some turbulence of fairly uniform intensity and scale as the present results show.

It is instructive to briefly review the salient features of the influence of roughness on the cross-flow around a cylinder in steady flow in order to delineate the differences between the steady and harmonic flow about rough-walled cylinders.

Among others, primarily the experiments of Fage and Warsap [10], Achenbach [11], Szechenyi [12], and Güven et al. [13] have shown that roughness in steady flow about a cylinder precipitates the occurrence of 'drag crisis' and gives rise to a minimum drag coefficient which is larger than that obtained with a smooth cylinder. This is partly because of the transition to turbulence of the free shear layers at relatively lower Reynolds numbers due to disturbances brought about by the roughness elements and partly because of the retardation of the boundary-layer flow by roughness (higher skin friction) and, hence, earlier separation. Evidently, the drag crisis in steady flow about a roughened cylinder is a state even more precarious than that for a smooth cylinder for the occurrence of a laminar-separation and turbulent reattachment bubble is hastened by the retardation of the flow by roughness. It is also evident that the Reynolds number must be sufficiently high for a given roughness to bring about a drag crisis.

The conditions leading to the occurrence of the drag crisis are therefore quite important. Not only the relative size of the roughness elements but also their shape and distribution may be quite important in addition to the parameters characterizing the ambient flow about an otherwise smooth bluff body. It is in fact partly for the difficulty of uniquely specifying the 'roughness' and partly for the differences in other test conditions (free stream turbulence, relative length of the cylinder, end gaps, etc.) that there are considerable differences between the data reported by various workers, particularly in the drag crisis region. For example, the effective surface roughness may be larger or smaller than the nominal relative roughness based on the geometric size of the roughness element depending on the shape and arrangement of the roughness elements [14]. Also, a higher turbulence level precipitates the drag crisis. Thus, the critical range is wider for higher free stream turbulence [13]. Attempts have been made [14] to experimentally determine an equivalent sand-grain roughness through the use of uniform flow in a channel. An equivalent roughness determined in this manner may not necessarily give a meaningful measure of the effect of roughness as far as the boundary layer flow over a circular cylinder is concerned.

In the supercritical and transcritical regions, the drag coefficient for a roughened cylinder is considerably larger than that for a smooth cylinder primarily because of the larger wake which is brought about by the earlier separation due to the retardation of the boundary layer. Several facts are worth noting. Firstly, the transcritical drag coefficient depends on both the character of the flow and the surface condition of the cylinder. In other words, the particular value of the transcritical drag coefficient in steady flow over a roughened cylinder is not necessarily identical to that for a time-dependent flow over the same cylinder. Experiments with steady flow over roughened cylinders show that the drag coefficient in the transcritical region returns more or less to its steady sub-critical value. Other flows may exhibit a similar behavior provided that the spanwise coherence is maintained. In other words, the subcritical value of the drag coefficient for a given flow may give an indication of its transcritical value for the same flow over a roughened cylinder. Evidently, what is specified here is the functional dependence of velocity on time and not the magnitude of the characteristic velocity.

Secondly, the larger the effective roughness, the larger is the retardation of the boundary layer. This leads to earlier separation and larger drag coefficient. Thirdly, the pressure distribution about the cylinder is affected not only by the location of the separation point but also by the development of the retarded boundary layer ahead of separation [13]. This in turn is affected not only by all the parameters characterizing the roughness but also by the character of the ambient flow (time-dependence, angle of attack, shear, turbulence, just to name a few of the parameters).

It seems from the foregoing that the disturbances generated by the roughness elements cause an incalculable change in the critical region of

the flow and that a more thorough examination of the one-parameter characterization of roughness, k/D , is required in order to understand the effect of roughness, because the packing, size distribution, and shape may be important. Although, wind- and water-tunnel experiments on flow past rough-walled cylinders have been made for about 50 years, there is still a lack of precision in the definition of even the roughness let alone the force and pressure coefficients. The purpose of this paper is not to study this question but rather to show, among other things, that different types of roughness elements (sand paper, polystyrene beads, sand) can give rise to different drag-coefficient curves in the critical region appropriate to the particular flow. It is in fact partly for this reason that it has been thought advisable to investigate afresh the effect of roughness on cylinders in harmonic flow using only sand of uniform size and packing rather than three different types of roughness [3].

IN-LINE AND TRANSVERSE FORCES AND GOVERNING PARAMETERS

The in-line force which consists of the drag force F_d and the inertia force F_i is assumed to be given by [15]

$$F = F_d + F_i = 0.5C_dLD\rho|U|U + 0.25C_mLD^2\pi\rho.dU/dt \quad (1)$$

in which C_d and C_m represent respectively the drag and inertia coefficients and U the instantaneous velocity of the ambient flow. For an oscillating flow represented by $U = -U_m\cos\theta$, with $\theta = 2\pi t/T$, the Fourier averages of C_d and C_m are given by Keulegan and Carpenter as [16]

$$C_d = -0.75 \int_0^{2\pi} (F_m \cos\theta / \rho U_m^2 LD) d\theta \quad (2)$$

and

$$C_m = (2U_m T / \pi^3 D) \int_0^{2\pi} (F_m \sin\theta / \rho U_m^2 LD) d\theta \quad (3)$$

in which F_m represents the measured force.

The method of least squares consists of the minimization of the error between the measured and calculated forces. This procedure yields [5]

$$C_{dls} = -(8/3\pi) \int_0^{2\pi} (F_m |\cos\theta| \cos\theta / \rho DLU_m^2) d\theta \quad (4)$$

and $C_{m|s} = C_m$. Evidently, the Fourier analysis and the method of least squares yield identical C_m values and that the C_d values differ only slightly.

The transverse force has been expressed in terms of the maximum lift coefficient defined by

$$C_L = (\text{maximum amplitude of the transverse force in a cycle}) / (0.5\rho DLU_m^2) \quad (5)$$

In addition, the frequency of the oscillations of the transverse force and the Strouhal number have been evaluated.

It is recognized that the coefficients cited above are not constant throughout the cycle and are either time-invariant averages or peak values at a particular moment in the cycle. A simple dimensional analysis of the flow under consideration shows that the time-dependent coefficients may be written as

$$F/(0.5DL\rho U_m^2) = f(U_m T/D, U_m D/\nu, k/D, t/T) \quad (6)$$

in which F represents the in-line or the transverse force. Equation (6), combined with Eq. (1), assuming for now that the latter is indeed valid, yields

$$C_d = f_1(K, Re, k/D, t/T) \quad (7)$$

$$C_m = f_2(K, Re, k/D, t/T) \quad (8)$$

in which $K = U_m T/D$ and $Re = U_m D/\nu$, and k/D represents the relative roughness. Evidently, it is assumed that the effect of roughness may be characterized by the parameter k/D alone, with k defined as the average grain size. Experiments necessary to obtain an equivalent sand height or some other representative length are costly and time consuming and are not available for the oscillating flow data analysed here.

There is no simple way to deal with Eqs. (7) and (8) even for the most manageable time-dependent flows. Another and perhaps the only other alternative is to eliminate time as an independent variable and consider suitable time-invariant averages as given by Eqs. (2), (3), and (4). Thus, one has

$$[C_d, C_m, C_L, \dots] = f_i(K, Re, k/D) \quad (9)$$

It appears, for the purposes of Eq. (9), that the Reynolds number is not the most suitable parameter involving viscosity. The primary reasons for this are that the effect of viscosity is relatively small particularly for $Re < 20,000$ and that U_m appears in both K and Re . Thus, replacing Re by $\beta = Re/K = D^2/\nu T$ in Eq. (9), one has

$$C_i(\text{a coefficient}) = f_i(K, \beta, k/D) \quad (10)$$

in which $\beta = D^2/\nu T$ and shall be called the 'frequency parameter.'

From the standpoint of dimensional analysis, either the Reynolds number or β could be used as an independent variable. Evidently, β is constant for a series of experiments conducted with a cylinder of diameter D in water of uniform and constant temperature since T is kept constant in a U-shaped oscillating flow tunnel. Then the variation of a force coefficient with K may be plotted for constant values of β . Subsequently, one can easily recover the Reynolds number from $Re = \beta K$ and connect the points, on each $\beta = \text{constant}$ curve, representing a given Reynolds number.

From the standpoint of the laminar boundary layer theory, β represents

the ratio of the rate of diffusion of vorticity through a distance δ (the boundary layer thickness) to the rate of diffusion through a distance D . This ratio is also equal to $(D/\delta)^2$ and, when it is large, gradients of velocity in the direction of flow are small compared with the gradients normal to the boundary, a situation to which the boundary layer theory is applicable. It should also be noted in passing that β is of special importance even for oscillations at very low Reynolds numbers. For example, for a cylinder or sphere undergoing harmonic oscillations without separation in a fluid otherwise at rest, the added mass and drag coefficients are uniquely determined in terms of β [17, 18].

A re-analysis of the data given by Keulegan and Carpenter [16] through the use of β , K , and Re in the manner just described clearly shows [3, 4] that (a) C_d depends on both K and Re and decreases with increasing Re for a given K ; and that (b) C_m depends on both K and Re for K larger than approximately 15 and decreases with increasing Re . A similar analysis of Sarpkaya's data [2] also shows that C_d and C_m depend on both K and Re and that C_m increases with increasing Re . Notwithstanding this difference in the variation of C_m between the two sets of data, these results put to rest the long standing controversy regarding the dependence or lack of dependence of C_d and C_m on Re and show the importance of β as one of the governing parameters in interpreting the data, in interpolating the K values for a given Re , and in providing guide lines for further experiments as far as the ranges of K and β are concerned.

BRIEF DESCRIPTION OF THE EXPERIMENTAL ARRANGEMENT

The oscillating flow system consisted of a large U-shaped vertical water tunnel with a 3 ft by 3 ft test section. The cross-section of the two vertical legs is twice that of the test section. The two corners of the tunnel were carefully streamlined to prevent flow separation. The auxiliary components of the tunnel consisted of plumbing for hot and cold water, butterfly-valve system, and the air-supply system. Oscillations in the tunnel were obtained through the use of the butterfly valves (mounted on top of one of the legs of the tunnel) and a rack and pinion system actuated by an air-driven piston and a three-way control valve. The fluid oscillated smoothly with a period of $T = 5.500$ seconds. The elevation, acceleration, and the in-line and transverse forces were monitored continuously by means of appropriate transducers. The analogue traces were absolutely free from secondary oscillations so that no filters were used between the outputs of the transducers and the recording equipment (see sample trace in Fig. 1).

Circular cylinders with diameters ranging in size from 2 inches to 6.5 inches have been used in this study. The cylinders were turned on a lathe from aluminum pipes or plexiglass rods. The length of each cylinder was such that it allowed 1/32 inch gap between the tunnel wall and each end of the cylinder. A doubleball precision bearing was inserted at each end of the cylinder in aluminum housings which sealed the cylinder air tight.

In view of the discussion concerning the one-parameter characterization of the roughness in terms of k/D , it was decided to use only one type of roughness element. The possible use of sandpaper, glass beads, wire screens, etc. was disregarded for they would have exhibited different packing as well as different size distribution characteristics. Clean sand was sieved through the use of standard ASTM sieves in order to obtain a given grain size.

Each cylinder was mounted horizontally on a specially constructed, manually operated, rotating apparatus and covered with a thin layer of air-drying epoxy resin using a brush. When the epoxy coating reached a certain degree of consistency, then the finely pre-sieved sand was transferred into a slightly larger sieve and sprinkled over the rotating cylinder. Within about 10 minutes, the epoxy hardened and the cylinder was left alone for the epoxy to cure. Then the cylinder surface was cleaned to remove excess sand and extra sand particles that at times attached to each other forming an easily breakable spike. This procedure has been followed for all cylinders and has invariably resulted in cylinders of roughness with perfect uniformity. A sample photograph of the rough surface, taken with a scanning electron microscope, is shown in Fig. 2.

In order to determine the variation of the force coefficients with Reynolds number for a given Keulegan-Carpenter number and relative roughness, all cylinders were tested at the same relative roughnesses ($k/D = 1/800, 1/400, 1/200, 1/100,$ and $1/50$), and the experiments were carried out at three or four water temperatures.

Fig. 1 Sample in-line force and acceleration traces.

Fig. 2 Distribution of sand particles, ($k = 0.0055$ inch).

Two identical force transducers, one at each end of the cylinder, were used to measure the instantaneous in-line and transverse forces. The gages had a capacity of 500 Lbf with an overload capacity of 200 percent. The deflection of the gages under 500 Lbf load was 0.01 inch. For the largest cylinder and amplitude encountered in the experiments, the maximum load was less than 200 Lbf, and the deflection of the beam was less than 0.008 inches.

The in-line and transverse forces were simultaneously recorded with the instantaneous acceleration on two two-channel Honeywell recorders running at a speed of 10 divisions per second. The amplitude of the transverse force, instantaneous value of the in-line force, and the flow characteristics such as $U_m T/D$ and Re were determined from these traces. The root-mean-square value of the lift force was determined for each cycle by reading the force at every division or 0.1 second intervals.

Three transducers were used to generate three independent d.c. signals, each proportional to the instantaneous value of the elevation, velocity, and acceleration. These transducers were calibrated and their linearity checked before each series of experiments. In addition, the velocity at the test section was directly measured with a magnetic velocity meter. Suffice it to say that all four methods gave nearly identical results and yielded the amplitude, velocity, or acceleration, to an accuracy of about two percent relative to each other. These comparisons, as well as the perfectly sinusoidal and noise-free character of all pressure and force traces, speak for the suitability of the unique test facility used in this study. The additional details of the apparatus and procedure are given in Ref. [3].

DISCUSSION OF THE RESULTS

The drag and the inertia coefficients, obtained through the use of equations (2) and (3) have been plotted for each cylinder and relative roughness as a function of K for various constant values of β . Then the Reynolds number for a particular value of K has been calculated simply through the use of $Re = K\beta$. As described earlier, such a procedure enables one to express C_d or C_m as a function of the Reynolds number for a given K and k/D . In view of the fact that each coefficient depends on at least three independent parameters (Re , K , and k/D), it is not possible to show on two-dimensional plots the variation of either C_d or C_m for all values of Re , K , and k/D . However, this difficulty is alleviated by the fact that the variation of a given force coefficient for a given Re and k/D is not very strong from one K to another. Thus it has been decided to choose five representative K values, namely $K = 20, 30, 40, 60,$ and 100 , to present the variation of C_d and C_m with Re .

Figures 3 through 12 show C_d and C_m for five values of K as a function of the Reynolds number. Each curve on each plot corresponds to a particular relative roughness. Also shown on each figure is the corresponding drag or inertia coefficient for the smooth cylinder at the corresponding K value.

The $k/D = \text{constant}$ curves on each C_d plot are quite similar to those found for steady flow about rough cylinders [10-13]. For a given relative roughness, the drag coefficient does not significantly differ from its smooth cylinder value at very low Reynolds numbers. As the Reynolds number increases, C_d for the rough cylinder decreases rapidly, goes through the region of drag crisis at a Reynolds number considerably lower than that for the smooth cylinder and then rises sharply to a nearly constant transcritical value. The larger the relative roughness the larger is the magnitude of the minimum C_d and the smaller is the Reynolds number at which that minimum occurs. However, there appears to be a minimum Reynolds number below which the results for rough cylinders do not significantly differ from those corresponding to smooth cylinders. In other words, the Reynolds number must be sufficiently high for the roughness to play a role on the drag and

flow characteristics of the cylinder.

The figures for the drag coefficient also exhibit a few other interesting features. First, even a relative roughness as small as $1/800$ can give rise to transcritical drag coefficients which are considerably higher than those for the smooth cylinder. Secondly, the asymptotic values of the drag coefficient for roughened cylinders (e.g., $k/D = 1/100$), within the range of Reynolds numbers encountered, can reach values which are considerably higher than those obtained with steady flows over cylinders of similar roughness ratios. In other words, it is not safe to assume that the transcritical drag coefficient in harmonic flows will be identical to those found in steady flows and will not exceed a value of about unity. On the basis of the present results it may be said that such a conjecture is not accurate even for K values as large as 100 (corresponding to a wave height-to-diameter ratio of about 30). It is therefore important to remember that the effect of roughness depends not only on the relative size of the roughness element but also on the characteristics of the ambient flow as well as on the body about which this flow takes place. The characteristics of the ambient flow determine to a large extent the state of the flow (subcritical, critical, and transcritical) during a given cycle of oscillation. The geometry of the body dictates, together with the flow, the variation with time of the separation points. It is therefore not easy to draw a parallel between the behavior of steady flow and that of harmonic flow over a smooth and rough cylinder. In fact, the steady as well as the oscillating flow results for rough cylinders show that, in either case, the transcritical drag coefficient nearly returns to its subcritical values.

The Reynolds number at which the drag crisis occurs gives rise to an 'inertia crisis.' In other words, for a given relative roughness, C_m rises rapidly to a maximum at a Reynolds number which corresponds to that at which C_d drops to a minimum. At relatively higher Reynolds numbers, C_m decreases somewhat and then attains nearly constant values which are lower than those corresponding to the smooth cylinders. It is also apparent from the inertia coefficient curves that the smaller the relative roughness the larger is the maximum inertia coefficient. For relatively smaller roughnesses such as $k/D = 1/800$, the terminal value of C_m is nearly equal to that of a smooth cylinder. The behavior of C_m is not entirely unexpected. It has long been noted [16] that whenever there is a rise in the drag coefficient, there also is a decrease in the inertia coefficient.

Before closing the discussion of the drag and inertia coefficients, it is necessary to point out the remarkably consistent behavior of the data points, particularly for C_d . Perhaps it would not have been too surprising had the data been obtained for one relative roughness through the use of only one cylinder. In the present investigation, the use of several cylinders and several temperatures for a given cylinder always provided data for nearly identical k/D , Re , and K values. For instance, the C_d and C_m values obtained at a given K , Re , and relative roughness k/D ,

using a 5 inch cylinder at a low temperature corresponds to the C_d and C_m values using a 4-inch cylinder at a high temperature. Remembering the fact that not only the actual size of the cylinders but also the size of the sand grains differed in order to obtain the same k/D , and the fact that the experiments were carried out at different temperatures and times, one fully realizes that the correlation of the data and the relatively small scatter are indeed quite remarkable. This is due not only to the repeatability of the tests but also due to the vibration-free operation of the entire tunnel system.

The correlation length along the cylinders was not directly measured. However, one series of experiments was conducted with a 2.18-diameters (12 inches) long, centrally located, section of a 5.5 inch cylinder which 'floated' on the ends of the force transducers with small gaps (1/32 inch) between the section and the rest of the rigidly supported 12-inch long sections. The floating and the dummy sections were coated with sand for a relative roughness of $k/D = 1/100$. The comparison of the lift, drag, and inertia coefficients obtained with the short section with those obtained with the longer section spanning the entire test section has shown (at least for five Reynolds numbers, five K values, and one k/D) that the two sets of coefficients are nearly identical. Evidently, the force-cancelling effects of phase shifts which may have been brought about by three-dimensional effects were either insignificant or non-existent. Thus, it is concluded that both the three-dimensionality effects and the boundary-layer effects play very little or no role in the present experiments. However, the comparison of the results shown in Figs. 3 through 12 with the previously reported [4, 6] preliminary results for $K = 50$ alone indicates the effect, particularly in the drag-crisis region, of the type of roughness element used on the variation of the force-transfer coefficients with the Reynolds number. Previously, sand paper, sand, and polystyrene beads were used as roughness elements for a given cylinder in order to achieve the desired relative roughness in a given Reynolds number range. A detailed study of the effective roughness of each type of roughness element and the discussions with the manufacturer have shown that the effective roughness of the sand paper is larger than the height of the mean sand particles applied on it. Furthermore, the gluing of the sand paper on the cylinder invariably resulted in a 'joint' along the cylinder which might have generated larger disturbances and promoted earlier transition. The polystyrene beads, on the other hand, present an effective-roughness height which is often smaller than their actual size [14]. In spite of these differences in the 'effective roughness' of various types of roughness elements, however, the terminal values of the drag coefficients in the transcritical region remained practically the same for a given actual effective relative roughness whether the data were obtained with sand alone or with a combination of other roughness elements. Evidently, it will be most interesting and desirable to carry out similar experiments with cylinders roughened in the ocean environment. The testing of such cylinders with steady uniform flow [9] is not sufficient for the purposes under consideration, namely the determination of the fluid loading on offshore structures.

APPLICABILITY OF MORISON'S EQUATION

Since its inception, questions have been raised regarding the applicability of Morison's equation to time-dependent flows in general and to wavy flows in particular. It has been known that the equation predicts quite accurately the in-line force for both very small values of K (K smaller than about 10) and for large values of K (K larger than about 20). For intermediate values of K , differences have been observed between the measured and calculated values. These differences have been attributed either to the imprecise measurement of the kinematics of the flow or to the shortcomings of the equation. It is now realized that not only these two factors (namely the heuristic nature of the equation and the difficulty of measuring the local velocities and accelerations) but also the three-dimensional nature of the wavy flows and decreased spanwise coherence must be partly responsible for the differences between the measured and calculated forces. In fact, it would have been extremely difficult to draw meaningful conclusions concerning the applicability of Morison's equation through the use of the field data. It is only through the use of carefully conducted two-dimensional harmonic flow experiments that one can ascertain the degree of applicability of Morison's equation.

Figure 13 shows the calculated and measured forces normalized by $0.5\rho D L U_m^2$ together with the normalized velocity and the difference between the measured and calculated forces for a relatively large value of K . It is evident that there is often a remarkable correspondence between the measured and predicted forces particularly for K values larger than about 20. This is also true for K values smaller than about 10. In the disturbance-sensitive region of vortex formation, the onset of asymmetry ($K \approx 4.5$) and the subsequent growth and shedding of single or alternating vortices have profound effects not only on the measured in-line force but also on the coefficients calculated. Morison's equation assumes that the in-line force F is an odd harmonic function, i.e., $F(\theta) = -F(\theta+\pi)$, for a flow represented by $U = -U_m \cos\theta$. Thus, the drag and inertia coefficients calculated through the use of an in-line force for which $F(\theta) \neq -F(\theta+\pi)$ are not quite correct. Thus, it is clear that part of the reason for the larger differences between the measured and calculated forces even in two-dimensional harmonic flows is due to the use of the force-coefficient expressions [Eqs. (2) and (3)] which are derived by assuming the in-line force to be given by an odd harmonic function. In the range of K values from about 10 to 20, particularly for low values of Re , this assumption is not quite correct as evidenced by the present experiments [3, 4, 6].

The reason for the asymmetry in the magnitude of the in-line force and the differences between the measured and calculated forces is primarily the fractional shedding of vortices and vortex induced oscillations in the in-line force. It is a well-known fact that in steady flow the vortex shedding causes a gradient of fluctuating pressure across the body and gives rise to periodic force fluctuations in the in-line force. In harmonic flow, the fully grown vortices move back and forth about the cylinder and do not necessarily shed alternately. Thus, it is possible that the oscillations in the in-line force due to eddy shedding are relatively larger than those in steady flow. The effect of these oscillations may be incorporated into Eq. (1) as follows,

$$F/(0.5\rho DLU_m^2) = (\pi^2 D/U_m T) C_m \sin\theta - C_d |\cos\theta| \cos\theta - \eta C_L \cos(St.K.\theta - \phi) \quad (11)$$

in which η represents a coefficient, ηC_L the amplitude of the normalized difference between the measured and calculated forces, St the Strouhal number defined by fD/U_m with f as the frequency of lift oscillations, and ϕ the phase angle. In the range of K values from 10 to about 15, $St.K$ should be taken equal to 3. For larger values of K , $St.K$ may be taken equal to $0.20K$. Extensive calculations through the use of appropriate values of the parameters cited above with $\eta = 0.1$ have shown that the above equation considerably reduces the difference between the measured and calculated in-line forces. These calculations will not be reproduced here for their purpose was simply to demonstrate that the eddy-induced in-line oscillations can account for most of the error in the predictions of the Morison equation in the range of K values from 10 to about 20. For larger K values, the predictions of the Morison equation are indeed excellent as evidenced by Fig. 13.

Fig. 13 Comparison of measured and calculated forces for large values of K and Re .

In considering the relevance of the coefficients presented herein and of the equation devised by Morison to wave induced loads on offshore structures, it is of course important to take into account the differences between uniform two-dimensional harmonic motion and the wave motion where the velocity vector both rotates with time at a point and decays in magnitude with depth. The spanwise variations of the flow in general lead to reduced spanwise coherence. It is safe to assume that both the three-dimensionality of the flow and the reduction of the correlation length along the cylinder, in an ocean environment, tend to increase the base pressure and thus give rise to transcritical drag coefficients which are smaller than those obtained with purely two-dimensional flows. The drag coefficients presented herein obviously represent their maximum possible values since they have resulted from a uniform, two-dimensional flow where the instantaneous wake of the cylinder has the highest possible degree of spanwise coherence. The similarity between the reduced drag coefficient due to lack of spanwise coherence in wavy flows and the drag coefficient in steady flows (both for roughened cylinders) is pure coincidence and certainly the wrong reason in arriving at the right value. It is rather unfortunate that even the experiments with wavy flows cannot be expected to isolate the effect of reduced spanwise coherence since such experiments surely bring in other factors whose influence is combined in a complex way with that of the reduced correlation. Thus, the value of the results presented herein lies in the fact that the designer now knows the maximum possible value of the coefficients under consideration, if not the values which might be more appropriate to the conditions under which the structure must survive and function. These conditions might include, among other things, currents and wave induced oscillations. Under these circumstances, the coefficients obtained either with two-dimensional harmonic flows or with waves without a current superimposed on them cannot be expected to apply to the design of the structures. Furthermore, the equation proposed by Morison needs major changes to accommodate the existence of the currents.

TRANSVERSE FORCE

The transverse force coefficients for smooth cylinders have been presented in Refs. [3, 4, 6]. The results for the rough cylinders are presented in Fig. 14 as a function of K for various values of β and one particular value of k/D . Additional details and data may be found in [19].

Evidently, C_L does not vary appreciably with either β or Re . The data presented in [19] for other values of k/D show that C_L does not vary with k/D also within the range of the parameters encountered. If there is some variation with these parameters (Re and β), it is certainly masked by the scatter in the data. The transverse force coefficient inevitably exhibits a larger scatter than that for the in-line force coefficients because of the somewhat random nature of the shedding of the vortices. Consequently, it is not too uncommon to obtain a variation of 20-25% for a given K value. This fact is of importance in discussing the effect of the Reynolds number on the lift coefficient.

Fig. 14 Transverse force coefficient for various values of β for $k/D = 1/200$.

Also shown in Fig. 14 is the lift coefficient for smooth cylinders for β in the range 1000 to 2000. It is rather surprising that the smooth cylinder data at relatively low values of β form more or less the upper limit of the rough cylinder data. In other words, the lift coefficient for rough cylinders does not depend on Re and become almost identical with those for smooth cylinders at very low Reynolds numbers. The consequences of this observation for model testing purposes are rather obvious.

As noted earlier, the alternating nature of the transverse force is as important as its magnitude. It is for this reason that the frequency of the alternating force has also been calculated [14]. A close examination of the frequency ratios shows that f_v/K remains essentially constant at a value of about 0.22. To be sure, there are variations from one cylinder to another and from a given combination of Re and K to another one. Nevertheless, the Strouhal number ($St = f_v D/U_m = f_v/K$) is fairly constant for all roughnesses, relative amplitudes, and Reynolds numbers larger than about 20,000. This fact is of special importance in determining the in-line and transverse vibrational response of the elements of a structure to wave-induced transverse forces. Once again it should be kept in mind that the spanwise coherence along a vertical cylinder in the ocean environment is reduced by the variation of the velocity vector with time and depth and that the coefficients presented herein represent the maximum possible values of the transverse force.

CONCLUSIONS

The extensive investigation of the in-line and transverse forces on roughened circular cylinders in harmonic flow warrants the following conclusions:

1. The drag and inertia coefficients depend on Re , K , and k/D . The effect of size distribution and packing of the grains has been minimized by using only sand and applying it as uniformly as possible over the test cylinders;

2. The drag coefficient undergoes a 'drag crisis' depending on the relative roughness and rises to an asymptotic value within the range of Reynolds numbers tested. The asymptotic values of the transcritical drag coefficient are larger than those corresponding to the smooth cylinder case. Furthermore, the larger the relative roughness the larger is the asymptotic value of the drag coefficient;

3. The inertia coefficient also undergoes an 'inertia crisis' at Re values corresponding to the 'drag crisis' at which C_m reaches a maximum value and then asymptotically decreases. The terminal values of C_m depend, as in the case of C_d , on K and k/D ;

4. The predictions of the Morison's equation through the use of the Fourier-averaged drag and inertia coefficients are in excellent agreement with the measured forces in the range of K values smaller than about 10 and larger than about 20;

5. Within the range of parameters tested, C_L does not depend on Re . Its distribution is, surprisingly enough, very close to that obtained with the smooth cylinders at very low Reynolds numbers. The Strouhal number for rough cylinders remains nearly constant for all Reynolds numbers at about 0.22 with the possible exception of those at very low Reynolds numbers.

ACKNOWLEDGMENTS

The results presented herein were obtained in the course of research supported by a grant from the National Science Foundation. This support and the assistance of Messrs. N. J. Collins, S. Evans, and P. Henning, students at the Naval Postgraduate School, are gratefully acknowledged.

CHAPTER 136

High Reynolds Number Oscillating Flow by Cylinders

by

Tokuo Yamamoto¹

and

John H. Nath²

ABSTRACT

In order to determine the added mass, drag and lift coefficients of a smooth cylinder at various distances from a plane boundary, the forced cylinder oscillation tests at high Reynolds number 10^5 to 10^6 and the wave force tests at moderate Reynolds number 10^4 to 10^5 have been carried out at the Wave Research Facility at Oregon State University.

It is found that the drag, lift and added mass coefficients are all strongly Reynolds number dependent. The effect of the near by plane boundary is to increase all of the force coefficients two to four times as compared to the free stream flow values. This is a most important factor to be aware of for design purposes.

INTRODUCTION

Fluid forces on submerged cylinders are important to ocean engineers who have to design pipe-like structures which are subjected to environmental fluid-dynamic loads. Some typical structures are submerged oil pipelines, ocean outfalls, offshore drilling rigs, submerged oil storage tanks and mooring cables. Although this subject has been investigated by many investigators for several years, the problem has not been completely understood because of the very complicated nature of the flow. These forces are influenced by Reynolds number, cylinder roughness, angle of skew, free stream turbulence, formation and collapse of the wake and the proximity of the free surface, the ocean bottom and other cylinder members.

This subject is a continuing study at Oregon State University. Rigid cylinders subjected to flow that is perpendicular to the central axis are considered as a beginning investigation to more general conditions. An extensive literature review was made early in the study (8). The influence of a plane boundary was first treated analytically in (8, 9). The theory has been extended to a group of cylinders (7) and applied to various types of engineering problems (10, 11).

Experimental verification of the theory was made for the simple case of a cylinder near a plane boundary (3,4,7,8,11). An excellent agreement between theory and experiment was obtained for the case when wake formation is small ($A/D < 1.5$ where A = the double amplitude of water particle displacement relative to the cylinder, and D = cylinder diameter). For the cases of large wake formation ($A/D > 1.5$) the experimental results deviate considerably from potential flow theory.

The above results suggest that the real fluid oscillatory flow around rigid cylinders can be classified into two major flow situations; 1) the potential flow, and 2) wake flow. The classification of these two flow situations is discussed briefly in the following.

Potential Flow. If the thickness δ of the boundary layer on the cylinder is small compared to the cylinder diameter and if the boundary layer does not separate, the flow around the cylinder can be essentially modeled with the potential flow theory. The thickness of the laminar boundary layer on the cylinder may be given by

$$\delta = C \sqrt{\frac{v}{\omega}} \quad (1)$$

in which

C is a constant slightly dependent on the diameter of cylinder (for a flat plate $C = 2\pi$, Ref. 12)

ν = kinematic viscosity

$\omega = 2\pi/T$ where T = period of oscillation.

The relative boundary layer thickness may be defined as

$$\delta^* = \frac{\delta}{D/2} = 2C \sqrt{\frac{\nu}{\omega D^2}} = \frac{4\pi}{D} \sqrt{\frac{\nu}{\omega}} \quad (2)$$

Sarpkaya (4) claims that $D^2\omega/\nu$ (which he calls the β - parameter) is very important in oscillatory flow, without physical explanation. From Eq. (2), β is related to δ^* as

$$\delta^* = 4\pi \sqrt{\frac{1}{\beta}} \quad (3)$$

The ranges of the oscillation period for ocean waves and for earthquake ground motions are about 1 to 15 sec. and .1 to 1 sec., respectively. According to Eq. 1, the boundary layer thickness ranges from 2.43 to 9.35 mm for ocean waves and .76 to 2.42 mm for earthquakes. This is small compared to the diameter of structural members for offshore structures which range from about 100 to 2000 mm. However, the boundary layer effect may not be negligible for small size models of offshore structures in laboratory experiments.

Due to the oscillatory nature of the flow, the boundary layer on the cylinder surface does not separate (or the wake formation after separation is small) if the amplitude of water particle displacement to the cylinder diameter is $A/D < 1.5$.

The authors have derived a closed form analytical solution for the hydrodynamic forces on any number of cylinders which may move in any manner as shown in Ref. (7). Several practical examples were solved (9, 10, 11).

Wake Flow. If the amplitude of the water particle displacement is large compared to the cylinder diameter, or $A/D > 1.5$, the boundary layer separates from the cylinder surface and a wake forms. The characteristics of the wake depend on the maximum Reynolds number, $U_m D/\nu$, as well as the wake parameter, A/D , where U_m = maximum water particle velocity relative to the cylinder. Since no complete theory is available for the prediction of hydrodynamic forces on cylinders in the wake flow situation, they must be determined experimentally.

The data in the open literature to date are limited to the lower values of $U_m D/\nu$ and A/D and only for the free stream flow condition (1,6). The present investigation considerably extends the range of the parameters to higher values and generates information for various values of e/D for the first time (e = the gap between the cylinder and a near by plane boundary).

An experiment specially designed to generate the hydrodynamic force coefficients at high Reynolds numbers (1×10^5 to 1.05×10^6) and large wake parameters is reported on herein. Newly generated wave force data with moderate Reynolds numbers (1×10^4 to 1×10^5) are also presented.

OSCILLATING CYLINDER EXPERIMENTS

In order to investigate the oscillatory flow around cylinders with a large wake formation at high Reynolds numbers, the experiments were conducted at the Wave Research Facility at Oregon State University. The facility has a wave and towing basin which is 104m long, 3.66m wide and generally 4.57m deep. The overall view of the experimental setup is shown in Fig. 1. The 30cm (12 in) diameter test cylinder, which nearly reaches across the width of the wave basin, (3.66m) was forced to oscillate in a large mass of water which is otherwise still. The wave board, with a 150 horsepower motor and piston, was used to move the cylinder through a cable linkage as shown. A dam was constructed to keep the wave board dry. The motion of the wave board was amplified and transmitted to the test cylinder through the wire ropes and sheaves. Wire ropes were anchored on the amplifier sheaves to avoid any possible slips and were tensioned by spring pulleys. The maximum amplitude of cylinder motion was 6m. The cylinder was located 2m from both the basin bottom and the free surface and 12m from the dam, to best approximate the free stream flow condition.

To investigate the effect of a near by plane boundary, a movable concrete false bottom covering the 12m section below the cylinder was located at various distances from the cylinder. The test cylinder is detailed in Fig. 2. The 76cm long test section is suspended between two dummy sections by two elastic bars on which strain gages were attached to measure the horizontal and vertical component of forces. Two accelerometers were attached to the inner cylinder to measure the horizontal acceleration of the cylinder. The total amplitude, A , of cylinder displacement was measured by eye.

Four amplitudes were studied, i.e. $A/D = 20, 15, 10$ and 5 . For each amplitude, the frequency of oscillation was varied to cover the maximum cylinder velocity, U_c , from $.3$ to 4.27 m/sec. The horizontal accelerations together with the wave board displacement were simultaneously recorded on a photosensitive strip chart recorder.

It should be noted that the flow past a stationary object is hydrodynamically equivalent to the flow due to the same object moved in the otherwise still fluid as long as the fluid is incompressible. The only difference is that the object in the moving fluid experiences an extra force, which is equal to the displaced mass of the fluid times the ambient fluid acceleration, due to the pressure field necessary to accelerate the fluid.

WAVE FORCE EXPERIMENTS

In order to investigate the oscillatory flow around cylinders in a large wake flow situation at moderate Reynolds numbers (1×10^4 to 1×10^5), wave force experiments were also made at the Wave Research Facility. A 76mm diameter horizontal cylinder was instrumented and mounted at various distances from a false bottom in 2m water. The horizontal and vertical forces, together with the water surface fluctuation, were recorded simultaneously. Since the detail of similar experimentation has been reported in our previous paper (Ref. 4), it will not be repeated here again.

ANALYSIS OF EXPERIMENTAL DATA

The analysis of the data from the oscillating cylinder tests and the wave force tests was based on the Morison equation. The horizontal force $F_x(t)$, on a cylinder undergoing sinusoidal motion may be given in the form of the Morison equation as

$$F_x(t) = C_D \frac{1}{2} \rho D L |\dot{x}(t)| \dot{x}(t) + (C_M \frac{1}{4} \rho \pi D^2 L + M) \ddot{x}(t) \quad (4)$$

wherein $x(t)$ is the cylinder displacement from the neutral position and $\dot{}$ and $\ddot{}$ on x designate d/dt and d^2/dt^2 respectively, ρ = density of fluid, C_D = drag coefficient, C_M = added mass coefficient and L = the length of test cylinder, M = mass of test cylinder.

For a sinusoidal motion, $x(t)$, $\dot{x}(t)$ and $\ddot{x}(t)$ are given as

$$x(t) = \frac{A}{2} \sin \omega t \quad (5)$$

$$\dot{x}(t) = \frac{A\omega}{2} \cos \omega t \quad (6)$$

$$\ddot{x}(t) = -\frac{A\omega^2}{2} \sin \omega t \quad (7)$$

From Eq. 6, the maximum velocity U_m is

$$U_m = \frac{A\omega}{2} \quad (8)$$

The maximum acceleration \dot{U}_m is given as

$$\dot{U}_m = \frac{A\omega^2}{2} \quad (9)$$

For a sinusoidal motion $\ddot{x}(t)$ vanishes when $\dot{x}(t)$ is maximum and vice versa. In a very simple analysis, C_D and C_M is often evaluated by measuring the horizontal force F_D at the instant of maximum ambient velocity and the force F_M at the instant of maximum acceleration.

For the simple approach,

$$C_D = \frac{F_D}{\frac{1}{2} \rho D L U_m^2} \quad (10)$$

and

$$C_M = \frac{F_M}{\frac{1}{4} \rho \pi D^2 L U_m} - \frac{M}{\frac{1}{4} \rho \pi D^2 L} \quad (11)$$

The measured cylinder motion was fairly sinusoidal. The maximum horizontal force at $A/D = 15$ and 20 occurred at the instant of maximum velocity. This indicates that there is no phase lag between the drag force and the ambient velocity. Thus, the simple approach was used in this paper. Some data from the forced cylinder oscillation tests were also recorded in digital form on magnetic tapes. If time and opportunity permit in the future, the least squared time average method used in Refs. 1 and 6 will be applied to the digital data to see the difference in the values C_D and C_M determined by the two methods.

The lift coefficient, C_L , is defined from the maximum vertical force, F_L , and the maximum velocity, U_m , as

$$C_L = \frac{F_L}{\frac{1}{2} \rho D L U_m^2} \quad (12)$$

In Eqs. 10, 11 and 12, U_m was computed from the measured value of A and ω and Eq. 8, and U_m was directly obtained from the measurement. The error between the measured value of U_m and the computed value from Eq. 9 using measured values of A and ω was usually small. For each run (which included several oscillations) the ensemble average of four to six samples was used to determine the force coefficients.

From wave force data, C_D and C_L were also evaluated based on Eqs. 10 and 12 utilizing the Airy wave theory and measured wave height and frequency.

EXPERIMENTAL RESULTS

Experiments were carried out for the following combinations of the parameters, e/D , A/D and $U_m D/v$:

Oscillating Cylinder Tests (D=30cm)

e/D : 6, 1, 0.5, 0.25, 0.083

Oscillating Cylinder Tests (D=30cm) continued

A/D : 20, 15, 10, 5

 $\frac{U_m D}{v} \times 10^{-5}$: 10.5, 7.88, 5.25, 2.63, 1.31Note: The maximum value of $\frac{U_m D}{v}$ depends on A/D.Wave Force Tests (D=7.62cm)

e/D : 3, 1, .5, .33, .063

A/D : 3.5 to 33

 $\frac{U_m D}{v}$: 10^4 to 10^5

Example Data. Typical force, acceleration and displacement records from the cylinder oscillation tests are shown in Fig. 3 for $e/D = 6$, $A/D = 10$ and $U_m D/v = 5.25 \times 10^5$, and in Fig. 4 for $e/D = 0.083$, $A/D = 10$ and $U_m D/v = 5.25 \times 10^5$. The cylinder acceleration is fairly sinusoidal and has practically no phase lag with the wave board displacement. This is a good indication that the actual cylinder motion was approximately sinusoidal. (Because of small cable slack, the motion of the cylinder cannot be exactly sinusoidal.) The high frequency noise at about 8 Hz is due to the natural vibration frequency of the test cylinder in water.

Compare the vertical forces for $e/D = 6$ and $.083$. For the free stream flow condition, $e/D = 6$, the lift force fluctuates equally up and down at six times the oscillation frequency for this particular condition. This is due to the alternating vortex shedding. However, for the near-bottom flow condition, $e/D = .083$, the lift force is toward the boundary or downward during a very short period where the velocity is small, but for the remainder of the flow cycle, where the velocity is significantly large, the lift force is away from the boundary, or upward. The explanation for this is that due to the oscillatory nature of the flow, there is a moment where the wake does not clearly exist, so the force is toward the boundary as for the potential flow condition. But as soon as the wake is clearly formed, the force becomes upward, due to the asymmetric flow due to the near by boundary. For this case, the lift force always fluctuates at twice the flow oscillation frequency.

This effect of a near by boundary may be important with regard to the design of submerged pipelines.

The force coefficients, C_D , C_M and C_L , are plotted versus the Reynolds number, $U_m D/\nu$, with the wake parameter, A/D , and the relative gap, e/D , as parameters, and are discussed in the following section.

Drag Coefficient. The plots of the drag coefficient versus the Reynolds number for the "free stream" flow condition are shown in Fig. 5. Actual values of e/D are 6 and 3 for oscillating cylinder tests and wave force tests, respectively. The general trends of the oscillatory cylinder data and the wave force data match continuously. This may be a good indication of the physical similarity between the two flow conditions. The oscillatory flow data (1,6) and the steady flow data (5) available in the literature are also shown for comparison.

The oscillatory flow results from the three investigations agree fairly well. For the range of the wake parameter studied, i.e., A/D from 3.5 to 33, C_D from oscillatory flow varies gently as $U_m D/\nu$ varies from 10^4 to 10^6 . This is distinguishably different from the well known steady state data which has an abrupt transition of the high subcritical value of C_D to the low supercritical value.

Does the oscillatory flow value of C_D approach the steady state value as A/D approaches infinity? This question still remains to be answered.

The plots of C_D vs. $U_m D/\nu$ for the near boundary flow condition ($e/D = .083$ for the oscillating cylinder tests and $e/D = .063$ for the wave force tests) are shown in Fig. 6. The general tendency is similar to that of the free stream flow case except that the value of C_D for this case is considerably higher than that for the free stream flow. The steady flow data by Jones (2) happens to give a lower limit of the oscillatory flow data shown.

Similar plots for three intermediate values of e/D were made but are not shown here because of space limitation. The general trends are similar to those in Figs. 5 and 6 but the value of C_D varies depending on e/D .

The plots of C_D versus $U_m D/\nu$ at the largest $A/D = 20$ are shown in Fig. 7. As noted before, the general trends are the same for all e/D . The value of C_D decreases until it reaches the minimum at $U_m D/\nu =$ about 3×10^5 , then it increases gradually as $U_m D/\nu$ increases from 10^4 to 10^6 . The absolute value of C_D increases as the cylinder approaches the boundary. The value of C_D for the near boundary flow ($e/D = .083$) is about two times as large as that for the free stream flow. This is probably due to the flow blockage effect of the plane boundary.

Added Mass Coefficient. The added mass coefficient, C_M , obtained from the oscillating cylinder tests is plotted versus $U_m D/\nu$ for the free stream flow condition ($e/D = 6$) in Fig. 8. The data from the present study are compared with the data by other investigators. Again, all

of the data agree fairly well. The value of C_M increases gradually until it reaches the maximum at about $U_m D/\nu = 3 \times 10^5$, then it decreases gradually as $U_m D/\nu$ increases from 10^4 to 10^6 . The experimental value of C_M is always smaller than the theoretical value ($C_M = 1.0$). This is due to the wake effect which strongly depends on the Reynolds number, $U_m D/\nu$. The effect of A/D on C_M is not so clear.

Similar plots for the near boundary flow condition ($e/D = .083$) are shown in Fig. 9.

The plots of C_M versus $U_m D/\nu$ at $A/D = 20$ are shown for various values of e/D in Fig. 10. The theoretical value of C_M , which is independent of $U_m D/\nu$, increases from 1.0 to 2.3 as the cylinder approaches from the free stream to the plane boundary. The experimental value of C_M increases by the same order of magnitude as e/D decreases, but is strongly dependent on the Reynolds number.

Lift Force Coefficient. Plots of C_L versus $U_m D/\nu$ for the free stream flow condition ($e/D = 6$ for the oscillatory cylinder tests and $e/D = 3$ for the wave force tests) are given in Fig. 11. The OSU data are compared with the data in Ref. 6. The data from the two investigations agree very well at all values of A/D . The value of C_L increases as A/D decreases in the range of A/D 5 to 20. For a given A/D , C_L decreases gradually as $U_m D/\nu$ is increased. For the free stream flow condition the lift force fluctuates many times up and down in a half cycle of oscillation due to alternating vortex shedding as shown in Fig. 3. The fluctuation frequency depends on A/D .

The plots of C_L versus $U_m D/\nu$ for the near boundary flow condition ($e/D = 0.83$ for the oscillating cylinder tests and $e/D = .063$ for the wave force tests) are shown in Fig. 12. As explained before, the lift force for this case is not due to the vortex shedding but due to the flow asymmetry. Therefore, the lift for this case is always at twice the oscillation frequency of the flow and independent of A/D .

The plots of C_L versus $U_m D/\nu$ at $A/D = 20$ are shown for various values of e/D in Fig. 13. The positive lift force increases significantly as e/D decreases. The value of C_L for $e/D = .083$ is about four times larger than C_L for the free stream flow condition for the entire range of $U_m D/\nu$. The dependence of the negative lift force on e/D is not as clear as that of the positive lift force.

PRACTICAL APPLICATIONS

Real design oscillatory flows such as ocean waves and earthquakes should be classified into either the potential flow situation ($A/D < 1.5$) or the wake flow situation ($A/D > 1.5$) according to the wake parameter.

For the potential flow situation, such as earthquake problems, a closed form solution for the hydrodynamic forces on any number of cylinders is available in Ref. 7. The calculated force coefficients for one, two and three cylinders near a plane boundary (11) and for a 4x4 cylinder arrays (10) are also available.

For the wake flow situation, such as wave force problems, the experimental data of drag, lift and added mass coefficients covering the Reynolds number, U_D/ν , of from 10^4 to 10^6 , the wake parameter, A/D , from 3.5 to 33, the relative gap between the cylinder and a plane boundary, e/D , from .065 to 6.0, are presented herein for the design of pipelines, offshore platforms and other pipe structures.

CONCLUSIONS

To determine the added mass, drag and lift coefficients of a smooth cylinder at various distances from a plane boundary, the forced cylinder oscillation tests at high Reynolds numbers 10^5 to 10^6 and the wave force tests at moderate Reynolds numbers 10^4 to 10^5 have been carried out at the Wave Research Facility at Oregon State University. The following conclusions are drawn from the results.

1. The data from the forced cylinder oscillation tests matched continuously with the data from the wave force tests. This indicates the physical similarity between the two flow situations.
2. The drag, lift and added mass coefficients are all strongly Reynolds number dependent. Unlike steady flow, C_D from oscillatory flow for $A/D = 5$ to 20 decreases gradually from a high value until it reaches a minimum at about $U_D/\nu = 3 \times 10^5$ and then increases gradually as the Reynolds number increases from 10^4 to 10^6 . The value of C_L monotonically decreases as the Reynolds number increases. The value of C_M has a maximum at about $U_D/\nu = 3 \times 10^5$. This is true for all values of e/D .
3. The drag and lift coefficients are generally higher for the smaller values of A/D . Both C_D and C_L become fairly independent of A/D when this parameter becomes as large as 15 or 20. The influence of A/D on C_M is less clear. This tendency is true for all values of e/D .
4. The effect of a near by plane boundary is to increase all of the force coefficients. At $A/D = 20$, C_D increased about two times, C_L about four times and C_M about two times as e/D decreases from 6 to .083. This may be due to the blockage effect of the near by plane boundary. *This is a most important factor to be aware of for design purposes.*

5. The wake characteristics are completely different between the free stream flow and the near boundary flow conditions. In the free stream flow, many alternate vortexes shed during a half cycle of oscillation. The numbers of vortexes varies depending on the value of A/D . Near a plane boundary, the vortex shedding is suppressed. The flow changes from the potential flow situation to the wake flow situation during a half cycle. So the lift force also changes from negative to positive during the half cycle. This frequency characteristic of lift force near a plane are independent of the value of A/D as long as $A/D > 1.5$.

ACKNOWLEDGEMENT

The forced cylinder oscillation study was supported by the National Science Foundation under contract ENG75-06901. The wave force study was supported by the National Oceanic and Atmospheric Administration (maintained by the U.S. Department of Commerce) Institutional Sea Grant contract 04-6-158-44004 at Oregon State University. Y. W. Chan assisted in conducting the experiments.

ABSTRACT

Flow separation of a laminar boundary layer on the surface of a circular cylinder developed by monochromatic waves has been investigated both theoretically and experimentally, and next, characteristics of vortex formation and shedding have been discussed with Keulegan-Carpenter's number and Reynolds number, and finally, local depressions of the wave pressure around the cylinder induced by wake vortices have been examined in the experiment.

INTRODUCTION

A number of studies have been made with respect to wave forces on marine structures, especially on a circular cylinder. However, in order to estimate the wave forces more correctly, it is necessary to make clear the mechanism of wave force action. For this purpose, it is important, as the first step, to investigate the transformation of waves by the circular cylinder and induced flow along the cylinder, and next, to evaluate the magnitude of pressures acting on the cylinder exerted by such an affected wave field.

In case of steady flow, it has already been ascertained that both the behavior of fluid around a cylinder and forces on it are principally subject to Reynolds number $Re = UD/\nu$, in which U :flow velocity, D :diameter of cylinder and ν :dynamic viscosity. Son and Hanratty^{1),2)} indicated that in the range of lower Reynolds number the position of separation point moves forward from the back stagnation point with increase in Reynolds number. For instance when $Re = 500$, the angle of separation point from the front stagnation point θ_s is about 95° , and when Re increases between 4000 and 100000, it becomes about 80° .

Then it is well known that such a separation causes wake vortices and their configurations are also subject to Reynolds number; that is, a pair of symmetric and stable vortices is formed at values of Re lower than 40 and Karman vortex street appears at values of Re between about 70 and 2500³⁾. In this case, the frequency of vortex generation is known by using Strouhal number determined by Reynolds number⁴⁾.

Hereupon, corresponding to such patterns of fluid motion, the distributions of pressure and shearing stress around a cylinder are determined. Among the fluid forces on the cylinder, the drag force due to the shearing stress is predominant in the range of lower Reynolds number. However, with increase in Reynolds number, another kind of drag force becomes predominant owing to depression of pressure induced by wake vortices at the rear part of the cylinder. It is too familiar to state that these results are shown by a figure in text books as the relationship between the drag coefficient and Reynolds number⁴⁾.

On the other hand, in case of wave fields, the separation point, the behavior of wake vortices and the pressure distribution have not been made so clear that there exist unknown facts about the correspondence of the drag and inertia coefficients to the conditions of fluid motion.

From this point of view, in the present study, general characteristics of the flow separation of a laminar boundary layer on the surface of a circular cylinder developed by monochromatic waves are shown by using the theory presented by the authors in the previous paper⁵⁾, and then, experimental results of the separation point obtained by taking photographs using the method of flow visualization are compared with the theoretical ones, and next, vortex formation and shedding are investigated by means of successive photography. Finally, wave pressure distributions around the cylinder are measured by using a small pressure gauge and depressions of the pressure induced by wake vortices are discussed.

FLOW SEPARATION

1. THEORY

The coordinate system is shown in Fig.1. Denoting the water particle velocity in the boundary layer along the cylinder in the polar coordinate (θ, r, z) or in the boundary layer coordinate (x, y, z) by u , the separation point of a streamline in the boundary layer is generally determined by the condition that

$$\partial u / \partial r |_{r=R} = 0 \quad \dots\dots\dots (1)$$

Fig.1 Coordinate system.

The authors have already obtained the second approximate solution of the water particle velocity in the boundary layer in the following dimensionless form by means of the boundary layer approximations and the perturbation method in the previous paper⁵⁾:

$$u_{2nd} = u_0 + \epsilon_1 u_1, \quad \dots\dots\dots (2)$$

$$u_0 = \zeta_0^+ u_0 e^{i\sigma t}, \quad \dots\dots\dots (3)$$

$$u_1 = (\epsilon_2 / \epsilon_1) \zeta_1^+ u_0 e^{i\sigma t} + \zeta_{1a}^- (u_0 \hat{u}_{0x} + \hat{w}_0 \hat{w}_{0z}) e^{2i\sigma t} + \zeta_{1d}^- (u_0 \hat{w}_{0z} - \hat{w}_0 \hat{u}_{0z}) e^{2i\sigma t} + \zeta_{1b}^- \{ (\hat{u}_0 \hat{u}_{0x} + \hat{u}_0 \hat{u}_{0x}) + (\hat{w}_0 \hat{u}_{0z} + \hat{w}_0 \hat{u}_{0z}) \} + \zeta_{1c}^- \{ (\hat{u}_0 \hat{u}_{0x} - \hat{u}_0 \hat{u}_{0x}) + (\hat{u}_0 \hat{w}_{0z} - \hat{u}_0 \hat{w}_{0z}) \} + \zeta_{1e}^- \{ (\hat{u}_0 \hat{w}_{0z} + \hat{u}_0 \hat{w}_{0z}) - (\hat{w}_0 \hat{u}_{0z} + \hat{w}_0 \hat{u}_{0z}) \}, \quad \dots\dots\dots (4)$$

$$\epsilon_1 = \pi H / L, \quad \epsilon_2 = \sqrt{\nu T} / 2\pi R, \quad \dots\dots\dots (5)$$

$$\left. \begin{aligned} \zeta_0^+ &= 1 - e^{-(1+i)\eta^+}, & \zeta_1^+ &= \frac{1}{\sqrt{2}} \eta^+ e^{-(1+i)\eta^+}, \\ \zeta_{1a}^- &= -\frac{i}{2} e^{-\sqrt{2}(1+i)\eta^-} + \frac{i}{2} e^{-(1+i)\eta^-} + \frac{1-i}{2} \eta^- e^{-(1+i)\eta^-}, \end{aligned} \right\} \dots\dots\dots (6)$$

$$\left. \begin{aligned}
 \zeta'_{1d} &= \frac{7i}{4}e^{-\sqrt{2}(1+i)\eta'} + \frac{3i}{2}e^{-(1+i)\eta'} + \frac{1-i}{2}\eta'e^{-(1+i)\eta'} + \frac{i}{4}e^{-2(1+i)\eta'}, \\
 \zeta'_{1b} &= \frac{3}{4} + \frac{1}{4}e^{-2\eta'} + e^{-\eta'} \left(\frac{1}{2}\cos\eta' + 2\sin\eta' \right) - \frac{\eta'}{2}e^{-\eta'} (\cos\eta' - \sin\eta'), \\
 \zeta'_{1c} &= \frac{3}{4} - \frac{1}{4}e^{-2\eta'} + e^{-\eta'} (\cos\eta' - \frac{1}{2}\sin\eta') + \frac{\eta'}{2}e^{-\eta'} (\cos\eta' + \sin\eta'), \\
 \zeta'_{1e} &= \frac{1}{2} + e^{-\eta'} \left(\frac{1}{2}\cos\eta' + \sin\eta' \right) - \frac{\eta'}{2}e^{-\eta'} (\cos\eta' - \sin\eta'),
 \end{aligned} \right\} \dots\dots\dots (6)$$

$$\eta' = ky\sqrt{Re^*/2}, \dots\dots\dots (7)$$

in which, ϵ_1 :very small quantity of the order of the wave steepness in magnitude, ϵ_2 :very small quantity of the order of the ratio of the boundary layer thickness to the radius of cylinder in magnitude, σ :angular frequency, H :wave height, L :wave length, T :wave period, R :radius of cylinder, k :wave number, $Re^*(= c/vk)$:convenient Reynolds number using the wave celerity c instead of the fluid velocity, and U_0 and W_0 :amplitudes of dimensionless velocities derived by eliminating both the dimensional part $\pi H/T$ and time variation part $e^{i\sigma t}$ from the water particle velocities of diffracted waves on the surface of cylinder in the direction of the coordinates x and z respectively. Suffixes x and z indicate differentiations with respect to x and z respectively, and \wedge and \vee indicate real and imaginary parts respectively.

By applying this velocity u_{2nd} to the velocity u in Eq.(1), Eq.(1) is rewritten as follows:

$$\partial u_{2nd}/\partial \eta' |_{\eta'=0} = \partial u_0/\partial \eta' |_{\eta'=0} + \epsilon_1 \partial u_1/\partial \eta' |_{\eta'=0} = 0. \dots\dots\dots (8)$$

Using Eq.(3) and Eq.(4), $\partial u_0/\partial \eta' |_{\eta'=0}$ and $\partial u_1/\partial \eta' |_{\eta'=0}$ are expressed as follows:

$$\begin{aligned}
 \partial u_0/\partial \eta' |_{\eta'=0} &= (1+i)U_0e^{i\sigma t}, \dots\dots\dots (9) \\
 \partial u_1/\partial \eta' |_{\eta'=0} &= (\epsilon_2/\epsilon_1) \frac{1}{\sqrt{2}}U_0e^{i\sigma t} \\
 &+ (1-\frac{1}{\sqrt{2}})(1-i)(U_0\hat{u}_{0x} + W_0\hat{u}_{0z})e^{2i\sigma t} + (\frac{5}{2}-\frac{7\sqrt{2}}{4})(1-i)(U_0\check{w}_{0z} - W_0\check{u}_{0z})e^{2i\sigma t} \\
 &+ \frac{1}{2}\{(\hat{u}_0\hat{u}_{0x} + \hat{u}_0\hat{u}_{0z}) + (\check{w}_0\hat{u}_{0z} + \check{w}_0\hat{u}_{0z})\} - \frac{1}{2}\{(\hat{u}_0\check{u}_{0x} - \hat{u}_0\check{u}_{0z}) + (\hat{u}_0\check{w}_{0z} - \hat{u}_0\check{w}_{0z})\}. \dots (10)
 \end{aligned}$$

It is impossible to express the separation point θ_s explicitly from Eq.(8) so that the separation point is obtained as the point that the sign of left hand side of Eq.(8) is just changed in varying θ by 1° in computations.

2. COMPUTATIONS AND DISCUSSIONS

Fig.2 shows an example of the time variation of the water particle velocity in the boundary layer u_{2nd} . In this case, Keulegan-Carpenter's number ($[K.C.]_m = U_{max}T/D$) is 6. The water particle velocity at $\theta = 150^\circ$ denoted by a dotted line becomes negative value after t/T is about 0.125, which means the occurrence of flow separation behind the cylinder and the generation of subsequent reverse current. On the other hand, the water particle velocity at $\theta = 30^\circ$ denoted by a solid line becomes positive during the phase of wave trough, which also means the occurrence of flow separation. The shadow regions in this figure show the duration and intensity of these reverse currents.

Fig.3 shows an example of the time variation of flow separation point with a parameter of Keulegan-Carpenter's number (hereafter, it is denoted as K.C. number for abbreviation). As the water particle velocity varies in magnitude with the wave phase, the separation

point proceeds from behind of the cylinder to front of the cylinder with increase in t/T during the phase of wave crest and its reverse movement is seen during the phase of wave trough. Especially when K.C. number is small, for example 3, the separation point varies quickly in the wide range, and this phenomenon is peculiar to flow separation under oscillatory waves. The reason may be explained by the fact that the phase of the water particle velocity in the boundary layer proceeds faster than the phase of ambient velocity. On the other hand, when K.C. number is large, for example 15, the separation point does not vary so widely, which is similar to the flow separation in steady flow.

Fig.2 Variation of water particle velocity u_{2nd} in boundary layer with time.

Fig.3 Variation of flow separation point with time.

Fig.4 shows the shift of separation point due to K.C. number, in which the phase t/T is fixed to 0.25 and kR is taken as a parameter. In this figure, for example, when kR is 0.01, the flow separation does not occur if K.C. number is smaller than 2, and with increase in K.C. number, the separation point moves from 180° toward 90° . And finally it approaches to a definite point asymptotically for each kR . If K.C. number is constant, it is found that the smaller kR , the smaller angle of separation point; that is, the wake region behind the cylinder becomes wider. In this calculation, it is also found that Reynolds number $U_{max}D/\nu$ and the relative water depth kh do not much affect the separation point.

Fig.5 shows the vertical distributions of separation point. If we consider the case that $h = 40$ cm, $D = 3$ cm and $\nu = 0.01112$ cm²/sec, the wave period of each curve becomes 0.5 sec \sim 5.0 sec as shown in the figure. In this calculation, K.C. number at the position where $z/h = -0.1$ is 6. In the figure, when the wave period is as short as 0.5 sec or 0.7 sec, the flow separation occurs only near the water surface. On the other hand, when the wave period is as long as 2 sec or 5 sec, the separation point does not change vertically so much. This is caused by the vertical distributions of water particle velocity of the main flow, which means vertical change of K.C. number.

Fig.4 Shift of flow separation point.

Fig.5 Vertical distributions of flow separation point.

3. EXPERIMENTS AND CONSIDERATION

In the experiment of flow separation, a circular cylinder made of Lucite with a diameter of 3 cm was installed in the center of a wave tank, which is 27 m long, 50 cm wide and 70 cm deep. As shown in Fig. 6, from this cylinder surface, a platinum wire with a diameter of 0.05 mm was stretched horizontally, and trains of hydrogen bubbles were generated from the platinum wire by using a pulse generator, and photographs were taken through the glass bottom. As the cylinder was made rotatable around the vertical Z-axis in Fig. 1, the separation point was examined by rotating the cylinder every 5° in the range of angle from 90° to 160° during the phase of wave crest.

The water depth h was 40 cm and the measuring point z_p was 5 cm below still water level, and the correspondence of experimental cases to the wave characteristics is shown in Table 1, in which $Re_m = u_{max}D/\nu$.

Fig. 6 Sketch of experimental apparatus for flow separation.

Table 1 Experimental condition for flow separation.

Case	T(sec)	H(cm)	$h=40$ cm, $z_p=-5$ cm	
			[K.C.] _m	$Re_m \times 10^{-3}$
I-1	2.0	1.5~1.6	2.5~2.7	1.02~1.09
I-2	2.0	2.4~2.6	4.1~4.4	1.64~1.77

I-11	3.0	4.5~4.9	11.2~12.2	3.11~3.39

Some examples of photographs taken about flow separation are shown in Photo. 1(a), (b) and (c). Photo. 1(a) shows that when $t/T = 0.279$, the flow is not separated yet at the position of the platinum wire where $\theta = 100^\circ$, in which K.C. number is 6.6. Photo. 1(b) is an example of such a critical condition that the flow is just separated at the position of platinum wire, in which $t/T = 0.306$, $\theta = 120^\circ$ and K.C. number is 4.5. Photo. 1(c) is the case when $t/T = 0.323$ and the position of the platinum wire, $\theta = 125^\circ$, is in the region of reverse current because of flow separation, in which K.C. number is 4.8.

(a) Not separated.

(b) Critical.

(c) Separated.

Photo.1 Visualization of flow separation.

Fig.7 shows the comparison between theoretical separation points and experimental values. In this figure, experimental data are divided into three flow conditions by the photographs; that is, at the intersection point of the platinum wire and the cylinder surface, the separation has not occurred yet, just occurred and already occurred as shown in Photo.1(a), (b) and (c) respectively. This figure indicates that the experimental values agree well with the theoretical ones except Cases I-6, I-10 and I-11, in which K.C. numbers are so large that the vortices generated before a half period of waves in front of the cylinder become to disturb the boundary layer during their shedding along the cylinder surface toward the rear part of the cylinder by the return flow.

Fig.7 Comparison of theoretical flow separation point with experimental data.

WAKE VORTICES

1. EXPERIMENT

In the experiment of wake vortices, platinum wires were stretched horizontally from the cylinder surface at the angles of about 90° and 270° , and photographs of hydrogen bubble lines were taken successively with an interval of about 0.25 sec by using a motor driven camera. Other experimental apparatus were same as in the case of flow separation. Experimental conditions were as follows: $h = 40$ cm, $z_p = -5$ cm, $v = 0.01141$ cm²/sec, and the wave period T in the range from 1 sec to 8 sec and the wave height H from 1.5 cm to 7.5 cm were used in this experiment.

Examples of successive photographs showing the time process of vortex formation and shedding are shown in Photo.2 and Photo.3, which are an example of a pair of symmetric vortices and that of extremely asymmetric vortices or almost Karman vortex street respectively.

From Photo.2, it is recognized that after flow separation, a new pair of vortices begins to form behind the cylinder at the phase $t/T = 0.30$ and is growing up symmetrically till $t/T = 0.50$, in which another pair of vortices at the right side of each photographs is an old one generated in front of the cylinder before a half period of waves and transported by main flow, and that as the main flow changes its direction after $t/T = 0.5$, the vortices are transported toward the front of the cylinder at each side of the cylinder. In this case, K.C. number is 7.4.

On the other hand, it is recognized from Photo.3 that a pair of small vortices appears slightly at the phase $t/T = 0.15$, but only one vortex at the lower side of the cylinder in the photographs is growing large till $t/T = 0.23$ and begins to shed at $t/T = 0.31$, and the other vortex at the upper side of the cylinder in the photographs is growing till $t/T = 0.51$. In this case, K.C. number is as large as 19.8, and hydrogen bubble lines are quite turbulent because of the remaining effects of some vortices generated before a half period of waves.

2. DISCUSSION OF RESULTS

The relationship between vortex configurations and both Reynolds number Re_m and K.C. number $[K.C.]_m$ is shown in Fig.8(a). The explanation of each symbol is shown in Fig.8(b), in which dotted lines show the path of vortices in return flow. In this figure, it is found that the vortex configurations are generally transformed by K.C. number; that is, when K.C. number is smaller than 2, flow separation does not occur both theoretically and experimentally, and when K.C. number is smaller than about 7.5, a pair of symmetric vortices appears. With increase in K.C. number, a pair of vortices becomes asymmetric, especially when K.C. number is larger than 15, it becomes extremely asymmetric as shown in Vortex-Pattern C, and finally, when K.C. number reaches about 20, vortices become similar to Karman vortex street.

It is apparent that such transformations of vortex configuration are caused by the characteristics of vortex generation and shedding. The former is closely related to the characteristics of flow separation and the latter is due to the sweeping effect of a main flow and the stability of vortices. In other words, when K.C. number is small, the flow separation does not continue so long time as to form vortices, and even when Reynolds number is high to some extent, the wake vortices may not be formed so easily in the wave field as in the steady flow. On the other hand, as the angle of separation point becomes smaller with increase in K.C. number and does not vary so quickly with the wave phase which means that the wake region becomes larger for a longer time, the generation and shedding of wake vortices in the wave field become similar to those in steady flow.

It is considered that the state of vortex shedding in the wave field may be known by using the relationship between Reynolds number and Strouhal number obtained in the case of steady flow⁶). Denoting the frequency of vortex shedding, the wave frequency and Strouhal

$D=3\text{cm}$, $h=40\text{cm}$, $Z_p=-5\text{cm}$, $T=4.9\text{sec}$, $H=1.9\text{cm}$, $Re_m=1220$, $[K.C.]_m=7.4$

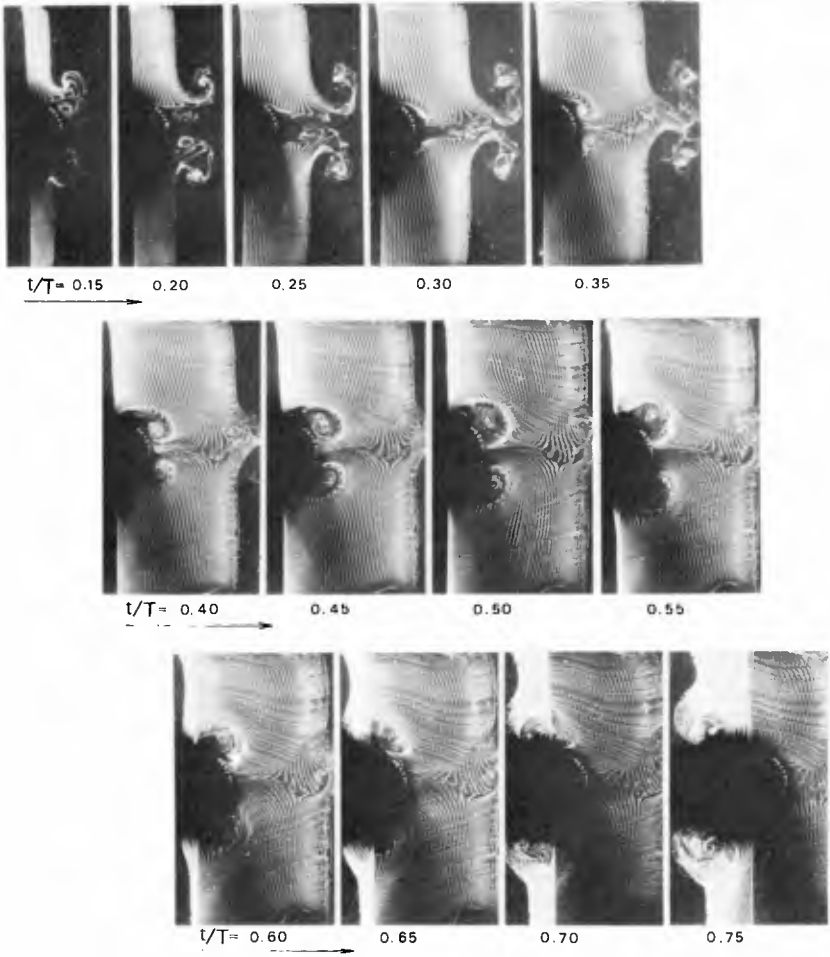

Photo.2 Time variation of wake vortices in case of a pair of symmetric vortices.

$D=3.2\text{cm}$, $h=10\text{cm}$, $Z_0=-1.5\text{cm}$, $T=7.2\text{sec}$, $H=3.2\text{cm}$, $Re_{D1}=2110$, $K.C._{D1}=110$

$t/T = 0.15$ 0.19 0.23 0.27

$t/T = 0.31$ 0.35 0.39 0.43

$t/T = 0.47$ 0.51 0.55 0.59

Photo.3 Time variation of wake vortices in case of Karman vortex street.

number by f_s , f and S respectively, the value of f_s/f means the number of shedding vortex during one wave period, which is estimated by the following equation:

$$f_s/f = (Re/Re_m) \cdot S \cdot [K.C.]_m, \dots\dots\dots(11)$$

in which the validity of Eq.(11) is easily confirmed by substituting $Re = UD/v$, $Re_m = U_m D/v$, $S = f_s D/U$ and $[K.C.]_m = U_m/(Df)$ into the right hand side of Eq.(11).

Therefore, $f_s/f = 2$ corresponds to the condition that a pair of vortices are generated during a half period of wave and the direction of flow in the wave field is reversed just before a subsequent vortex appears, which is considered to be similar to the configuration of Vortex-Pattern C. The dotted line denoted by $f_s/f = 2$ in Fig.8(a) shows the condition in the case of applying the average value of Re during a half period and the value of S corresponding to Re_m , which corresponds well to Vortex-Pattern C appearing when $[K.C.]_m$ is about 16.

PRESSURE DISTRIBUTION

1. EXPERIMENT

In the experiment of wave pressure measurements, a wave tank which is 17.5 m long, 1.5 m wide and 75 cm deep was used, in which, a circular cylinder consisting of three parts, as shown in Photo.4, with a diameter of 3 cm and a total length of 85 cm was installed vertically at the position of 9 m and 25 cm apart from the wave generator paddle and the side wall respectively. A very small pressure gauge with a diameter of 2.8 mm shown in Photo.5 was attached to the surface of the middle cylinder part at the position A shown in Fig.9, and its linearity was confirmed to be very well.

Distributions of wave pressure were measured by rotating this cylinder intermittently around the center axis, and then, the water depth h was 40 cm and the measuring point Z_p was 5 cm below still water level. In Table 2, wave height H , wave period T , K.C. number, Reynolds number and the angle of separation point calculated theoretically at the wave phase $t/T = 0.25$ are shown correspondingly to each experimental case.

for wave pressure.

Case	T(sec)	H(cm)	[K.C.] _m	Re _m × 10 ⁻³	θ _s
					(t/T=0.25)
III-1	0.7	3.5	2.6	2.77	147°
III-2	0.7	7.5	5.3	5.80	115°
III-3	1.0	3.8	3.5	2.71	128°
III-4	1.0	8.7	8.0	6.25	106°
III-5	1.5	3.3	4.2	2.21	120°
III-6	1.5	6.5	8.6	4.43	105°
III-7	2.0	3.0	5.1	2.01	115°
III-8	2.0	7.9	13.3	5.30	100°
III-9	2.5	3.0	6.1	1.96	110°
III-10	2.5	6.0	12.5	3.90	100°

2. DISCUSSION OF RESULTS

In the analysis of experimental data, it is assumed that the wave conditions are constant even if the angle of measuring point is changed, and the value of wave pressure at each angle is determined by averaging the data during three cycles of successive waves.

Some examples of pressure distributions around the cylinder at the wave phases $t/T = 0, 0.25, 0.5$ and 0.75 are shown in Fig.10(a) and (b), and correspondingly, time variations of wave pressure at the angles $\theta = 30^\circ, 90^\circ$ and 150° are shown in Fig.11(a) and (b). In each figure, (a) and (b) show the results of Cases III-1 and III-7 respectively.

In Case III-1, Reynolds number is 2770 and K.C. number is as small as 2.6. In this case, flow separation occurs but any wake vortex does not appear distinctly, and therefore, pressure distributions are roughly smooth as shown in Fig.10(a) and time variations of pressure are almost sinusoidal as shown in Fig.11(a), corresponding to the water level variation.

In Case III-7, Reynolds number is 2010 and K.C. number is 5.1. In this case, a pair of symmetric vortices appears and causes local depressions of wave pressure; that is, in Fig.10(b), the pressures at the angles $\theta = 120^\circ$ and 60° are extremely decreased by each wake vortex at the wave phases $t/T = 0.25$ and 0.75 respectively. And moreover, it is found in Fig.11(b) that the time variation curve of wave pressure at $\theta = 150^\circ$ fluctuates near $t/T = 0.25$, which is also regarded as the effect of wake vortices.

It is understood from these examples that wake vortices cause the local depressions of wave pressure and induce the drag force, and moreover, it is considered that if wake vortices neither vanish nor shed soon and remain near $\theta = 0^\circ$ or 180° even when $t/T = 0$ or 0.5 respectively, the inertia force tends to decrease due to their vortices. This phenomenon may occur in the case of Vortex-Pattern C.

CONCLUSION

As a process of making clear the generation mechanism of wave forces acting on a circular cylinder, following the previous study of the water particle velocity in the laminar boundary layer, the characteristics of flow separation, wake vortices and wave pressure have been investigated, and the results obtained are as follows:

1. The separation point of the laminar boundary layer developed by wave motion on the cylinder is mainly varied with the wave phase and K.C. number. When K.C. number is small, apparent flow separation occurs so that the separation point varies quickly in short time. However, when K.C. number becomes large, the variation of separation point with the wave phase becomes more gradual and characteristics of flow separation become similar to those in steady flow.
2. Experimental values of separation point agree well with the theoretical ones in the case when K.C. number is smaller than about 9. However, when K.C. number becomes larger, the difference between both values becomes noticeable by the reason that wake vortices generated before a half period of waves disturb the boundary layer during their reverse shedding.
3. Within the range of this experiment, the configuration of wake vortices is successively transformed from a pair of symmetric vortices to asymmetric ones and finally Karman vortex street with increase in K.C. number. Generally speaking, the configuration of wake vortices is subject to the ratio of the frequency of vortex generation to the wave frequency, which may be determined by K.C. number, Reynolds number and Strouhal number.
4. Wave pressures around a cylinder are affected by wake vortices and the dynamic pressure in addition to the static pressure caused by water level variation. Wake vortices induce local pressure depressions in the wave field as well as in steady flow, and therefore, it is considered that fully developed vortices may cause to not only increase the drag force but also decrease the inertia force.

ACKNOWLEDGEMENT

The authors wish to express their gratitudes to Mr. W. Kioka and Mr. Y. Motoyama for their assistances through the experiments. This work was partly supported by Scientific Research Funds from the Ministry of Education.

CHAPTER 138

CYLINDRICAL CAISSON BREAKWATER: STRAIN MODEL TESTS

Helge Gravesen¹, Finn P. Brodersen²,
Jørn S. Larsen², H. Lundgren³

ABSTRACT

The distribution of *shock pressures on a vertical face breakwater* is so random from one shock to the next that the determination of the *internal forces in a thin-walled reinforced-concrete structure* is difficult even when a large number of pressure cells is used in a model test. Therefore a technique has been developed that allows the direct determination of the internal stresses by means of strain gauges.

The new technique has been applied to a breakerwater consisting of a series of cylindrical caissons. The results show that a strain gauge model is more advantageous than a pressure cell model because of its simpler data analysis and better determination of the quantities required for design.

1. INTRODUCTION

It is well known that *vertical face breakwaters* may be exposed to heavy shock forces of short duration. Such impacts have often resulted in the *sliding* of individual breakwater caissons, see for example Refs. 2 and 8, where the slidings/nonslidings of breakwaters in Japan have been used for the evaluation of various wave pressure formulae. Because of the large inertia of the masses involved in rotation, it is much less frequent that breakwaters have been damaged due to insufficient stability against *overturning*. A third effect of the shock pressures is the production of *internal stresses* in thin-walled caissons of reinforced concrete.

A distinction may be made between *ventilated*, *hammer* and *compression shocks*, see Ref. 5, 6 or 7. While it is advisable by the design of the cross section to avoid hammer and compression shocks, there are many cases where ventilated shocks are inevitable. The development of a ventilated shock is described in Refs. 6 and 7.

The influence of the *geometry of the front face* on the magnitude of the shock forces is described in Refs. 6 and 7, the latter giving ranges of dimensionless coefficients in the formulae for forces and pressures.

¹Senior Research Engineer, Danish Hydraulic Institute (DHI), Agern Allé 5, DK-2970 Hørsholm, Denmark.

²Hydraulic Engineer, DHI.

³Professor of Marine Civil Engineering, Institute of Hydrodynamics and Hydraulic Engineering, Technical University of Denmark, Building 115, DK-2800 Lyngby, Denmark. — Consultant, DHI.

The various *types of caissons* (rectangular, cylindrical, diaphragm, multicellular) are discussed in Ref. 7.

In comparison with traditional rectangular caissons, breakwaters of caissons containing *cylindrical, reinforced-concrete shells* are highly economical structures for three reasons:

- (a) The cylindrical shell is better capable of resisting the wave forces and the pressure from sand fill, resulting in smaller thickness of the outer walls, less cracking, less weight and less steel.
- (b) Transverse walls can be given a larger spacing (diaphragm type) or completely eliminated (cylindrical type), depending upon the method of construction (Ref. 7), thus resulting in smaller weight of the caisson, as well as less concrete and steel.
- (c) The stability is improved because of the delay in development of shock pressures from the front generatrix to the reentrant corner, as described in Refs. 6 and 7. This effect is pronounced in the cylindrical type, but of little importance in the diaphragm type.

Investigations during the last 16 years of breakwaters containing cylindrical shells have also led to a series of *developments in model testing techniques*:

- (1) The first application of large-diameter cylindrical shells to breakwaters was for the Hanstholm harbour, Denmark, for which the model tests took place in 1960 (Ref. 4). While, previously, the forces on vertical face breakwaters had been measured by pressure cells only, the stability of the Hanstholm breakwater was investigated by measuring on the model caisson the *total horizontal and vertical forces*, as well as the overturning moments. In subsequent investigations a three-component strain gauge dynamometer has been used. For the Hanstholm breakwater shock forces could be almost entirely eliminated by the introduction of a *top face sloping 30°* with the horizontal, starting from about still water level (Ref. 4), because at Hanstholm there is little variation of the water level for all western gales.
- (2) The next step in the development of testing technique was a method for *generation of wave trains of natural shape* directly from wave records, thus producing shock pressures in a flume only 15 m long. At the same time a method was devised for the determination of the *re-reflection from the generator* by measuring the energy in the flume during the test. These methods, which are described in Ref. 3, were first used in 1971 in tests for the breakwater of the Brighton marina, U.K. (Refs. 1 and 7).
- (3) Because of the random and complex distribution of shock pressures on cylindrical caisson breakwaters, as much as *20 pressure cells* have been applied in model tests (Refs. 6 and 7), with a view to the determination by computer programs of the internal forces in the shells.
- (4) The stability and strength designs require that the forces and pressures measured in model tests be extrapolated to rare situations as statistical parameters. A method of *statistical analysis* combining the statistics of the wave climate with the statistical distributions of the model data has been developed.

Because of the difficulties of extrapolating complex and random pressure distributions to rare situations, Danish Hydraulic Institute felt the necessity of developing a model technique by which the *strains* (and hence also the stresses), induced in the cylindrical shell by the wave pressures, are *directly determined by means of strain gauges*.

This technique was developed in cooperation with the Institute of Hydrodynamics and Hydraulic Engineering and the Structural Research Laboratory, Technical University of Denmark.

The present paper gives a description of this technique, as well as a comparison between the directly measured internal forces and the forces calculated by a computer program from pressure cell recordings.

2. STRAIN GAUGE MODEL

The model (Figs. 1 and 2) is geometrically similar to the prototype. The model material is *araldite* with $E = 3.2 \text{ GN/m}^2$, which is about twice as much as required for dynamic similarity at a model scale 1:20. This deviation from dynamic similarity is without significance, however, because the inertial forces of the prototype concrete shell are negligible even for the fastest shocks.

Fig. 1 Strain gauge model placed in a 600 mm wide flume

Fig. 2 Strain gauge model (dimensions in mm)

The determination of the *complete stress situation at one point* of the shell requires two rosettes (outside and inside), each containing 3 strain gauges. The rosettes on the outside are embedded so as to give a minimum insulation of 100 MΩ.

The rosettes A-H (Fig. 2) are placed along one vertical line on the cylinder. In order to determine the full stress distribution in the shell, the cylinder is rotated 22.5° between one test series and the next one. For this reason rosettes I-L are mounted at the same level as E in order to give reference time values for the initiation of a shock pressure at the front generatrix.

Normal forces are considered positive as tension in the shell. Bending moments are positive when there is tension on the inside.

Fig. 3 Longitudinal section of the cylinder in the flume

The model has a diameter of 512 mm, a height of 650 mm, and a thickness of 15 mm. It is placed in 350 mm of water (Fig. 3) inside a 600 mm wide flume that is part of a 4 m wide flume (Fig. 4), in which the undisturbed generated waves can be recorded.

Fig. 4 Plan showing cylinder in the 600 mm flume inside the 4 m flume

The median values of the strains recorded in 10 repeated tests at a specified time for a specific shock wave have been calculated for comparison with the stresses computed from the pressure cell model mentioned below. The *standard deviation* is estimated to be about 10%.

3. PRESSURE CELL MODEL

The pressure cell model has the same diameter and height as the strain gauge model. 16 or 14 pressure cells are used. Fig. 5 shows to the left the arrangement of cells for the measurement of shock

pressures around the front generatrix and, to the right, the arrangement determining shock pressures in the corner between two caissons.

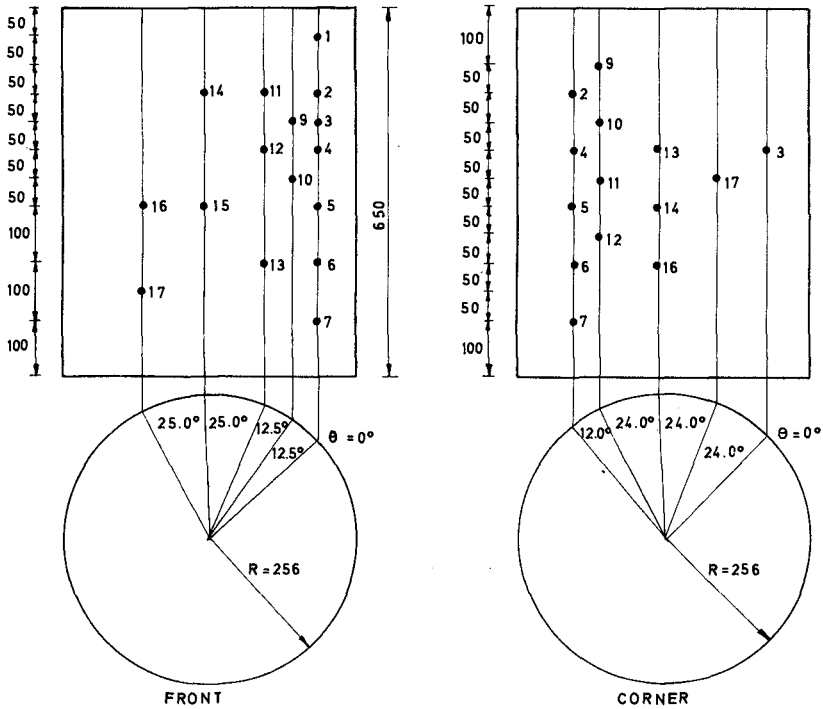

Fig. 5 Pressure cell model

For 10 repeated tests median values of the pressures have been used as input in a *computer program* for the calculation of the internal forces in a circular cylindrical shell of constant wall thickness and elastic material.

The program BAC, developed at the Structural Research Laboratory of the Technical University of Denmark, has been chosen. This program is based upon the development of the load in fourier terms $\cos n\theta$ and $\sin n\theta$ with $n \leq 9$. In the vertical direction the shell is divided into a large number of equidistant horizontal rings. With the use of finite elements in the vertical direction, the program calculates the internal forces (and the deformations) at these equidistant levels.

Because of the limited number of pressure cells and the large gradients exhibited by shock pressures, the actual pressure distribution is poorly defined. In addition, the limited number of terms in the fourier series are unable to give an exact representation of the recorded pressures.

As an illustration of the *approximations involved*, the dotted line in Fig. 6 shows the pressure distribution as defined by pressure cells

spaced 22.5° along the most exposed horizontal section in the model tests for the Brighton marina breakwater (scale 1:22), at a moment where the shock pressure on the front generatrix is particularly high. It will be seen that the maximum fourier series load (the full line) is much lower than the recorded pressure. It is estimated that this discrepancy results in a standard deviation of about 10% for the internal forces.

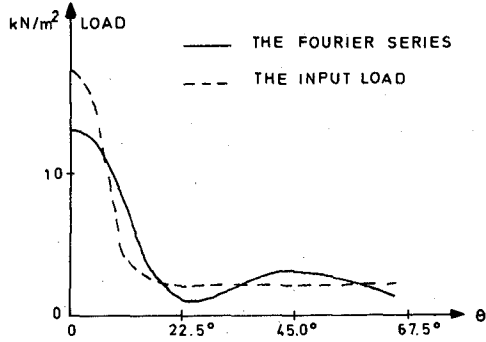

Fig. 6 Shock pressure distribution along horizontal section

Including the large scatter of the pressure distributions in 10 repeated tests, the total *standard deviation* is estimated to be 15% on the median values of bending moments, with a maximum scatter of about 30%.

The fourier series in Fig. 6 represents 10 terms, $n = 0-9$, which give the contributions shown in Figs. 7 and 8, respectively, to the normal force N_θ and the bending moment M_θ in the vertical section through the front generatrix, as well as to the normal force N_x and the bending moment M_x in the horizontal section.

Fig. 7 Forces in vertical section from fourier terms $\cos n\theta$

Fig. 8 Forces in horizontal section from fourier terms $\cos n\theta$

It appears that the values for $n > 9$ would have contributed essentially to the bending moments had the computer program been extended to higher terms. (It may be mentioned that the computational error increases with the order of the term.)

4. COMPARISON OF THE RESULTS FROM THE TWO MODELS

The median values of the normal forces and bending moments are presented in Fig. 9 at the instant when a large shock wave hits the front of the caisson, and in Fig. 10 at the slightly later instant when the same wave hits the corner between two caissons. The results from the strain gauge model are shown as dots, while the forces computed from the pressure cell model appear as full curves.

Fig. 9 Internal forces along the front generatrix

When the two sets of results are compared, the following circumstances should be borne in mind:

- (a) For the pressure cell model the load is defined by a number of cells that is small compared to the irregular variation of the shock load. Between the cells the pressures have been estimated by linear interpolation.

- (b) For the pressure cell model it has been assumed that the load is symmetrical around the plane through the middle of the flume. Because of the sensitivity of the shock pressures to small disturbances, the full curve in Fig. 9 may be slightly incorrect.
- (c) The times chosen for the analysis of data from the two models may not correspond exactly to each other.

The comparison shows large differences between the two models at the most exposed points of the cylinder (level 240 mm in Fig. 9 and level 360 mm in Fig. 10). The discrepancy in the bending moments might be the result of a smaller extent of the highest pressures than inherent in the linear interpolation mentioned under (a) above.

Fig. 10 Internal forces along the corner generatrix

5. COMPARISON OF PRESSURE CELL AND STRAIN GAUGE MODELS

As a result of this investigation it is concluded that a strain gauge model (SGM) is more advantageous than a pressure cell model (PCM). This conclusion is based upon the following comparison of the two techniques:

(a) Construction of Model

A PCM is less expensive than an SGM because the former need to have only the correct outside shape while the latter must be moulded out of a special material of good elastic properties. In addition, the wall thickness of the SGM should not deviate too much from geometric similarity with the final design.

(b) Instrumentation of Model

The acquisition of a large number of pressure cells with amplifiers and equipment for simultaneous recording of many channels is expensive. On the other hand, the same instrumentation may be used for several breakwater projects.

The number of rosette gauges required for an SGM is considerably larger than in the investigation reported in this paper, because the cylinder cannot be rotated due to its structural connection with the neighbouring caissons. Qualified workmanship is a prerequisite for the installation of the gauges. However, the costs of the gauges and their installation add little to the costs of the investigation. Simultaneous recording of 6 channels (two rosettes) is an absolute minimum, because two rosettes are required for the determination of the complete stress situation at one point.

(c) Test Runs

If sufficient pressure cells are available the PCM requires only one test run for a given wave train, while the SGM requires many runs to give records from, say, 20-30 rosettes. The repetitive runs, however, is a matter of routine that can be performed by one technician.

(d) Adequacy of Information

While the SGM gives complete information for the design of the reinforcement at each rosette point, the information from the PCM is insufficient because of the difficulties of defining the shock pressure distributions in connection with the large local pressure gradients. As a consequence of this, the results from the PCM may also depend upon the shell computer program applied, cf. Figs. 7-10.

(e) Data Analysis

For the SGM the analysis of the distribution functions for the strain maxima under the heaviest shocks is relatively simple, cf. Fig. 11 below. Also, the extrapolation to rare situations with due consideration of the wave climate can be done with reasonable accuracy, see Figs. 12-15 below.

For the PCM it does not seem feasible to carry out the stress analysis by computer program for so many load situations that the distribution functions for the stresses at the various points can be determined with sufficient accuracy. Hence, it is necessary to extrapolate the pressure distributions to rare situations and to apply the computer program for a few loads only. Thus, it is hardly possible to take sufficient regard to the wave climate, and the indirect determination of the design stresses may become somewhat problematic.

6. STRAIN DISTRIBUTION FUNCTIONS

For each zero-crossing period T_z and significant wave height H_s , the strains may be assumed to be *exponentially distributed*. The distribution functions have been determined for a number of combinations of T_z and H_s by means of trains of 1000 waves reproduced as described in Ref. 3.

As an example, Fig. 11 shows the distribution functions from one test run for point D on the front generatrix of the cylinder (Fig. 2). The abscissa PN is the so-called *probability number*, i.e. the relative occurrence per wave for which the strains shown are exceeded. The ordinate is the strain with the unit microstrain μS , where $1 \mu S = 10^{-6}$.

For each value of PN the 6 strains plotted are simultaneous values from the records. The strains measured are arranged after the peak order of ϵ_{ho} , i.e. the horizontal strain on the outside of the shell. Thus, the extreme value $\epsilon_{ho} = -22 \mu S$ recorded for 1000 waves is exceeded with a probability number of $PN = 0.55 \cdot 10^{-3}$ per wave, while the next value $\epsilon_{ho} = -21 \mu S$ is exceeded $1.5 \cdot 10^{-3}$ times per wave.

Fig. 11 Strain distribution functions at point D for $T_z = 1.52$ s and $H_s = .134$ m

Except for the inside diagonal strain (under 45°), the arrangement after the peak order of ϵ_{ho} also gives nearly monotonous arrangements of the other simultaneous strains. Thus, the result of this test run may be expressed by the following linear relationships:

$$\text{Outside horizontal strain} = \epsilon_{ho}$$

$$\text{Outside vertical strain} = \epsilon_{vo} = \epsilon_{ho} + 13 \mu\text{S} \quad (1)$$

$$\text{Outside diagonal strain} = \epsilon_{do} = \epsilon_{ho} + 8 \mu\text{S} \quad (2)$$

$$\text{Inside horizontal strain} = \epsilon_{hi} = -1 \mu\text{S} \quad (3)$$

$$\text{Inside vertical strain} = \epsilon_{vi} = (\epsilon_{ho} + 11 \mu\text{S}) \cdot (-0.4) \quad (4)$$

$$\text{Inside diagonal strain} = \epsilon_{di} = +4 \mu\text{S} \quad (5)$$

The fact that the rare strains are not proportional indicate that the shell carries the high shock pressures in different ways, with little variation of the strains on the inside.

7. STATISTICAL STRAIN ANALYSIS

For the design of the shell it is necessary to know the *stress conditions* that are exceeded only once in, say, 100 years, with appropriate choice of the factors of safety for steel and concrete.

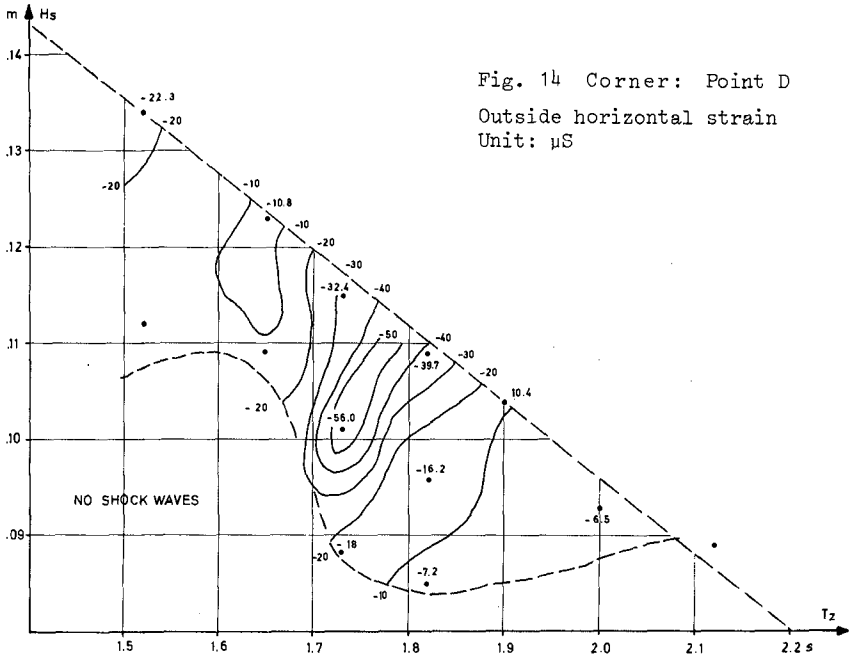

The *purpose* of the statistical analysis of the strains is to find the annual number of waves, ANWS, that exceed various strain values S . If the distribution function ANWS is plotted against S and extrapolated to the value $\text{ANWS} = 10^{-2}$, the corresponding value of S will occur once in 100 years.

In principle, the statistical analysis should be based upon the *probability density function* $p(T_z, H_s, WL, WD)$, i.e. the wave climate expressed as a function of zero-crossing period T_z , significant wave height H_s , water level WL and wave direction WD. Evidently, it is necessary to know the density function only for the larger values of H_s . In addition, if the wave direction deviates more than, say, 20° from the normal to the breakwater alignment, the shock forces are much reduced. Thus, in practice it is usually possible to introduce several simplifications in the complete statistical analysis.

As an *illustration* of the application of the results of the strain gauge model tests, Fig. 12 shows, for $\text{PN} = 0.55 \cdot 10^{-3}$ per wave, the outside horizontal strain ϵ_{ho} at point D along the front generatrix (Fig. 2) as a function of T_z and H_s . (The dotted straight line represents the limitation of wave conditions that could be generated in the flume.)

In order to find ANWS_{ho} as a function of ϵ_{ho} one could consider the areas within the curves where ϵ_{ho} takes the values $-40 \mu\text{S}$, $-50 \mu\text{S}$ and $-60 \mu\text{S}$, respectively. For each of these areas a summation is performed of the density function $p(T_z, H_s)$ for the determination of ANWS_{ho} that exceed the corresponding strains. For this calculation it is useful to know the logarithmic slope of the exponential distribution of ϵ_{ho} , which is plotted in Fig. 13.

After $ANWS_{ho}$ has been found for the three values of ϵ_{ho} mentioned, the approximately exponential distribution function $ANWS_{ho}$ is extrapolated to the value 10^{-2} . The corresponding value of ϵ_{ho} is used for the calculation of the remaining 5 strains by means of linear relationships such as (1) - (5) above.

Figs. 14 - 15 give the statistics of ϵ_{ho} for a corner point, in analogy to Figs. 12 - 13 for a front point.

It will be seen from Figs. 12 and 14 that the highest strain values occur within a rather narrow interval of mean period T_z . Hence, it is an important conclusion of the present investigation that the shock loads seem to depend considerably on the wave period. This result will have a significant influence on the test programs for future projects.

8. DESIGN OF REINFORCEMENT

During heavy shock loads the fine cracks always occurring in reinforced concrete will open (and close again). This phenomenon cannot be represented in a purely elastic strain model or in the calculation by a computer program. Because of the plasticity inherent in the opening of cracks, it is permissible to distribute the reinforcement much more uniformly than indicated by force diagrams such as Figs. 9 - 10.

CHAPTER 139

NEAR-BOTTOM WATER MOTION UNDER OCEAN WAVES

by

Robert A. Grace*

SUMMARY

A two-year ocean experiment involving wave-induced forces on a test pipe mounted on the sea floor [Grace and Nicinski (1976)] involved the measurement of various quantities other than the pipe forces per se. A pair of these involved surface wave characteristics and wave-induced water motion at the level of the pipe centerline but off to one end of the pipe. These wave-kinematics data have been combined, and the results of this work make up this paper in which the emphasis is on the deterministic approach to data interpretation. Presented are comparisons of the velocity and acceleration data with the predictions of Airy and stream function theories plus discussion of the dispersion of the field data. The primary intent of the paper is to suggest to designers of bottom-laid structures, such as pipes, how values of the peak velocity and maximum acceleration of the water motion associated with a non-breaking design wave of specified characteristics can be chosen.

TEST SITE AND WAVE CONDITIONS

A site was chosen on a moderately level area of coral rock bottom 1400 feet from the reclaimed shoreline near Kewalo Basin, the fishing and tour boat harbor for Honolulu, where the water depth was 37 feet. Peak-to-trough tidal variations in Hawaiian waters are in the 1-to-2-foot range, so that the depth can be considered constant for all practical purposes.

We installed at this test site various structures. The major one related to the topic of this paper consisted of a heavy base composed of steel I beams and a wave mast bolted to it. This mast consisted of two parts; the lower one remained vertical and occupied approximately half the water column, whereas the upper one tilted down when not deployed and vertically upwards when a buoyancy chamber mounted permanently on it was blown. Both 3-inch and 2-inch-diameter steel pipe were used in the mast. The graduated upper part of the mast in part resembled the mast of a sailboat. A line over a pulley enabled us to pull the top of a 15-foot-long, wire-wound electrical wave staff to the summit; an acme thread bracket well down the tilting mast portion permitted us to then tighten the staff parallel to the mast. A cable ran from an oscillator at the top of the staff over the water to the project boat where suitable power supply and recording instrumentation were available. The boat, incidentally, was a 31-foot-long catamaran with 12-foot beam, an excellent work platform for our purposes.

A ducted-impeller velocity sensor was attached, by means of U bolts, to a small pipe cantilevered out from the end of the base for the 16-inch test pipe. The sensor was always located 15 inches from the bottom and 38 1/2 inches from

*Professor of Civil Engineering, University of Hawaii, Honolulu, Hawaii.

the end of the test pipe. The latter dimension was a compromise (for the pipe force work) between having the sensor close enough to represent the water motion incident upon the test pipe and yet far enough away not to be influenced by water motion around the end of it. A cable extended from the current meter up to associated d.c. power supply and recorder in the instrument shack on the boat.

We gathered concurrent data for waves and associated water motion on twelve different occasions, and the peak wave height measured overall was about 12 1/2 feet. However, we did encounter waves too big to measure accurately; one of these, a fluke, overtopped everything by quite a margin, severely bent the wave mast even though stiffened by a stout line from its top, and gave us all a fright; another snapped off the whole (repaired) mast at the base, along with all five stays set seaward, and wrote an end to wave-measuring for the remainder of the project.

Our test waves arrived between March and September of 1975 and 1976. The origin of these swells was in the Southern Hemisphere chiefly in the Tasman Sea as well as in the Pacific and Great Southern Ocean east of New Zealand. Swell from the latter source is generally the larger in Hawaii. Measured periods ran from 7 to 19 seconds, but by far the bulk of the observations lay in the range between 12 and 17 seconds.

PAST RELATED WORK

We were by no means the first to carry out at-sea measurements of waves and wave-induced water motion in the sea. Various types of field investigations have been run, and these are typified by Inman and Nasu (1956), Shonting (1967a, b) and Thornton and Krapohl (1974). A considerable amount of laboratory research has also been carried out on wave-induced water motion. Perhaps the most significant of such studies was the work of Goda (1964), and a particularly relevant part of his data, as far as this project is concerned, is shown in Tables 1 and 2. These data were kindly supplied to the writer by Goda for re-working.

The variables shown in Tables 1 and 2 are as follows: \bar{H} is the average and s_H the unbiased standard deviation of a sample of ten ostensibly identical waves of period T ; d is the water depth; g is the acceleration due to gravity; c_{Airy} and L_{Airy} are the wave celerity and wave length predicted by Airy wave theory; $u_{c_{\text{Airy}}}$ and $u_{c_{\text{s.f.}}}$ are the peak horizontal flow speeds under the waves, for a measurement location off the bottom of 0.13 times the depth, predicted by Airy and stream function theories; \bar{U}_c and s_u are the mean and standard deviation of the sample of ten measured peak flow velocities for each wave, and r_{HU} is the product-moment correlation coefficient between measured wave heights and velocities.

Goda's data appear to show clearly that the predictions of the stream function theory [Dean (1965, 1974), Dalrymple (1974)] are too high when long waves are involved. Le Méhauté *et al* (1968) have concluded, on the basis of laboratory experiments, that the Airy theory provides the best estimate of near-bottom peak velocity of a number of classical theories.

BACKGROUND TO DATA

The pulse output of the velocity sensor and the stepped history of the wave staff were recorded on the same d.c. chart recorder. We found it easier to calibrate the staff against the graduated wave mast than by noting readings on the digital readout which was updated at a rate of ten per second. There were various problems with the wave staff but by and large these were compensated for in some way - e.g. by using the staff in a potentiometer arrangement, by reading trough values from the mast in cases when there were aberrations in wave staff behavior, and in reading crest levels from the mast when a particularly large wave went above the top of the staff.

The velocity history, a series of pulses whenever one blade magnet of the three-bladed impeller passed a reed switch enclosure on the side of the duct, was translated into a velocity history as follows. A sequence of between-pulse times was first lightly smoothed. The starting point for the translation of pulse history into a velocity trace was at the shortest interval or intervals within a trough or crest where the steady-state calibration of the sensor should be best represented. The rectangular-area rule was used until the between-pulse time changed. From then on the trapezoidal-area rule was followed - until the last (or first) pulse before (after) the change in flow direction. Points worked forward in time from a trough and backwards in time from a following crest were joined with a smooth curve whose maximum slope provided our best estimate of the peak acceleration under the wave.

The major advantage to the ducted meter is that it works - and one can see easily whether it is working or not. However, one pays a price for this. First, there is the time-consuming translation of the pulse history into a smooth velocity trace as outlined above. A second problem could concern off-angle use of the ducted meter. However, we oriented our meter directly into the approaching swell (as judged by the feel of the water motion and the movement of sand along the sea floor) and so there should be a minimal problem of this nature.

There are mixed emotions about the electromagnetic current meter. Some researchers feel that it is a first-class measuring device and various others are diametrically opposed. On one occasion we borrowed an electromagnetic sensor (spherical) and its owner-operator in order to compare the output of the ducted and electromagnetic types. I mounted these two meters side by side myself. Subsequently, the ducted meter ran perfectly; the electromagnetic meter yielded a trace that was very much in step with the output of the ducted meter but one that had nothing to do with the supposed calibration of the instrument.

VELOCITIES: DETERMINISTIC APPROACH

The comparisons between theoretical and measured kinematics data are shown in Figures 1 through 4. The sample size for the velocity data is 236, for the acceleration data 171.

During the final month and a half of the project, much of the higher velocity information in Figures 1 and 2 was obtained. Before these data were gathered and processed, it appeared that Airy theory provided predictions that were not only very good but also superior to those of the stream function theory. However, it is clear from Figures 1 and 2 that Airy theory tends to underestimate the high speeds while the stream function theory overestimates them. The Airy theory still provides the lower standard error of estimate, s_e (0.43 versus 0.54 fps), for the data, but such a measure of fit is of course biased by whatever data constitute the sample - i.e. high or low speeds.

Even if the data for higher flow speeds (Figure 1) were to lie along the line as for the lower speeds, it is still obvious that the peak flow speed for any particular wave can exceed that predicted by Airy theory by approximately up to 40%. In the past it was suggested [e.g. Grace and Rocheleau (1973)] that a powerful approach to the prediction of extreme peak flow speeds would be to use the Airy theory predictions and then to tack on a probabilistically-chosen residual. It was suggested that the distribution of residuals be considered Gaussian with zero mean and a standard deviation given by 0.007 times the Airy theory celerity of the wave. Although the number 0.007 was based on field work, the same figure applies in an average sense to the data of Goda (1964) in Table 2.

Figure 1 indicates, however, that for ocean swell approaching those used in design the above approach may be unworkable. For this reason, since the stream function theory predictions provide a vague upper boundary for the velocity data (Figure 2), it is suggested that the predictions of this theory be used as the best theoretical estimate of U_{\max} , the value near the top of the distribution for the true peak horizontal, near-bottom flow speed. An alternate approach would be to use 1.4 times $u_{\max, \text{Airy}}$.

ACCELERATIONS

The standard errors of estimate for the acceleration predictions of Airy theory (Figure 3) and the stream function theory (Figure 4) are respectively 0.56 and 0.48 ft/sec². It is clear from the Figures that both theories underestimate \dot{U}_{\max} for the higher waves, a failing of some considerable import in engineering design situations. A line given by the equation $\dot{U}_{\max} = 2.5 \dot{u}_{\max, \text{Airy}}$ provides an upper envelope to the Figure 3 data, and it is provisionally

suggested that non-breaking wave near-bottom accelerations for design (\dot{U}_{\max}^{\max}) be adopted by using this equation when $0.05 \leq d/L_{\text{Airy}} \leq 0.10$.

Graphical differentiation of the near-bottom ($S/d = 0.05$) velocity plots in Iwagaki and Sakai (1970) have resulted in the data shown in Table 3.* There is substantial scatter in these data due to the double-humped nature of some of the waves and conceivably also to the technique used by the researchers in linking forward-flow and rearward-flow parts of the hot film anemometer velocity traces. But it is fairly clear that there is a general tendency for R to grow with increasing d/L_{Airy} and that the numbers obtained largely mirror those found in this field investigation.

VELOCITIES: STOCHASTIC APPROACH

Consider three ocean waves with the same gross characteristics of height, period and water depth. Classical wave theory predicts the same near-bottom peak flow velocity and acceleration for all three waves.

There is virtually an infinity of possible water surface configurations that could exist between vertical constraints (wave height) and horizontal constraints (wave length, inferred from wave period and water depth), and there is no reason to suppose that three real waves of identical gross characteristics would have the same near-bottom maximum flow velocity and acceleration. See Figure 5.

A sample of n waves with the same H , T and d would give n values of U_{\max} and n values of \dot{U}_{\max} . This dispersion can be accounted for with a deterministic wave model either by taking account of the actual surface profile (rare, and not applicable in design) or by using the theoretical prediction as an initial estimate and then adding on a probabilistically-chosen residual as remarked earlier.

The standard modern method for accounting for dispersion, however, involves the use of a probabilistic approach, the so-called Gaussian wave model. An infinity of independent, infinitesimal-mean-square sinusoids is assumed to be propagating in the same direction. A Gaussian distribution then applies to the overall surface wave ordinate; the same probability density function also applies to the (horizontal, near-bottom) flow speeds and accelerations due to the linear relationship between such quantities and the wave ordinate according to the Airy theory which applies to sinusoidal waves.

*Other laboratory data such as those of Elliot (1953) (referenced in Wiegel (1964)), Le Méhauté *et al* (1968) and Tsuchiya and Yamaguchi (1972) do not yield near-bottom accelerations.

3.66	3.40	0.23	0.038	86.3	25.9	3.33

** $R = \frac{U_{max}}{u_{maxAiry}}$

The mean-square spectral density, commonly called the spectrum, of surface wave ordinate displays the absolute amounts of mean-square value contributed by the different-frequency components in the sea surface. Such a measured spectrum can be transformed analytically into one for the near-bottom water particle flow speed by using the (frequency-dependent) Airy theory transformation factor.

In Figure 6 a surface wave ordinate spectrum is presented. In addition, there are two near-bottom flow speed spectra shown, one theoretical and the other measured. It is clear that the theoretical curve has only about half the mean-square content of the measured one; in addition the theoretical peak is about 25% less than that for the measured data. Thus, although the probabilistic wave model yields dispersion, its predictions for relatively shallow water swell are out of line with reality, at least according to our results.

ACKNOWLEDGEMENTS

The National Oceanic and Atmospheric Administration, National Sea Grant Programs, provided the basic funding for this project. Matching funds were provided by the State of Hawaii. I am very grateful for this financial support and for the physical support of the following project members: Henry Ho; Frederick Casciano; Steven Nicinski; Arthur Shak; Wilfred Ii; Elizabeth Leis; Sylvia Khong; Kent Reinhard; Gabriel Zee; Charles Schuster; James Sands; Shepard Williams; Edward Noda; Michael Rayfuse; Joseph Castiel; Edgar Bilderback. Jacques Legrand assisted in processing data from other sources.

CHAPTER 140

WAVE FORCES ON SUBMERGED OBJECTS

by

and

Richard Silvester
Department of Civil Engineering
University of Western Australia

ABSTRACT

Limitations of the Morison equation for computing wave forces on small submerged structures have encouraged the use of dimensionless relationships containing only height, period and water depth. However in dividing the force by the theoretical drag force or inertia force a relationship can be found with the Keulegan parameter ($U_{im} T/D$) over a wide range of conditions and different types of wave. The U_{im} value can be determined from empirical and theoretical data for all depths and wave steepnesses. The relating coefficients for various dimensions and shapes of submerged object are predictable from potential theory or modified slightly because of viscous and such other forces induced by bottom and free surface boundaries.

For computing wave forces on a submerged object which is large compared to the wave length, the Morison equation is replaced by the Diffraction theory. Criteria for selecting the latter theory are presented.

INTRODUCTION

Much work has been carried out in recent years on wave forces exerted on submerged structures (1) (2) (3) (4) (5) (6) (7). Work prior to 1974 has been summarised by Hogben (8). The bodies studied have included cylinders, spheres, blocks and other symmetrical shapes. The more complex units being employed as gravity structures in the oil exploration industry (9) are being equated to these simple forms and also tested individually in flumes (10). There is a dire need to further this work and rationalise the whole procedure (8).

The original achievements in this topic were made by Morison et al (11) whose relationship in equation 1, has been used for a number of decades,

$$F_{Ti} = \frac{1}{2} \rho C_{Di} A_i |U_i| U_i + \rho C_{Mi} \psi dU_i/dt \quad (1)$$

where the symbols are as listed in the notation at the end of the paper.

Equation 1, is the addition of a drag and inertial component, whose validity is being questioned on a number of counts. Apart from the necessary assumption that the object must be small compared to the incident wave length (e.g. D/L small), there are a number of limitations to Morison's approach, as follows:

- (i) the summation infers the addition of two terms that reach their peak at different times during the wave cycle. The proportions of the drag component to the inertial component vary with the wave conditions making it difficult to assess such a maximum force.
- (ii) the velocities and accelerations of water particles must be known in a prototype situation in order to compute the force. These kinematic variables must be calculated from the specified wave characteristics using either linear theory or a more sophisticated approach. It has been pointed out (12) (13) that no theory can presently predict the vertical distribution of water-particle velocities. The linear theory appears to be accurate (14) for $h/L > 0.3$ but for shallower depths an empirical approach will be presented later. There is much more work required to completely solve this problem of velocities and accelerations of fluid particles.
- (iii) each term on the RHS of equation 1, contains a coefficient, the values of which have ranged widely and wildly in the literature (15). This constant, relating force to wave conditions, is specific to the object shape and dimension. Normally linear theory has been employed to determine velocities and accelerations in flume tests. It may be the inappropriateness of this application in the shallower conditions that has caused such confusion in this matter. On some occasions values from unidirectional flow have been applied but more recently (4) tests with oscillating tunnels have produced consistently good results.

- (iv) in spite of the improving quality of coefficient assessment under laboratory conditions, the operative values in complex prototype situations need full-scale verification. Some oil exploration structures are being instrumented for this purposes but some simple full-sized objects need to be installed in the sea and tested, as suggested by Hogben (8).
- (v) the summation in equation 1, does not allow for any interaction of the two terms. For example, the influence of acceleration on the drag force in such a way as to produce a maximum value when the velocity is not at its peak.
- (vi) once the structure assumes proportions that commence to modify the incident wave the Morison equation is no longer valid. This may be due to the member itself being large or adjacent members influencing the water motions. Whilst theory may account for wave scattering at some limiting condition there is a vast transition range in which the wave/structure interaction has not been determined.

Because of the difficulties outlined above some workers have recently by-passed the need for computing the velocity and acceleration, and the concomitant coefficients, by relating the maximum force measured to the basic wave variables of height and period in a specified water depth (1) (7) (16). These have been related by dimensionless parameters which appear to follow consistent curves.

Whilst it is proposed to promote the use of velocity terms rather than basic characteristics of waves the case of objects extending through large proportions of the depth needs special attention. Since different levels of the structure, say a vertical cylinder, are receiving differing pressures it is extremely difficult to integrate them into some peak value. Such integration has been suggested (17) using linear theory but as noted already this does not apply for $h/L < 0.3$ which is normally the case. In this event it is better to relate a maximum measured force to some dimensionless parameter made up of H , T and h (16). This approach has been used by Silvester (13) in his suggested computation of forces on piles, using data and coefficients given by Goda (18).

VARIABLES EMPLOYING VELOCITY

The Morison equation (1) in nondimensionalized form gives

$$\frac{F_{Ti}}{\rho V (dU_i/dt)_m} = C_{Mi} \sin \sigma t + \frac{C_{Di}}{4\pi} \frac{U_{im} T}{(V/A_i)} |\cos \sigma t| \cos \sigma t$$

$$= f_n [C_{Mi}, D_{Di}, \frac{U_{im} T}{(V/A_i)}, \frac{t}{T}] \quad (2)$$

for an inertia formulation; and,

$$\begin{aligned} \frac{2F_{Ti}}{\rho A_i U_{im}^2} &= 4\pi C_{Mi} / \left[\frac{U_{im} T}{(W/A_i)} \right] \sin \sigma t + C_{Di} |\cos \sigma t| \cos \sigma t \\ &= f_n [C_{Mi}, C_{Di}, \frac{U_{im} T}{(W/A_i)}, \frac{t}{T}] \end{aligned} \quad (3)$$

for a drag formulation.

Alternatively, by dimensional analysis factors can be derived which include orbital velocities of water particles. These are

$$\frac{F_{Tim}}{\rho V (dU_i/dt)_m} = f \left[\frac{D}{L}, \frac{U_{im} T}{D}, \frac{U_{im} D}{v}, \frac{U_{im}}{\sqrt{g(h-d)}} \right] \quad (4)$$

for an inertia formulation;

$$\text{or} \quad \frac{F_{Tim}}{\rho A_i U_{im}^2} = f \left[\frac{D}{L}, \frac{U_{im} T}{D}, \frac{U_{im} T}{v}, \frac{U_{im}}{\sqrt{g(h-d)}} \right] \quad (5)$$

for a drag formulation. Relative roughness can also be introduced as an independent variable, as has been done by Sarpkaya (19).

The inclusion of the orbital velocity term, preferably the maximum value (U_{im}) at the centre line of the body, is preferred over the wave parameters for the following reasons:

- (i) the force is directly dependent upon the water motion which varies throughout the water depth in a complicated manner not amenable to any current theory, except linear for $h/L > 0.3$.
- (ii) utilization of the velocity retains a link with other phenomena such as flow separation, vortex generation and wake formation.
- (iii) limits of applicability for drag and inertial terms can be determined, in terms of velocity or amplitude of water excursion proportional to dimensions of the object. This is preferable to ratios of object size to wave height alone which does not consider other conditions such as wave steepness and depth ratio.
- (iv) inclusion of velocity in the dimensionless parameters permits the assessment of Reynolds number ($U_{im} D/v$). This might be disregarded for clear water conditions of $20 \times 10^3 > R_D > 10^3$. However, suspended sediment may so alter the apparent kinematic viscosity in prototype conditions that this parameter may have to be considered. Correlations of Reynolds number with force coefficients have met with little success (5) (20) (21). Only at very high Reynolds numbers

($R_D > 20 \times 10^3$) the drag coefficient shows the trend to decrease with increased R_D , whereas the inertia coefficient exhibits the opposite trend [Sarpkaya, 19].

- (v) the Froude number in equations (4) and (5) ($\frac{U_{im}}{\sqrt{g(h-d)}}$), which includes the velocity term, will influence the force as the object gets closer to the bottom. The effect of e/D on the inertia coefficient of submerged cylinders has been computed from potential flow theory and verified experimentally (3). As the object gets closer to the surface the Froude number, $\frac{U_{im}}{\sqrt{g(h-a-e)}}$, or the ratio $(h-a-e)/D$ are sufficiently sensitive to detect surface effect.

- (vi) the term $U_{im} T/D$ in equations (2) - (5) is commonly called the Keulegan parameter. It is the ratio of drag to inertia force, but is equally the ratio of excursion length ($2\pi\xi$) of the fluid particles in progressive waves to the transverse dimension of the object (D). This has been shown by Keulegan and Carpenter (20) to correlate better with forces averaged over a wave cycle than the other factors in equations (4) and (5). Sarpkaya (4) has displayed a similar correlation for the sphere and cylinder. Even forces on discs (21) can be related to $\frac{dU_i}{dt} D/U_{im}^2$ which is equivalent to $2\pi/(U_{im} T/D) = 1/(\xi/D)$. There is little doubt (22) that this parameter is the dominant variable to which non-dimensional forces should be correlated. Such correlations are illustrated in Fig. 1 for submerged cylinders, where their dependencies are explicitly shown.

WATER PARTICLE VELOCITIES

Any assessment of forces, be they drag or inertial in character, must rely finally on an accurate determination of velocity or acceleration. Tests by Le Méhauté et al (12) have indicated that no single theory predicts the velocity distribution throughout depth as recorded in flume tests. Silvester (13) has placed eleven theories in order of accuracy, as judged by these experimental results, for motions at the surface, still water level (SWL), and the bed. For the latter two, or the main body of water, the modification of the Airy theory by Goda (18) proved closest to the measured data. For surface velocities the solitary wave theory by Boussinesq, as reported by Munk (23), was nearest to experiment. Overall, Goda's empirical formula was assessed number one and Stokes second order theory least accurate. Reference (13) should be inspected to see the order of other theories.

The report by Goda (18) contains results of an extensive series of

flume tests from which maximum horizontal velocity (U_{xm}) at the SWL was listed over a wide range of h/L and H/h ratios. Silvester (14) plotted $(U_{xm})_{SWL}/\sqrt{gh}$ against HL/h^2 and found the points aligned parallel to 1st order theoretical lines of varying h/L . For constant $HL/h^2 = 1$, it was shown that

$$\frac{(U_{xm})_{SWL}}{\sqrt{gh}} = \frac{2}{3} \frac{h}{L} \quad (6)$$

which indicated a complete relationship of

$$\frac{(U_{xm})_{SWL}}{\sqrt{gh}} = \frac{2}{3} \frac{h}{L} \frac{HL}{h^2} = \frac{2}{3} \frac{H}{h} \quad (7)$$

Replotting of $(U_{xm})_{SWL}/\sqrt{gh}$ versus H/h verified equation (7). For greater depths (i.e., $h/L > 0.3$) the 1st order Airy theory matched the experimental data extremely well. This can be expressed, for $HL/h^2 = 1$ as

$$\frac{(U_{xm})_{SWL}}{\sqrt{gh}} = 1.255 \frac{H}{h} \left[\frac{h}{L} \right]^{0.5} \quad (8)$$

Horizontal velocities at the bed were also measured from the vertical distribution graphs supplied by Goda (18). These were plotted as percentages of SWL values and were found to follow the linear theory down to $h/L = 0.14$. For smaller ratios the experimental points deviated below those predicted by linear theory.

It can be seen from equations (6) and (8) for constant HL/h^2 that $(U_{xm})_{SWL}/\sqrt{gh}$ varies only with h/L , as depicted in Fig. 2. The linear theory is shown for SWL and bed elevations, as also the curves from Goda's experiments (18). It is seen that at small depth ratios these two empirical lines tend towards the hyperbolic theory for SWL and bed velocities as given by Iwagaki and Sakai (25). The break from the theoretical curve occurs at $h/L = 0.3$ for SWL values and at $h/L = 0.14$ for bed velocities. Note the maximum for the latter at $h/L = 0.25$. The two scales of HL/h^2 and $(U_{xm})_{SWL}/\sqrt{gh}$ are necessary to obviate wave breaking at $H/h = 0.78$ approximately.

To obtain percentage values of horizontal velocity at other depths a graph of $[U/U_{SWL}]_m$ % was graphed versus h/L . For $h/L > 0.3$ linear theory could be used. For $h/L < 0.04$ the hyperbolic theory (25) could assist. For transitional depths the cnoidal theory as modified by Mejlhede (26) could be of assistance. Smooth transitions from deep to shallow water should be expected for any proportional depths, from which percentages of U_{xm} at SWL as given by equation (7) can be derived. These are contained in the lower parts of Fig. 3 and Table I.

Velocities at levels above SWL are much more dependent on H/h than those within the body of water. Goda's modified Airy theory for maximum horizontal velocity at the crest is

$$(U_{xm})_c = \frac{\pi H}{T} \sqrt{1 + \alpha \left[\frac{H}{h}\right]^{1/2} \left[\frac{Z}{h}\right]^3 \frac{\cosh 2\pi \frac{Z/L}{h/L}}{\sinh 2\pi \frac{Z/L}{h/L}}} \quad (9)$$

where α is a factor dependent on h/L

Z is height from the bed, such that at the crest

$$\frac{Z}{h} = 1 + 0.885 \left[\frac{H}{h}\right]^{1.275} \quad (10)$$

Goda provides graphs for SWL and surface values versus h/L for a range of H/h . Ratios of $[U_c/U_{SWL}]_m$ were obtained and plotted in Fig. 3, and included in Table I. The theoretical curves so derived have been modified slightly from the experimental trends recorded by Goda (18). The two percentage scales in Fig. 3 to the right and left of $h/L = 0.1$ have been used to improve the accuracy of the diagram.

The procedure thus suggested is that U_{xm} at SWL be determined by equation (7), which applies for $h/L < 0.2$. U_{xm} Values at SWL for $h/L > 0.2$ and other depths for all depth ratios can be computed by the percentage values.

Once an acceptable value of U_{xm} is available at any particular level maximum horizontal amplitude $x_m(\xi)$ and maximum acceleration (dU_x/dt) can be determined from linear theory as follows

$$\xi = \frac{U_{xm} T}{2\pi} \quad \text{and} \quad \left[\frac{dU_x}{dt}\right]_m = \frac{2\pi U_{xm}}{T} \quad (11)$$

until suitable modification is suggested from experiment.

Values of vertical maxima of velocity, acceleration and amplitude of water motion, based upon linear theory, are all given by the simple ratio $\tanh 2\pi Z/L$. Table II provides percentages over a range of h/L and Z/h , those at the bed being zero.

The values given in the tables and graphs of this paper will no doubt be refined as further experimental data and theoretical analyses become available, but they are believed to be the closest approximation to this data. It is submitted that the large fluctuations in coefficients of drag and inertia derived from flume tests in the past have occurred due to calculation of velocities etc. from linear theory when this was inapplicable for the depth ratios tested. More recent evaluations by water tunnel tests (4) have provided more consistent and realistic results.

APPLICATION OF PARAMETERS

It has been shown above that Reynolds and Froude numbers can be ignored over a wide range of prototype conditions, leaving the pre-dominant parameters of D/L and $U_{im} T/D = 2\pi \xi/D = 2\pi \left[\frac{dU_i}{dt} D/U_{im}^2\right]$.

It is thus convenient to discuss the application of relevant theories within ranges of D/L and $2\pi\xi/D$.

When $D/L < 0.2$ the diffraction theory gives $C_{Mx} = C_{Mp}$ as from Figs. 4 to 6 for various shapes of objects. This relative size serves as an upper bound value for selecting the Morison equation. On the contrary when $D/L > 0.2$ the incident wave is scattered and the action changes the flow field in the vicinity of the boundary. Though the Morison equation may become unreliable, it does not necessarily call for the application of the diffraction theory because this size factor does not necessarily ensure negligible viscous effects or predominance of inertia. Such condition is gauged from the relative magnitude of the drag to inertia force or the total force to the drag force. This is dictated by the value of the Keulegan parameter above $[U_{xm} T/D = 2\pi\xi/D]$ as seen in Fig. 7.

In this figure can be seen the predominance of inertia when $U_{xm} T/D < 3$. It is in this region that diffraction theory should be used for force calculation. Between 5 and 12 for this parameter both drag and inertial components make up the total drag. It is to be noted that for the same region the phase difference between F_{Txm} and U_{xm} change by 90° due to the alteration in major force. Between 12 and 25 is a transition region to the predominantly drag force condition. Beyond $U_{xm} T/D = 25$ the dimensionless force and hence the coefficient C_D remains essentially constant even though the ratio of drag to inertia increases continually.

In the section (b) of Fig. 7 the actual coefficients C_{Mx} and C_{Dx} are compared with the potential flow value C_{Mp} and the steady flow value C_{Ds} respectively, at similar Reynolds numbers (27). For $U_{xm} T/D < 3$ it can be observed that $C_{Dx} = C_{Ds} = 0$ and that $C_{Mx}/C_{Mp} = 1.0$. At the other extreme of $U_{xm} T/D > 25$ constant coefficients exist, namely $C_{Mx}/C_{Mp} = 0.75$ and $C_{Dx}/C_{Ds} = 1.5$. The major difference in the theoretical and experimental coefficients in the transition zone are to be noted, with maxima or minima at $U_{xm} T/D = 12$ or $\xi/D \approx 2$.

USE OF COEFFICIENTS

By employing only the $U_{im} T/D$ term on the RHS of equations (2) - (5) as independent variable the U_{im} force equation can be written as

$$\frac{2F_{Tim}}{\rho A_1 U_{im}^2} = f\left[\frac{U_{im} T}{D}\right] \quad (12)$$

This is the ratio of measured force to the theoretical drag force at the same U_{im} value. Data of several workers listed in Table III have been utilized according to this equation (12) as in Figs. 8, 9, 10a and 10b. The data have been collected mainly for $U_{im} T/D < 3$ and $D/L < 0.32$ for

different types of objects. Some have been conducted in flumes (6) (19) (28) (29) (30) (31) (32) (33) whilst others have involved the use of tunnels with oscillating flow (4). The measurement of velocity in the latter is direct, whereas in the former it is computed from the wave characteristics through some theory. As already noted this can introduce some error, the magnitude of which varies with both H/h and h/L .

The plots from Figs. 8 to 10 indicate the dimensionless force to vary inversely with $U_{im} T/D$ for small values of this parameter for all shapes of objects used and different wave types. When the relationship in equation (12) is algebraically manipulated it can be written as

$$\frac{F_{Tim}}{\rho V (dU_i/dt)_m} = \text{constant} \quad (13)$$

The constant in equation (13) is then the experimental coefficient of inertia (C_{Mi}) which can be compared with the theoretical potential values C_{Mp} as drawn in Figs. (8) - (10) (and also Fig. 1). Thus the relationship between the dimensionless forces, Keulegan parameters, and inertia coefficient from potential flow theory can be fairly established in this range of $U_{im} T/D < 3$; both for the objects laid on the bottom, $e/D = 0$, and lifted from the bottom, $e/D \neq 0$.

When the cylinder is half a diameter lifted from the bottom as in Fig. 9, $e/D = 0.5$, the inertia coefficient is not deviated much from potential value ($C_{Mp} = 2$ for no boundary effect); but due to bottom effect, $e/D = 0$, C_{Mp} is modified from value of 2 to that of about 3.3.

The relative effect of the free surface is distinctly seen in Fig. 5 for shell structure (35). For half cylinder, Table III indicates that with $(h-e-a)/D > 1.0$ or $(h-e-a)/D > 0.944$ the free surface effect has not come to change the coefficient values (see Fig. 10 b). As the object is nearer to the surface, $(h-e-a)/D < 0.5$, change in value of the coefficient is clearly seen (see Fig. 6).

CONCLUSION

1. Fundamental formulation of Morison equation gives rise to a number of practical limitations mainly confined within the inability to determine accurately the velocity and acceleration of fluid particles.
2. Through interaction of theory and empiricism, means to obtain more accurate velocity is given for all depth ratios and wave steepness.
3. Morison equation is appropriate for computing forces when the size of the submerged object $D/L < 0.2$. The equation is replaced by the Diffraction theory when $D/L > 0.2$ and $U_{im}T/D < 3$.
4. Proper choices of forms of non-dimensional forces and independent variables are shown to give good correlations and links with either potential flow or steady flow, over a practical range of dependent variables.
5. Both the non-dimensional inertia and drag formulations are shown to correlate with the Keulegan parameter well for varieties of object shapes and wave types.
6. Effects of bottom and free surface are found to be relatively influential at $e/D < 0.5$ and $(h-a-e)/D < 0.5$ respectively.

NOTATION

(i) Variables

A	:	projected area
a	:	radius of cylinder or sphere
C	:	coefficient
D	:	diameter of the cylinder or sphere
d	:	submergence depth
d	:	differential
e	:	vertical space between object and bed
F	:	force
g	:	gravitational acceleration
H	:	wave height
h	:	depth of water
L	:	wave length
ℓ	:	transverse length of object
R_D	:	Reynolds number
α	:	factor in equation (9)
T	:	period
t	:	time
U	:	fluid velocity at centroid of object
Z	:	height above bed
ρ	:	fluid density
ν	:	kinematic viscosity
σ	:	wave angular velocity
V	:	displaced volume
ξ	:	horizontal excursion length from mean position
ψ	:	phase difference

(ii) Subscripts

c	:	crest of wave
D	:	drag
M	:	inertia
m	:	maximum
p	:	potential flow
s	:	steady state
SWL	:	still water level
T	:	total
x,z,i	:	horizontal, vertical and any i-directions respectively of forces or coefficients or velocity
y	:	lateral direction

CHAPTER 141

FORCES ON A SPHERE UNDER LINEAR PROGRESSIVE WAVES

Scott A. Jenkins and Douglas L. Inman
Scripps Institution of Oceanography, University of California
La Jolla, California 92093

ABSTRACT

The rms horizontal forces which result from the action of a linear, deep and intermediate water, laboratory scale waves were measured on submerged spheres removed several diameters from the free surface. The study focuses on unseparated flows encountered at small values of (d_0/D) , where d_0 is the orbital diameter and D is the sphere diameter. Under these conditions, a steady streaming around the vertical equator of the sphere was observed, giving rise to a circulation in the sense of rotation of the orbital motion. This phenomena was found to diminish the resultant of the wave pressure on the sphere predicted by potential theory. In approaching the onset of separation, the drag coefficients were found to compare in size with those reported for similar motions in steady unidirectional flow.

INTRODUCTION

Much of the experimental work addressing the problem of wave induced forces on submerged circular bodies have used in-line oscillatory flows; where the motion is simply back-and-forth and $w_{\infty}/u_{\infty} = 0$ (as in Keulegan and Carpenter, 1956; Seymour, 1974; and Sarpkaya, 1975). While the conditions of these experiments may approximate the flows encountered under shallow water waves, it is not clear whether these data are appropriate to the design of offshore structures encountering intermediate or deep water waves, under which the motion is orbital and $w_{\infty}/u_{\infty} = \tanh k(z + h)$, after linear theory.

Previous experiments in which progressive waves have been used to create oscillatory motion (O'Brien and Morison, 1952; and Grace and Casciano, 1969) have involved separated local flow over spheres usually in close proximity to the bottom. Under waves, unseparated motions are a consequence of vorticity being confined by small particle orbits to the immediate neighborhood of the body, when $d_0/D < 1$, despite the fact that large Reynolds numbers may prevail. The unseparated flow regime has not yet received thorough experimental scrutiny, particularly for orbital motion, and this lack of information is critical in the design of submerged structures whose cross-sectional dimension may exceed the amplitude of the water motion.

The following study explores these areas by providing measurements of the wave loads on a smooth sphere which result from the orbital motions under linear, intermediate and deep water laboratory scale surface waves, when the local flow is unseparated.

Force Estimates

Instead of pursuing estimates of the wave force time history, we seek estimates of rms values of the force from Morison's equation as useful "engineering numbers". In this way, the time invariant coefficients of the drag and

inertial terms are physically plausible as time averaged values. With these coefficients, only a spectrum of the free surface is required to establish the relative size of horizontal rms values of the drag to the inertia forces at a given frequency by the following

$$\frac{F_f}{F_m} = \frac{c_f \rho A_0 (u_\infty |u_\infty|)_{\text{rms}}}{c_m \rho V_0 (\dot{u}_\infty)_{\text{rms}}} = \frac{3\sqrt{3}}{8} \frac{c_f}{c_m} \left(\frac{d_0 \text{ rms}}{D} \right)$$

where $d_0 \text{ rms} = H_{\text{rms}} \frac{\cosh k(h-b)}{\sinh kh}$

The anticipated Strouhal dependence arising from a ratio of convective to unsteady inertial terms is equivalent for linear waves to a ratio of the size of the undisturbed particle orbits to the body, (d_0/D). Thus, under the condition for which unseparated motions are found, namely ($d_0/D < 1$), the inertia force appears as the larger component of the wave load.

The inertia force can be estimated with a scattering description under the hypothesis of potential flow for a sphere submerged at least one diameter, D , under linear deep water waves. The inertia force is the resultant of the local wave pressure,

$$F_{mi} = \iint \rho \frac{\partial \phi}{\partial t} n_1 dS$$

where three independent wave profiles combine linearly to give ϕ on the surface of the sphere. The first of these is the undisturbed incident wave, ϕ_∞ . Thus, if $kD \ll 1$, the undisturbed incident wave acts to accelerate the sphere into orbital motion like an equivalent volume of water, and contributes $\rho V_0 \dot{u}_\infty$ to the inertia force, giving a time independent value of unity for the inertia coefficient. However, the undisturbed incident wave cannot alone meet the condition of no flow through the sphere, and so a disturbance, ϕ_s , due to the presence of the sphere is added. This disturbance or scattered wave is determined so that the normal velocity over the surface of the sphere is zero

$$\frac{\partial}{\partial r} (\phi_\infty + \phi_s) = 0 \quad \text{at} \quad r = D/2$$

There is an additional pattern of disturbances, Froude waves, as a consequence of the proximity of the sphere to the free surface. However, if the sphere is at rest, and, if the depth of submergence is taken to be D , where $d_0/D < 1$, then the Froude number is $O(\epsilon d_0/D)^{1/2}$ and it may be verified that any contribution to the force by Froude waves is altogether negligible after first order linear theory due to Havelock (1952) and after complete second order theory due to Kim (1969).

Expanding the spatially dependent parts of the incident and scattered waves into a series of tesseral spherical harmonics, Lamb (1932, art 86 and 106) as,

$$\exp(kz + ikx) = \exp(kr \sin\theta \sin\omega + ikr \cos\theta) = \sum_n \sum_s A_n^s P_n^s(\cos\theta) \cos s\omega$$

yields a scattering formulation which does not rely on the plane wave approximation as for acoustic scattering, or for scattering of surface waves by a vertical cylinder. The orthogonality on a spherical surface of the set of surface harmonics,

$$P_n^S(\cos\theta) \cos s\omega$$

taken with the condition of no flow through the sphere and the radiation condition,

$$\phi = \phi_\infty + \phi_\infty (D/2x)^{\frac{1}{2}} (|\phi_r = D/2|/|\phi_\infty|)$$

as $x \rightarrow \infty$ yields the coefficients, A_n^S , for the incident and scattered waves. These have been evaluated in Havelock¹ (1954) and specify the pressure over the surface of the sphere resulting in the following expressions for the horizontal and vertical components of the inertia force

$$F_{m_x} = \frac{1}{4} \rho g D^2 (2\pi)^{3/2} \frac{H}{2} e^{-kb} (1 + 1/2)(kD/2)^{-1/2} J_{3/2}(kD/2) \sin(-\sigma t)$$

$$F_{m_z} = \frac{1}{4} \rho g D^2 (2\pi)^{3/2} \frac{H}{2} e^{-kb} (1 + 1/2)(kD/2)^{-1/2} J_{3/2}(kD/2) \cos(-\sigma t)$$

Normalizing the amplitudes of the horizontal and vertical components by the amplitudes of $\rho V_0 u_\infty$ and $\rho V_0 w_\infty$ respectively gives the following time independent inertia coefficient for both components

$$c_m = \frac{3}{2} (1 + c_a)(kD)^{-3/2} J_{3/2}(kD/2)$$

where $c_a = 1/2$ and is plotted in Figure 1. When the sphere becomes small in relation to the wave length, c_m is found to converge to 1.5, the value for a sphere in an unbounded uniformly accelerating fluid, and thereby supporting assumptions made in this regard in the early work of O'Brien and Morison (1952). Furthermore the horizontal and vertical components are found to lead the wave profile in time by constant phase angles of $\pi/2$ and π respectively. However, once $kD/2 \gg 1$, c_m becomes small and oscillating as

$$c_m = \frac{g}{4} \sqrt{\frac{2}{\pi}} (kD/2)^{-2} \cos(kD/2 - \pi)$$

for $kD/2 \gg 1$. As a result, the phase of the inertia force relative to the incident wave profile varies rapidly with wave number, since the incident wave is now leaking around a very large obstacle. The lack of a dependence in c_m on the depth of submergence is a consequence of neglecting the effects of Froude waves by limiting the analysis to the case where $b > D$.

If the sphere is subjected to shallow water waves, then $w_\infty/u_\infty^2 \neq 0$ and the acoustic plane wave approximation appears admissible. Scattering of plane waves by a spherical obstacle is treated in Lamb (1932, art no 296) and results in an inertia coefficient which converges in the small body limit, $kD/2 \ll 1$, to 1.5 as

$$c_m = 1 + \frac{2 + (kD/2)^2}{4 + (kD/2)^4}$$

Figure 1. Spherical deep water scattering solution for the inertia coefficient, c_m , after Havelock (1954), where k is the wave number = $2\pi/\text{wave length}$; D is the sphere diameter.

Experiment

The horizontal component of the wave load was measured for polished spheres of 10 cm and 20 cm diameters subjected individually to discrete frequency waves of 0.2, 0.4, 0.6 and 0.75 Hz and heights of 5, 10, 15, and 20 cm, for a total of 32 separate experiments in the 2.5 meter wide wind and wave channel in the Scripps Institution Hydraulics Laboratory. The spheres were situated at mid-depth in 154 cm of water. This choice of experimental parameters limited the investigation to be consistent with the previously stated assumptions and regimes of interest by insuring negligible Froude wave effects ($0.012 < F_r < 0.11$), orbital motion, ($0.24 < w_\infty/u_\infty < 0.93$), and thorough coverage of the regime of small amplitude motion up to the onset of separation ($0.053 < d_0/D < 3.5$). The study however was limited to examination of the small body limit ($0.017 < kD/2 < 0.216$) due to the problem of cross channel waves when attempting to generate waves which are shorter than the sphere diameter in a channel which must necessarily be significantly wider than D .

The measured horizontal force, F , was resolved in the frequency domain into the drag and inertia components of the Morison estimator, \hat{F} , by a harmonic analysis technique adapted from Seymour (1974), involving minimizing the mean squared error in $\langle (F - \hat{F})^2 \rangle$ where

$$\hat{F} = c_1 u_\infty |u_\infty| + c_2 \dot{u}_\infty$$

$$c_1 = \rho C_f A_0$$

$$c_2 = \rho C_m V_0$$

$$\begin{aligned} \langle (F - \hat{F})^2 \rangle = & \langle F^2 \rangle + c_1^2 \langle (u_\infty |u_\infty|)^2 \rangle + 2c_1 c_2 \langle u_\infty |u_\infty| \dot{u}_\infty \rangle + c_2^2 \langle \dot{u}_\infty^2 \rangle - 2c_1 \langle F u_\infty |u_\infty| \rangle \\ & - 2c_2 \langle F \dot{u}_\infty \rangle \end{aligned}$$

If the incident waves are linear, then

$$\langle u_\infty | u_\infty | \dot{u}_\infty \rangle = 0$$

Expressing the covariance and variance in terms of the cospectral and spectral estimates, $\langle xy \rangle = C_{X,Y}$ and $\langle x^2 \rangle = S_X$, and taking $\partial/\partial c_i \langle (F - F)^2 \rangle = 0$, solving for c_1 and c_2 gives

$$c_f = \frac{8 C_{F, u_\infty | u_\infty}}{\rho \pi D^2 S_{u_\infty | u_\infty}}$$

and

$$c_m = \frac{6 C_{F, \dot{u}_\infty}}{\rho \pi 0^3 S_{\dot{u}_\infty}} = \frac{6 C_{F, X}}{\rho \pi 0^3 \sigma^2 S_X}$$

To arrive at c_f and c_m using this scheme each individual experiment was repeated four times during which time histories of horizontal force and free surface elevation were sampled and stored on magnetic tape using an IBM 1130 computer system. As much frequency resolution as possible was desirable. However, a limit of 2048 samples per record was imposed by the 1130 system and a need for as many samples per wave cycle as possible to adequately define the wave profiles led to the compromise of sampling at 20 Hz to allow each run a duration of 102.4 sec and a frequency resolution of 0.0097 Hz. After transforming these time series using Fast Fourier transform routines, the Fourier coefficients for the horizontal particle position required to construct S_X and $C_{F,X}$ were obtained from those of the free surface through phase shifting $\pi/2$ by reversing the cosine and sine coefficients, changing the sign of the cosine coefficient and then multiplying by

$$\frac{\cosh k(h - b)}{\sinh kh}$$

after linear theory. The Fourier coefficients for $u_\infty | u_\infty |$ were obtained by taking derivatives (slopes) of the free surface time series, squaring, and then transforming to the frequency domain. The resulting Fourier pairs representing the square of the vertical velocity at the free surface were then phase shifted by $\pi/2$ as before and attenuated to the depth of submergence as;

$$\left(\frac{\cosh k(h - b)}{\sinh kh} \right)^2$$

The drag and inertia coefficients realized in this way from the principle frequency band of each run were then averaged among the set of quadruplicate runs comprising each separate experiment.

Because this method relies heavily on the average time dependence of u_∞ being zero, care was taken to minimize seiche and reflection in the wave channel by submerging a tethered floating breakwater at the beach end. In addition, only wave forms of small steepness were used, with $0.008 < \epsilon < 0.22$. To minimize generation of a free second harmonic due to the paddle motion, the

paddle throw was adjusted to a flapper mode for the deep water waves and to a semi-piston/flapper mode for the intermediate water waves.

Results of the Force Experiment

An example of the grouped spectra of horizontal force and the free surface when unseparated local flow persists is found in Figure 2, using a 10 cm sphere under a 0.75 Hz, 20 cm wave. The linear character of the incident waves is evidenced by the negligible energy appearing at harmonics above the driving frequency. The second harmonic in the force spectra is two orders of magnitude below the peak at the driving frequency where a phase difference of $\pi/2$ with the free surface is seen, indicating the predominance of the inertia force.

Figure 2. Grouped spectra of the free surface and horizontal force for unseparated orbital motion.

Flow visualization using dye injection from three parts embedded in the spheres at 90° increments around the horizontal equator demonstrated as in Figures 3-5 that the local flow is both laminar and unseparated for $\pi d_0/D < 3.2$. Surprisingly, the dye streaks from the forward and aft ports produced by several cycles of motion show in Figures 3 and 4 a steady streaming close to the surface of the sphere, superposed on the local particle motion, causing a circulation around the vertical equator in the sense of rotation of the orbital motion, despite the linear character of the incident waves. Similarly, dye released from the side port in Figure 5 circulates in multiple cycles as laminar streaming around latitudinal belts in the vertical plane. As $\pi d_0/D$ exceeded 3.2 and the orbits became increasingly flattened the circulation became turbulent as seen in Figure 6, in response to adverse pressure gradients imposed by the wave field prior to each flow reversal. By $\pi d_0/D = 7$ the onset of separation was observed when portions of the dye plume would break away from the sphere at the moment of reversal of the local flow, disrupting the turbulent circulation.

Figure 3. Dye streak produced by two cycles of motion showing circulation proceeding over the top of the sphere at $\pi d_0/D = 3.2$. Waves progressing from left to right.

Figure 4. Circulation carries dye 6 cm in two cycles from rear port towards the underside of the sphere at $\pi d_0/D = 0.32$. Waves progressing from left to right.

Figure 5. Dye spreading in a spiral from the side port towards the vertical equator at $\pi d_0/D = 1.1$. Waves progressing from left to right.

Figure 6. Turbulent circulation carrying dye plume from the rear port around the bottom of the sphere for $\pi d_0/D = 4.0$.

The drag coefficients measured in this investigation were found to vary systematically with the Keulegan-Carpenter form of the Strouhal number as shown in Figure 7. For $\pi d_0/D < 3.2$, the sizes of the drag coefficients were typical of those for unseparated steady unidirectional flow around a sphere at low Reynolds number ($0.6 < R < 25$). In the range $3.2 < \pi d_0/D < 7$ where turbulent circulation was observed, c_f was found to be comparable to values measured for steady unidirectional flow when closed streamlines behind a separation bubble are found for $25 < R < 150$. Indeed the turbulent circulation may evolve as a separation bubble formed near flow reversal and then convected around the sphere under the influence of orbital motion. When $\pi d_0/D > 9$ and the onset of separation is clearly developed the values of c_f measured here are found to compare in size with those reported for a sphere in steady translation with fully separated flow and open-ended streamlines at about $R = 10^4$. The range of Reynolds numbers covered in this study was from 0.5×10^4 to 4×10^4 , based on the amplitude of the horizontal velocity component.

Figure 7. Measured drag coefficients, c_f , against the inverse of the Strouhal number, $u_m T/D = \pi d_0/D$, where u_m is the maximum horizontal particle velocity in the undisturbed wave; T is the wave period and d_0 is the orbital diameter.

The measured inertia coefficients, c_m , Figure 8, defy explanation in terms of the results of the scattering problem. To find the values all less than unity is particularly surprising, and, since the sphere is so small in relation to the incident wave length, the pressure of the undisturbed wave

alone should result in an inertia coefficient of unity. Any scattering of the incident wave would add to this. The circulation, which could not be generated in the absence of viscosity for simple harmonic motions appears to be the only physical explanation for these values.

Figure 8. Measured inertia coefficients, C_m , against $kd/2$.

Circulation Streaming

Nonlinear free-surface effects as considered in Kim (1969) for a submerged sphere do not appear a likely mechanism for generating the circulation observed in this study due to the remoteness of the sphere from the free surface ($3.8 D < b < 7.7 D$) and the small size of the sphere with respect to the incident wave length. Furthermore, the streaming appears most intense near the surface of the sphere. Therefore, the boundary layer does seem a likely mechanism.

Schlichting (1966) has treated the problem of steady streaming as developed by a circular cylinder executing small amplitude oscillations in still water. Photographic evidence of similar streaming near a cylinder due to acoustic waves in air may be found in a paper by Holtsmark, et al (1954). However, the streaming developed by these in-line oscillatory flows does not result in a net circulation because the streaming flows away from the cylinder along the axis in line with the oscillations, and towards it at locations transverse to these oscillations.

Streaming over a flat bottom under the orbital motion of progressive waves, "bottom wind", has been treated in Longuet-Higgins (1953) and shown to be a consequence of the retarding influence of the boundary layer being greater for that portion of the orbit in closest proximity to the wall. Consider, then, in Figure 9, the solid path lines of deformed, closed orbits in the vicinity of a submerged sphere under linear inviscid, irrotational waves when $kd/2 \ll 1$. There is negligible decay in the amplitude of the motion vertically over one sphere diameter, and no net time independent motions result. But if viscosity and the formation of boundary layers is allowed in the model,

then the orbits can no longer remain closed and a "bottom wind" results around the sphere to give rise to a time independent circulation in the sense of rotation of the orbital motion. Considerably more vigorous streaming may be realized around a sphere than over a flat bottom, because in diffracting around the sphere the local velocities and orbital diameters are increased relative to those in the undisturbed field, with diffraction velocities approaching $3/2 u_\infty$ for $kD/2 \ll 1$.

Figure 9. "Bottom wind" around a sphere as a mechanism for circulation streaming.

The streaming velocities around the vertical equator were estimated for each wave condition in the force experiments by measuring the progress of the leading edge of a dye streak for an integral number of wave cycles. The dye was released from the rear port from where it proceeded around the bottom of the sphere and was thus not perturbed by the small diameter sting used to support the sphere from the surface. The circumferential streaming velocity $\langle u_\theta \rangle$, was found to be almost linear with $(d_0 W_\infty / \pi D)$ as shown in Figure 10. At large values of $(d_0 W_\infty / \pi D)$ the streaming was more difficult to measure due to turbulence, but tended to decay and then quickly degenerate with the onset of separation. These results demonstrate that for a given wave height the circulation will be most intense for a deep water wave and diminishes as the wave becomes shallow water in character, and cease altogether once the motion is merely back-and-forth, assuming separation has not yet set in.

With such a circulation added to the diffracting velocity field, the action of fluid inertia must result in a force historically termed as lift, F_L , which acts normally to the instantaneous far field velocity and will therefore rotate through 2π in a wave cycle. Because the circulation is in the sense of rotation of the orbital motion, and because the phase of the inertia force lags the wave profile in space by a constant $\pi/2$ when $kD/2 \ll 1$, the lift opposes the inertia force at any given wave phase as illustrated schematically in Figure 11. Because the streaming is generated at the top of the ac boundary layer, $O(\nu/\sigma)^{1/2}$, it is assumed that the Kutta-Joukowski theorem is appropriate to estimate rms values of the horizontal

component of lift. This presupposes that the streaming velocity $\langle u_\theta \rangle$, decays as $(1/r)$ and this has not yet been verified. In addition, the circulation distribution from the vertical equator to the sides transverse to the waves must be specified. The expanding spiral shaped dye streak issued from the side port in Figure 5 show that the streaming diminishes towards the sides of the sphere. If an assumption of solid body rotation is applied to the region within the vortex tube which results from the circulation around the vertical equator, then the streaming velocity $\langle u_\theta \rangle$, decays from the vertical equator to zero at the sides as $\cos\omega$. The rms value of the horizontal component of lift can then be estimated from only knowing the streaming around the vertical equator, $\langle u_\theta \rangle$ and from $w_{\infty rms}$ by

$$F_{l rms} = \frac{2}{3} \rho \pi D^2 \langle u_\theta \rangle (w_{\infty})_{rms}$$

where the vertical motion gives rise to the horizontal component of lift. Because the horizontal component of F_l opposes the horizontal component of the inertia force, its rms values can be normalized by $\rho V_0 (\dot{u}_{\infty})_{rms}$, and then added to the measured values of, c_m in Figure 6, thereby subtracting the viscous effects due to circulation to give apparent inviscid values for the inertia coefficient plotted in Figure 12. Many of these values are comparable in size with the expectations of the scattering solution. However, due to the approximations in computing $F_{l rms}$, these are presented here only to illustrate that the circulation can augment the inertia force at least to an extent that can account for the very small values of c_m measured in this study.

Figure 10. Streaming velocities $\langle u_\theta \rangle$, measured around the vertical equator of the sphere against $(d_0 w_\infty / \pi D)$ where w_∞ is the amplitude of the vertical particle velocity in the undisturbed wave. Velocities are expressed in units of cm/sec.

Figure 11. Phase relationships between drag, F_f , the inertia force, F_m , and lift, F_l , relative to the wave profile when a circulation, Γ , in the sense of the orbital motion is present.

Figure 12. Apparent inviscid inertia coefficients, c_m , obtained by correcting measured values of c_m for the horizontal component of lift.

Conclusions

Even when the gross viscous effects associated with separation are avoided, the smaller viscous effects which prevail in unseparated orbital motion and give rise to circulation streaming are sufficiently important to render potential theory as a rather poor description of the problem of forces induced by linear progressive waves. Because the circulation phenomena cannot be accounted for by in-line oscillatory flow, such studies are inappropriate to the design of circular members which exceed the amplitudes of the motions under deep and intermediate water waves.

Symbols

A_n^s	solid harmonic coefficient
A_o	frontal area of a sphere = $\pi D^2/4$
b	depth of submergence
c_a	added mass coefficient
c_f	drag coefficient = constant in the time domain
c_m	inertia coefficient = constant in the time domain
C_{xy}	cospectral estimate
D	sphere diameter
d_o	orbital diameter in the undisturbed wave
F_f	drag force
F_l	lift force
F_m	inertia force
F_r	Froude number = u_ω/\sqrt{gb}
\hat{F}	Morison estimator
g	acceleration of gravity
H	wave height
h	water depth
$J_{n+1/2}$	Bessel function of the first kind and half odd integral order with argument = $kD/2$
k	wave number
n_i	direction cosine

P_n^s	Legendre function of order s and degree n with argument $= \cos \theta$
r	radial coordinate
R	Reynolds number
s	order
S	spherical surface area
S_x	spectral estimate
t	time variable
V_0	volume of the sphere $= \pi D^3/6$
u_∞	horizontal particle velocity in the undisturbed wave $= \partial \phi_\infty / \partial x$ at the depth of submergence of the sphere
\dot{u}_∞	horizontal particle acceleration in the undisturbed wave at the depth of submergence of the sphere
u_θ	circumferential velocity component
V_0	volume of the sphere $= \pi D^3/6$
w_∞	vertical particle velocity in the undisturbed wave, $= \partial \phi_\infty / \partial z$ at the depth of submergence of the sphere
x, y, z	Cartesian coordinates with the x -axis in the direction of wave advance, the y -axis transversely, and the z -axis positive upwards
Γ	circulation
ϵ	wave steepness $= kH/2$
ϕ	local velocity potential $= \phi_\infty + \phi_s$
ϕ_∞	velocity potential of the undisturbed incident deep water waves $= (H\sigma/2k) \exp(kz) \sin(kx - \sigma t)$
ϕ_s	velocity potential of the scattered wave
ρ	fluid density
σ	radian frequency $= 2\pi/\text{wave period}$
θ	angular coordinate in the xz plane
ω	angular coordinate in the xy plane
$ $	absolute value
$\langle \rangle$	time average

CHAPTER 142

NEW DESIGN PRINCIPLES FOR RUBBLE MOUND STRUCTURES

by
Per Bruun and Ali Riza Günbak
The Norwegian Institute of Technology

Abstract

This paper describes the effect of wave period on the stability of rubble mound breakwaters. Introductorily wave run-up and run-down on smooth slopes and on rubble mounds were measured, and breaker types were observed and recorded for different incoming wave and slope characteristics. The surf similarity

parameter, $\xi = \frac{tg\alpha}{\sqrt{H/L_0}} = \sqrt{\frac{g}{2\pi}} \cdot \frac{tg\alpha}{\sqrt{H}} \cdot T$ was found practical for

description of breaker type, run-up and run-down on both smooth and permeable slopes. Pressure measurements along the smooth slopes and in the core of a rubble mound were undertaken with two different core materials. It was shown that the most dangerous condition for the stability of rubble mounds occurs at the so-called "resonance condition". Resonance refers to the situation that occurs when run-down is in a low position and collapsing-plunging wave breaking takes place simultaneously and repeatedly at or close to that location. This corresponds to a range of ξ values in between 2 and 3. Photographic instrumentation was introduced and tested to quantify the initial damage on a rubble mound.

This paper is a 1/3 abstract of a thesis for the Dr. Eng. degree by Ali Riza Günbak.

WAVE PROPAGATION TOWARDS A SLOPING STRUCTURE

GENERAL

Waves that propagate from deep water towards a beach will change characteristics due to shoaling. If the beach slope is not very mild and the deep water wave steepness (H_0/L_0) is not too small, the wave will finally break somewhere on or in front of the beach. The condition before breaking is called the "non-breaking wave" condition; the condition at the point of breaking is the "breaking wave" condition, and the condition towards the shore is the "broken wave" condition. In this paper only waves that are "non-breaking" until they reach the structure are studied.

TYPES OF BREAKERS REFLECTION

The main types of breakers are described by Galvin (20) as "collapsing", "plunging" and "spilling". For a fixed slope, breakers will change form from collapsing towards spilling as steepness increases. Battjes (3) described the transition from one breaker type to the other on smooth slopes based on Galvin's data. Using the so-called "offshore surf parameter",

$$\xi_0 = \frac{\text{tg}\alpha}{\sqrt{H_0/L_0}} \quad \text{breaker types and limiting criteria are listed}$$

below:

<u>Breaker Type</u>		<u>Limiting Criteria</u>
Surging or Collapsing	if	$3.3 < \xi_0$
Plunging	if	$0.5 < \xi_0 < 3.3$
Spilling	if	$\xi_0 < 0.5$

Replacing ξ_0 by ξ_b the surf parameter defined as $\xi_b = \frac{\text{tg}\alpha}{\sqrt{H_b/L_0}}$

one has:

<u>Breaker Type</u>		<u>Limiting Criteria</u>
Surging or Collapsing	if	$2.0 < \xi_b$
Plunging	if	$0.4 < \xi_b < 2.0$
Spilling	if	$\xi_b < 0.4$

These breaker types are shown in Fig. 1, from which it is seen that the distance between the breaker point and the mean water line varies. Battjes (3) estimated this distance (x_b) roughly as

$$\frac{x_b}{\frac{1}{2}T\sqrt{gd_b}} \cong 0.8 \xi_b^{-1} \quad (1)$$

where $x_b = d_b \cot\alpha$ and $H_b = d_b$ (shallow water).

Observations (3) showed that this estimate was qualitatively correct, but quantitatively about 20% higher than experimental values.

The reflection coefficient, $r = \frac{H_r}{H_1}$ is given for waves breaking on a slope ($\xi < 2.5$) as:

$$r = 0.1 \xi^2 \quad \text{where} \quad \xi = \frac{\text{tg}\alpha}{\sqrt{H/L_0}} \quad (2)$$

and H is the incoming wave height in front of the structure. For non-breaking waves, r can be taken as one.

RUN-UP IN RELATION TO TYPE OF BREAKING

Theoretical run-up calculations for breaking waves mainly investigate the behaviour of a bore on a slope. Most of the theories (15, 26, 57) describe the breaking phenomenon by a non-linear long wave theory. In this respect they use the method of characteristics for integration which was first introduced by Stoker (52).

According to the above-mentioned theories, the height of a bore approaches zero near the water line, and run-up starts beyond this level. The highest run-up that can be obtained corresponds to the velocity head $R_u = \frac{u^2}{2g}$ of the flow at the water line when the bore is at that point.

Theoretical investigations by Daubert and Warluzel (15) showed that run-up on a dry slope by the first incoming wave is higher than run-up for the following waves, which run up against down-rushing water from the preceding wave. This is in agreement with experimental results (24).

The run-up theory for bores refers to the situation for a fully developed bore. It is not concerned with an intermediate phase in the form of a spilling breaker, which occurs on mild slopes. This intermediate phase is given by Le Méhauté's "Non-Saturated Breaker Theory" (38). It is based on a semi-theoretical account of the energy balance for a spilling breaker. This theory includes the friction (f) and bottom slope characteristics (s) where it is assumed that:

$$f = 14.6 \frac{n^2}{d^{1/3}} \quad n = \text{Manning Coefficient} \approx 0.02$$

$$d = \text{Water Depth (ft)}$$

$$s = \text{bottom slope}$$

With the above assumptions it is concluded that:

1. If $s < 0.37 f$, waves never break. All energy is dissipated by bottom friction and no run-up takes place.
2. If $0.37 f < s < 0.37 f + 0.01$, waves break as spilling breakers, and the rate of energy dissipated by the breaker increases as the bottom slope increases. All the wave energy is dissipated before the waves reach the beach. There is practically no run-up. Wave set-up, however, occurs as a result of mass transport and momentum in the breaker. The set-up can be calculated by the available methods (5, 42).
3. If $s > 0.37 f + 0.01$, a fully developed bore occurs. The run-up may be calculated by means of run-up theories for bores (15, 26, 38, 57).

Run-up of breaking waves may be evaluated by the method of characteristics (52). To obtain a solution, many assumptions, including the initial bore characteristics, must be made.

Long mathematical calculation procedures are needed for each incidental case, and they do not provide a direct method for calculating run-up on a slope from the properties of swells far from the shore. Empirical calculations of run-up of breaking waves are therefore usually preferred. The change of wave characteristics from deep to shallow water, needless to say, should be considered in calculating the wave height occurring before run-up (21, 33, 41, 56, 58).

UPRUSH OR UPRUN

Investigation by Inoue (30) on smooth slopes, demonstrated that $\frac{R_u}{H_0}$ maximizes when the value of $\frac{d}{H_0}$ is approximately one, which means that wave breaking may take place at the toe of the structure or right in front of it (21). Fig. 2 is a characteristic result by Inoue (30) demonstrating the effect of water depth on wave run-up, which increases with decreasing $\frac{d}{H}$ until it equals about 1.

The effect of water depth on wave run-up was investigated by Saville (13), who concluded that the depth effect is negligible when $\frac{d}{H} > 3$ for all steepnesses. Hunt in (28), using the available experimental data on wave run-up, gives an empirical equation for calculation of run-up on continuous smooth slopes for waves breaking on the slope,

$$\frac{R_u}{H} = \left(\frac{2.3 \operatorname{tg} \alpha}{\sqrt{H/T^2}} \right)$$

where H is the incoming wave height in front of the structure in feet. Using the ξ parameter the above formula reduces to

$\frac{R_u}{H} = \xi$ for $\xi < \xi_{br} = 2.3$. Fig. 3 relates Hunt's formula to various experimental results.

Battjes and Roos (4) conducted experiments on smooth slopes $\left(\frac{1}{3} < \cot \alpha < \frac{1}{7}; 0.54 < \xi < 1.97 \right)$. They found the following expressions: Maximum velocity

$$V_{\max} = \sqrt{gh} (0.5 \text{ to } 0.75) \xi \text{ for } \frac{x}{\sqrt{HL_0}} < 0.6 \quad (3)$$

Average run-up front velocity above SWL

$$C = gH \cdot 0.6 \xi^2 \quad (4)$$

Run-up time

$$t_u = T \cdot 0.7 \xi^{-1/2} \quad (5)$$

where x is defined in Fig. 4.

Regarding uprush on slopes with friction elements, the reader is referred to (8) and (54).

Permeability decreases wave run-up relative to smooth impervious slopes. The effect increases as the slope angle decreases and the relative run-up (R_U/H) increases with increasing ξ values. The trend of the increase is getting milder with higher ξ values. Savage's (45) results contradict the above conclusion, but his results referred to beaches with uniform grain size and not to a typical breakwater slope

Uprush on composite slopes is dealt with in ref's. (8, 10, 24, 28, 46, 47, 54). Wave set-up and set-down both have minor effects on run-up/run-down, as mentioned later (3, 16, 29, 40, 48).

DOWNRUSH OR RUN-DOWN

Run-down (R_D) is defined as the vertical distance between the SWL and the water level at the lowest point of water recession on the slope. It can therefore be positive as well as negative. A positive quantity of run-down means that run-down cannot be completed. The slope is continuously under water below SWL, and the run-up meets the water which remained from the previous run-down and accordingly decelerates considerably. The importance of different run-up/run-down conditions on the beach formation has already been shown by Kemp (35, 36), who also measured uprush and downrush velocities (37). Semi-theoretical approaches to down-rush velocities are mentioned in ref's. (6, 7, 9). Battjes and Roos (4) conducted experiments for wave run-down on smooth slopes. ($\text{Cot}\alpha = 3.0, 5.0, 7.0, 10.0$) ($0.02 < H/L_0 < 0.03$). The above experiments refer to waves breaking on the slope. ($0.3 < \xi < 1.9$). They define run-down:

$$R_D = R_U(1 - 0.4 \xi) \quad (6)$$

From the above-mentioned it is known that breaking occurs for $\xi < 2.3$. For $\xi = 2.3$, R_U is always positive. This means that if the above formula is applicable for all ranges of breaking waves ($\xi < 2.3$) on smooth slopes, then run-down cannot be completed in full for the waves breaking on the slope and run-up and run-down are always going to interact above SWL. The existence of the above flow condition is analysed by assuming the movement of a water mass along the slope under the action of the gravity only. With such an assumption one has (fig. 4):

$$\sqrt{H} \overline{L_0} / \cos\alpha = 0.1 \cdot g \cdot \sin\alpha \cdot t^2$$

Using $L_0 = \frac{g}{2\pi} T^2$ one obtains,

$$\frac{t}{T} = \sqrt{\frac{1}{\pi} \cdot \frac{1}{\cos\alpha} \cdot \frac{1}{\sqrt{\xi}}}$$

Assuming that $\cos\alpha \approx 1$, which is true for slopes less than 1 in 3 with an error of maximum 5%, one has:

$$\frac{t}{T} = 0.564 \xi^{-\frac{1}{2}} \quad (7)$$

Equation (7) gives the relative time of travel of a water particle from the maximum run-up position, down to SWL. Therefore this is the shortest time that run-down can reach SWL. Equation (7) predicts the run-up time experimentally. For regular waves, the relative time t_1/T left for the wave front to retreat back down to SWL without interacting with the new run-up is then:

$$\frac{t_1}{T} = 1 - \frac{t_u}{T} = 1 - 0.7 \xi^{-1/2} \quad (8)$$

From equations (7) and (8) it may be noted that on smooth slopes, for $\frac{t}{T} > \frac{t_1}{T}$ run-up and run-down always interact above SWL. Actually during run-down, pressure forces and boundary resistance will all retard the run-down. Therefore, the question of interaction of run-down and run-up for breaking waves on smooth slopes ($\xi < 2.3$) remains to be checked experimentally.

Fig. 5 shows the variation of run-up and run-down with ξ on Dolos covered rubble-mound breakwater slopes. The data is taken from ref. (25) for 1/73.7 scale model tests. Although there is scattering of data in fig. 5, it shows a trend of increasing run-up values with increasing ξ values. If a regression line is drawn from these data, run-up will become nearly constant for high ξ values ($\xi > 4.0$).

Run-down also increases with increasing ξ values and becomes nearly constant at high ξ values ($\xi > 4.0$). Data in fig. 5 show higher run-down values for $\text{Cot}\alpha = 3.0$ than for $\text{Cot}\alpha = 2.0$ at the breaking range when $\xi < 3.0$. This may be due to the fact that the water running up and down on the 1 in 3 slope travels a longer distance than on the 1 in 2 slope. This may cause a higher possibility of penetration of water deep into the breakwater body and will therefore cause deeper run-down on the 1 in 3 slope.

Fig. 6, 7, 8 and 9 show the relative run-up and run-down variation with ξ on a permeable breakwater slope of 1 in 1.5. Data are from Dai & Kamel's tests (14) on rough quarrystones, smooth quarrystones, rough quadripods and smooth quadripods. It should be noted that these data were obtained on three different model scales. All data are included in the above figures. The water depth to deep water wave height ratio (d/H_0) is not always > 3.0 and run-up and run-down is as indicated above affected by depth. Although the above-mentioned may cause increase of the scatter (data are only available for $\xi > 2.0$), the general remarks made for run-up and run-down on rubble-mound breakwater slopes with increasing ξ values hold qualitatively for these data.

Based on the above review it may therefore be concluded that relative run-up (R_u/H) and relative run-down (R_d/H) on rubble-mound slopes show a trend with ξ values for $d/H_0 > 3.0$. Both increase from spilling breakers, towards plunging, collapsing and surging breakers and assume approximately a constant value for surging breakers when $\xi > 4.0 - 5.0$.

THE STABILITY
OF RUBBLE-MOUND BREAKWATERS

GENERAL

Today, the most frequently used formula for breakwater design is the Irribaren formula which was modified by Hudson (27) and given by:

$$W = \frac{\gamma_r H^3}{K_D \left(\frac{\gamma_r}{\gamma_w} - 1 \right)^3 \text{Cotg} \alpha} \quad (9)$$

where

$$\begin{aligned} \gamma_r &= \text{specific weight of stone} \\ \gamma_w &= \text{specific weight of water} \\ \frac{1}{K} &\sim K_D = \text{stability coefficient} \end{aligned}$$

Its popularity comes from the extensive tabulation of the K_D values by scale model tests. They are given for regular waves, for no overtopping conditions and for certain specific breakwater cross-sections. Much criticism has been raised against this formula and its background (1, 2, 9, 10, 11, 18, 19, 20, 21, 22, 23). Ref. (55) states that different laboratories in the world list different K_D values for determining the initial damage. These differences are caused by lack of consideration to the effects of water depth, porosity of and friction between units and to the fact that tests were conducted at different ranges of these parameters. Ref.'s (10, 11) give a detailed analysis of the effect of porosity and friction on the stability of rubble-mounds. Due to the scarcity of data and the wide range of variables, it is not possible at this time to give quantitative figures for these parameters.

Accepting the hydrodynamic nature of the phenomena (flow causing drag and inertia forces), it is not logical to ignore the different flow characteristics occurring on the breakwater by assuming a constant stability coefficient K_D for the whole range of wave periods. Therefore a hypothesis was developed which includes the effect of wave period on the stability, using the knowledge of flow characteristics explained above.

THE IMPORTANCE OF WAVE PERIOD ON THE STABILITY OF SLOPES

The importance of wave period on the formation of beach profiles was, as already mentioned, investigated by Kemp (35, 36) who found that "the phase-difference was the dominant factor in the relation between waves and geometry of beach profile". He defined the phase-difference as the ratio of the run-up time (t_u) to the wave period (T). The run-up time (t_u) has a different meaning than the one used here. It is defined as the time needed for the water front to advance from the breaking

point up to maximum run-up. Kemp also mentions the occurrence of vortexes at the sea bottom due to the interaction of run-down water with the incoming breaker (fig. 3 of ref.(35)).

His experiments showed that for low phase differences ($\frac{t_u}{T} \leq 0.3$) a step profile and for high phase differences ($\frac{t_u}{T} \geq 1.0$) a bar profile developed. A transition from step to bar profile exists when t_u/T is in between 1.0 and 0.3.

Bruun in (10) and (11) compares step profiles from beaches with stabilized breakwater profiles. The stable breakwater profiles are cross-sections of some prototype breakwaters which finally obtained a stable cross-section. The step beach profiles are taken from experimental data and converted to prototype scale using model laws. From comparisons it is concluded that a stable breakwater profile assumes a cross-section similar to a step profile of a beach. This together with Kemp's results brings out the fact that flow characteristics affect breakwater stability, and a phase difference smaller than 1.0, as defined above, is responsible for the stable breakwater profile.

Sigurdsson (50) measured slope parallel and normal forces using spheres as armour units. His tests were performed on 1 in 1 and 1 in 3 slopes. From his measurements Sigurdsson categorizes the forces acting on the armour units based on different flow conditions as shown in table (1) in reference to fig. 10.

TABLE (1) CLASSIFICATION OF HYDRAULIC FORCES

Force Category	Resulting Extreme Values			
	Parallel Maximum	Force Minimum	Normal Maximum	Force Minimum
Incipient breaker preceded by outflow	x		x	
Incipient breaker preceded by backflow	x		x	
Flow into the breakwater				x
Flow out of the breakwater		x	x	
Changes in the buoyancy force	x	x	x	x
Impact	x	x		x
Uprush	x			
Backflow		x		

The following is part of his conclusion:

- i - "The most important hydraulic forces occur under the toe of an advancing breaker or when water is flowing out of the breakwater".

- ii - "The lowest level of wave retreat is an important factor in determining the distribution of hydraulic forces with depth".
- iii - "Considerable impact forces occur when the breaker front strikes the capstones in a rubble-mound breakwater. These forces are directed upward and parallel to the breakwater face. They are strongest for flat breakwater slopes".

Sandström (44) conducted experiments similar to Sigurdsson's. His tests were run for constant wave height of $H = 7$ cm, with wave periods of $T = 0.8$ sec and $T = 1.0$ sec. The steepest test slope was 1 in 1.5. This corresponds to a ξ value lower than 3.15 which indicates that for continuous slopes wave forces occurring with plunging breakers were relatively close to resonance, and the plunging breaker hit a barren slope. Sandström also mentions maximizing of normal forces on armour units below SWL due to the sudden turning of the flow resulting from the interaction of the run-down with the incoming breaker. For armour blocks above SWL run-up is more decisive for slope gradients 1 in 3 and 1 in 4.

Hedar (23) expressed this much earlier and insists that breakwater stability is different for run-up and run-down. He introduced two stability equations for the two different phases of flow. Analysis of his formulae together with the given experimental coefficients show that the design for slopes steeper than 1 in 3 must be based on the run-down formula.

Carstens et al (12), from their experiments with regular waves, showed a relation between wave run-up and the stability of rubble-mound breakwaters. Run-up and run-down, however, are closely related.

RESONANCE CONDITION

The resonance phenomenon was first mentioned in ref.'s (10,11). On page 20 of ref. (10) the occurrence of this phenomenon is defined: "Such a situation may occur if the uprush-downrush period or what may be termed the downrush period is equal to the wave period, assuming that downrush is at its lowest position at the toe of the breaking wave so that every downrush meets a breaking wave at the lowest position of the downrush." It was indicated that, at resonance, the hydrostatic pressure from the core structure would also be maximized causing uplift forces on the armour blocks. Attempt was not made to define resonance condition more specifically in terms of structure and wave characteristics.

With reference to fig. 11 the time history of the wave front along the slope above still water level (SWL) is drawn. Three different conditions may occur in all ranges of slope and wave characteristics, in other words, in all ranges of ξ .

Fig. 11a shows the condition at which run-down will never come below SWL, and run-up and run-down always interact above SWL. This condition occurs for $\xi < 1.60$. This range of ξ values includes plunging and spilling breakers. On rubble-mound slopes the condition described in fig. 11a may only occur at ξ values much lower than 1.60, due to permeability.

Fig. 11b represents the interaction of run-up and run-down at SWL. On smooth slopes this corresponds to a ξ value of 1.60 or somewhat higher. On permeable slopes this will be a much lower ξ value (fig.'s 5-8). Fig. 11c demonstrates how run-down may reach below SWL. It may then be completed before the arrival of the next wave, or it may interact with the run-up below SWL. On smooth slopes this corresponds to $\xi > 1.60$. Fig. 11d gives the description of the resonance condition as defined above, in terms of time history plots where point "B" refers to the breaking point and the dotted line shows the wave profile at the maximum run-up position. In this study, the breaking point refers to the point at which the wave front becomes vertical as shown in fig. 11d.

From the above-mentioned, it is known that waves break when $\xi < 2.5$. This, together with the above deductions, restricts the resonance condition to the range of $1.60 < \xi \leq 2.5$ for smooth slopes and to $\xi \leq 2.5$ for permeable slopes.

Analysis of fig.'s 5-9 shows that run-down on rubble-mounds does not reach its maximum value at $\xi \leq 2.5$. Therefore, the earlier definition of resonance had to be changed to "the condition that occurs when run-down is in a low position and wave breaking takes place simultaneously and repeatedly at that location". The verification of the above definition and its point (range) of occurrence in the ξ spectrum, referring to smooth and permeable slopes, was looked further into by experiments.

The importance of "resonance" is its relation to maximum forces on sloping structures. This is due to the kinematic conditions occurring below the breaker causing lift forces. Strong drag and inertia forces also occur on the armour blocks due to the high run-up and run-down and the accompanying large scale turbulence. The impact forces on the blocks also seem to maximize around the resonance condition. At the same time the mean water table elevation in the core rises due to the high run-up, causing an outward pressure on the armour blocks, as mentioned later. This effect will become even more significant when it is combined with the set-down of the mean water table outside the breakwater (22, 34).

Iversen (31) measured the velocities under a breaking wave, and Kemp and Plinston (37) velocities in the uprush and downrush zone. Wiegel (59) calculated the horizontal accelerations occurring in and under a breaking wave using the data given in ref. (31). Fig. 12 shows the kinematic conditions under two breaking waves with equal breaker heights (H_b) on 1 in 10 and 1 in 50 slopes. It may be observed that the backflow due to

run-down water in front of the breaker is higher for 1 in 10 slope than 1 in 50 slope. High horizontal forward velocities exist directly under the breaking wave crest. When high run-down velocities interact with the high forward velocities in the toe, they cause rotating flows under the sloping front of the breaking wave (fig. 12). During this rotation, velocities and accelerations normal to the slope occur. On a rubble-mound breakwater, the rotating flow causes high drag and inertia forces on armour blocks trying to pull them out of their place. This force corresponds to the lift forces measured by Sandström (44) and by Sigurdsson (50) under ideal assumptions.

Impact forces on the slope also maximize around the resonance condition. With reference to fig. 13, this may be explained as follows:

Assuming that a water mass plunges from the crest of a breaking wave with a velocity of $C_{br} = \sqrt{g(H_b + z)}$ and travels a distance " X_p " along the slope under the action of gravity only (neglecting air resistance). For $\gamma \approx 0$, the fall time " t_b " for this mass can be written:

$$t_b = \sqrt{\frac{2(H_b + z - X_p \sin\alpha)}{g}} \quad (10)$$

The horizontal distance this mass can travel may be written as:

$$X_p \cos\alpha = C_{br} t = \sqrt{g(H_b + z)} \sqrt{\frac{2(H_b + z - X_p \sin\alpha)}{g}} \quad (11)$$

Solving equations (10) and (11) for X_p , one obtains:

$$X_p = (H_b + z) \left\{ \frac{\sqrt{\sin^2\alpha + 2\cos^2\alpha} - \sin\alpha}{\cos^2\alpha} \right\} \quad (12)$$

Assuming $H_b = \gamma_b \cdot X_B \sin\alpha$ and replacing this in (34),

$$X_p = \left(\gamma_b \cdot X_B + \frac{z}{\sin\alpha} \right) f(\alpha) \quad (13)$$

where

$$f(\alpha) = \frac{\sin\alpha (\sqrt{\sin^2\alpha + 2\cos^2\alpha} - \sin\alpha)}{\cos^2\alpha}$$

The values of $f(\alpha)$ are given in table (2) below for some slope angles (α):

TABLE (2)
SLOPE CONSTANTS FOR PLUNGE DISTANCE

α°	$\text{Cot}\alpha$	$f(\alpha)$
38.66	1.25	0.660
33.69	1.5	0.598
26.57	2.0	0.500
21.80	2.5	0.428
18.43	3.0	0.373
15.95	3.5	0.331
14.04	4.0	0.297
11.31	5.0	0.246

Equation (13) needs information on "z", " X_B " and " γ_b " values. It is known that γ_b is the maximum for plunging-collapsing breakers (ξ value around 2.5). On smooth slopes it can be assumed to be about 1.2. Inserting this value of γ_b in equation (13) together with an assumed value of $z = \frac{1}{2} X_B \text{Sin}\alpha$, one obtains:

$$X_p = 1.7 f(\alpha) X_B \quad (14)$$

Solving equation (14) for $f(\alpha)$ when $X_p = X_B$, one finds $f(\alpha) = 0.588$.

The above calculations show that a plunging water mass will always hit below SWL for slopes less than 1 in 1.5 (table 2). If it was assumed that the run-down prediction given by equation (6) was true for $\xi = 2.5$, run-down would only penetrate below SWL at $\xi > 2.5$, which means that a plunging water mass always hits a layer of water remaining from the previous run-down on slopes less than 1 in 1.5. This water-pad will act as an absorber and decrease the strength of impact forces on the slope. Therefore, it is much more likely to obtain high impact forces on steep slopes with ξ values close to the resonance condition.

The maximum water flow velocity may occur at the impact point. This is point "p" in fig. 13. The magnitude of the velocity at point $p_1 (V_p)_1$ can be calculated in reference to fig. 13 from the energy equation assuming negligible energy loss as:

$$\frac{1}{2} m V_p^2 = \frac{1}{2} m C_{Dr}^2 + mg(H_b + z - X_p \text{Sin}\alpha) \quad (15)$$

where datum line was passed from the impact point "p" in fig. 13. In the above equation "m" refers to the water mass which plunges. Solving equation (15) for V_p :

$$V_p = \sqrt{C_{Dr}^2 + 2g(H_b + z - X_p \text{Sin}\alpha)} \quad (16)$$

From equation (11) one can write:

$$g X_p^2 \text{Cos}^2\alpha = 2(H_b + z - X_p \text{Sin}\alpha) \quad (17)$$

Using equation (17), equation (18) becomes:

$$V_p = \sqrt{C_{br}^2 + \left(\frac{g X_p \cos \alpha}{C_{br}} \right)^2} \quad (18)$$

Equation (18) shows that $V_p > C_{br}$. Therefore, maximum flow velocity will occur at the impact point. The orientation of this velocity vector " V_p " at the moment of impact may influence the stability. As the magnitude of this component parallel to the slope is bigger, it will cause more overturning moments on the blocks trying to move them out of their place.

In order to define resonance condition in terms of structure and wave characteristics and to observe the nature of the destructive forces at this condition, experiments were performed on smooth impermeable slopes and on rubble-mounds.

TESTS ON UPRUSH/DOWNRUSH

Tests were run on smooth slopes, 1 in 2, 1 in 3 and 1 in 5. Resistance wires were used for recording run-up and run-down. Wave heights between 4 cm $\leq H \leq$ 15 cm were used with periods 0.8 sec $\leq T \leq$ 2.43 sec, wave steepnesses thereby $H/L_0 < 0.1$. This corresponds to average prototype conditions covering the 1.33 $< \xi < 7.96$ range, which include all types of breakers except spilling. During the tests water depth was constantly 0.5 m. In the experimental range, this corresponds to $d/H_0 > 3.0$ at which wave run-up is not affected by the water depth.

The results are plotted in fig.'s 14 and 15. Breaker types are also shown using different symbols for each breaker type. Another set of experiments was conducted with wave heights of $H = 9.0$ cm and 13.0 cm only, but for different wave periods. Breaking points (B) of the waves were recorded visually only on 1 in 2 and 1 in 3 slopes. Data were converted to $(x_E/H) \sin \alpha$ and plotted in fig. 15 together with run-down data.

Fig. 14 shows a trend in run-up with ξ . It may be seen that R_u/H increases sharply with ξ reaching a maximum at $2.0 < \xi < 3.0$ and decreases again with further increase of ξ . It attains approximately a constant level for high ξ values ($\xi > 4.0$). Types of breakers as also indicated in fig. 14 show that plunging breaking occurred until $\xi = 3.19$ and collapsing breaking until $\xi = 3.42$. For $1.0 < \xi < 2.5$ only plunging breakers were observed. From $\xi = 2.5$ to $\xi = 3.2$ plunging and collapsing breakers became mixed. At $3.20 < \xi < 3.40$ collapsing and surging were mixed, and after $\xi = 3.40$ only surging waves occurred. This observation of breaking conditions was very similar to the results mentioned above except that breaking might occur up to $\xi \approx 3.40$ instead of at $\xi \approx 2.5$. The value $\xi \approx 2.5$ is a theoretically obtained figure referring to a situation halfway between breaking and non-breaking. Hunt's run-up prediction, which was mentioned above ($R_u/H = \xi$), seems to hold for these data also at $\xi < 3.0$. The above results show that for the range of $2.2 < \xi < 3.2$, wave run-up on smooth slopes obtain maximum

values. This result should be considered in designing the crest elevation of any impermeable sloping wave protection structure. Data on overtopping were not considered in this study. The reader is referred to ref.'s (3, 8, 13, 32, 43, 53, 54 and 55). Wave run-down data have less scatter than wave run-up data. Fig. 15 shows these data together with breaking point data and demonstrates that wave run-down increases continuously with ξ and assumes approximately a constant value for high ξ values ($\xi > 4.0$). The mean curve crosses the SWL roughly at a ξ value of 2.2. For $\xi < 2.2$ run-down cannot take place below SWL and run-up and run-down always interact. The model developed above (22) gave $\xi \approx 1.60$ for the run-down penetrating down to SWL. The difference between these two results is undoubtedly caused by neglect of the effects of friction and pressure forces on the flow.

Analysis of breaking point data and run-down data showed that true resonance can hardly ever be achieved. There will always be a run-down "tongue" remaining from the previous wave in front of the breaking wave. Also, for this reason, the resonance condition defined earlier should be changed to "the condition that occurs when run-down is in a low position and wave breaking takes place simultaneously and repeatedly close to that location".

PRESSURE MEASUREMENTS

Pressure measurements were conducted on slopes 1 in 2 and 1 in 3. The combination of wave height, period and slope angle was arranged so that data were obtained for different types of breakers. Fig. 16 is an example of the variation of dynamic pressures along the slope. From this figure, it may be seen that the impact pressures (maximum dynamic pressures) and the suction pressures (minimum dynamic pressures) penetrate deeper on the slope with increasing ξ values.

Analysis of fig.'s 17 and 18 show that the impact pressures and the suction pressures maximize in the range of $2.0 < \xi < 3.0$, that is, close to the resonance condition. The sudden increase of the impact pressures at the resonance condition supports the hypothesis on impact pressures introduced above. Indeed, if the mathematical formulation of the plunge distance given by equation (13) is used together with fig. 15, some quantitative results may be obtained. Calculating the plunge distance for $\text{Cot}\alpha = 2.0$

$$x_p = \left(\gamma_b \cdot x_B + \frac{z}{\text{Sin}\alpha} \right) f(\alpha)$$

Assuming $z = \frac{1}{2}x_B \text{Sin}\alpha$ and inserting the value of $f(\alpha) = 0.5$ from table (2), x_p becomes

$$x_p = 0.5 x_B (\gamma_b + \frac{1}{2})$$

At $\xi = 3.0$ with a plunging breaker, the value of γ_b can be assumed 1.2. The value of x_B can be calculated using fig. 14 as:

$$x_B = 1.40 H \frac{1}{0.447} = 3.13 H$$

For a wave height of $H = 9.0$ cm,

$$x_p = 0.5 \cdot 3.13 \cdot 9(1.2 + 0.5) = 23.94 \text{ cm}$$

and

$$x_B = 28.17 \text{ cm}$$

For this reason the maximum point upslope where the plunging water crest may cause an impact would be $(28.17 - 23.94) = 4.23$ cm below SWL. If the maximum run-down value is checked for this case from fig. 15, it will be 22.13 cm. Therefore, the plunging wave crest will undoubtedly hit the bare slope and therefore cause a high impact. If similar calculations are made for $\xi = 1.5$, one finds that the maximum upslope point where the plunging wave crest may cause an impact would be 4.53 cm below SWL. From fig. 15 one can see that $\xi = 1.5$, run-down ends 6.35 cm above SWL. Therefore, the plunging wave will always hit a layer of water remaining from the previous run-down and cause less impact pressures. As mentioned below, fig.'s 17 and 18 support the result of the above analysis. Some Russian data (49, 51) on impact pressures also support the above hypothesis. Popov (51) made some experiments on 1 in 4 smooth slope with different incoming wave steepnesses for waves breaking on the slope. During the test he used constant wave height and changed the wave period. His results show (22) that impact pressures on the slope increase with increasing ξ values or periods. The linear increase may be due to decreasing water layer thickness which the plunging wave crest hits. Selivanov (49) made some prototype measurements on smooth slopes. He (also) concluded that the maximum impact pressures occur with deep run-down.

From fig.'s 17 and 18 it may be seen that suction pressures are highest at the resonance condition, that is, close to $\xi = 3.0$. On fully impervious slopes the static head of the wave will tend to compensate this suction pressure and no buoyancy forces are exerted upon the cover layer. In rubble-mounds, armour blocks which are submerged are subjected to buoyancy forces which will decrease the weight of the block and thereby its resistance to uplift. Therefore, the combined suction forces on a rubble-mound may be able to lift (suck) blocks out of the mound. As mentioned above, the breaking wave and wave run-up/run-down conditions are similar on smooth impermeable slopes and permeable slopes. It may, therefore, be assumed that force patterns would tend to be similar on permeable and on smooth impermeable slopes, although various degrees of permeability and roughness may cause more turbulence, therefore also more scatter on the permeable rough slope.

TESTS ON FLUCTUATIONS
OF WATER TABLE IN THE MOUND
IN RELATION TO UPRUSH/DOWNRUSH

Wave run-up and run-down were measured using resistance wires. Synchronized water table fluctuations in the core and in the filter were recorded by Sand-Born recorders simultaneously with the run-up/run-down time history on the rock slope. Measurements in the core by resistance wires were obtained 5 cm inside the core from the filter. Another wire system was stretched on the armour stone surface along the slope for uprush/downrush recording.

Tests were conducted with a constant water depth of 50 cm. The wave heights were ranged between $3.8 \text{ cm} < H < 16 \text{ cm}$ and the wave period between $0.8 \text{ sec} < T < 2.43 \text{ sec}$. Breakwater slope was 1 in 2.5. The range of ξ was $1.37 < \xi < 4.77$. A synchronization signal was transmitted and marked on all channels using a push-button system.

Relative wave run-up (R_u/H) and run-down (R_d/H) on the breakwater were plotted against ξ values as shown in fig. 19. It may be seen that wave run-up and run-down increase with increasing ξ values. The relative wave run-up and run-down at the filter layer and in the core are given in fig.'s 20 and 21. Fig. 22 shows a variety of wave run-up data derived from tests plotted in fig.'s 3, 14, 19 and others (22). The lower values of Hudson's data in fig. 22 is a result of the approximation $H \sim H_0$.

Fig. 22 shows that wave run-up on a rubble-mound breakwater and on a smooth slope do not assume a constant ratio for all ξ ranges. A ratio of 0.5 seems to be valid for the maximum run-up on smooth slopes and maximum run-up on rubble-mound breakwater slopes.

Fig. 19 shows that wave run-down increases continuously with ξ in the test range. From fig.'s 6, 7, 8 and 9, it is apparent that wave run-down on breakwater slopes assumes a constant value for $\xi > 5.0$. Therefore a constant level of relative run-down (R_d/H) may be expected at fig. 19 for $\xi > 5.0$. A comparison between wave run-down on smooth slopes and on rubble-mound breakwaters reveals some differences. For $\xi < 2.20$, run-down on smooth slopes does not penetrate below SWL. On rubble-mound slopes, it does. This difference is mainly due to inflow of water into the breakwater body causing lower run-up and higher run-down values on breakwaters. For $1.5 < \xi < 4.0$, wave run-down on smooth slopes increases much faster than on rubble-mound breakwaters. This undoubtedly is due to the friction forces which retard the run-down on breakwaters and the outflow from the breakwater body which feeds the run-down. Both of these effects decrease the run-down on rubble-mound breakwaters. From data on the type of breakers occurring at different ξ values, it may be concluded that wave breaking on rubble-mounds ceases at smaller ξ values than on smooth slopes. Plunging breakers occur until $\xi \approx 2.0$. Around $2.0 < \xi < 2.60$ plunging and collapsing breakers become mixed. Collapsing breakers occur until $\xi \approx 3.10$. It was observed that the type of breaker also depends

on the height of the incoming wave. At the same ξ value a higher wave may cause a plunging breaker while a lower wave breaks collapsing on the rubble-mound. Although there will not be much change in the above transition values given for breakers on rubble-mounds, a higher wave than the maximum wave used during the tests may shift the breaker transitions somewhat towards higher ξ values.

Fig.'s 20 and 21 show the maximum and minimum elevations of the water table inside the filter and core respectively for different ξ values. It may be noted that until $\xi \approx 3.0$ the maximum water level in the filter stays much lower than maximum run-up on the slope. After $\xi \approx 3.0$ the water table in the filter follows wave run-up values. This means that inflow cannot be completed for small ξ values. The minimum water table elevation in the filter stays very close to SWL for $\xi < 2.5$. For $\xi > 2.5$ it goes below SWL and decreases (comes further down) with increasing ξ values.

A similar trend of water table fluctuations inside the core may be seen from fig. 21. For $\xi \leq 3.0$ the water level does not go below SWL in the core and all fluctuations remain above it. This causes an extra head above SWL which undoubtedly affects the stability. It may be seen that for small ξ values, water level fluctuations inside the core become very small. This means that for small ξ values, the water table fluctuations take place around a certain point inside the core close to the filter layer (22). This result refers mainly to the finer core materials. For high ξ values the water level fluctuations inside the core increase. Tests demonstrate that for $\xi < 4.0$ the water table in the core remains above SWL at the run-down position of the water profile on the breakwater. Fig. 23 shows the approximate quasi-stationary water table profiles at three different ξ values at the run-down position on the breakwater. Data from the tests were used to plot these figures. It may be seen that for small ξ values, flow into the core is not completed when run-down occurs on the breakwater. Fig. 23 also shows that a force inside the breakwater caused by the sloping water surface at the quasi-stationary state, may be transferred to the armour rock in the form of an added buoyancy force. Pressure measurements were conducted inside the breakwater on a horizontal plane 20 cm below SWL for the two different core materials used. The time history of the pressure was drawn with 0.2 sec intervals using linear interpolation in between the discrete points. The main difference between the pressure measurements with two different core materials is a relative increase of the build-up of pressures in the finer material. This effect of permeability causes that the maximum and minimum pressure fluctuations are shifted up with finer core material. For details, the reader is referred to (22).

Fig. 24 shows the mean pressure gradients in fine and coarse core at $\xi = 3.0$. It is drawn using detailed results and linear interpolation in between the discrete readings. Maximum mean pressures occur at $P_2 - P_3$ or between $(P_2' - P_3')$ causing concave

mean pressure distribution curves as shown in fig. 24. These mean pressure gradients ($d\bar{p}/dx$) occurring inside the core reveal the existence of a force acting from inside the core towards the slopes. In the range of the experimental pressure measurements a similar pattern of the $d\bar{p}/dx$ distribution is observed inside the core for two different permeabilities. This means that in the distance $P_1 - P_1'$ the force acting in the core does not show much difference with the core permeability, but it is likely that this build-up of pressure head inside the core will act upon the highly permeable filter or armour layer due to pressure gradients in the core close to filter layer. It may therefore be concluded that the difference in pressures inside the core will be maximum close to the filter layer, which may be seen from fig. 24, where filter and armour layers are shown at -20 cm elevation. The forces occurring inside the core due to the build-up of hydrostatic head are directed towards the filter layer and the armour rock. Due to the complex flow situation, nothing can be said about the actual magnitude and distribution of this force which attempts to push the rocks outward. It may therefore be interpreted as an extra bouyancy force indirectly caused by the waves. This force increases with decreasing permeability. For a constant wave height the build-up of pressures inside the core increases with increasing wave period or ξ value. This increase develops faster with finer core material and has a sharp increase with ξ for $\xi < 3.0$, but increases less after this value. In addition, it should be noted that wave set-up on a slope diminishes with increasing ξ values. Indeed Fairchild (17) mentioned that in the experiments with smooth slopes of 1 in 3 and 1 in 6 no set-up could be measured, but only set-down occurred. A similar conclusion may be transferred to a rubble-mound breakwater which means that set-sown in front of a breakwater increases with increasing ξ values. This makes another contribution to increase of outward pressure, thereby to reduction of armour stability (16, 17).

OVERALL STABILITY OF ARMOUR

The dislocation of the armour stone on the breakwater is a result of the existence of various forces which may join in combinations that cause maximum destructive forces. From the above-mentioned it is known that wave run-up and run-down increase with increasing ξ values and assume a constant level approximately for $\xi > 5.0$. This may cause higher run-down velocities on the breakwater for increasing ξ values acting on the armour blocks as drag and inertia forces. It is therefore more probable that damage will occur with the longest period waves when ξ is less than 5. It is mentioned above that the maximum impact forces on the armour blocks occur at or close to the resonance condition. The suction forces occurring under a breaking wave due to the interaction between the breaker forward velocities and run-down velocities generally also maximize close to or at the resonance condition.

Maximum impact and suction forces seem to occur under breaking waves for $2.0 < \xi < 3.0$. The increase in core pressures and

run-down drag forces is relatively small for $\xi > 3.0$. In this range no wave breaking occurs. Therefore, it may be assumed that the first dislocations of the armour stones on the breakwater will occur around the ξ values between 2 and 3 where wave breaking still takes place. After the dislocation of some stones from the breakwater surface, the armour blocks may roll down due to the run-down forces which may be highly turbulent. This means that for the advancement of the damage, long period waves which surge up on the breakwater are as responsible as the waves at the resonance condition. For advance of damage waves occurring in the wave spectrum with $\xi > 2.0$ therefore are all critical.

The above-mentioned general conclusions are supported by tests undertaken at the Coastal Engnerg Research Center (1, 2) in 1974. These tests were performed in a wave flume 193.5 m long, 4.57 m wide and 6.1 m deep. Wave heights of $0.55 \text{ m} \leq H < 1.83 \text{ m}$ with periods $2.8 \text{ sec} < T < 11.3 \text{ sec}$ were tested. They were conducted at a constant water depth of 4.57 m. A rip rap covered breakwater was tested with slopes of 1 in 2.5, 1 in 3.5 and 1 in 5.0. Test results were presented in terms of the zero damage wave height "H_{ZD}". Zero damage wave height was defined as the highest wave height which will create no damage to the structure. A 10% increase of this wave height will cause damage. Wave heights were measured in front of the structure. The original data obtained from these tests are plotted in fig. 25 in terms of zero damage stability number "N_{ZD}" versus ξ where N_{ZD} and ξ were defined as,

$$N_{ZD} = \frac{H_{ZD}}{\left(\frac{W_{50}}{Y_r}\right)^{\frac{1}{3}} (S_r - 1)} \quad (19)$$

and

$$\xi = \frac{\text{tg} \alpha}{\sqrt{H_{ZD}/L_0}} \quad S_r = \frac{Y_r}{Y_w}$$

When equation (19) is compared with equation (9), N_{ZD} is equivalent to $(K_D \text{ Cot} \alpha)^{\frac{1}{3}}$. Results of tests of earlier date (1959) are also presented in fig. 25, which clearly shows the effect of wave period on the stability of rubble-mound breakwaters. When the range of breakwater and wave characteristics covered are considered, they verify the above conclusions for the stability of rubble-mound breakwaters, which were based on the hydrodynamic analysis of the phenomenon.

Fig. 25 shows that the stability number N_{ZD} depends on the slope angle much more than expressed by ξ . In fig. 26, curves were drawn from the lowest zero damage stability numbers of each slope. This shows that the minimum stability point shifts from a ξ value around 2 to a ξ value of around 3 with increasing slope angle. It also shows the effect of ξ on stability and demonstrates that minimum stability occurs for $2.0 < \xi < 3.0$.

It may be questioned whether results from tests on rip rap can be transferred to rubble-mounds as rip rap would tend to be a little denser than rubble-mounds. The answer undoubtedly is that it is possible, as nothing has changed in the overall hydrodynamic situation, but due to turbulence spreading may be more pronounced with rubble-mounds. The instrument mentioned in the next section confirmed the general validity of a "transfer".

THE OPTICAL BREAKDOWN DEVELOPMENT SENSOR

This instrument (the OBDS) was developed to quantify the breakdown by measuring the actual movements in a mound, thereby replacing the earlier procedures of counting blocks "which moved out of place" or "rolled down the slope" - a very subjective method by "figures and facts".

The OBDS is a photographic instrument. Its main item is a "Mamiya Universal" camera with accessories. Its principle is called "solarization" or "bas-relief" effect in photography. It is based on the trick of applying a negative film to mask out all highlights passing through a positive film. A Polaroid Type 105 Positive/Negative Pack Film was used. First a picture of the test section was taken. The negative of this film was inserted into the camera in such a way that negative film masked all highlights coming from the structure. This alignment of the negative film with the structure may be achieved by slight axial and rotational movements of the camera. The camera is set at this position and a photocell connected to an amplifier is put on to the eyepiece of the camera. Any change on the original test structure will affect the alignment of the negative and the structure, and more light will come to the photocell. This will cause a deflection on the amplifier.

The above described working principle necessitates the use of high contrast colours on the test object. For this purpose, it was decided to paint the test object in partial black and white. The light coming on to the test object should be very uniform. The calibration of the system is done by causing some known amount of deflection in the test object or on the camera and observing the corresponding deflections on the amplifier. In the ideal case, if the test object can be painted as a chess-box, this calibration procedure may be done easily. Fig. 27 is a schematic view of the masking procedure for a chess-box-like test object. It represents the condition where the negative completely masks the highlights coming to the photocell causing minimum deflection on the amplifier. At this position the amplifier is set to "zero" deflection. Then the camera is tilted until maximum deflection is observed on the amplifier. This corresponds to one square deflection "L" on the test object shown in fig. 27 because all the lights will pass the negative due to

the ordered pattern of the test object. Assuming the linearity of the system in between the maximum deflection "D" and the zero deflection, a calibration coefficient "c" can be calculated as,

$$c = D/L \quad (\text{deflection/length})$$

and any deflection occurring on the amplifier "d" can be converted to the test objects deflection "l" from the relation,

$$l = d/c \quad \text{for } l < L$$

The above calculation of the deflection assumes that movement of the test object as a whole is in one direction. It also has a condition that this deflection should be less than a square size. If the test object is a rubble-mound, movement may be measured similarly. To make recording clearer, stones may be painted white and black. Calibration and actual use of the instrument is described in (22) and will be published in detail in the near future as a separate paper (ASCE, Waterways, Harbors and Coastal Engineering Division).

Fig. 28 is an example of rock movements recorded by OBDS for different wave characteristics. It includes data for all wave periods tested and for wave heights which cause dislocation. As it could be expected, movements of stones increase for increase of wave heights. The start of major movements takes place when $H \geq 11$ cm.

Fig. 29 shows the effect of ξ on movements. For $H = 11.8$ cm, movements are bigger than for $\xi = 2.3$, as well as for $\xi = 1.45$ and $\xi = 3.32$. This is in agreement with the maximization of damaging forces at or close to the resonance condition mentioned in the earlier sections of this paper.

SUMMARY

The main goal of the paper was to determine the flow conditions which maximize destructive wave forces occurring on a sloping wave-protection structure. It includes both impermeable as well as permeable structures. Special emphasis is put on the latter.

The study only covers the wave protection structures at $d/H \geq 3.0$ where flow patterns occurring on the structure are not affected by the depth. The slope (α), the wave height (H) and the wave period (T) are main parameters. The flow characteristics occurring with different combinations of α , H and T are explained with the "surf similarity parameter", $\xi = \text{tg}\alpha/\sqrt{H/L_0}$. The effect of any other parameter on the flow characteristics is included by inserting empirical coefficients into the system.

Wave breaking and wave run-up/run-down characteristics were first summarized from the available literature. The result of these investigations is analysed relative to ξ and most of the data are re-plotted against ξ . This showed that wave breaking and wave run-up/run-down on sloping structures may be described in terms of ξ .

A theory was developed about the maximization of forces on the slope based on the flow characteristics. It suggests that forces maximize at $2.0 < \xi < 3.0$. Run-up/run-down and pressure experiments on smooth slopes are described. It was found that on smooth slopes wave run-up has a maximum at $2.0 < \xi < 3.0$, where plunging and collapsing breakers are mixed on the slope. Wave run-down cannot go below SWL for $\xi < 2.20$, and run-up and run-down always interact. Run-down increases continuously with increasing ξ values until $\xi \approx 5.0$ and assumes a constant value after this. It is shown that maximum impact pressures on the slope occur at $2.0 < \xi < 3.0$ when a plunging breaker crest strikes the bare slope

Run-up/run-down and core pressure tests on a rubble-mound breakwater are also described. It was found that wave run-up and run-down increase continuously with increasing ξ and assume a constant value approximately at $\xi > 5.0$. A build-up of hydrostatic head occurs inside the core due to the existence of the waves and exerts an outward force on the armour stones mainly due to high pressure gradients in surface layers and filters. This build-up of hydrostatic head inside the mound increases with increasing ξ values for $\xi < 4.0$. It was shown that decreased core permeability causes increased build-up of hydrostatic pressure. Maximum destructive forces acting on an armour unit trying to dislocate it seem to occur around $2.0 < \xi < 3.0$. This was verified by actual stability experiments. Due to the desire of obtaining more exact (quantitative) recordings, an instrument (the OBDS) was developed. It is described briefly and is subject to further testing.

A summary of the flow conditions and forces occurring on smooth impermeable and rubble-mound breakwater slopes are given in

tables (A) and (B). The tables describe the conditions in terms of ξ parameter. The limits indicated in these tables differentiating various phases of the characteristic parameters relative to ξ are not yet rigid boundaries, but indicate approximate transition values only. It is believed that in the very wide range of structure and wave characteristics these tables may be useful for a preliminary design of wave protection structures.

1) Based on experimental results on 1 in 2.5 slope breakwater. Data is given in Appendix IV.
 2) Transferred from smooth slope results. No data is available.
 3) Shown in fig.'s 5, 6, 7, 8, 9 and 22.
 4) Transferred from smooth slope results. No data is available.
 5) Shown in fig.'s 68, 69, 70, 71 and 72 of ref. (22)
 6) Deducted from smooth slope measurements presented by fig.'s 17 and 18. No data is available.
 7) Transferred from smooth slope measurements. No data is available.
 8) Shown by fig.'s 25 and 26.

CONCLUSION

The conclusion given in twelve points below only covers sloping structures at a relative water depth of $d/H > 3.0$ where non-breaking wave conditions occur until the structure is reached. They are mostly applicable to wave-protection structures with steep continuous sloping faces, permeable as well as impermeable. They refer to monochromatic wave conditions.

- i) Most of the overall flow characteristics like breaking, run-up, run-down may be defined by single parameter $\xi = \text{tg}\alpha/\sqrt{H/L_0}$.
- ii) On smooth slopes in the range of $0.5 < \xi < 2.0$, wave run-up may be predicted using Hunt's formula $R_u/H = \xi$.
- iii) On smooth slopes, maximum wave run-up occurs for waves breaking on the slope in the range of collapsing - plunging breakers. This corresponds approximately to $2.0 < \xi < 3.0$.
- iv) On rubble-mound breakwaters, wave run-up increases continuously with ξ until ξ approximately equals 5. From there on run-up assumes a constant level.
- v) Wave run-down on slopes increases with increasing ξ values until ξ approximately equals 5.0. From there on it assumes a constant level.
- vi) Wave run-down on smooth slopes cannot penetrate below SWL for $\xi < 2.20$, and run-up and run-down always interact above SWL.
- vii) Maximum impact pressures on smooth slopes occur at $2.0 < \xi < 3.0$ where the breaking wave crest hits the bare slope.
- viii) A build-up of hydrostatic pressure occurs inside a rubble-mound due to wave uprush. It increases with decreasing permeability and with increasing ξ values for $\xi < 4.0$.
- ix) Stability of rubble-mound breakwaters is also affected by the wave period. Forces trying to dislocate the armour maximize with deep run-down occurring simultaneously and repeatedly with collapsing - plunging wave breaking. This corresponds to $2.0 < \xi < 3.0$ at which the initial stability of the rubble-mound is most critical.
- x) With reference to fig. 2 and similar plottings (30), results for $d/H < 3.0$ will undoubtedly show a similar trend even if adjustments on ξ and ξ ranges are likely. This is subject to further research as are scaling and checking of the OBDS instrument that was developed to quantify rock movement in a reliable way.
- xi) As seen from tables A and B, the $\xi = \frac{\text{tg}\alpha}{\sqrt{H/L_0}}$ parameter is useful for description of a great many single phenomena included in wave action on sloping structures.
- xii) Finally - and as already expressed in ref 11:

"The significance of wave period is clearly demonstrated. This underlines the necessity - demonstrated with much pain in many practical mishaps - of designing rubble-mounds and other sloping structures based on design criteria which includes wave period. It is not enough to select a "design wave" and a "proper" K_{Δ} value based on some more or less realistic laboratory experiments. It is also not enough to select a "design storm" or a specific "design spectrum". The design wave or the design spectrum gives a "load" which is sometimes regarded as the maximum exposure that can occur. This could be far from the truth, however. A much more reliable, scientifically as well as practically, better reasoned design procedure is first to select one from a technical and economical view attractive design. The next step is to examine a number of actual wave spectra from the site including analyses of extreme events (11) and trains of approximately regular waves with special reference to the correlation between succeeding waves as described in ref.'s 23 and 27. Tests should then concentrate on irregular waves and on combinations of certain waves and periods that occur in the actual spectra with particular reference to conditions that produce the most dangerous resonance phenomena. This confirms actual experiences from a great number of actual observations in the North and Arctic seas and also the inadequacy of design-formulas that ignore wave period and spectral characteristics as well."

DESIGN AND CONSTRUCTION OF HUMBOLDT JETTIES, 1880 to 1975

by

Orville T. Magoon¹, M. ASCE

Robert L. Sloan², M. ASCE

Nobuyuki Shimizu³

ABSTRACT

In the Chief of Engineers annual report of 1877, it was concluded that "The only way...in which a safe entrance could be obtained into this harbor would be by the construction of two parallel jetties, of very heavy stone, about 500 yards apart, from the north and south spits at the entrance."

In 1882, a special Board of Engineers concluded that the "occupation of the south breaker spit by a structure...carried to low water and running from the south head (spit) in a north-westerly direction..." be built. Construction of the south jetty began in 1889 and of the north jetty, subsequently authorized, in 1891.

Due to the severe wave action, a number of rubble-mound construction techniques including stone, concrete cubes, tetrahedrons, and finally dolos armor units have been used. A description will be given of the construction and associated results. Experience with the reinforced and unreinforced concrete dolosse units will also be discussed.

INTRODUCTION

A 19th-century Corps of Engineer report contains a description of the Humboldt Bay entrance area by the San Francisco District Engineer as follows:

-
1. Civil Engineer, U. S. Army Engineer Division, South Pacific, San Francisco, California, Chief, Coastal Engineering Branch, Planning Division
 2. Civil Engineer, U. S. Army Engineer District, San Francisco, California, Assistant Chief, Water Resources and Urban Planning Branch, Engineering Division
 3. Civil Engineer, U. S. Army Engineer District, San Francisco, California, Chief, Foundations and Materials Branch, Engineering Division

"It has been reported by masters of vessels that no such heavy seas have been encountered elsewhere in the world, unless perhaps south of the Cape of Good Hope and Cape Horn. Waves have been seen to break in 8 or 10 fathoms of water. It was originally believed that no jetties or such construction could possibly withstand the forces brought to bear by waves during storms, so that the improvement was undertaken with great misgiving."¹

A very vivid description indeed of the severe wave conditions encountered by navigators and those engaged in attempting to provide a stable entrance to Humboldt Bay.

The Humboldt Jetties are two of the oldest manmade structures on the Pacific coast subjected to extreme wave attack. Inasmuch as these structures have been constructed and maintained over a long span of time and have used a variety of design and construction techniques, they represent a significant coastal engineering case history. The material presented here represents a summary of all known information on these jetties; however, any additional information on this subject from readers of this paper would be welcomed by the authors.

GENERAL DESCRIPTION

Humboldt Bay, a land-locked harbor on the coast of Northern California, is about 420 kilometers (225 nautical miles) north of San Francisco and about 290 kilometers (156 nautical miles) south of Coos Bay, Oregon. The entrance is protected by two rubble-mound jetties, which are about 0.7 kilometers (0.5 mile) apart and extend from the ends of two long and narrow sand spits separating the bay from the ocean. The width of the bay varies from 0.8 kilometers (0.5 mile) to about 6.5 kilometers (4 miles), and the length is 23 kilometers (14 miles). The southern portion of Humboldt Bay extends about 6.5 kilometers (4 miles) south from the entrance, widening gradually from 0.8 kilometers (0.5 mile) to 3.6 kilometers (2.25 miles) in width. A dredged channel extends for some 3 kilometers (2 miles) from the entrance to Fields Landing, which lies about midway along the east side of the South Bay. Humboldt Bay is shown on Figure 1.

The entrance is dredged to a 12.2 meters (40 feet) depth. Inside Humboldt Bay north of the entrance, a fairly deep natural channel closely follows the north spit. A 10.7 meters (35 feet) channel is dredged for almost 3 kilometers (2 miles) along the waterfront of the City of Eureka.

The tides are semidiurnal with a range between mean lower low water and mean higher high water of 1.95 meters (6.4 feet) at the south jetty and 2.04 meters (6.7) feet at Eureka. The entrance channel is exposed to high waves generated by local coastal storms accompanied by high winds, and to high waves or swell produced by offshore, distant, Pacific Ocean storms, unattended by high winds. Both types of waves generally occur during the period from November through April

with the critical area of approach being from southwest through northwest. More detailed information on Bathymetry and wave climate is given in Magoon and Shimizu,² and in model studies by the Waterways Experiment Station in Vicksburg, Mississippi, U.S.A.³ There is also a paper on channel shoaling by Noble.⁴

The initial Federal investigation of Humboldt Bay looking toward a possible improvement of the entrance by jetties was made in 1878.⁵ This report states:

"This bay affords fine shelter after vessels have once got into it, but it is a bar-harbor, the bar being composed of shifting sands, with heavy breakers even in moderate summer weather.

To give an idea of the great height of waves rolling over this bar, we will state that when the Board of Engineers for the Pacific Coast arrived off the bar, in the Coast Survey steamer Hassler, the weather was very moderate, with only the usual summer wind from the northwest, yet, although there was 20 feet of water on the bar at the time, the pilot refused to take in the Hassler, drawing only 12 feet of water at the time, stating that he could not do so without running the risk of the vessel striking bottom and her possible loss in the breakers.

The shores on both sides of the entrance are low and sandy, and there is no stone in the immediate vicinity.

The only way, as it appears to the Board, in which a safe entrance could be obtained into this harbor would be by the construction of two parallel jetties of very heavy stone, about 500 yards apart, from the north and south spits at the entrance.

If such jetties were built, the very large area of the inner bay would probably afford sufficient tidal prism to keep open a deep channel over the bar, against all drifts from the action of sea-waves. But such construction would be attended with immense difficulties and enormous expense. It is a question even, with the members of the Board, whether such construction would be physically possible, and one, too, upon which we dare not express an opinion without a searching examination of all the contingencies upon which the stability or instability of such works would hinge. We have not, therefore, made any plan or estimate of cost for a breakwater at this place, deeming it, if not impossible of execution, highly improbable that a breakwater or jetties will be attempted here at the present time."

This report correctly identifies the major problems that have continued until the present: "shifting sands", "high waves", "lack of stone in the immediate vicinity", and lack of understanding of structure stability. The report also notes that if two jetties could be built, there would probably be sufficient tidal prism to keep the jetties open.

Jetty layout and construction on the Pacific Coast is mentioned by Symons⁶ in 1893 who indicates that the Humboldt Jetties were designed to be high tide jetties and that their construction was similar to that at other Pacific Coast harbors, but was "done by single broad gauge track" rather than the double narrow gauge track. He also expresses his desire to see the construction of a "single curved jetty, concave to the channel, instead of a pair of nearly parallel jetties, with the hope that a good and satisfactory channel would be developed, as along the concave bank of a river." The concept of a single "reaction breakwater" which would develop the potential energy of the ebb currents, rendering them kinetic, and applying them locally on the crest of the bar where they are needed for scour was discussed in detail by Haupt in 1899.⁷ Perhaps because of the above subsequently stated interest in the single jetty concept, the Chief of Engineers recommended the construction of a single jetty at the Humboldt Bay south spit—a low enrockment (rising to the level of ordinary low water) of rubble stone. A length of 6000 feet and a depth of 6 feet were assumed to be necessary (73,000 tons of stone) in addition to "an enlargement of the sea head" and beach and shore protection (17,000 tons of stone). The report also notes that from 1851 to 1882, the entrance channel had varied in width from 2200 to 4200 feet and in depth from 21 feet to between 10 to 12 feet.

INITIAL CONSTRUCTION

The initial contract for construction of the south jetty was let in 1888.⁸ By 1890 it was realized that the southern end of the north spit was eroding rather than holding firm and providing a deep entrance. The Chief of Engineers Annual Report of 1891⁹ states:

"In October, 1890, a Board of Engineers was convened to consider and report upon a project for the improvement of Humboldt Bay. The board met at Eureka on December 11, 1890. After study of the subject, it was decided to modify the existing project so as to embrace shore protection work on the north spit, and the construction of a jetty starting from there and running seaward nearly parallel to the jetty on the south spit, both jetties to extend out to the 18-foot contour and be raised to the plane of high water, thus confining the tidal flow within definite bounds and securing the full benefit of its scouring capacity."

It was also apparently concluded that the jetties would have to extend to "high water."

By late 1891 an additional contract had been completed, and the south jetty was about 4000 feet long, and the north jetty about 1500 feet long. This latter contract used 28,000 cubic yards of brush mattresses and 100,000 tons of stone.

The jetties were built from a timber trestle which was constructed with an overhanging pile-driver revolving on a turntable. The trestle

consists of four-pile bents sixteen feet apart supporting two standard gauge tracks of forty-pound T rails and is designed to last only long enough to complete the jetty beneath it. A typical pile bent is shown in Figure 2.

Filter material used was a layer of brush mattresses approximately forty-four feet wide.

"A mattress is built upon two piles swung under the trestle by wire cables made fast to the cap timbers. First is laid upon these sling-piles a grillage of poles bound at every intersection with strong wire. Upon the grillage are placed in successive layers bundles of brush about twelve feet long, the bundles in each layer being at right angles with those of the next. When the brush has a thickness of about six feet, another grillage is placed on the top. The two grillages are made to compress the brush to two-thirds of its original volume by means of long screws extending through the mattress. The grillages are then bound together by numerous wires, previously brought up through the brush from the bottom. The screws are removed, and the mattress is ready.

Cars filled with small rock are brought, and a layer of stone is thrown by hand upon the mattress to serve as ballast. Six men are stationed on the cap timbers. They stand with uplifted axes ready to cut the lashings and free the cable ends. Others stand by the car doors ready to release the rock. The word is given. With a cracking and a crash, the mattress strikes water. In a second a rattling volley of rock drives it out of sight to the bottom."⁸

These jetties resulted in a fixed channel, at least 700 feet wide and 25 feet deep until 1905. As the jetties deteriorated from lack of maintenance, the channel shoaled and by 1907, the outer ends of the jetties were completely buried in the sand.

REBUILDING OF JETTIES

Between 1911 and 1915 the south jetty was reconstructed. Between 1915 and 1925 the north jetty was rebuilt. The new jetties were built on the foundations derived from the old structures. Due to the inability of driving piles for a new trestle through the old stone "foundation," the new structures were built by the "cap method." The crane that was used has a capacity of 20 tons at a 35-foot radius, with a maximum reach of 50 feet. The crane operates in a 17-foot gauge track, placed on wooden ties imbedded usually in about 18 inches of concrete cap. In the original reconstruction, no parapet stones were used on the jetty.

"The concrete cap method has proved a success. While used as an incident of construction to prevent the tracks from being washed away,

it was found, as anticipated, to retard the action of the sea in tearing down the jetty structure. The average cost of the concrete cap, 22 feet wide and 18 inches deep, was about \$20 per linear foot, including tracks and foundation of stone. No forms were used after 1914.

The plant for concrete mixing consists of one standard-gauge flat car and a Foote batch mixer of 21-cubic-foot capacity, end discharge, and steam-operated. The concrete is placed by a foreman and four laborers, the regular stone unloading crew. A section of this concrete cap is usually built in two hours, including the leveling of the foundation and placing of ties and standard-gauge rails. Difficulty is experienced during rough weather in protecting fresh concrete from being washed out by the waves. This condition was improved by placing a parapet of larger stone seaward of it, and covering the fresh concrete with canvas and boards weighted down with old rails.

When the south jetty was completed in 1915, a concrete monolith weighing about 1,000 tons was built at the end for the protection of the jetty head, the most exposed and vulnerable part. The concrete block was 30 by 30 by 14 feet, with the base at five feet above mean lower low water. It is reinforced with old 60-pound steel rail made fast with old cables and U-bolts. When the work of reconstruction was completed, the depth of water at the sea end was 31 feet, instead of 18 feet as before. The bottom of the block was laid at about high-water elevation. The top of the block was at an elevation of 19 feet above low water. The concrete block has proved a success in protecting the sea end."

The next phase of construction of the north jetty began in late 1915. Armor stones were from 6 to 20 tons and the larger stones were placed in the upper layer on a slope of 1 on 2 on the exposed side and 1 on 1-1/2 on the protected side. The crest was raised to about 19 feet above mean lower low water, and a reinforced concrete monolith 32 feet wide, 14 feet thick (above high water), and 32 feet in length. Steel reinforcing consisted of old railroad rails. Seaward of the monolith a 7 foot thick by 32 foot wide by 30 feet long slab was placed, and large stones were placed around the slab and monolith. A typical section of the north jetty is shown in Figure 3.

LATER CONSTRUCTION ACTIVITIES

Due to the adverse sea conditions at the site, floating equipment could not be utilized for construction or repairs of the jetties, thus all work was conducted from the jetty crest. With these limitations the sizes of stones or shape that could be placed in the jetties were limited to the capacity of the available equipment or additional other methods were improvised to place larger armour protections. Generally, the structures could not be built from the seaward toe upward. Prior to 1970, the weights of stones and shapes were limited to about 20 tons. Since units of sufficient sizes to provide the required protection could not be placed effectively, the jetties at Humbolt Harbor have required constant maintenance during the past years. Sources of

stone over the years have been generally located in surrounding areas of fairly close proximity, however, stone has been brought in from as far away as Oregon. A record of the maintenance work conducted at the jetties is presented in Table 1 at the conclusion of this report.

The north and south jetties were completed to their full lengths in 1925 and 1927, respectively. During this period the parapet wall was constructed and the concrete cap was placed on the crest of the jetties. Concrete was also placed on the channel-side slope of the jetties to hold the armour stones together.

When construction was completed, the side slopes of the jetties were approximately 1 vertical to 1.5 horizontal with a crest width of approximately 20 feet. The elevation of the crest varied from about 12 feet to 19 feet msl at the seaward end. The parapet walls were located on the south sides of the jetties and were about 4 feet in height and 6 feet in width. Above msl elevation the armour stones of the side slopes were imbedded in concrete. The parapet walls were located on the south sides of the jetties due to predominant waves from the southwesterly direction and the wide channel being approximately 3,000 feet in width.

Emergency repairs and periodic maintenance works were required during 1930 and 1957. Primarily, work consisted of using mass concrete to fill the eroded areas in the crest and imbedding the armour stones on the side slopes and the replacement of armour stones in areas that were breached or washed out. To provide the necessary protection, concrete blocks weighing over 100 tons were used as early as 1932. These blocks measured 11 by 11 feet and were cast on the crest at the site of the repair work on greased or oiled sheet board. The jetty side of the sheet platform was picked up and the blocks were launched by compressed air into washed-out areas of the slope. Actual placement of these blocks could not be accomplished due to lack of equipment that would handle these size units. It should be noted that many of these 100-ton blocks broke when they hit the water. They did not appear to break as often, however, when they struck other blocks or stone. In the 1930s and 1940s 12-ton tetrahedrons were also used for repairs. These units were considerably smaller than we would now consider stable.

During the winter of 1957-1958, severe storms deteriorated the north and south jetties to such an extent that repair work constituted a major construction project. The repairs of the north jetty commenced in 1960 and were completed in 1961. The south jetty was repaired during 1962 and 1963. The trunk portions of the jetties were repaired by mass concrete and 12-ton stones were placed on 1 vertical to 1.5 horizontal slopes in the eroded areas. The heads of the jetties were varied to about elevation 25 feet. Construction of the heads was accomplished by using 20-ton blocks for perimeter forming and placing mass concrete within block forms. The concrete was reinforced with large reinforcing bars and track rail. The heads were protected with 12-ton stones placed on 1 vertical to 1.5 horizontal side slopes with a cover layer

of 100-ton cubic concrete blocks. Most of the 100-ton blocks were washed away during the winter storms of 1964-65. Both the north and south jetties progressively deteriorated due to wave action. By 1970 the heads of the jetties were totally destroyed and another major rehabilitation work was required.

Extensive model studies were conducted for this rehabilitation work. Various concrete shapes were investigated. The adopted design consisted of placing 42 and 43-ton dolosse on 1 vertical to 5 horizontal slopes against the heads of the jetties. The placement slope was dictated by the existing conditions around the jetty heads which were covered with stones and concrete blocks from the jetties. The dolosse were to be placed a maximum of 230 feet from the heads of the jetties in two layers, placed at random with 11 dolosse per 1,000 square feet of slope area. The dolos units were to be placed from the toe to the head in two layers.

The rehabilitation work² on the south jetty was accomplished in 1971 and the north jetty in 1972. The Model VC 4600 Monitowac Crane, "Ringer," was used for the placement of the dolosse. Prior to construction, the Contractor made scale models of the dolos to study the placement of the dolos. Then the locations for each dolos to be placed to provide the necessary coverage were plotted and predetermined. The boom angle of the crane provided the distance from the head and the deflection of the boom from a given line provided the exact location for each dolos. The dolosse were picked up in the center of the trunk by a wide two-prong claw, lifted, the boom was moved to the deflection and lift angles, and the dolosse were lowered and placed. When placed the dolosse of the lower layer were positioned to locate the standing fluke seaward and the trunk in line with the direction of the waves where possible. The dolosse in the upper layers were placed and positioned to provide the greatest interlocking stability.

The dolosse have been in place for 5 and 4 years for the south and north jetties, respectively, and although there has been some breakage of the dolos units¹⁰ and settlement of perhaps 5 feet at portions of the south jetty head, the structural integrity of the jetties is not endangered.

The following tabulation presents a historical summary of the quantities of stone placed for new construction and maintenance (including concrete and special concrete armor units) from initiation of construction activities in 1889 to the present time. These records have been obtained from annual reports prepared by the Office, Chief of Engineers, U. S. Army, dating from 1891, and from early reports.

Table 1
SUMMARY OF NEW WORK AND MAINTENANCE QUANTITIES,
1889 - 1973

YEARS	NEW WORK		MAINTENANCE		REMARKS
	Quantity (tons)	Concrete (c.y.)	Quantity Stone (tons)	Concrete (c.y.)	
1889-1899	1,150,000	—	—	—	North and south jetties, including shore protection.
1911-1921	855,713 ^{1/2}	473	132,979	—	Includes provision of 950-ton reinforced concrete monolith at the seaward head of the south jetty in 1915-16.
1922-1931	196,393 ^{1/2}	—	442,612	10,221	Includes reinforced concrete monolith at the seaward end of the north jetty, completed in 1925 and weighing 1050 tons.
1932-1941	—	—	10,340	68,729 (plus 43,853 tons)	Includes restoration of jetty ends with mass concrete and placement of precast concrete blocks on slopes.
1942-1951	—	—	—	40,693	Includes placement of 100-ton blocks on both jetties
1952-1961	—	—	34,205	3,142	Includes six 100-ton blocks
1962-1971	—	—	232,839	20,919	Excludes 225 20-ton concrete-form blocks, 116 100-ton concrete form blocks, 2,259 42- & 43-ton concrete dolosse & 5,257 20-ton concrete form blocks.
1971-1973	—	—	64,622	2,740	Excludes 2,533 42- & 43-ton concrete dolosse and 95 20-ton concrete form blocks.

^{1/2}Although the major jetty rebuilding activities of this period were classified as "new work," the quantities could be considered as maintenance figures since the original jetty structures had long since been completed.

CONCLUSIONS

Engineering decisions made over a period of nearly a century by competent people in search of solutions to the Humboldt Bay entrance problem have shown that corrective actions are available and can be applied with an increasing degree of confidence given today's technology. The design of protective structures for severe wave climate areas such as Humboldt Bay is a difficult and challenging, but certainly not insurmountable, task.

CHAPTER 144

DESIGN OF MAIN BREAKWATER AT SINES HARBOUR

John Dorrington Mettam*

Introduction

In March 1972 the author's firm in association with two Portuguese firms of consulting engineers, Consulmar and Lusotecna, were appointed by the Portuguese Government agency Gabinete da Area de Sines to prepare designs for the construction of a new harbour at Sines on the west coast of Portugal. The location is shown in Figure 1.

The main breakwater, which is the subject of this paper, is probably the largest breakwater yet built, being 2 km long and in depths of water of up to 50 m. It is exposed to the North Atlantic and has been designed for a significant wave height of 11 m. Dolos units invented by Merrifield (ref. 1) form the main armour.

The project programme required that studies be first made of a wide range of alternative layouts for the harbour. After the client had decided on the layout to be adopted, documents were to be prepared to enable tenders for construction to be invited in January 1973. This allowed little time for the design to be developed and only one series of flume tests, using regular waves, was completed during this period. Further tests in the regular flume were completed during the tender period and a thorough programme of testing with irregular waves was commenced later in the year, continuing until August 1974 when the root of the breakwater was complete and the construction of the main cross-section was about to start.

The model tests, which were carried out at the Laboratorio Nacional de Engenharia Civil in Lisbon, were reported by Morais in a paper presented to the 14th International Coastal Engineering Conference in 1974. (ref. 2)

Layout

Sines was selected as the most suitable place on the whole Portuguese coastline for development of a maritime industrial complex served by a new deepwater harbour.

The first phase of the project was to be a new oil refinery with a harbour handling tankers up to 500,000 DWT. Later development would include provision for tankers up to 1,000,000 DWT as well as a wide range of other berths to serve other industries.

* Partner in the firm of Bertlin and Partners, Consulting Engineers of Redhill, Surrey, U.K.

FIG. 1 SITE LOCATION

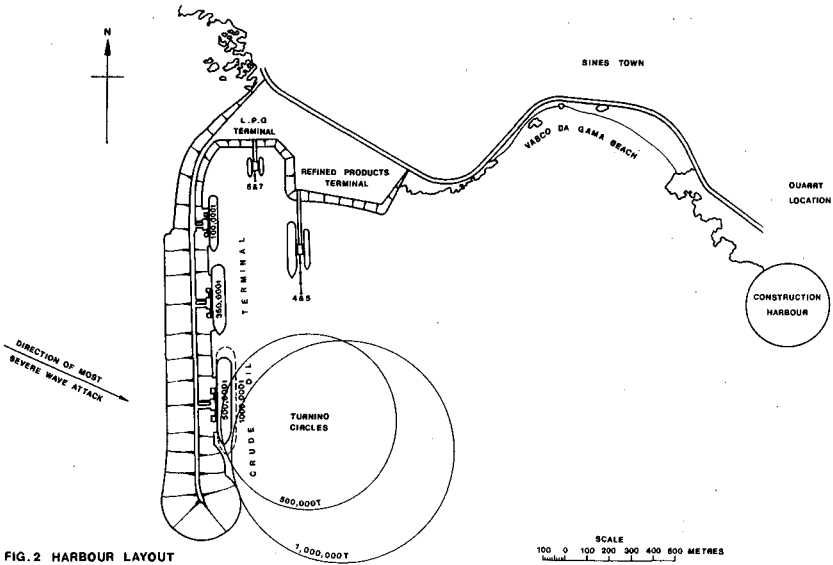

FIG. 2 HARBOUR LAYOUT

The layout of the first phase of the West Breakwater is shown in Fig. 2. Details of the adjacent berths are given in Table 1.

Upgrading of Berth 1 to handle ships of 1,000,000 DWT would require strengthening of the breasting dolphins, and some dredging to enlarge the turning circle.

Table 1 - Details of Berths 1 - 7

Berth No.	Commodity	Max. Ship Size (DWT)	Draft (m)	Depth at Berth (m. below chart datum)
1	Crude oil	500,000 (1,000,000)	28 (33)	39 (see note 1)
2	Crude oil	350,000	25	28
3	Crude/Products	100,000	15	18
4	Products)	45,000	12	19
5	Products)	(100,000)	(15)	(see note 2)
6	L. P. G.)	3,000	6	7
7	L. P. G.)			

Note

(1) It is envisaged that a second berth for 1,000,000 DWT could be provided by a southward extension of the breakwater.

(2) Berths upgraded to 100,000 DWT in Phase 2.

Other berths for dry bulk commodities, general cargo etcetera would form a separate complex adjacent to the South Breakwater, the precise layout of which has not yet been decided. Construction of this complex will be by stages to suit development of industries.

A construction harbour near the South Breakwater was included in the contract near the quarry site to assist the contractor to handle the enormous volume of rock required for breakwater construction. This will finally be used for harbour craft, fishing vessels and coastal shipping.

Design Wave Height

A wave recorder had been installed at Sines in September 1971, as soon as it had become clear that this site would be selected for the harbour. This however had only yielded records for one winter when design of the breakwater started, and for two winters when the final decision had to be made on the weight of armour unit. To supplement this record an analysis was made (ref. 3) to assess the probable wave climate at Sines from some earlier detailed observations made at Figueira da Foz (ref. 4) over a period of 7 years.

In view of the uncertainty regarding the best method of extrapolating extreme values from short period records four different methods were used. No method gave consistently better fit to the available data and no conclusion could be drawn regarding relative reliability. The method of calculation of waves at Sines from those at Figueira da Foz was considered likely to give slightly too high a value - because of the difficulty of allowing for the fact that Sines is further from the main storm areas. Equal weight was therefore given to the shorter period of records at Sines even though these gave a lower result. Table 2 gives the results of the various methods of extrapolation together with the value of significant wave height finally adopted.

Table 2 - Extrapolation of Extreme Waves (Significant Height)

Source	Method of Extrapolation	Return Period (years)			
		1	10	30	100
Figueira da Foz	Gauss	6.5	9.8		14.0
	Weibull	6.3	8.6		11.0
	Weibull Modified(ref.5)	6.5	8.7		11.0
	Exponential	6.5	8.8		11.2
	Mean	6.5	8.9		11.8
Sines Waverider	Gauss	7.8	9.2		11.5
	Weibull	6.1	7.0		8.0
	Weibull Modified (ref.5)	5.8	6.5		7.2
	Exponential	7.0	8.8		10.4
	Mean	6.7	7.9		9.3
Adopted Value for Design		6.5	8.5	9.5	11.0

For the irregular wave flume tests damage criteria were established on the lines proposed by Ouellet (ref. 6). These are shown in Table 3, which also includes overtopping criteria. The wave spectrum used was the Pierson - Moskowitz, based upon site storm records.

Table 3 - Breakwater Design Criteria

Storm Return Period (Years)	Significant Wave Height H_s (m)	Dolos Movement	Overtopping
1	6.5	Nil	Begins with H_{max} individual 10 - 11 m
10	8.5	Oscillation only	-
30	9.5	Beginning of displacement	Severe overtop with 15-16 m H_{max} individual
100	11.0	1% Damage	-

When testing with regular waves the same criteria were applied as far as practicable using wave periods corresponding to a fully risen sea. Wave heights and periods are given in Table 4.

Table 4 - Wave Periods for Regular Wave Flume

Height (m)	8	9	10	11	12	13	14	15
Period (sec.)	11.5	12.3	12.9	13.5	14.2	14.8	15.3	15.8

Development of Design for Main Cross-Section

In the initial design stages consideration was given to a range of possible solutions. The main choice was between rubble mound construction and composite construction with a vertical face structure founded on a rubble mound.

Some preliminary tests of the composite section showed that very large wave forces would be exerted on the vertical structure even if it was founded as deep as -20 m CD. Such forces could probably have been much reduced by the introduction of a perforated face construction. Even so, with the construction problems on such an exposed site it was decided that a rubble mound design would be more economical.

In this decision the availability of a suitable rock, in very large quantities, was of course a major consideration.

With the great depths at the site it was important to adopt a form of armouring which allowed the seaward face to be as steep as practicable, to reduce the volume of rubble core, and to restrict the reach required for the cranes placing heavy armour units.

Discussions with Mr. Merrifield convinced the designers that Dolos units would be the best solution currently available. Comparative studies of dolos and tetrapods during the first phase of regular wave flume tests confirmed this view. Attendance by the author at the 13th International Coastal Engineering Conference in Vancouver in 1972 was also most helpful and the author is indebted to the many people at that conference with experience in research on dolos, and in their use, who generously shared their knowledge.

In preparing breakwater designs it is the author's view that preliminary designs based upon past experience must always be fully tested by flume testing using the precise conditions of waves and topography for the site. This is particularly important when dolos are being used because classic design formulae such as Hudson's (refs. 7 & 8) developed initially for rock armouring, do not allow properly for the type of interlock displayed by these units which alters the importance of slope and specific gravity. Such formulae also omit the effect of wave period, which must be a major factor in determining the wave forces particularly at Sines where wave periods are longer than at many other sites.

For this reason the design was mainly developed by flume testing, first on the regular wave flume and later on the irregular wave flume. The initial design submitted to contractors for tendering, Fig. 3, was based on the first series of tests in a regular wave flume.

This design would in any case have been subject to change when further flume tests were completed. In addition the successful tenderer (Societa Italiana per Condotte d'Acqua S.p.A) submitted an alternative design which was accepted in principle by the Client subject to model testing, Fig. 4. The purpose of the change was twofold; to widen the breakwater crest to provide space for the oil pipelines which would otherwise have required a separate structure; and to provide more space for constructional equipment. This design was considerably modified after carrying out irregular flume tests, the final cross-section being shown in Fig. 5.

FIG.3 TENDER DESIGN

FIG.4 CONTRACTOR'S ALTERNATIVE DESIGN

FIG.5 FINAL DESIGN

The main changes resulting from the irregular wave tests were:-

- 1) Increased crest height on wave wall.
- 2) Adoption of curved profile wave wall.
- 3) Increased width of dolos armouring in front of wave wall.
- 4) Increased weight of capping and introduction of sliding joint at junction with caissons at back.
- 5) Introduction of heavier armour (16-20t) at toe of dolos slope.

The weight of dolos armouring, which had been changed from 30t to 40t nominal (actually 42t) as a result of the second series of regular wave tests was confirmed by the irregular flume tests.

The final design is discussed, section by section, below.

Foundation

The main length of the breakwater is founded, in depths varying from 30m to 50m, on granular deposits overlying shaley mudstone. The deposits consist of sand and gravel in thicknesses of up to 12m.

Site investigations completed after tenders were invited, showed that these deposits were sufficiently dense to support the breakwater. Calculations were made to check the stability under surcharge loadings of up to 60 m of rubble filling. Detailed consideration was also given to the possibility of liquefaction under earthquake conditions (ref. 9) and under the reversal of pressure resulting from severe wave attack. It was concluded that it would not be necessary to remove any bed material before placing the rubble mound.

To guard against scour a toe protection was provided consisting of a 1 m thick filter layer of 5 mm to 100 mm graded stone on which a 2-m thick layer of core material was placed. A narrower strip of filter material under the back slope of the breakwater guards against leaching of the foundation material through the toe of the rubble core.

Rubble Core

The main rubble core was obtained from a quarry sited close to the shore near the site of the construction harbour. Borings showed massive rock, with unbroken cores up to 3 m long. The rock, which has a specific gravity of 2.9, consists of gabbro and diorite.

Two grades of core material were specified. The principal grade complies with the following: "Core material shall not contain overburden or any clayey organic or other deleterious material. It shall consist of rock evenly graded from 1 kg to 3,000 kg. It may contain broken rock fines under 1 kg not exceeding 5% by weight. The quantity of rock under 10 kg in weight shall not exceed 15% of the total weight."

The 'selected' grade, used in the main cross section only above level -2.5 m CD and in the root of the breakwater is similar but the finer material under 10 kg is restricted to between 5% and 10% by weight.

Placing of most of the core material is by dumping from 1,000 t hopper barges. Up to -20 m CD there is no restriction on placing but above this level core construction is not allowed more than 50 m ahead of the secondary armour, which itself is not allowed more than 50 m ahead of the dolos. The purpose of this is to restrict the amount of work at risk during storms. (Fig. 6). The upper part of the core is tipped from 70 t lorries running on top of the core which is at level +5.5 m CD (c.f. high water level +3.8 m CD)

Settlements are being recorded during construction and concreting of the cap is not allowed until 3 months after placing of the core by which time the main settlement has taken place.

The effect of earthquakes on the breakwater was checked using the analysis suggested by Newmark (ref. 10) and developed by Goodman and Seed (ref. 11). This analysis, which is a dynamic method of approach, is used to determine the displacement of the breakwater during the passage of the design earthquake.

Under an earthquake of intensity between 7 and 8 on the modified Mercalli scale, which is expected with a return period of 100 years, a settlement of about 0.5 m is expected.

Rock Armouring and Underlayers

Secondary armour of 3 t to 6 t rock is provided under the main armouring of dolos units. The size is determined partly by the size of the main armour - so that it cannot be drawn through the gaps in between the dolos - but also by the requirement that it should resist attack by 3m to 4m waves during construction.

This secondary armour should be able to retain the core material, after fines have been leached out of the surface of the core. However a tertiary layer of $\frac{1}{2}$ t to 1 t stone was added in the most vulnerable zone to reduce the amount of fines leached out of the core near the seawall. This material can only withstand minor wave attack and must be placed just before the 3 t to 6 t stone.

Fig. 6 Breakwater under construction

Fig. 7 40 tonne dolos

Fig. 8 Dolos moulds

At the toe of the dolos face irregular wave tests showed that draw down under severe wave attack caused damage with 6 t to 9 t rock as originally provided. Stone of 16 t to 20 t weight, supported on 9 t to 20 t rock proved sufficiently stable, but only with the revised shape shown in Fig. 5. This toe armour rests on 0.5 t to 3 t rock which also extends down the seaward face.

On the rear face armour is only provided to a depth of 15 m below low water. Rock of 3 t to 6 t weight proved adequate because overtopping water is thrown clear of the vertical back face of the cap and its energy is dissipated in water.

The 3 t to 6 t armour is also required to resist waves running along the back of the breakwater due to direct attack in southerly storms which are infrequent and diffracted waves from more westerly storms.

Main Dolos Armour

The main dolos armour units have a volume of 16.56 cu m and with a concrete specific gravity of 2.53 weigh approximately 42 t.

The dimensions, shown in Fig. 7, provide a waist: leg ratio of 0.35. Fillets at the junction of the legs have a dimension of 5% of the leg length. Tests by Lillevang (ref. 12) show that this size of fillet greatly reduces the stress concentration compared with a sharp corner but that a better stress pattern is obtained with a radius. When these results were made available to us the moulds had already been fabricated and units had been cast which showed little or no tendency for cracking at this corner, and it was decided not to alter the design.

Consideration was given to providing reinforcement but it was not done. The benefit from reinforcing this type of unit is very doubtful and the potential danger of damage due to corrosion of the steel is more serious. Instead it was decided to provide a high strength concrete - 400 kg/sq cm at 28 days - made with a low heat pozzolanic cement. The contractor's design for moulds, shown in Fig. 8, is considered a very good one. The arrangement of casting with the trunk vertical allowed concrete to be placed and vibrated carefully in the critical area at the corners between the legs and trunk. A compressible joint in the moulds reduced the tendency for shrinkage to put the trunk into tension.

Time did not permit photoelastic analysis of stresses in the dolos. Some comparisons were however made between concrete stresses (ignoring the notch effect of sharp corners) in these and earlier units. These are presented in Tables 5, 6, and 7 in terms of static and dynamic stresses under loads equal to the dolos unit weight.

Table 5 - Comparison of dimensions of Dolos units

Project	East London	Sines	Ratio $\frac{\text{Sines}}{\text{East London}}$
Weight	20 U. S. tons	41.9 metric tonnes	2.31
Volume (cu. m)	7.55	16.56	2.19
Overall Length (m)	3.693	4.540	1.23
Waist Thickness (m)	1.108	1.589	1.43
Waist Ratio	0.30	0.35	1.17

Table 6 - Comparison of maximum static tensile stress in Dolos units

Note (1) Applied load = self weight of 1 Dolos unit

(2) All stresses are in tonnes/sq. m.

Load Case	1	2	3	4	5	6	7
Loading Condition							
East London Dolos	93 (100%)	80 (100%)	193 (100%)	243 (100%)	112 (100%)	205 (100%)	287 (100%)
Sines Dolos	84 (90%)	63 (80%)	186 (97%)	173 (71%)	104 (92%)	131 (64%)	200 (70%)

Table 7 - Relative dynamic stresses in Dolos units

Load Case	1	2	3	4	5	6	7
East London Dolos	100%	100%	100%	100%	100%	100%	100%
Sines Dolos	100%	89%	108%	79%	102%	71%	78%

The design of the armour face was based upon the recommendations of Zwamborn and Beute (ref. 13) and 155 units were specified per 1,000 sq. m of armour face. To ensure maximum interlock it was required that the complete face be built in a single operation rather than in separate layers.

This method has also been specified for placing rock armour (ref. 14) and is no more difficult than proper placing of separate layers. Hydraulic model tests showed that the number of dolos required could be placed in three separate layers but comparative tests confirmed at a very early stage that the specified method of placing in one operation gave a much more stable face. No comparisons were made with the thinner, two layer, armouring recommended by Waterways Experimental Station (ref. 8) but the author considers that detailed comparisons would show that the two layer system would require heavier dolos to give equal stability.

The specified method of placing is particularly advantageous in assisting interlocking on steep slopes, such as the $1 : 1\frac{1}{2}$ slope adopted at Sines, and it is considered that there would be little if any improvement in stability if a flatter slope were adopted because interlock during placing would be reduced.

Full records of damage during placing have not yet been made available to the designers, who are not responsible for site supervision, but it is reported that breakages of the order of 2-3% have occurred. Broken units are removed unless they are so interlocked that removal is impracticable. This rather high rate of damage no doubt stems from the use of floating cranes, already available to the contractor from another project, instead of cranes mounted on the breakwater. On such an exposed site this involves placing dolos with waves of up to 1 m and even so there is considerable down-time even during summer months.

Concrete Capping

The capping carries a road and pipelines. Its width reduces beyond each oil berth as fewer pipelines are required. To avoid damage to the pipelines the rubble mound is allowed to settle for 3 months before concreting commences. Despite this precaution the slab is heavily reinforced to resist stresses induced by settlement which may be expected to continue particularly during storms or earthquakes. Some damage to pipelines and minor structures during extreme storms and severe earthquake is of course acceptable provided that the main structure survives.

Fig. 9 shows the capping proposed by the contractor which model tests indicated would not be satisfactory, even after incorporating the vents shown in Fig. 10. The tests showed that it is important to have a sliding joint between the capping slab and the small caissons at the rear of the breakwater. Details are shown in Fig. 11. The difference in type of failure is illustrated in Figs. 12 and 13. Without a joint the cap tends to lift and rotate about the back corner of the caisson causing a local failure at the back of the rubble mound. With the joint the cap slides over the caisson and the cut off at the front of the cap tends to dig into the top of the rubble. Provided the cut off is sufficiently strongly reinforced, failure can only occur by a deep shear through the main body of the rubble mound.

Fig. 9 Contractor's alternative capping design

Fig. 10 Model test on contractor's alternative capping design

FIG. 11 FINAL DESIGN CAPPING DETAIL

FIG. 12 MODE OF FAILURE - CONTRACTOR'S ALTERNATIVE CAPPING DESIGN

FIG. 13 MODE OF FAILURE - FINAL CAPPING DESIGN

Model tests on the alternative wave walls shown in Fig. 10 showed the value of curving the front of the wall, above the top of the dolos, to throw back the stream of water which comes over the dolos, thereby delaying the onset of overtopping. The proportions are based upon extensive research by Vera-Cruz at the LNEC hydraulic laboratory in Lisbon. Tests were made to determine the bending moments due to wave forces on the upper part of the wall which are of course very substantial. (Fig. 14)

The cap is cast in lengths of 15 m between joints. The total weight of each bay (excluding pipelines and the caisson below the sliding joint) ranges from 4,000 t to 5,000 t. The total wave force with the maximum individual wave in the 100 year storm is calculated to be 60 t/m, producing a bending moment at the base of the wave wall of 200 t f-m/m. Measurements on a model of the section of wave wall above road level gave a maximum prototype bending moment of 180 t f-m/m. Reinforcement in the cut off is designed to transfer a force of 160 t/m or 2,400 t/bay.

The vents in the cap, which are designed to minimise uplift pressures from water movements in the rubble core, are 300 mm diameter and are provided at 3 m centres. The bottom of each vent pipe is surrounded by a filter of 50 mm to 100 mm size rock to prevent leaching out of fine material. The vents have been observed to pass a mixture of air and water during a storm with maximum individual wave less than 10 m.

The joint between the capping slab and the small caisson is formed by a very careful steel float finish to the concrete which is covered by polythene sheeting to ensure a free sliding joint. Expanded polystyrene, as shown in Fig. 11, prevents any possible transfer of shear forces through stones being caught between the slab and the caisson. The sliding joint is formed only over half the top of the caisson. The other half, near the harbour, is covered with sand which is subsequently flushed out to leave a 100 mm gap. This is to ensure that vertical loads are applied to the caisson in a way which gives the most favourable distribution of stress on the foundation.

Root of Breakwater

The topography of the site is such that there is a clearly defined section of breakwater on shallow rock foundations before the bed drops steeply into deep water where the main cross-section, already described, is required.

The root section is not only protected by shallow water but also by a number of rocks to seaward so that waves are depth limited and tend also to be divided. The length closest in-shore is armoured with natural rock. Fig. 15 shows the design for a typical length of the root section in a depth of about 4 m at low water where the armour is 15 t dolos. It will be seen that the wave wall design is more closely related to the contractor's alternative cross-section (Fig. 4) for the main breakwater but the crest height and cut off arrangements were modified in light of the model test results for the main cross-section. No model tests

Fig. 14 Final design model study of forces on wave wall

Fig. 15 Root of breakwater

were made for the root section because the broken nature of the sea bed makes any flume tests unrealistic.

Breakwater Head

The design of the head of the breakwater is still being studied on a wide flume at the LNEC in Lisbon. The original intention was to use a caisson head in the form of a vertical cross wall founded at about -24 m CD. This design would have had the advantage that future extension is very easy.

At this site it is necessary to design for earthquake forces and the worst wave attack is from WNW. Both factors require any caisson to be very wide to resist heavy forces from the shoreward side making this design more costly than a round head armoured with dolos.

Since the need for further extension, which would provide a second berth for ships of 1,000,000 DWT, appears to be very remote it has been decided to adopt a roundhead design.

Acknowledgements

This paper is produced with the kind permission of the Gabinete da Area de Sines which is gratefully acknowledged. Thanks are due to Mr. Berry of Bertlin and Partners who helped in the preparation of this paper. The author wishes to acknowledge the kind help of Mr. Merrifield who invented the dolos unit and generously made it freely available.

He also thanks many others interested in research on the behaviour of dolos units and in their use who have exchanged information privately and through papers and discussions at the 13th and 14th International Coastal Engineering Conferences.

CHAPTER 145

EXPERIMENTAL STUDIES OF STRESSES WITHIN THE BREAKWATER ARMOR PIECE "DOLOS "

Omar J. Lillevang,* F.ASCE and Wayne E. Nickola**

Introduction

Stresses induced within the breakwater armor piece "Dolos", when it is subjected to loads, are not reliably inferred from the two-dimensional techniques of analysis used in conventional design of structures. Other methods that take the solid geometry of the dolos into consideration are available, and comprehensive application of one of them, three-dimensional photoelastic stress analysis, is reported here.

Breakage of Dolosse

Breakage experienced at 15 projects throughout the world, where nearly 150,000 dolosse ranging from 3 to 42 short tons (2,000 pounds or 907 Kg.) in weight are in use on breakwaters, is digested for the reader by Table I. It has been impressively low. With the exception of one project, Humboldt Bay, none of those dolosse are reinforced.

It is well known that most of the breakage of pre-cast armor pieces takes place during the manufacture and storing and during the construction of the breakwater. Table I illustrates it. Several details within the table that stand out are commented upon in the following notes, each note being identified by the line number from the table:

Line 3. According to the owner's report, the relative high breakage during manufacture stems from 100°F air temperatures during casting, which contributed to development of shrinkage stresses and minute cracking.

A wave storm during construction rolled numerous dolosse that were not yet nested in the armor matrix and they suffered impact fractures.

Breakage in service is attributed by the owner's report to battering during severe storms by loose large quarrystones.

Line 4. Most of the in-service breakage occurred when a localized area of the foundation eroded, and an abrupt subsidence into the pit caused 10 dolosse to break.

* Includes breakage during consolidation of the structures, e.g. during first storms.

- Lines 5, 6, 7. Extensive litigation over the project has made factual discussion of breakage unavailable, but subsequent to consolidation of the structure it appears breakage has been nominal.
- Line 12. All but 26 of the dolosse contained steel bar reinforcement. The owner's representative reports the unreinforced versions were placed in low areas after completion of the armoring, and were thus "not integrated with other units". Of the 36 dolosse broken, 9 were not reinforced.
- Lines 13, 14. Owner's representative reports manufacturing breakage was reduced by halting cold-weather pours and changing the cementing ingredients, from 50/50 Portland cement/"slagment" to all Portland cement, during cold-weather pours.
- All the dolosse were made with "all-in", pit run sandstone aggregate, resulting in concrete that was sometimes over-sanded and sometimes under-sanded. Cement was 50% Portland and 50% "Slagment", blast furnace slag.
- Line 14. In-service breakage can be separated into 1.7% initial consolidation fractures caused by insufficient fitting, and by some abrupt localized downslope adjustments, and 0.3% breakage since the consolidations during the first storms.
- Line 15. Contractor tried to use a form made of concrete for the lower half of these dolosse. Those unyielding form surfaces proved to be warped and bulged, and tended to lock in the newly cast dolosse. Excessive force was needed to remove them. When the problem was diagnosed, new fabricated steel forms were substituted and breakage immediately was all but eliminated.
- Lines 21, 22. Heavy breakage during manufacture was attributed to removal of forms when castings were only 4 hours old.
- Line 29. Contractor surmises breakage relates to steam heating of the new castings while still in the forms.

The various projects listed in Table I include many variations in materials, in quality control during manufacture, in strength of concrete and in dimensional proportions. Thus it would be surprising if there were systematic relationships between breakage intensity and size, and there is none to be seen in the table.

Popov (4) and Danel, et al (1) have shown that armor pieces of different sizes but identically similar shape, and made of the same material, will break on impact with an unyielding surface from the same height of fall. The theory and Danel's experiments with dropping 295 tetrapods, of from 20 ounces to 25 tons weight, suggest design

loads for impulsive forces on the dolos would be the same for any size piece. With other types of loads, however, steady ones or dynamic forces less severe than impacts, stresses sustained by a dolos under design conditions may be larger or smaller as the size and weight of the piece is larger or smaller. In that case there would be reason to modify the larger pieces with stress reducing measures that smaller dolosse would not require.

Three approaches toward stress management which could be combined, or be mutually exclusive, are discussed in this paper. They are:

1. Incorporating steel bars to take the tensile stress;
2. Reduction of force moments by thickening the shank, and consequently shortening the flukes;
3. Reduction of stress concentrations at critical parts of the dolos by minor geometric modifications, viz. at the intersections of the flukes with the shank, to keep stresses below the modulus of rupture of the concrete.

The photoelastic tests indicate that, to have any useful effect toward preventing fracture of a dolos at its intersections of flukes with the shank, steel bar reinforcement would have to be placed so close to the skin of the piece that loss of the steel by corrosion in a short time would be unavoidable; the cost of such steel thus would be wasted and its effect would be ephemeral.

The tests suggest some stress reduction does result from thickening of the shank, but not significantly when the extent of thickening is kept below sensible limits that are proposed by the dolos' conceptor, Eric M. Merrifield. It is his view, expressed in personal communications with the senior author, that thickness of shanks in excess of 36 per cent of the height of the dolos would cause undesirable losses of interlocking characteristics.

Modifying the intersections between flukes and shank showed significant reductions of stress concentrations in the test pieces. Making dolosse of all sizes in future with a small curved fillet at those corners is proposed, not only to reduce stress concentrations but also to minimize concrete imperfections that often occur at sharp corners during pouring of concrete.

Photoelastic Stress Analysis

Among methods of experimental stress analysis that have been developed and proved is the photoelastic study of loaded two-dimensional plastic models. Either reflection or transmission of polarized light from or through various plastic materials yields light interference patterns that are rationally related to stresses within the plastic. Knowledge of this phenomenon is not new. It has been available with use of two-dimensional models for a century, and has been in widening use since the 1930's. Beginning with discoveries made in 1936, three-dimensional plastic models of complicated geometry have been loaded in

laboratory ovens, at temperatures above the softening point of the model material. In this temperature range the material does soften but remains linear and deforms elastically under the applied loads. After being held under load at carefully controlled specific elevated temperatures, the oven heat is systematically and very slowly withdrawn until the model piece has reached room temperature. During this cooling phase of the "stress-freeze" process, which may take several days, the loads on the model are sustained. When the model has reached room temperature the loads can be removed, but the stress patterns persist within the plastic. The model can then be cut into thin slices at any planes of interest, and polished. When polarized light is transmitted through those slices and examined with appropriate optical equipment each one shows the stress patterns that were induced along that plane by the test loads. Calibrations and rational computation procedures relate the patterns to definitive stress values. These techniques are commonly relied upon by industry. Complicated forgings, castings, fabrications, pressure vessels, struts, bearing housings and a host of other shapes and devices have been evaluated by this method. Except for some work that may have been done in England, it apparently has not been used before on a breakwater armor piece.

Description of Models

Sixteen three-dimensional models of dolosse for the present tests were cast from photoelastic thermal-setting plastic. All were made with the dimension h equal to 6 inches, which is 15.24 centimeters. As will be seen in several figures in this paper, the dimension h is present in two ways in the dolos. It is the overall height from tip to tip of two adjoining flukes, and is also the overall length of the piece, measured parallel to the axis of the shank. Half the models were made with shank thickness 32 per cent of h and the other half with 35 per cent. For each thickness ratio, four different versions were cast that varied the geometric details at the intersection of the fluke with the shank. The traditional dolos, with sharp intersections between fluke planes and the planes forming the shank, was tested at both thickness ratios. Those specimens were identified by codes 32HS and 35HS, the letter S identifying the sharp intersection characteristic for pieces with shanks 32 per cent as wide and 35 per cent as wide, respectively, as the height. Other versions of corner geometry, also tested for both 32 and 35 per cent shank thickness, had chamfers created by planes (32HC and 35HC), a small-radius circular fillet (32HF and 35HF), and a larger-radius circular fillet (32H ϕ and 35H ϕ).

In the stress-freeze tests, stresses frozen into the model dolosse were produced with two different loading patterns. In the "Tension" series, equal forces that were all directionally parallel with the shank's axis were applied at the ends of the four flukes. Pairs of forces were oppositely directed, in a normal sense placing the shank in tension; therefrom the "Tension" term for describing those tests. In the "Torsion" series, equal forces were again applied at the ends of the four flukes, but acting in planes perpendicular to the axis of the shank and directed to twist the shank; therefrom the "Torsion" term for that series. Sixteen models were made and stressed. Fifty-eight sections were sliced from various parallel or intersecting planes, to find the stress characteristics within the dolosse resulting with

all the variations that were involved. Figure 1 shows and compares the four details of the corner that were studied, being cross-sections in

Figure 1

the plane common to both the fluke axis and the shank axis. As illustrated in Figure 2, the chamfer tapered to a point in the corners between planes either side of the ones cut for the profiles that are shown in Figure 1. The circular fillets in those same two flanking corners had to have radii 1.5 times as long as those in the central corner, because the angle of intersection of planes adjoining ac is larger than the angle of intersection along ab. The circular fillets did not taper to a conical point.

All the models were made with flukes whose cross-sections normal to their axes were not symmetrical octagons. The left side of Figure 3 shows the awkward geometry that develops at the intersections of flukes with the shank if a symmetrically octagonal fluke is made. To eliminate the intersection problem a slab of constant thickness, S, should be taken off the whole octagonal side of the fluke, above the shank at the intersection ab. If the maximum breadth of the octagon at the tip of the fluke is the commonly used .20h, and t is the thickness or breadth of the shank octagon, then the thickness of the slab to be removed, shown at the right side of Figure 3, is:

$$S = \frac{0.12132(.2t/h - t^2/h^2)}{(t/h)\tan 22.5^\circ - 1} (h)$$

The models with chamfered and filleted corners, consistently for comparison values, also were made with flukes of asymmetrical cross-sections.
