Rubber moulds for casting all the photoelastic models were formed by pouring a silicone rubber compound around a precisely machined acrylic resin master dolo that had sharp corners. To modify the master in order to make moulds for the chamfer and fillet versions, pattern maker's beeswax was hand-tooled into the corners of the master pattern. At the scale of these models, the corners of the hand-molded chamfer planes were not as sharp as one would expect intersections to be in the prototype, where structural steel plate is the likely material from which such forms would be fabricated. Because the

Figure 2

Figure 3

chamfer intersections probably were slightly rounded, the stress concentrations shown by the photoelastic models with the chamfered corners probably are less severe than they would be at prototype size, or than they would have been had the model chamfers been precisely machined instead of being hand formed of beeswax on the master pattern.

The theory of photoelastic stress analysis is well covered in reference works that are readily available in technical libraries, so there is no development of the theory in this paper. However, the laboratory techniques employed in the present tests and the analytical procedures that were followed deserve description.

A reconnaissance test program was carried out before the stress freeze models were made, to compare at least qualitatively the effects of six different arrangements of loading. For the reconnaissance, a specially compounded aluminum-filled epoxy resin was selected, and model dolosse cast from it were clad with a thoroughly bonded bi-refractive coating material. The bond was made with an epoxy-based reflective cement. A reflection polariscope was used to view the model while it was under each loading arrangement. Elastic deformations induced by the loads were transferred from the dolos to the cladding by shear forces developed at their interface. When polarized light was reflected from the surface of the model through the bonded layer, the coating exhibited patterns of birefringence which were quantitatively analyzed. Out of those preliminary tests it was concluded that the "Tension" and "Torsion" loading patterns previously described would best develop the internal stress information that was wanted from the stress-freeze photoelastic procedures.

Internal Stress Data, Quasi-Dimensionless Form

Stresses that were shown in the photoelastic models were reported in quasi-dimensionless form, to enable easy calculation of stresses in prototype dolosse of any size and for any selected value of the moment and shear producing forces. Stresses in the prototype were related to stresses in the model by:

$$\sigma_p / \sigma_m = (F_p / F_m) (h_m / h_p)^2$$

Where σ_p , σ_m = Stress in prototype and model, respectively
 F_p , F_m = Load on prototype and model, respectively
 h_p , h_m = Corresponding dimensions of prototype and model, respectively.

If F_p is expressed in units of the total dead weight of the prototype dolos, and ρ is the unit weight of the concrete from which the prototype dolos is made, and V is the volume of the dolos, then

$$\sigma_p / \sigma_m = (n V \rho / F_m) (h_m / h_p)^2$$

where n is the number of units of the dolos' weight, a convenient way to express the design load. All models were six inches high, i.e. $h = 0.5$ feet. Thus, for models where the shank thickness t is 32 per cent of h , and Volume consequently equals $.1550h^3$,

$$\sigma_p = .03875 h_p \rho n (\sigma_m / F_m)$$

For the models with $(t/h) = 0.35$ the volume is

$$V = .1739h^3,$$

So for those models it can similarly be shown that

$$\sigma_p = .043475 h_p \rho n (\sigma_m / F_m)$$

The test results for surface stresses then could be presented as the parameter $\sigma/\rho h$, and for internal stress components on the plane of each slice as $(\sigma_1 - \sigma_2)/\rho h$. In all cases, the numerical values of the parameter were calculated with n equal to 0.5, that is to say they are stresses induced by two forces whose sum is the dead weight of the dolos. Multiplying the numerical values of the stress parameters by the unit weight of concrete intended for a prototype dolos, in pounds per cubic foot, and the product by the height of that dolos in feet, yields stress in the prototype in pounds per square inch.

Presentation of Results

Figures 4, 5 and 6 are examples of the forms in which stress analyses from most of the 58 slices in the complete test program were reported. Figures 4 and 5 are examples of reports on those slices that presented "Tension" test results and Figure 6 is for a "Torsion" test.

At upper right on Figures 4 and 6 the dimensions of the dolos are shown and the loading patterns of the forces F are displayed.

At top center of all sheets like Figures 4 and 6 is shown where the reported-upon slice was cut from the stress-freeze three-dimensional model.

In the photoelastic examination of each slice the optical system presented the lines of constant stress, the isochromatic fringe patterns $(\sigma_1 - \sigma_2)$, at full model size. It also projected the slices at ten times model size. The enlarged projections were examined to identify the locations of maximum stress concentrations at the surface and the direction of steepest gradient of stress variation within the dolos. That part of each slice was reproduced as a line drawing at the lower left of all the sheets like Figures 4 and 6, showing the surface lines of the fluke and of the shank and the intersection profile and the "contours" of the stress parameter $(\sigma_1 - \sigma_2)/\rho h$. These slice displays were oriented to place the direction of the visually determined transect of steepest gradient of stresses parallel with the horizontal direction of the data sheet.

The diagram at lower right on all the sheets like Figures 4 and 6 is a direct projection, from the left, of the stress values at the surface of the dolos, and illustrate the rate of stress increase toward

the maximum concentration at the corner. These values at the surface are the tensile stress, because σ_2 must be zero at a free surface and the load pattern is such that σ_1 in this case must be tensile.

At top left, the internal stress variation along the transect of steepest gradient was projected upward from the cross-section at lower left.

Stress gradients in the sharp cornered dolosse were extremely steep at the surface, and absolute determination of values at the corners was not possible. This is indicated on all plots of surface stress and of internal stress for sharp cornered pieces by small arrows, emphasizing that the value of $\sigma/\rho h$ was not determined, and the curves stop short of joining on the Surface Stress graph and of reaching the $h = 0$ abscissa on the Internal Stress graph. In fact, if it were possible to make an absolutely sharp corner, the $h = 0$ line would be the vertical asymptote of the internal stress curve.

Four slices were taken from each "Tension" model for analysis. In models with sharp corners and with chamfered corners and with small radius filleted corners the slices were all taken at the planes described at the upper right of Figure 5. The lower parts of Figure 5 show the equal stress contours for each of the whole slices of the Tension Tests for Sharp Corners, not just the enlarged detail close to the corners that were reproduced on Figures 4 and 6. As before, numerical values for the maximum concentration of stress in the corners could not be shown, but the analysts estimated they would be on the order of 0.30 to 0.32. The rapidity with which stresses reduce, as one considers planes removed from the shank's shoulder at Slice B, is apparent when one examines the stress patterns on Figure 5 of slices C and D at successively greater offsets from the axis of the piece.

There were three slices removed from each "Torsion" test model that had sharp or chamfered or short-radius filleted corners. Two of the locations are shown at the upper right on Figure 7 and the third, a surface slab containing the corner and called Slice A, is shown on the sketch at upper left. Stress contours for all three slices are shown as before, and orthogonal trajectories of the principle stresses in Slice A are also shown. The solid orthogonals indicate the direction of the maximum tensile stress, and the dashed ones indicate the direction of the maximum compressive stress. These stress trajectories are not to be confused with the lines of constant stress, isochromatic fringe patterns ($\sigma_1 - \sigma_2$), referred to as "stress contours" before in this paper. The stress trajectories represent the force flow lines of principal stress direction and are of variable stress intensity along the trajectory. Data sheets similar to Figure 7 were prepared for the Torsion tests of the chamfered and of the small radius filleted corners, but are not reproduced here.

When all data were available from testing the first three variants, with sharp, chamfered and small-radius filleted corners, comparisons were made that suggested yet another corner variation should be investigated. Table II shows maximum stress values at the surface in the corners of the three variants, all expressed as fractions of the stress

Considering the analysts' view, that imprecise moulding of intersections of the chamfer planes with the fluke and shank planes tended toward understatement of stresses by the chamfered models, it appeared that the minute-radius fillet reduced stresses essentially as well as did the chamfer.

Guided by published stress reduction factors for details of common structures, a judgment was made that a dolos with circular fillets of a radius equal to 4 per cent of the dimension h should be tested. With larger radii, the published factors suggested, incremental reduction of stress concentrations became less significant. There was a concern, lest the fillet become so large that the very desirable nesting or tangling characteristic of dolosse in an armor matrix should be impaired. New stress-freeze model dolosse were made, with circular fillets of .04h radius on the corner labelled ab in Figures 2 and 3 and of 1.5 x .04h on the side corners, ac of Figures 2 and 3. As before their h dimension was 6 inches and the same Tension and Torsion loads were applied.

There were models, also as before, where the shank thickness was 32 per cent of h (t/h = .32) and where it was 35 per cent. Figures 8, 9, 10 and 11 show the results, and are directly comparable with Figures 4-7 inclusive. The pattern of slices taken from "Tension" models in these experiments was modified, as can be seen by comparing the descriptive drawing at the upper right of Figures 5 and 9. By cutting Slice C from the large fillet models on a plane radial to the fluke axis it became possible to identify the inclination and direction of the plane through the crotch of the dolos where all stress gradients were of maximum steepness. The new slice E_A was then cut along that plane. As can be seen on the slice E_A stress contour plot, at the bottom of Figure 9, the stress magnitudes are negligible along that plane. Thus, recognizing that the E_A plane is perpendicular to the A slice, and nominally coincident with the maximum gradient transect lines of the A and B slices, it is practical and conservative to use the internal stress values from slices A and B as indicative of the maximum principal stress σ_1 (tension) rather than the principal stress difference $\sigma_1 - \sigma_2$.

In certain instances it is desirable to know the shear stress magnitude in concrete. This information is readily available from the

stress contours. The contours as shown are for the difference of principal stresses ($\sigma_1 - \sigma_2$). From Mohr's Circle the maximum shear stress τ_{\max} is:

$$\tau_{\max} = (\sigma_1 - \sigma_2)/2$$

and the contours truly display $2 \tau_{\max}$ as shown.

Figures 12 and 13 each summarize and provide direct visual comparison of the internal stress gradients for all sixteen of the models that were tested. Figure 12 compares the effects of corner details and shows, to the immediate right from each graph, the numerical value of the stress parameter at the surface for each of the three corners that were not square. Recalling the analysts' estimate, that the sharp cornered dolosse had surface stress values between .30 and .32 ρh , it appears the circular fillet with radius of .04h would reduce the critical stress in the corners by 50 per cent, at least, of the sharp cornered stress value.

Figure 13 presents the same curves as Figure 12, but arranged to evaluate the effect of varying the ratio of shank thickness to dolos height, t/h .

Flexural Strength of Concrete

In 1957 Paul Klieger (3) presented data from comprehensive flexural tests of concretes that are remarkably systematic and are useful in considering fracture stresses in the dolos.

Beams 6 by 6 inches and supported over 18-inch spans were loaded to failure, and the tensile strengths of their concretes were calculated as the Modulus of Rupture. Strengths were determined for ages varying from one day to one year. Six-inch cubes were prepared from the ends of the broken beams and tested as compression specimens. A sufficient number of standard 6-inch diameter by 12-inch length standard cylinders also were cast from the same batches of concrete made for the beams, and they also were broken in compression. That permitted developing a reliable factor for converting cube compressive strengths to standard cylinder compressive strengths. It was determined that, for the aggregate being used, the ratio of 6" by 12" cylinder compressive strength at all ages of test specimens to the compressive strength of 6-inch modified cubes was 0.93.

One of the experimental series dealt with a concrete typical of marine structures, made with ASTM Type II cement and with air entrainment of 4.5%. One hundred forty-three test beams of ages ranging from one day to one year were tested in flexure. There is very little scatter of data from the straight line $R = 1.1 (f_c)^{.75}$, where

R = Modulus of Rupture, the flexural tensile stress in pounds per square inch at the beams' extreme fibre at loads producing failure;

f_c = compressive strength of a standard cylinder at the age of the flexural test specimen.

Figure 14 comes from another arrangement of Klieger's data (points not plotted), to show how the Modulus of Rupture in his tests was found to vary with age of the concrete. It can be put to good practical use when making judgments as to how soon after casting a dolos one can handle it, with acceptable risks of damage to its structural integrity.

Concrete for dolosse has commonly been specified with a minimum acceptable compressive strength at 28 days of 5,000 pounds per square inch, roughly 350 Kg/cm². The Modulus of Rupture at age 28 days for that specified compressive strength could be estimated from the Krieger experiments at 650 pounds per square inch, or 46Kg/cm². At one day, according to Figure 14, that same concrete might have a flexural strength of 200 pounds or more per square inch, or 15 Kg/cm².

A project being planned in the United States will use dolosse of the unprecedented weight of 62 short tons, which is just over 56 metric tons. If made from concrete with a specific gravity of approximately 2.4, their h dimension will be 17.5 feet, or 5.33 meters. On the same project smaller dolosse also will be placed, weighing 40 and 11 short tons. Respectively, their h dimensions would be 15.1 and 9.8 feet. Table III has been calculated from the transect curves of Figures 12

and 13 to illustrate the stress magnitudes, under the loads F of the photoelastic experiments, at various depths in the three sizes of dolosse for the planned project.

Good practice in reinforced concrete design for hydraulic structures, particularly for a sea water environment, requires that there be substantial thickness of dense, hard, sound concrete between embedded steel and the water that surrounds or splashes the concrete. A 3-inch cover, which is 7.5 cm, commonly is required and 4 inches, nominally 10 cm, or more is required by some.

The stresses displayed in Table III suggest the reason for the low breakage experience with dolosse at existing projects that achieved uniformly high quality concrete and that were faithfully built in compliance with appropriate breakwater designs. The largest existing dolosse with sharp corners are those at East London, South Africa, and weigh just under 20 tons each. Larger ones at Hong Kong's High Island East Cofferdam (27.5 tons), Richards Bay, South Africa (33 tons), Crescent City, California (40 tons), Humboldt Bay, California (42 and 43 tons) and Sines, Portugal (44 tons) all are chamfered. Under the loading conditions used in calculating the Table III stresses, all would have surface maximum stresses of less than 650 pounds per square inch. At 4 inches depth, the closest to the surface many experienced

engineers want reinforcing steel placed in concrete immersed in or splashed by sea water, the stresses shown in Table III are so low that the effect of steel bar reinforcement on crack prevention might not be discernible. Such steel then would be redundant at best, because it could only act if some mortal blow striking the dolos opened a crack the bars would be incapable of preventing. For some time, the bars in such a cracked dolos might stop separation into fragments, but probably only so long as oxygenated sea water seeping to the bars through the crack had not yet completed corroding the bars to the point of severing or to exerting swelling stresses on the surrounding concrete that typically makes it spall away and create failure by that condition. It appears that reinforcing steel in dolosse must be an economic waste. However, a possibly stronger reason for not burying them within the piece is a concern such bars could induce shrinkage cracks, during hydration of cement in the freshly poured concrete.

The authors are persuaded that large dolosse, say 30 tons and heavier, need to have eased corners between flukes and shank to reduce stress concentrations to prudent maximum levels. The use of central fillets of radius .04h and side fillets of .06h radius is seen as the best means for easing those corners, because important collateral benefits in concreting derive. Other easing geometries that are almost as effective in stress reduction do not provide as clear a concreting

advantage. The relative simplicity of incorporating the fillet details when fabricating steel forms suggests it will be useful to have filleted corners in dolosse of all sizes, the concrete placing advantages being the justification.

The viewpoints expressed in the foregoing paper and conclusions reached are those of the authors. The photoelastic testing that made the paper possible were performed for Public Service Electric and Gas Company, of Newark, New Jersey. Their permission to publish the test data for the benefit of practicing engineers is acknowledged, with appreciation.

CHAPTER 146

EFFECT OF BROKEN DOLOSSE ON BREAKWATER STABILITY

by

D. Donald Davidson¹ and Dennis G. Markle²

Introduction

Although the use of rubble-mound structures for protection of coastal areas is common throughout the world and considerable hydraulic design data have been developed to aid the designer, very little data are provided on the structural integrity of individual armor units and the effect of broken units on the stability of such structures. The forces to which such structures are subjected are complicated and vary with type and geometry of the structure, depth of water, bottom configuration seaward of the structure, water level relative to the crown of the structure, and wave dimensions. Since all of these parameters are involved, accurate determination of wave forces cannot be calculated; and although it is not impossible to model the structural strength of armor units or measure forces on individual armor units, there are physical limitations which make the tasks extremely difficult. There is one way, however, that a breakwater stability model, as it exists today, can provide useful information on this subject and that is to purposely break given numbers of armor units and observe the effect on the overall stability of the structure. Such tests have been conducted at the U. S. Army Engineer Waterways Experiment Station for the Atlantic Generating Station (AGS) Breakwater in which specific answers were desired; thus, the data are limited to the dolos armor unit. The data do provide, however, significant indications regarding the type and extent of breakage (cluster or random) that is most detrimental to the overall stability of the structure; whether costly reinforcing steel is warranted to assure reduced armor breakage; and where necessary, data from this type study can be used as a basis for setting maintenance criteria that will prevent deterioration of the breakwater due to armor unit breakage.

Background

The AGS Breakwater is a 104-ft high, horseshoe-shaped, rubble-mound breakwater proposed for construction about three miles off the coast of New Jersey in about 30-40 ft of water (Figure 1). The purpose of the breakwater is to provide protection for two floating nuclear power plants. Initial tests conducted with unbroken dolosse indicated that for a selected condition of 16-sec, 40-ft waves at a still water level of +16.3-ft mean low water (mlw), 37-ton and 62-ton dolosse would be completely stable (practically no movement) on the trunk and heads of the breakwater, respectively. The broken-unit tests evolved from the question that if for some reason (i.e., reinforcing steel were not used,

¹Chief, Wave Research Branch, USAE Waterways Experiment Station.

²Research Hydraulic Engineer, USAE Waterways Experiment Station.

Figure 1. Layout of the Atlantic Generating Station

higher storm conditions, etc.), the armor units experienced breakage, what number of dolosse could be broken without having a detrimental effect on stability of the breakwater. Actual field experience for most projects throughout the world indicates that not over 2 percent of the total number of primary armor units are broken during the process of armor curing, placement of armor units, and exposure to wave attack not exceeding the design conditions. Therefore, if it can be shown that a significantly higher percentage of the armor units can be broken without deteriorating the stability of the structure, there is no need to use costly reinforcing steel to prevent breakage; or if the breakage should approach the critical percentage predicted by the model, proper maintenance can be initiated to preclude serious damage to the structure.

Two-Dimensional Model Tests

Normal Design Condition, Uniform Breakage

Several set of broken unit tests were conducted for the AGS Breakwater; however, only two sets of these tests are addressed in this paper--normal design conditions and extreme wave conditions. Both sets of tests used, for their respective water levels, the worst breaking wave condition that could occur on the structure. The first set of two-dimensional broken unit tests were conducted at an undistorted scale of 1:45 for the 16-sec, 40-ft wave condition at a swl of +16.3 ft mlw (condition for which model tests had already determined that unbroken 37-ton dolosse were completely stable on the trunk section of the structure, see Photograph 1). Using the unbroken unit test results as a base condition, up to 25 percent (in 5-percent increments) of the top layer of dolosse were broken and uniformly distributed (represents random breakage) over the test section.

The test section was constructed in the model in the same manner as two-layer unbroken unit test sections were constructed, which on the average requires about 55 percent of the total number of dolosse in the bottom layer and about 45 percent in the top layer. Once the unbroken unit test section was completed and the number of dolosse in the top layer determined, the number of broken dolosse specified for that test was determined and randomly placed in the top layer by removing an unbroken dolos and dropping a whole dolos in two parts in its place. Individually broken dolosse were never represented by more than two pieces. It is believed the model procedures used yield conservative results, since the disruptive action of replacing the unbroken armor unit with pieces does not occur in the prototype (i.e., most unbroken armor units simply break in place). Tests of each percent broken dolosse were conducted at least twice and sometimes three times with each repeat test verifying the original results. Test waves for all the tests were monochromatic and were subjected on the test sections in specific cycles (i.e., given time duration of about 30-sec increments with about 7-10 minutes between cycles to eliminate wave reflection effects). Each breakwater section was tested until stabilization (no progressive damage with time) or until damage had progressed to an unacceptable level.

Photograph 1. Test section of whole dolosse after testing with a design condition of 16-sec, 40-ft waves at a swl of +16.3 ft mlw.

Results

Observed results of the 5 and 10 percent broken unit tests indicated that individual dolosse were not displaced or did not move in place any more than that which occurred with a test section of whole dolosse. Photograph 2 shows an after testing view of a test with 10 percent of the top layer of dolosse broken and uniformly distributed (dots on the photo represent the breakage density). Tests with 15 percent of the top layer of dolosse broken indicated that there was a slight readjustment of a few of the units in the top layer of dolosse (Photograph 3). This readjustment was not significant to the overall stability, but one could tell some reneesting had occurred. It is believed that 15 percent uniform breakage is the upper limit in which this type breakage can be allowed without initiating small areas of spot damage. After testing, results of the tests with uniform breakage of 20 percent (Photograph 4) and 25 percent (Photograph 5) substantiates this belief in that spot damage tends to increase with breakage above the 15 percent level. During the 5 to 15 percent uniformly distributed broken dolos tests, it was observed that the individual broken pieces of dolosse were not significantly displaced up and down the slope but tended to nest into the void areas nearest their initial position. As the broken percentage increased (20-25 percent breakage), the half pieces reached such numbers that they began to break down the interlocking characteristics of the whole units and displacement of both the whole and half dolosse was more evident.

Extreme Wave Conditions, Uniform Breakage

The second set of two-dimensional broken dolos tests, in which only 10 and 15 percent of the top layer of dolosse were broken and uniformly distributed, were conducted at the 1:45 scale to compare with the same basic armor protection provided in test series one (whole 37-ton dolosse) but with an extreme storm condition* of 15-sec, 48-ft waves at a swl of +27.4 ft mlw. In this series, both the whole dolos and uniformly distributed broken dolos tests accrued a higher degree of damage than test series one (16-sec, 40-ft waves), but neither progressed beyond repairable damage.

Results

Photographs 6, 7, and 8, respectively, show a whole dolos test section, a test section with 10 percent of the top layer broken and uniformly distributed, and a test section with 15 percent of the top layer broken and uniformly distributed after testing with the extreme wave conditions. Again, the results show that uniformly distributed breakage up to about 15 percent of the top layer of dolosse did not show significant change in stability relative to that for unbroken units.

* The extreme wave condition described herein was a first estimate of a Probable Maximum Hurricane that could occur in this area but was deemed unreasonably high and subsequently has no relation on the selection of the final design condition.

Extreme Wave Conditions, Cluster Breakage

Since prototype armor breakage could occur in concentrated numbers as well as randomly, two-dimensional tests of the extreme wave condition were extended to include units broken in clusters. These tests consist of 10, 5, and 3 dolos units broken in a cluster. For each set of cluster breakage, individual broken clusters were positioned on the structure at the swl, about halfway between the swl and the toe of the structure, and about halfway between the swl and the structure crown (Photograph 9). Similar to the uniform breakage construction procedure, it is believed these tests present a certain amount of conservatism since the test sections were constructed with unbroken dolosse, then for each cluster the respective number of dolosse were removed through both layers and the correct number of broken dolosse dropped into the hole. Even though this was done as gently as possible, these procedures could not help but disrupt the interlocking action of the armor units.

Results

Results of this type of cluster breakage indicate that clusters of 10 broken units would allow deterioration of the cover layers (Photograph 10, dashed circles represent initial positions of clusters) and could, with extended storm duration, cause major damage that might or might not be repairable. The results of tests using the 5 broken unit clusters also indicate deterioration (Photograph 11); however, it is not as severe and takes longer for the damage to occur, thus the more likelihood the area influenced by the cluster breakage can readjust to interlocking. During the 5 and 10 broken unit cluster tests, the failure of the breakage area seemed to occur in the following manner. The first few waves settled the broken units into rather tight clusters and the unbroken dolosse surrounding the clusters did not have any place to interlock; consequently, the unbroken dolosse around the clusters were displaced. This caused a loosening of the armor units in the area of the cluster until such time that the broken units had no "pocket protection" and were themselves displaced, which added to deterioration of the cover layer. Test results for the cluster of 3 broken units (Photograph 12) do not show this characteristic; and, in fact, indicate that clusters with three broken units are similar in stability to that of the unbroken dolos tests.

Three-Dimensional Model Tests

Extreme Wave Conditions, Uniform Breakage

Although the data are limited, a three-dimensional stability test (waves at an angle of 60 degrees to the trunk and end portions of the breakwater) using 15 percent of the top layer of dolosse broken and uniformly distributed was conducted at a 1:55 scale to compare with the results of similar unbroken unit tests. This particular test, which was conducted twice, used 62-ton dolosse on the heads of the breakwater which had been determined by previous tests to meet the no-damage stability criterion for the normal design condition (16-sec, 40-ft waves). As

Photograph 11. Test section with 5-unit clusters broken after testing with an extreme wave condition of 15-sec, 48-ft waves at a swl of +27.4 ft mlw.

Photograph 12. Test section with 3-unit clusters broken after testing with an extreme wave condition of 15-sec, 48-ft waves at a SWL of +27.4 ft MLW.

indicated earlier, it was expected that both the whole dolosse test section and the 15 percent broken unit test section would sustain damage for the extreme wave condition (Photographs 13 and 14, respectively). However, the point to be made is that the results show that similar damage occurred for both the broken unit condition and the whole unit condition. This is in agreement with the two-dimensional tests and indicates that if the breakage is uniformly distributed, up to 15 percent of the top layer of dolosse can be broken without having a detrimental stability effect over that obtained using unbroken units under similar conditions.

Conclusions

Based on the findings of this study, it is concluded that:

- a. Concentrations of broken dolosse are more detrimental to stability of the breakwater against wave attack than uniform or random breakage.
- b. If the uniform or random breakage exceeds 15 percent of the number of dolosse in the top layer and the cluster breakage exceeds 3 dolosse in a cluster, the stability of the breakwater will be less than that exhibited by a breakwater composed of unbroken dolosse.
- c. For the type of movement indicated by the no-damage criterion used in this study, the value of using reinforcing steel to reduce potential breakage of armor units is highly questionable.

Acknowledgments

The hydraulic model tests described in this paper were conducted intermittently by the U. S. Army Engineer Waterways Experiment Station (WES) for Public Service Electric and Gas Company (PSE&G), Newark, New Jersey, during the period May 1973 through August 1974 in the Wave Dynamics Division (Dr. R. W. Whalin, Chief) of the Hydraulics Laboratory (Mr. H. B. Simmons, Chief). Technical Director of WES was Mr. F. R. Brown. The tests were conducted by Mr. D. G. Markle, Research Hydraulic Engineer, with the assistance of Messrs. C. Lewis and W. G. Dubose, Engineering Technicians, under the immediate supervision of Mr. D. D. Davidson, Chief of the Wave Research Branch. Most of the contents of this paper are extracted from the final project report presently being prepared by Messrs. Davidson and Markle.

The support of PSE&G in funding the investigation reported herein and in granting permission for publication of this paper is gratefully acknowledged. Special acknowledgment is due all the managerial personnel of PSE&G and in particular Messrs. F. Brandt and B. Johanson.

The Office, Chief of Engineers is gratefully acknowledged for granting permission to conduct the study and for authorizing publication of this paper.

CHAPTER 147

ARMOUR BLOCKS AS SLOPE PROTECTION

By

A F. Whillock¹ and W. A. Price²

Introduction

Dolosse blocks were first described in 1966 by Merrifield and Zwamborn in a paper to the 10th Coastal Engineering Conference held in Tokyo. They reported a block whose design weight was one-fifth to one-sixth that of natural stone to resist the same wave height. The reaction of the profession was surprise and perhaps a little disbelief that the new block could have such a high K_D value. A considerable amount of testing followed in a number of hydraulic laboratories. Quite a lot of work was done at the Hydraulics Research Station at Wallingford and some interesting points came to light. The paper discusses how wave period and angle of attack affect block stability and suggests a way in which engineers might approach the problem of design of breakwaters.

The effect of wave period

The equation normally used to describe the performance of armout units is the Hudson equation:-

$$W = \frac{w_r H^3}{K_D (S_r - 1)^3 \cot \theta}$$

-
- | | |
|---|---|
| 1. Senior Scientific Officer |) Hydraulics |
| 2. Senior Principal Scientific Officer) | Research Station,
Wallingford, Oxon,
England. |

- W = weight of armour units in lbs
 w_r = unit weight of armour unit lbs/ft³
H = design wave height - ft
 S_r = specific gravity of armour unit relative to water
 θ = angle of breakwater to horizontal
 K_D = stability coefficient

The Hudson equation does not include any allowance for wave period. During an investigation carried out for the design of Dolosse for the High Island Breakwater in Hong Kong, various slopes of breakwater were subjected to waves of different periods. Having selected a wave period the wave height was increased until failure occurred. A definite influence of wave period was observed and this is illustrated in Fig 1, which refers to tests carried out with 5.7 ton Dolosse on a 1:2 slope. Although more experiments are necessary, enough has been done to show that the observed period dependence is real and a possible explanation for it is as follows. As the wave period increases the wave tends to surge on to the protective layer rather than break. This sets up high velocities over the surface layer. It is suspected from watching many tests with Dolosse that although they are very stable to plunging breakers acting normal to the slope, their weakness lies in their inability to resist the drag caused by this surface flow.

Type of failure

The advantage of a properly designed tipped-stone breakwater is that as the wave heights build up, the extent of the damage will occur gradually. This is not the case with Dolosse. Approaching the state of serious damage small changes in wave height will produce large changes in damage - considerable rebuilding rather than repair being necessary to the breakwater.

An attempt has been made in Fig 2 to illustrate the difference in behaviour of Quarry stone, Dolosse and Tetrapods. It demonstrates that what would be acceptable damage for Quarry Stone would be very serious damage for a Dolosse breakwater; Tetrapods occupying an intermediate position. (It should be noted that strictly comparative data was not available to make the analysis - averaged values from a number of sources were therefore used.) The indications are that any increase of stability which can be brought about by an open form of block with a high voids ratio and designed to interlock will result in a reduction of the margin of safety as failure is approached.

Engineers when they design breakwaters are faced with the choice between a number of blocks and rightly suspect that the performance is adequately described by one number. It would help if all results were reduced to a common form as we have attempted to do here. The correct block for a particular situation could then be chosen.

Fig 2 also shows that the K_D ratios (Dolos/rock) decrease as the percentage of damage is increased. At failure, when the movement of large numbers of blocks is involved, the assembly is fluidised by the passage of water through the layers and the benefit of interlocking and friction disappear. The only restraint to block movement is then the weight. It follows that sophisticated blocks should only be used with a large factor of safety. Keep well away from the serious failure situation by designing a block weight which gives little damage at extreme wave heights. Even so, the advantages of a high K_D factor will still be available to give an economical design.

The effect of angle of attack

It is commonly assumed that breakwaters are more stable to oblique wave attack since the wave heights are reduced by refraction and the armour units are effectively on a reduced slope. Experiments with quarry stone support this view. There is reason to believe that such an improvement in stability might not occur with blocks that are susceptible to drag forces. To check the possible effects a short series of tests were carried out in a wave tank (Fig 3).

The Dolosse breakwater which was constructed on a framework could be readily turned at angles to the direction of wave approach. Regular waves were increased in steps at each angle until the number of removals was such that failure was imminent. Fig 3 shows that the overall stability of the blocks decreased up to an angle of 60° and then improved dramatically.

The explanation is similar to the one given earlier for period dependence. In breaking at an angle to the slope some flow takes place along it and this coupled with velocities up the slope due to the wave break or surge causes high velocities and hence high drag. The increase in stability found above 60° is due to adverse effects of surface flow being overtaken by the benefit of wave height reduction. The rapid improvement again stresses that the difference in wave attack between acceptable damage and failure can be small.

Conclusions

- (a) Tests have shown that wave period affects the stability of Dolosse.
- (b) The way in which failure builds up should be an important factor in design.

- (c) The angle of attack of waves significantly affects the stability of a breakwater armoured with open type blocks having high drag coefficients.
- (d) Serious consideration should be given to adopting a uniform method of presenting test results so that direct comparisons can be made between various types of block.

LARGE SCALE MODEL TESTS of PLACED STONE BREAKWATERS

by

Charles K. Sollitt

National Data Buoy Office

Abstract

Large scale model studies reveal that Reynolds scaling can affect the apparent stability and wave modifying properties of layered breakwater structures. Results of a study for a breakwater configuration designed to protect offshore power and port facilities in water depths to 60 feet are presented and discussed. The armor layer of this structure is formed from quarried rock of irregular rectangular parallelepiped shape, individually placed perpendicular to 1:2 seaward slope and crest. The resulting armor layer is relatively smooth, densely packed and very stable. Model studies of similar configurations were studied at 1:10, 1:20 and 1:100 scale ratios. Stability, runup, rundown and reflection were measured for a variety of water depths, wave heights and periods. Analysis of the large scale test results establish that the placed stone armor is approximately as stable as dolos armor units. Runup, rundown and reflection respond similar to rough, impermeable slopes. Comparison of large and small scale results demonstrate that relative increases in drag forces at lower Reynolds numbers decrease stability and runup in small scale models.

Introduction

The challenge of offshore power production and deep draft port facilities has stimulated interest in large protective breakwater structures. Some elegant wave attenuation schemes have been proposed and a variety of artificial armor unit shapes are being investigated. There are, however, many offshore locations where natural rock structures are the most economical alternative for protective breakwaters. One method of stone or rock construction which has received little attention is the placed stone construction technique. This method has been used with considerable success for two decades along the Pacific Northwest coast of the continental United States and yet the advantages of this type of breakwater construction have not been carefully studied.

A unique feature of this specific construction technique is that rock is quarried for an approximately rectangular parallelepiped shape with one major axis. Then the rock is individually placed on the breakwater surface with the long axis perpendicular to the slope. A single layer of armor units placed in this manner provides a densely packed, relatively smooth surface with stability approaching that of dolos armor units.

This construction technique was studied superficially in 1961 (Jackson, 1963). Although the tests indicated that placed stone was more stable than random stone, an increase in the stability coefficient was not recommended because of the limited number of tests. However, the outstanding maintenance record of jetties along

the coasts of Oregon and Washington indicate that these structures have been conservatively designed. In order to compensate for the lack of sound design information, this study was undertaken to investigate the overall hydraulic behavior of placed stone armor breakwaters. Included in the study are runup, rundown, reflection and stability.

The specific design being considered is a 100 foot high structure which is proposed for use in relatively deep water (50 ± 10 feet) to protect offshore nuclear power plants and superports. A cross section of the structure is presented in Fig. 1. The crest of the structure is 35 feet wide. It slopes at 2:1 on the seaward face to MLLW where it breaks to a slope of 1.5:1. The back face falls away quickly at 1.25:1 and encounters a concrete caisson at MHHW. The caisson provides a working platform for constructing the breakwater and maximizes mooring area on the leeward side of the structure. The placed stone armor material is represented by the A+, A and B designation in the figure. All other materials are barge dumped or randomly placed. The largest armor, A+ (25-35 tons) extends from ten feet below MLLW to ten feet above MHHW. This is considered to be the region which experiences the largest wave impact loads.

The study was conducted at a large scale to minimize scale effects. It is known that drag forces are an important mechanism for retarding runup, dissipating energy and loading armor units so that, in general, Reynolds similarity cannot be neglected in breakwater modeling. Since drag coefficients increase at low Reynolds Number, one would expect small models to produce relatively high drag

forces and therefore less runup, less reflection and less stable conditions. Therefore, extrapolating small model results to prototype scale could yield an uneconomical, overdesigned armor unit and an underdesigned crest elevation.

In order to quantify the scale effect, this study was conducted at three scale ratios: 1:10, 1:20 and 1:100. Froude similarity was used to dimension each model, and model results expressed in dimensionless form were compared. The hypothesized scale effects were found to occur and to be significant in the small model.

The structure was found to behave like a rough, impermeable slope in terms of runup and rundown. The placed stone armor units were found to be extremely stable, with stability coefficients approaching that of dolos.

Test Conditions and Procedures

A test program of monochromatic wave excitation was conducted at the Oregon State University Wave Research Facility. The wave channel is 342 feet long, 12 feet wide, 15 feet deep and has a 290 foot test section. The wave board is of the flap type variety which is hinged at the bottom in a section which has a total depth of 18 feet. The board is controlled by a 150 HP, 3500 psi pump with an attached hydraulic servomechanism activated by an electronic function signal generator. The installation is unique in that it has water on only one side of the wave board. This scheme reduces the power requirements of the wave generator by one-half and eliminates the need for a dissipative media behind the wave board. The facility has the capability of producing solitary waves, periodic waves and random waves for modeling ocean wave spectra. Breaking waves up to five feet high can be generated and the useful frequency range is from 0.2 to 2.0 hertz.

Three model scales were tested, 1:10, 1:20 and 1:100. Each scale was exposed to prototype waves periods of 9, 13.5 and 16 seconds. Wave heights were increased from prototype heights of approximately 15 feet to breaking wave heights which exceeded 45 feet for the two longer wave periods. Each wave condition was continued until 500 waves had been produced or significant damage had occurred.

Two bottom slope conditions were modeled during the test. The model itself was supported on concrete slabs approximately five feet above the bottom of the test channel. A "flat" bottom was created by extending the false bottom horizontally to an equivalent prototype distance of 1000 feet from the toe of the structure. A "sloped" bottom was created by shoaling the bottom at a 1:12 slope from 40 feet (prototype) in front of the structure to a greater depth 520 feet seaward. The bottom proceeded horizontally from that point. Tests of all three scales were conducted using the flat bottom configuration first, followed by the sloping bottom. The flat bottom limited wave heights due to breaking of finite amplitude partial standing waves in the vicinity of the breakwater. The sloping bottom permitted sustained large amplitude waves during stability tests.

In addition to varying bottom slope, wave height and period, three different still water depth conditions were investigated; 40, 50 and 60 feet. Each test run proceeded by establishing the slope, depth and wave period and incrementally increasing the wave height relative to the previous run at the same period. The waves were allowed to interact with the structure until a quasi-steady state wave environment was established. Then, each of the following parameters were measured: incident and reflected wave height and period, runup, rundown and damage.

Incident and reflected wave heights were resolved using the wave envelope method. The partial standing wave envelope was profiled using an acoustic wave gauge mounted on a moving carriage. Incident and reflected wave heights were solved from the sum and difference of antinode and node amplitudes. Runup and rundown were quantified relative to elevation gradelines on the channel walls adjacent to the model. Average values across the width of the model were recorded. Damage was recorded as it occurred by stopping the test and noting the number of stones and surface area affected. Progressive damage was evaluated by continuing the tests without repairing the damaged area until catastrophic failure was imminent or 500 waves had passed.

Interpretation of Results

Runup

Runup is the vertical distance above still water attained by a wave rising on some prescribed surface. Its magnitude is a function of both the wave and surface properties. Runup is an essential design parameter for ocean and coastal structures if overtopping is to be minimized or avoided.

It is common to express runup relative to the offshore wave height which produced this condition. This measure of relative runup allows a design engineer to proceed directly from offshore wave forecasting to runup calculations at the structure if refraction does not alter the wave form. Local wave conditions probably dominate the runup process, however, it may be very difficult to calculate local modifications caused by wave interaction with a complex structure. Attempts to predict runup analytically have generally not been successful except for conditions of simple, mild, impermeable slopes (Le Mehaute, *et. al.*, 1968). In the absence of dependable runup predictions, experimentally determined values of runup have been an essential recourse.

Runup data collected in the context of this study have been assembled to facilitate comparison with other studies. Accordingly, relative runup (runup divided by deepwater wave height, R_u/H_0) is presented graphically as a function of a deepwater wave steepness parameter (H_0/T^2). According to linear wave theory deepwater wave steepness is:

$$\begin{aligned} \text{steepness} &= \text{wave height/wave length} \\ &= H_0/L_0 = 2\pi H_0/gT^2 \end{aligned}$$

where g = gravitational acceleration
and T = wave period.

The constant, $2\pi/g$, had been dropped from this expression for numerical expediency. The resulting steepness parameter is dimensional, with units of ft/sec².

The data are presented in Figures 2 through 5. Flat and sloped bottom results are combined at the 1:10 and 1:20 scales (Figs. 2 and 3) and separated at the 1:100 scales (Figs. 4 and 5). Note that depth and period identities have been retained for clarity by utilizing a uniform symbol notation as indicated in the legend on each figure.

Mean trends interpreted from these figures indicate that relative runup increase with:

- 1) increasing wave steepness
- 2) increasing wave period
- 3) increasing bottom slope
- 4i) increasing depth on flat bottoms
- 4ii) decreasing depth on sloping bottoms.

This behavior is a significant contrast to that depicted in popular design resources, such as the *Shore Protection Manual* (U.S. Army, 1973), wherein period and depth dependence are often difficult to resolve. Curves represented by the dashed lines in Figs. 2-5 serve to illustrate this apparent dichotomy. Both curves were taken from the *Shore Protection Manual*; curve B represents runup on a graded riprap, 1:2 impermeable slope while curve C represents runup on a rubble, 1:2 permeable slope. The curves are presented as a synthesis of data for combinations of wave periods, heights and water depths. One would interpret from these curves that relative runup decreases for increasing values of $H_0/T^2 > 0.1$. In contrast, consider the 9 second period data in Figure 4. Here it is clearly shown that relative runup increases with wave steepness for a given constant value of wave period and water depth. The same behavior can be observed in the 1:10 scale results in Fig. 2. The reason for this behavior is a strong dependence on wave period. In all of the figures, the short wave periods occur below and to the right while the long wave periods occur above and to the left. For a given wave steepness, the shorter period waves are not as high and propagate at a slower speed than longer waves. Therefore, less power is available for conversion to runup, and less runup occurs. Viewed as an entire collection of data, the mean trends follow the dashed lines because for a given range of design wave heights, the steeper waves are dominated by short periods while the less steep waves are dominated by long periods.

The reference lines, B and C, in each of Figs. 2-5 reveal additional information about general runup characteristics on this structure. In Fig. 2 it is apparent that the large scale data tends to group around line B indicating that the densely packed, placed stone surface responds to runup similar to an impermeable riprap slope. Line C, representing a permeable rubble slope, yields less runup because surging flow on this surface can penetrate the interstices of the relatively porous rubble. The response at the 1:20 scale in Fig. 3 is similar to the 1:10 scale. However, at the 1:100 scale, (Figs. 4 and 5) essentially all data points fall below reference line B, indicating less overall runup at smaller scales. This concurs with the anticipated scale effect, i.e., flow at low Reynolds number in the small model produces higher drag forces relative to the inertia of the surging fluid, thereby retarding runup to a greater degree than at large scale and at prototype conditions. Because the 1:20 and 1:10 scale data is so similar, it would appear that the Reynolds number at these two scales is high enough to yield a nearly constant surface drag coefficient. Since this drag coefficient should also be suitable for all larger Reynolds numbers, it is to be concluded that the 1:20 and 1:10 scale results are also representative of prototype conditions. The 1:100 scale results, however, tend to underestimate prototype runup by approximately 20%.

Fig. 2. Relative Runup, 1:10 Scale, Sloped and Flat Bottom

Fig. 3. Relative Runup, 1:20 Scale, Sloped and Flat Bottom

Fig. 4. Relative Runup, 1:100 Scale, Sloped Bottom

Fig. 5. Relative Runup, 1:100 Scale, Flat Bottom

Comparing Figs. 4 and 5 indicates that flattening the bottom slope in front of the breakwater tends to reduce runup. This behavior is to be anticipated and has been demonstrated in other studies as well. The flat bottom imposes a depth restriction on the finite amplitude partial standing waves seaward of the structure. The waves break within one wave length on the flat bottom reach if the superimposed incident and reflected wave heights exceed approximately one still water depth. This breaking limitation does not develop on the sloping bottom until the incident wave height alone exceeds the depth at some point along the slope. Thus, the flat slope combined with reflection from the breakwater surface protect the structure from very high incident waves.

Wave period and water depth dependence may be separated graphically by non-dimensionalizing runup in terms of water depth rather than deepwater wave height. This is accomplished in Figs. 6 and 7 where the data for the 1:10 scale model and the 1:100 scale model are presented. Least square exponential fit lines are drawn through the data at indicated constant values of d/T^2 . Note that d/T^2 is proportional to the water depth divided by deepwater wave length. The effect of wave period is evident in both figures with long period data on the left and short period data on the right. For a given value of wave steepness and depth, the short period waves always produce less absolute runup. The effect of water depth also separates well on these graphs. It is readily apparent within each group of constant period data that water depth increases from left to right. Therefore, for a given wave period and steepness, shallower water produces more runup relative to the depth. This simply demonstrates that the shoaling effect is more pronounced in shallow water.

Rundown

Rundown is the vertical distance between the still water level and the minimum elevation attained by a wave on a specified surface. Rundown is an important design parameter because it identifies the minimum elevation exposed to large wave impact loads and large local velocities. The region between maximum runup and rundown requires the greatest care in the selection and placement of breakwater armor material. Placement of armor to some depth less than maximum rundown may initiate failures at the toe of the structure which later propagate up the slope.

Rundown data for the 1:10 and 1:100 scale models are presented in Figs. 8 and 9, respectively. The dashed line in each figure is reproduced from the Shore Protection Manual and represents relative rundown on an impermeable, graded riprap, 1:2 slope. Interpretation of the data on these curves reveals that relative rundown increases with:

- 1) increasing depth
- 2) increasing period
- 3) decreasing steepness
- 4) decreasing model size.

Although not presented in this discussion, the flat bottom tends to increase rundown relative to the sloping bottom at the 1:100 scale.

Comparison of runup and rundown dependence on depth and steepness suggests a useful analogy to wave profile distortions resulting from finite amplitude effects. Waves of finite height tend to develop higher crests and shallower troughs as wave steepness increases and as the ratio of water depth to wave length decreases. Similarly, runup increases with increasing steepness and decreasing depth while rundown decreases under the same conditions. Thus, the ratio of rundown/runup re-

Fig. 6. Runup Divided by Depth, 1:10 Scale, Sloped and Flat Bottom

Fig. 9. Relative Rundown, 1:100 Scale, Sloped Bottom

sponds as the ratio of trough amplitude/crest amplitude to similar changes in depth and steepness.

The scale effect also produces opposite changes in runup and rundown. Small scale models tend to reduce relative runup due to increased friction. Comparing Figs. 8 and 9, however, indicates that rundown increases in the small model. This response can be explained in terms of the cyclic behavior of runup and rundown. Each event repeats once each wave period so that if a greater portion of a period is required for runup, then less time will be available for rundown before the next runup cycle begins. In large models, relative runup is increased and a greater fraction of the wave period is required for maximum runup to be attained. A reduced fraction of the wave period remains for rundown, hence, maximum rundown is reduced in large models. Conversely, small models take less time for reduced runup so more time is available to yield increased rundown. The scale effect is accentuated in rundown, as evidenced by the least squares, best fit, solid line through the data at both scales. The 1:100 rundown results are approximately 40% larger than the 1:10 rundown results.

Reflection

The reflection coefficient is defined as the ratio of the reflected wave height to the incident wave height. Reflection is important because the resulting partial standing wave condition can impose a limit on marine traffic activity in the vicinity of the structure and influence adjacent sediment shoaling patterns.

Reflection coefficient (C_r) data for the 1:10 and 1:100 scale models are presented in Figs. 10 and 11, respectively. The solid line through the data represents a least squares, best fit average for the entire collection. An examination of these figures discloses that reflection increases with:

- 1) decreasing depth
- 2) increasing period
- 3) decreasing steepness
- 4) increasing model size.

Although not presented in this discussion, the reflection coefficient behavior is not significantly different for flat bottom configuration when compared to similar conditions on a sloping bottom.

The response to period and steepness is consistent with energy dissipation considerations along the breakwater surface. Surface drag is a nonconservative force which increases with the square of local velocities. Wave particle velocities increase with increased wave steepness and reduced period. These changes induce higher drag forces, more energy dissipation and therefore consume energy available for generating the reflected wave. Conversely, a reduction in wave steepness or increase in period causes a reduction in local velocities and energy dissipation, thereby increasing reflection as observed in Figs. 10 and 11. The observed scale effect also follows this trend. Low Reynolds number flow in the small model causes proportionately higher drag and reduces reflection by up to 10%.

Stability

Stability is a measure of the ability of breakwater armor to resist damage from wave attack. Ultimately, the integrity of the entire structure is dependent upon design considerations which adequately account for stability requirements. Several definitions for stability are currently in use, some more elegant than

Fig. 10. Reflection Coefficient, 1:10 Scale, Sloped and Flat Bottom

Fig. 11. Reflection Coefficient, 1:100 Scale, Sloped Bottom

others. The one definition which is subject to the least confusion quantifies stability as that wave height which causes an "acceptable" level of damage to a particular structure under specified conditions of water depth and wave period. "Acceptable" damage is most always less than 5% of the seaward armor surface area, usually less than 1%. This limiting wave height has been found to be weakly dependent on water depth and wave period. Attempts to develop a dimensionless stability coefficient for comparison of alternative armor units have led to a variety of expressions which are proportional to the zero damage wave height divided by the cube root of the armor unit volume. Hudson's formula (Hudson, 1953), was developed to quantify stability of units which rely only on their submerged weight for stability. Although it was not intended for use in describing units which have interlocking strength, Hudson's stability coefficient is still the most widely used standard for armor unit comparison.

No damage is often an uneconomical and unnecessary design requirement. Paul and Baird (1971) have attempted to identify alternative failure modes for more flexible design requirements. These modes or failure zones are:

- Zone 1: No movement of armor units
- Zone 2: Local movement but no displacement
- Zone 3: Few units displaced
- Zone 3a: Damage stops before 10 units are displaced per 100 lineal feet of breakwater
- Zone 4: Continuous damage will ultimately destroy armor layer
- Zone 5: Immediate, complete failure of the armor layer.

This failure mode analysis was used to identify levels of failure in the placed stone study. Results for the 1:10 and 1:100 scale models are presented in Figs. 12 and 13, respectively. Damage to A and A+ armor materials are summed in these figures.

The failure mode analysis indicates a slight dependence on relative depth. This results from long waves at shallow depths (high T^2/d) attacking the A- layer below MLLW. Smaller wave heights can damage this layer in shallow water. Higher waves are required to cause the same damage in water of greater relative depth (low T^2/d). At both scales, increasing wave heights cause increasing levels of damage. However, proportionately higher prototype waves are required to cause the same level of damage in the large model. Zone 4 could not be achieved at the 1:10 scale because equivalent prototype wave heights in excess of 55 feet could not be generated.

Levels of damage can also be quantified in terms of the percent of the armor surface area experiencing displaced units after exposure to 500 design waves. This data is presented in Fig. 14, for all three scales and all combinations of wave period and water depth. Least squares, best fit lines have been extended through the data at each scale. Again, larger waves cause more damage. The scale effect is readily apparent in this figure. The 1:100 scale model indicates that comparable damage will be caused by a wave height which is less than 80% of that indicated by the 1:10 scale results. Zero damage wave heights (H_{ZD}) extrapolated from Fig. 14, provide the following estimates for Hudson's stability coefficient (K_D) at each scale:

Scale	H_{ZD}	K_D
1:10	35'	29
1:20	35'	29
1:100	28'	23

Fig. 13. Failure Mode Zones, 1:100 Scale

Fig. 12. Failure Mode Zones, 1:10 Scale

Fig. 14. Area I Damage versus Wave Height

Fig. 15. Stability Scale Effect

Stability scale effects have been investigated by Thomsen, et.al. (1972), for several armor unit shapes. The results are summarized in Fig. 15. In this study, a zero damage stability coefficient, N_{ZD} , and Reynolds number, R_N , have been defined as presented on the figure, wherein:

- H_{ZD} = zero damage wave height (Zone 3-a or less)
- W_{50} = average armor unit weight
- γ = material specific weight
- S = material specific gravity
- γ_f = fluid specific weight
- μ = fluid dynamic viscosity.

The scale effect is defined as the ratio of the large scale stability coefficient, N_{ZD} , divided by a smaller scale stability coefficient, N_{ZD} . Data from the placed stone study are superimposed on the results of Thomsen, et.al., as indicated in the legend. Thomsen concluded that Reynolds numbers in excess of $3 \cdot 10^5$ must be achieved to avoid scale effects. Also, the no damage wave height will be overestimated by approximately 60% if the scale is reduced by another factor of five. The results from the present study support this conclusion. The 1:20 scale model occurs at the limiting Reynolds number and shows no significant scale effect. The 1:100 scale model is one-fifth of the limiting Reynolds number size, and a 40% reduction in stability is indicated, as shown in Fig. 15. Thus, small models underestimate prototype stability due to the magnification of drag forces at low Reynolds number.

Summary

The results of this study provide research and design information about the total hydraulic behavior of placed stone armor breakwaters. The armor surface responds to runup similar to an impermeable, graded riprap slope. Rundown, however, is reduced. Reflection coefficients are relatively low, compared to a smooth, impermeable reflecting surface. The structure is extremely stable, similar to that of dolos armor. Comparison of large and small model results indicate that scale effects distort small model results by decreasing runup, reflection and stability while increasing rundown.

CHAPTER 149

DESIGN AND CONSTRUCTION OF PROTECTIVE STRUCTURE FOR NEW REEF RUNWAY HONOLULU INTERNATIONAL AIRPORT

by

Wilfred D. Darling, F. ASCE*

ABSTRACT

This paper describes the design and construction of the protective structure for a new Reef Runway at the Honolulu International Airport with special emphasis on the use of dolosse concrete armor units.

INTRODUCTION

A 12,000-foot long runway located parallel to and 6,700 feet south (seaward) of the existing 12,380-foot runway 8L-26R, which will permit increased capacity, noise abatement, and increased safety to downtown Honolulu and its suburbs, is nearing completion at the Honolulu International Airport as shown in Figure 1. The Reef Runway and associated taxiways are located on land created by over 19 million cubic yards of dredged coral placed on an existing reef. In order to protect the land fill from erosion by wave action, a 16,100 foot long protective structure has been built out of stone and 18,000 dolosse concrete armor units. The protective structure, which has a top elevation varying from plus 4.0 feet to plus 20.0 feet msl, is located approximately 1,000 feet south (seaward) from the centerline of the Reef Runway.

DESIGN STUDIES

Initial hydraulic model studies were made under contract with the University of Hawaii Look Laboratory under the Department of Ocean Engineering (1). Extensive three-dimensional and two-dimensional hydraulic model studies were

*Consultant on Coastal Engineering during the project, The Ralph M. Parsons Company, Honolulu, Hawaii.

made to facilitate design of the protective structure. The three-dimensional model was used initially to obtain storm wave information at the protective structure location to be used in two-dimensional studies, and later to study tsunami waves for possible interaction effect between the proposed structure and the adjacent harbors and shore properties and to measure run-up on the protective structure. Computer refraction studies were made to provide input for the three-dimensional study. The major conclusion resulting from the model study and refraction study was that the water depth fronting the proposed structure determines the design wave, which is a breaking wave, the size of which is dependent on the water depth at the seaside toe of the structure and bottom slope. The water depth on the reef along the protective structure varies from slightly below zero elevation msl at the shallow end to as much as 27 feet below zero msl at the deep end. A still water level of plus 3.0 feet msl was adopted for design resulting in design breaking waves of over 25 feet in part of the deep water section. The shallow water section of the structure is protected by a fringing coral reef that varies in width from 400 to over 2000 feet.

The two-dimensional study by Look Laboratory was completed to develop design criteria for overtopped and non-overtopped sections subjected to breaking waves. Armor units tested consisted of quarry stone and tribars. Subsequent to completion of the above mentioned initial studies, Tetra Tech, Inc., of Pasadena, California, was engaged to design the protective structure (2,3). Additional two-dimensional hydraulic model studies were made to develop overtopped and non-overtopped structure sections subjected to breaking waves. Quarry stone and dolosse armor units were tested. In addition to conventional side slopes, a seaside berm section was tested. Design parameters were adopted for use in design of the structure based on the above mentioned testing plus information available from previous studies by the U. S. Army Corps of Engineers (4), and the Port of East London, South Africa (5,6). For the dolosse the stability factor, K_p , as used in the Hudson formula, was based on a certain percent damage, namely 2% and 4%, resulting in K_p factors of 32 and 64, respectively, for the two conditions. This was considered acceptable in view of the infrequent occurrence of design storms. A layer coefficient K_d , of 1.3 was used resulting in a requirement for 75 4-ton dolosse for each 1,000 square feet of area covered and 55 6-ton dolosse for each 1,000 square feet. The design as completed for advertising included five alternates for the seased armor for the westerly 4,650 lineal feet of the deep water portion of the structure. The five alternates were as follows: 4 and 6-ton dolosse; a combination of stone and 4 and 6-ton dolosse; 8, 12, and 24-ton tribars; a combination of stone and 12 and 24-ton tribars; and all stone with a seaside berm 200-feet wide with top

elevation at minus 12 feet msl. The low bidder, Hawaiian Dredging and Construction Company, chose the dolosse alternate. For the shallow water reach the section consisted of ledge coral protected on the seaside by 2 layers of basalt armor stone with sizes varying from 250 lb nominal size at the shallowest end to 3000 lb in the deeper water. For the deep water portion of the structure, the first 1,650 lineal feet consisted of quarry run core stone with 2 layers of basalt underlayer stone protected by 2 layers of 5-ton armor stone, with the westerly 4,650 lineal feet protected by 4 or 6-ton dolosse armor. On the land side armor stone varied from 1300 lb to 8-ton size at the head section, with the majority of the land side armor stone being 5-ton size.

Figure 2 shows the typical non-overtopped section of the deep water portion of the structure on coral foundation with dolosse armor. The structure has a 15-foot top width, with 1 vertical to 1.5 horizontal side slopes on both sides except for the head section where the slopes are 1 vertical to 2.25 horizontal. Two layers of 2000 lb underlayer stone were used underneath the 4-ton dolosse while 2 layers of 3000 lb underlayer stone were used underneath the 6-ton dolosse. The land side apron shown on figure 3 was used in 3 reaches where overtopping during design storms is expected. The seaside foundation stone blanket shown was not included in the original contract but was added after construction was started when substantial areas of sand, with depths as much as 14-feet, were discovered in the foundation as a result of an underwater survey using a jet probe. Six reaches required the protective stone blanket under the dolosse armor with a total length of 870 lineal feet.

QUARRY OPERATIONS

Over 800,000 tons of stone was required for the core, underlayer, and armor of the protective structure. Twelve different sizes of stone were specified for use varying from quarry run core stone to 8-ton armor. The majority of the stone, 88%, was obtained from a quarry on the Island of Molokai, a distance of about 60 miles from the project location. The remainder of the stone was obtained from the Island of Oahu, including 51% of the 5-ton armor stone. The quarry at Molokai included andesite and basalt with the latter being the most predominant type of stone present. Investigations at the quarry were accomplished by percussion drilling only, no cores were obtained, thus very little was known of spacing of natural fractures in the formation. As it turned out the majority of the area opened up had quite closely spaced fractures, both vertically and horizontally, thus only a small percentage of the large size stone could be produced from any one blast.

In addition there were numerous areas where cinders and residual soil were encountered which resulted in the handling of a large quantity of waste material to permit recovery of acceptable stone. The specifications for the quarry run core stone permitted not more than 10% smaller than 4-inch size and required at least 10% exceeding 18-inch size. Because of the high percentage of small spalls and residual soil present, it was necessary to install a screening plant to scalp the core stone in order to meet the 10% maximum minus 4-inch requirement. Figure 4 is a view of the screening plant; after the large stone was picked from each blast, the quarry run material was hauled from the quarry floor to the top of bank and dumped into the hopper at the screening plant where the excess objectionable fines were removed.

Hauling of stone from the quarry to the wharf at Kaunakakai, Molokai, was done with 5 semi-trailer trucks, each carrying 2 20-ton steel containers which were picked up and dumped into barges by a crane. Figure 5 shows one of the trucks with the steel containers, while figure 6 shows the crane dumping one of the containers into a barge at the wharf. Five and six barges were generally used in the haul from Molokai to the project site with capacities varying from 600 to 1800 tons of stone per trip. The two smaller barges with 600 ton capacity were bottom dump barges used in hauling core stone for the deep portion of the structure.

CASTING OF DOLOS ARMOR UNITS

Casting of 6-ton dolos was started during October 1973. There were a total of 29 forms available. Forms for the 4-ton dolos were available in January 1974, from that time the normal daily casting included 80 4-ton and 29 6-ton dolosse. Special steel hinged forms were fabricated in Portland, Oregon, for the project. Figure 7 shows part of a row of forms with the traveling conveyor depositing concrete into one of the forms. Figure 8 shows a form opened for cleaning after removal of the dolos cast the previous day. Consolidation of the concrete was accomplished by the use of a form vibrator located under the horizontal section of the dolos form, as well as by the use of a cylindrical hand held vibrator which was inserted from the top of the vertical leg. The forms were filled each day with crews reporting on an early shift to remove form bolts and open the forms so that a fork lift could remove the dolosse cast the previous day and place them in storage where membrane curing compound was sprayed on the concrete. Forms were immediately cleaned and re-oiled and closed so that filling could start again. Figure 9 shows a form opened with the dolos ready for removal. Figure 10 shows the fork-lift carrying the dolos to the storage area.

CONSTRUCTION OF THE PROTECTIVE STRUCTURE

Construction was started at both ends. The bottom dump barges were used to dump core stone along the centerline at the west end with alignment provided by a laser beam. Also a floating crane was used to unload core and underlayer stone from non-dump barges at the deep end. At the east end ledge coral existed in a thin layer, 6 to 12 inches thick in the safety areas, where it was ripped by a D-9 tractor and loaded by drag line on trucks for hauling to the structure alignment. After the seaside slope was completed, a clamshell crane followed along and placed two layers of the size armor specified for the area involved. Armor stone which was off-loaded at a temporary wharf at the east end was hauled by truck and dumped on the adjacent work road on the landward side which is part of the safety area fill; the work road was kept at elevation plus 2 to 3 feet msl. A gradall and a crane were both used for placing the 250 and 550 lb stone; cranes only were used for the larger sizes of armor stone. At station 149+00, 6,400 feet from the west end of the structure, the transition to the deep section was started and core stone was trucked from the temporary wharf and end dumped to continue the work. Two layers of underlayer stone were placed by crane and another crane followed up after a short interval placing two layers of 5-ton armor stone. This continued for 1,750 lineal feet where the seaside armor changed to dolosse. Four-ton dolos were used for a total of 3,550 lineal feet, 13,692 were placed, while 6-ton dolos were used for a total of 1,100 lineal feet, including the head section, 4,317 were placed. The underlayer and back side armor for a major portion of the deep section of the structure was initially placed by one or two floating cranes, however, a great deal of work was required by cranes working on top of the structure, 7 to 9 feet below final crest, in straightening the sections to conform to plans. Batter boards were installed at regular intervals to assist the crane operators in placing the stone to line. Even with the use of batter boards it was noted that below the water surface a few feet the tendency was for the slope to steepen from 1 vertical to 1.5 horizontal specified since the natural angle of repose of the stone was steeper than the required slope. In order to check the seaside toe of the core, underlayer, and mark the toe for the dolosse, an offset centerline was established by divers on the sea bottom by anchored cables 25 or so feet seaward of the final structure toe. This facilitated locating the toe line for each item. Floats were placed for each toe line in turn which guided the crane operators in placing stone and dolosse.

DOLOSSE PLACING

Placing of dolosse concrete armor units was started during October 1974. A Manitowac 3000 crane equipped with special steel tongs was used for handling the dolos. At first the dolosse were loaded by fork lift truck on flat bed semi-trailors and hauled along the work road to the location where needed. Six 4-ton dolosse were hauled per load while four 6-ton dolosse were hauled per load. Figure 11 shows a load of 4-ton dolosse which have been delivered to the unloading point with the crane ready to lift a dolos prior to placing in the structure. The placing rate averaged about 20 dolosse per hour. Later a small barge with a capacity to haul 70 4-ton dolosse was used as shown in figure 12, however, because of the time required to load the barge and tow it from the east end temporary wharf out to sea and around the west end of the structure to a location behind the structure, placing of dolosse was limited to 70 per day, or less when swells would not permit the small tow boats to operate in the open sea. The use of flat bed semi-trailer trucks was resumed for hauling dolosse from the storage area to the structure and placing continued intermittently until the project was completed. One crane worked ahead on preparation of underlayer stone to final line for the dolosse, however, it could not keep ahead of dolosse placement so that at times two cranes worked on underlayer, and when 100 feet or so was approved dolosse placement would resume. Figure 13 shows a crane placing dolos as well as a view from the sea side showing a portion of completed dolosse armor. Figure 14 is a view of completed dolosse from the back side prior to placement of back-up stone.

Breakage of dolosse during placing operations amounted to 1.4% of the unreinforced units handled. Although the design specified two layers of dolosse, the requirement to place 75 4-ton and 55 6-ton dolosse for each 1,000 square feet of area to be protected resulted in a three-layer cover. A large percentage of the breakage resulted from trying to fit the top layer of dolosse in place. Data resulting from studies by the Waterways Experiment Station, U. S. Army Corps of Engineers, completed subsequent to design of this project, indicate that a layer coefficient, K_{Δ} , of 1.0 rather than 1.3 could be used to provide a two-layer cover without any loss of stability (7). Using this lower value would result in a requirement of 51 4-ton and 39 6-ton dolosse per 1,000 square feet of area protected, a considerable reduction from the number used on this project. This should be considered for future projects. Another interesting item on this project based on sections adopted where dolosse armor were used and unit prices for the stone and dolosse, is that protection by the 6-ton dolosse cost less than protection by the 4-ton dolosse, amounting to nearly \$1500 less cost for each 1,000 square feet of area protected by the 6-ton dolosse, as compared with the 4-ton dolosse. This is impor-

tant to consider when design contemplates accepting a percentage damage of dolosse armor. It could be less costly to design for no-damage with larger units than to accept damage of smaller units. Although the present structure was designed based on accepting 2% and 4% damage of the dolosse armor units, a calculation of the actual stability factors, K_D , along the structure based on actual depths of water at the seaward toe and slope of ocean bottom indicates that for a majority of the area stability factors fall well below the no-damage range as shown in the U. S. Army Corps of Engineers Shore Protection Manual (7). The Manual does recommend minimum slopes of 1 vertical to 2 horizontal for dolos armor until further test data is available*. However, the Reef Runway Protective Structure is designed for breaking waves throughout, thus there should be no question of adequacy of the present design where stability factors are below the values considered adequate for the no-damage condition.

ACKNOWLEDGEMENT

Acknowledgement is gratefully made to the State of Hawaii, Department of Transportation, Airports Division, for permission to present this paper.

*Dr. Robert Whalin, Chief, Wave Dynamics Division, U. S. Army Waterways Experiment Station, Corps of Engineers, indicated during the conference that additional testing of dolosse armor units has indicated that slopes of 1 vertical to 1.5 horizontal are stable and the Shore Protection Manual will be revised accordingly.

CHAPTER 150

RESPONSE OF SEADYKES DUE TO WAVE IMPACTS

A. Führböter¹⁾, H. H. Dette²⁾ and J. Grüne³⁾

ABSTRACT

Damages on seadykes and revetments are mainly caused by wave impacts due to breaking waves. These impact forces act on small areas for a very short time and cause crater-like formations, when the forces are transmitted instantaneously to the side-walls of cracks in the cover of dykes or through joints into and below revetments.

In this paper the results of investigations on impact forces are presented. A comparison of field data and laboratory data proves considerable differences, which must be explained mainly by the different air entrainment for prototype and small-scale conditions in the breaking waves. Both the data from field and small-scale model emphasize, that the slope of the dyke or revetment is responsible at first for frequency and magnitude of the impact forces.

Furthermore the effect of impact forces is demonstrated by the results of investigations on the stability of stone revetments with joints.

forschungsbereich 79 of the Techn. Univ. Hannover

INTRODUCTION

The wave impact force due to breaking wave is the main factor causing damages on seadykes and revetments at a level around the highest storm surge stillwater level.

These impact forces occur, when the water particles of the breaker tongue are stopped abruptly by the outer layer of dykes or revetments. The impacts stand out for very high pressures during a very short time (10^{-2} to 10^{-3} seconds) on small areas. This cause consequences, which are like detonations of the surface materials of seadykes. The effects of impacts are presented schematically in Figure 1 for different types of seadykes and revetments.

Fig. 1 Effects of wave impacts on seadykes and revetments

On dykes made from or covered with clay, a crater-like formation can be caused, when the impact force hits directly upon a crack in the clay surface (Fig. 1 a). Even more dangerous effects may occur, when these impact forces act on cracks of asphalt covered sand core dykes. The total force is transmitted instantaneously to the side-walls of the cracks and into the sand core beneath the asphalt cover. In combination with thixotrope effects of this water-saturated sand, also caused by the impacts, a sudden destruction of the dyke may be possible (Fig. 1 b).

Similar effects occur on revetments made from artificial concrete blocks with joints (Fig. 1 c).

The above mentioned effects occurring on the outer layer of dykes or revetments will become even more complicated when these covers are placed on natural or artificial filter layers.

Figure 2 and Figure 3 show some typical damages in the field caused by impact forces during heavy storm surges. Fig. 2 gives an example for a crater-like formation. The diameter was about 6.0 m, the depth about 2.0 m. The significant wave height during the attacking storm surges in 1973 has been hindcasted to 0.75 m.

Fig. 2 Damage of clay-covered sand dyke due to wave impacts (after Forschungs- und Vorarbeitenstelle Neuwerk)

Fig. 3 Damage of a stone revetment due to wave impacts

First investigations of BAGNOLO 1939 (1) and DENNY 1951 (3) proved, that the occurrence of impact forces only can be described statistically. DENNY 1951 (3) showed, that by using regular waves the frequency distribution can be described with the normal distribution. This distribution even for regular waves is affected by the random effect of the breaking process itself. In prototype additionally the random effect of the breaker point due to random waves takes part, so that two random effects are superimposed to the occurrence of impacts.

INVESTIGATIONS ON IMPACT FORCES

In Germany in recent years some investigations on this phenomena have been carried out: FÖHRBÜTER 1966(4,5) simulated the impact forces of breakers in laboratory; results of field investigation and small-scale model tests are described by FÖHRBÜTER 1971 (6) and BOELKE, RELOTIUS 1974 (2).

FULL-SCALE LABORATORY TESTS

The laboratory tests of FÖHRBÖTER 1966(4,5) were carried out in prototype scale. This has been done by simulation only of the breaker tongue collapsing on the dyke surface. Figure 4 shows the principle of the simulation.

Fig. 4 Principle of the full-scale laboratory simulation of wave impacts (FÖHRBÖTER 1966)

The test equipment consisted of a pipe with a deflector for simulation of the breaker tongue and a surface with pressure cells for simulation of the dyke. The test conditions corresponded to wave heights of 1 to 3 m.

In Figure 5 as an example of the test results the frequency distribution of the maximum pressures

p_{max} has been plotted, in the lower part as an histogram, in the upper part as a log-normal distribution. The essentials of these tests were at first the verification of a normal distribution for occurrence of impact forces and secondly the demonstration that already a thin water-sheet due to the backflow of the preceding wave is damping the impact force magnitude (Fig. 6). For a thickness of the water-sheet of 0.1 m no more impact forces have been observed.

Fig. 5 Frequencies of maximum pressures p_{max}
 (FÜHRBÜTER 1966)

Fig. 6 Damping effect of a water-sheet
 (FÜHRBÜTER 1966)

FIELD INVESTIGATIONS

Field investigations have been carried out at the storm surge barrage of the Eider-river in Germany. At one adjacent asphalt covered sand dyke, which has a slope of 1 to 6, an additional testsection with a slope 1 to 4 has been added for research purpose (Figure 7). On both slopes pressure cells have been installed in steps of 0.25 m in vertical direction.

Fig. 7 Asphalt covered sand dyke of the Eider storm-surge barrage with test section (pressure cells before fitted in the asphalt cover)

Fig. 8 shows the time history of the occurrence of impact forces during one of the heavy storm surges of 1973 for both slopes. The influence of the slope comes out very clear as well for the total number of the impact forces as for the magnitude.

More distinct this effect comes out in Figure 9, which shows a comparison of the field data of three storm surges.

For a slope 1 to 4 a further comparison of laboratory and field data is

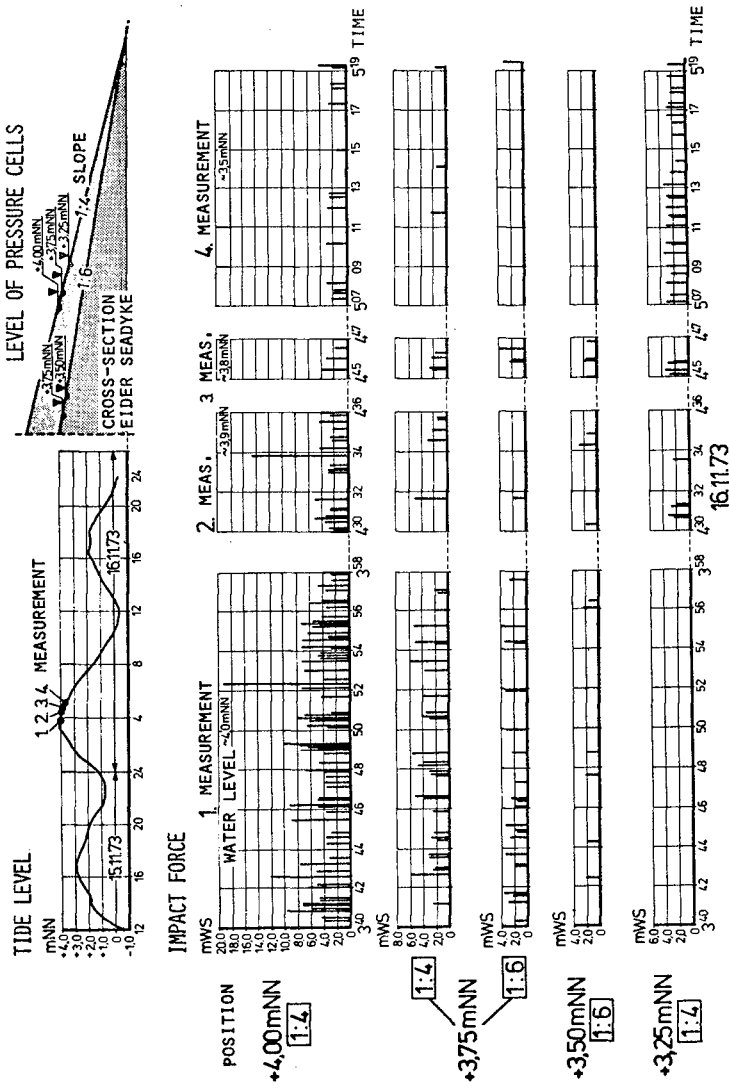

Fig. 8 Time history of impact forces during the storm surge of 16.11.73 (BOELKE, RELOTIUS 1974)

Fig. 9 Field data of three different storm surges (BOELKE, RELOTIUS 1974)

plotted in Fig. 10. The impact force distributions have been plotted as a multiple value compared to significant wave height H_s . The smallscale model tests were carried out with waveheights of about 0.2 m (approximately a scale 1 to 10 compared to field data); the field data were obtained for wave heights of 0.9 to 1.8 m and the prototype scale simulation in laboratory, which is mentioned before, corresponded to wave heights of about 1.0 to 3.0 m. This comparison confirmed theoretical treatments, that the impact forces cannot be reproduced in magnitude of transferred quantitatively for prototype conditions due to the different air entrainment in dependence of the absolute magnitude of waveheight.

Fig. 10 Comparison of results for investigations on impact forces (slope 1:4) (BOELKE, RELTIUS 1974)

MODEL TESTS

Additionally to the field investigations further feedback model tests were carried out in order to know at which horizontal distances $\pm \Delta h$ from the

still water level impact forces do occur.

For different slopes 1 to 4, 1 to 5 and 1 to 6 Figure 11 shows the results.

On the horizontal axis $\pm \frac{\Delta h}{H_s}$ is equal the vertical distance of the impact

attack from the still water level referred to the significant wave height H_s .

The number of impacts within a sequence of 100 waves is defined as multiple

value of H_s ranging from $k = 1$ up to 2. It was found that the main impact

forces can be expected approximately in the range of Δh equal half the

significant wave heights H_s below the still water level.

Furthermore secondary-impact forces occur additionally around the still water

level and above. This can be explained by the effect, that the water particles

on the dyke surface are elevated due to the collapsing breaker tongue and

plunged down again on the surface.

INVESTIGATIONS ON THE STABILITY OF REVETMENTS

The results of impact force investigations have been confirmed by investigations on the stability of revetments made from concrete stones.

With regard to economical considerations heavy quarry stone revetments on seadykes which are stable due to their weight are more and more replaced by various types of light-weight concrete slabs and blocks which are different by the kind of interlocking and by the kind of surface roughness.

During heavy storm surges in 1973 and 1976 damages occurred on the concrete block revetment of a new seadyke in the Elbe-estuary. It was observed that the damage started due to the uplifting of single blocks out of the cover layer. This was continued by the washing-out of gravel which was used as filter layer and finally resulted in a damage of the revetment with holes having diameters of several meters (Fig. 12).

In order to explain the reasons for damages the revetment was rebuilt in model and attacked by waves as they have been observed during the storm surge. With the model-scale 1 to 5 it was found that the damage pattern in model was similar to that in nature so that this test series could be regarded as a calibration reference for further and more detailed investigations with regard to the selection of different filter layers.

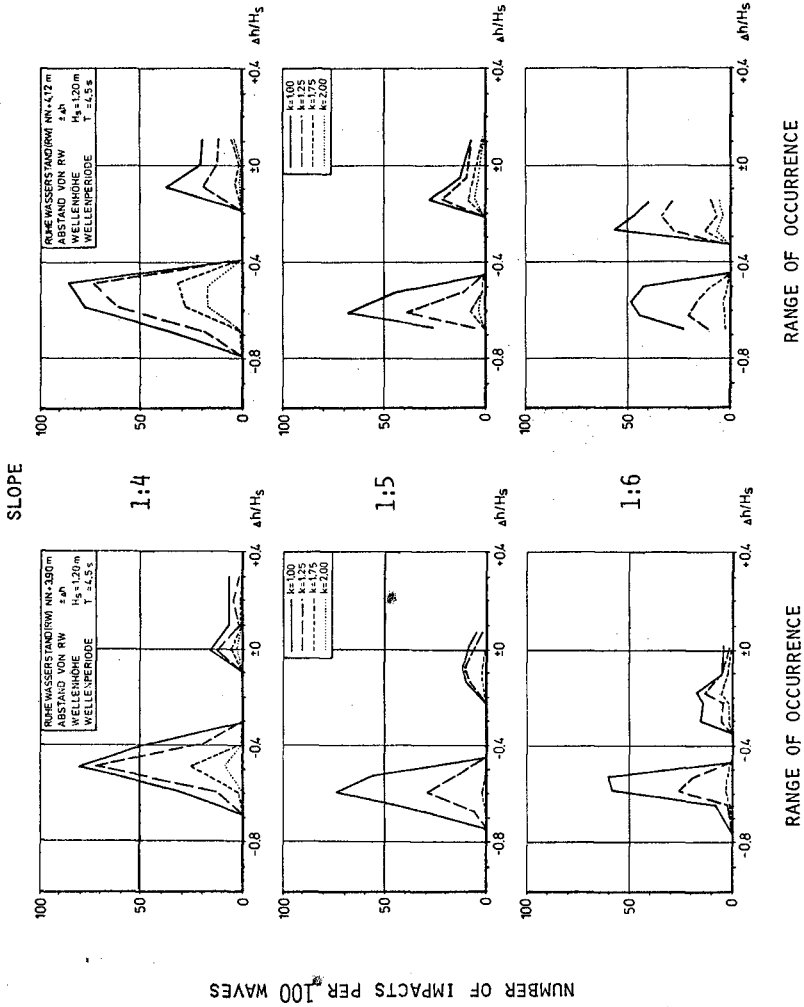

Fig. 11 Results of model tests on the occurrence range of wave impacts (BOELKE, RELOTIUS 1974)

Fig. 12 Typical damage of stone revetments due to wave impacts

One type of concrete stones (type HARINGMAN, prototype size: 0.5 x 0.5 x 0.15 m) which have been tested, were arranged in three different kinds on the seadykes with a slope of 1 to 3:

- revetment I: the stones are positioned on a 0.15 m thick (in prototype) layer of gravel (three-dimensional filter) and a nylon filter mat below the gravel for the protection of the sand core
- revetment II: the stones are positioned on a 0.05 m thick (in prototype) layer of gravel (three-dimensional filter), which lies on clay
- revetment III: the stones are directly fitted on concrete or asphalt

Fig. 13 shows a plan view of the revetment I and II, where the detached stones have been marked. For each test both revetments side by side have been attacked simultaneously by the same waves. These tests confirmed the occurrence

Fig. 13 Plan view of the revetment I and II with detached stones as an example for the range of the occurrence of detached stones

range of impact forces found in the model tests mentioned before. Fig. 14 shows an example of the damaged revetments in the model tests.

Fig. 14 Damaged revetment I and II after wave attack

In Fig. 15 and 16 the total number of detached stones is plotted as a function of the number of waves for the three revetments.

Damages occurred for all these arrangements. This can easily be explained by the effect of the impact forces, as the total force is transmitted instantaneously through the joints into the gravel layer.

The worst results were obtained for revetment II with a filter thickness of only 0.05 m (Fig. 15). For the 0.15 m thick gravel layer (revetment I)

Fig. 15 Detached stones as a function of the number of waves

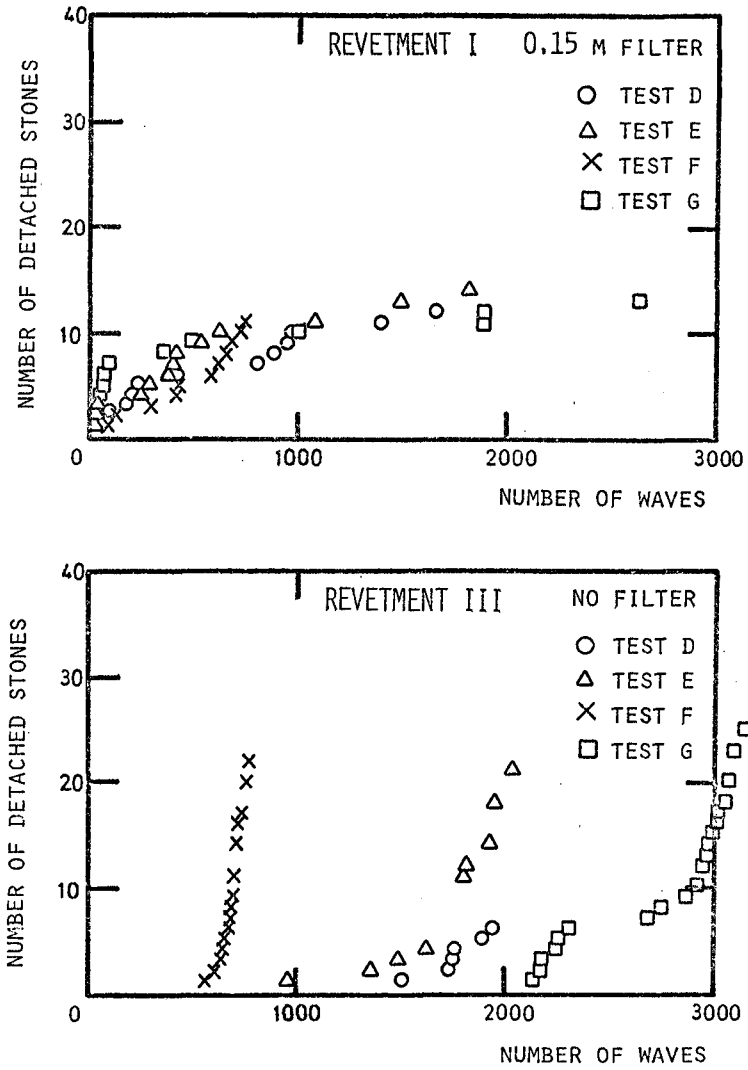

Fig. 16 Detached stones as a function of the number of waves

stabilisations of some damages have been observed, due to a gliding of the stones into the holes of the gravel layer and a guying there. For both gravel filters it was observed, that in addition to the damages due to impacts further damages occurred in that moment, when during the wave trough the water level in the filter was higher referred to the actual level of the wave. This is caused by the less faster draining of the water in the filter layer through the joints of the revetment in dependence of the wave movement. By this effect stones loosened by impact forces were uplifted and then slid down to the bottom of the revetment.

A comparison of revetment I and revetment III shows Fig. 16. The significant result is, that in the first stage of the wave attack there was no damage for revetment III (which has no filter), but after the first damages due to impact forces only this process preceded faster compared to the other types of revetments.

The important influence of filters has been tested for another type of concrete stones (type TERRAFIX, prototype weight 45 kg). In combination with a thin filter mat (two-dimensional filter) these blocks resisted more than 12.000 waves (H_s in prototype 1.6 m) with no damage.

The above mentioned investigations showed the complex behaviour of different filter layer types. It can be pointed out that filter layers cannot be selected independently of the type of the revetment; there are strong interactions between the different parameters. Further investigations on this subject will be carried out by the authors.

CHAPTER 151

PERMEABLE SEAWALL WITH RESERVOIR AND THE USE OF "WAROCK"

by

Takeshi IJIMA*, Enzoh TANAKA** and Hideaki OKUZONO***

Abstract

Interesting facts that a uniformly permeable seawall of vertical faces with appropriate reservoir has remarkable characteristics of absorbing wave energy even for long period waves in the same degree of usual sloped-face seawall and that these characteristics appear most clearly for permeable seawall of trapezoidal cross-section with backward-sloped reservoir wall are found theoretically and experimentally. Moreover, it is shown that a perforated wall with reservoir has similar characteristics to those for uniformly permeable wall with reservoir.

"Warock" is a type of concrete blocks which was invented in order to realize the wave absorbing seawall in practical works. Several examples of ever constructed wave absorbing seawalls, quaywalls and breakwaters by means of "Warock" in Japan are introduced.

I Introduction

A type of seawall with reservoir has been investigated by Jarlan (1961), Boivin(1963), Cote(1964), Terrett(1968), Marks(1968), Sawaragi (1973,1975) and others. And, they are concerned solely with perforated, thin wall and the effect of the width of the perforated wall in relation to the width of reservoir is entirely ignored. However, the width of permeable wall plays an important role to absorb the incident wave energy. In this paper, we are concerned with wide wall of uniform porosity and of perforated wall, and not only with permeable wall of vertical faces but also of sloped faces.

Since the ability for seawall to absorb incident wave energy is represented by the reflection coefficients, we are limited to the consideration on them. Moreover, since the wave absorbing ability appears clear-

ly for relatively long period waves, we first introduce a simple analysis for vertical-face reservoir seawall of uniform porosity by long wave theory and then a precise numerical analysis for seawall of arbitrary cross-section by means of the authors' method proposed in the paper entitled "A Method of Analyses for Two-Dimensional Water Wave Problems", which is submitted to this Conference. Finally, comparing the perforated wall with uniformly permeable wall experimentally, we introduce "Warock" as a practical tool to realize the reservoir seawall in actual field.

II Theory and Experiment on The Vertical-Face Seawall with Reservoir

In Fig.2-1, suppose that ABCD is a vertical wall of uniform porosity with width ℓ , placed in front of impervious wall EF with reservoir space d and on bottom FDB of constant water depth h . The origin of coordinate system is taken at still water surface on foreshore face AB and x-axis is in horizontal, z-axis is vertically upwards. The incident wave is assumed to be long wave with frequency ω .

Dividing the fluid region into three parts (0) ($x \geq 0$), (I) ($0 \geq x \geq -\ell$) and (II) ($-\ell \geq x \geq -(\ell+d)$) and indicating the quantities in these regions by subscripts 0, 1 and 2, respectively, the mass and momentum equations and the resulting horizontal fluid velocity u and surface displacement ζ by long wave assumption are as follows:

Region (0):

$$\frac{\partial \zeta_0}{\partial t} = -h \frac{\partial u_0}{\partial x}, \quad \frac{\partial u_0}{\partial t} = -g \frac{\partial \zeta_0}{\partial x} \quad (2.1)$$

Assuming incident wave of unit amplitude and reflected wave with complex reflection coefficient ψ_0 , the surface displacement ζ_0 is written as Eq.(2.2). Then, the fluid velocity u_0 and wave number k_0 are derived from Eq.(2.1) as Eq.(2.3) and (2.4).

$$\zeta_0 = (e^{ik_0x} + \psi_0 e^{-ik_0x}) e^{i\omega t} \quad (2.2)$$

$$u_0 = -\frac{gk_0}{\omega} (e^{ik_0x} - \psi_0 e^{-ik_0x}) e^{i\omega t} \quad (2.3)$$

$$\lambda_0^2 = \omega^2 h / g \quad \text{where} \quad \lambda_0 = k_0 h \quad (2.4)$$

Region (I):

Denoting the porosity as V , the linearized drag force coefficient for the porous material as μ and the mass force coefficient as \mathcal{E} , the mass

and momentum equations are as follows:

$$\frac{\partial S_1}{\partial t} = -\frac{h}{V} \frac{\partial u_1}{\partial x}, \quad \frac{1}{V} \frac{\partial u_1}{\partial t} = -g \frac{\partial S_1}{\partial x} - \frac{\mu}{V} u_1 - \frac{\varepsilon(1-V)}{V} \frac{\partial u_1}{\partial t} \quad (2.5)$$

Taking the surface displacement S_1 as Eq.(2.6), the fluid velocity u_1 and wave number K_1 are derived as Eq.(2.7) and (2.8).

$$S_1 = a_1 [e^{iK_1(\lambda+t)} + \psi_1 e^{-iK_1(\lambda+t)}] e^{i\omega t} \quad (2.6)$$

$$u_1 = -\frac{\sigma \nabla a_1}{k_1 h} [e^{iK_1(\lambda+t)} - \psi_1 e^{-iK_1(\lambda+t)}] e^{i\omega t} \quad (2.7)$$

$$\lambda_1^2 = [1 + \varepsilon(1-V) - i \frac{\mu}{\sigma}] \frac{\sigma^2 h}{g} \quad \text{where } \lambda_1 = k_1 h \quad (2.8)$$

Region (II):

Eq.(2.1) is valid here, and putting the surface displacement S_2 as Eq.(2.9), the fluid velocity u_2 is provided by Eq.(2.10).

$$S_2 = a_2 [e^{iK_0(\lambda+l+d)} + \psi_2 e^{-iK_0(\lambda+l+d)}] e^{i\omega t} \quad (2.9)$$

$$u_2 = -\frac{g K_0 a_2}{\sigma} [e^{iK_0(\lambda+l+d)} - \psi_2 e^{-iK_0(\lambda+l+d)}] e^{i\omega t} \quad (2.10)$$

On the boundary EF ($x = -(\ell+d)$), horizontal fluid velocity u_2 must vanish, so that we have

$$\psi_2 = 1, \quad S_2 = a_2 [e^{iK_0(\lambda+l+d)} + e^{-iK_0(\lambda+l+d)}] e^{i\omega t} \quad (2.11)$$

On the boundary CD ($x = -\ell$) and OB ($x = 0$), horizontal velocity and surface displacement should be continuous.

$$\begin{aligned} S_1 &= S_2 & \text{and} & & u_1 &= u_2 & \text{at } x = -\ell \\ S_1 &= S_0 & \text{and} & & u_1 &= u_0 & \text{at } x = 0 \end{aligned} \quad (2.12)$$

Accordingly, we have

$$a_1(1+\psi_1) = a_2(e^{iK_0 d} + e^{-iK_0 d}), \quad \alpha a_1(1-\psi_1) = a_2(e^{iK_0 d} - e^{-iK_0 d}) \quad (2.13)$$

$$1+\psi_0 = a_1(e^{iK_1 \ell} + \psi_1 e^{-iK_1 \ell}), \quad 1-\psi_0 = \alpha a_1(e^{iK_1 \ell} - \psi_1 e^{-iK_1 \ell}) \quad (2.14)$$

where $\alpha = \frac{V \Gamma}{\lambda_0 \lambda_1}$ and $\Gamma = \sigma^2 h / g$ (2.15)

From Eq.(2.13) and (2.14), ψ_0 is obtained as follows:

$$\Psi_0 = \frac{1 - \alpha^2 - \gamma(1 + \alpha)^2 + 4\alpha e^{-2ik_r d}}{(1 + \alpha)^2 - \gamma(1 - \alpha^2)} \quad (2.16)$$

where

$$\gamma = e^{-2ik_r d} + e^{-2ik_r l} - e^{-2i(k_r d + k_r l)}$$

The reflection coefficient K_r is given by the absolute value of Ψ_0 .

$$K_r = |\Psi_0| \quad (2.17)$$

Fig.2-2 is the calculated and measured reflection coefficients for various reservoir width d , when the permeable wall width l is equal to water depth h and the incident wave frequency $\alpha^2 h/g$ is 0.25 (the depth to wave length ratio h/L is 0.083). Horizontal axis shows the ratio of total width $X (= l + d)$ to depth h or to wave length L .

The model wall in experiments is made by armor blocks of 500 cm³ with porosity $V = 0.63$ in wave flume of length 22 m with water depth $h = 50$ cm. The reflection coefficients are measured by Healey's method with incident wave height of 5 ~ 7 cm. Calculated values are obtained by Eq.(2.16)(2.17) with $\xi = 0$, $V = 0.40$ and $\mu/\rho = 1.1$.

From the figure, it is found that the reflection coefficient decreases with the increase of total width X and reaches the minimum 0.1 at $X \approx 2.2h$ or $X \approx 0.18L$ and then increases gradually.

Fig.2-3 is the one for $l = h$ and $\alpha^2 h/g = 0.5$ ($h/L = 0.123$).

Fig.2-4 is for $l = 0.5h$ and $\alpha^2 h/g = 0.50$ ($h/L = 0.123$).

In both cases, the tendency of the change of reflection coefficient with the increase of reservoir width (or increase of total width X for fixed width of permeable wall) is entirely similar to each other and to the one in Fig.2-2, and the minimum coefficient appears at $X = 0.18L$ in every cases.

From above results, it is clear that if a vertical permeable wall is equipped with a reservoir behind it, the reflection coefficient decreases remarkably and reaches minimum at an appropriate width of reservoir. And the total width of seawall at that most effective wave absorbing ability is about 0.18 times the wave length, when the width of permeable wall is half or equal to the water depth, more generally, when the width is the same order of water depth.

Above-described analysis is based on the long wave assumption. As for general waves, the problem has been analyzed by the author(1972) by the method of continuation of velocity potentials. Fig.2-5 is an example

of calculated results by above method for $\ell = h$ and $\alpha^2 h/g = 0.25, 0.50, 1.0$ and 2.0 , taking $V = 0.5$, $\mu/\rho = 2.0$ and $\xi = 0$. From this figure, it is clear that the minimum reflection coefficient appears to each $\alpha^2 h/g$ but the minimum value itself is smaller for smaller $\alpha^2 h/g$, that is, for longer wave length. That is to say, the effect of reservoir to wave absorbing ability appears clearer for longer period waves than for shorter waves.

These minimum values of reflection coefficients are the same order of those which are attained by usual sloped-face seawall. That is, the permeable seawall with reservoir has a same degree of ability for absorbing incoming energy as sloped-face seawall, though it is limited to some particular period wave, corresponding to the width of permeable wall and reservoir.

Above results of theoretical and experimental investigations are summarized as follows:

(i) Permeable vertical seawall without reservoir cannot absorb incoming wave energy effectively, even if the wall is sufficiently wide, that is, the wave absorbing ability of vertical seawall without reservoir is unsatisfactory for ordinary period waves and it is impossible to expect the same degree of absorbing effect as permeable sloped seawall, especially for long period waves. This is due to the fact that on general sloped surface the incident wave deforms gradually or abruptly due to sudden decrease of water depth on the slope and accelerates the fluid velocity or otherwise breaks and dissipates the greater part of the energy, but on the contrary, for vertical permeable wall the incident wave penetrates partly into the wall without deformation or breaking, so that only a part of the energy is lost solely by turbulence in permeable wall. Consequently, in order to induce an effective energy dissipation in permeable wall, it is necessary to accelerate the fluid velocity inside the wall. The reservoir behind the permeable wall plays a role of accelerating the fluid flow across the permeable wall for ordinary or even for longer period waves. This situation is as follows: When a wave crest comes, the permeable wall dams up the flow of incoming wave in front of the wall and the reservoir stores the inflow water. And the water level in the reservoir rises up gradually with some lag following to the rising up of outside water level. When a trough comes, the situation is reversed. Such a difference of water levels along inside and outside faces of permeable wall and therefore,

the surface slope of flow in permeable wall is always steeper than the one for flow without reservoir. This is the reason why the reservoir accelerates the flow across the wall and induces a large amount of energy loss. And, there exists the most effective width of reservoir for given width of permeable wall, wave period and water depth to induce the maximum amount of energy loss.

(ii) For ordinary or longer period waves, the reflected wave is minimized when the total width of seawall with reservoir (the permeable wall plus the reservoir width) is about 0.18 times the wave length, when the width of permeable wall is the same order of water depth. This total width is considerably shorter than the one for perforated, thin wall. Sawaragi(1973) has shown that the total width for the latter to provide the minimum reflection coefficient is $0.25L$, that is, one-fourth of wave length. This is due to the fact that in case of thin, perforated wall the reflected wave from the backwall of the reservoir (EF in Fig.2-1) constitutes a standing wave system with the incident wave and the maximum horizontal fluid flow appears at nodal point (at the point of $L/4$ from EF) and that the maximum energy dissipation is induced by this flow through perforated wall. Therefore, the reservoir in this case does not play any particular role to accelerate the fluid flow through perforated wall.

(iii) The reflection coefficient attained by the reservoir seawall of above total width is sufficiently small in the same degree as the one by permeable sloped-face seawall. And at the same time, the surface wave elevation along the foreside face of wall is much smaller than the one for vertical permeable wall without reservoir, which results in the smaller amount of overtopping waves than the latter.

III Generalized Analysis for Reservoir Seawall of Arbitrary Cross-Section

In Fig.3-1, suppose that AA'B'B is a uniformly permeable wall of arbitrary cross-section placed on impervious sea bottom CB'A'O' with variable water depth. The origin of coordinate system is taken at still water surface and is sufficiently distant from the seawall at constant water depth h . x-axis is in horizontal and z-axis is vertically upwards. Then, fluid region is divided into four parts (O), (I), (II) and (III).

Assuming that the drag force for the porous material in region (II) is linearized to be proportional to fluid velocity, the fluid motion in region (II) has a velocity potential.

Then, the velocity potential in each region is represented in the form of Eq. (3.1) with potential function ϕ_c , $\phi^{(1)}$, ϕ^* and $\phi^{(3)}$, denoting the incident wave amplitude as S_c and frequency as ω .

$$\bar{\Phi}(x, z, t) = \frac{\gamma S_c}{\gamma} \phi(x, z) e^{i\omega t} \tag{3.1}$$

After the same manner as the method proposed in our separate paper "A method of Analyses for Two-Dimensional Water Wave Problems", the boundary-values and its normal derivatives of potential functions for region (I), (II) and (III) are in the following relations, where potential functions on the boundaries are defined as shown in Fig.3-1:

Region (I):

On \overrightarrow{OA} : $\bar{\Phi}_1^{(1)} = \Gamma \Phi_1^{(1)}$ where $\Gamma = \frac{\rho^2 h \gamma}{\rho}$ (3.2)

On $\overrightarrow{AA'}$: $\bar{\Phi}_2^* = \bar{\Phi}_2^{(1)}$, $\Phi_2^* = \frac{1}{\beta} \Phi_2^{(1)}$ where $\beta = \frac{\alpha}{\bar{\nu}}$ (3.3)

On $\overrightarrow{A'O'}$: $\bar{\Phi}_3^{(1)} = 0$ (3.4)

On $\overrightarrow{O'O}$: $\bar{\Phi}_c = i\lambda_c(1-\psi)A(RZ)$, $\Phi_c = (1+\psi)A(kZ)$ (3.5)

Region (II):

On \overrightarrow{BA} : $\bar{\Phi}_1^* = \alpha \Gamma \Phi_1^*$ where $\alpha = 1 + \varepsilon(1 - \bar{\nu}) + i\mu/\rho$ (3.6)

On $\overrightarrow{AA'}$: Same as Eq. (3.3) (3.7)

On $\overrightarrow{A'B'}$: $\bar{\Phi}_3^* = 0$ (3.8)

On $\overrightarrow{B'B}$: $\bar{\Phi}_4^* = \bar{\Phi}_3^{(3)}$, $\Phi_4^* = \frac{1}{\beta} \Phi_3^{(3)}$ (3.9)

Region (III):

On \overrightarrow{BC} : $\bar{\Phi}_1^{(3)} = \Gamma \Phi_1^{(3)}$ (3.10)

On $\overrightarrow{CB'}$: $\bar{\Phi}_2^{(3)} = 0$ (3.11)

On $\overrightarrow{BB'}$: Same as Eq. (3.9) (3.12)

Thus, the Green's identity formula for every region are as follows:

(i) Region (I)

$$\begin{aligned}
 & -\Phi^{(1)}(i) + \sum_{j=1}^{N_1^{(1)}} (\bar{E}_{ij} - \Gamma E_{ij}) \Phi_i^{(1)}(j) + \sum_{j=1}^{N_2^{(1)}} [\bar{E}_{ij} \Phi_2^{(1)}(j) - E_{ij} \bar{\Phi}_2^{(1)}(j)] + \sum_{j=i}^{N_3^{(1)}} \bar{E}_{ij} \Phi_j^{(1)}(j) \\
 & + \psi \sum_{r=1}^M G_{ir} A(kZ_r) = - \sum_{r=1}^M G_{ir}^* A(kZ_r) \\
 & \quad (i = 1 \sim N_1^{(1)}, 1 \sim N_2^{(1)}, 1 \sim N_3^{(1)}, (0, Z_p) \text{ on } \overrightarrow{O'O}) \tag{3.13}
 \end{aligned}$$

(ii) Region (II)

$$\begin{aligned} \phi^{*(i)} + \sum_{j=1}^{N_1^*} (\bar{E}_{ij}^* + \alpha \Gamma E_{ij}^*) \phi_i^*(j) + \sum_{j=1}^{N_2^{(i)}} \left[\frac{1}{\beta} \bar{E}_{ij}^* \phi_2^{(i)}(j) - E_{ij}^* \bar{\phi}_2^{(i)}(j) \right] \\ + \sum_{j=1}^{N_3^*} \bar{E}_{ij}^* \phi_3^*(j) + \sum_{j=1}^{N_3^{(3)}} \left[\frac{1}{\beta} \bar{E}_{ij}^* \phi_3^{(3)}(j) - E_{ij}^* \bar{\phi}_3^{(3)}(j) \right] = 0 \end{aligned}$$

$$(i = 1 \sim N_1^*, 1 \sim N_2^{(i)}, 1 \sim N_3^*, 1 \sim N_3^{(3)}) \quad (3.14)$$

(iii) Region (III)

$$-\phi^{(i)} + \sum_{j=1}^{N_1^{(3)}} (\bar{E}_{ij} - \Gamma E_{ij}) \phi_i^{(3)}(j) + \sum_{j=1}^{N_2^{(3)}} \bar{E}_{ij} \phi_2^{(3)}(j) + \sum_{j=1}^{N_3^{(3)}} [\bar{E}_{ij} \phi_3^{(3)}(j) - E_{ij} \bar{\phi}_3^{(3)}(j)] = 0$$

$$(i = 1 \sim N_1^{(3)}, 1 \sim N_2^{(3)}, 1 \sim N_3^{(3)}) \quad (3.15)$$

The notations used in above equations are the same as those in our separate paper (1976).

Eq. (3.13) (3.14) (3.15) are $(N_1^{(i)} + 2N_2^{(i)} + N_3^{(i)} + N_1^* + N_3^* + N_1^{(3)} + 2N_3^{(3)} + N_2^{(3)} + 1)$ linear equations with respect to the same number of unknown quantities $\phi_i^{(i)}$, $\phi_2^{(i)}$, $\bar{\phi}_2^{(i)}$, $\phi_3^{(i)}$; ϕ_i^* , ϕ_3^* ; $\phi_i^{(3)}$, $\phi_2^{(3)}$, $\phi_3^{(3)}$, $\bar{\phi}_3^{(3)}$ and ψ . Solving above equations simultaneously, we obtain all of the unknowns and the potential values at points in every region are calculated by Green's theorem. The reflection coefficient K_r is given by the absolute value of ψ . In addition, the surface wave profiles are calculated as follows:

$$\text{From C to B: } S_3(j)/S_0 = -i \phi_1^{(3)}(j) e^{i\sigma t}, \quad j = N_1^{(3)} \sim 1 \quad (3.16)$$

$$\text{From B to A: } S^*(j)/S_0 = -i \phi_1^*(j) e^{i\sigma t}, \quad j = 1 \sim N_1^* \quad (3.17)$$

$$\text{From A to O: } S_i(j)/S_0 = -i \phi_1^{(i)}(j) e^{i\sigma t}, \quad j = N_1^{(i)} \sim 1 \quad (3.18)$$

Above method is applied to reservoir seawall with various cross-sections, where the permeable wall is of rectangle, trapezoid and inverse trapezoid, and the backwall of reservoir is vertical or sloped, as shown in Fig.3-2. The width of rectangular wall is taken as $h/2$ and those of trapezoidal wall at still water level, half depth and bottom are taken as $h/4$, $h/2$ and $3h/4$, respectively, so as to be of the same cross-sectional area as the rectangle. The slope of the backwall is taken as $\pm 60^\circ$ to the horizontal bottom.

In Fig.3-2, the type (A) is of vertical backwall, the type (B) is of backward-sloped backwall and the type (C) is of forward-sloped backwall. As shown in later, since the characteristics of the reservoir are represented by its width at still water level, the representative width of the seawalls

is better to be taken as X , which is the distance from the half-depth point on the foreside face of permeable wall to the water line of the backwall of reservoir.

In numerical calculations, we take the geometrical surface OO' at the distance $3h$ from the seawall and $N_1'' = 15$, $N_2'' = 10$, $N_3'' = 12$, $M = 21$ for region (I), $N_1^* = 5$, $N_2^* = 5$ for region (II). As for the region (III), we take $N_3^{(3)} = 10$, and $N_1^{(3)}$, $N_2^{(3)}$ are taken as $6 \sim 10$, according to the variable width of the reservoir. The porosity V is taken as 0.7 and the coefficient μ/ρ is as 0.9, \mathcal{E} is 0.

Fig.3-3 is the calculated reflection coefficients of the type (A) with respect to the ratio of total width X to the water depth or the ratio to the wave length L , for $\alpha^2 h/g = 0.50$ ($h/L = 0.123$). It is seen that in every wall, the minimum reflection coefficient appears at $X = 1.5h$ or $X = 0.18L$ and that the wave absorbing ability of the inverse trapezoidal wall is inferior to those of the others. Therefore, it will be reasonable to exclude the inverse trapezoidal wall from further considerations.

Fig.3-4 shows the calculated reflection coefficients for the type (B) and (C), excepting the inverse trapezoidal wall, in comparison with the one for rectangular wall with vertical backwall. It is found that in every wall the minimum reflection coefficient appears at nearly the same value of X as before, and that for smaller values than that X , the type (B) provides lower reflection coefficients than those of the type (C). Therefore, it will be reasonable to conclude that the rectangle or trapezoidal wall of the type (B) is better, of which the trapezoidal wall will be the most preferable, because of the smallest volume of the reservoir.

Above characteristics for various types of reservoir seawall based on the calculated results are proved by experiment.

Fig.3-5 shows the measured reflection coefficients for the type (A). The model walls are made by quarry stones of mean diameter 5 cm with porosity $V = 0.53$ in wave flume with water depth $h = 50$ cm and length 22 m, and reflection coefficients are measured by Healey's method for incident wave height $H = 6.7$ cm. From the figure, it is clear that the minimum reflection coefficient appears at the same value as the one calculated before, and that the inverse trapezoidal wall shows the highest reflection coefficient.

Fig.3-6 is the measured reflection coefficient for the type (B). This shows that the rectangular or trapezoidal wall is better.

Above results for various types of seawall are summarized as follows:

(i) As for the cross-section of permeable wall, the rectangular or trapezoidal wall is better than the inverse trapezoidal wall. As for the back-wall of reservoir, the backward-sloped one is better and forward-sloped one is to be avoided.

(ii) The reservoir is characterized not by the volume but by its free surface width. And, the total width for the seawall to provide the minimum reflection coefficient is about 0.18 times the wave length and the value at that width is the same order of the one attained by permeable sloped-face seawall.

IV Characteristics of the Perforated, Wide Wall with Reservoir

In the uniformly permeable wall, the energy dissipation is induced by the turbulence of flow inside the wall. While, in the perforated wall, the energy is dissipated mainly by jet flow turbulence through the wall. Therefore, the situation seems to be quite different. However, the experiments on the perforated wall show that the wave absorbing characteristics of the permeable and perforated walls quite resemble to each other.

Fig.4-1 is the measured reflection coefficients of perforated walls with reservoir, where the water depth h is 50 cm, wave frequency $\omega^2 h/g$ is 0.50 ($h/L = 0.123$) and incident wave height is $H_i = 4 \sim 6$ cm. The diameter of the circular holes of the wall is kept as $D = 5.0$ cm, average porosity is $V = 0.33$ and the width of the wall is varied as 4, 10 and 20 in cm, that is, $l/h = 0.08, 0.20$ and 0.40 .

From the figure, it is found that the minimum reflection coefficient appears at $X/L = 0.25$ for $l/h = 0.08$, at $X/L = 0.20$ for $l/h = 0.20$ and at $X/L = 0.18$ for $l/h = 0.40$, that is, for wide wall the total width for minimum reflection coefficient is nearly $0.18L$, which is the same value as the one for uniformly permeable wall and for thin wall the total width for minimum reflection coefficient approaches to $L/4$, which is also the same value as permeable wall.

Fig.4-2 is the measured reflection coefficients for constant width of perforated wall $l = 10$ cm. Water depth is 50 cm and wave frequency is $\omega^2 h/g = 0.50$, the incident wave height is $4 \sim 6$ cm. The diameter of horizontal holes varies as 3.2 cm, 5.0 cm and 8.0 cm, with average porosity $V = 0.33$. From this figure, it is seen that the reflection coefficients for larger diameter than incident wave height are higher than those for smaller

diameter but the minimum values for every diameter appear at nearly the same value of $X/L = 0.20$.

From above results, it will be estimated that the perforated wall has similar characteristics on wave absorbing ability to the one of the uniformly permeable wall, though the situation of energy dissipation is quite different from each other. Therefore, it seems to be reasonable to replace the uniformly permeable wall by perforated wall without loss of the characteristics on wave absorption.

V The Use of "Warock" for Wave Absorbing Structures

The "Warock" is a type of concrete blocks to construct the seawall with reservoir. As shown in Fig.5-1 and Photo.5-1, it consists from the fore-side part of hexagon column with franges at both ends and the rearside part of vertical slab, which are connected by horizontal beam. Placing the block in a row along the shoreline and piling up in several columns to the required height, a seawall with reservoir is constructed, where the foreside parts of blocks constitute the perforated wall of average porosity 0.48 and the rearside parts provide the backwall, between which we have reservoir of porosity 0.75 because of the existence of horizontal beams. Photo.5-2 shows a "Warock" hanged by crane in construction of a wave absorbing quay-wall in actual place. The weight of this block is 20 tons, the length is 4.5 m, width is 2.0 m and the height is 1.7 m.

In order to oppose several period waves in various water depth, we have three sizes of blocks. The size A is 3.5 m in length, 1.6 m in width, 1.4 m in height and 10 tons in weight; the size B is as shown in Photo.5-2 and the size C is 6.0 m in length, 2.4 m in width, 2.0 m in height and 40 tons in weight.

Photo.5-3 shows the quaywall under construction by "Warock", piling up in four columns. The rightside of the figure constitutes vertical retaining wall, that is, the backwall of reservoir and leftside constitutes a perforated wall and between them is the reservoir. Photo.5-4 shows the front view of a part of the quaywall.

In this way, various types of seawall, quaywall and breakwater with wave absorbing ability are constructed by "Warock".

Fig.5-2 is the cross-section of quaywall constructed at water depth 10.4 m at Muroran Harbour, in Hokkaido. "Warock" of 20 tons are placed in three columns on the foundation by cellar block and rubble mound.

Fig.5-3 is the quaywall of depth 3.0 m constructed at Ushibuka Harbour in Kyushu with four columns of "Warock" of 10 tons in weight. Fig.5-4 is the breakwater at depth 4.5 m, constructed against wave period 5.0 seconds and height 1.20 m at Odo Marina in Fukuoka City, by 20 tons "Warock" in three columns. Fig.5-5 is the breakwater of double rows in three and four columns of 20 tons and of 10 tons "Warock", constructed at depth 7.0 m at Hiakari harbour in the Port of Kita-Kyushu at North Kyushu. The outside face of the breakwater is against the open sea waves of period 5.2 seconds and height 1.70 m and the inside face is to absorb the induced waves in harbour.

The use of the "Warock" for reservoir seawall is limited to the place where water depth is less than about 6 m and wave period is shorter than about 6 seconds. For larger depth and longer period waves, the seawall is better to be prefabricated in one body, transported by crane berge and placed on the site.

Fig.5-6 is the cross-section of breakwater by prefabricated reservoir seawall, constructed at depth 3.0 m at Tannawa Marina in Osaka Bay, against wave period 6.1 seconds and wave height 1.9 m. Photo.5-5 is the prefabricated body on the shore, whose length is 6.0 m, width is 5.6 m, height is 7.0 m and weight is 260 tons. Fig.5-7 is the seawall constructed at depth 7.0 m at the north coast of Kashima Harbour against open ocean waves of period 9.11 seconds and height 6.0 m. Photo.5-6 is the prefabricated body, whose widths of perforated wall and reservoir are 5.0 m and 6.0 m, respectively, the total width is 13 m, length is 13 m, height is 11 m and weight is 1800 tons.

VI Conclusions

The characteristics of the seawall with reservoir are summarized as follows:

- (i) The uniformly permeable wall with reservoir has the best ability of wave absorption when the total width is about 0.18 times the wave length, if the width of permeable wall is the same order of water depth. If the permeable wall is thin, the total width of best ability approaches to $L/4$.
- (ii) The most effective cross-section for the permeable wall with reservoir to absorb wave energy is thought to be of trapezoidal wall with backward-sloped backwall of reservoir.
- (iii) The perforated wall with reservoir has similar characteristics on

wave absorption to the uniformly permeable wall with reservoir.

(iv) The permeable or perforated wall with reservoir in total width of about 0.18 times the wave length has the same degree of wave absorbing ability as the permeable sloped-face seawall, even for long period waves.

(v) Such a seawall with reservoir is realized by means of "Warock" for actual field. For larger depth and longer period waves, it can be realized by prefabricated perforated wall.

ABSTRACT

Effects of permeable core layer installed in trapezoidal and rectangular breakwaters have been studied experimentally and analytically. As the materials for armour and core use of the lattice composed of circular cylinders was made in addition to rocks. Perforated plates were also applied as a kind of very thin core.

Experimental results show that the reflected wave heights from breakwater could be reduced considerably by locating the core layer shoreward within it while core thickness controls the transmitted wave heights in the protected water area. Harmonic analysis about the water surface in lattice armour reveals that the second harmonic waves take a pattern of standing wave distribution having a node at the seaward face of breakwater. Thin perforated plates work successfully for reducing the transmitted wave heights when they are installed at the rear face of breakwater.

An analytical approach to predict the transmission and the reflection coefficients is applied for the present experimental data and shown to be useful.

INTRODUCTION

It is well understood by coastal engineers that pervious breakwaters bring less seaward reflective wave energy and wave run-up than impervious ones do, as observed in several laboratory and field experiments.

However they have disadvantage of allowing shoreward wave energy penetration which results in the transmitted waves behind it.

In order to obtain less transmitted wave energy without precluding the merits stated, for instance, a rubble-mound breakwater usually has a permeable core layer which has less permeability compared with armour ones, or it is said to be composed of pervious multi-layers. Effects of hydraulic characteristics of pervious cores on wave transmission and reflection have not been known despite their importance

in functional design of pervious breakwaters. The present study deals with fundamental effects of pervious cores installed within porous breakwaters based on experiments on model breakwaters as well as analytical approach.

EXPERIMENTAL FACILITIES AND PROCEDURE

Experiments were performed on horizontal bottom in a wave channel of 18.5 meter long, 0.4 meter wide and 1.0 meter deep. Waves were generated with a regular and flap type generator. Parallel wire wave gages were used to measure water surface fluctuations. Fig. 1 presents arrangement of experimental equipments.

Cross sectional configurations of model breakwaters were of rectangular and trapezoid as shown in Fig. 2.

Photo. 1 Trapezoidal Breakwater Made of Lattice (No Core)

Table 1 Hydraulic Coefficients of Breakwater Materials

		Porosity λ (%)	Diameter D (cm)	Turbulent Coefficient C_3	(Turbulent Frictional Slope) / v^2 $\left(\frac{\Delta h}{l}\right) t \frac{1}{v^2}, (\text{sec}^2 \cdot \text{m}^{-2})$
Armour	Lattice ($\phi 34$)	60.7	3.4	0.11	2.0
	Rock A	44.8	3.8	0.4	30.0
Core	Lattice ($\phi 11$)	60.7	1.1	0.11	6.0
	Rock C	43.0	2.9	0.3	36.0

Three kinds of the core thickness tested were 13, 20 and 26 cm for the core location at center of breakwaters. With thickness of 20 cm, the core location was varied in three ways, i.e., the front, center and rear, respectively. Distance between the center core and the front or the rear cores was 20 cm. Main armour material of

Fig. 1 Arrangement of Experimental Equipment

Fig. 2 Cross Section of Model Breakwaters

breakwaters was the lattice of $D = 3.4$ cm (Photo.1), and the core ones were the another lattice of $D = 1.1$ cm and the rock of the median diameter (D_m) = 2.9 cm. Hydraulic characteristics of the lattice were discussed in detail previously¹⁾. Some of the hydraulic properties are cited in Table 1. Coefficient C_3 in the table is of one to turbulent resistance, and is related to the frictional slope as in the following equation.

$$\frac{\Delta h}{\ell} = \frac{V^2}{2g\lambda^5 D} \cdot \left[\frac{C_2}{(DV/\nu)} + C_3 \right], \quad (1)$$

where V , g , ν , and C_2 are steady discharge velocity, acceleration of gravity, kinematic viscosity, and another coefficient for laminar flow resistance, respectively. The turbulent frictional slope, denoted $(\Delta h/\ell)_t$, is defined as that neglecting the laminar term in Eq.1, and is expressed as,

$$\left(\frac{\Delta h}{\ell} \right)_t = \frac{C_3 V^2}{2g\lambda^5 D}. \quad (2)$$

The ratio of the turbulent frictional slope of the lattice armour to that of core is 1:3 for the lattice core, and it is 1:18 for the rubble core. The ratio for a typical rubble mound breakwater²⁾ having artificial concrete blocks of $\lambda = 0.5$ and $C_3 = 0.67$ as armour and rock of $\lambda = 0.4$ and $C_3 = 0.4$ as core¹⁾, is 1:15 provided weight of the core unit is 1/200 of the armour one, which is close to 1:18.

Uniformly perforated steel plates were also employed since they were expected to represent one of the thin cores. The plates with circular holes of 1.2 and 2.0 cm in diameter and of porosity of 20 and 34 % were tested. The rock as armour material was used mainly with the plates.

The incident wave height H_I and the reflected one H_R were determined by moving one or two gages to measure amplitudes at loops and nodes, and adding or subtracting the latter to the formers. The transmitted wave height through breakwater H_T was measured at location about one quarter wave length shoreward from the point of the rear face which intersects with the still water surface.

The transmission coefficient and reflection coefficients are defined as H_T/H_I and H_R/H_I , and denoted hereafter K_T and K_R , respectively.

The internal water surface fluctuations of lattice armour were measured by inserting small gages vertically into voids between cylinders. Dimensions of experimental waves were the ranges shown below. while the water depth h was kept constant of 50 cm.

Incident wave heights $h = 1 - 10$ cm, Wave periods $T = 0.7 - 2.2$ sec.

RESULTS AND DISCUSSIONS

In the statement followed results about trapezoidal breakwaters will be mainly presented except for the ones with plates. Rectangular breakwaters will be discussed in comparison with the trapezoidal ones in a few sections.

1) Comparison of K_T and K_R between No-core and With-core Breakwaters

First of all, function of the core installed in a porous breakwater has been investigated. Fig. 3 shows the case of lattice core,

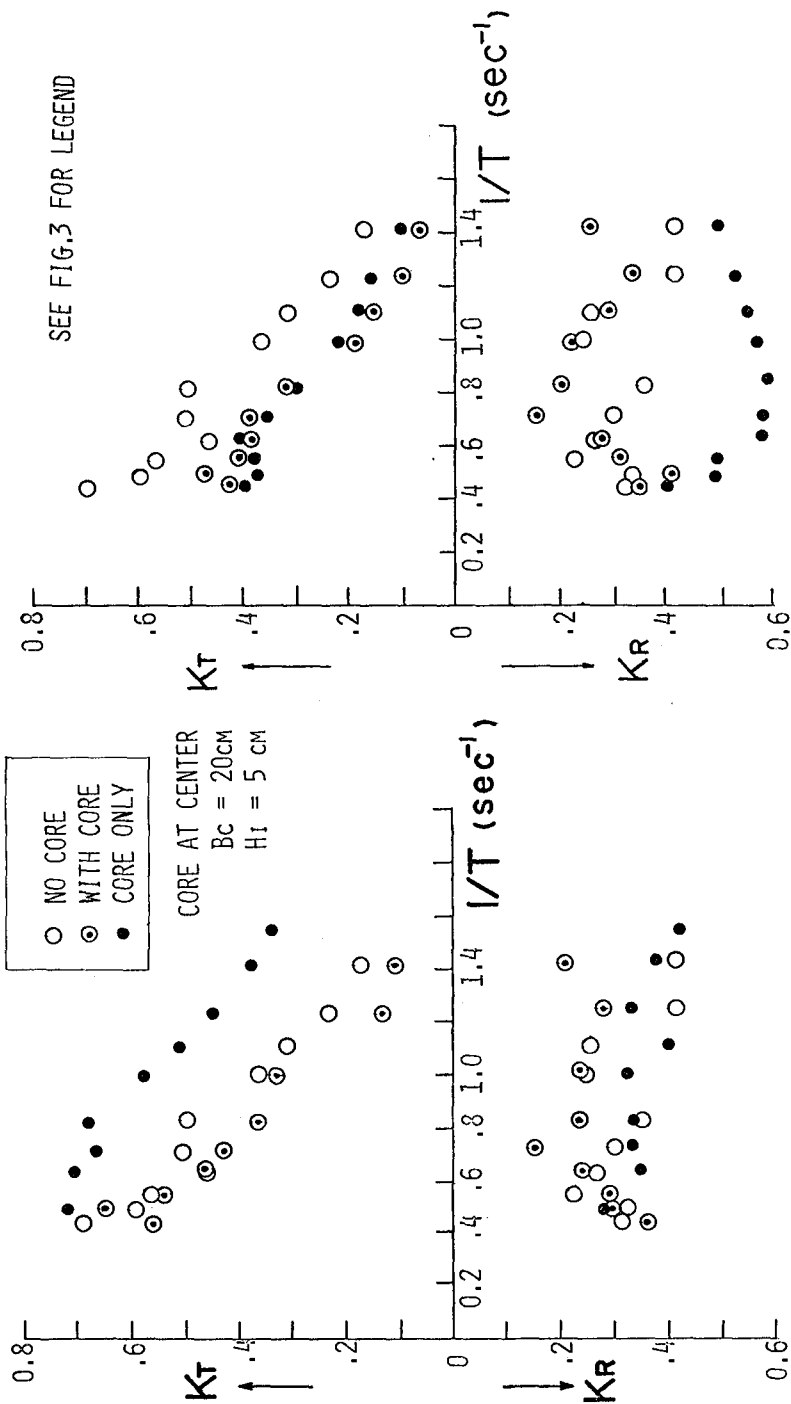

Fig. 3 Effect of Lattice Core on K_T and K_R

Fig. 4 Effect of Rubble Core on K_T and K_R

in which the ordinate is taken as the transmission coefficient upward and as the reflection coefficient downward, and the abscissa is frequency. K_T of the with-core breakwater is nearly the same as no-core one. In this case the core doesn't work effectively since the frictional slope of the core is only three times that of armour. Fig. 4 presents the case of rubble core, in which K_T of with-core is dominated by the core and almost coincides with that of the case of core layer only. K_R of with-core, however, is considerably smaller than that of the core only, and approaches to that of no-core and is a little smaller than it as a whole. This suggests that installing a suitable core layer possibly decreases K_R besides K_T .

2) Effect of Core Thickness on K_T and K_R

Effect of the thickness of core on decreasing K_T is greater for the rubble core than for the lattice core as expected. K_T and K_R for cases of rubble core are shown in Fig. 5 for three kinds of thickness. In the figure, relative width of breakwater B/L which has been known as one of the most important parameters to determine K_R for single layer breakwaters¹⁾ and to wave pressures on the impervious wall behind the permeable absorbers³⁾. The thickness, however, doesn't give appreciable change of K_R , especially for the rubble core.

3) Effects of Core Location on K_T and K_R

With a kind of core, the location of core in a armour greatly affects K_R but scarcely does K_T , an opposite trend to the effect of thickness. Fig. 6 presents the case that a rubble core is installed at three different locations in lattice breakwater of trapezoidal cross section. It shows that the breakwater with the rear core gives considerably smaller K_R than the others do for waves of the relative width B/L less than 0.7. Most of prototype breakwaters and waves are satisfied with the above B/L condition. To the contrary, K_T hardly depends upon the core location.

Fig. 7 is an example to explain effect of the relative wave height H_I/h on the transmission and reflection coefficients, with location as parameter. K_T decreases as H_I/h increases, irrespectively of core location. Meanwhile K_R decreases slightly with H_I/h in the range of experiment, H_I/h less than 0.14.

4) Wave Height Distribution in and around Breakwaters

Fig. 8 exhibits wave height distributions measured at seaward and shoreward water areas of breakwaters, and in the armour layers of lattice, too. The case of rear core has another maximal wave height in addition to the one appearing near the seaward face of breakwater. The latter maximal of the rear-core breakwater is remarkably smaller than those found for the front-core and no-core ones. Behind the location of the rear-core, the two wave heights of cases with core are almost the same and scarcely depends upon the core location.

Inspecting the distribution characteristics, it may be assumed that the reflected waves appearing in front of breakwater with core are composed of the two reflective waves, namely, the one from seaward face of armour and the another from seaward face of core. Accordingly, a larger distance between the two faces contributes to obtain less reflected wave energy and consequently lower K_R because of a greater phase difference between the two reflected waves at the seaward water area. On the other hand, the transmitted waves may be approximated with the one kind wave which penetrates through the breakwater and

Fig. 5 Effect of Core Thickness on K_T and K_R (Rubble Core)

Fig. 8 Wave Height Distribution in and near Breakwaters

appear in the shoreward water area.

The following several figures show the results of harmonic analysis of water surface fluctuations in and around various kinds of breakwater. They bring wave height distribution of higher harmonics other than that of fundamental one whose period is that of the incident wave, as seen in Figs. 9-14. Wave height distribution of fundamental harmonic almost coincides with the directly determined height of crest to trough from the recorded profile, depicted with triangles in the figures. Types of standing wave prevail in front of structures and progressive wave pattern do behind them for the two waves.

Dimensionless wave heights, H_N/H_1 in the figures, for slit walls made of single row or double rows of cylinders are less than 0.2 everywhere for 2nd and 3rd harmonics. The case of two rows is shown in Fig. 9 in which distribution of the higher harmonics looks like a standing wave too and the size is nearly the same to that found for incident waves.

Inside of the single layer breakwater made of lattice, 2nd harmonic has nodes at the front and the rear faces of breakwater (See Fig. 10). The higher harmonics are considered to be generated due to the quadratic loss of internal flow within breakwaters ⁴). As for the rubble core layer itself, 2nd harmonic gives a clear pattern of standing wave in the seaward water area, especially for longer waves, which suggests the higher harmonics are generated in the case due to abrupt change of water particle velocity.

The wave height distribution of 2nd harmonics for the rubble core breakwaters of $B_c=20\text{cm}$ was investigated in the armours of both sides of core. In the seaward armour, it has usually a node near the front face, but at the rear face of armour it doesn't necessarily has a loop. The latter trend possibly relates to that the fundamental or the directly determined waves do not necessarily take a loop at the rear face of armour. In the shoreward armour behind core, however, it has always nodes at the both faces, while the fundamental ones have loops at the front face and nodes at the rear face.

Heights of 2nd harmonic in armours are relatively greater for rectangular ones. The cause of this trend can be sought in the fact that a kind of resonance which brings large difference of horizontal velocity within breakwater, likely occurs for rectangular one than for trapezoidal one.

5) Comparison Between Rectangular and Trapezoidal Breakwaters

K_T and K_R of trapezoidal breakwaters are compared with those of rectangular ones which have the width B that coincides with the mean width below the still water of the trapezoidal ones. K_T is larger for the trapezoidal ones, as expected. K_R of rectangulars oscillates more sharply with B/L than that of trapezoids. Distribution of K_R plotted against B/L gives different trends for the two cases, which suggests a difference of location of reflective planes between the two structures. Discrepancy of the two K_R becomes smaller as the core location moves shoreward, as seen in Figs. 15 and 16.

6) Analytical Prediction of K_T and K_R

Several analytical approaches to estimate K_T and K_R for porous breakwaters have been proposed recently ⁵⁾⁻⁸⁾. But they deal with essentially breakwaters made of one kind of materials and take no account of the effect of core location as found hitherto.

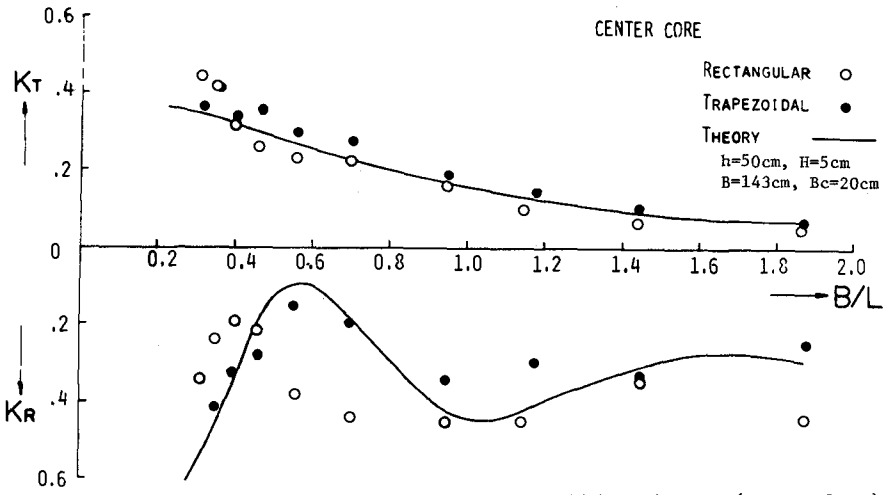

Fig. 15 Comparison Between Rectangular and Trapezoidal Breakwaters (Center Core)

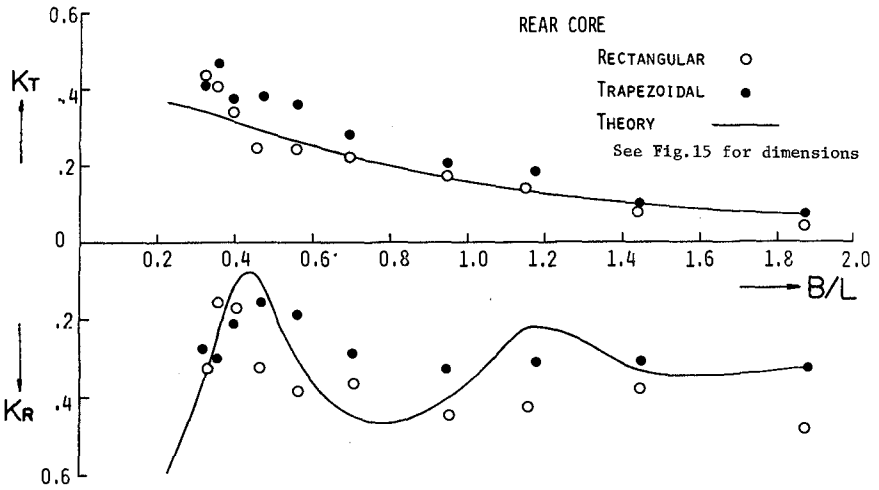

Fig. 16 Comparison Between Rectangular and Trapezoidal Breakwaters (Rear Core)

Problems of wave transmission and reflection coefficients for multi-layered porous breakwaters may be solved as one of boundary value problems as performed by a few researchers for single layer pervious breakwaters^{6), 7)}. But such a solution will become extremely cumbersome as number of layers increases for multi-layered breakwaters.

A simplified approach to estimate K_T and K_R for multi-layered porous breakwaters has been proposed⁹⁾, whose summary is presented in APPENDIX. It is applied for the experimental data, which seems to be useful for K_T of both rectangular and trapezoidal breakwaters and K_R of trapezoidal ones, as we can see in Figs. 15 and 16.

K_T and K_R of three kinds of prototype breakwater, namely, center-core, rear-core and no core ones, are calculated for cases $H_I = 1.0$, and 5.0 meter with varying T . The result is shown in Figs. 17 and 18. K_T can be successfully reduced by installing a core, while K_R can be lowered by locating the core shoreward in breakwater.

7) Perforated Plate Breakwaters

Employment of pervious core for porous breakwaters can be expected to reduce the transmitted wave height. One of the simplified pervious cores may be thin plates or slab with pores and/or slits. Several studies have been disclosed about perforated wall breakwaters with chambers, but not with those filled with granular materials. Perforated steel plates with circular holes were used as thin cores. Breakwaters of rectangular cross section were only tested (Photo. 2). One to three plates were installed at the front and the rear faces of, and at the center of breakwaters

K_T and K_R of the plate breakwaters are shown in Figs. 19 and 20. The plate installed at the rear face of breakwater works successfully for reducing K_T especially for longer waves. Breakwaters having the two plates at the both faces bring higher K_R than the cases of rear plate only and no plate, though they can lower K_T considerably.

Photo. 2 Rubble Breakwater with Perforated plates

CONCLUSIONS

- 1) Pervious core layers installed in porous breakwaters effectively decrease the transmitted wave height, and possibly reduce the reflected wave height too provided they being placed shoreward in breakwaters.
- 2) The simplified analytical approach is confirmed to be useful to predict the transmission and reflection coefficients for pervious core breakwaters.
- 3) Thin perforated plates set at the rear face of pervious breakwa-

ters are effective to decrease K_T without increasing K_R . They may replace the cores made of granular materials in prototype breakwaters if practically feasible.

ACKNOWLEDGEMENTS

This study has been carried out with the science research grant offered by the Ministry of Education in the period of 1973 - 75.

The writers would like to acknowledge Professor Yuichi Iwagaki of Kyoto University, who had organized a nationwide research project to which the present study belonged.

The writers wish to express their gratitudes to former research assistant, Katsuei Kasai, and former students, Hidetoshi Sōma, Etsurō Yamada, Shigeru Kobiyama and Ryūichi Satou of Department of Civil Engineering, Muroran Institute of Technology, for their co-operation given during the course of study.

APPENDIX

AN APPROACH TO PREDICT TRANSMISSION AND REFLECTION COEFFICIENTS FOR MULTI-LAYERED POROUS BREAKWATERS 9)

The present approach is derived on the basis of linearized Forchheimer's law for the frictional loss in breakwaters provided waves are of shallow water, which is in accordance with the line of the previous approach for single layer one^{5),1),10)}.

Besides, the following assumptions are made.

- (1) Breakwaters are composed of rectangular layers, and the boundaries between layers are vertical.
- (2) The transmitted waves appearing in the protected water area are the one component waves to which the incident waves develop after passing through all the layers consecutively. The components come to the area after reflected back once or more are neglected.
- (3) The reflected waves are sum of the waves reflected one time only, each of which is generated when the incident waves of (2) pass a boundary between adjacent two layers.

According to the above assumptions, the transmission coefficient K_T of a breakwater composed of N layers (See Fig. 21), are given by,

$$K_T = K_{t,1} \cdot K_{t,2} \dots K_{t,J} \dots K_{t,N} \cdot K_{t,N+1} \cdot \exp[-(n_1 B_1 + n_2 B_2 + \dots + n_J B_J + \dots + n_N B_N)], \quad (3)$$

where n_J is the damping factor of wave height while advancing in the J layer of the width B_J , and $K_{t,J}$ is the transmission coefficient when waves penetrates into the layer $J+1$ from J passing through the boundary J 5),1).

The equation of the water surface for the resultant reflected waves, η_R , is expressed as the sum of reflected waves, $\eta_{r,J}$ original-

Fig. 21 Scheme of Wave Transformation by Multi-Layered Breakwater

ly generated at the boundary J, (J = 1, 2,N, N+1), as

$$\eta_R = \eta_{r,1} + \eta_{r,2} + \dots + \eta_{r,J} \dots + \eta_{r,N} + \eta_{r,N+1} , \quad (4)$$

where,

$$\begin{aligned} \eta_{r,1} &= \frac{H_I}{2} \cdot K_{r,1} \cdot \sin(\sigma t + m_0 x + \alpha_{r,1}), \quad m_0 = 2\pi/L, \\ &\vdots \\ \eta_{r,J} &= \frac{H_I}{2} \cdot K_{t,1} \cdot K_{t,2} \dots K_{t,J-1} \cdot K_{r,J} \cdot K_{tb,J-1} \dots K_{tb,1} \cdot \exp[-(n_{i,1} + n_{r,1})B_1 + (n_{i,2} + n_{r,2})B_2 \dots + (n_{i,J} + n_{r,J-1})B_{J-1}] \cdot \sin[\sigma t + m_0 x - (m_{i,1} + m_{r,1})B_1 - \dots - (m_{i,J-1} + m_{r,J-1})B_{J-1} + \alpha_{t,1} \dots \alpha_{t,i-1} + \alpha_{r,J} + \alpha_{tb,J-1} + \dots + \alpha_{tb,1}], \\ &\vdots \\ \eta_{r,N+1} &= \frac{H_I}{2} \cdot K_{t,1} \cdot K_{t,2} \dots K_{t,J-1} \dots K_{t,N} \cdot K_{r,N+1} \cdot K_{tb,N} \dots K_{tb,1} \cdot \exp[-\sum_1^N (n_{i,J} + n_{r,J})B_J] \cdot \sin[\sigma t + m_0 x - \sum_1^N (m_{i,J} + m_{r,J})B_J + \sum_1^N \alpha_{t,J} + \alpha_{r,N} + \sum_1^N \alpha_{tb,J}], \end{aligned}$$

where m_j is the wave number in the J layer and α is a phase angle. Subscript i, r and t for m, n, K_t , K_r , α and η correspond to the incident, reflected and transmitted waves, respectively. That denoted tb corresponds to the waves transmitting back seaward after reflected at one of the boundaries.

Consequently, the reflection coefficient is obtained as,

$$K_R = [A_1^2 + A_2^2 + \dots + A_{N+1}^2 + 2\{A_1 A_2 \cos(\beta_1 - \beta_2) + A_1 A_3 \cos(\beta_1 - \beta_3) \dots + A_J A_N \cos(\beta_J - \beta_N) \dots + A_N A_{N+1} \cos(\beta_N - \beta_{N+1})\}]^{1/2} , \quad (5)$$

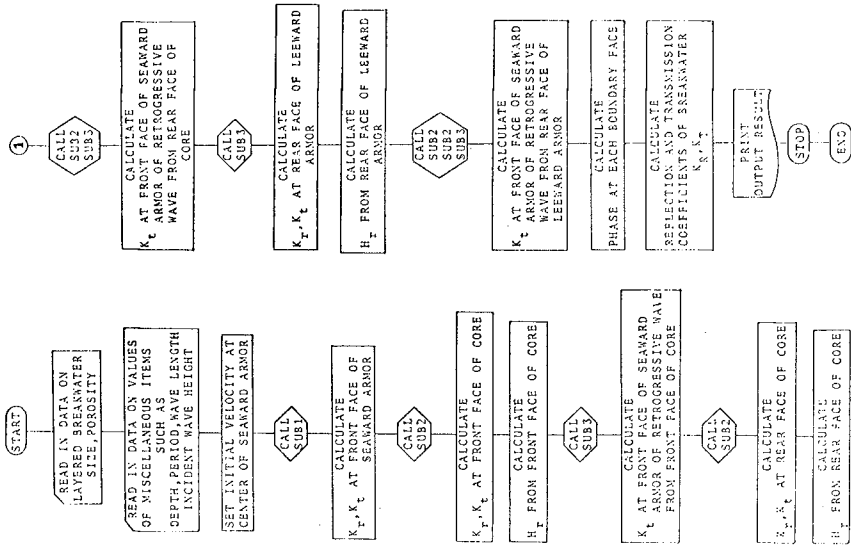

where,

$$\begin{aligned} A_1 &= K_{r,1}, \quad A_2 = K_{t,1} \cdot K_{r,2} \cdot K_{tb,1} \cdot \exp[-(n_{i,1} + n_{r,1})B_1], \dots \\ A_J &= K_{t,1} \cdot K_{t,2} \dots K_{t,J-1} \cdot K_{r,J} \cdot K_{tb,J-1} \dots K_{tb,1} \cdot \exp[-(n_{i,1} + n_{r,1})B_1 + \dots + (n_{i,2} + n_{r,2})B_2 + \dots + (n_{i,J} + n_{r,J})B_J], \dots \\ A_{N+1} &= K_{t,1} \cdot K_{t,2} \dots K_{t,J} \dots K_{t,N} \cdot K_{r,N+1} \cdot \exp[-(n_{i,J} + n_{r,J})B_J]. \end{aligned}$$

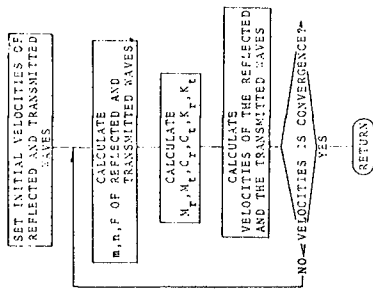

Also,

$$\begin{aligned} \beta_1 &= \alpha_{r,1}, \quad \beta_2 = -(m_{i,1} + m_{r,1})B_1 + \alpha_{t,1} + \alpha_{r,2} + \alpha_{tb,1}, \dots \\ \beta_J &= [-\{(m_{i,1} + m_{r,1})B_1 + (m_{i,2} + m_{r,2})B_2 + \dots + (m_{i,J} + m_{r,J})B_J\} + \alpha_{t,1} + \alpha_{t,2} + \dots + \alpha_{t,J-1} + \alpha_{r,J} + \alpha_{tb,J-1} + \dots + \alpha_{tb,1}], \dots \\ \beta_N &= [-\sum_1^N (m_{i,J} + m_{r,J})B_J + \sum_1^N \alpha_{t,J} + \alpha_{r,N+1} + \sum_1^N \alpha_{tb,J}]. \end{aligned}$$

CHAPTER 153

WAVE TRANSMISSION THROUGH TRAPEZOIDAL BREAKWATERS

by

Ole Secher Madsen ⁽¹⁾, M.ASCE and Stanley M. White ⁽²⁾, A.M. ASCE

Introduction

Previous publications resulting from this study dealt with certain aspects of the interaction of normally incident waves with a porous structure. Madsen and White (1976a), hereafter referred to as (I), developed a semi-empirical procedure for the prediction of reflection coefficients of rough impermeable slopes. Madsen (1974) with discussion by Kondo (1975) and Closure by Madsen (1976), collectively referred to as (II) hereafter, developed an explicit solution for the transmission and reflection coefficients of homogeneous rectangular crib-style breakwaters. When viewing the interaction of incident waves with a trapezoidal, multilayered breakwater as a problem of energy dissipation, the problem treated in (II) may be regarded as an idealized analysis accounting for the internal dissipation of energy within the structure, whereas (I) may be regarded as an idealized analysis of the energy dissipation on the seaward face of the breakwater, i.e., the external energy dissipation. The present paper presents a synthesis of the results obtained in (I) and (II) into an approximate procedure for the prediction of wave reflection from and transmission through trapezoidal, multilayered breakwaters.

The present paper presents only the major points of the approximate procedure. Thus, extensive references to (I) and (II) are made and only the determination of the hydraulically equivalent breakwater is presented in some detail. For a presentation of the entire development of this model for the reflection and transmission characteristics of trapezoidal, multilayered breakwaters the reader is referred to Madsen and White (1975) or Madsen and White (1976b) where detailed numerical examples of the use of the procedure may also be found.

Description of the Approximate Procedure

The basic assumptions of the approximate procedure are, of course, those inherent in the analyses and procedures developed in (I) and (II):

(1) Associate Professor of Civil Engineering, R.M. Parsons Laboratory, Massachusetts Institute of Technology, Cambridge, MA 02139

(2) Design Civil Engineer, J. Ray McDermott Company, New Orleans, LA 70160 (formerly Research Assistant, R.M. Parsons Laboratory, Massachusetts Institute of Technology)

- (a) Relatively long normally incident waves which may be considered adequately described by linear long wave theory.
- (b) The incident waves do not break on the seaward slope of the breakwater, so that the external energy dissipation may be considered mainly due to bottom frictional effects.
- (c) The cover layer on the seaward slope of the breakwater consists of natural stones, so that the empirical relationships developed in (I) may be considered valid.

With these assumptions stated the following procedure is suggested as being physically realistic although approximate in nature.

For most multilayered trapezoidal breakwaters the stone size in the layer under the cover layer of the seaward slope is small relative to the stone size of the cover layer. As a first approximation the structure may therefore be regarded as resembling an impermeable rough slope. Thus, with the incident wave characteristics and the stone size of the cover layer as well as the seaward slope of the trapezoidal breakwater specified, the procedure developed in (I) may be used to account approximately for the energy dissipation on the seaward slope, i.e., the external energy dissipation may be estimated. This energy dissipation accounts approximately for the dissipation of energy associated with the top layer of stones in the cover layer. The remaining wave energy may be expressed as the energy associated with a progressive wave of amplitude

$$a_I = R_I a_i \quad (1)$$

in which a_i is the amplitude of the actual incident wave and R_I is the reflection coefficient determined by the procedure developed in (I).

With the energy dissipated on the seaward slope accounted for, the remaining energy is partitioned between reflected, transmitted and internally dissipated energy. This partition of energy is the problem dealt with in (II), and it is evaluated by regarding the remaining energy as an equivalent wave of amplitude a_I normally incident on an equivalent homogeneous rectangular breakwater. The role of this homogeneous rectangular breakwater is to reproduce the internal energy dissipation associated with the trapezoidal, multilayered breakwater, i.e., the two breakwaters should in this sense be hydraulically equivalent. A rational method for obtaining a homogeneous, rectangular breakwater which is hydraulically equivalent to a trapezoidal, multilayered breakwater is developed in the following section based on steady flow considerations. By employing the procedure developed in (II) the partition of the remaining wave energy among reflected, transmitted and internally dissipated energy is therefore approximately evaluated by determining the reflection coefficient, R_{II} , and the transmission coefficient, T_{II} , of the hydraulically equivalent homogeneous rectangular breakwater subject to an equivalent incident wave of amplitude a_I .

Having now accounted for the external as well as for the internal energy dissipation, the amplitude of the reflected wave is found to be

$$|a_r| = R_{II} a_I = R_I R_{II} a_i \quad (2)$$

and the transmitted wave amplitude is

$$|a_t| = T_{II} a_I = R_I T_{II} a_i \quad (3)$$

The approximate values of the reflection and transmission coefficient, R and T , of a trapezoidal, multilayered breakwater are therefore

$$R = \frac{|a_r|}{a_i} = R_I R_{II} \quad (4)$$

and

$$T = \frac{|a_t|}{a_i} = R_I T_{II} \quad (5)$$

It should be emphasized that the approximate procedure outlined above is predictive in the true sense of the word, i.e., no other information than what may be expected to be available is needed.

Determination of the Equivalent Rectangular Breakwater

From the description given of the approximate method for obtaining the reflection and transmission coefficients of a trapezoidal, multilayered breakwater, the missing link for carrying out this analysis is the determination of the hydraulically equivalent homogeneous rectangular breakwater.

In Madsen and White (1976b) it was shown that a simple analysis, which essentially neglected unsteady effects, gave transmission and reflection coefficients equal to those obtained from the more complete analysis for structures of small width relative to the incident wavelength (II, eqs. 32 and 33). This observation suggests that a rational and reasonably simple determination of the hydraulically equivalent breakwater may be based on steady flow considerations. Therefore, a hydraulically equivalent breakwater is taken as the homogeneous rectangular breakwater which gives the same discharge, Q , as the discharge through the trapezoidal, multilayered breakwater. This definition will, according to the simple analysis presented in (II), preserve the equality of transmission coefficients for the two structures and hence essentially give the same internal dissipation. This definition of the equivalent breakwater is illustrated schematically in Figure 1.

Figure 1 shows schematically a trapezoidal, multilayered breakwater consisting of several different porous materials. These porous materials

Figure 1. Definition Sketch of Trapezoidal Multilayered Breakwater and Its Hydraulic Equivalent Rectangular Breakwater.

are identified by their stone size, d_n , and their hydraulic characteristics, β_n , in the flow resistance formula (II, eq. 18). To keep the following determination of the equivalent breakwater reasonably simple, the flow resistance is assumed to be purely turbulent although in principle it is possible to perform the determination of the equivalent breakwater based on the more general form of the Dupuit-Forchheimer resistance formula. Since the energy dissipation associated with the top layer of stones on the seaward slope has been accounted for in the determination of the external energy dissipation, the rectangular homogeneous breakwater which accounts approximately for the internal dissipation should be hydraulically equivalent to the trapezoidal, multilayered breakwater with the top layer of cover stones removed.

The homogeneous rectangular breakwater consists of a reference material of stone size, d_r , and hydraulic characteristics, β_r . The reference material should be taken to be representative of the porous materials of the multilayered breakwater. In keeping with the assumption of long waves the flow is assumed to be essentially horizontal and the horizontal discharge velocity is found from

$$\rho g \frac{\Delta H_e}{l_e} = \rho \beta_r U^2 \quad , \quad (6)$$

in which l_e is the width of the equivalent breakwater and ΔH_e is the head difference defined in Figure 1, ρ is the fluid density and g is the gravitational acceleration. The discharge per unit length is therefore obtained from equation (6) to be

$$Q = U h_o = \left\{ \frac{g \Delta H_e}{\beta_r} \right\}^{1/2} \frac{h_o}{\sqrt{l_e}} \quad (7)$$

in which h_o is the depth of water.

To evaluate the discharge per unit length of the trapezoidal, multilayered breakwater a horizontal slice of height, Δh_j , is shown schematically in Figure 2. This horizontal slice consists of segments of the different porous materials of lengths l_n . From the assumption of purely horizontal flow it follows that the discharge velocity of the slice considered, U_j , must be the same in all segments and the total head loss across the breakwater must be equal to ΔH_T , the head difference shown in Figure 1. From this it is seen

$$\Delta H_T = \sum_n (\Delta H_n) \quad . \quad (8)$$

in which ΔH_n is the head loss associated with the segment of length, l_n ,

Figure 2. Horizontal slice of thickness, Δh_j , of multilayered breakwater. and hydraulic characteristics, β_n . From equation (6) it is seen that

$$\Delta H_n = \beta_n l_n \frac{U_j^2}{g} = \beta_r \frac{U_j^2}{g} \left(\frac{\beta_n}{\beta_r} l_n \right) \quad (9)$$

in which β_r is the hydraulic characteristic of the reference material. Equation (8) may therefore be written:

$$\Delta H_T = \beta_r \frac{U_j^2}{g} \sum_n \left(\frac{\beta_n}{\beta_r} l_n \right) \quad (10)$$

in which the summation is carried out over the n different porous materials of the horizontal slice of thickness, Δh_j .

From equation (10) the discharge associated with the slice of thickness Δh_j is found to be

$$\Delta Q_j = U_j \Delta h_j = \left\{ \frac{g \Delta H_T}{\beta_r} \right\}^{1/2} \frac{\Delta h_j}{\left\{ \sum_n \left(\frac{\beta_n}{\beta_r} l_n \right) \right\}^{1/2}} \quad (11)$$

and by adding the contributions from all horizontal slices of the trapezoidal breakwater one obtains

$$Q = \sum_j \Delta Q_j = \left\{ \frac{g \Delta H_T}{\beta_r} \right\}^{1/2} h_o \sum_j \left\{ \frac{1}{\left[\sum_n \left(\frac{\beta_n}{\beta_r} \lambda_n \right) \right]^{1/2}} \frac{\Delta h_j}{h_o} \right\} \quad (12)$$

Thus, requiring that the discharges per unit length given by equations (7) and (12) be identical, the width, ℓ_e , of the equivalent rectangular breakwater is

$$\ell_e = \left\{ \sum_j \left(\frac{1}{\left[\sum_n \left(\frac{\beta_n}{\beta_r} \lambda_n \right) \right]^{1/2}} \frac{\Delta h_j}{h_o} \right)^2 \right\} \left(\frac{\Delta H_e}{\Delta H_T} \right) \quad (13)$$

This equation shows that the width of the equivalent breakwater may be determined from knowledge of the configuration of the trapezoidal, multilayered breakwater and the corresponding head differences, ΔH_e and ΔH_T .

As described in the previous section the equivalent breakwater is subject to an equivalent incident wave of amplitude a_I given by equation (1). A simplified analysis of the interaction of incident waves and a rectangular homogeneous breakwater of small width relative to the length of the incident waves was presented in (II). This simplified analysis essentially neglected unsteady effects and any phase difference between the incident, reflected, and transmitted waves. The runup on the seaward slope of the hydraulically equivalent rectangular breakwater is taken as a representative value of the head difference, ΔH_e , across the equivalent breakwater. With this assumption, which neglects the influence of a transmitted wave of small amplitude, one obtains

$$\Delta H_e = (1 + R_{II}) a_I = (1 + R_{II}) R_I a_i \quad (14)$$

in which R_{II} is the reflection coefficient of the equivalent breakwater, determined by the procedures developed in (II).

The value of the head difference across the trapezoidal breakwater, ΔH_T , is in accordance with the argument presented for the equivalent rectangular breakwater taken as the runup on the seaward slope of the trapezoidal breakwater. This runup may in principle be determined by the procedure developed in (I). However, there is reason to believe that such an estimate, which would correspond to an impermeable slope, would be somewhat on the high side. In general one may, however, take

$$\Delta H_T = 2R_u a_i \quad (15)$$

where R_u is the best estimate available for the ratio of the runup to the

incident wave height $H_i = 2a_i$ for given slope characteristics. If R_u is taken as determined from Figure 3 in (I) the estimate of ΔH_T is expected to be conservative.

Equations (14) and (15) show that the ratio

$$\frac{\Delta H_e}{\Delta H_T} = \frac{(1 + R_{II})R_I}{2R_u} \quad (16)$$

is a function of the reflection coefficient, R_{II} , of the equivalent breakwater. Since this reflection coefficient cannot be determined until the width of the equivalent breakwater, l_e , is known one is faced with a tedious iterative procedure. However, in most cases a sufficiently accurate estimate of R_{II} may be obtained by assuming initially that $\Delta H_e/\Delta H_T$ is unity and use this estimate along with the best estimate of R_u to obtain a new value of $\Delta H_e/\Delta H_T$ from equation (16).

To evaluate Equation (13) the hydraulic characteristics, β_n , of the various layers must be known. Since β_n in general is unknown the use of empirical relationship suggested in (II, eq. 40) is necessary. This relationship

$$\beta = \beta_o \frac{1-n}{n} \frac{1}{d} \quad (17)$$

is strongly dependent on the value of the porosity, n , which must be assumed. Since this empirical relationship is valid only for natural stones, in fact it is established for sands, its use is limited to rubble-mound breakwaters. The empirical, dimensionless constant β_o is a function of stone shape, etc., and $\beta_o = 2.7$, as suggested in (II) seems to be a reasonable value. Since equation (13) depends on the relative value of β_n/β_r the value of β_o is immaterial so long as it may be assumed the same for all layers.

Computation of Transmission and Reflection Coefficients for Trapezoidal, Multilayered Breakwaters

To apply the approximate method outlined in the preceding sections it is assumed that the incident wave characteristics are known, i.e., $H_i = 2a_i$, h_o , T or L are given. The procedure is therefore

a. Determination of the External Dissipation. The first step is to estimate the external energy dissipation on the seaward slope using the procedure developed in (I). To perform this analysis the necessary information, in addition to the incident wave characteristics, is

$$\text{Surface Roughness} = d_r ; \text{ Seaward Slope} = \tan\beta_s \quad (18)$$

This information is sufficient for carrying out the procedure developed in (I) for the determination of the reflection coefficient of impermeable rough slopes, R_I . Since the rate of energy dissipation on a rough impermeable slope is related to its reflection coefficient this step in the analysis may be viewed as an approximate evaluation of the energy dissipation on the seaward slope of a trapezoidal, multilayered breakwater.

The empirical relationships for the frictional effects established in (I) are valid only for slopes whose roughness is adequately modeled by gravel, i.e., natural stones, which is reflected in the previously stated assumption, (c).

b. Determination of the Internal Dissipation. Having determined the energy dissipation on the seaward slope, the remaining wave energy is equivalent to an equivalent incident wave of amplitude a_I given by equation (1). The partition of the remaining energy among reflected, transmitted and internally dissipated energy is estimated from the procedures developed in (II). To perform this analysis the hydraulically equivalent breakwater is determined as outlined in the previous section. The information necessary for the determination of the hydraulically equivalent rectangular, homogeneous breakwater is

Breakwater Geometry;
 Material Properties (including porosity); (19)
 Runup on trapezoidal breakwater.

The use of equation (17) to estimate the hydraulic characteristics of a porous material reduces the necessary information to generally available quantities except for the porosity and the runup on the seaward slope in order for equation (13) to be evaluated. Use of $n = 0.4$ seems reasonable in conjunction with $\Delta H_e / \Delta H_T = 1$ for preliminary calculations.

With these assumptions the equivalent breakwater is readily determined and the explicit procedure developed in (II) may be used to obtain an estimate of the partition of the remaining energy among reflected, transmitted and internally dissipated energy, i.e., the reflection and transmission coefficients R_{II} and T_{II} , respectively, of the equivalent breakwater may be obtained.

c. Determination of the Transmission and Reflection Coefficient of Trapezoidal, Multilayered Breakwaters. From the results obtained in steps a and b it is now possible to estimate the transmission and reflection coefficient of a trapezoidal, multilayered breakwater since the external as well as the internal energy dissipation has been accounted for. From the description of the procedure given previously it follows that the transmitted and reflected wave amplitudes, $|a_t|$ and $|a_r|$, are given by

$$|a_t| = T_{II} a_I = T_{II} R_I a_i \quad (2)$$

and

$$|a_r| = R_{II} a_I = R_I R_{II} a_i \quad (3)$$

The transmission coefficient, T, and reflection coefficient, R, are therefore obtained from

$$T = \frac{|a_t|}{a_i} = T_{II} R_I \quad (4)$$

and

$$R = \frac{|a_r|}{a_i} = R_I R_{II} \quad (5)$$

Comparison Between Predicted and Observed Transmission and Reflection Coefficients of a Trapezoidal, Multilayered Breakwater

The preceding section has illustrated the use of the approximate method for the determination of transmission and reflection coefficients of trapezoidal, multilayered breakwaters. This procedure was followed choosing values of the incident wave characteristics and breakwater characteristics corresponding to the laboratory experiments performed by Sollitt and Cross (1972), and the predictions may therefore be compared directly with the experimentally observed values of the transmission and reflection coefficients given by Sollitt and Cross (1972, App. G). This comparison between predicted and observed transmission and reflection coefficients is shown in Figure 3, where the values of T and R are plotted against the incident wave steepness, H_i/L , corresponding to a value of $h_o/L = 1/12$, i.e., relatively long waves as assumed throughout this paper.

From the comparison presented in Figure 3 the predicted reflection coefficients are in excellent agreement with the observed reflection coefficients for lower values of the incident wave steepness. For larger values of the incident wave steepness the predicted reflection coefficient is seen to increase slightly whereas the observed reflection coefficients exhibit a decreasing trend with increasing wave steepness. As discussed by Madsen and White (1975 and 1976b) this trend of the experimental reflection coefficients is generally observed and may be partly due to experimental errors in the determination of the reflection coefficient. This was discussed briefly in (I) and in detail in Madsen and White (1975 and 1976b).

The transmission coefficients predicted based on the assumption $\Delta H_e/\Delta H_T = 1$ are seen to be lower than the experimentally obtained values. This, of course, is the expected type of discrepancy since the runup on the seaward slope of the trapezoidal breakwater is almost certain to exceed the runup on the equivalent rectangular breakwater. Adopting the theoretical value of the runup, R_u , on the trapezoidal breakwater predicted by the procedure developed in (I) is expected to give transmission coefficients

Figure 3. Comparison of predicted and observed reflection and transmission coefficient of trapezoidal, multilayered breakwater tested by Sollitt and Cross (1972, App. G, kh = 0.5).
 ■ Experimental reflection coefficient, ● experimental transmission coefficient,
 — prediction based on $\Delta H_e/\Delta H_T = 1$, --- prediction based on $\Delta H_e/\Delta H_T$ given by equation (16)

slightly on the high side. This anticipated behavior is not exhibited by the predicted transmission coefficients plotted in Figure 3. In fact, the agreement between observed and predicted transmission coefficients is excellent.

A slightly different estimate of the runup on the seaward slope of a trapezoidal breakwater may be obtained by adopting, for example, the results obtained by Jackson (1968), who reported values of R_{11} approximately equal to unity for test conditions similar to those of Sollitt and Cross (1972). In the present case this value of R_{11} would result in a slightly lower prediction of the transmission coefficient than the prediction indicated by the full line in Figure 3.

The procedure developed here for the prediction of transmission and reflection coefficients of a trapezoidal, multilayered breakwater did not rely on the experimental data shown in Figure 3 to obtain a "good fit." The overall comparison between predicted and observed transmission and reflection coefficients, which is analogous to the comparison given by Sollitt and Cross (1972, Fig. 4-14), must therefore be considered very good.

Summary and Conclusions

This paper presents the synthesis of the results of an analytical study of the reflection and transmission characteristics of porous rubble-mound breakwaters. An attempt was made at making the procedures entirely self-contained by introducing empirical relationships for the hydraulic characteristics of the porous material (II) and by establishing experimentally an empirical relationship for the friction factor that expresses energy dissipation on the seaward slope of a breakwater, (I).

The results are presented in graphical form and require no use of computers, although the entire approach could be programmed. The procedures were developed in such a manner that the information required to carry out the computations can be expected to be available. Thus, for a trapezoidal, multilayered breakwater subject to normally incident, relatively long waves the information required is:

- (a) Breakwater configuration: breakwater geometry and stone size and porosity of the breakwater materials
- (b) Incident wave characteristics: wave amplitude, period, and water depth.

Only the porosity of the breakwater materials may be hard to come by. It is recommended that the sensitivity of the results to the estimate of the porosity, n , be investigated.

The hydraulic flow resistance in the porous medium is expressed by a Dupuit-Forchheimer relationship and empirical formulas are adopted. The investigation shows that reasonably accurate results are obtained by taking

$$\beta_0 \approx 2.7$$

$$\alpha_0 \approx 1150$$

(20)

in equation (40) of (II). To estimate reflection and transmission characteristics of a prototype structure only the value of β_0 needs to be known. For laboratory experiments the value of the ratio, α_0/β_0 is important in assessing the influence of scale effects. In a laboratory setup it is possible to determine the best values of α_0 and β_0 from the simple experimental procedure used by Keulegan (1973). Thus, it was found that the porous materials tested by Sollitt and Cross (1972) showed a value of $\alpha_0 = 2,700$, a better value than that given by equation (20). However, the important thing to note is that the analysis carried out in (II) presents a method for assessing the severity of scale effects in hydraulic models of porous structures. The empirical relationships for the flow resistance of porous materials have been demonstrated to be fairly good for porous materials consisting of gravel-size stones, diameter less than 2 inches (5 centimeters), which is a considerable extension of the conditions from which they were derived (sand-size). The use of the formulas for rubble-mound breakwaters is, however, a further extension and caution is recommended.

The energy dissipation on a rough, impermeable slope was investigated in (I). The experimental investigation revealed the need for an accurate method for the determination of reflection coefficients from experimental data. The simple procedure of seeking out the locations where the wave amplitudes are maximum and minimum, respectively, may lead to reflection coefficients which are much too low, unless the recorded surface elevation is analyzed and only the amplitude of the first harmonic motion is used to determine the reflection coefficient. Accurately determined reflection coefficients for slopes with roughness elements consisting of gravel led to an empirical determination of the friction factor (I, eqs. 32 and 34) expressing the energy dissipation on a rough slope due to bottom friction. Adopting this empirical relationship a procedure for estimating the reflection coefficient of rough impermeable slopes was developed. This procedure was quite accurate in reproducing the experimentally obtained reflection coefficients in a separate set of experiments. The procedure for the determination of the reflection coefficient of rough impermeable slopes is limited to slopes having roughness elements consisting of natural stones. To make the procedure generally applicable, empirical relationships for the friction factor should be determined for slopes whose roughness elements consist of models of concrete armor units.

The synthesis of the investigation presented in this paper, is the development of an approximate procedure for the prediction of the reflection and transmission characteristics of trapezoidal, multilayered breakwaters. This procedure is entirely self-contained and yields excellent results when compared with the model scale experimental results obtained by Sollitt and Cross (1972).

It is emphasized that the analytical model for the reflection and transmission characteristics of trapezoidal, multilayered breakwaters developed here needs further verification before it can be used with complete confidence. However, the good agreement between predictions and observations exhibited in Figure 3 is encouraging and does indicate that a simple analytical model which may be used for preliminary design of rubble-mound breakwaters has been developed.

To improve the physical realism of the approximate model for the interaction of waves and porous structures a more accurate description of the flow over the sloping seaward face of the porous breakwater should be developed. Development of such an analytical model is presently being pursued and should lead to improved results, in particular, in the prediction of runup on the permeable seaward slope. In addition an experimental investigation is called for to resolve the problem of whether or not the discrepancy between predicted and observed reflection coefficients, exhibited in Figure 3, is due mainly to experimental errors.

Acknowledgment. This work is a result of research sponsored by the United States Coastal Engineering Research Center under Contract DACW72-74-C-0001. Funds to present and prepare this paper were provided through a National Science Foundation Grant ENG 7608982 under which further research into this topic will be performed.

CHAPTER 154

QUAY WALL WITH WAVE ABSORBER "IGLOO"

Naofumi Shiraishi,* Robert Q. Palmer,** Hiroshi Okamoto***

ABSTRACT

This report summarizes the results of the research on a gravity type quay wall comprising several layers of concrete blocks with a special shape called "Igloo" as shown in Photograph-1.

INTRODUCTION

The recent trend for higher utilization of the basin in the ports and harbors by using the vertical wall as the facilities for berthing and cargo handling presents extreme difficulties for securing the calmness within the ports as the vertical wall would keep on reflecting the invading waves and increase the wave energy. Much research has been conducted on the vertical wave absorbing structure in Japan in recent years.

Research has proved that a vertical wave dissipating structure had an optimum wall depth which absorbs waves most effectively in accordance with the incident wave period.^{1), 2)} This report is an article on the gravity type structure which is contrived to actual application with the best wave dissipating effect, and is made of concrete blocks.

Our first step is to conduct a two dimensional model test look into the relationship between inci-

** President, Tribars Incorporated

*** Engineer, Development Section, Nippon Tetrapod Co., Ltd.

dent wave period and dissipating effect, and then to conduct a three dimensional model test where we will investigate how the vertical wave dissipating structure calms the basin.

WAVE DISSIPATING PRINCIPLES OF IGLOO SYSTEM

The principles of the Igloo wave dissipating system are shown on the illustrations (Fig-1) and are summarized as follows:

The horizontal plate converts the vertical wave movement into the horizontal flow, then induces the water to enter the block which rotates the water inside cylindrical chambers and reduces the energy through the friction with the wall surface through the forced diversion and merging of the flows.

Further in detail, the column shaped front wall lets the waves into the block smoothly, hardly reflecting the waves. The horizontal plate converts the vertical movement of the waves (the circular movement, to be more precise) into a horizontal flow. In physical terms, the potential wave energy is converted to kinetic energy. The converted water causes friction alongside the wall surface in the block chambers and diverts and merges as it rotates, thus losing the energy. The loss ratio of water energy that flows in a void encountering resistance is the subject of studies in various universities. It has been found that the ratio is proportionate to 2nd or 3rd power of the velocity. That is, the more distance the water flows at a faster velocity, the more energy is lost.

Igloo system is contrived for the water to flow the longer distance at the faster speed. When the Igloos one piled together, the chambers formed by these blocks take a circular shape with a narrow entrance and a wider inside. Thus shaped blocks impart

Fig-1

faster velocity to the mass of water and induce the water into the chambers. The water advances directly into the innermost part of the chamber and then separates into two, and rotates alongside the walls. When the water rotates, the distance of the water flow increases. Even though the chamber space may be limited, the water revolves within the chambers at a high velocity and the energy thus lost is quite big.

As the phase between the water level in front of the seawall and that of the chambers is quite different, the water level in front of the seawall lowers, causing energy loss when the water is discharged from the chambers.

TWO DIMENSIONAL MODEL TEST

The model tests of this structure were carried out in the laboratory to investigate the hydraulic properties.

1. Test Facilities

Two dimensional wave channel with a wind tunnel owned by the Hydraulic Research Center of Nippon Tetrapod Co., Ltd. was used.

Dimensions of the channel:

Length 49.0m, Height 1.0m, Width 1.0m (50cmx2)

Wave generator

Flap type (hydraulic system, irregular waves)

Wave high: 25 cm Max

Period: 0.6~3.0 sec

Blower: Suction type, propeller system (Wind volume, 600 m³/min.)

2. Test Model

We used a mortar-made 1:25 scale model of Igloo blocks and its specific weight was 2.3 ton/m³, which is the same weight of actual Igloo blocks. The model is 15.2~26.0 cm in depth, 12 cm in width and 4.4~6.8 cm in height; their actual block size is 3.8~6.5 m in depth, 3.0 m in width and 1.1~1.7 m in height.

3. Test Method

(1) The wave measuring method:

The reflection coefficient is measured by the method provided by Healy, and the variation of the water level is checked by a volmetric wave meter. The change in the electric volume caused by the change in the water level is converted into an electric current, amplified by an amplifier and recorded by an oscillograph.

(2) Wave generation method:

Sinoidal waves made by the function generator send the wave to the wave making control device, which generates regular waves with the required periods and heights.

4. Test Conditions

The cross section of the tests is shown in Fig-2. Test conditions are shown in Table-1.

5. Test Results

Non-dimensional factors affecting Igloo's wave dissipation include B/L: the ratio of wall depth against wave length, hc/H: the ratio of Igloo crown height above still water level against wave height, i: bottom slope, h/L: relative water depth, h/H: the ratio of wave height against water depth, H/L: wave steepness and others.

If the design conditions are limited to $h/H > 2, 3 < T < 10$ sec, $0.3 < H < 2$ (m) in case of actual application, influence of non-dimensional factors such as h/L, H/L, and others are not so great. Out test condition is always set at $i=1/30$. The remaining non-dimensional factors such as B/L and hc/H will play an important role. Therefore we summarized the test results concerning reflection coefficient KR which is shown in Fig-3 (a)~(e) with B/L on the horizontal axis of coordinates and with hc/H as a parameter.

The following were made clear.

(1) In all tests, wave dissipating

List of Notation

- B: Igloo depth
- B: Effective depth of Igloo
- h: Water depth at the toe of the seawall
- T: Wave period
- Lo: Wave length in deep water
- L: Wave length of progressive waves at the toe of seawall
- H: Height of progressive waves at the toe of seawall
- hc: Distance from still water level to the crown height of Igloo (i.e, clearance)

effect gives the best result when $B/L=0.14\sim 0.19$.

(2) Under the condition of $hc/H < 0.5$, Igloo's performance is not satisfactory.

The above two conclusions are almost enough in designing Igloo system. Namely, in compliance with the local wave conditions, Igloo wall depth B will be set at $B/L=0.14\sim 0.19$. The crown height of Igloo should be designed high enough to enable berthing and cargo handling. It is particularly important to set hc at $hc < \frac{1}{2}H$ for the designed wave height H .

It has been previously indicated that the reflection coefficient becomes minimized when B/L is given a certain value. This is worth noting and can be explained as follows:

The extreme example of long wave is shown in "Seiche", in that the longer the period, the bigger the reflection coefficient becomes. The water level ascends and descends very slowly. The same can be said for the Igloo chambers where the water level that ascends and descends requires exactly the same length of time. Regardless of the shape of Igloo void, the waves reflect completely against the rear wall.

Conversely, if the incident wave period is too short, the reflection coefficient becomes larger. Such phenomenon can be explained as

Fig-3 Reflection Coefficient of Igloo

the responsive characteristics of water surface in the chambers. Depending upon the volume and shape of the Igloo void, the water in the void is composed of a responsive system with natural frequency. If water movement in front of Igloo system is considered as an external force and the frequency of this external force increases extremely, the Igloo system can hardly respond to the external force. In other words, despite the violent up-and-down motion of the waves in front of the Igloo system, the water in the void is almost tranquil. In this case, the waves reflect against the system as if it were a vertical wall.

Where there is a certain gap between the frequency of the external force and the natural frequency of the Igloo, the wave energy is most effectively reduced in the chambers. Also, the energy dissipates due to disturbances in front of the wall where two types of waves with different phases cause turbulence in order to keep the continuity of water surface. In our experiments, scattering waves with extremely short length were observed within the one wave length in front of the structures. We have to provide the theory behind this observation.

THREE DIMENSIONAL MODEL TEST

1. Reflection coefficient of incident waves from an oblique direction

Wave dissipating effect of incident waves from a right angle is obtained in the two dimensional test, but that from an oblique direction will be found in the three dimensional test. The measuring method of reflection coefficient for the incident waves from an oblique direction can be obtained by Hadly's theory. But due to the scattering waves against the wave dissipating structure, accurate measurement is difficult. Therefore, we use the indirect method to obtain reflection coefficient of incident waves from an oblique direction.

The calmness in the water basin using various types of center line structure is measured by changing boundary conditions (equivalent to reflection coefficients) through a computer's mathematical simulation method and the results will be compared with the hydraulic tests. The reflection coefficient is obtained from the boundary conditions where the two results coincide with one another. This is the exact opposite of the common method. Although some questions remain as to whether the given boundary conditions are accurate and yet reflection coefficient of the structure is correctly reflected. Considering the recent improvements made in the accuracy of the mathematical simulation method and the relative comparison with traditional vertical walls being the focal point of discussions, this method is considered to be reasonable.

2. Experimental Facilities

Three dimensional wave tank owned by Hydraulic Research Center of Nippon Tetrapod Co. was used. Fig-4 shows the tank dimensions and a wave generator.

3. Experimental method and conditions

Fig-5 shows one of the structure models. The water depth of the wave generator is 56 cm and that of the structure is 16 cm. And the slope is three to one. Small gravel and film wastes are placed around the side walls of the tank in order to avert reflection waves from the side walls.

The vertical wall model is made of mortar. The Igloo model is made of hard rubber 6 cm in width, 2.8 cm in height, 9.0 cm in depth, which is equivalent to 1:50 scale model. The regular waves in this experiment are 2.0 cm in height, 0.71 sec and 1.13 sec in period at the place where the water depth is 56 cm. Fig-6 shows the center line of the model and Table-2 shows test conditions.

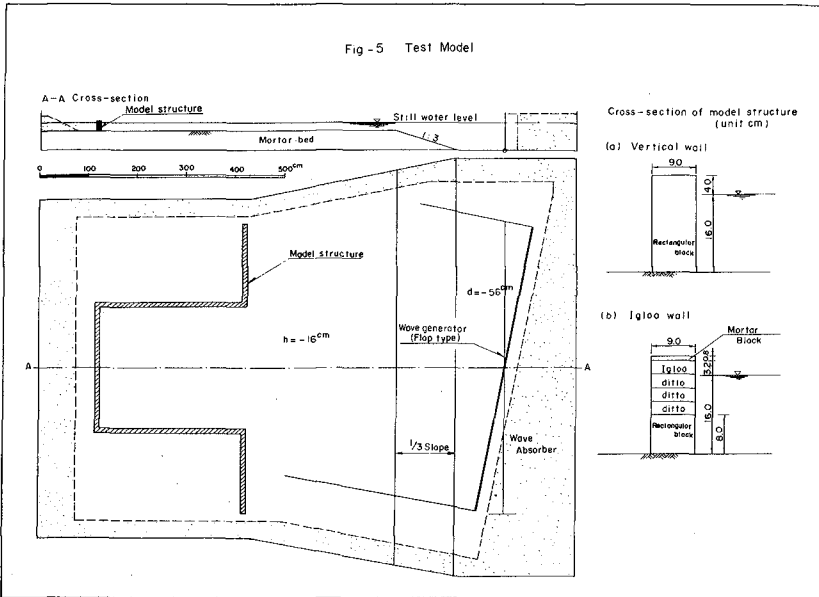

The wave height in front of the structure are measured by a capacitance probe type wave meter placed under a movable platform across the tank. This meter reads wave height at the points distributed with 20 cm intervals length-wise and cross-wise.

4. Results

Some cases are shown in Fig-7 through 9. Fig-7(a) (b) show the waves at a 45° angle on the center line of the structure. Vertical wall produced a net-like wave pattern in the basin because the crests of incident waves and reflected waves mix with one another. Amplitude at this point is two times that of incident wave height and more than two times at the wall. Those points of intersection run along the model front with the waves. Crests at even interval seem to run along the wall. Actual crest speed will be 5m/sec~10m/sec with waves of 10 sec in period at 45° angle. These waves cause overtopping, exert an unfavorable influence upon ships.

Igloo will absorb most of the crests of reflection waves. Crests of the incident waves run along the Igloo wall, when water level in the chambers rises shortly afterwards causing chain reaction in the adjacent chamber. Eddies and turbulences arisen will then diminish the wave energy. Photograph-2 shows the wave conditions of the Igloo wall.

Fig-8(a), (b) show an experiment concerning the waves on V-shaped center line. The effect of the Igloo wall will be more distinct than that of a straight center line. Vertical wall will produce the standing waves from the three direction such as incident waves and reflec-

ted waves from two different directions. In this experiment, wave amplitude is five times more than the incident wave height where amplitude is highest. Amplitude in the Igloo wall will be only twice that of the incident wave on the same spot. Photograph-3 shows the wave manners on the vertical wall and Igloo wall.

Photograph-4 shows the waves in the basin between the two wharfs. In the case of conventional vertical wall, a net-like wave pattern is seen in the basin. The pyramidal waves at the intersections of the net becomes several times higher than the incident waves. Excessive overtopping is observed at a quay wall. On the otherhand, in the case of Igloo wall, results of the test showed that waves in the basin presented the similar appearance to those of the incoming waves as though there were no structure.

Fig-9(a), (b) show the experiment of a port model. Vertical wall in the innermost part of the ports shows the same wave height as those of incident wave. But through the proper placement of a wave absorbing structure, reflection waves in the port decrease. In coming waves from the open sea diffract into the port, but wave heights in the innermost part of the port becomes smaller.

5. Comparison with a Mathematical Simulation Model

Wave height distribution of the basin can be obtained by the mathematical model using the same conditions as the physical model. Experimental results of each mathematical model using various boundary conditions with the same reflection coefficient as the structure can be compared with the experimental results of the physical model to find out the values of boundary conditions where two results coincide most closely. This is the method to identify the reflection coefficient of oblique incident waves. The mathematical model does not include the nonlinear wave effect, while the physical model does. So that amplitude of the mathematical model should be modified accordingly.

Tajbakhsh and Keller's three dimensional approximation formula shows the standing wave as follows:

$$\eta' = \left[1 + \frac{\varepsilon^2}{256} (9\omega_0^{-8} + 6\omega_0^{-4} - 15 + 8\omega_0^4) \right] \cos x$$

$$+ \frac{1}{8} \varepsilon (\omega_0^{-2} + 3\omega_0^{-6}) \cos 2x$$

$$+ \frac{3}{256} \varepsilon^2 (9\omega_0^{-12} + 6\omega_0^{-6} + 30\omega_0^{-4} - 16 + \omega_0^{-4} + 2\omega_0^8) \cos 3x$$

$$\varepsilon = ka$$

$$\omega_0 = gk \tanh kh$$

$$k = 2\pi/L$$

$$\eta' = a^{-1} \eta$$

a : amplitude of standing waves in deep water .

η : crest height at a certain water depth

Photograph-2

Fig-8(c), (d) show the experimental results of the mathematical model and they can be compared with those of the physical model. Given an incident wave angle of 45° , the values of the physical model coincided closely with those of the mathematical model in which boundary conditions are 30% of reflection coefficient.

Fig-10 shows the reflection coefficients acquired by comparing the physical model with the mathematical model concerning many incident angles. The tests proved that reflection coefficient of Igloo hardly varied according to incident angles.

Fig-9(c), (d) show the mathematical model tests conducted under proper boundary conditions. These results coincide with one another so that the mathematical model is considered to be a useful method in estimating the wave height distributing in a port. It will be effectively used in the layout of a port including wave absorbing structures.

Photograph -3

Photograph-4

CONCLUSIONS

1. The wave dissipating characteristics of Igloo are shown in Fig-3. The best results are obtained at $B/L=0.14\sim 0.19$.
2. The reflection coefficient at $B/L=0.14\sim 0.19$ showing the minimum value can be explained in the responsive characteristics of Igloo system.
3. We confirmed by the three dimensional model test that Igloo helped improve calmness of a port.
4. Through the use of mathematical simulation model with the proper boundary conditions, the wave height distribution chart in the port was compared to that of the physical model. Then, we confirmed that the two results coincided with one another.
5. Fig-10 shows the summarized reflection coefficient values from the physical and mathematical model tests for oblique incident waves. The reflection coefficient of oblique incident waves does not vary according to the angle of incident waves.

ACKNOWLEDGEMENT

We obtained very useful advice from Dr. K. Horikawa, Professor of Tokyo University, and Dr. S. Sato, Head of Marine Hydrodynamics Division, Port and Harbour Research Institute of Ministry of Transport, and received guidance from Mr. H. Kato, Chief engineer, Hydraulic Research Center of Nippon Tetrapod Co., Ltd., in composing a Mathematical Simulation method, to whom we are most grateful.

APPLICATION

Igloo walls have been actually constructed and are going to be installed in several ports. Examples are given to show a standard type cross-section.

- (a) As a revetment for a reclaimed land in a port (Fig-11)

Waves from the outer sea do not directly invade into the port. This wave dissipating structure is designed against the waves of short period and of high frequency as they are undesirable for navigation. Igloo wall was less expensive than the inclined armour block structures such as Tetrapod and Doloss.

- (b) As a revetment for a pier (Fig-12)

Out of many sectional profiles of deep-water mooring facility, pier structure was selected. And Igloo was planned as revetment for the pier to keep calm the port.

- (c) Igloo wall on sheet piles (Fig-13)

We could use a dry method in constructing mooring facilities in a port which is expanded into the land. And Igloo wall was constructed on the sheet-piles as a quay wall because of its advantages in economics and construction work.

- (d) Igloo wall in front of an existing quay wall (Fig-14)

The old sheet-piles quay wall was re-constructed by placing Igloo in front of the existing quay wall on the excavated ground making the water depth from 3 to 3.5m. This wall also helped calm the port. An extra safety measure was taken by providing a provisional sheet-pile in front of the existing sheet-pile wall during the construction period.

(e) As a revetment for a fishing area (Fig-15)

Igloo wall was planned in front of the existing breakwater made of concrete caisson with three fold objectives: preventing overtopping and reflection waves and providing a fishing area for the community people.

The Igloo wall seemed to become comfortable dwellings for small fish, as other type of wave absorbing structures such as Tetrapod and Doloss. But the latter are not suitable for fishing.

(f) As a wave absorber for bay with narrow entrance or for lake (Fig-16)

Igloo wall is planned as a wave absorbing breakwater because wind waves produced in the lake are less 1.5m in height and reflection waves from breakwater are harmful to fishing and fish culture.

(g) As a revetment for a waterway to prevent reflection waves (Fig-17)

As the port entrance is narrow and a number of ships pass this waterway, Igloo wall was constructed because it could dissipate invading waves from the outer sea as well as waves from navigating ships. The wall harmoniously matched with the aesthetics of nearby beach.

CHAPTER 155

Slit-type Breakwater; Box-type Wave Absorber

by

Shoshichiro Nagai* and Shohachi Kakuno**

ABSTRACT

A box-type wave absorber, which is composed of a perforated vertical front-wall and a perforated, horizontal bottom-wall, has been proved by a number of experiments to show lower coefficients of reflection and more distinguished reduction of wave pressures than the perforated vertical-wall breakwater.

A breakwater of composite-type, which is 1500 m long and to be built at a water depth of 10 to 11 m below the Datum Line in the Port of Osaka, is being designed to set this new type of wave absorber in the concrete caissons of the vertical-walls which is named "a slit-type breakwater". The typical cross-section of the breakwater and the advantages of the slit-type breakwater are presented herein.

INTRODUCTION

Since the papers of a perforated vertical wall breakwater were published by Jarlan (1961)¹ and Boivin (1964)² on the Dock and Harbour Authority, some papers on the perforated breakwater and quay-wall have been published in Britain³ and Japan⁴.

However, the physical principles in the wave attenuation of the perforated vertical breakwater has not been made clear, therefore, decisive relationships between the characteristics of incoming waves and the optimum width of the chamber have not been obtained.

EXPERIMENTAL EQUIPMENT AND PROCEDURES

All experiments concerning the basic studies of the box-type wave absorber and the comparisons of reflection coefficient between the box-type wave absorber and the perforated vertical wall breakwater were

carried out on a model-to-prototype scale of 1/25 in a 50 m-long wave channel of 1 m-width and 1.65 m-height with one side of glass wall at the Harbour and Coastal Engineering Laboratory of Osaka City University.

The height of an incident wave, H_I , and those of composite waves, H_C , generated in front of the box-type wave absorbers and the perforated vertical wall breakwaters were measured by visual observation through the glass wall and by wave-recorders. The reflection coefficients were calculated by means of the expression $K_R = (H_C - H_I)/H_I$. Each test was repeated several times to make sure of the results. The fluctuations of the water level inside the chamber were measured by two wave-gauges and the horizontal and vertical velocities of water particles at the perforations (circular holes of 6 cm-diameter) were measured by current-meters of photo-transister-type.

The depth of water was constant 94 cm in most of the experiments in the 50 m-long wave channel, and only when the effects of the water depth and the water level on the reflection coefficient of the composite waves were investigated, the water depth was changed $h = 59$ cm, 72 cm, 78 cm, 86 cm, 94 cm, and 102 cm. Two groups of $H_I \cong 3$ cm to 6 cm and $H_I \cong 10$ cm to 14 cm were used for the incident wave height, but the period of the incident wave was widely changed $T_I = 0.8$ sec, 1.0 sec, 1.2 sec, 1.4 sec, 1.6 sec, 1.8 sec, 2.0 sec, 2.2 sec and 2.4 sec.

The width of the 1/25-model of box-type wave absorber, l , was changed from 16 cm to 80 cm, shown in Fig. 1. In most of the experiments the height of the models were constant 24 cm and the vertical front-wall had two rows of the perforations as shown in Fig. 1. The models of perforated vertical wall breakwaters and box-type wave absorbers were made of 4 cm-thick plywood, and most of the perforations used in the experiments were circular holes of 6 cm-diameter after the tests of the effect of the shape on the reflection coefficient, K_R .

Fig. 1. Kinds of box-type wave absorber used in the experiments

The void ratio of the perforated vertical front-wall, λ , and that of the perforated bottom-wall, λ' , were widely changed from 0.00 to 0.47 to investigate the effects of λ and λ' on the K_R , but in most of the experiments λ was kept nearly constant 0.22, and $\lambda' \cong 0.13$ or 0.15 and 0.25, as shown in Fig. 1. The small void ratios of $\lambda' = 0.13, 0.15$ and 0.17 were made by closure of the seaward half of the perforated horizontal bottom-wall of $\lambda' = 0.25$ or 0.26.

The chamber width of the perforated vertical wall breakwater was changed $l = 30$ cm, 40 cm and 80 cm, and the void ratio of the vertical wall was kept constant $\lambda = 0.23$.

The experiments of the slit-type breakwaters which took advantage of the box-type wave absorber have been conducted on a scale of $1/15$ in a 100 m-long wave channel with a wind blower, 2 m-deep and 1.2 m-wide at the laboratory, the one side of the walls of which is made of 2 cm-thick glass plate to be able to make visual observation of the waves in front of and inside of the breakwater. The wave pressures were measured at several points of the perforated front-wall and the vertical solid back-wall of the slit-type breakwaters, as shown in Fig. 2, to be compared with the wave pressures on the solid vertical wall of the conventional composite-type breakwaters, and also the uplift pressures were measured at the bottom-wall of the box-type wave absorber. The widths of the box-type wave absorber of the slit-type breakwater, l , were changed 5.50 m and 3.75 m in prototype. The models were made of iron plates. The void ratio of the perforated vertical front-wall was $\lambda = 0.22$, and that of the perforated bottom-wall $\lambda' = 0.14$.

Fig. 2. Location of the wave pressure gauges

PHYSICAL PRINCIPLE OF WAVE ATTENUATION

According to the experiments and theory, which have been carried out in our laboratory, it may be stated that the wave attenuation in the perforated vertical wall breakwater is fundamentally and mainly due to the phase difference between the wave motion outside the chamber and the

fluctuations of the water level inside. As the phase difference increases, larger mass of incoming waves plunge into the chamber as jets which dissipate the energy of the waves due to turbulence inside the chamber. Energy loss due to friction created by passage of the jets through the perforations may be stated negligible small. Therefore, the shape and thickness of the wall of the perforation have few effects on the wave attenuation. But it is naturally important to select an adequate value of the percentage of the void of the perforated wall. As the coefficient of transmission, γ_T , of the perforated vertical wall or the perforated front-wall of the box-type absorber approaches to 0.62, the coefficient of reflection, K_R , of the composite waves generated in front of the perforated vertical wall or the box-shape wave absorber decreases toward zero.

If standing waves predominate in the waves in front of the perforated vertical wall, the water particles move only upward and downward or toward the sea and the land, reciprocally, but there is no mass transport which can create strong jets diffusing into the chamber. From the viewpoint of wave dynamics, it is definitively necessary that progressive waves are always predominant in front of the perforated vertical wall in order to create strong jets diffusing into the chamber. For this purpose the extension of the perforated vertical wall to the bottom or deeper portion of the water depth should be avoided lest standing waves should be predominant in the waves in front of the perforated vertical wall, and moreover it becomes much expensive in its construction cost as the depth of water becomes deep at a given site.

If a box-shape absorber composed of a perforated vertical front-wall and a perforated horizontal bottom-wall is attached near the sea surface to the impermeable vertical wall, as shown schematically in Fig. 1, incoming waves can plunge into the chamber of the box-shape absorber as a progressive wave, creating strong jets diffusing through the perforations into the chamber. Moreover, if adequate devices are made for the perforation of the horizontal bottom-wall of the box-shape absorber, the phase of the fluctuations of the water level inside the chamber would be possible to be delayed up to about 90° from the wave motion outside the chamber.

The width of the chamber, l , is also an important factor to reduce the reflection coefficient, K_R . When the ratio of l to the length of an incoming wave, L , that is l/L , is adequately selected, K_R of the composite waves in front of the perforated vertical wall or the box-shape absorber shows the minimum value. According to the experiment and theory, the perforated vertical wall breakwater showed the $(K_R)_{\min}$ for $l/L = 0.18$, and the box-type absorber for $l/L = 0.15$ to 0.18 .

The large phase difference, the adequate values of γ_T and l/L would be the fundamentally important factors for the box-type wave absorber.

The advantages of this wave absorber in the low coefficient of reflection and the distinguished attenuation of shock pressures exerted by breaking waves have been proved by extensive experiments.

DIFFERENCES BETWEEN THE BOX-TYPE WAVE ABSORBER AND THE PERFORATED VERTICAL WALL BREAKWATER

Although both progressive waves and partial standing waves are generated at the seaward domain of the box-type wave absorbers, the for-

mer are always predominant and plunge against the absorbers. In the box-type wave absorbers of Model 8 which has $l = 80$ cm, $\lambda = 0.22$ and $\lambda' = 0.25$ and Model 8-1 which has $l = 80$ cm, $\lambda = 0.22$ and $\lambda' = 0.13$, the wave motions outside the chamber, the fluctuations of the water levels at the sea-side and land-side inside the chamber, the horizontal velocities in the circular holes (middle hole) of the perforated vertical front-wall and the vertical velocities in the circular holes (landside) of the perforated horizontal bottom-wall were measured for various incident waves of $H_I = 5$ cm to 14 cm and $T_I = 1.4$ sec to 2.4 sec. The measured values for an incident wave of $T_I = 1.8$ sec and $H_I = 12.9$ cm are shown in Figs. 3 (a) and (b). Fig. 3 (a) shows the wave motion outside the chamber (thick full line), the fluctuation of the water level at the sea-side (dotted line) and that at the land-side (broken line), and the horizontal velocity of water particle in the circular hole located at the middle part of the perforated vertical front-wall (thin full line). Fig. 3 (b) shows the vertical velocity of water particle in the circular hole located at the land-side in the chamber (thin full line).

According to Fig. 3, it is known that the fluctuation of the water level at the sea-side in the chamber of Model 8-1 is delayed to a large extent from the wave motion outside the chamber. The maximum horizontal velocity of water particle of the incident wave calculated is $(u_c)_{\max} = 24$ cm/sec, and that passing through the circular hole is estimated $(u'c)_{\max} = (u_c)_{\max}/0.22 = 109$ cm/sec, which is comparable with the measured maximum horizontal velocity $u'_{\max} = 120$ cm/sec in Fig. 3 (a). The maximum vertical velocity of water particle of the standing wave of $2H = 20$ cm generated on the vertical wall is calculated $(v_c)_{\max} = 28$ cm/sec, and that passing through the circular hole of the horizontal bottom-wall of Model 8 is estimated $(v'c)_{\max} = (v_c)_{\max}/0.25 = 112$ cm/sec, which is close to the measured vertical velocity in the circular hole at the land-side in the chamber, $v'_{\max} = 120$ cm/sec, shown in Fig. 3 (b).

It is also seen from Figs. 3 (a) and (b) that the maximum horizontal velocity measured at Model 8-1 ($\lambda = 0.22$) is $u'_{\max} = 130$ cm/sec, which is larger than $u'_{\max} = 120$ cm/sec measured at Model 8 ($\lambda = 0.22$), and the maximum vertical velocity measured at Model 8-1 ($\lambda' = 0.13$), $v'_{\max} = 80$ to 110 cm/sec, is smaller than $v'_{\max} = 120$ cm/sec at Model 8 ($\lambda' = 0.25$). The fluctuations of the water level at the land-side in the chamber at Model 8-1 decrease considerably compared with those at Model 8.

These facts indicate that at Model 8-1 which closes the sea-side half of the perforated horizontal bottom-wall to make $\lambda' = 0.13$, the wave motion at the loop of the standing wave generated at the vertical (non-perforated) wall is controlled considerably, and this means the suppression of the energy of the standing wave at the vertical wall which results in the increase of the horizontal velocities of the incoming wave, causing large discharges of the incoming waves plunging into the chamber, with strong jets diffusing into the chamber through the perforations. Due to this, the coefficient of reflection, K_R , of Model 8-1 decreases to 0.20 to 0.34 for larger incident waves of $H_I = 10$ cm to 14 cm, and moreover the values of K_R are levelled over a wide range of wave periods of 1.6 sec to 2.4 sec, as shown in Fig. 4. These characteristics of Model 8-1 would be most desirable advantages for wave absorber.

Fig. 3 (a). Horizontal velocities at the perforated horizontal front-wall

Fig. 3 (b). Vertical velocities at the perforated horizontal bottom-wall

Fig. 3. Fluctuations of the water levels inside the chamber and the curves of velocities through the circular holes

Fig. 4. Coefficients of reflection of box-type wave absorber Models 8 and 8-1

In most cases of perforated vertical wall breakwaters, standing waves with a loop at the solid vertical wall are generated at the sea-side of the perforated walls, therefore the waves do not progress towards the breakwaters, and the waves moves upwards somewhat earlier than the rising of the water level inside the chamber. This phase difference is considerably smaller than that at the box-type wave absorber described above. The horizontal velocities of water particles passing through the circular holes of the perforated vertical wall measured at the experiments were close to those calculated of standing waves generated at the solid vertical wall, and the water particles passed through the perforations towards the land and the sea, reciprocally, every a half period of the standing wave. Therefore it was observed that the discharges of the mass of the waves flowing into the chamber were smaller than those of the box-type wave absorbers, and the jets diffusing the chamber were weaker than those of the box-type absorbers. These facts resulted in larger values of $K_R = 0.42$ to 0.46 for incident waves with heights of $H_I = 12$ cm to 14 cm and periods of $T_I = 1.6$ sec to 2.4 sec in the Model 80 of perforated vertical wall breakwater which had a chamber width of $l = 80$ cm.

Fig. 5 shows the behaviours of the wave motion outside the chamber as well as the jet diffusion and strong wave spray inside the chamber when an incoming wave with $H_I = 13$ cm and $T_I = 1.8$ sec plunged against the Model 6-1 of box-type wave absorber which had chamber width of $l = 60$ cm, $\lambda = 0.22$, and $\lambda' = 0.15$. Fig. 6 shows the behaviours of the wave motion outside the chamber and the standing wave at the vertical wall when the same incoming wave as that of Fig. 5 came to the Model 80 of perforated vertical wall breakwater.

Fig. 6. Standing wave outside and inside the wave chamber of a perforated vertical wall breakwater

EFFECT OF THE VOID RATIO OF PERFORATION
ON THE COEFFICIENT OF REFLECTION

(1) The void ratio of the perforated front-wall

The coefficients of reflection, K_R , for the periods $T_I = 1.4$ sec to 2.4 sec of incident wave are shown in Fig. 7 when the void ratios of the perforated vertical front-wall were changed $\lambda = 0.12, 0.22, 0.30$ and 0.47

at Model 8-1 which had the chamber width $l = 80$ cm and the constant void ratio of the perforated horizontal bottom-wall of $\lambda' = 0.13$. It is seen from Fig. 7 that K_R are at minimum values of 0.1 to 0.2 and 0.2, respectively, for $\lambda = 0.22$ and 0.30.

Fig. 7. Coefficients of reflection of Model 8-1 with variable λ

Fig. 8 shows the values of K_R for the different values of $\lambda = 0.00$, 0.22, 0.34 and 0.47 at Model 3 which has $l = 30$ cm and the constant value of $\lambda' = 0.25$. It is known that K_R also shows minimum values 0.20 to 0.24 and 0.18 to 0.37, respectively, for $\lambda = 0.22$ and 0.34.

Fig. 8. Coefficients of reflection of Model 3 with variable λ

(2) The void ratio of the perforated bottom-wall

In order to investigate the effect of the void ratio of perforated horizontal bottom-wall on the coefficient of reflection, a large number of experiments were carried out by changing the values of the void ratio $\lambda' = 0.00$ to 0.43 at Model 2, 3, 4, 5, 6, 7 and 8 which all had a constant value of $\lambda = 0.22$. The experimental results showed that K_R were at minimum values of 0.10 to 0.20 for $\lambda' = 0.13$ to 0.17 where were made by closing the sea-side half of the perforated bottom-wall, Figs. 4 and 9 show the experimental results of two models of Model 8 and Model 3, respectively.

Fig. 9. Coefficients of reflection of Model 3 with variable λ'

(3) The void ratio of the top-wall

The experiments showed that the void ratio of the perforated horizontal top-wall, λ'' , had no effect on the coefficient of reflection if the top-wall had sufficient perforations so that it would not considerably control the upward motion of the water level inside the chamber.

THEORY

The perforated front-wall of the box-type wave absorber or the perforated vertical wall of the breakwater is situated at $x = 0$, shown in Fig. 10, and the vertical solid back-wall is located at $x = l$ which defines the width of the wave chamber. The incident waves incoming in the positive x direction normally on the perforated vertical wall are written

$$\eta_I = a \sin (kx - \sigma t), \tag{1}$$

in which a = wave amplitude, k = wave number = $2\pi/L$, L = wave length, $\sigma = 2\pi/T$ and T = wave period.

Fig. 10. Definition sketch

If the coefficient of reflection and the coefficient of transmission of the perforated vertical front-wall are denoted by γ_R and γ_T , respectively, the reflected and transmitted waves of the front-wall are written

$$\eta_R = -\gamma_R \cdot a \sin (kx + \sigma t) \quad (2)$$

and

$$\eta_T = \gamma_T \cdot a \sin (kx - \sigma t) \quad (3)$$

From the law of the conservation of mass the following relation is obtained

$$\gamma_R + \gamma_T = 1 \quad (4)$$

If η_T is supposed to be totally reflected from the solid back-wall at $x = l$ without any structure between $x = 0$ and $x = l$, the reflected wave η_{TR} is written

$$\eta_{TR} = -\gamma_T a \sin (kx + \sigma t - 2kl) \quad (5)$$

In the cases when the incident waves transmit the box-type wave absorber or the perforated vertical wall breakwater, the phase of the reflected waves from the back-wall is delayed as if a length Δl were added to the length l by passing through the perforations, and the reflected waves can be given by

$$\eta_{TR} = -\gamma_T a \sin \{ kx + \sigma t - 2k (l + \Delta l) \} \quad (6)$$

Then the composite waves generated at the sea-side of the wave absorber (shown as domain \textcircled{D} in Fig. 10) can be given by

$$\begin{aligned} \eta_C &= \eta_I + \eta_R + \gamma_T \cdot \eta_{TR} \\ &= a \sin (kx - \sigma t) - \gamma_R a \sin (kx + \sigma t) \\ &\quad - \gamma_T^2 a \sin \{ kx + \sigma t - 2k (l + \Delta l) \} \end{aligned} \quad (7)$$

Eq. 7 can be written

$$\eta_C = a \sqrt{A} \sin (\sigma t + \beta_1), \quad (8)$$

in which

$$\begin{aligned} A &= \gamma_T^4 + \gamma_T^2 - 2\gamma_T^3 \cos 2k (l + \Delta l) + 2 (\cos 2kx + 1) \{ 1 - \gamma_T \\ &\quad + \gamma_T^2 \cos 2k (l + \Delta l) \} + 2\gamma_T^2 \sin 2k (l + \Delta l) \sin 2kx \end{aligned} \quad (9)$$

Eq. 9 can be rewritten

$$\begin{aligned} A &= \gamma_T^4 + \gamma_T^2 - 2\gamma_T + 2 + 2\gamma_T^2 (1 - \gamma_T) \cos 2k (l + \Delta l) \\ &\quad + 2 [\gamma_T^4 + \gamma_T^2 - 2\gamma_T + 1 + 2\gamma_T^2 (1 - \gamma_T) \cos 2k (l + \Delta l)]^{1/2} \\ &\quad \times \sin (2kx + \beta_2) \end{aligned} \quad (10)$$

A takes the maximum value at $x = x_0$ where the condition of $\sin (2kx_0 + \beta_2) = 1$ is satisfied, and then $A = A_0$ is

$$\begin{aligned} A_0 &= [\{ \gamma_T^4 + \gamma_T^2 - 2\gamma_T + 1 + 2\gamma_T^2 (1 - \gamma_T) \cdot \cos 2k (l + \Delta l) \}^{1/2} \\ &\quad + 1]^2 \end{aligned}$$

thus

$$\sqrt{A_0} = \{ \gamma_T^4 + \gamma_T^2 - 2\gamma_T + 1 + 2\gamma_T^2 (1 - \gamma_T) \cos 2k(1 + \Delta l) \}^{1/2} + 1 \tag{11}$$

The reflection coefficient, K_R , of the composite waves in the domain ① in Fig. 10 can be obtained by

$$K_R = \frac{a\sqrt{A_0} - a}{a} = \sqrt{A_0} - 1 = \{ \gamma_T^4 + (1 - \gamma_T)^2 + 2\gamma_T^2 (1 - \gamma_T) \cdot \cos 2k(1 + \Delta l) \}^{1/2} \tag{12}$$

Fig. 11 shows the relationships between K_R and l/L which are obtained with the parameters of $\Delta l/L$ and $\gamma_T = 0.77$ (constant). It can be seen that as the values of $\Delta l/L$ increase from 0 to 7/100, 1/10 and 1/8, the points where minimum value of K_R occurs approach from $l/L = 0.25$ to 0.125. Fig. 12 shows the relationships between K_R and l/L when the values of γ_T are varied from 0.1 to 0.9 at the constant value of $\Delta l/L = 1/10$. It is known that as γ_T increases from 0.1 to 0.6, K_R decreases to 0 at $\gamma_T \approx 0.62$, and on the contrary, K_R increases again as γ_T increases from 0.62 to 0.90.

Fig. 11. Relationships between K_R and l/L with a parameter of $\Delta l/L$

Fig. 12. Reflection coefficient dependence on γ_T

From Figs. 11 and 12, it is known that since the value of $1/L$ where $(K_R)_{min}$ occurs decreases as the value of $\Delta l/L$ increases, it may be stated that such a wave absorber as can give as large value of $\Delta l/L$ as possible would be most favourable. Thus the maximum value of $\Delta l/L$ which can be expected as the wave absorber is obtained from the condition

$$2k (1 + \Delta l) = \pi \tag{13}$$

$$\left(\frac{\Delta l}{L} \right)_{max} = \frac{1}{8} \quad \text{for} \quad \frac{\Delta l}{L} = \frac{1}{L} \tag{14}$$

It may therefore be concluded that the objectives of the wave absorber are

- i. the transmission coefficient γ_T should approach to 0.62, and
- ii. the value of $\Delta l/L$ should approach to $1/8$.

Fig. 13 shows the values of K_R for the various values of $1/L$ measured in Models 30 ($l = 30$ cm), 40 ($l = 40$ cm) and 80 ($l = 80$ cm) of perforated vertical wall breakwater ($\lambda = 0.23 = \text{constant}$). The full line in Fig. 13 is a theoretical line obtained by Eq. 12, in which γ_T is taken 0.77, an average value of γ_T measured in Model 80.

Fig. 13. Reflection coefficient dependence on l/L (perforated vertical wall breakwater)

Fig. 14 shows the values of K_R for the various values of $1/L$ measured in Models 1 to 8 of box-type wave absorber, in which λ' , the void ratio of the perforated bottom wall, are 0.13 to 0.17 except $\lambda' = 0.29$ of Model 1. The full, broken, and chain lines are all theoretical lines obtained by Eq. 12. The full line is obtained by the use of $\gamma_T = 0.70$ and $\Delta l/L = 0.10$, and it may be stated that the full line would show the average of the experimental values of K_R when $1/L \leq 0.15$. The chain line obtained by $\gamma_T = 0.70$ and $\Delta l/L = 0.07$ may be said to show the average of the experimental values of K_R when $1/L > 0.15$, and the broken line, obtained by $\gamma_T = 0.63$, the average value of γ_T measured in Model 8-1, would represent the smallest values of K_R in the vicinity of $1/L = 0.15$.

Fig. 14. Reflection coefficient dependence on $1/L$ (box-type wave absorber)

SLIT-TYPE BREAKWATER

How to attach the box-type wave absorber to the seaward side of the caisson of breakwater and what kind of perforation would be best for the construction and structure of the caisson were discussed from the viewpoint of practical harbour engineering, and finally slits were decided as the perforations of the vertical front-wall and horizontal bottom-wall to be attached to the caisson as shown in Fig. 15.

Fig. 15. Slit-type breakwater to be built in the Harbour of Osaka

All experiments to measure wave pressures exerted on the slit-type breakwaters have been carried out by generating breaking, non-breaking and standing waves by the use of models of $1/15$ scale in the 100 m-long wave channel. Some of the cross-sections of the breakwaters and the characteristics of the waves used in the experiments are shown in Tables 1 and 2.

At the outset of the experiments it was confirmed that the $1/15$ -scale model had the same values of reflection coefficients as those in the $1/25$ -scale model, that is, K_R showed a minimum value of about 0.20 at waves of $T = 5$ sec for the breakwater of $l = 5.50$ m, and at $T = 4$ sec for the one of $l = 3.75$ m.

Table 1. Models of slit-type breakwater

Base rubble-mound			Water depth	
Top D.L.	Bottom D.L.	Top width B	h_1	h_2
- 6.5 m	- 10.5 m	10.5 m	6.6 m	10.2 m
			8.2 m	12.2 m
			9.7 m	13.7 m
- 5.0 m	- 10.5 m	10.5 m	5.1 m	10.6 m
			6.7 m	12.2 m
			8.2 m	13.7 m
- 5.0 m	- 10.5 m	15.0 m	5.1 m	10.6 m
			6.7 m	12.2 m
			8.2 m	13.7 m

Cross-section of the slit-type breakwater model

Table 2. Characteristics of incident waves used in the experiments

Period T(sec)	Height H(m)	Length L(m)	H/L	Wind velocity V(m/sec)
10.0	4.4	95	0.046	30
8.0	4.1	72	0.057	30
7.0	4.0 to 4.3	61 to 66	0.065 to 0.069	30
7.0	3.7 to 4.3	61 to 66	0.061 to 0.065	0
6.0	3.3 to 3.4	49 to 52	0.065 to 0.067	0

The experimental results have proved that the wave pressures exerted on the slit-type breakwaters by breaking waves remarkably reduce to be less than 60 % of those on the conventional breakwaters with solid vertical caisson, and the reduction of the wave pressures becomes larger as the intensity of the shock pressure becomes higher. The upward pressures exerted on the horizontal bottom-walls are also very small. The physical reasons of the considerable reduction of wave pressures may be considered as follows.

(1) When a wave recedes from the vertical wall of the breakwater to the lowest level, the water in the chamber of the box-type wave absorber would be empty or nearly empty. Since the void ratio of the slotted bottom-wall, $\lambda' = 0.14$, is smaller than that of the slotted vertical front-wall, $\lambda = 0.22$, the phase of rising of the water level inside the chamber is delayed from the upward moving of the incoming wave outside the chamber. The shock pressure which would be exerted on the vertical front-wall by the attack of the crest of the breaking wave is remarkably reduced by diffusing through the slits into the chamber due to this retardation.

(2) Then the water level inside the chamber rises and jets diffusing through the slits of the front-wall dissipate large part of their energy by turbulence in the water inside the chamber and reduce substantially their horizontal velocities. This results in the remarkable reduction of the wave pressures on the solid vertical back-wall.

There has been no case when shock pressures were exerted by breaking waves on the front-walls and solid vertical back-walls of slit-type breakwaters even at conventional breakwaters in which shock pressures of so high intensities as 12.0 t/m^2 to 14.0 t/m^2 exerted on the vertical walls.

The wave pressures exerted on the slit-type breakwaters by standing waves were almost same as those on the conventional breakwaters with solid vertical wall.

(3) The upward pressures exerted on the horizontal slotted bottom-wall by the waves transmitted underneath the wave absorber are also as small as 1.1 t/m^2 to 2.5 t/m^2 due to the dissipation of the wave energy through the slits.

Fig. 16 and Table 3 show the comparisons of the maximum simultaneous pressures on a conventional composite-type breakwater and a slit-type breakwater.

$P_e \text{ max}$ (slit) in Table 3 defines the sum of the resultants of the maximum simultaneous wave pressures exerted on the slotted vertical front-wall and that on the solid vertical back-wall. There is actually a little time difference in their occurrences, but for the safety the two maximum resultant pressures were considered to be occurred at the same time. $P_c \text{ max}$ is the maximum resultant pressure calculated by the wave pressure formulas⁵.

CHAPTER 156

METHOD OF ANALYSES FOR TWO-DIMENSIONAL WATER WAVE PROBLEMS

by

Takeshi IJIMA*, Chung Ren CHOU** and Akinori YOSHIDA**

Abstract

One of the most powerful tools to analyze the boundary-value problems in water wave motion is the Green's function. However, to derive the Green's function which satisfies the imposed boundary conditions is sometimes difficult or impossible, especially in variable water depth. In this paper, a simple method of numerical analyses for two-dimensional boundary-value problems of small amplitude waves is proposed, and the wave transformation by fixed horizontal cylinders as an example of fixed boundaries, the wave transformation by and the motion of a cylinder floating on water surface as example of oscillating boundaries and the wave transformation by permeable seawall and breakwater as example of permeable boundaries are calculated and compared with experimental results.

I Introduction

The author (1971) has investigated the problem of wave transformation by permeable breakwater and seawall with vertical faces by the method of continuation of velocity potentials. Sollitt (1972) has also calculated the same problem by the similar method to the author's and recently Madsen and White (1976) have investigated the problem with long wave assumption. Such a problem can be analyzed theoreticall when the structure is of vertical faces, but as for the sloped-faces, it is possible only to estimate under several conventional assumptions.

The problem on wave transformation by and the motion of floating rectangular body in constant finite water depth area has been analyzed by one of the authors (1972) by the method of continuation of velocity potentials. Such a problem for floating cylinder with arbitrary cross-section shall be solved by means of Green's function, being derived by John (1950). However, the process is rather complicated and can not be applied to the case

** Master of Engineering, Graduate Student at the Kyushu University

of variable water depth.

The proposed method in this paper is not to use Green's function but to use logarithmic function of the distance between the point on the boundary and the inner point of fluid region, according to Green's theorem. By means of our method, above-described problems concerning to the sloped-face permeable structures, the floating body in variable water depth area and so on are easily formulated and numerically analyzed. In the followings, the formulations and numerical evaluations for small amplitude waves are described and compared with experimental results.

II Green's Theorem and Identity Formula

We assume that a potential function $\phi(x, z)$ is defined in a closed domain enclosed by a curve D in (x, z) plane as shown in Fig.2-1. Indicating the point on the boundary curve D by (ξ, η) , the outward normal by ν , the distance between the point (ξ, η) and a point (x, z) in the domain by r , that is, $r = \sqrt{(\xi - x)^2 + (\eta - z)^2}$, and the constant reference length to the geometrical size of the domain by h_0 , it follows by Green's theorem that the potential value at point (x, z) is provided by the potential values $\phi(\xi, \eta)$ and its normal derivatives $\partial \phi(\xi, \eta) / \partial (\nu / h_0)$ on the boundary curve as follows:

$$\phi(x, z) = \frac{1}{2\pi} \int_D \left[\phi(\xi, \eta) \frac{\partial \log(r/h_0)}{\partial (\nu/h_0)} - \frac{\partial \phi(\xi, \eta)}{\partial (\nu/h_0)} \log(r/h_0) \right] \frac{dS}{h_0} \quad (2.1)$$

If the point (x, z) lies on the boundary at (ξ', η') , Eq.(2.1) leads to the Green's identity formula as follows:

$$\phi(\xi', \eta') = \frac{1}{\pi} \int_D \left[\phi(\xi, \eta) \frac{\partial \log(R/h_0)}{\partial (\nu/h_0)} - \frac{\partial \phi(\xi, \eta)}{\partial (\nu/h_0)} \log(R/h_0) \right] \frac{dS}{h_0} \quad (2.2)$$

where $R = \sqrt{(\xi - \xi')^2 + (\eta - \eta')^2}$

In Eq.(2.1) and (2.2), the integration denotes the line integral along the curve D. Then, dividing the boundary curve into N small elements by N points and indicating the length and the central point of the j-th element as ΔS_j and (ξ_j, η_j) , as shown by Fig.2-2, Eq.(2.1) and (2.2) are approximated by the following summation equations, respectively.

$$\phi(x, z) = \frac{1}{2} \sum_{j=1}^N [\bar{E}_{xj} \phi(j) - E_{xj} \bar{\phi}(j)] \quad (2.3)$$

$$\phi(i) = \sum_{j=1}^N [\bar{E}_{ij} \phi(j) - E_{ij} \bar{\phi}(j)] \quad (2.4)$$

where

$$\phi(j) = \phi(\xi_j, \eta_j), \quad \bar{\phi}(j) = \partial\phi(\xi_j, \eta_j)/\partial(\nu/h_0) \quad (2.5)$$

$$E_{xj} = \frac{1}{\pi} \int_{\Delta S_j} \log\left(\frac{r_{xj}}{h_0}\right) \frac{dS}{h_0}, \quad \bar{E}_{xj} = \frac{1}{\pi} \int_{\Delta S_j} \frac{\partial}{\partial(\nu/h_0)} \log\left(\frac{r_{xj}}{h_0}\right) \frac{dS}{h_0} \quad (2.6)$$

$$E_{ij} = \frac{1}{\pi} \int_{\Delta S_j} \log\left(\frac{R_{ij}}{h_0}\right) \frac{dS}{h_0}, \quad \bar{E}_{ij} = \frac{1}{\pi} \int_{\Delta S_j} \frac{\partial}{\partial(\nu/h_0)} \log\left(\frac{R_{ij}}{h_0}\right) \frac{dS}{h_0}$$

E_{xj} , \bar{E}_{xj} , and E_{ij} , \bar{E}_{ij} are integrated values over the j -th element referring to the point $x = (x, z)$ and $i = (\xi_i, \eta_i)$, respectively, and they are calculated numerically as follows:

$$E_{ij} = \frac{1}{\pi} \log\left(\frac{R_{ij}}{h_0}\right) \cdot \frac{\Delta S_j}{h_0}, \quad \bar{E}_{ij} = \frac{1}{\pi} \left(\log \frac{\Delta S_i}{2h_0} - 1\right) \cdot \frac{\Delta S_i}{h_0} \quad (2.7)$$

$$\bar{E}_{ij} = \theta_{ij}/2\pi, \quad \bar{E}_{ii} = 0$$

where θ_{ij} is the subtending angle of the point $i = (\xi_i, \eta_i)$ to the j -th element, and

$$R_{ij} = \sqrt{(\xi_j - \xi_i)^2 + (\eta_j - \eta_i)^2}, \quad \Delta S_j = \sqrt{(\Delta \xi_j)^2 + (\Delta \eta_j)^2}$$

$$\Delta \xi_j = \frac{1}{2}(\xi_{j+1} - \xi_{j-1}), \quad \Delta \eta_j = \frac{1}{2}(\eta_{j+1} - \eta_{j-1})$$

E_{xj} , \bar{E}_{xj} are calculated, replacing the point $i = (\xi_i, \eta_i)$ by $x = (x, z)$ in Eq. (2.7).

Eq. (2.1) or (2.3), the Green's theorem, states that the potential function at any point in the domain is determined by its boundary-values and normal derivatives. In other words, to solve a boundary-value problem is equivalent to determine the boundary-values and its normal derivatives of the interested potential function.

Eq. (2.2) or (2.4), the Green's identity formula, states that the boundary-values $\phi(\xi, \eta)$ and its normal derivatives $\bar{\phi}(\xi, \eta)$ are in linear

relationships which are defined by the geometrical shape of the domain.

This is the first set of relations between ϕ and $\bar{\phi}$ on the boundary.

Therefore, if another set of relations between ϕ and $\bar{\phi}$ is provided, it follows that they should be determined by solving the two set of relations, simultaneously. And, in our problems, this second relation is given by dynamical or kinematical boundary conditions on the boundaries of the interested domain.

III Wave Transformation by Fixed Cylinder

As an example of fixed boundaries, we consider the wave transmission through and wave forces to the semi-immersed cylinder with arbitrary cross-section in variable water depth area. In Fig.3-1, the origin O of the coordinate system is at still water surface, x- and z- axis are horizontal and vertically upwards, respectively. We assume that CDC' is a fixed cylinder at variable depth area, where the depth at sufficiently distant from the cylinder is constant h to the right and constant h' to the left and that the incident wave of frequency σ and amplitude S_0 comes from the right. We take the geometrical boundaries AB and A'B' at $x = \ell$ and $- \ell'$, where the depths are h and h', respectively, and divide the fluid region into three parts (O), (I) and (O') as shown in the figure.

The fluid motion is assumed to have velocity potential with potential function $\phi(x, z)$ as shown by Eq. (3.1).

$$\bar{\phi}(x, z; t) = \frac{g S_0}{\sigma} \phi(x, z) e^{i\sigma t} \quad (3.1)$$

where g is gravity acceleration and t is time. The potential functions in region (O), (I) and (O') are denoted by $\phi_0(x, z)$, $\phi(x, z)$ and $\phi'_0(x, z)$, respectively. Then, since region (O) and (O') are of constant depth and so far from the cylinder that the scattering waves are damped to be vanished, the potential functions for them are expressed simply by Eq. (3.2) and (3.3) without scattering terms.

$$\phi_0(x, z) = [e^{iK(x-\ell)} + \psi e^{-iK(x-\ell)}] A(KZ) \quad (3.2)$$

$$\phi'_0(x, z) = \psi' e^{-iK'(x-\ell')} A(R'Z) \quad (3.3)$$

In Eq. (3.2), the first term is for the incident wave and the second term is for reflected wave with complex reflection coefficient ψ . Eq. (3.3) is for transmitted wave with complex transmission coefficient ψ' .

The functions $A(kz)$ and $A(k'z)$ are given by Eq.(3.4) with wave numbers k and k' for region (O) and (O'), which are determined by Eq.(3.5). The reflection- and transmission coefficient K_r and K_t are provided by Eq.(3.6).

$$A(kz) = \frac{\cosh k(z+h)}{\cosh kh} \quad A(k'z) = \frac{\cosh k'(z+h')}{\cosh k'h'} \quad (3.4)$$

$$kh \tanh kh = \frac{\sigma^2 h}{g} \quad k'h' \tanh k'h' = \frac{\sigma^2 h'}{g} \quad (3.5)$$

$$K_r = |\psi| \quad K_t = |\psi'| \quad (3.6)$$

Now, we consider the dynamical or kinematical conditions on the boundaries of fluid region (I).

On the free surface AC, C'A' at $z = 0$, we have Eq.(3.7).

$$\frac{\partial \phi}{\partial z} = \frac{\sigma^2}{g} \phi \quad \text{or} \quad \bar{\phi} = \frac{\partial \phi}{\partial(\nu/h_0)} = \Gamma \phi \quad \text{where} \quad \Gamma = \frac{\sigma^2 h_0}{g} \quad (3.7)$$

and h_0 is taken as the distance between point A and B'.

On the immersed surface of fixed cylinder CDC' and on bottom BB', we have Eq.(3.8) because of the impervious boundaries.

$$\frac{\partial \phi}{\partial \nu} = 0 \quad \text{or} \quad \bar{\phi} = \frac{\partial \phi}{\partial(\nu/h_0)} = 0 \quad (3.8)$$

Finally, on the geometrical boundaries AB ($x = \ell$) and A'B' ($x = -\ell'$), we have from Eq.(3.2) and (3.3)

$$\phi_0 = (1 + \psi) \cdot A(kz), \quad \bar{\phi}_0 = h_0 \frac{\partial \phi_0}{\partial x} = i\lambda_0 (1 - \psi) \cdot A(kz) \quad (3.9)$$

$$\phi'_0 = \psi' \cdot A(k'z), \quad \bar{\phi}'_0 = -h_0 \frac{\partial \phi'_0}{\partial x} = -i\lambda'_0 \psi' \cdot A(k'z) \quad (3.10)$$

$$\text{where} \quad \lambda_0 = kh_0 \quad \lambda'_0 = k'h_0 \quad (3.11)$$

As shown in Fig.3-2, we divide the boundaries AC, CDC', C'A' and BB' into N_1 , N_2 , N_3 and N_4 elements, respectively and geometrical boundaries AB, A'B' into M and M' elements, and denote the potential functions on them by $\phi_1, \phi_2, \phi_3, \phi_4$ and ϕ_0, ϕ'_0 , respectively. Then, substituting the relations (3.7) ~ (3.10) into the Green's identity

formula (2.4) for the fluid region (I), the following simultaneous linear equations with respect to the potential functions on the boundaries and coefficients ψ and ψ' are provided:

$$\begin{aligned}
 -\phi(i) + \sum_{j=1}^{N_1} (\bar{E}_{ij} - \Gamma E_{ij}) \phi_1(j) + \sum_{j=1}^{N_2} \bar{E}_{ij} \phi_2(j) + \sum_{j=1}^{N_3} (\bar{E}_{ij} - \Gamma E_{ij}) \phi_3(j) \\
 + \sum_{j=1}^{N_4} \bar{E}_{ij} \phi_4(j) + \psi \sum_{r=1}^M G_{ir} A(kz_r) + \psi' \sum_{s=1}^{M'} G'_{is} A(k'z_s) \\
 = - \sum_{r=1}^M G_{ir}^* A(kz_r)
 \end{aligned} \quad (3.12)$$

where

$$G_{ir} = \bar{E}_{ir} + i\lambda_0 E_{ir}, \quad G'_{is} = \bar{E}_{is} + i\lambda'_0 E_{is}, \quad G_{ir}^* = \bar{E}_{ir} - i\lambda_0 E_{ir} \quad (3.13)$$

In above equations, the first term $\phi(i)$ should be written as follows, according to the position of point (i):

$$\begin{aligned}
 \text{For } i = 1 \sim N_1, \quad \phi(i) = \phi_1(j) \quad ; \quad i = 1 \sim N_2, \quad \phi(i) = \phi_2(i); \\
 i = 1 \sim N_3, \quad \phi(i) = \phi_3(j) \quad ; \quad i = 1 \sim N_4, \quad \phi(i) = \phi_4(i);
 \end{aligned} \quad (3.14)$$

For point (i) on AB and A'B', putting $i = (\ell, z_p) = (p)$, $i = (-\ell', z_q)$ = (q), we take

$$\phi(i) = (1 + \psi) \cdot A(kz_p), \quad \phi(i) = \psi' A(k'z_q) \quad (3.15)$$

Eq.(3.12) yields $(N_1 + N_2 + N_3 + N_4 + 2)$ linear equations with respect to the same number of unknown quantities. Solving these equations, all of the unknowns are determined and by means of Eq.(2.3), the potential function at any point in fluid region is calculated, and at the same time those of regions (0) and (0') are obtained by Eq.(3.2) and (3.3).

The fluid pressure at point (j) = (ξ_j, η_j) on the immersed surface of the cylinder is given as

$$\frac{p(j)}{\rho g S_0} = -i \phi_2(j) e^{i\alpha t} \quad (3.16)$$

Consequently, the horizontal and vertical resultant forces P_x and P_z and the resultant moment T around the point (x_0, z_0) are calculated as follows:

$$\frac{P_x}{\rho g S_0 h_0} = -i e^{i\omega t} \sum_{j=1}^{N_2} \phi_2(j) \cdot \frac{\Delta \zeta_j}{h_0} \quad (3.17)$$

$$\frac{P_z}{\rho g S_0 h_0} = i e^{i\omega t} \sum_{j=1}^{N_2} \phi_2(j) \cdot \frac{\Delta \xi_j}{h_0} \quad (3.18)$$

$$\frac{T}{\rho g S_0 h_0^2} = i e^{i\omega t} \sum_{j=1}^{N_2} \left(\frac{\xi_j - x_0}{h_0} \cdot \frac{\Delta \xi_j}{h_0} + \frac{\zeta_j - z_0}{h_0} \cdot \frac{\Delta \zeta_j}{h_0} \right) \phi_2(j) \quad (3.19)$$

The first calculated example is a semi-immersed circular cylinder whose center is fixed at still water surface on constant water depth area and whose diameter D is 0.8 times the water depth h . The geometrical surface AB and $A'B'$ are taken at $x = 3h$ and $-3h$, respectively. The numbers of calculation points on the boundaries are taken as $N_1 = 20$, $N_2 = 14$, $N_3 = 20$, $N_4 = 30$ and $M = M' = 20$. The second example is double cylinders whose diameters are the same as above and whose centers are apart by three times the diameter D .

Fig.3-3 shows the calculated and measured transmission coefficients with respect to the non-dimensional frequency $\sigma^2 h/g$ or to the ratio of diameter to wave length D/L for the first and second examples, where the solid line and open circles are for single cylinder and the broken line and solid circles are for double cylinders. From the figure, it is seen that the transmission coefficient for single cylinder decreases gradually and the one for double cylinders decreases rapidly with increasing frequency and that the measured values are somewhat lower than the calculated values for higher frequencies but the tendencies of both are in good agreement. The discrepancies between measured and calculated values are thought to be due to the non-linear effect of measured waves. (The experiments were carried out in wave flume of length 22 m with water depth $h = 40$ cm and incident wave amplitude $S_0 = 3 \sim 4$ cm.)

IV Wave Transformation by and the Motion of Floating Cylinder

In Fig.4-1, it is assumed that a cylinder of cross-section $CDD'C'$ with gravity center at (\bar{x}_0, \bar{z}_0) and center of buoyancy at (x_b, z_b) in equilibrium condition is moored by spring lines DE and $D'E'$ with spring constant K on the variable sea bottom $B'E'EB$, and is subjected to the incident wave of frequency σ and small amplitude S_0 from the right. Then, the position of

the gravity center of the cylinder (x_0, z_0) and the rotation angle δ of the cylinder around gravity center at any time t in motion are expressed by the complex amplitude of horizontal and vertical displacements X, Z and of the rotation angle Θ as follows:

$$x_0 = \bar{x}_0 + X e^{i\omega t}, \quad z_0 = \bar{z}_0 + Z e^{i\omega t}, \quad \delta = \Theta e^{i\omega t} \quad (4.1)$$

Similarly to the previous section III, the velocity potential is expressed by Eq. (3.1) and the potential function in region (O), (O') are by Eq. (3.2), (3.3) with reflection and transmission coefficients ψ and ψ' . And also, the potential function at free surface and at bottom in fluid region (I) are in the relation of Eq. (3.7) and (3.8), respectively. However, on the oscillating surface CDD'C', the normal derivatives of the potential function ϕ_2 is given by the following expression, due to the kinematical boundary condition:

$$\bar{\phi} = i \Gamma \left[\frac{X}{S_0} \frac{dz}{ds} - \frac{Z}{S_0} \frac{dx}{ds} - \frac{\Theta a}{S_0} \left\{ \frac{x - \bar{x}_0}{a} \frac{dx}{ds} + \frac{z - \bar{z}_0}{a} \frac{dz}{ds} \right\} \right] \quad (4.2)$$

where a is a reference length to the horizontal size of the cross-section, for example, a is taken as half width for rectangular cylinder and as radius for circular cylinder. (x, z) is the coordinate of point on the surface CDD'C' and s is the length measured along CDD'C'.

The complex amplitudes X, Z and Θ in Eq. (4.2) can be expressed by the potential function ϕ_2 on the immersed surface of cylinder, taking account of the following equations of motion of the cylinder:

$$M \frac{d^2 x_0}{dt^2} = P_x + F_x, \quad M \frac{d^2 z_0}{dt^2} = P_z + P_s + F_z \quad (4.3)$$

$$I_0 \frac{d^2 \delta}{dt^2} = T_\theta + T_s + M_\theta$$

where M is the mass of the cylinder; I_0 is the moment of inertia around the gravity center; P_x, P_z, T_θ are the resultant horizontal and vertical fluid forces and moment around gravity center due to the fluid pressure acting to the immersed surface; P_s, T_s are the restoring force and moment for vertical displacement and rotation of cylinder due to statical fluid pressure; F_x, F_z, M_θ are the mooring forces and moment by the mooring lines induced by the motion of the cylinder.

Indicating the fluid density by ρ , the draught in mooring condition

by qh ($l > q > 0$), the mass M , the moment of inertia I_θ and the immersed volume of the cylinder V are expressed with positive constants ν_1 , ν_2 and ν_3 as follows:

$$M = \nu_1 \int a q h, \quad I_\theta = \nu_2 \int a^2 (q h)^2, \quad V = \nu_3 a q h \quad (4.4)$$

Since the fluid pressure on the immersed surface is expressed by Eq. (3.16), P_x , P_z and T_θ are given as follows:

$$\begin{aligned} P_x &= -i \rho g \zeta_0 e^{i\sigma t} \int_S \phi_2(x, z) dz \\ P_z &= i \rho g \zeta_0 e^{i\sigma t} \int_S \phi_2(x, z) dz \\ T_\theta &= i \rho g \zeta_0 e^{i\sigma t} \int_S \{ (x - \bar{x}_0) dx + (z - \bar{z}_0) dz \} \phi_2(x, z) \end{aligned} \quad (4.5)$$

where integrations are taken along the surface CDD'C'.

Denoting the length of water line as $2l_0$, P_S and T_S are given as

$$P_S = -2 \rho g l_0 Z e^{i\sigma t}, \quad T_S = -\rho g V \left\{ \frac{3}{2} \frac{l_0^3}{V} - (\bar{z}_0 - Z) \right\} \Theta e^{i\sigma t} \quad (4.6)$$

For simplicity, we assume that the cross-section of the cylinder and the mooring condition are symmetrical with respect to the vertical line through the gravity center. Taking the angle of mooring line with horizontal as β and the mooring point on the cylinder as (a_0, b_0) and $(-a_0, b_0)$, the mooring forces and moment to the cylinder F_x , F_z and M_θ are expressed as follows:

$$\begin{aligned} F_x &= -2K(X - S\Theta) \cos^2 \beta e^{i\sigma t}, \quad F_z = -2K \sin^2 \beta e^{i\sigma t} \\ M_\theta &= 2KS(X - S\Theta) \cos^2 \beta e^{i\sigma t} \end{aligned} \quad (4.7)$$

where

$$S = b_0 - \bar{z}_0 - (a_0 - \bar{x}_0) \tan \beta$$

Substituting Eq. (4.1) (4.4) (4.5) (4.6) and (4.7) into Eq. (4.3), it follows that X , Z and Θ are expressed by $\phi_2(x, z)$.

$$\frac{X}{S_0} = \frac{i}{\delta} \int_S \phi_2(x, z) \cdot \left\{ k_{x\theta} \frac{x - \bar{x}_0}{a} \frac{dx}{a} + (k_{z\theta} \frac{z - \bar{z}_0}{a} - \alpha_3) \frac{dz}{a} \right\} \quad (4.8)$$

$$\frac{Z}{S_0} = \frac{i}{\alpha_2} \int_S \phi_2(x, z) \frac{dx}{a} \quad (4.9)$$

$$\frac{\partial a}{S_0} = \frac{i}{\gamma} \int_S \phi_2(x, z) \left\{ \alpha_1 \frac{x - \bar{x}_0}{a} \frac{dx}{a} + \left(\alpha_1 \frac{z - \bar{z}_0}{a} - k_{x0} \right) \frac{dz}{a} \right\} \quad (4.10)$$

where

$$\begin{aligned} \gamma &= \alpha_1 \alpha_3 - k_{x0}^2, & \alpha_1 &= k_{xx} - \nu_1 \frac{qh}{h_0} \Gamma, \\ \alpha_2 &= k_{zz} - \nu_1 \frac{qh}{h_0} \Gamma + \frac{2l_0}{a}, & \alpha_3 &= k_{00} - \nu_2 \frac{(qh)^2}{a h_0} \Gamma \\ &+ \frac{2}{3} \left(\frac{l_0}{a} \right)^3 - \nu_3 \frac{qh}{a} \frac{\bar{z}_0 - z_b}{a}, & k_{xx} &= \frac{ZK}{\rho g a} \cos^2 \beta \\ k_{zz} &= \frac{ZK}{\rho g a} \sin^2 \beta, & k_{00} &= \frac{ZKS^2}{\rho g a^3} \cos^2 \beta, & k_{x0} &= \frac{ZKS}{\rho g a^2} \cos^2 \beta \end{aligned} \quad (4.11)$$

Introducing Eq. (4.8) (4.9) (4.10) into Eq. (4.2), $\bar{\phi}_2$ on the immersed surface of cylinder is written by ϕ_2 as follows:

$$\bar{\phi}_2(x, z) = \Gamma \int_S \phi_2(u, v) \cdot F(x, z; u, v) \quad (4.12)$$

where

$$\begin{aligned} F(x, z; u, v) &= \left[\left(\frac{1}{\alpha_2} + \frac{\alpha_1}{\gamma} \cdot \frac{u - \bar{x}_0}{a} \cdot \frac{x - \bar{x}_0}{a} \right) \frac{dx}{ds} - \frac{1}{\gamma} \left(k_{x0} - \alpha_1 \frac{z - \bar{z}_0}{a} \right) \cdot \right. \\ &\cdot \left. \frac{u - \bar{x}_0}{a} \frac{dz}{ds} \right] \frac{du}{a} + \frac{1}{\gamma} \left[\left(\alpha_1 \frac{v - \bar{z}_0}{a} - k_{x0} \right) \frac{x - \bar{x}_0}{a} \frac{dx}{ds} + \left\{ \left(\alpha_3 - \right. \right. \right. \\ &\left. \left. \left. k_{x0} \frac{z - \bar{z}_0}{a} \right) - \left(k_{x0} - \alpha_1 \frac{z - \bar{z}_0}{a} \right) \frac{v - \bar{z}_0}{a} \right\} \frac{dz}{ds} \right] \frac{dv}{a} \end{aligned} \quad (4.13)$$

where (x, z) and (u, v) are the coordinates of the points on the immersed surface. Indicating the calculation points on the surface as (ξ_j, ζ_j) and (ξ_m, ζ_m) , corresponding to (x, z) and (u, v) , Eq. (4.12) is written as follows:

$$\bar{\phi}_2(j) = \Gamma \sum_{m=1}^{N_2} F(j, m) \cdot \phi_2(m) \quad (4.14)$$

Similarly to the preceding section III, applying Eq. (3.7) (3.8) (3.9) (3.10) and (4.14) to the Green's identity formula (2.4) for the fluid region (I), we have linear simultaneous equations with respect to the potential functions ϕ on the boundaries and ψ, ψ' . They are written by replacing the term $\sum_{j=1}^{N_2} \bar{E}_{ij} \Phi_2(j)$ in Eq. (3.12) by $\sum_{m=1}^{N_2} \sum_{j=1}^{N_2} [\delta_{jm} \bar{E}_{ij} - \mathcal{P} E_{ij} F(j, m)] \Phi_2(m)$, where δ is Kronecker's delta and $\delta_{jm} = 0$ ($j \neq m$): $= 1$ ($j = m$).

Solving the equations, we can obtain all of the boundary-values of potential function of region (I) and the transmission-, reflection coefficient, similarly to the section III. Then, the amplitudes of motion of cylinder are calculated by Eq. (4.8) (4.9) (4.10) and also the mooring force F to the wave-side mooring line DE is calculated as follows:

$$\frac{F}{S_o K} = \left[\frac{X}{S_o} + \frac{Z}{S_o} \tan \beta - \frac{D a}{S_o} \frac{S}{a} \right] \cos \beta \cdot e^{i \omega t} \quad (4.15)$$

The mooring force F' to the lee-side line D'E' is given by replacing β by $-\beta$ in above expression.

As an example, we consider the case when a circular cylinder is moored on constant water depth h . The diameter $D = 2a$ is $0.914h$, the draught is $0.67h$ ($q=0.67$), the mooring points on the cylinder are ($\pm 0.486h, -0.114h$) and $\nu_1 = 1.467, \nu_2 = 0.670, \nu_3 = 1.646$. The cylinder is of uniform density 0.584 and the center is at $0.114h$ below still water surface. The spring constant $K/\rho g a$ is 0.227 and mooring angle β is 33° . Fig.4-2 is the calculated (solid line) and measured (open circles) transmission coefficients with respect to the non-dimensional frequency or to the ratio of diameter to the wave length D/L . Experiments were carried out in wave flume with water depth $h = 35$ cm and a circular cylinder of diameter $D = 32$ cm, whose center was at depth 4.0 cm below still water level in equilibrium condition. The figure shows that the calculated and measured values are in good agreement. Moreover, it shows an interesting fact that the incident wave is perfectly intercepted even by floating cylinder, if the frequency $\omega^2 h/g$ is 0.42 and 1.74 , that is, D/L is 0.10 and 0.26 . Fig.4-3 is the calculated reflection coefficient and amplitudes of motion of cylinder.

V Wave Transformation by Permeable Seawall and Breakwater

In Fig.5-1, suppose that ABC is a permeable seawall placed on impervious bottom BCO'. The geometrical boundary is taken at OO', which is sufficiently distant from the seawall and of constant water depth h. Dividing the fluid region into three regions (O), (I) and (II), the velocity potentials in region (O) and (I) are assumed to be expressed in the form of Eq.(3.1) with potential functions $\phi_0(x,z)$ and $\phi(x,z)$, respectively. In permeable region (II), indicating the quantities by superscript *, the mass and momentum equations are written with horizontal and vertical fluid velocities u^* , w^* and fluid pressure p^* as follows:

$$\begin{aligned} \frac{\partial u^*}{\partial x} + \frac{\partial w^*}{\partial z} &= 0 \\ \frac{1}{V} \frac{\partial u^*}{\partial t} &= -\frac{1}{\rho} \frac{\partial p^*}{\partial x} - \frac{\mu}{V} u^* - \frac{\varepsilon(1-V)}{V} \frac{\partial u^*}{\partial t} \\ \frac{1}{V} \frac{\partial w^*}{\partial t} &= -\frac{1}{\rho} \frac{\partial p^*}{\partial z} - g - \frac{\mu}{V} w^* - \frac{\varepsilon(1-V)}{V} \frac{\partial w^*}{\partial t} \end{aligned} \quad (5.1)$$

where ρ is the fluid density, V is porosity of the seawall, μ is the coefficient of drag force to the porous material which is linearized to be proportional to the fluid velocity and ε is the added mass force coefficient to the material. The fluid motion represented by Eq.(5.1) has velocity potential, which is expressed by Eq.(5.2) with potential function Φ^* , and fluid velocities, pressure and surface profile are provided by Eq.(5.3).

$$\Phi^*(x,z;t) = \frac{gS_0}{\sigma} \phi^*(x,z) e^{i\sigma t} \quad (5.2)$$

$$u^* = \partial \Phi^* / \partial x, \quad w^* = \partial \Phi^* / \partial z, \quad p^* / \rho g S_0 = -i\beta \phi^*(x,z) e^{i\sigma t} \quad (5.3)$$

$$S^*/S_0 = -i\beta \phi^*(x,0) e^{i\sigma t}, \quad \beta = \frac{\alpha}{V}, \quad \alpha = 1 + \varepsilon(1-V) + i\mu/\sigma$$

The potential function ϕ_0 in region (O) is given by Eq.(3.2), so that the boundary conditions of fluid region (I) are provided by Eq.(3.7) on \vec{OA} , by Eq.(3.8) on $\vec{OO'}$ and by Eq.(3.9) on $\vec{O'O}$. As for the conditions on \vec{AC} , since the mass flux and energy flux through the boundary AC should be continuous, it follows from Eq.(3.16) and (5.3) that

$$\bar{\phi}^* = \bar{\phi}, \quad \phi^* = \frac{1}{\rho} \phi \quad (5.4)$$

As for the porous region (II), we have Eq.(5.5) on free surface \vec{AB} from the kinematical condition, and Eq.(5.6) on impervious boundary BC.

$$\frac{\partial \phi^*}{\partial Z} = \alpha \frac{\rho^2}{g} \phi^* \quad \text{or} \quad \bar{\phi}^* = \alpha \Gamma \phi^*, \quad \Gamma = \frac{\rho^2 h_0}{g} \quad (5.5)$$

$$\frac{\partial \phi^*}{\partial Z} = 0 \quad \text{or} \quad \bar{\phi}^* = 0 \quad (5.6)$$

As shown in Fig.5-2, denoting the potential functions on the boundaries \vec{OA} , \vec{AC} , \vec{CO}' and $\vec{O}'\vec{O}$ by ϕ_1 , ϕ_2 , ϕ_3 , ϕ_0 and on the boundaries \vec{BA} , \vec{AC} and \vec{CB} by ϕ_1^* , ϕ_2^* and ϕ_3^* , dividing these boundaries into N_1 , N_2 , N_3 , M and N_1^* , N_2^* , N_3^* and taking the outward normal for region (I) and inward normal for region (II), and applying the boundary conditions (3.7) (3.8) (3.9) to the Green's identity formula (2.4) for region (I) and conditions (5.4) (5.5) and (5.6) to Eq.(2.4) for region (II), we have the following equations:

(i) For fluid region (I):

$$\begin{aligned} & -\phi(\omega) + \sum_{j=1}^{N_1} (\bar{E}_{ij} - \Gamma E_{ij}) \phi_1(j) + \sum_{j=1}^{N_2} [\bar{E}_{ij} \phi_2(j) - E_{ij} \bar{\phi}_2(j)] \\ & + \sum_{j=1}^{N_3} \bar{E}_{ij} \phi_3(j) + \psi \sum_{\gamma=1}^M G_{i\gamma} A(kZ_\gamma) = - \sum_{\gamma=1}^M G_{i\gamma}^* A(kZ_\gamma) \end{aligned} \quad (5.7)$$

($i = 1 \sim N_1, 1 \sim N_2, 1 \sim N_3$ and $(0, Z_p)$ on $O'O$)

(ii) For porous region (II):

$$\begin{aligned} & \phi^*(\omega) + \sum_{j=1}^{N_1^*} (\bar{E}_{ij}^* + \alpha \Gamma E_{ij}^*) \phi_1^*(j) + \sum_{j=1}^{N_2^*} \left[\frac{1}{\rho} \bar{E}_{ij}^* \phi_2(j) \right. \\ & \left. - E_{ij}^* \bar{\phi}_2(j) \right] + \sum_{j=1}^{N_3^*} \bar{E}_{ij}^* \phi_3^*(j) = 0 \end{aligned} \quad (5.8)$$

($i = 1 \sim N_1^*, 1 \sim N_2, 1 \sim N_3^*$)

Eq.(5.7), (5.8) are $(N_1 + 2N_2 + N_3 + N_1^* + N_3^* + 1)$ linear equations with respect to the same number of unknowns ϕ_1 , ϕ_2 , $\bar{\phi}_2$, ϕ_3 , ψ , ϕ_1^* and ϕ_3^* . Consequently, solving these equations simultaneously, we can determine all of the unknowns, from which the potential values at points in fluid region are calculated by Eq.(2.3).

The surface wave profiles are calculated as follows:

$$\begin{aligned} \text{From B to A: } S^*(j) &= -i\beta \phi_i^*(j) e^{L\sigma^2 t} & j &= 1 \sim N_1^* \\ \text{From A to O: } S(j) &= -i \phi_i(j) e^{i\omega t} & j &= N_1 \sim 1 \end{aligned} \quad (5.9)$$

Fig.5-3 and 5-4 are the calculated and measured reflection coefficients with respect to non-dimensional frequency $\sigma^2 h/g$ for model seawall of 1:1 slope and of vertical face, respectively, made by quarry stones of mean diameter 6 cm with porosity $V = 0.43$ in constant water depth $h = 40$ cm. The widths of both seawalls at still water level are equal to twice the water depth h . The solid lines in figures are calculated values, taking $V = 0.5$, $M/\sigma = 1.0$ and $\xi = 0$ for all frequencies. The measured and calculated values are almost in good agreement.

Wave transformation by permeable breakwater is analyzed in the similar manner. In Fig.5-5, solid line, solid circles and broken line, solid triangles are the calculated and measured reflection and transmission coefficients, respectively, for model permeable breakwater with 1:1.5 sloped faces and the width at still water level h . Other conditions are the same as the seawall. The calculated values are somewhat different from measured values but the tendencies are nearly in agreement. Fig.5-6 is for permeable breakwater model with rectangular cross-section of width $2h$. The measured and calculated values are in good agreement.

Fig.5-7 is the calculated distribution of equi-potential lines (solid lines) and its orthogonals (broken lines) for permeable breakwater in Fig. 5-5 at $\sigma t = 0^\circ, 30^\circ, 60^\circ$ and 90° , when the incident wave crest approaches to the breakwater.

VI Conclusions

It is clear that the proposed method provides a convenient and simple analysis for two-dimensional boundary-value problems of small amplitude waves. And, if the difficulties arising in solving simultaneous equations of so many unknown quantities were overcome, this method is extended directly to the problem of three-dimensional waves and also to the finite amplitude wave problems by means of perturbation method.

CHAPTER 157

WAVE OVERTOPPING EQUATION

by

J. Richard Weggel¹

INTRODUCTION

In the early 1950's the Corps of Engineers' Jacksonville District initiated a series of laboratory tests to investigate the overtopping of proposed levee sections for Lake Okeechobee, Florida. For economic reasons, the alternative to build levees with crest elevations that were at times below the limit of wave runup was investigated and the quantities of water carried over the structures for various freeboard allowances, structure slopes and wave conditions determined. The initial tests were conducted at the Waterways Experiment Station (WES) in Vicksburg, Mississippi for the Jacksonville District at what was taken to be a 1 to 30 model scale. Model wave heights varied from 4.05 cm to 12.2 cm (0.133 to 0.40 ft). In order to expand the range of test conditions investigated, the Beach Erosion Board, currently the Coastal Engineering Research Center (CERC), commissioned an expanded series of tests that considered the overtopping of riprap faced, curved and stepped seawalls as well as the overtopping of "smooth" slopes. These tests, also conducted at WES, were considered to be at a 1 to 17 scale with model wave heights ranging from 5.36 cm to 21.5 cm (0.176 to 0.706 ft). A number of tests were subsequently conducted in CERC's large wave tank to determine the influence scale effects might have on overtopping. These tests are referred to as 1 to 2 1/2 scale tests. The model wave heights investigated ranged from 48.8 cm to 140.2 cm. (1.60 to 4.60 ft).

¹Special Assistant, U.S. Army Coastal Engineering Research Center, Fort Belvoir, VA 22060

Much of the overtopping data obtained during these tests has been presented by Saville (2)* and by Saville and Caldwell (1) and summarized in CERC's TR-4 (3); however, in this latter publication the data were presented in dimensional form making their general application difficult. In keeping with the decision to present information in CERC's Shore Protection Manual (4) in dimensionless form whenever practicable, the overtopping data was reanalysed and an empirical expression derived. The broad range of model scales used in the overtopping experiments also provide an opportunity to investigate the effect of model scale on test results. A summary of overtopping test conditions investigated is given on Table 1.

Figure 1. Definition of terms.

on 1 on 25 beach	33	0.998
Recurved Wall		
on 1 on 10 beach	5	0.999

DIMENSIONAL ANALYSIS

The variables describing the overtopping of a given structure are depicted on figure 1. They include:

H'_0 = deepwater wave height	[L]
T = wave period	[T]
g = gravitational acceleration	[L] [T] ⁻²
Q = overtopping rate (volume per unit time per unit crest length)	[L] ² [T] ⁻¹
R = runup height measured vertically from the still water level (SWL) (e.g. the height to which the water would runup if the structure were high enough to preclude overtopping)	[L]
d_s = water depth at the structure toe	[L]
h = height of the structure crest above the bottom	[L]
ν = kinematic viscosity	[L] ² [T] ⁻¹
θ = structure slope	[dimensionless]

plus any other geometric parameters necessary to describe the various structure types. A dimensional analysis of the preceding 9 variables having 2 dimensions gives the following dimensionless terms:

$$d_s / H'_0 = \text{relative water depth at the structure toe}$$

$$H'_0/gT^2 = \text{wave steepness parameter}$$

$$F = (h-d_s)/H'_0 = \text{relative height of structure crest above SWL}$$

$$F_0 = R/H'_0 = \text{relative runup or height of structure crest required to preclude overtopping}$$

$$Q^* = Q^2/gH'_0{}^3 = \text{relative overtopping rate}$$

$$\theta = \text{structure slope, and}$$

$$R_e = \frac{H'_0{}^2}{\nu T} = \text{a Reynolds' number.}$$

The phenomenon is scaled primarily according to Froude similarity; however, the Reynolds' number serves as a measure of any scale effects. Other formulations of R_e are possible, the present one having been adopted for its simplicity.

Generally it is not permissible to eliminate dimensionless terms by combining them unless an analytic or empirical relationship between two of the variables is known. If it is assumed that such a satisfactory relationship is available for the runup R , the overtopping rate can be expressed in terms of R and the ratio $F/F_0 = (h-d_s)/R$ can be substituted for F and F_0 . The preceding dimensionless terms are obviously not the only combinations of terms possible; however, they were selected after considerable trial and error because they provided the greatest possibility for keeping dimensionless variables constant and investigating the variation of Q^* with individual parameters.

DATA ANALYSIS

For a given structure and set of incident wave conditions (e.g. constant d_s/H'_0 , H'_0/gT^2 and θ), the dimensionless overtopping rate, Q^* was plotted against the dimensionless crest height, $F/F_0 = (h-d_s)/R$.

A typical plot showing two data sets differing only in model scale, is shown in figure 2. Generally, all data sets when plotted semi-logarithmically exhibited a linear variation of Q^* with F/F_0 for small values of F/F_0 ; also, the value of Q^* must approach zero as the relative crest height, F/F_0 approaches 1.0 (i.e., as the crest of the structure approaches the limit of wave runoff). The curve therefore approaches $F/F_0 = 1.0$ asymptotically on the semi-logarithmic plot. The hyperbolic tangent function exhibits identical behavior; hence, an equation of the form,

$$\frac{F}{F_0} = \alpha \tanh \left[\log \frac{Q^*}{Q_0^*} \right] \quad (1)$$

was used to approximate the data. Here α and Q_0^* are empirical coefficients to be established by comparing the equation with the data. The value of α generally establishes the shape of the curve since it is the slope of the curve at $F/F_0 = 0$. Q_0^* represents the value of Q^* for a structure with its crest elevation at the SWL. Figure 3 depicts equation 1 for various values of α . To establish values of α and Q_0^* a transparent template was made of figure 3 and used as an overlay to Q^* vs F/F_0 data plotted at the same scale on semi-logarithmic graph paper. By moving the template vertically until one of the curves coincided with the trend of the data, the value of α could be directly determined. The value of Q_0^* was determined by reading the value of Q^* where the α curves intersected $F/F_0 = h-d_s/R = 0.0$ on the data plot. Thus, by overlaying the template to each data set, values of α and Q_0^* were established for each structure type and set of incident wave conditions. Interestingly, the form of equation 1 is such that it could be used to describe the overtopping of all of the structures for which data were available; consequently, figures similar to figure 4 could be prepared for each structure type. Such figures, which give α and Q_0^* as functions of d_s/H_0 and H_0'/gT^2 for a given structure type, are presented in the SPM (4) for other structure slopes and types.

Figure 2. Typical data plot, 1 on 1 1/2 smooth slope, $H_0'/gT^2 = 0.00455$;
 $d/H_0' = 0.75$.

Figure 3. Presentation of equation 2 for various values of α .

Figure 4. Variation of α and Q_0^* with incident wave conditions - initial data analysis, 1 on 3 smooth slope.

By substituting the dimensionless variables into equation 1 and solving for Q , one finds,

$$Q = \left(g Q_o^* H_o^3 \right)^{1/2} \exp \left\{ - \frac{0.217}{\alpha} \tanh^{-1} \left[\left(\frac{h-d}{R} \right) \right] \right\} \quad (2)$$

or equivalently, since $\tanh^{-1} \left(\frac{a}{b} \right) = \frac{1}{2} \log_e \left(\frac{b+a}{b-a} \right)$,

$$Q = \left(g Q_o^* H_o^3 \right)^{1/2} \exp \left\{ - \frac{0.217}{2\alpha} \log_e \left[\left(\frac{R+h-d}{R-h+d} \right) \right] \right\} \quad (3)$$

Either equation 2 or 3 can be used in conjunction with figures such as figure 4 to determine overtopping rates.

To evaluate the ability of equation 2 or 3 to predict the overtopping rates measured in the experiments, the values of α and Q_o^* as published in the SPM, were used with equation 2 and computed overtopping values compared with measured values. Table 2 presents the correlation coefficients found in the analysis. In general, agreement was excellent; the worst case was for the vertical wall data with $r = 0.980$. (The small number of data points for the recurved wall make the correlation analysis for that structure inconclusive).

Subsequent to publication of the SPM, further analysis of the data for smooth slopes was undertaken in an attempt to relate α and Q_o^* to incident wave conditions and structure slope. For a given slope, the variability of α with incident wave conditions was relatively small, suggesting that an average α could be used and the data reanalysed to establish the Q_o^* value that best fit the data for the average α . The average value, $\bar{\alpha}$, is shown on figure 5 for four smooth structure slopes with data obtained at three different scales.

The effect of decreasing model scale seems to result in a more rapid drop-off of the overtopping rate with increasing structure height. (see figure 2). This effect is also related to the value of R used to compute F/F_o , however, an expression relating $\bar{\alpha}$ with structure slope (smooth

Figure 5. Average values of α as a function of structure slope.

slopes only) is given by,

$$\bar{\alpha} = 0.06 - 0.0143 \log_e (\sin \theta) \quad (4)$$

The data for smooth slopes was reanalysed using the values of α given by equation 4 for each slope and appropriate best fit values of Q_o^* selected. These Q_o^* values could then be compared with an expression calculated as an upper bound on Q_o^* .

Physically, the value of Q_o^* corresponds to the dimensionless quantity of water transported over the structure if the structure crest were at the SWL (i.e., $F/F_o = 0$). For waves that do not break before hitting a structure, the volume of water above the SWL in a wave profile will define an approximate upper limit for Q_o^* . Defining the volume of water above the SWL as V ,

$$V = \epsilon HL \quad (5)$$

where H = wave height, L = wave length and ϵ = a dimensionless factor depending on the shape of the wave profile. For a sinusoidal wave, $\epsilon = 1/(2\pi)$, while for various cnoidal wave profiles, ϵ can be obtained from figure 6 if the appropriate value of the modulus of the complete elliptic integral k^2 is known. (see Reference 5). Then, the overtopping rate is given by,

$$Q = \frac{V}{T} = \frac{\epsilon HL}{T} \quad (6)$$

Recalling that Q_o^* is defined by,

$$Q_o^* = \frac{Q^2}{gH_o^3}$$

and using linear wave theory expressions for H/H_o' and L/L_o' ,

$$Q_o^* = \frac{\left[\frac{\epsilon}{2\pi} \right]^2 \left[\frac{H'}{H_o} \right]^2 \tanh^2 \left[\frac{2\pi d}{L} \right]}{H_o'/gT^2} \quad (7)$$

Figure 6. Dimensionless fluid volume per unit crest length above the SWL for cnoidal waves.

Equation 7 is plotted on figure 7 for both $\epsilon = 1/(2\pi)$ (labelled linear theory) and for ϵ values determined from cnoidal wave theory. Also shown on figure 7 are the Q_o^* values determined by the analysis for constant \bar{a} described above. In general, data from the 1 to 17 scale tests falls well below the cnoidal wave curves for all slopes for which data were available. Data from the 1 to 2 1/2 scale tests (squares on figure 7), however, are in general conformance with the cnoidal curves when $d_s/H_o' > 1.5$ (non breaking waves). Agreement appears best for long waves of small steepness. Steeper waves, and waves that break have considerably lower values of Q_o^* than predicted by the linear theory or cnoidal theory curves.

SCALE EFFECTS

Scale effects arise because of an inability to model all aspects of a phenomenon simultaneously, usually because of the limited range of fluid properties practically achievable; hence, to achieve both Froude and Reynolds' similarity in a model, the model fluid viscosity would have to vary as the scale ratio to the 3/2 power times the prototype fluid viscosity. Therefore, if as is usually the case, the same fluid is used in both model and prototype, only one similarity law can be satisfied at the expense of the other. If surface tension is also a factor, the problem is even more complex. Since the wave overtopping phenomenon is dominated by wave motion, a Froude modelling law governs; however, turbulent and viscous dissipation also influence overtopping; thus Reynolds' effects must also influence the phenomenon. If viscosity is included in the original dimensional analysis, a Reynolds' number arises from the analysis and serves as a "scale factor" or as a measure of scale effects. The formulation of the Reynolds' number adopted to investigate scale effects was, $R_e = H_o'^2/\nu T$.

The influence of R_e on an individual data set for which all other dimensionless variables are constant is shown in figure 2. Both sets of points on the figure are from what were termed 1 to 17 scale tests; however, the wave height in the one test was 10.76 cm (solid circles, $R_e =$

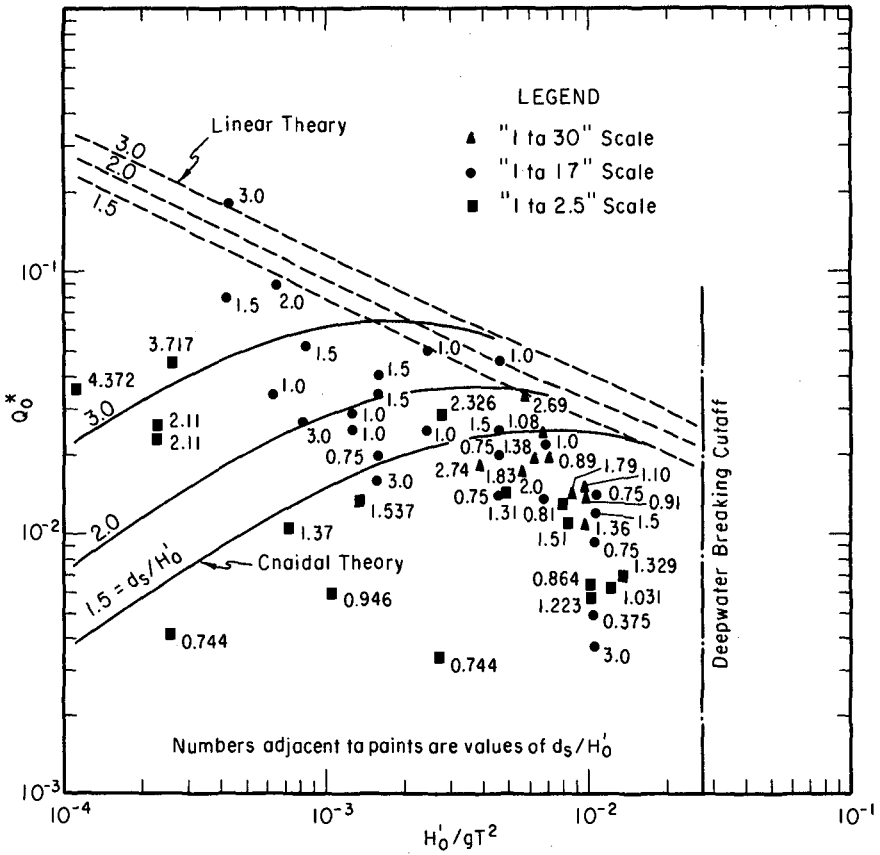

Figure 7. Comparison between measured and predicted values of Q_o^* (Based on reanalysis of data with constant $\alpha = 0.0765$, 1 on 3 smooth slope).

8030) while in the other test, the wave height was 21.52 cm (open circles, $R_e = 22700$). The greatest influence of scale appears when the structure crest is near the limit of wave runup (e.g. at the tail of the curve near $F/F_0 = (h-d_s)/R \rightarrow 1.0$). It is in this relatively thin layer of fluid that viscous effects can be expected to increase in importance. Inasmuch as it is the shape of the curve that is affected, it is the value of α that is, to a limited extent, influenced by scale. This slight dependence of α on scale is shown on figure 8. For the 1 on 3 slope, the SPM values of α are plotted against R_e for a broad range of d_s/H_0' and H_0'/gT^2 values. While it is difficult to draw firm conclusions regarding scale effects from figure 8 since d_s/H_0' and H_0'/gT^2 varied, there appears to be a decrease in α with increasing R_e . Note that the test designated as the 1 to 30 scale (triangular points) when characterized by $R_e = H_0'^2/vT$ as a "scale factor" are actually not at a smaller scale than the 1 to 17 scale tests (circles) since the smaller wave heights also had correspondingly smaller wave periods.

The effect of scale on Q_0^* appears to be negligible since no systematic variation of Q_0^* with R_e could be found. Since Q_0^* represents the dimensionless overtopping rate for a structure with its crest at the SWL, a relatively thick layer of flow, insensitive to viscous effects, tends to minimize any dependence of Q_0^* on R_e for smooth slopes.

In general, it appears that the primary influence of scale on the overtopping of smooth sloped structures is through scale effects manifest in the runup phenomenon. In the data analysis described herein, the actual measured or "correct" runup was used; consequently, the influence of scale effects on the runup was not considered. Other investigators have demonstrated that small scale runup experiments tend to significantly underpredict runup at larger scales. The observed effect of scale on overtopping itself appears to be relatively small; thus if the runup values used in equations 2 or 3 are corrected for scale effects, the predicted overtopping rates (using appropriate α and Q_0^* values) will provide good estimates of prototype overtopping rates.

Figure 8. Variation of α with Reynolds' number (scale factor).

EXAMPLE

A levee is constructed with a 1 on 3 slope to just preclude overtopping by a wave 1.05 m high when the water depth at the structure toe is 1.5 m deep. If the design wave period is 5 sec, determine the rate at which water is carried over the structure by the design wave if a storm surge of 0.6 m occurs. The unrefracted deepwater wave height can be estimated from the linear theory; $H/H'_0 = 1.073$ for $d_s/L_0 = 0.0384$; hence, $H'_0 = 1.05/1.073 = 0.98$ m. From reference 4, the relative runup is $R/H'_0 = 2.2$, which, when corrected for scale effects, becomes $R/H'_0 = 2.2(1.12) = 2.464$. Thus, $R = 2.464(0.98) = 2.41$ m and the height of the structure crest above the bottom is $h = 1.5 + 2.41 = 3.91$ m. To determine the overtopping rate, calculate $d_s/H'_0 = (1.5 + .6)/0.98 = 2.14$ and $H'_0/gT^2 = 0.98/9.81(5)^2 = 0.0040$. From figure 4, interpolating, $\alpha = 0.08$ and $Q^*_0 = 0.024$. From equation 2,

$$Q = \left[(9.81)(0.024)(.98)^3 \right]^{1/2} \exp \left\{ \frac{0.217}{0.08} \tanh^{-1} \left[\frac{(3.91-2.1)}{2.41} \right] \right\}$$

$$Q = 0.471 \exp \left\{ -2.713 \tanh^{-1} (0.751) \right\}$$

$$Q = 0.471 \exp \left\{ -2.713 (.975) \right\}$$

$$Q = 0.0334 \text{ m}^3/\text{sec-m}$$

If the average α value (equation 4) had been used with the cnoidal curves of figure 7, the value of α would have been 0.0765 and $Q^*_0 = 0.033$. Using these values in equation 2 gives $Q = 0.0347 \text{ m}^3/\text{sec-m}$.

CONCLUSIONS

1. Equation 2 or 3 along with the empirically established values of α and Q^*_0 of reference 4 can be used to predict overtopping rates for various structure slopes and structure types if accurate predictions of runup are available.

2. Alternatively, for smooth slopes, if conservative (high) estimates are desired, equation 2 or 3 can be used with the average α given by equation 4, and the value of Q_o^* given by equation 7 with ϵ determined from figure 6. This corresponds to using the Q_o^* values given by the cnoidal curves of figure 7.

3. Scale effects in overtopping tests arise primarily in modifying the runup. If scale effect corrected values of runup are used in equations 2 or 3, the predicted overtopping values will have been corrected for most viscosity induced scale effects.

ACKNOWLEDGEMENTS

Much of the original data analysis discussed herein was performed while the author was in the Design Branch, Engineering Development Division at CERC under the general supervision of Robert A. Jachowski. Philip N. Stoa performed the initial data reduction and analysis and Harold McClung assisted in the computer runs associated with the analysis. Their assistance is gratefully acknowledged.

The research described herein was conducted under the Civil Works Program of the Corps of Engineers. Permission to publish this material is appreciated.

CHAPTER 158

OVERTOPPING OF RUBBLE-MOUND BREAKWATERS BY IRREGULAR WAVES

by Yvon Ouellet* and Pierre Eubanks**

ABSTRACT

This paper describes the results of an experimental study on the effect of waves on rubble-mound breakwaters, wave transmission subsequent to wave overtopping, the stability of the three sides subjected to wave action and the effect of the breakwaters on waves. Two different rubble-mound breakwaters were tested, i. e. one with a rigid impermeable crest and the other with a flexible permeable crest. Tests were performed with both regular and irregular wave train systems. To obtain the simulated irregular wave trains, four theoretical spectra were chosen: Neumann, Bretschneider, Moskowitz, and Scott. Results obtained from tests with irregular wave trains were compared to those obtained from tests with regular wave trains. It was found that more information was obtained on the behaviour of the structure when it was submitted to the attack of irregular waves than when submitted to regular waves, and that the use of irregular wave trains gave more interesting results.

1. INTRODUCTION

In some cases, it is not necessary to protect completely the lee side of a breakwater and some overtopping is allowed. An example of this is the use of an overtopped breakwaters for the partial protection of the Pilgrim Nuclear Power Station⁽⁶⁾. Some research works have been made on the overtopping effect, of which the following ones have been consulted: Cross and Sollitt⁽³⁾, Hiroyoshi

* Associate professor, Department of Civil Engineering, Laval University

** Graduate student, Department of Civil Engineering, Laval University

and Tsugio⁽⁵⁾, Lording and Scott⁽⁶⁾, Ouellet⁽⁹⁾, Shiraishi, Numata and Endo⁽¹³⁾, Tsurata and Goda⁽¹⁵⁾, and the U.S. Corps of Engineers⁽¹⁶⁾. Most of the experimental works have been done under regular wave conditions.

It was then intended to establish an experimental programme to study the effect of irregular wave overtopping on structures as well as the effect of structures of waves. Although the stability of the structures and the wave overtopping are part of the study, the wave transmission subsequent to wave overtopping was mainly concerned.

2. THEORETICAL CONSIDERATIONS

Transmission Coefficient - The transmission of regular wave trains past a structure may be described in terms of the transmission coefficient, K_t , which is defined as the ratio of the height of the wave transmitted past the structure to the height of the wave incident on the structure

$$K_t = \frac{H_t}{H_i} \quad (1)$$

Transfer Function - When a structure is submitted to the attack of irregular trains, the characteristics are best described in terms of its transfer function⁽¹⁾. If $x(t)$ and $y(t)$ are, respectively, the incident and transmitted wave profiles, and $X(f)$ and $Y(f)$ are, respectively, the Fourier transforms of $x(t)$ and $y(t)$, then the transfer function may be defined as:

$$H(f) = \frac{Y(f)}{X(f)} \quad (2)$$

where $X(f)$ and $Y(f)$ are respectively the Fourier transform of $x(t)$ and $y(t)$:

$$\left. \begin{aligned} X(f) &= \int_{-\infty}^{\infty} x(t) e^{-i2\pi ft} dt \\ Y(f) &= \int_{-\infty}^{\infty} y(t) e^{-i2\pi ft} dt \end{aligned} \right\} \quad (3)$$

in which f = the frequency, in Hertz. In fact, we know that the transfer function is the Fourier transform of the system to a unit impulse.

In practice, however, the following relation is used to determine the transfer function:

$$H(f) = \frac{S_{yx}(f)}{S_{xx}(f)} = \frac{X^*(f) Y(f)}{X^*(f) X(f)} \quad (4)$$

in which $S_{yx}(f) = Y(f) X^*(f)$ represents the cross power spectral density function of $y(t)$ with respect to $x(t)$, $S_{xx}(f) = X(f) X^*(f)$ represents the auto power spectral density function of $x(t)$, and $X^*(f)$ represents the complex conjugate of $X(f)$. This procedure makes it possible to retain the phase information without the need of having to synchronize the two signals.

Coherence Function - The preceding equations are based upon linear systems. Even if, in practice, linear systems do rarely occur, the use of the constant parameter linear system is often justified. In order to judge the applicability of the linear model it is possible to estimate the accuracy of the transfer function by means of the coherence function

$$\gamma_{xy}^2(f) = \frac{|S_{xy}|^2 / S_{xx}^2}{S_{yy} S_{xx}} = \frac{S_{xy} S_{xy}^*}{S_{yy} S_{xx}} = \frac{|S_{xy}|^2}{S_{yy} S_{xx}} \quad (5)$$

which represents the ratio of the magnitudes of the response function obtained, respectively from the cross-spectral density function and from the input and output density spectra. The coherency for an ideal system with no noise in measured input and output is unity. The presence of noise or the nonlinearity of the system reduces the coherence function. The coherence function is then an indicator of the system behavior in showing those parts of the output not correlated with the input over the frequency range.

3. TEST PROCEDURE

Wave Flume - A sketch of the wave tank layout is shown in Fig. 1. The channel is 111 ft (36 m) long, 6 ft (1.86 m) wide, and 4 ft (1.3 m) deep. The distance between the wave paddle and the model breakwater (center of crest) is about 65 ft (21 m).

The wave generator consists of a paddle operated by a hydraulic piston, the movements of which are controlled by an electric signal from a programming device capable of generating regular and irregular wave trains. A wave filter which absorbs, to some extent, waves reflected by the model is in front of the wave generator.

The flume was divided into two sections, i.e., the front one of 3.5 ft (1.1 m) and the back one of 2.5 ft (0.76 m). The front section was used as the test section whereas the back section was used to measure the incident wave characteristics. This arrangement made possible the measurement of the incident, reflected and transmitted wave profiles.

Wave heights and periods were measured with resistance type wave gages. A first gage, located in the smaller section of the flume where reflection is almost eliminated by a wave absorber placed at the end of the flume, was used to measure the incident wave characteristics. A second gage, placed behind the structure in the larger section of the flume measured the transmitted wave characteristics, while a third movable gage, placed in front of the structure, measured the incident and reflected wave characteristics. Measurements taken on the third gage, which also included the envelope of the incident and reflected waves, were only used to perform some verifications in cases of experiments with regular waves.

Wave data were analysed using a Fourier Analyzer model HP-5451A, a product of Hewlett Packard Company⁽⁴⁾. Fig. 2 shows an overview of the analyzer system

Fig. 1 — SKETCH OF WAVE TANK LAYOUT.

and details of its operation are available in user manuals furnished with the instruments.

Fig.2—FOURIER ANALYSER SYSTEM.

Description of Models - A simplified sketch of the cross-section of the two models studied is shown in Fig. 3. The first model consists of a rubble-mound breakwater formed by two layers of dolos armor units seaside, two layers of rubble on the lee side, and a thick concrete cap crest. The second structure is similar to the first differing only at the crest; the crest of the latter is formed by two layers of dolos armor units. Because both models were placed behind observation windows, the observation of certain characteristics, such as overtopping height, was made possible.

Test Conditions - In order to verify the models and to make possible further comparisons, both models were first tested under regular wave attack. All tests were carried out at four different water depths varying both the wave height and

Fig. 3 — SKETCH OF RUBBLE-MOUND BREAKWATER.

the frequency. Typical results of these tests are shown in Fig. 4 and 5, respectively for the concrete cap breakwater and the breakwater covered with dolosse. The transmission coefficient, expressed as a percentage, is plotted versus the frequency. The transmission coefficient was also represented as a function of the relative depth, but for the present paper only the frequency is used.

The two models were also submitted to the attack of irregular wave trains which were produced by adjusting the variable amplitudes and phases of the 20 different harmonic components of the programming device. As in the case of regular wave tests, the water depth varied from 45 cm to 60 cm. In order to make even further comparison possible, four different types of wave spectra were simulated on the model on a scale of 1:16. These consist of Neumann⁽⁸⁾, Bretschneider⁽²⁾, Moskowitz^(7,11) and Scott⁽¹²⁾ which are shown in Fig. 6, with the corresponding wind velocities used. The related equations are the same as those in previous studies^(9,10), from which simulated spectra were obtained (Fig. 7).

4. TESTS RESULTS AND ANALYSIS

Fig. 8 and 9 show typical examples of recorded surface profiles of incident and transmitted waves, and the results of the spectral analysis of the above signals in the case of a simulated Neumann spectrum. Fig. 8 corresponds to the concrete cap breakwater with the depth $h = 60$ cm and the simulated significant wave height $H_s = 4.25$ m (13 ft). Fig. 9, on the other hand, corresponds to the other structure for the same values of h and H_s .

By means of spectral analysis^(1,14), the following results were obtained and plotted for all tests involving irregular wave trains: the incident wave spectrum, S_I , from which the significant wave height may be obtained; the transmitted wave spectrum, S_T , from which the transmitted significant wave height

may be obtained; the magnitude of the cross power spectrum, $|S_{IT}|$; the magnitude of the transfer function, $|H(f)|$; and the coherence function $\gamma^2(f)$. Both structures were submitted to the same tests under similar conditions using all four simulated wave spectra. The results were analyzed individually and then compared to each other as well as to regular wave tests. Under the test conditions examined, the following results were found to be the most interesting:

1° Single test analysis

- a) The incident wave energy, S_I , is much greater than the transmitted wave energy, S_T ; consequently the incident significant wave height is also greater than the transmitted significant wave height.
- b) The magnitude of the transfer function, $|H(f)|$, is weak, showing there is very little energy transmitted over the structure.
- c) At frequencies containing energy the coherence function γ^2 generally varies from 0.8 to 1.0, meaning the output signal is affected very little by the presence of noise or the nonlinearity of the signal.

2° Comparison between spectra

- a) When the incident energy spectra were reverted to significant wave heights it was found that only the Neumann and Bretschneider spectra gave values corresponding to the simulated wave height; Moskowitz and Scott with smaller energies gave wave heights about 1 m smaller than the simulated wave height.
- b) For equivalent values of incident energy disregarding the actual wave height as compared to the simulated height, it was found that the transmitted energy varies very little between different spectra.

3° Comparison between structures

- a) The concrete cap breakwater is much more stable than the dolos

crest breakwater, yet the former allows more overtopping than the latter.

- b) Damage tends to occur at almost the same overtopping wave heights for both structures.

4° Comparison with regular wave tests

- a) Observations allowed to establish that 3 or 5 out of every 20 waves would overtop the structure with irregular waves whereas all 20 would overtop the structure with regular waves.
- b) Damage occurs at a faster rate with regular waves than with irregular waves.
- c) The ratio $H_t/H_i(K_t)$ was as high as 50% whereas the ratio H_{ts}/H_{is} only reached 28%.

Figs. 10a and 10b show the relationship between significant wave height and overtopping wave height for all four spectra respectively for the concrete and dolos crest breakwater in 60 cm depth. The same relationship was also found in the case of regular wave trains as shown in Fig. 11a, for the concrete cap and in Fig. 11b for the dolos crest breakwater. Other depth curves have been added on these figures but without the measured points in order not to overcharge the figures. The dispersion of the points is approximately the same for the ones given.

The slope of the curves are approximately the same for the different water depths the difference being only in the ordinate at the origin. Furthermore, visual observations allowed to establish at which overtopping height the breakwater was damaged or destroyed completely. These observations were made for all three exposed faces. Having established that an incident wave height and an equivalent significant wave height have almost identical overtopping heights,

Fig.10 — SIGNIFICANT WAVE HEIGHT VS OVERTOPPING HEIGHT, IRREGULAR WAVES.

Fig.11 — WAVE HEIGHT VS OVERTOPPING HEIGHT, REGULAR WAVES.

it would be possible to predict at which significant wave height the structure will be damaged, using only regular wave trains, the main difference being the quantity of damage.

A comparison between the results obtained for the concrete cap breakwater and the dolos protected breakwater shows that on one hand the former is much more stable than the latter, whereas, on the other hand, the concrete cap structure allows more energy to be transmitted than the dolos protected structure. These differences are primarily due to the difference in the shape of their respective crests.

In order to estimate the relative efficiency of either structure, the ratio of the transmitted significant wave height to the incident significant wave height has been calculated. The characteristic wave height,

$$H_{m_0} = 4\sigma = \sqrt{\int_0^{\infty} S(f) df} \quad (6)$$

σ^2 being the variance of the process, has been used to represent the significant wave height from which the ratio of the transmitted wave height to the incident wave height has been determined. From the results it has been found that, for the concrete cap breakwater, the maximum values of this ratio vary between 0.06 [h = 45 cm ; H = 4.25 m Bretschneider spectrum] and 0.28 [h = 60 cm ; H = 4.25 m ; Neumann spectrum] while the corresponding values for the dolos crested breakwater vary from 0.04 [h = 45 cm ; H = 4.25 m ; Bretschneider spectrum] to 0.19 [h = 60 cm ; H = 4.25 m ; Neumann spectrum]. It should be remembered, however, that this parameter does not take into account the frequency which is an important factor in such a study.

5. CONCLUSIONS

The described tests have shown that the response of a structure gives more information when submitted to the attack of irregular waves than regular

waves. However, the zone of damage caused by given overtopping wave heights is the same regardless of the type of waves used, which implies the predictability of damages. Furthermore, such parameters as the quantity of damage, the rate of wave overtopping, and the total energy of overtopping, and the total energy of overtopping waves are always of greater magnitude when the structure is submitted to regular wave trains.

All the tests with regular waves have been carried out varying the frequency by a small amount at each step. It was noticed that, for one reason or another, the transmission coefficient curves show an oscillating tendency as a function of frequency. Furthermore, the same tests pointed out that the incident wave height curves versus frequency are also oscillating. However, the fact that the incident wave heights may oscillate does not explain entirely the transmission coefficient oscillation; this is subject to further research.

The magnitude of the transfer function shows how the two breakwaters examined are efficient when submitted to irregular wave tests. From the results obtained it can be seen that these breakwaters will, beyond the slightest doubt, prevent or reduce to a minimum energy transmission from the seaside to the lee-side of the structure. Further, to support this affirmation, it has already been seen that the maximum ratio of transmitted significant wave height to incident significant wave height was 0.28.

Results have also shown that the structures are quite stable up to 12 cm (1.9 m prototype) of wave overtopping, major damage begins to occur between 12 and 14 cm of wave overtopping depending on the structure, and total destruction occurs for overtopping heights beyond 16 cm (2.6 m prototype).

CHAPTER 159

FLOATING BREAKWATER PERFORMANCE

by

Bruce H. Adee*

INTRODUCTION

The Pacific Northwestern United States contains large areas of protected waters with abundant recreational boating opportunities. The area also supports many commercial fishermen who use small boats in their fishing operations. As a result, there is a large demand for sheltered moorage for all these vessels. Traditionally, this demand has been accommodated by constructing rubble-mound breakwaters for marina protection. At present, most of the sites where rubble-mound breakwater construction is economically feasible have been used. Conditions at many of the remaining areas for marina development are unsuitable for traditional techniques of marina construction. In general, the cost is too great because the water is too deep, or the environmental degradation resulting from marina development is unacceptable. To satisfy the demand for moorage, while at the same time overcoming the other restrictions, floating breakwaters have been employed at many new marina facilities.

In order to optimize the configuration of floating breakwaters and to overcome the problems which have been encountered with their use, the University of Washington has undertaken a continuing program of research. The aim of this research has been to monitor the performance of existing breakwaters and to develop a theoretical model to predict performance. Using the theoretical model supplemented with appropriate model-scale tests, a series of parametric variations will be tested to determine the effects of these variations on breakwater performance.

At present, several comparisons of the theory with model tests and full-scale performance have been reported by Adee (1975a, 1975b, 1976). This report is a continuation of this effort incorporating data obtained at the Friday Harbor, Washington floating breakwater.

FLOATING BREAKWATER OPERATION

A floating breakwater is illustrated in Figure 1. An incident wave approaches the breakwater. Part of the energy contained in the incident wave is reflected, part passes beneath the breakwater, and some is lost through dissipation. Another part of the incident wave energy excites the motions of the breakwater. These motions are restrained by the mooring system. The oscillating breakwater in turn generates waves which travel away from the breakwater in the direction of the reflected and transmitted waves. The total transmitted wave is the sum of the component which passes beneath the breakwater and the components generated by the breakwater

* Associate Professor, Department of Mechanical Engineering,
University of Washington, Seattle, Washington

motions. The total reflected wave is composed similarly.

To assess the performance of a floating breakwater one single parameter which has been widely used is the transmission coefficient. This is found by dividing the transmitted wave height by the incident wave height. In conducting field experiments or in developing theoretical models the variables affecting performance which need to be measured include:

- (1) Total transmitted and reflected waves (in theoretical predictions the individual components should be predicted).
- (2) Wave forces on the breakwater.
- (3) Motions of the breakwater.
- (4) Forces on the mooring lines.

FIELD MEASUREMENTS

From the outset, obtaining data on the field performance of floating breakwaters was an important component of the research program. A suite of instruments designed to record breakwater performance data was designed and installed at a floating breakwater in Friday Harbor, Washington.

The breakwater at Friday Harbor forms an L shape with the shorter leg extending from a fixed dock connected to shore. The shorter leg is 227 feet and the longer leg 627 feet. The topography at the site offers relatively good protection to the marina and breakwater. Prevailing southwest winds approach almost parallel to the neighboring shore perpendicular to the short leg. The fetch is about one mile in this direction. The most serious exposure is in the northeast direction through a channel affording about a 1.7 mile fetch. Although storms with winds from this direction are not common, a few severe storms of this type may be expected during a Winter storm season. The layout of the breakwater and marina are shown in Figure 2.

Although the original plan was to instrument the longer leg of the breakwater, it became necessary to alter plans and place the instruments in a position to monitor the shorter leg. Several large barges were tied to the longer leg to prevent a recurrence of damage which had occurred in previous severe storms with winds from the northeast.

Figure 2 also shows the instrument locations. Included in the instrument suite were:

- (1) Incident wave measuring buoy.
- (2) Wave buoy located in incident and reflected wave field.
- (3) Two transmitted wave measuring staffs.

- (4) Four load cells in the anchor lines.
- (5) One horizontally mounted accelerometer.
- (6) Two vertical accelerometers mounted near the seaward and shoreward sides of the breakwater.

The horizontal accelerometer provided surge acceleration directly while the average of the vertical accelerometers and the difference yielded heave and roll accelerations, respectively.

A more detailed description of the equipment is provided by Christensen and Richey (1976).

THE FRIDAY HARBOR BREAKWATER

The Friday Harbor floating breakwater is constructed quite differently from other floating breakwaters. This breakwater has a continuous structure whereas most other floating breakwaters have been constructed using discrete modules connected together.

Figure 3 shows a cross section of the Friday Harbor breakwater. The stringers provide continuous lengthwise support for the decking. The breakwater pontoons are made from a centrifugally molded polyolefin. Each pontoon is about 10 feet long and 5 feet wide but very irregular in shape. A view of the breakwater under construction without decking is given in Figure 4. Ballast is required to insure that the breakwater floats at the design water level. This is provided by 1.5 feet of water in each pontoon.

The breakwater is held in position by mooring lines on the seaward and shoreward side at about 50 foot intervals. The mooring line is chain extending about 45 feet below the breakwater. The next portion of each mooring line is double-braided nylon rope followed by another section of chain which connects to piling driven into the bottom.

Further information on this breakwater may be found in Adee (1975b).

THEORY

When one considers the myriad possible breakwater configurations which have been proposed to date and the different conditions which prevail at each potential breakwater site, the number of required model tests and the attendant expense of selecting a configuration becomes very large. To avoid this expense and also to permit parametric studies aimed at obtaining optimum breakwater configurations, a theoretical model was developed. The goal was to theoretically predict the performance which could be measured in laboratory studies or at prototype installations.

The initial restriction imposed on the theoretical model was to consider only two-dimensional conditions. Under this restriction the breakwater is assumed to be very long in one direction with long-crested waves

approaching so that their crests are parallel to the long axis of the breakwater. At most breakwaters where the wave climate results from wind-generated waves, this condition would rarely be approached. However, experiments performed using a boat wake to generate incident waves on the beam and at an angle to a breakwater indicate larger breakwater motions and larger transmitted waves when the incident wave crests approach parallel to the long axis of the breakwater. As a design tool, a two-dimensional theory provides information on the worst conditions which might be expected to occur. In addition, the information available from extensive two-dimensional wave-channel experiments provide the data needed to test the theoretical model.

The approach used here has been to employ the techniques which naval architects have developed to deal with ship-motion problems. Mathematically, the hydrodynamic equations are formulated in terms of a boundary-value problem for the velocity potential. Solution of this complete problem is presently impossible because the free-surface boundary condition is non-linear. An approximate solution may be obtained if restrictions are imposed on the boundary-value problem, and the procedure of linearization is applied. The restrictions limit the applicability of the solution to cases of small incident wave amplitude and small motion response of the breakwater.

Once the equations have been linearized, the performance of the breakwater may be obtained. The calculation procedure is illustrated in the block diagram of Figure 5.

Results obtained using the theory are in good agreement with laboratory and field data (Adee, 1975b, 1975c, 1976). The theory also provides an indication of the influence of fixed-body transmission, and of sway, heave and roll motions on the transmission coefficient at varying values of the beam to wavelength ratio.

RESULTS FROM FRIDAY HARBOR BREAKWATER

The instruments were placed at the Friday Harbor breakwater and a great deal of data was obtained during the Winter season of 1975. While no extreme storm event occurred during the time of observation, there were many occurrences of storms with mean wind speeds on the order of 20 miles per hour. It is interesting to note that when the transmission coefficient is plotted as a function of frequency the results are very consistent.

Because of the great similarity of the results, one record (FH 7-8) was selected for presentation. In this case the wind was nearly perpendicular to the short leg of the breakwater and the average wind speed was 22.9 miles per hour. The average tidal elevation was 5.3 feet above mean lower low water.

The measured and theoretically predicted transmission coefficient as a function of frequency is shown in Figure 6.

The field data was high-pass filtered with a cutoff frequency of 0.05 Hertz in order to remove the influence of tidal variations or wave buoy

motions. After initial processing the data were directly transformed using fast Fourier transformation procedures and smoothed by averaging adjacent raw spectral components. The complete details of data analysis are contained in Adee, Richey and Christensen (1976).

Extensive comparisons between theory and experiment have shown that the hydrodynamic theory is excellent so long as roll motions are small. In the frequency regions where the theory predicts higher roll motions the transmission coefficient may be in error. This is because nonlinear damping is an important factor in determining roll motion. Nonlinear damping is not included in the theory but may be artificially approximated. Experience has shown that by arbitrarily doubling the calculated hydrodynamic damping, better agreement is produced. Damping has been doubled for the theoretical prediction presented in Figure 6.

One advantage of the theory is that it doesn't simply produce a transmission coefficient, but produces sufficient information to determine what factors have an effect on the wave transmission. For the Friday Harbor floating breakwater as for other floating breakwaters the very low frequency waves are unaffected by the structure's presence yielding a transmission coefficient of nearly unity. The first trough in the transmission coefficient at about 0.3 Hertz results from heave- and roll-generated waves cancelling the fixed-body wave transmission. This transmission coefficient is well below the transmission coefficient which would be obtained with the breakwater rigidly restrained and only fixed-body transmission waves passing through. As frequency increases, there is a peak at about 0.38. At this point, the heave-generated wave has almost vanished, and the fixed-body transmission is also small. The larger predicted transmission coefficient is primarily the result of a roll-generated wave with a smaller component resulting from sway motion. The next trough at 0.43 occurs as the heave motion-generated wave increases and cancels the roll and sway motion-generated components. The fixed-body transmission is very small at 0.43. As frequency increases above 0.43 the transmitted wave is almost totally a result of the sway motion of the breakwater.

Another result of great interest to the designer is the force in the mooring lines. In presenting this data a mooring force coefficient is used which is defined as the amplitude of the force oscillation divided by the incident wave amplitude times the weight per unit length of the breakwater.

The mooring-force coefficient for the seaward mooring line of the Friday Harbor breakwater is shown in Figure 7. Here again, the field data has been high pass filtered to eliminate tidal effects and also a low frequency spike which occurs in the mooring-force spectrum. The theoretical prediction is based on computing the spring constants for the three degrees of freedom, multiplying these by the motions and summing force components. From the designers standpoint, the theory predicts the trends accurately and the overprediction at the peak would add to the margin of safety.

The main conclusion which should be reached from these results is that it is possible to measure the performance of floating breakwaters in

the field and that the theory which has been developed predicts the trends of the data and can play a very useful role in design.

PROBLEM OF COMPARISON

The floating breakwater at Friday Harbor, Washington represents one type of breakwater which provides protection by reflecting the energy contained in the incident wave. Other, more compliant breakwaters have been proposed which provide protection by dissipating this energy or by setting up waves which "interfere" with the incident wave. Still other proposed breakwaters attempt to reduce the energy in the incident wave by forcing it to break over some obstacle. Because these concepts are quite different and because few have been tested at prototype scale, a rational comparison of performance is quite difficult with the data presently available. Clearly, from a users point of view, the breakwater offering the best performance for the least cost would be the most attractive.

To present the performance of various types of floating breakwaters in terms of performance per dollar is very difficult. There has been a great variation in the cost of the floating breakwaters constructed to date, even among those of the same type. Besides, with the diversity of materials available and the rapid fluctuations in their prices which has recently taken place, such information would rapidly become obsolete.

In the course of the study of floating breakwaters at the University of Washington, we have often used beam divided by wavelength as the parameter which characterizes the size of the breakwater. This seems to work well so long as the discussion is centered on breakwaters which protect primarily by reflection. When different types such as the reflecting and tethered float breakwater are to be compared using beam to wavelength is inadequate.

An alternative procedure which seems to have merit is to use the square root of the underwater volume per unit length divided by the wavelength as the independent variable. If we are to ever be able to draw fair general comparisons among proposed floating breakwaters, a consistent scheme for presenting performance data should be developed.

NONLINEAR BEHAVIOR

Figure 8 shows a recorded time history of the mooring forces measured at the Tenakee, Alaska floating breakwater. Looking at this figure one can observe an oscillation with a period of about 60 seconds superimposed on the expected shorter period oscillations.

The linear theoretical model permits the system to respond only at the frequency of the incident wave. In order to explain the presence of these long-period oscillations, nonlinearities must be included in the analysis. To perform a mathematically complete analysis including all nonlinear effects is beyond the present state of the art. However, in the case of the floating breakwater, one can show that if two incident waves are considered and second-order terms are retained, then an exciting force is present at the difference between the frequencies of the incident waves. Normally, this

small exciting force would have little effect. Since the structure is only lightly restrained in sway, the natural period is very long for sway motion. The existence of a small exciting force at the sway natural frequency could explain the large oscillation in mooring force.

Because the mooring lines are critical to floating breakwater survival in extreme storm conditions, further research effort on the long-period oscillations is justified.

ACKNOWLEDGEMENT

Financial support for floating breakwater research at the University of Washington has been provided by the U.S. Army Corps of Engineers Coastal Engineering Research Center and through the National Oceanic and Atmospheric Administration Sea Grant Program. Their support is gratefully acknowledged.

CHAPTER 160

DESIGN, ANALYSIS AND FIELD TEST OF A DYNAMIC FLOATING BREAKWATER

D. J. Agerton¹, G. H. Savage², K. C. Stotz³

Interest in floating breakwaters has been generated in recent years because the concept offers the potential of providing a less expensive alternative to traditional, solid wall type barriers for providing permanent wave protection to the thousands of new recreational boat harbors and marinas that have been built in the past 20 years. Also, they may be able to provide temporary, mobile wave protection during construction and installation of offshore facilities for oil transfer and production operations, defense facilities and other offshore structures in deeper water (depths exceeding 50 to 100 feet).

The engineering director of one of the largest and most active offshore oil producing companies recently stated that they would be willing to pay up to \$6 million for a mobile, floating breakwater that had the proven capability to significantly reduce risks due to wave action during offshore erection in the North Sea or elsewhere. Considering the investment in just one deep water oil production platform already exceeds \$100,000,000, the worth of such a reusable, wave protection system during the critical erection period of a platform should be large.

The tethered float concept - a dynamic breakwater: In 1974, Seymour and Isaacs (1) introduced the concept of a submerged, tethered float breakwater, an approach that shows promise of being able to attenuate long period, large, deep-water, storm waves at a sufficiently low cost to be feasible. The system is made up of an array of independently moored, spherical buoys submerged just below the water surface (See Fig. 1). Seymour and Isaacs (1) proposed that, with proper specification of tether length and buoy size, each buoy would have a resonant frequency near that of the anticipated predominant waves for a given location. Owing to their dynamic response, it seemed possible to cause the buoys to pendulate back and forth in the incoming waves out of phase with the wave orbital motions; thus the name: Dynamic Breakwater. The effect of this wave excited buoy motion would be to transform wave energy into water turbulence and then heat in the wake of the buoy.

¹Engineering Ph.D. Candidate, University of New Hampshire.

²Professor of Engineering, University of New Hampshire.

³Associate Professor of Electrical Engineering, University of New Hampshire.

Additions and modifications to the tethered float concept: Before and during Isaacs's and Seymour's work Savage and others (2,3,4) had been investigating solid rubber filaments for various buoy mooring applications, and suggested that the use of such moorings would improve the survivability and longevity of such a floating breakwater. Follow-up of this idea soon presented the possibility of significantly increasing the wave attenuation efficiency of the Isaacs-Seymour system. A buoy tether's spring constant might be chosen so it resonated with the predominate wave frequency in the vertical as well as in the horizontal direction. Thus, each buoy could be expected to create more turbulence and dissipate more energy than an inelastically-tethered one. Wave tank model studies of this approach with a single elastically-tethered buoy in 1974 confirmed the possibility of achieving orbital buoy response out of phase with the orbital water particle motion, and encouraged us to proceed.

Research objectives and scope: The three aspects of our investigation were:

- 1) to compare the dynamic response and wave attenuation by tethered buoys with different tether elasticities, float shapes, spacings, and levels of submergence in a wave tank,
- 2) to develop predictive mathematical models of buoy response and wave attenuation in wave tank and field tests,
- 3) to conduct a large enough lake scale model test so that the Reynolds number and period parameter would be large enough for fully turbulent wake conditions to be developed in the buoy field; a condition that we expected to prevail in a full scale system.

The last objective seemed the most significant because successful achievement of fully turbulent flow conditions in a model would permit model results to be used to predict full scale breakwater performance. At the time no other field tests had been carried out for a tethered float array.

WAVE TANK TESTS

The wave tank tests were conducted in the ship model towing facility of the Massachusetts Institute of Technology, Cambridge, Massachusetts. One set of tests measured the dynamic response of a single buoy to sinusoidal wave of various heights and frequencies. Several different shapes of buoys and tethers with different spring constants were used. Buoy response was recorded by means of an optical displacement follower which could continually track the oscillating buoy using only light and no instruments in direct contact with the buoy or its tether. The three float shapes tested were a sphere, a sphere with a concentric disk around its girth (a "Saturn ring"), and an egg. The scale size of the buoy was assumed from Seymour and Isaacs (1) work with a sphere which had shown that "reasonable diameters for the breakwater will be of the same order as the significant wave height".

The buoy shape and tether selected were a sphere with a tether with a low spring constant so that the buoy response to the significant waves in our model sea state and water depth was a near circular orbit (See Fig. 2). The preliminary mathematical model of the system had indicated that such an orbital response would result in the greatest energy dissipation due to form drag for a single buoy. The spherical buoy shape was selected over the other two tested because it was the shape that gave significant vertical as well as horizontal response; *i.e.* near-circular buoy motion.

We then constructed arrays of both wire and elastically-tether buoys across the wave tank and subjected these model dynamic breakwaters to both regular and irregular seas (See Fig. 3). The incident and attenuated waves were measured and recorded and the respective wave energies were calculated. These wave tank breakwater model tests gave results that supported the validity of our first analytical prediction models that elastically-tethered floats dissipated more energy than wire-tethered ones. Other results are shown in Fig. 4.

MATHEMATICAL MODELING

Modeling an elastically-tethered dynamic breakwater requires four steps: (a) writing equations of motion for a tethered buoy in two dimensions; (b) solving those equations for buoy relative velocity; (c) computing the rate of energy dissipation (drag power) of a row of buoys; (d) compounding the drag power row-by-row through the array. In light of the two-dimensional nature of the problem and the complexities introduced by elastic tethers, we did not rely solely on the simplified linear-model approach of Seymour (5). Solution to the non-linear, coupled problem is detailed in a dissertation by Agerton (6) and summarized below. It is a solution of the general case; not restricted to a wire-tethered system.

Modeling wave forces: Force on a fixed object in one-dimensional oscillatory flow can be formulated by the Morison equation as the sum of nonlinear drag and inertial components (7). Frontal area A and flow coefficients C_D and C_M are considered constant.

$$F = F_D + F_I \quad (1)$$

$$F = \frac{1}{2} \rho A C_D |u|u + \rho V_o (1 + C_M) \dot{u} \quad (2)$$

In one-dimensional oscillatory flow, the only dimensionless parameter correlated with drag and mass coefficient is period parameter (8,9) defined as:

$$PP = U_m \tau / d = 2\pi a / d \quad (3)$$

where a is the amplitude of water motion relative to the object. However, the relationship between flow parameters, object dimensions, and flow-force coefficients is not well understood, particularly in two-

dimensional oscillatory flow as would occur in waves in a field experiment. Furthermore, if the amplitude to diameter ratio were the only important parameter, then the scaling of drag forces would present no problem. We have heard no investigator propose that to be the case.

Complexity of the problem increases for two-dimensional flow problems -- as occur for waves acting on a submerged tethered sphere or horizontal cylinder parallel to the wave crests. In such cases, the turbulent wake would appear to rotate around the object during the wave cycle. The vector force can be written by the Morison formulation. Area presented to the flow is the same from all directions. Also, it is assumed C_D and C_M do not change with direction.

$$\vec{F} = \vec{F}_D + \vec{F}_I \tag{4}$$

$$\vec{F} = \frac{1}{2} \rho A C_D |\vec{r}| \vec{r} + M_W (1 + C_M) \ddot{\vec{r}} \tag{5}$$

where \vec{r} is the relative velocity of the fluid and $\ddot{\vec{r}}$ is its relative acceleration. Both can be resolved into horizontal and vertical components. The one and two-dimensional formulations are compared below:

Two-dimensional formulation

One-dimensional formulation

$$F_x = D u \sqrt{u^2 + v^2} + N \dot{u}$$

$$F_x = D |u| u + N \dot{u} \tag{6}$$

$$F_y = D v \sqrt{u^2 + v^2} + N \dot{v}$$

$$F_y = D |v| v + N \dot{v} \tag{7}$$

If only maximum force predictions are of interest, both formulations give the same result. However, when considering wave-force history and energy dissipation, the two-dimensional problem should be formulated as such or justifiably de-coupled into a pair of one-dimensional equations.

By computing the drag work during a wave cycle, one finds that about 15% less energy is dissipated by the one-dimensional formulation. A similar comparison for an elastically tethered sphere is not as simply accomplished because the object has both horizontal and vertical relative velocity whose magnitudes are not necessarily equal. However, the 15% difference in calculated dissipation represents the maximum.

Coefficients of mass and drag: Data on which to base estimates of drag and mass coefficients for spheres in waves are neither plentiful nor consistent. Seymour (5) was first to estimate flow coefficients for tethered spheres in irregular waves in both the laboratory and the ocean. He concluded that at values of rms a/d greater than 0.80, the average C_D was constant. This indicated to him that the flow was fully turbulent -- that is, the wake was fully developed. He further observed that C_M decreased in a gradual linear fashion with increasing a/d ratio, so assuming a single value over a particular excitation spectrum was an acceptable approximation. When the sphere was less rigidly restrained, Seymour observed that C_D increased almost two-fold. He hypothesized that lateral vibration increased the width of the wake and, therefore, the form drag. Laird (10) made similar observations for cylinders. Sarpkaya (9) recently calculated C_D and C_M over a range of period para-

meters in one-dimensional oscillatory flow. The sphere was not rigidly restrained. At a/d ratios greater than about 3.0, C_D was constant at about 0.75, much higher than Seymour had measured. Below 3.0, it decreased in an almost linear fashion. In an ocean experiment, Seymour (5) inferred values of 0.35 and 0.25 for C_M and C_D respectively for a tethered sphere in two-dimensional flow. These were about 70% higher than those calculated in laboratory experiments, a difference he attributed to transverse vibration. Values of flow coefficients estimated by Seymour in the field were initially adopted to carry out the design of our experiments because he had made the only large-scale measurements in two-dimensional flow.

Modeling buoy response and energy dissipation: Fig. 5 depicts the geometry of an elastically-tethered sphere in waves. Based on wave tank observations and on the analysis of elastic tethers, articulation and catenary were assumed negligible (4,11). The working range of the elastic tether is approximately linear (11). Depending primarily on the thickness of the tether, drag forces on the mooring may be substantial. Formulating drag force on a differential section of tether whose free end moves with the velocity of the buoy \dot{x} , and integrating over the length yields:

$$F_{Dt} = \frac{1}{6} \rho A_t C_{Dt} |\dot{x}| \dot{x} \quad (8)$$

Buoyancy, acceleration, wave, and tether forces on the tethered buoy can be resolved into horizontal and vertical components, summed, and algebraically re-arranged to yield non-linear coupled equations of motion.

$$M_x \ddot{x} + D_x |\vec{r}| (\dot{x} - u) + D_t |\dot{x}| \dot{x} + T \sin(\theta) = N_x \dot{u} \quad (9)$$

$$M_y \ddot{y} + D_y |\vec{r}| (\dot{y} - v) + T \cos(\theta) - F_B = N_y \dot{v} \quad (10)$$

$$\text{where } u = a w e^{-kz} \cos(\omega t - kx) \quad v = -a w e^{-kz} \sin(\omega t - kx) \quad (11)$$

Drag power is written:

$$P_{D_x} = \frac{1}{2} \rho A C_D |\vec{r}| u_r^2 \quad P_{D_y} = \frac{1}{2} \rho A C_D |\vec{r}| v_r^2 \quad (12)$$

$$\text{where } u_r(t) = \dot{x}(t) - u(t) \quad v_r(t) = \dot{y}(t) - v(t) \quad (13)$$

$$\text{Total drag is then: } P_D = P_{D_x} + P_{D_y} \quad (14)$$

Integrated over a wave period τ , the drag power and wave power are compared to yield the proportion of wave energy dissipated by a single row of buoys. This is adjusted for buoy packing density β .

$$\lambda_1(\omega_1 a_1) = \beta \frac{\int_0^{\tau} P_D dt}{\int_0^{\tau} P_W dt} \quad (15)$$

It is assumed that the amplitude reduction is completed a short time after the buoy and water have interacted. Therefore the attenuated amplitude is the incident wave amplitude for the second row of buoys.

Through compounding successive simulations, attenuation by an array of buoys can be modeled. However, because dissipation by each row is small, large error is not incurred by assuming all rows are equally effective (6). Dissipation by an array of n rows can therefore be estimated as:

$$a_n^2/a_1^2 = (1-\xi)^n \quad (16)$$

Solving for the number of rows to provide a particular level of dissipation requires solving the equations of motion.

Solution by simulation: The IBM Continuous System Modeling Program (CSMP) was used to simulate the response of an elastically-tethered buoy. Simulation in regular waves permitted calculation of frequency response, energy dissipation, and spatial plotting of the orbiting buoy. Results indicated that elastically-tethered elements could be more effective than comparable wire-tethered elements even though the former required deeper submergence to avoid broaching the surface. Although dissipation in the horizontal direction was actually less, this reduction was more than compensated for by an increased contribution in the vertical dimension. To simulate the response of the tethered element in irregular waves, we used the sum of thirteen randomly phased Fourier components as measured in a lake for the excitation. At a selected time interval, data was written to disk file for subsequent spectral analysis.

The previously discussed one and two-dimensional drag-force formulations were compared through simulation. C_D and C_M were assumed constant for each direction. Linear elongation of the elastic tether was varied over a range of values from 4% to 200%. Regardless of the elastic constant selected, response and dissipation varied no more than 10% in all cases tested; therefore, using the simpler, one-dimensional drag force formulation is an acceptable approximation for a linear model.

To discuss the relationship in irregular waves between relative velocity and energy dissipation requires a linearized model of dissipation so the phenomenon can be treated as a sum of Fourier components (6). Furthermore, complete linear analysis permits more design insight than the trial and error approach of simulation.

Linear analysis: The restoring forces in the equations of motion can be decoupled and linearized. Expressions for the water particle kinematics in a deep-water Airy wave can be simplified by assuming the spatial movement of the buoy will not substantially affect the water velocities and accelerations adjacent to the buoy.

Seymour (5) extended Jacobsen's (12) damping linearization to broadband irregular flows using a statistical approach and minimizing the difference in dissipation calculated by linear and non-linear models. The linearized drag term for the buoy drag is of the form DU_0u_r . U_0 is the "characteristic" relative velocity:

$$U_0 = 16\sigma_{u_r}/3\sqrt{2\pi} \quad (17)$$

where σ_{u_r} is the square root of the variance of relative velocity in one dimension. Seymour's approach was applied to linearizing the drag

of the tether. The linearized tether drag is of the form $D_t U_t \dot{x}$ where:

$$U_t = 16\sigma_x / 3\sqrt{2\pi} \quad (18)$$

Equations 9 and 10 in linearized form are written:

$$M\ddot{x} + [D'_x + D'_t]\dot{x} + K_x x = D'_x u + N\dot{u} \quad (19)$$

$$M\ddot{y} + [D'_y]\dot{y} + K_y y = D'_y v + N\dot{v} \quad (20)$$

where $D'_x = D_x U_0$ and $D'_t = D_t U_t$ (21)

$$K_x = (\rho V_0 - M_s)g/l_0 \quad K_y = k_t \quad (22)$$

Equations 19 and 20 are analogous; only operations on the first will be discussed. Lumping linearized drag terms ($D'' = D'_x + D'_t$) and taking the Laplace transform of each side of the Eq. 19, yields the transfer function of the buoy in the horizontal dimension:

$$H_x(s) = \frac{X(s)}{P(s)} = \frac{D's + Ns^2}{Ms^2 + D's + K_x} \quad (23)$$

The transfer function of relative velocity is:

$$H_{u_r}(s) = \frac{(N-M)s^2 - D_t's - K_x}{Ms^2 + D''s + K_x} \quad (24)$$

Changing from the Laplace transform to a Fourier transform, the predicted spectrum of horizontal relative velocity is:

$$S_{u_r}(\omega) = S_u(\omega) |H_{u_r}(\omega)| \quad (25)$$

where $S_u(\omega)$ is the spectrum of horizontal water particle velocity. The variance of relative velocity is calculated as:

$$\sigma_{u_r}^2 = \int_{-\infty}^{\infty} S_{u_r}(\omega) d\omega \quad (26)$$

The three previous equations are solved iteratively using estimates of the variances of buoy velocity \dot{x} and buoy relative velocity u_r to initiate the double transcendental solution.

Average drag power of a buoy over a frequency band is:

$$\bar{P}_{D_x}(\omega) = \frac{1}{2} D'_x U_r^2(\omega) \quad (27)$$

Therefore, $\bar{P}_{D_x}(\omega) = \frac{1}{2} D'_x S_{u_r}(\omega)$ (28)

Drag dissipation due to the tether is relatively small and therefore, neglected. Energy dissipation by a row of buoys is modeled over each averaged frequency band as the sum of the dissipation by Fourier components in each dimension.

$$\bar{x}(\omega) = \frac{1}{2} \beta \frac{[D'_x S_x u_r(\omega) + D'_y S_y v_r(\omega)]}{P_w(\omega)} \quad (29)$$

Knowing the transcendental solution to each equation, one can calculate the resonant frequencies of the system. Natural frequencies for a tethered buoy whose mass is small and respect to the displaced water and whose tether is a linear spring are written:

$$\omega_{nx} = \sqrt{g/(C_m l_o)} \quad \text{and} \quad \omega_{ny} = \omega_{nx} \sqrt{l_o/(l_o - r_o)} \quad (30)$$

where r_o is the unstretched tether length and l_o is its stretched length. Damping ξ is calculated as $D/2M\omega_n$. Resonant frequency is calculated according to the equation:

$$\omega_r = \omega_n \sqrt{1 - \xi^2} \quad (31)$$

The linearized model provides the analytical tool for matching the system response to predicted wave frequency by indicating the proper tether length and spring constant. The analysis indicates that vertical resonance will always be at a higher frequency than horizontal resonance. One possibility for altering this relationship may lie in using an ellipsoidal buoy so that the area exposed to the flow and the flow co-efficients are different in the horizontal and vertical dimensions.

FIELD TEST

The field test model was designed for installation about 100 yards off the northwest shore of Diamond Island in Lake Winnepesaukee, the largest lake in New Hampshire (See Fig. 6). The storm winds from the northwest had a six to nine mile fetch over which to build wave energy to test the system. We anticipated a maximum of three to four-foot significant waves with a three second peak period based upon the historical observation of long-time residents in the area.

The dynamic breakwater array: The breakwater float array was moored by a level steel frame anchoring grid designed by Vidal (13) with adjustable legs to level it on the bottom like a multilegged table. Buoys were then tethered to their anchoring frame so each tether was the same length. Such an anchoring system would not be practical for a working prototype system, but was used here because it provided an immobile base and simplified the subsequent analysis. It also focused the project on the effects of the elastic tethers and the floats. Such an anchoring frame was also consistent with the installation equipment, funds and talents available to us. The anchoring surface of the frame was 21 feet below the mean

free water surface after installation. The bottom sloped from approximately 27 feet to 35 feet from the shore side to the weather side of the frame.

The 90 floats in the array were 22 inch diameter plastic, inflatable, near-spherical floats. They were tethered with two parallel, one inch diameter solid rubber filaments as shown in Fig. 7. From previous work done by Savage (2,3) and our own tests of the spring constant for available solid rubber filaments, we had specified a filament with a linear spring constant of 15 lbs/foot elongation after initial loading to 120 pounds. However, the material we finally received did not meet specification by a wide margin. Its spring constant was about 35 lbs/foot elongation; so we were unable to obtain the desired magnitude of vertical response of the buoys in even the highest sea states. After discussions with several large manufacturers of rubber we have concluded that knowledge of rubber creep and elastic properties is not sufficiently complete to provide consistent and predictable material properties of the kind we have been seeking.

The array and instrumentation: Fig. 8 shows the plan and side views of the breakwater array that was installed at Lake Winnepesaukee and the location of wave staffs to measure the incident and attenuated waves. Details of the design of these transmission line wave staffs will be available in a publication by Winn, Stotz and Delano (14). As indicated in Fig. 8, one tether was instrumented to permit measurement of buoy motion response. Data from this buoy provided a check on our analytical models of dynamic response.

The effects of diffraction were not directly addressed in this experiment, but we believe such effects were not significant because our breakwater was not a thin, impervious wall. Also, the wave staff measuring the attenuated waves behind the breakwater was located in the middle and close to the breakwater as shown in Fig. 8. It would therefore have received the minimum possible energy transmitted by diffraction if there was any at all.

The greatest difficulty in the field experiment arose from the excessive creep of the rubber tethers that caused some of the floats to come to the surface, and these had to be pulled back down with shortened tethers to maintain design depth. It was here that the lack of quality control on the delivered rubber filaments showed up to seriously hinder the project, but the problem was overcome at the expense of greatly increasing the spring constant of the tethers which altered the breakwater vertical response from the original design.

RESULTS AND DISCUSSION OF THE FIELD EXPERIMENT

The least controllable aspect of the field experiment was the weather. Moderate cold fronts during the fall brought waves only as high as 2.0 feet significant height. A week before winter ice set in, waves 2.5 feet in significant height were recorded. The energy dissipation by the breakwater averaged over nine five-minute records from December 18, 1975 was 51%. Averaged over five records from November 5, it was 53%.

Several adjacent records from each day were selected for detailed analysis and modeling. Averaged incident and attenuated wave spectra measured over a ten-minute interval are shown in Fig. 9. Assuming rows were equally efficient, then each row dissipated about 8% of its incident wave energy.

Modeling buoy response and dissipation: In general, the measured horizontal buoy response was about five times greater than the vertical -- less than we had sought due to the undesirably high tether modulus.

C_D and C_M were estimated by matching the model results to the measured response of a wire-tethered buoy which was switched temporarily into the array so buoy response data with minimum cable drag could be acquired. The best correspondence between measured and modeled buoy motions was for a $C_D = 0.42$ and $C_M = 0.50$. These high values, coupled with the estimated rms a_T/d ratio of 0.65, indicated that the buoy wake was not fully developed as we had expected.

C_D and C_M of 0.42 and 0.50 respectively also yielded the closest fit between measured and modeled response for the elastically-tethered buoy. Fig. 10 compares the measured and modeled frequency response for several averaged records from December 18, and Fig. 11 makes the same comparison for the spectrum of horizontal relative velocities.

From horizontal and vertical spectra of relative velocity, the linearized drag power was computed over each frequency band in each spectrum. Results are compared with those measured in the field in Fig. 12. The lines of least-squares fit correspond in the region of highest energy density. Discrepancies at high frequencies may be due to breakdown of the model in that region. The results of the linear model correspond reasonably well with those of the coupled non-linear model.

CONCLUSIONS

From further investigation of the linear and non-linear models, it appears that their results are within 10% of one another for tether elongations from 0% to 30%, the measure of tether compliance used in our work. At 100% elongation, it appears most elastically-tethered systems can be more effective than their wire-tethered counterparts. However, their performance advantage is marginal because the buoys with more compliant tethers must be submerged deeper to avoid broaching the surface. Also the elastic tether is many times thicker than its wire counterpart and adds damping to the horizontal response; thereby reducing the energy dissipation by the buoy. Finally, it appears that a fully-developed wake (analogous to supercritical, steady flow) is not a necessary condition for maximum energy dissipation. Assuming that $C_D = 0.25$ and $C_M = 0.35$ characterize fully turbulent flow and that $C_D = 0.42$ and $C_M = 0.50$ characterize sub-critical turbulent flow, the models indicate that maximum dissipation by a tethered sphere system could be the same for each flow regime. However, the optimum tether length would be different for a given buoy operating in one flow regime or the other.

In summary, we found it was possible to remove 50% of the wave energy using a nine-row array of tethered buoys, and that we could model the

energy dissipation fairly accurately. Our test of the performance advantage of elastic tethers was not conclusive because of manufacturing problems and present state-of-the-art limitations. Our understanding of relationships between wake development and buoy size relative to wave parameters over a range of scales in two-dimensional oscillatory flow is incomplete.

CHAPTER 161

PROTECTION OF MARITIME STRUCTURES AGAINST SHIP COLLISIONS

by

Kazuki Oda* and Shoshichiro Nagai**

ABSTRACT

This paper deals with the analytical and experimental studies on a new device to prevent the accidents of ship collisions with maritime structures. The practical protection device was designed on the basis of this study and it has been in use for the prevention of ship collisions of a class of 1,000 G/T with a boring tower for the geological survey of the sea beds of a narrow straits in which quite a many ships navigate.

INTRODUCTION

For the recent several years, maritime structures such as drilling platforms, intake towers of cooling water for thermal and/or nuclear power plants and also bridge piers have been constructed nearshore and offshore throughout the world. When they are constructed in seas or straits where many ships navigate, there exists a great possibility of ship collisions with such maritime structures.

In the case of Japan in which several long bridges are being constructed to span the narrow straits with strong tidal currents and quite a many navigation ships, this problem has been considered to be very serious from the points of view of safety navigation as well as the protection of the bridge pier from ship collisions. Even during the terms of the preliminary geological survey of the sea beds at the projected construction sites of the piers of the long bridges, there have been already a lot of accidents of ship contacts with the boring towers for the geological survey. Therefore, it has been urgently needed to find ways for prevention of the accidents of contacts and collisions with erection jackets during the construction of the piers and the piers themselves after the completion of the bridges.

As a result, a new protection device capable of turing securely the original course of approaching vessels to the piers in front of them was proposed by our laboratory and the Honshu-Shikoku Bridge Authority. It consists of three large buoys anchored to the sea bottom and two pressure pneumatic rubber tubes-lines which are tightened with the restoring forces of mooring buoy system and float on the water surface as shown in Fig.1.

** Professor of Hydraulic Engineering, Faculty of Engineering, Osaka City University, Osaka, Japan.

Fig.1. Schematic diagram of the protection device

The analytical and experimental studies were carried out in the hydraulics laboratory of Osaka City University to examine the effect of the proposed protection device and to predict the tensions of the mooring lines of the buoys and the rubber tubes-lines.

APPROACHING CONDITIONS OF SHIPS TO THE DEVICE

(1) Gross tonnages of ships

The results of the investigation on ships passing through the Akashi Straits, the Eastern Bisan Straits and the Kurushima Straits in the Seto Inland Sea, which was conducted by Kobe Mercantile Marine College and Maritime Safety Agency of Japan in July of 1971, are shown in Figs.2, 3 and 4 respectively.

According to these figures, the average number of ships per day passed through is more than 1,000 in every straits. Especially in the Akashi Straits, it comes up to more than 2,000. It will be noted, however, that more than 80% of total ships, including almost all of passenger boats, ferry boats and fishing boats, are smaller ships than 500 G/T while large ships greater than 3,000 G/T are very few in every straits.

It is considered to be quite difficult to protect the piers from the collisions of ships greater than 10,000 to 20,000 G/T by the aid of the device proposed here because of their much larger momentum. For the protection of piers against the collisions of such larger ships, the another way using a steel jacket fender system fixed on the pier is being examined now.

Consequently, it was decided that the gross tonnages of ships considered here to be approaching vessels were 1,000 to 2,000 G/T.

Fig.2. Statistics of ships per day passed through the Akashi Straits

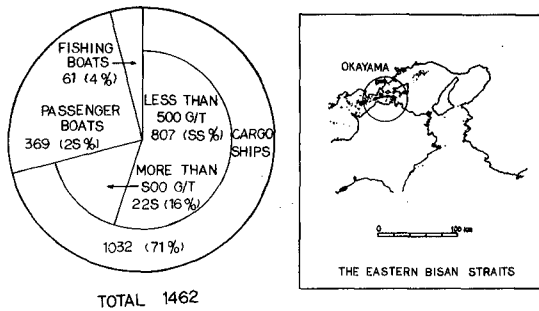

Fig.3. Statistics of ships per day passed through the Eastern Bisan Straits

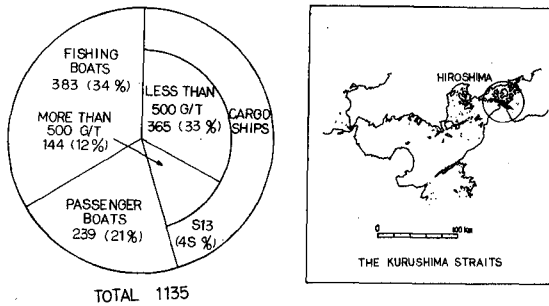

Fig.4. Statistics of ships per day passed through the Kurushima Straits

(2) Approaching speeds and heading angles

According to an annual report "Statistics of Vessels in 1970" published by Ministry of Transportation, 83 to 87% of vessels between 1,000 to 3,000 G/T travel with a speed of 10 to 14 knots.

Since the traveling speeds of ships, however, will be decelerated by the captain in emergency, it may be considered that the approaching speeds into the protection device are less than the usual traveling speeds. As a result, the approaching speeds of ships of a class of 1,000 to 2,000 G/T into the protection device were decided to be 8 to 10 knots in this study.

In general, ships are steered to be almost paralleled to the seaways regulated in narrow straits. Accordingly, the approaching heading angles into the device were taken to be 10 to 15 degrees to the direction of seaway.

THEORETICAL ANALYSIS

1. Basic equations of motion of a ship

A set of co-ordinate axes, x_G, y_G with the origin fixed at the center of gravity of a ship as shown in Fig.5 is used to set up basic equations of motion of a ship. The x_G - and y_G - axes represent the longitudinal and transverse horizontal axes of the ship respectively.

Fig.5. Co-ordinate system

By reference to these co-ordinate axes, equations of motion of the ship in horizontal plane can be written as follows.

$$\left. \begin{aligned} m(\dot{u}_G - \omega v_G) &= X && \text{(sway)} \\ m(\dot{v}_G + \omega u_G) &= Y && \text{(surge)} \\ I_{ZZ}\dot{\omega} &= N && \text{(yaw)} \end{aligned} \right\} (1)$$

where: m = mass of the ship

I_{ZZ} = moment of inertia about the vertical axis through the center of gravity of the ship

u_G, \dot{u}_G = components of the ship velocity and acceleration in x_G -axis direction

v_G, \dot{v}_G = components of the ship velocity and acceleration in y_G -direction

$\omega, \dot{\omega}$ = angular velocity and acceleration about the vertical axis
 X, Y and N = total external forces and moments including hydrodynamic and other non-hydrodynamic forces and moments

The effects of waves and winds are not considered in this treatment. The effects of the coupling roll, pitch, and heave motions into horizontal motion are assumed negligibly small.

The components of external forces X, Y and moments N are expressed as follows for the case of zero rudder angle in linear theory:

$$\left. \begin{aligned} X &= X_u u_G + X_{\dot{u}} \dot{u}_G + X_v v_G + X_{\dot{v}} \dot{v}_G + X_{\omega} \omega + X_{\dot{\omega}} \dot{\omega} + f_x \\ Y &= Y_u u_G + Y_{\dot{u}} \dot{u}_G + Y_v v_G + Y_{\dot{v}} \dot{v}_G + Y_{\omega} \omega + Y_{\dot{\omega}} \dot{\omega} + f_p + f_y \\ N &= N_u u_G + N_{\dot{u}} \dot{u}_G + N_v v_G + N_{\dot{v}} \dot{v}_G + N_{\omega} \omega + N_{\dot{\omega}} \dot{\omega} + f_{\phi} \end{aligned} \right\} \quad (2)$$

where f_x, f_y and f_{ϕ} are the components of non-hydrodynamic external forces and moments. f_p is propulsive forces. $X_{\dot{u}}, X_{\dot{v}}, X_{\dot{\omega}}, Y_{\dot{u}}, Y_{\dot{v}}, Y_{\dot{\omega}}$, and $N_{\dot{u}}, N_{\dot{v}}, N_{\dot{\omega}}$ are hydrodynamic coefficients concerning added masses. $X_u, X_v, X_{\omega}, Y_u, Y_v, Y_{\omega}$ and N_u, N_v, N_{ω} are hydrodynamic coefficients concerning damping forces.

On the assumption that the ship is symmetric with respect to the longitudinal and transverse centerline plane, and that the center of gravity of added mass is coincident with that of the ship, $X_v, X_{\dot{v}}, X_{\dot{\omega}}, Y_u, Y_{\dot{u}}, Y_{\dot{\omega}}, N_{\dot{u}}$ and $N_{\dot{v}}$ can be regarded as zero.

Furthermore, neglecting the effect of damping forces and moments except the damping term $Y_v v_G$ in the surge motion and using nonlinear damping forces $C v_G^2$ instead of linear damping forces $Y_v v_G$, Eq.(2) may be simplified as follows.

$$\left. \begin{aligned} X &= -m_x \dot{u}_G + f_x \\ Y &= -m_y \dot{v}_G - C v_G^2 + f_p + f_y \\ N &= -J_{ZZ} \dot{\omega} + f_{\phi} \end{aligned} \right\} \quad (3)$$

where: $-m_x = X_{\dot{u}}$ added mass in X_G -axis direction
 $-m_y = Y_{\dot{v}}$ added mass in Y_G -axis direction
 $-J_{ZZ} = N_{\dot{\omega}}$ added moment of inertia about the vertical axis
 $C =$ dimensional coefficient of total ship resistances

2. Equations of motion of the ship after contact with the protection device

(1) Co-ordinate system

The co-ordinate system and the symbols used in the theoretical analysis concerning the protection device are shown in Fig.6.

Fig.6. Co-ordinate system and definition sketch of the protection device

The definitions of the symbols in Fig.6 are as follows.

X, Y = co-ordinate axes fixed on the earth with the origin at the center of the main buoy

x_G, y_G = co-ordinate axes with the origin at the center of gravity of the ship

A_{B1}, A_{Br}, B, C = anchor points of each buoy

l_{AB}, l_{AC} = initial distances between the main buoy and the sub-buoy

A, B, C = center points of each buoy

p = contact point with the rubber tubes-line

u_G, v_G = components of the ship velocity in the directions of x_G - and y_G -axes at the center of gravity G

u, v = components of the ship velocity in the directions of x_G - and y_G -axes at the contact point p

ω = angular velocity about the vertical axis of the ship

ϕ = heading angle of the ship to the Y-axis

f_x, f_y = components of the reaction forces on the contact point exerted by the deflection of the rubber tubes-line

The subscript 0, herein, denotes the quantities at the initial time.

(2) Basic assumptions

The following assumptions are introduced to simplify the theoretical analysis on the protection device.

- (a) The movements of the main buoy A are negligibly small.
- (b) Therefore, the movements of the rubber tubes-line AC of the opposite side to the line AB contacting with the ship can be also neglected.
- (c) The configurations of the mooring lines of every buoy can be regarded as straight without any slack.
- (d) The elongations of the mooring lines of the buoys and the rubber tubes-line can be neglected.
- (e) The hydrodynamic forces induced by the movement of the sub-buoy and the rubber tubes-line may be neglected.
- (f) The frictional forces between the rubber tubes-line and the ship hull are minor.
- (g) While the ship is in contact with the rubber tubes-line, the propulsive forces of the ship is constant and the rudder angles is stationarily zero.
- (h) The point of the ship in contact with the rubber tubes-line is stationarily on the bow shoulder of the ship.

(3) External forces and moments on the ship

On the above assumptions, the external forces and moments acting on the ship in contact with the rubber tubes-line are obtained as follows.

Referring to Fig. 7, components of the reaction forces, f_x and f_y on the contact point exerted by the deflection of the rubber tubes-line from the original straight line can be expressed as follows.

$$\left. \begin{aligned} f_x &= - \{ T_{BP} \sin(\theta_{BP} - \phi) - T_{AP} \sin(\theta_{AP} - \phi) \} \\ f_y &= - \{ T_{AP} \cos(\theta_{AP} - \phi) - T_{BP} \cos(\theta_{BP} - \phi) \} \end{aligned} \right\} \quad (4)$$

where: T_{AP}, T_{BP} = tensions of the segments AP and BP of the rubber tubes-line respectively

θ_{AP}, θ_{BP} = angles between the segments AP, BP of the rubber tubes-line and Y-axis respectively

Fig. 7. Definition sketch of the external forces and moments

Since the assumption (f) yields $T_{AP} = T_{BP}$, Eq. (4) can be rewritten as follows.

$$\left. \begin{aligned} f_x &= -T_{AB} \{ (\sin\theta_{BP} - \sin\theta_{AP}) \cos\phi - (\cos\theta_{BP} - \cos\theta_{AP}) \sin\phi \} \\ f_y &= -T_{AB} \{ (\cos\theta_{AP} - \cos\theta_{BP}) \cos\phi + (\sin\theta_{AP} - \sin\theta_{BP}) \sin\phi \} \end{aligned} \right\} \quad (5)$$

where T_{AB} , which is used in place of T_{AP} and T_{BP} , is the tensions of the rubber tubes-line.

From the geometrical relations shown in Fig. 8, the following equations are derived.

$$\left. \begin{aligned} \sin\theta_{AP} &= -\frac{x}{\sqrt{x^2 + y^2}} \\ \cos\theta_{AP} &= \frac{x}{\sqrt{x^2 + y^2}} \\ \sin\theta_{BP} &= \frac{x - b_x}{\sqrt{(x - b_x)^2 + (y - b_y)^2}} \\ \cos\theta_{BP} &= -\frac{y - b_y}{\sqrt{(x - b_x)^2 + (y - b_y)^2}} \end{aligned} \right\} \quad (6)$$

Substituting Eq. (6) into (5), Eq. (7) is obtained.

Fig.8. Geometrical relations of the rubber tubes-line

$$\left. \begin{aligned}
 f_x &= -T_{AB} \left\{ \left(\frac{x - b_x}{\sqrt{(x - b_x)^2 + (y - b_y)^2}} + \frac{x}{\sqrt{x^2 + y^2}} \right) \cos\phi \right. \\
 &\quad \left. + \left(\frac{y - b_y}{\sqrt{(x - b_x)^2 + (y - b_y)^2}} + \frac{y}{\sqrt{x^2 + y^2}} \right) \sin\phi \right\} \\
 f_y &= -T_{AB} \left\{ \left(\frac{y - b_y}{\sqrt{(x - b_x)^2 + (y - b_y)^2}} + \frac{y}{\sqrt{x^2 + y^2}} \right) \cos\phi \right. \\
 &\quad \left. + \left(\frac{x - b_x}{\sqrt{(x - b_x)^2 + (y - b_y)^2}} + \frac{x}{\sqrt{x^2 + y^2}} \right) \sin\phi \right\}
 \end{aligned} \right\} \quad (7)$$

External moments f_ϕ around the vertical axis through the center of gravity of the ship induced by these forces f_x , f_y are given by Eq.(8).

$$f_\phi = - (af_x - bf_y) \quad (8)$$

where a and b are the lengths of moment arms of f_x and f_y around the center of gravity of the ship shown in Fig.7 respectively. According to the assumption (h), these lengths are considered to be constant while the ship contacts with the line.

On the other hand, from the equations of equilibrium of the forces acting on the point B and the geometrical relations shown in Fig.9, the tensions T_{AB} of the rubber tubes-line in Eq.(7) can be written as follows.

$$T_{AB} = \{w_0 A_B (h_B - \sqrt{S_B^2 - l_B^2}) - W_B\} \frac{l_B}{\sqrt{S_B^2 - l_B^2}} \quad (9)$$

where: w_0 = specific weight of water

A_B = area of waterplane of the sub-buoy

W_B = weight of the sub-buoy

S_B = length of the mooring line of the sub-buoy

l_B = horizontal distance between the sub-buoy and its anchor point given by Eq.(10)

$$l_B = \sqrt{x^2 + y^2} + \sqrt{(x - b_x)^2 + (y - b_y)^2} - l_{AB} \quad (10)$$

Fig.9. Definition sketch of the forces on the sub-buoy

(4) Total ship resistances and propulsive forces

In general, total ship resistances R_T consisting of frictional resistances and residual resistances which include wave making resistances and eddy resistances are given by Eq.(11).

$$R_T = C v_G^2 \quad (11)$$

where: v_G = velocity of a ship in the direction of the longitudinal axis

C = dimensional coefficient of total ship resistances expressed by Eq. (12)

$$C = (C_f + C_r) \frac{1}{2} \rho S$$

where: ρ = density of water

S = area of wetted surface of the ship hull

C_f = coefficient of frictional resistances

C_r = coefficient of residual resistances

Assuming that a ship approaches into the protection device with a constant speed, the propulsive forces can be considered to equal to the total resistances of the ship traveling with the constant approaching velocity v_G in the direction of the longitudinal axis. Thus, the propulsive forces of the ship can be written as follows.

$$f_p = C v_G^2 \quad (13)$$

where f_p is the propulsive forces.

(5) Tensions of the mooring lines of the buoys

From the equations of equilibrium of the forces acting on the point A and the geometrical relations shown in Fig.10, the tensions of two mooring lines of the main buoy are given by the following equations respectively.

$$\begin{aligned} T_{Ar} &= \sec \theta_{A0} \operatorname{cosec} 2\alpha_0 \{ T_{AB} \sin(\alpha_0 - \theta_{Ap}) + (T_{AC})_0 \sin(\alpha_0 - \beta_0) \} \\ T_{Al} &= \sec \theta_{A0} \operatorname{cosec} 2\alpha_0 \{ T_{AB} \sin(\alpha_0 - \theta_{Ap}) - (T_{AC})_0 \sin(\alpha_0 + \beta_0) \} \end{aligned} \quad (14)$$

where: T_{Ar} , T_{Al} = tensions of the mooring lines AA_r and AA_l respectively

T_{AB} = tensions of the rubber tubes-line AB

$(T_{AC})_0$ = initial tensions of the rubber tubes-line AC

θ_{A0} = initial vertical angle of inclination of the mooring line of the main buoy

$2\alpha_0$, $2\beta_0$ = initial horizontal angle between the two mooring lines of the main buoy and initial angle between the two rubber tubes-lines respectively

In the same way, by references to Fig.9 again, the tensions of the mooring line of the sub-buoy are obtained as follows.

$$T_B = \{ w_O A_B (h_B - \sqrt{S_B^2 - l_B^2}) - W_B \} \frac{S_B}{\sqrt{S_B^2 - l_B^2}} \quad (15)$$

Fig.10. Definition sketch of the forces on the main buoy

(6) Equations of motion of the ship

Substituting Eq.(3) into Eq.(1), equations of motion of the ship after contact with the rubber tubes-line of the protection device can be expressed as follows.

$$\left. \begin{aligned} (m + m_x) \dot{u}_G &= m\omega v_G + f_x \\ (m + m_y) \dot{v}_G &= -m\omega u_G - C v_G^2 + f_p + f_y \\ (I_{ZZ} + J_{ZZ}) \dot{\omega} &= f_\phi \end{aligned} \right\} \quad (16)$$

Using the velocity components u and v of the point of the ship in contact with the rubber tubes-line in the directions of X- and Y-axes fixed on the earth as shown in Fig.11, the velocity components u_G and v_G of the center of gravity of the ship in x_G - and y_G -axes directions can be denoted as follows.

$$\left. \begin{aligned} u_G &= u \cos\phi + v \sin\phi + a\omega \\ v_G &= v \cos\phi - u \sin\phi - b\omega \end{aligned} \right\} \quad (17)$$

Substituting Eq.(17) into Eq.(16), the final equations of motion of the ship after contact with the rubber tubes-line can be written as follows.

$$\left. \begin{aligned} \dot{x} &= u, \quad \dot{y} = v, \quad \dot{\phi} = \omega \\ u &= -\left\{ \frac{\cos\phi}{M_x} + \frac{a}{I_Z} (a \cos\phi + b \sin\phi) \right\} f_x \end{aligned} \right\}$$

(to be continued to the next page)

$$\begin{aligned}
 & + \left\{ \frac{\sin\phi}{M_y} + \frac{b}{I_z} (a \cos\phi + b \sin\phi) \right\} f_y \\
 & - \frac{\sin\phi}{M_y} \{ f_p - C(v \cos\phi - u \sin\phi - b\omega)^2 - \omega v \\
 & + m\omega \left\{ \frac{\cos\phi}{M_x} (v \cos\phi - u \sin\phi - b\omega) + \frac{\sin\phi}{M_y} (u \cos\phi + v \sin\phi + a\omega) \right\} \\
 & \dot{v} = \left\{ \frac{\sin\phi}{M_x} + \frac{a}{I_z} (a \sin\phi - b \cos\phi) \right\} f_x \\
 & + \left\{ \frac{\cos\phi}{M_y} - \frac{b}{I_z} (a \sin\phi - b \cos\phi) \right\} f_y \\
 & + \frac{\cos\phi}{M_y} \{ f_p - C(v \cos\phi - u \sin\phi - b\omega)^2 + \omega u \\
 & + m\omega \left\{ \frac{\sin\phi}{M_x} (v \cos\phi - u \sin\phi - b\omega) - \frac{\cos\phi}{M_y} (u \cos\phi + v \sin\phi + a\omega) \right\}
 \end{aligned} \tag{18}$$

where: $M_x = m + m_x$, $M_y = m + m_y$, $I_z = I_{zz} + J_{zz}$

Eq.(18) is six simultaneous non-linear differential equations and can be solved by means of numerical analysis using the Runge-Kutta-Gill method.

Fig.11. Definition sketch of the velocities

MODEL EXPERIMENTS

Model experiments were conducted on a 1 to 50 model scale in the wave basin which is 42 m long, 12 m wide and 0.75 m deep as shown in Fig.12. A radio-controlled model ship corresponding to 880 G/T cargo ship in prototype was used in the experiments.

Fig.12. Wave basin used in the experiments

The arrangement and dimension of the model of the protection device are shown in Fig.13.

Fig.13. Arrangement and dimension of the model of the protection device

The variable quantities measured in the experiments are the approaching speeds v_{G_0} and the heading angles ϕ_0 of the model ship to the rubber tubes-line, the distances p_0 between the center A of the main buoy and the initial contact point P_0 , the lateral displacements δ_B of the sub-buoy in the X-axis direction, the tensions T_{Ar} , T_B of the mooring lines of the main buoy and the sub-buoy and the tensions T_{AB} of the rubber tubes-line as shown in Fig. 14.

Fig.14. Variable quantities measured in the experiments

The tensions were measured with sensitive ring-gauges made of brass which straingauges are mounted on both sides. Custom-made mini-turnbuckles were used to facilitate the adjustment of the initial tensions of the rubber tubes-lines.

The horizontal motions of the ship and the displacements of the sub-buoy were measured by analyzing 16 mm movies taken from a tower 6 m high above the water level. Fig.15 shows an example of frame-photographs of the 16 mm movies. Fig.16 shows the model ship approaching to the rubber tubes-line and going forward contacting with the line.

Fig.15. A frame-photograph of 16 mm movies

Fig.16(b). The model ship going forward contacting with the line

COMPARISON BETWEEN THEORY AND EXPERIMENTS

The theoretical values obtained by means of numerical analysis of the maximum tensions $(T_{AB})_{max}$ of the rubber tubes-line, the maximum tensions $(T_{Ar})_{max}$, $(T_B)_{max}$ of the main buoy and sub-buoy, and the maximum lateral displacements $(\delta_B)_{max}$ of the sub-buoy, were compared with the experimental ones as shown in Figs.17, 18, 19 and 20 respectively.

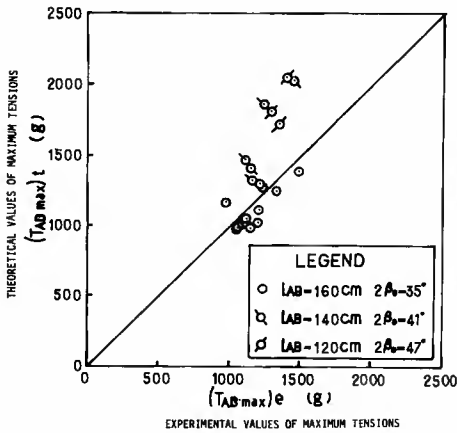

Fig.17. Comparison between the theoretical and experimental values on $(T_{AB})_{max}$

Fig.18. Comparison between the theoretical and experimental values on $(T_{Ar})_{max}$

Fig. 19. Comparison between the theoretical and experimental values on $(T_B)_{\max}$

Fig. 20. Comparison between the theoretical and experimental values on $(\delta_B)_{\max}$

These figures show that the agreement between the theoretical and experimental values concerning $(T_{AB})_{\max}$, $(T_{Ar})_{\max}$, $(T_B)_{\max}$ and $(\delta_B)_{\max}$ is good for the case of $l_{AB} = 160$ m, $2\beta_0 = 37^\circ$ but poor for the case of $l_{AB} = 140$ m, $2\beta_0 = 41^\circ$ and $l_{AB} = 120$ m, $2\beta_0 = 47^\circ$.

Namely, it may be said that the theoretical values reasonably agree with the experimental ones for the case of longer distances between the main buoy and the sub-buoy and smaller angles between the rubber tubes-lines, however, the theoretical values much deviate from the experimental results for the case of shorter distances and larger angles.

The major reasons for the much deviation may be considered as the followings.

In general, since the heading angles of the ship relative to the rubber tubes-line are larger in the case of larger angle between the two tubes-lines, the ship contacts with the rubber tubes-line near the bow end in such cases. In addition, in the case of shorter distances between the main buoy and the sub-buoy, the lateral motions of the sub-buoy and the rubber tubes-line tend to be quicker than in the case of longer distances. Therefore, it may be considered that the assumptions (e) and (h) are no longer reasonable for such cases.

From the comparison between the theoretical and experimental results, it may be concluded that the theory is limited to its application for the case of $l_{AB}/L_{pp} \geq 1.3$, $\psi_0 \leq 25^\circ$. Herein, L_{pp} is the length between perpendiculars of the ship and ψ_0 is the initial heading angle relative to the rubber tubes-line.

APPLICATION FOR PRACTICAL USE

A practical protection device for prevention of ship collisions of a class of 1,000 G/T against the floating drilling platform with the deck 43 m by 43 m shown in Fig.21, was designed under the following practical conditions;

gross tonnage of the approaching ship:	1,000 G/T
distance between the main buoy and sub-buoy:	$l_{AB} = 100 \text{ m}$
angle between two rubber tubes-lines:	$2\beta_0 = 36.5^\circ$
horizontal angle between two mooring chains of the main buoy:	$2\alpha_0 = 36.5^\circ$
vertical angles of the mooring chains:	$\theta_0 = 45^\circ$
area of water plane of the sub-buoy:	$A_B = 40 \text{ m}^2$
water depth (effects of the tidal range were taken into consideration):	$h = 50 \pm 1.0 \text{ m}$
approaching speed of the ship:	$v_{G0} = 10 \text{ kt}$
initial heading angle of the ship:	$\phi_0 = 0^\circ$
nondimensional initial contact position ($\lambda_0 = p_0/l_{AB}$):	$\lambda_0 = 0.5$
initial tensions of the rubber tubes-line at Mean Water Level:	$(T_{AB})_0 = 50 \text{ t}$

Fig.21. Picture of the floating drilling platform

The essential results of the numerical calculations for the practical device are summarized in Table 1.

Table 1. Essential Results of the Numerical Calculations for the Practical Device

Essential quantities	At Low Water Level	At High Water Level
Initial values		
$(T_{AB})_0$ (t)	21.2	88.3
$(T_B)_0$ (t)	30.0	125
$(T_{AR})_0$ (t)	21.2	88.3
Maximum values		
$(T_{AB})_{max}$ (t)	157	186
$(T_B)_{max}$ (t)	210	253
$(T_{AR})_{max}$ (t)	179	221
$(\delta_B)_{max}$ (m)	12.9	10.8

Fig.22. Schematic diagram of the practical protection device

Fig.22 shows the schematic diagram of the practical protection device designed on the basis of the above results of the numerical calculations.

The rubber tubes-line is composed of fourteen pressure pneumatic rubber tubes each 2 m in diameter and 5 m long with a steel pipe along the central axis and a parallel wire rope 105 mm in diameter with a break load of 988 t.

The main buoy is 10.2 m in diameter and 4.8 m high and the sub-buoy 8.5 m in diameter and 4.8 m high.

Anchor chains 95 mm in wire diameter with a break load of 920 t are used for the mooring line of the main-buoy and sub-buoy, and specially moulded cast iron sinkers 300 t in weight in the air were used for the anchors of the buoys.

The initial tensions of the rubber tubes-line can be arbitrarily adjusted by changing the buoy draft by means of pulling up the mooring chains into the buoy using an oil pressure jack equipped on the buoy deck.

Fig.23 shows the practical protection device set in front of the floating drilling platform in the Akashi Straits.

Fig.23. Picture of the practical protection device

CONCLUSION

The new device to protect maritime structures from ship collisions proposed here was proved in experimental and theoretical ways to be very useful to prevent the collisions of ships up to 1,000 to 2,000 G/T with usual traveling speeds of 10 to 14 knots.

The tensions of the rubber tubes-line and the mooring lines of the main buoy and sub-buoy, and the lateral displacements of the sub-buoy can be completely predicted by solving the equations of motion of the ships after contact with the rubber tubes-line by means of numerical calculations using the Runge-Kutta-Gill method.

CHAPTER 162

ADDED MASSES OF LARGE TANKERS BERTHING TO DOLPHINS

By

Taizo Hayashi¹ and Masujiro Shirai²

ABSTRACT

The added masses of large tankers berthing to dolphins are studied both theoretically and experimentally. The movements of large vessels in shallow water in the directions normal to their planes of symmetry cause counter-flows of appreciable velocities under the hulls. The inertia of these counter-flows is shown to have an important effect on the added masses of the vessels. A theoretical formula is derived to determine the mass factor of an ocean vessel in shallow water as a function of the ratio Draught/Water-depth, the Froude number of the vessel and the coefficient of head loss of the counter-flow under the hull.

Experiment is made to determine the mass factor. Comparison between the theory and the experiment shows a good agreement.

INTRODUCTION

The size of tankers has remarkably been increasing. For the design of the dolphins to which large tankers are berthed the accurate estimation of added masses of these vessels is essential.

When the depth of water is sufficiently large in comparison with the draught of a vessel, the added mass of the vessel can be estimated by the use of the formulae derived in the case of deep water [1, 2]. However, in consequence of the remarkable increase of the size of tankers, the depth of water in front of dolphins is usually not very large in comparison with the draught of a large tanker, and sometimes the latter ranges to as much as 80 percent, or even more, of the water depth in front of dolphins.

In the case when the clearance between the hull of a vessel and the bottom of water is small the added mass of the vessel is supposed to differ considerably from that in deep water. The purpose of this paper is to determine theoretically and experimentally the added masses of large tankers in shallow water.

THEORETICAL CONSIDERATION

When a large tanker is navigated with a constant speed in a normal

- 1 Professor, Hydraulic Laboratory, Department of Civil Engineering, Chuo University, Tokyo
- 2 Director of Department of Basic Engineering Research, Technical Research Institute, Taisei Corporation, Tokyo

direction toward dolphins by a tug-boat, it is theoretically supposed, from the consideration based on the equation of continuity of flow of water across the vertical plane in front of the hull of vessel, that the motion of the vessel toward the dolphins causes a counter-flow of an appreciable velocity under the hull bottom.

Figure 1 shows the flow of water caused by the steady movement of a model hull in an experimental flume. The flow was visualized by the use of

Fig. 1. Flow of water caused by the steady movement of a model hull.

aluminium flakes. The model was pulled with the fine wire, which is seen in the figure. We can clearly notice the counter-flow under the hull. Since the velocity of the counter-flow was appreciable, a vortex filament was induced in front of the hull by the counter-flow, this vortex filament being seen in the figure. The Froude number of the movement of this model hull was 0.0285.

In the steady motion of a vessel (Fig. 2) the equation of continuity for the flow around the vessel may be written as

$$D v_0 = C h' v_0' \tag{1}$$

Fig. 2. Steady movement of a vessel and the counter-flow.

where v_0 and v_0' are the steady velocities of the vessel and the counter-flow, respectively, D is the draught of the vessel, C the coefficient of contraction of the counter-flow, and h' the clearance of water under the hull.

When the vessel comes to be in contact with a dolphin, its velocity begins to be decelerated. It is to be noted, however, that even after the instant when the vessel comes to be in contact with the dolphin, the counter-flow under the hull tends to maintain its own velocity owing to its inertia. Consequently, due to the continuity of flow of water, the water level on the dolphin side of the hull goes down forming a negative surge, and the water level on the sea-side goes up forming a positive surge (Fig. 3), until the counter-flow will have eventually been ceased by the negative

Fig. 3. Negative and positive surges formed in consequence of the deceleration during the movement of a vessel. (ζ decreases as t increases.)

hydraulic gradient, the hydraulic gradient formed by $\zeta < 0$, acting on the counter-flow. Due to the difference of water levels on the both sides of the hull thus brought about, hydrostatic pressure acts on the hull in the direction of the dolphin, hence the force of impact of the vessel is increased. Since this increase of impact of the vessel is caused by the inertia of the counter-flow under the hull of the vessel, we can understand that the inertia of the counter-flow has an important effect on the added mass of the hull.

With all this in mind we make the theoretical analysis, which is shown in the next Chapter.

THEORETICAL ANALYSIS

First, the dynamic equation of the vessel per its unit length is given by

$$\rho D B \dot{v} = -k x - \rho g D \zeta - \tau B \quad (2)$$

Here, ρ is the density of sea-water, B the beam of the vessel, v the instantaneous velocity of the vessel, k the elasticity constant of the system consisting of the mooring structure, intermediate object and the vessel, as a whole, x the total elastic deformation of the same system, g the acceleration of gravity, ζ the instantaneous value of the difference of the

water levels on the both sides of the hull, and τ the shearing stress acting on the bottom of the hull. The second term in the right member expresses the hydrostatic pressure acting on the hull owing to the difference of water levels on the both sides of the hull.

The τ is expressed as

$$\tau = \frac{1}{2} \rho (v + v')^2 C_f \quad (3)$$

where C_f is coefficient of friction and v' is the instantaneous velocity of the counter-flow. We approximate this equation by the following equation.

$$\tau = \beta (v + v') \quad (4)$$

Here, β is a parameter.

As for the elastic deformation, x , it is related with the movement of the vessel as

$$\dot{x} = v \quad (5)$$

The equation of continuity of flow across the vertical plane in front of the hull is given by

$$D v - C h' v' = -c \frac{1}{2} (\zeta_0 - \zeta) \quad (6)$$

in which c is the celerity of surge and ζ_0 is the initial value of ζ . The term in the right member expresses the rate of discharge of water supplied to the counter-flow by the lowering of the water level on the dolphin side of the hull.

The dynamic equation for the counter-flow existing under hull bottom is

$$\rho B \dot{v}' = \rho g \zeta - h_f \quad (7)$$

Here, h_f is the head loss of the counter-flow. This h_f can be expressed as

$$h_f = \lambda v'^2 / 2g \quad (8)$$

in which λ is a coefficient. The above equation is approximated by the following equation

$$h_f = \alpha v' \quad (9)$$

where α is a parameter.

In the six equations, (2), (4), (5), (6), (7) and (9), we have six unknown quantities, v , v' , ζ , x , τ and h_f . Therefore, we can solve these equations. Eliminating v , v' , ζ , τ and h_f from these six equations we obtain

$$\begin{aligned} & \frac{c \rho D B^2}{g (2 C h' + c \alpha)} \ddot{x} + \left[\frac{B (2 \rho g D^2 + c \beta B)}{g (2 C h' + c \alpha)} + \rho D B \right] \dot{x} \\ & + \left[\frac{B c k}{g (2 C h' + c \alpha)} + \frac{2 \rho g D^2 + c \beta B}{c} - \frac{2 D (2 \rho g C D h' - c \beta B)}{c (2 C h' + c \alpha)} \right] x \\ & + k x = \rho g \zeta_0 \left[\frac{2 \rho g C D h' - c \beta B}{g (2 C h' + c \alpha)} - \rho D \right] \end{aligned} \quad (10)$$

which is an ordinary differential equation for x of the third order.

As illustrated in Fig. 4, although the time-variation of x is to be

quite unsymmetrical with respect to T_1 , the time of the maximum deformation of the elastic system, it may approximately be assumed that the variation of x for the range $0 \leq t \leq T_1$ is sinusoidal, namely,

$$x \propto \exp(i\sigma t) \text{ for } 0 \leq t \leq T_1$$

Then, (11)

$$\ddot{x} = -\sigma^2 x \tag{12}$$

Therefore, in Eq. (10) the first term having \ddot{x} can be combined with the third term having \dot{x} to give the damping force. Hence, the term which expresses the inertia force of the vessel is the second term having \dot{x} .

Fig. 4. Time-variation of x .

Obviously, the two terms within the square brackets of the second term in Eq. (10) may be interpreted as the added mass per unit length of the vessel, M , and the mass per unit length of the vessel, M_0 , namely

$$M = B (2 \rho g D^2 + c \beta B) / g (2 C h' + c \alpha) \tag{13}$$

$$M_0 = \rho D B \tag{14}$$

In Eq. (13) two parameters, α and β , are present, which parameters are to be expressed in terms of λ and C_f , respectively. The calculation for this is as follows:

As described previously, Eq. (9) is an approximate expression to Eq. (8) (Fig. 5). In order to determine α definitely, let us take α in such a way that the work done against the h_f given by Eq. (9) during the period $0 \sim T_1$ becomes equal to the work done against the h_f given by Eq. (8) during the same period. Therefore,

$$\int_0^{T_1} \lambda \frac{v'^2}{2g} \cdot v' dt = \int_0^{T_1} \alpha v' \cdot v' dt \tag{15}$$

Furthermore, we approximately assume

$$v' = v_0' \sin \frac{\pi}{2T_1} t \tag{16}$$

Then, substitution of Eq. (16) into Eq. (15) yields the following relation.

$$\alpha = \frac{4\lambda}{3\pi} \frac{v_0'}{g} = \frac{8}{3\pi} h_{f0} \tag{17}$$

in which h_{f0} is the initial value of h_f .

By a similar procedure β can be determined in terms of C_f as

$$\beta = \rho C_f (v_0 + v_0') \frac{8}{3\pi} = \frac{8}{3\pi} \tau_0 \tag{18}$$

where τ_0 is the initial value of τ_0 . Substituting the approximate relation,

Fig. 5. Approximation of h_f .

$v_o' = v_o D / C h'$; into Eqs. (17) and (18), we obtain the following equations.

$$\alpha = \frac{4\lambda}{3\pi} \frac{v_o}{g'} \frac{D}{C h'} \tag{19}$$

$$\beta = \frac{8}{3\pi} \rho C_f v_o \left(1 + \frac{D}{C h'} \right) \tag{20}$$

Denoting the water depth by h , the celerity of the surge is given by

$$c = \sqrt{g h} \tag{21}$$

Substitution of Eqs. (19), (20) and (21) into Eq. (13) yields the following equation.

$$\frac{M}{M_o} = \frac{D}{C h'} \frac{1 + \frac{4}{3\pi} C_f F_r \frac{B h}{D^2} \left(1 + \frac{D}{C h'} \right)}{1 + \frac{2}{3\pi} \lambda F_r \frac{h}{D} \left(\frac{D}{C h'} \right)^2} \tag{22}$$

Here, F_r is the Froude number of the vessel defined by

$$F_r = v_o / \sqrt{g h} \tag{23}$$

Since

$$\begin{aligned} O(C_f) &= O(10^{-2}), & O(F_r) &= O(10^{-2}), \\ O(\lambda) &= O(1), & O(Bh/D^2) &= O(1), \\ O(D/h) &= O(1), & O(D/C h') &= O(1) \sim O(10), \end{aligned}$$

the above equation may be approximated as

$$\frac{M}{M_o} = \frac{D}{C h'} \left/ 1 + \frac{2}{3\pi} \lambda F_r \frac{h}{D} \left(\frac{D}{C h'} \right)^2 \right. \tag{24}$$

This equation is written as the following equations.

$$\frac{M}{M_o} = \frac{C h'}{D} \left/ \left(\frac{C h'}{D} \right)^2 + \frac{2}{3\pi} \lambda F_r \left(1 + \frac{h'}{D} \right) \right. \tag{25}$$

$$= C \left(\frac{h}{D} - 1 \right) \left/ C^2 \left(\frac{h}{D} - 1 \right)^2 + \frac{2}{3\pi} \lambda F_r \frac{h}{D} \right. \tag{26}$$

The effect of friction on the mass factor is obvious. In the ideal case of no friction, λ disappears, and Eq. (26) is reduced to the following equation.

$$\frac{M}{M_o} = 1 / C \left(\frac{h}{D} - 1 \right) \tag{27}$$

Accordingly, the value of mass factor tends to infinity as the draught, D , approaches to the water-depth, h .

In actual fluid, however, friction has an important effect on the mass factor. In view of Eq. (8) λ can be assumed for practical purposes as

$$\lambda \sim 1 \tag{28}$$

Equation (26) for the values $\lambda = 1$ and $C = 0.5$ is drawn to scale in Fig. 6.

Fig. 6. The ratio Added Mass/Displaced Mass of the large tanker in shallow water.

Owing to the presence of friction the mass factor for a constant value of Froude number has a maximum with respect to the ratio, h/D .

In the calculation for Fig. 6, C has been assumed 0.5. The value of C during deceleration period of the vessel becomes smaller than that during the period of steady motion. In view of this, this value has been taken for C in this analysis.

EXPERIMENT

In order to check the validity of Eq. (26) the authors made laboratory experiment. It was conducted in a two-dimensional flume 30m long, 80cm wide and 90cm high in its side walls. A two-dimensional model of a part hull of a vessel was made (Fig. 7). The model extends to the whole width of the flume, and its dimensions are shown in Fig. 8.

Fig. 7. A part hull.

Fig. 8. The dimensions of the model (in mm).

The model hull was steadily pulled by the fine wire having a weight at its other end (Fig. 9). The model makes a steady motion until the weight touches a table installed downwards. During the steady motion the weight, W , is balanced with the sum of the frictional force exerted by fluid, ϵv^2 , and the friction of the side plates of the vessel moving along the side walls, F , namely,

$$W = \epsilon v^2 + F \tag{29}$$

Since F is the friction of solid bodies, few change of the value of F was observed for various values of v .

At the instant when the weight comes to be in contact with the table, the pulling force of the weight suddenly disappears, and the deceleration

Fig. 9. Device for pulling the model steadily for a while and removing the pulling force suddenly.

of the model hull begins. The balance of forces after the pulling force has disappeared is expressed as

$$(M_0 + M) \frac{dv}{dt} = -\epsilon v^2 - F \quad (30)$$

With the initial condition, $v = v_0$ for $t = 0$, the above equation can be integrated to give

$$v = \frac{\sqrt{\frac{\epsilon}{F}} v_0 - \tan\left(\frac{\sqrt{\epsilon F}}{M_0 + M} t\right)}{\frac{\epsilon}{F} v_0 \tan\left(\frac{\sqrt{\epsilon F}}{M_0 + M} t\right) + \sqrt{\frac{\epsilon}{F}}} \quad (31)$$

Further, this equation is integrated to

$$x = \frac{M_0 + M}{\epsilon} \ln \left\{ \cos\left(\frac{\sqrt{\epsilon F}}{M_0 + M} t\right) + \sqrt{\frac{\epsilon}{F}} v_0 \sin\left(\frac{\sqrt{\epsilon F}}{M_0 + M} t\right) \right\} \quad (32)$$

The decelerating motion of the model hull was recorded by the use of a 8mm motion-picture camera. Measuring the time-variation of the position of the model in this way and also the values of ϵ and F from preliminary experiment, we calculated the added mass, M , from Eq. (32).

Experiment was made for the range $h/D = 0.2 \sim 1$ and $F_r = 0.007 \sim 0.07$. The result of the experiment is shown in Fig. 6. The agreement between the theory and the experiment is pretty good, as a whole, and validity of the present theory is confirmed.

CONCLUSIONS

The movements of large tankers in shallow water in the directions normal to their planes of symmetry cause counter-flows of appreciable velocities under the hulls. The inertia of these counter-flows has an important effect on the added masses of the vessels.

The mass factor, M/M_0 , of large tankers in shallow water can be

determined by Eq. (26).

ACKNOWLEDGEMENT

The authors are grateful to Messrs. Banji SUZUKI, Yasuharu TERUI, Shigeki YASUDA and Shunichi HASHIMOTO, Then-Students at Chuo University, for their earnest assistance and cooperation in conducting the experiment.

CHAPTER 163

SUBHARMONIC COMPONENTS IN HAWSER AND FENDER FORCES

by

J.H. van Oorschot *

ABSTRACT

Forces in mooring lines and fenders of a moored vessel exposed to waves have a mixed harmonic and a subharmonic character. The subharmonic oscillations, with periods well beyond the range of wave periods, may cause forces that are as large as, or even larger than the forces associated with the harmonic oscillations.

The origins of the subharmonic oscillations are discussed and it is shown that in model testing, the correct reproduction of both the mooring arrangement and the irregular wave motion is essential.

The subharmonic motions, and consequently the total forces, can be partially reduced by specially adapted mooring arrangements as tests on various mooring systems have shown.

1. INTRODUCTION

During the past few decades there has been a rapid development in ship sizes, accompanied by the advent of highly specialised ships, such as LNG carriers, container vessels, etc.. This development has created many challenging problems, not only for nautical engineers in designing the vessels, but also for harbour engineers in providing adequate berthing facilities.

The increase in ship size led to the design and construction of loading and unloading facilities at more and more exposed locations in order to limit the dredging work and the costly construction of protection dams in deep water. Although at these exposed locations the docking itself will still be of importance for the actual design, the behaviour of the moored ship in waves has become an important, and often a determinative, parameter.

On the other hand, special mooring arrangements may be required, even in more or less protected areas, because the tolerable ship motions can be extremely small. For example container transshipment cannot take place if the motions of the container ship are appreciable, and LNG loading arms cannot follow very large ship motions.

The mooring and berthing facilities have to be designed so that the requirements regarding the allowable ship motions, and acceptable downtime, are met at tolerable forces. Wave forces on a ship may easily reach to thousands of tons, even in mild wave conditions. A certain amount of flexibility should,

* Head Maritime Structures Branch, Delft Hydraulics Laboratory, the Netherlands

therefore, be built in to prevent prohibitively large forces in the mooring lines and fenders.

Clearly the optimum between the dynamic behaviour of the ship and the loads in the mooring system has to be assessed for each situation.

In addition to these developments, the expansion of activities offshore should be mentioned, where drilling, construction and transshipment operations are taking place in extremely hostile conditions, using installations for which the wave-excited forces and motions are extremely important.

In the present study, which is primarily focussed on the problem of a moored vessel, the character of the wave-excited motions of a vessel and the corresponding forces in the mooring system are dealt with. However, the conclusions may also largely apply to any other form of anchored floating object.

2. SHIP OSCILLATIONS

In studying the response of a moored ship to a random wave motion, the following types of oscillation can be observed:

- a. Harmonic oscillations.
- b. Superharmonic oscillations.
- c. Subharmonic oscillations.

Ad a. The harmonic motions are the oscillations of the ship (6 components) with frequencies in the range of the wave frequencies. The harmonic wave forces and the harmonic ship motions of a freely-floating ship are generally fairly well linearly related to the wave amplitude. This is even so for the small keel clearances that are usually present at the berths, if only moderate wave amplitudes are considered. As an example one is referred to Figure 1 where the transverse motions (combined roll and sway) at about deck level of an ore carrier at a water depth 17% in excess of the draught are presented. The wave height of the regular waves ranged between about 1.0 m and 2.5 m, and the mooring system was linear. However, if the ship is tightly moored in a non-linear mooring system, the linear approach may no longer be justified.

Ad b. For particular elastic characteristics of the mooring system, oscillations with frequencies higher than the exciting wave frequency (superharmonics) may occur.

Ad c. Finally, subharmonic motions can be observed. These subharmonics have frequencies much smaller than those of the exciting waves. The subharmonic component in the motion or the force often forms a substantial part of the total motion or force. The subharmonic character can even become predominant, and is therefore clearly of importance for practical designs. In Figure 2, derived from Reference 1, some typical recordings are presented of springline and fender forces for a conventional mooring system, containing appreciable subharmonic components.

The subharmonic motions can have the following origins:

- The non-linear and asymmetric elastic character of mooring lines and fenders. Regular harmonic excitation of a mass in a non-linear and asymmetric spring system leads to frequencies different from the excitation frequency, also lower ones. If instead of one single excitation frequency, two discrete frequencies are applied, the resulting motion can also contain so-called combination tones (Ref. 9). In an actual sea condition, with a wave-energy spectrum covering a certain frequency band, these combination tones will show up as well.
- The second order slowly varying wave drift force. Due to this wave drift force subharmonic motions will occur, also with a strictly linear mooring system. However, only in irregular waves. Figure 3 shows an example of a model ship subjected to head waves, where the surging motion contains a predominant subharmonic component.
- Long periodic waves, like seiches and surf beats, may cause subharmonic motions,

particularly if the harbour configuration tends to amplify these phenomena (Ref. 8).

As the slowly varying wave drift force is an important parameter (and often the dominant one in this respect), this drift force will first be discussed.

3. THEORETICAL DESCRIPTION OF WAVE DRIFT FORCE

The study of the wave drift force was originally tuned to the determination of the wave-induced resistance of ships, but in recent years, the computations have been expanded to determine the behaviour of moored vessels. Havelock in the early 1940's published an approximative calculation of the steady drift force (Ref. 4). His computation was based on the observation that the drift force is most predominant near the natural periods of oscillation. It was shown that interaction between first-order effects, which in themselves are purely periodic, may through phase differences give rise to steady drift forces. For head waves:

$$F_D = \frac{1}{2}k(P.z \sin \beta_z + Q.\psi \sin \beta_\psi), \quad (1)$$

where P and Q are amplitudes of buoyancy and pitching moment, z and ψ are amplitudes of heaving and pitching, and β_z and β_ψ are phase lags. Comparable expressions have been derived by others for beam waves.

According to Reference 14 the interaction as described by Havelock only partly explains the steady drift force. The effects of interaction between the waves diffracted by the ship and the incoming waves, as well as the effect associated with the energy dissipation due to outgoing wave radiation resulting from forced ship motions, should be added. To obtain a less complex approach, Hsu and Blenkarn (Ref. 5) developed a description of the drift force, based on the same concept as the radiation stress. The conservation of wave momentum requires that if a wave train is reflected from an obstacle, there is a force exerted on that obstacle equal to the rate of change of wave momentum. The expression for the average drift force on a ship per unit length in regular beam waves becomes:

$$F_D = \frac{\rho g a^2}{2} \left\{ 2(Q-1) \left[1 + \frac{z}{a} \cos(\beta_z + kX_1) \right] - Q \frac{z}{a} \left[\cos(\beta_y + kX_1) + \frac{z}{a} \cos(\beta_y - \beta_z) \right] \right\}, \quad (2)$$

where $Q = [2 \cosh k(d-T)] / \cosh kd$ and X_1 is the average position of the leeward side of the vessel with respect to the centre line. It is assumed that all wave momentum between the free surface and the keel is reflected (at the average position of the ship side) and that the wave field below the keel is not disturbed. Similarly, Maruo (Ref. 6) in an earlier paper applied the wave momentum analysis on a control surface at a great distance from the ship to find the wave resistance in head waves. This computation is also approximative, as the boundary condition at the surface of the ship does not enter the analysis. Moreover, the expressions derived are for deep water.

The most recent description of the wave drift force, introducing the actual boundary conditions at the ship's surface, is from Pinkster (Ref. 12). The total hydrodynamic force in k-direction on the ship (which is allowed to make small amplitude motions about the mean position) is:

$$F_k = \iint p \cdot n_k \cdot dS \quad (3)$$

The pressure p follows from the Bernoulli equation:

$$p = -\rho gZ - \rho \phi_t - \frac{1}{2}\rho(\nabla\phi)^2 \quad (4)$$

The various parameters are then expanded to the second order using a small parameter ϵ (no higher orders, as the low frequency motions are supposed to be generated by the second-order force), so

$$\phi = \epsilon \phi^{(1)} + \epsilon^2 \phi^{(2)}$$

and

$$F_k = \iint \left(p^{(0)} + \epsilon p^{(1)} + \epsilon^2 p^{(2)} \right) \bar{n}_k dS + \iint \left(p^{(0)} + \epsilon p^{(1)} \right) \epsilon n_k^{(1)} dS + \iint p^{(0)} \epsilon^2 n_k^{(2)} dS + O^{(3)} \quad (5)$$

This integration can be carried out for the complete wetted surface S. After elaboration for the horizontal force in longitudinal direction (no roll, no sway) this expression gives:

$$F^{(1)} = \iint_{S_o} -\rho \phi_t^{(1)} \bar{n}_1 dS \quad (6)$$

$$F^{(2)} = \frac{1}{2} \rho g \oint_L \eta_r^{(1)} \bar{n}_1 dS + \psi^{(1)} \iint_{S_o} -\rho \phi_t^{(1)} \bar{n}_3 dS + \iint_{S_o} -\frac{1}{2} \rho (\nabla \phi^{(1)})^2 \bar{n}_1 dS + \iint_{S_o} -\rho \phi_t^{(2)} \bar{n}_1 dS - \rho g z_o^{(1)} \psi^{(1)} A_{wL} + O^{(3)} \quad (7)$$

Apparently the ship motions need only to be known to the first order, unlike the velocity potential. Also the actual wave elevation along the hull (η_r) should be known. Pinkster concludes therefore that a proper calculation for a practical case is for the time being too complex to be carried out.

In regular waves the drift force is of a constant value. As can be seen in Figure 5, which applies for a model ship in beam waves, the ship drifts away after the waves start to grow, and subsequently attains a constant offset. If the wave amplitude varies, the drift force will vary more than proportionally, and the ship will perform a forced oscillation at a frequency equal to the wave frequency and at a frequency matching the frequency of the wave groups (see also Figure 5).

Various investigators have tried to assess the wave drift force and the resulting motion in the general case of irregular waves, on the basis of the steady drift force as measured in regular waves. Hsu and Blenkarn (Ref. 5) computed the slowly varying drift force in irregular waves by assuming that the irregular sea can be characterised by a sequence of waves, each with a defined height, period and steady drift force, and that each wave acts on the ship as if it was one wave out of a sequence of regular waves. This can be written for a narrow-band spectrum in a general form (Refs. 10, 11) as:

$$\bar{F}_D = \rho g \int_0^\infty S_{\eta\eta}(\omega) R^2(\omega) d\omega \quad (8)$$

and

$$S_{FF}(\mu) = 2 \rho^2 g^2 \int_0^{\infty} S_{\eta\eta}(\omega) S_{\eta\eta}(\omega+\mu) R^4(\omega+\mu/2) d\omega \quad (9)$$

However, it has been shown that, particularly for larger vessels, this will yield incorrect results (Refs. 7, 10), because:

- a. The mean drifting force can be shown to be only dependent on the first-order potential, whereas the slowly-varying drifting force contains contributions of both the first- and second-order term of ϕ .
- b. The effect of the dimensions of the vessel relative to the "wave length" of the wave group is not negligible.

Rye et al. (Ref. 13) show that, indeed, already different results are obtained if R is determined in regular waves or in wave groups with constant wave and group period. The same can be seen in Figure 5, where the subharmonic motions are much larger than would follow from the regular wave tests (the amplification due to the response of the ship is only 1.24). It is also pointed out in Reference 13 that the extreme values of the forces or motions are liable to be underestimated if they are derived from the spectrum values S_{FF} , as the distribution, due to the quadratic character of the drift force, is far from normal.

4. EXPERIMENTAL STUDY

4.1 Model set-up

In order to study various aspects of the subharmonic behaviour from a practical point of view, a variety of tests has been made with a model of an ore carrier, in an 8 m wide wind-wave flume at the Delft Hydraulics Laboratory. The wave flume is provided with a flap-type wave generator with the flap being driven by two electronically-controlled hydraulic actuators. The steering signal is random (not a summation of a finite number of components) but can be reset, after which the same sequence of random waves is repeated. The required input signal is obtained by filtering so-called pseudo-random noise (Ref. 8). For the generation of regular waves, a normal function generator is used.

Ship

The data of the ship were:

V	=	320,000	m^3
L_{oa}	=	350	m
L_{pp}	=	330	m
B	=	55	m
T	=	20.5	m
d	=	24	m
C_B	=	about 0.85	m

The model (length) scale was 1 to 100.

Mooring system

The mooring systems used are shown in Figure 4. Due to the use of a high pretension and long linear springs, no slack occurred and the system was purely linear and symmetric (apart from the head waves for system A). The elasticities were chosen so as to coincide reasonably with the overall elasticity of fenders and mooring lines of a conventional mooring system.

Waves

The waves applied were regular and irregular long-crested waves, both beam-on and head-on. The regular waves had periods between 8 and 20 secs, the wave heights ranged be-

tween 1 m and 2.5 m.

The irregular wave had also significant wave heights between 1 m and 2.5 m. The periods corresponding to the peak of the wave energy spectrum were 12, 15 and 18 secs. At 15 secs a narrower and wider spectrum was also used (see Fig. 8).

4.2 Measurements in regular waves

In the tests with regular waves, the constant drift force has been measured, with the symmetric mooring systems, and the results are shown in Figures 6, 7. Particularly for the beam waves there is a considerable scatter. This is partly due to the small values of the drift force and the inherent measuring inaccuracies, but mainly to the fact that the springs were connected above the center of rotation, at the actual application point of mooring lines and fenders. Consequently there were some secondary effects in the force measurements due to the rolling motion, in spite of the long lines used. Nevertheless, a pronounced increase of the drift force can be observed for beam waves in the period range of 14 to 16 secs (natural periods of roll and heave), obviously due to the interaction between the harmonic ship motions and the wave-excited forces, as mentioned in Section 3. Corresponding results have also been presented in Reference 3.

In head waves the drift force increases with increasing wave period, without any distinct maximum in the period range applied. The harmonic motions (surge, pitch and heave) also increase with longer periods in the corresponding frequency band. Clearly, when studying the subharmonic behaviour of a floating object much attention should be given to the correct reproduction of the mooring system.

Together with the steady drift forces, the harmonic motions have been recorded. From these motions and the proper values for the added mass and the damping, the harmonic wave-exciting forces have been computed. The averaged results for the various tests are also shown in Figures 6 and 7. The steady drift force in regular waves appears to be barely a few percent of the harmonic wave force. For instance, for a wave amplitude of 1 m, the drift force for beam waves is only 2-4%, whereas for head waves in that case the drift force is even less than 1%.

Finally the transferfunctions between the line forces and the waves have been determined for the mooring system A (Fig. 4).

4.3 Measurements in irregular waves

Comparison with regular waves, and influence of wave height and period

Additionally to the measurements with regular waves, measurements have been carried out with irregular waves, both head-on and beam-on. In order to demonstrate the limited applicability of the linear transfer functions, and the regular wave tests in general, the 1% exceedance values of the wave-induced forces have been determined from the irregular wave tests, and compared with the 1% values that are obtained applying a linear transfer function $T_{(\omega)}$ between waves and forces. The results have been plotted in Figures 9 and 10, and some typical spectra, applied for both the computations and the measurements, in Figure 8. The differences between the computed and measured values are fairly well proportional to H^2 , as could be expected theoretically. This also means that the shape of the statistical distribution curve does not change significantly for different wave heights. The differences also increase with increasing wave period, and are particularly for $T_p = 18$ sec very pronounced. The computed 1% values followed from:

$$S_{FF}(\omega) = S_{\eta\eta}(\omega) \cdot T_{(\omega)}^2$$

and according to the Rayleigh distribution,

$$F_{1\%} = 3.0 \sqrt{M_{OF}} \quad \text{where} \quad M_{OF} = \int_0^{\infty} S_{FF}(\omega) d\omega$$

From some of the recordings with irregular waves, spectra of the ship motions (sway for beam waves and surge for head waves) and the waves have been made (see Fig. 12). The spectra of the motions shown on this Figure are typical. They contain two distinct maxima, one in the harmonic range and one in the subharmonic range, where there is no wave energy. The energy content of this subharmonic part M'_{OF} has been determined for all tests and normalised by the square of the total energy of the wave motion m_{on}^2 , according to the supposition expressed in (9).

The M'_{OF}/m_{on}^2 can then be supposed to be a function of the peak frequency of the wave spectrum and the energy distribution (shape of the spectrum) for a particular situation. The test results are plotted in Figure 14. It is interesting to note that the value M'_{OF}/m_{on}^2 is a fairly smooth function of the peak frequency of the spectrum. This is particularly surprising for sway, as the value of R in (9) varies very strongly with the wave period (Fig. 6). The spectrum width has not a large influence on this parameter. For beam waves the narrow spectrum results in the largest motions, as opposed to the situation with head waves. The same can be observed in Figures 9, 10 with respect to the subharmonic component of the 1% wave-induced force.

Influence of mooring system

The steady drift force in regular waves has been shown to be only a few percent of the harmonic wave forces. Although the regular-wave tests tend to underestimate the drift forces, the slowly-varying drift force in an actual case with irregular waves is still of second order. So the reason for the large subharmonic motions can only be found in the occurrence of a resonance type of motion of the vessel in its mooring system.

The conditions for resonance are available, as the natural frequencies of oscillation are within the band-width of the slow drift excitation and, moreover, the damping (both linear and quadratic) is extremely small in the low-frequency range (see Fig. 11^{*}). If the low damping is partly responsible for the large subharmonics, it may be expected that improvements can be obtained if special elastic characteristics of mooring lines and fenders are used. In particular if some energy dissipation is applied. With regard to this, some tests have been carried out with other than linear mooring systems. Some typical recordings are presented in Figure 15 together with the wave recordings. For each test the same motion control programme for the wave machine has been applied. Apart from minor details, the wave recordings were similar. The mooring system was changed in each test. The upper curve (System I) shows a subharmonic surging motion, which is reduced for System II where some energy dissipation was built in. In System III the restoring force at positive displacements was constant at a value of 400 tf (average of forces recorded for System I), moreover an appreciable energy dissipation was built in. Nevertheless, the subharmonic motion increased dramatically, but only for parts of the recording. In the remaining parts the subharmonics were of the same order as, or smaller than those for System I.

It is surprising that there was no direct correlation between the occurrence of these extremely large subharmonics and those for System I, as also can be seen in Figure 15. So the adverse effect is not only very large, but also fairly unpredictable. This is the more important, as System III is a type of system that may be found in practice, applying the widely-used constant tensioning winches,

* The damping and added mass coefficients have been derived from data for a ship which is only slightly smaller, and are expected to be accurate within 10%.

with different pull-in and pay-out loads. In Figure 13 the energy spectra of the motions are given for the various mooring systems. In beam waves, the motions for System III became so large that they were beyond the range of the displacement transducers, and could not be analysed.

Influence of a steady force

Not only will the elastic properties of the mooring system depend on the particular types of lines and winches applied, but they may also vary for a particular lay-out as a result of an extra "pretension" caused by a steady wind or current. The effect on the ship motions can be quite significant, as shown by Hsu and Blenkarn (Ref. 5). The wind- and current forces, if present, should therefore always be reproduced in the model experiments. Due to the subharmonic motion, the relative speed of the wind or the current will vary, which may also affect the subharmonic motion in another way. Let U be the permanent velocity of wind or current, and \dot{x} the momentaneous ship velocity, the resistance is then,

$$F_R = \frac{1}{2} \rho C_d A (U - \dot{x})^2 = \frac{1}{2} \rho C_d A (U^2 + \dot{x}^2) - \rho C_d A \dot{x} U$$

if U is a constant, the last term at the right hand side has the character of a linear damping, $2F_R \dot{x}/U$. Due to the higher value of U this virtual damping will for the wind generally be rather small. However, for a steady current this term may be of the order of magnitude of the linear damping in the subharmonic range as shown in Figure 11. In that case it will be required to reproduce not only the steady current force, but the whole current pattern.

5 CONCLUSIONS

Subharmonic components form, particularly in more exposed locations, a substantial part of the total horizontal ship motions or mooring forces. The second order slowly varying wave drift force is an important parameter in this respect.

The slowly varying drift force and consequent subharmonic motions occurring in irregular waves are larger than follow from the steady drift force in regular waves. Moreover, the so-called combination tones in irregular waves may introduce subharmonic motions that will not be found in the case of regular waves.

The second-order drift force in regular waves depends strongly on the harmonic ship motions, as a result of interactions between incident, diffracted and radiated waves.

As opposed to the harmonic motions, subharmonics can to some extent be reduced by applying special elastic characteristics for the mooring system, or more particularly energy dissipating devices. The effect of a variation of the elastic properties, however, seems to be fairly unpredictable.

In irregular waves the subharmonic components increased proportional to H_s^2 . They also continuously increased with increasing peak period of the energy spectrum (T_p), for both sway and surge.

LIST OF SYMBOLS

A	- area	p	- pressure
A_{WL}	- area of water plane	$R_{(\omega)}$	- transfer function
a	- amplitude of wave	S_{xx}	- energy density of x
B	- breadth	T	- wave period; draught
C_B	- block coefficient	$T_{(\omega)}$	- transfer function
C_d	- resistance coefficient	t	- time
c	- spring constant	U	- wind or current velocity
d	- depth of water	X	- horizontal coordinate
F_D	- drift force	x	- surging motion
F_k	- force in k-direction	y	- swaying motion
F_R	- resistance	z	- heaving motion
f	- frequency	Z	- vertical coordinate
g	- acceleration of gravity	β	- phase lag
H_s	- significant wave height	ϵ	- small parameter
k	- wave number = $2\pi/\text{wave length}$	ϕ	- velocity potential
L_{oa}	- length over all	η	- surface elevation
L_{pp}	- length between perpendiculars	ρ	- mass density
M_{oF}	- total energy of harmonic force	ψ	- pitching motion
M'_{oF}	- total energy of subharmonic force	ω, μ	- angular frequency
$m_{o\eta}$	- total energy of wave motion		
n_k	- directional cosine of surface element in k-direction

CHAPTER 164

LOW-COST SHORE PROTECTION ON THE GREAT LAKES: A DEMONSTRATION/RESEARCH PROGRAM

by

Dr. John M. Armstrong

Associate Professor, Department of Civil Engineering
and
Director, Coastal Zone Laboratory
The University of Michigan
Ann Arbor, Michigan

BACKGROUND

Shore erosion is currently causing millions of dollars of damage to shoreline property along the Great Lakes (1,2). Erosion is caused by the energy of waves and currents which are produced by large wind storms.

The erosion process on the Great Lakes is most severe when lake levels are near the top of their 6-foot (1.8 meter) range for several years as is currently being experienced. The severe erosion process continues even after lake levels fall, as the bluffs have become unstable and waves from intense storms can still attack them. In order to alleviate the erosion damages to beaches and bluffs, shoreline owners must rely on shore protection methods.

Effective methods of shore protection are designed to slow or stop the erosion process by dissipating wave energy and/or preventing bluff attack. However, the most effective methods are very expensive, costing over \$200 per foot (\$656 per meter) of shoreline. (Costs are calculated, for the purposes of this study, as the length of shoreline which is expected to be protected by the shore protection methods. For sites utilizing revetments, artificial nourishment, and seawalls, the length is the stretch of shoreline actually covered by the method. For locations utilizing groin systems and breakwaters, the system was designed to protect the entire length of the sites; the costs have been calculated on that basis. Whether these systems actually protect that length of shoreline is to be determined by this study.) Shoreline homeowners are usually not able to meet such expenses, and often resort to less efficient and costly alternatives. Private shoreline owners need accurate, reliable information about effective low-cost shore protective methods in order to reduce or alleviate the severe erosion damages to their shoreline.

INTRODUCTION

In response to the urgent need described above, 19 sites were selected along the coast of Michigan in 1973 for the examination of methods of shore protection. The objective of this program was to select, design, install, and evaluate a series of low-cost shore

protection systems. The test sites were distributed around the state in areas which experienced severe erosion. Sites were selected on public land where erosion processes were active and typical. Table 1 lists and Figure 1 shows the test site locations. Site selections were in part determined by the willingness of local agencies to share expenses and by the value of the property being threatened.

Methods of shore protection were chosen to demonstrate the effectiveness of well-known, as well as innovative, concepts. Each project was documented and evaluated with respect to the reduction of erosion rates, cost, construction problems, and durability. A particular effort was made to find reasonable effective and low-cost methods which the homeowner could personally utilize. Emphasis was placed on providing sufficient information to shoreline owners for comparing costs of protective structures against reasonable chances for effective protection.

The selection of the method of shore protection to be used at each site was based upon several criteria. The first criterion corresponds to the stated objective of the program in testing shore protection procedures suitable for use by shoreline owners. It was necessary to stay within an acceptable cost range for property owners. This range had risen over the past 20 years from \$25 per foot (\$82 per meter) of shoreline to \$100 per foot (\$328 per meter) based on previous interactions with homeowners. All of the structures were intended to be in the "low-cost" category, defined for study purposes as costing less than \$100 per foot (\$328 per meter) of shoreline protected. The average cost of methods selected for examination was approximately \$50 per foot (\$164 per meter) of frontage, a desired goal of the study. This cost constraint limited the design options severely. For example, a structure which would be expected to provide protection for all but very rare storms, such as 25- or 50-year frequency storms, would cost from \$200 to \$400 per foot (\$656 to \$1,312 per meter). The low-cost designs used in the demonstration projects can be expected to suffer damage from much less severe storms, such as 5- to 10-year frequency storms.

The second criterion involved testing innovative ideas and procedures with the objective of keeping costs low while maintaining reasonable effectiveness. Innovative, yet untested, methods were important aspects of the program as it was as essential to demonstrate to the homeowner what not to do as well as to show proper shore protection methods. Methods which reflected strong public interest and offered hope for permanence and low-cost effectiveness were also examined for potential testing. Shore protection methods were not included, however, which could adversely affect the environment or degrade the aesthetic qualities of the shoreline. This excluded from the study poorly designed structures and such attempts as the placement of discarded automobiles or straw and hay on the bluff.

The methods of shore protection included in the study are artificial nourishment, groins, revetments, offshore breakwaters, and "seawalls." (The term seawalls as used in this paper does not refer to the traditional concept of seawalls. The term applies to structures which combine the characteristics of seawalls and revetments, yet which resemble neither in the traditional sense.) Materials used in the projects vary from sand to reinforced concrete walls.

Artificial nourishment consists of adding sand to a nearshore area. This raises the beach bottom profile enough to cause waves to break and lose their energy before reaching the former shoreline. This method is aesthetically pleasing as it preserves the beach in its natural condition. It is also an excellent means of shore protection.

Groins are protective structures, similar to a wall, built approximately perpendicular to the shore, which trap sand from the littoral drift. A groin is anchored in the toe of the bluff and extends into the water. Groins used in the study were constructed of wood piling, steel piling, asphalt mastic, rock-filled timber cribs, gabions, giant sandbags, and Longard tubes. (Giant sandbags are nylon bags which can be pumped full of sand. Two of the sizes referred to as "giant" are 2 feet by 5 feet by 10 feet [1.6 meters by 1.5 meters by 3.0 meters] and 1.5 feet by 6 feet by 20 feet [1.46 meters by 1.8 meters by 6.1 meters]. Longard tubes consist of high density polyethylene casings lined with low density polyethylene. These casings are filled with sand to form tubes). The sand trapped by the groin raises the beach profile and protects the bluff. Regular spacing of groins along the shoreline enhances their effectiveness in building up the beach.

Revetments are protective blanket-type structures built at the toe of a bluff. The bluff is graded to a stable slope of three or two to one, horizontal to vertical, before placement of the revetment. Rock, asphalt mastic, and preformed concrete rings were used for the construction of revetments. Any material utilized must be strong enough to resist wave attack and built high enough to prevent overtopping. The toe of the revetment should be protected from undercutting as wave energy during storms accelerates erosion at the toe. Revetments are very effective in areas where groins cannot be constructed. They also often leave a portion of the beach available for recreational activities.

Seawalls are built in front of a bluff and backfilled so that the bluff is continuous to the wall. The purpose of a seawall is to prevent wave energy from reaching the bluff. However, due to the violent turbulence created when waves strike the structure, erosion is greatly accelerated in front of the wall. This undercutting combined with the pressure of saturated soil on the land side, often leads to structure failure. Seawalls were constructed of Longard tubes and giant sandbags. Seawalls traditionally are not suitable methods of shore protection in recreational areas due to the difficulty of water access and the development of deep water in front of the walls. Seawalls are useful in areas where

no other means of protection will work and/or the bluff requires support (the seawall becomes a retaining wall). Caution must be exercised to properly design the seawall which can be expensive.

Offshore breakwaters are walls installed in the water parallel to the shoreline. They attenuate wave energy and depending on their distance from shore the reduced turbulence immediately behind the breakwater enhances the deposition of sand. Offshore breakwaters were built with precast concrete panels and Longard tubes.

To evaluate the effectiveness and durability of the shore protection examined as well as their effect on the nearshore environment, a field monitoring program was established. This involved photographic and subaerial/subaqueous surveys of the sites to obtain profiles of the bluff and beach. The procedure for surveying seawalls, revetments, breakwaters, and nourishment projects consisted of establishing profile lines. Profiles originated inland behind the top of the bluff and extended into the water (limited to the depth a man could wade). These profile lines were established 25 feet (7.6 meters) apart over the length of a project. Groins also were surveyed using profile lines as described above. These profiles, however, were located along the centerline of the structure, immediately adjacent to it, as well as 10 and 25 feet (3.0 and 7.6 meters) on both sides.

Data was collected during and immediately after construction and additionally during the year to provide further site observations. During the first year of study, the surveys were conducted after major storms so that surveys could be conducted at optimum times in terms of checking a structure's effectiveness. Such a storm was defined as one that will be equalled or exceeded on an average of three or four times each year. Initially, major storms were described only by onshore wind speeds and duration because winds play an important role in wave formation. Later, major storms were described by wave size: a 6-foot (1.8 meter) breaking wave at the site was established as the criterion. In subsequent years, sites were surveyed in the spring and fall. It was possible to record the major storms between surveys and still obtain the desired information.

In summary, the 19 locations were monitored utilizing the photographic reviews and conventional surveying techniques described previously. This monitoring program collected data regarding structure effectiveness and durability as well as the feasibility of shoreline owners employing these methods themselves. The following section describes some sites in detail and provides preliminary observations.

SITE DESCRIPTION AND ANALYSIS

Sites 1-4, 16, and 19 were evaluated using photographs and will not be discussed at further length. However, Tables 2 and 4 provide summary information concerning these sites. The remaining sites were surveyed using the conventional surveying techniques previously discussed. Summary information for these sites

can be found in Tables 2 and 3. Complete and reliable data regarding structure effectiveness and durability will be available only after a number of years. Evaluations are based on the structure's performance over time and in various storm conditions. However, general observations of the effectiveness of some of these structures can be made after the first two years of study. Data have been collected continuously since installation. This paper includes all data collected through the fall of 1975.

Site 6, Sanilac 26

A roadside park 4 miles (6.4 kilometers) south of Port Sanilac in Sanilac Township was selected for testing six different groin types. This location has high steep clay bluffs and a tough clay lake bottom. These bluffs have been eroding over the years. The clay lake bottom makes the driving of any type of piles difficult. Thus, the groins selected for this site were designed to rest on the lake bottom. An important aspect of this project was the 200-foot (61.0 meter) spacing between each of the groins. Groins are usually spaced two to three times the length of the groin extending into the lake (3). The distance between the study groin systems was three to four times their length. Table 5 describes the various groin systems installed as well as costs incurred for construction. The structures are listed in successive order from the north end of the site progressing south. Four of the structures can be seen in Figure 2. A plan view of the site is shown in Figure 3. Discussions of each structure's performance will be followed by observations of the entire system's effectiveness.

Two 40-Inch (101.6 cm) Diameter Longard Tubes. These tubes are 100 feet (30.5 meters) long and were installed in the fall of 1973 at a cost of \$30 per foot (\$98 per meter) of shoreline. A third tube was planned to be stacked on those two in a pyramid fashion. Storm interruption during construction prevented placement of the third tube. The two tubes installed were monitored and were found to be trapping sand. This groin appears to be working well. Although some settlement has occurred along both tubes (particularly the southern tube), this movement has not hurt the groin's performance. The tubes have helped to build up the beach and thus resist wave attack. Recession at the top of the bluff has been about 10 feet (3.0 meters) in the immediate vicinity and some slumping has occurred. This could be due to terrestrial processes or the movement of the slope to reach a more stable position.

One 69-Inch (175.3 cm) Diameter Longard Tube. This tube is 50 feet (15.2 meters) long and was installed in the spring of 1974 at a cost of \$25 per foot (\$82 per meter). It was expected to trap sand more effectively than the 40-inch (101.6 cm) diameter tube because it has more freeboard. Freeboard is the height of a structure above the still waterline. However, as of the last survey both groins have performed equally well. Only minor settlement was experienced with this tube. The lack of settlement indicates that this structure can be placed directly on the lake bottom

(without a supporting foundation) in areas where the soil is clay. This tube has effectively trapped sand and prevented direct wave attack on the bluff, although minor recession rates have been recorded in the immediate area.

Gabion Groin. The gabion groin installed at this site in the spring of 1975 is 70 feet (21.3 meters) long and costs \$30 per foot (\$98 per meter) to construct. It has not been under examination long enough to provide significant data. It is in very good condition and has trapped sand as expected. Despite the beach build-up, slumping of the bluff has occurred. This may be due to natural processes other than wave attack.

Giant Sandbag Groin. The giant sandbag groin was installed in the late fall of 1973 and suffered major damage in the first year. The length of the groin is 60 feet (18.3 meters) and costs \$30 per foot (\$98 per meter) to install. Nearly 15 feet (4.6 meters) of sandbags were lost at the lake end of the groin. Vandalism is probably not the cause since the lost bags are at the lakeward end of the structure. No further sandbag loss has been detected, but some bags have shifted since April 1975. The structure appears to be effectively trapping sand despite the damage. Preliminary conclusions as to its effectiveness and durability indicated that sandbag groins could only offer temporary protection. After further study under mild storm activity, it appears that the bags can offer more than just temporary protection. However, they are not as durable as other structures. With annual replacement of damaged bags and protection against tearing, sandbag groins could function effectively for several years.

Asphalt-Mastic Groin. This asphalt-mastic groin was completed in the fall of 1973. Design and construction supervision of this groin was provided by The University of Michigan's Coastal Zone Laboratory. The successful installation of this structure demonstrated that asphalt mastic could be placed through deeper water than previously documented. The asphalt-mastic groin is 60 feet long (18.3 meters) and was installed at a cost of \$45 per foot (\$146 per meter). To date the structure has performed very well. Large amounts of sand have been trapped, providing a protective beach. No movement of the groin has been visible at all; however, there has been minor damage to the north edge. A section of the mastic and underlying rock was broken off at the lake edge. Minor recession and slumping of the bluff has occurred, probably due to terrestrial processes. This type of structure has proven stable and effective although it lacks the aesthetic qualities of other methods. The lack of maintenance requirements indicated that only an initial expense for building will be incurred. This structure has performed as well as the more expensive conventional layered rock with armor stone groin, and is a good example of successful low-cost shore protection.

Timber Crib Groin. Very few data are available for the timber crib groin installed at the extreme south end of the site in the fall of 1975. It extends 50 feet (15.2 meters) and costs \$30 per

foot (\$98 per meter) to install. To date it has remained in excellent condition.

In general, the wider spacing between the different groins has proven effective. Minor bank recession has been recorded for small stretches of the shoreline. However, as stated earlier, this could be completely due to terrestrial processes. Of the six groins studied at Sanilac 26, the asphalt-mastic groin has been the most stable. The sandbag groin has suffered the most damage. The Longard tube groins are performing adequately. Both the gabion and the timber crib groins are in excellent condition.

Site 7, Sanilac 11

Site 7 is located about 1.5 miles (2.42 kilometers) north of Site 6 and has the same high clay bluff shoreline. Two 69-inch (175.3 cm) diameter Longard tubes were installed here as a seawall rather than as the groin system utilized at Site 6. The tubes were placed end-to-end at the toe of the bluff parallel to the shoreline, extending 400 feet (121.9 meters). Cost of construction was \$65 per foot (\$213 per meter) of shoreline at the time of installation in the early fall of 1974. Figure 4 shows the condition of the site in the spring of 1975. While the tubes appear to have performed well at this location, there has been minor shifting and damage. Some sand has been lost at the center of the structure where the tubes meet. The north end of the seawall has moved lakeward by more than 5 feet (1.5 meters), but the entire structure has, in general, resisted back pressure from the slumping bluff. Only slight vertical settlement of the tubes has been detected. The one major storm experienced at this site had no effect on the seawall's performance.

Site 8, Tawas City

Tawas City Park was selected for the examination of a sand nourishment project. The site is sheltered by Tawas Bay and has a sand shoreline with no bluff. Sand nourishment was the selected method of shore protection due to its aesthetic qualities and the site's sheltered location. There is an existing pier (jetty) at the southwest end of the project area. Tawas City installed a timber crib groin at the northeastern limit of the site, which was not included in the study. Installation of the sand fill began in the fall of 1973 and was completed by the spring of 1974. Four hundred linear feet (122.0 meters) of shoreline (between the groin and jetty) was protected with 4,350 cubic yards (3,328 cubic meters) of sand fill. The fill sand used had a size distribution similar to the natural beach sand. The nourishment project costs \$20 per foot (\$66 per meter). (As some sand would probably have been lost without the addition of the timber groin, total cost including the groin is \$80 per foot [\$262 per meter] of shoreline.) After some initial shifting the sand remained relatively stable through the spring of 1975. Minor shifting was again detected upon completion

of the fall survey of that year. The timber crib groin and pier have helped to hold the fill sand in place as well as trap additional sand. However, only minor storm activity has been experienced, so further evaluation of this project is required to determine overall effectiveness. To date the nourishment project has been very successful and inexpensive at this site. This project requires minimal maintenance, thus its long-term effectiveness is high.

Site 9, East Tawas

East Tawas City Park in Tawas Bay was selected as another test site. The same shoreform is found at this site as at Tawas City and a similar method of shore protection was examined. Sand nourishment was used, but without any groins or jetties for protection, at a cost of \$15 per foot (\$48 per meter). Three thousand cubic yards (2,295 cubic meters) of sand fill were placed along 400 feet (121.9 meters) of shoreline in the spring of 1974. For nearly a year the sand nourishment remained stable. During the winter of 1974-75 much of the sand was dispersed. By the fall survey of 1975, some sand had shifted back into the area of the original nourishment. This site experienced the same storm activity as Site 8, yet had much more sand movement. This suggests that stabilization of sand nourishment by a groin system will maintain the initial fill over a longer period of time.

Site 10, Tawas Point Coast Guard Station

A rock revetment was selected for testing at this site and was constructed in the summer of 1974. The shoreline is exposed to direct wave attack and has 10-foot (3.0 meter) sand bluffs. To install the 400-foot (121.9 meter) revetment, a foundation layer of rock (4- to 10-inch [10.6 to 24.4 cm]) was graded to a 3:1 slope 30 feet (9.1 meters) wide. At the top of the revetment a 3 by 5 foot (.9 meter to 1.5 meter) trench was dug and filled with smaller rock (1 to 3 inch [2.5 to 7.6 cm]). This would prevent erosion in back of the revetment caused by wave overtopping. Only the north half of the structure was capped with medium size armor stone (11 to 16 inch [27.9 to 40.6 cm]). Total cost of construction was \$50 per foot (\$164 per meter) of shoreline.

The revetment has been effective in preventing further bluff recession. Although only minor storm activity has been experienced, slight slumping and shifting of the rock is evident. Further rock movement may occur if major storms are experienced. While this structure is very effective in protecting the shoreline, it lacks any aesthetic qualities. This method of shore protection should not be installed in areas where beach use, such as swimming, is allowed.

Site 11, Michiana

This site in the Village of Michiana is an open coast area with 30-foot (9.1 meter) sand bluffs. North and south of the project area there is an existing seawall on a narrow beach. This shoreline is exposed to long fetches from the west and northwest and has been undergoing severe erosion for many years. A new concept in revetment construction on the Great Lakes was chosen for testing at this site. An inexpensive European technique using rock and asphalt mastic (a mixture of sand, mineral filler, and asphalt) was adapted for constructing the revetment. The structure was installed at an expense of \$70 per foot (\$230 per meter) in the fall of 1973 and is 400 feet (121.9 meters) long.

During the first year of study the structure performed very effectively and withstood four major storms. The revetment is shown in Figure 5. However, a storm in the spring of 1975 which produced breaking waves of about 7 feet (2.1 meters) for a duration of 24 hours caused most of the structure to collapse. The damage can be seen in Figure 6. The long duration of the storm rather than the wave heights had the most damaging effect. The storm was so severe that the steel seawall at the top of the bluff was threatened. Damage to the revetment resulted in a change of its slope from a ratio of 2 to 1 to 4 to 1. This left the backside 3 feet (.9 meters) lower after the storm. The underwater region immediately offshore had been severely eroded. The deeper water permitted waves larger than the revetment was designed to withstand to reach the shore. This contributed to the loss of sand behind the structure. Undermining of the revetment was probably caused by scour at the toe and overtopping. The asphalt-mastic revetment was more effective than the seawall as it was able to protect the bluff (and the road) even in its damaged condition.

It appears that the asphalt-mastic revetment performs quite well during most storm activity. The damage to the revetment from the unusually long storm also may have been caused by wave reflection off the steel wall at the north end. This is supported by the fact that 75 feet (22.9 meters) of revetment closest to the wall suffered severe slumping whereas the next 75 feet (22.9 meters) was hardly damaged.

Until it failed, the revetment was able to withstand all wave attacks. Even in its collapsed position, it provides a small level of protection from minor storms. The revetment has remained unchanged since the spring storm. Bluff recession has continued, however, and the road at the top of the bluff is threatened.

Site 12, Lincoln Township

Lincoln Township Park was the site selected for this project and is located near Stevensville. The shoreline is unprotected with a narrow beach backed by 20-foot (6.1 meter) sand dunes. An

existing steel seawall marks the southern border of the site and a concrete wall forms the northern border.

The shore protection structures installed at this site consist of a groin system with two groins 240 feet (73.2 meters) apart. Two types of groins were used: a 40-inch (101.6 cm) diameter Longard tube, 120 feet (36.6 meters) long, and a 90-foot (27.4 meter) long timber pile groin. The two structures are shown in Figure 7.

The Longard tube was the first structure installed at this site in the spring of 1973 at a cost of \$30 per foot (\$98 per meter). The tube was torn by construction equipment during installation of the timber pile groin.

Despite the initial tear, the Longard tube has suffered only moderate damage. The lake end of the tube (approximately 30 feet [9.1 meters]) has been lost and the whole structure has settled about 3 feet (.9 meters) along the centerline. It is very possible that the tube would have settled in this locale even without the influence of the heavy equipment. The rate of settlement increased again in the fall of 1975 after remaining relatively stable for about a year. It has not been determined if this is due to sand washing out of the tube from the lakeward end or by settlement. The tube still acts successfully as a groin in trapping sand and protecting the bluff. Design modifications could be incorporated, such as placing the tube on a foundation (preferably rubble) and covering the tube with an armored protective coating. This modified groin would be a good low-cost method of shore protection, though not as inexpensive as the present design. The present method of placing a 40-inch (101.6 cm) diameter Longard tube on a sandy lake bottom will only serve as a temporary method of erosion control.

The timber pile groin was completed while working through the ice in the winter of 1973 at a cost of \$50 per foot (\$164 per meter). This structure has performed well and shows no sign of any deterioration, thus providing additional evidence that wood is an excellent material for groin construction. An impervious timber pile groin is an old and proven means of shore protection in areas where there is adequate littoral drift.

The wide spacing between groins has proven quite successful and the entire system has worked very effectively in protecting the site by trapping sand and raising the beach profile. Both structures are still stabilizing the bluff although it has slumped somewhat. This slumping is probably due to factors other than wave attack, such as terrestrial processes or heavy human traffic on the bluff, as the beach profile is still raised around the groins and immediately adjacent to the bluff.

Site 14, Pere Marquette Township

This site is located 1 mile (1.6 kilometers) south of the Pere Marquette navigation structure. The shoreline consists of 20-foot (6.1 meter) sand bluffs and a narrow beach. A new concept in breakwater design was selected for testing at this site. The breakwater consists of precast, reinforced concrete panels bolted together to form zig-zag walls. Two 70-foot (21.3 meter) walls and one 56-foot (17.1 meter) wall were constructed. The zig-zag walls were placed offshore parallel to the shoreline with 50-foot (15.2 meter) spacings between structures. The panels were originally to be placed at a water depth giving 1 foot of freeboard. Depth increased so rapidly that panels were placed only 50 feet (15.2 meters) from shore. Such a short distance causes high-water velocities between the bank and breakwater which accelerates erosion. Cost per foot (per meter) of shoreline "protected" equalled \$70 (\$230) when installed in the fall of 1973.

The breakwater system performed quite effectively in building up a beach and preventing bluff recession for the first year. Figure 8 shows the structure in the spring of 1974. Eight major storms were experienced at this site. A major storm with 6- to 10-foot (1.8 to 3.0 meter) waves in the winter of 1975 caused extensive damage to the structure and bluff. All three structures were damaged by settlement and panel breakage. The north section lost two entire panels and settled over 3 feet (.9 meters). It is now completely submerged; this can be seen in Figure 9. One panel was lost off of the center section which also settled and tilted radically. The remaining walls are badly chipped and cracked and have tilted toward shore. Major bluff recession has continued, up to 30 feet (9.1 meters) during the second study year. The bathhouse protected by the breakwater has been completely destroyed.

This experimental use of precast zig-zag walls was intended for onshore use only. Unless redesigned, this type of structure should not be used as an offshore breakwater. Necessary design modifications, however, would eliminate this system from the low-cost category. The private homeowner could not install this structure himself because heavy construction equipment is required. This is not a recommended method of shoreline protection as used in this program. Other breakwater designs, although very expensive, should be used if site conditions require that method of shore protection.

Site 15, Ludington State Park

Ludington State Park was selected for testing two steel pile groins. The low, wide sand beach in front of high dunes was suitable for this method of protection. The groins were installed 125 feet (38.1 meters) apart to stabilize the beach. The north groin is 100 feet (30.5 meters) long and the south groin is 70

feet (21.3 meters) long. It is not possible to determine the final costs of construction as some materials and labor were provided at no charge. Improper anchoring and tie back into the beach has prevented the north groin from performing well. This groin was flanked shortly after construction and deep holes scoured in the lake bottom. This scour caused some shifting of the groin and the breaking of the vales. Repairs had to be made to the north groin. The lake portion had to be pulled out, straightened, and redriven. Above normal maintenance and sand fill has been required for these structures. With the additional filling the groins have successfully prevented beach erosion and protected an adjacent parking area. Since the original construction related problems, the groins have remained stable.

The problems experienced at this site illustrate that good design, when improperly installed, may fail. Steel sheet piling groins are normally effective shore protective structures.

Site 17, Empire

Recession rates as high as 30 feet (9.1 meters) a year have been experienced at the Village Park in Empire Village. This open coast area with 3-foot (.9 meter) sand bluffs was selected for testing a 40-inch (101.6 cm) diameter Longard tube utilized as a seawall. The 300-foot (91.4 meter) tube was laid on a filter cloth foundation parallel to shore at a cost of \$30 per foot (\$98 per meter) of shoreline. The tube can be seen immediately after it was installed in the fall of 1973 in Figure 10. Shortly after construction, the tube was attacked by 5-foot (1.5 meter) breaking waves for a 14-hour period. Probable maximum wave height was 11 feet (3.4 meters). Due to the shoreline configuration, waves pounded directly against the structure. The single tube was unable to withstand this wave attack and was destroyed. The damage can be seen in Figure 11. If the tube had been sewn to the filter cloth, it may have been more effective.

Site 18, Moran Township

This site is located along U.S. 2 in Moran Township. The 30-foot (9.1 meter) sand bluffs found here have been severely eroded. Two styles of seawalls were selected for testing. Three 40-inch (101.6 cm) diameter Longard tubes were installed in a pyramid configuration (one on top of two) on filter cloth parallel to the shoreline within 10 feet (3.0 meters) of the waterline. The tubes extended for 300 feet (91.4 meters). The second structure consisted of giant sandbags placed in four different stacking patterns at the toe of the bluff, parallel to the shoreline, for 250 feet (76.2 meters). The different stacking sequences were incorporated to test their relative effectiveness. All Longard tubes were installed in the fall of 1973. At the east end of the tubes, the sandbag structure was installed in the spring of 1974. A view of this site can be seen in Figure 12. The costs of construction

per foot (meter) of shoreline for each was \$60 (\$197). Five major storms have since been experienced but only minor problems have been experienced. The top Longard tube shifted out of position due to back pressure from the slumping bluff and had to be shimmed up. The western 50 feet (15.2 meters) moved lakeward about 3 feet (.9 meters). The lower tube is now covered with sand, apparently from sand washing in and around it (no vertical movement of the tube has occurred). The condition of the structures in the fall of 1975 is shown in Figure 13. Despite this, the tubes have retained their original effectiveness. The top of the bluff behind the structures has continued to recede and slump. This occurred because the sand bluff was not in a stable position. The most dramatic bluff loss has occurred behind the sandbags and between the two structures. The sandbag structure, despite some bag loss due to vandalism, has remained stable and performs effectively. Both structures have effectively protected the bluff from major erosion damage (although the shoreline adjacent to the structures has also only experienced minor recession). There is a wider expanse of beach in front of the Longard tubes than the sandbags. This appears to be more of a natural phenomenon than an indication of relative structure effectiveness.

Tables 2, 3, and 4 present summary details of the research effort. A brief description of all the sites is included in Table 2 along with method of protection. Table 3 reports the number of major storms at the surveyed sites since the time of construction as well as the condition of the structure and near-shore environment. Table 4 gives structure and nearshore environment condition for the sites studied utilizing photographic methods.

CONCLUSIONS

The durability of shore protective structures depends on the number of major storms that occur, their intensity and duration as well as on soil type, geologic structure of the lake bottom, topography of the shoreland, etc. These site specific variables prevent broad comparisons of structure effectiveness. Long-term effectiveness of the installations cannot be judged until more time has passed. Some of the test sites have not been exposed to a number of major storms common to the Great Lakes. This makes it difficult to evaluate the structure's performance as a form of low-cost shore protection. The ongoing nature of this study is designed to gather the data necessary to fully evaluate the test methods.

Over the short period of the program, the methods of shore protection at East Tawas, Michiana, and Empire have been lost. The breakwaters at Pere Marquette Township and the Longard tube at Lincoln Township have been damaged and the effectiveness of these structures has been substantially reduced. Sandbags have been lost from the Sanilac 26 and Moran Township projects. The loss documents the necessary replacement of sandbags on a yearly basis.

The shore protection methods used at the remaining project sites have experienced only minor changes.

The following observations can be made based on the two years of study:

-- Artificial nourishment projects are very effective methods of shore protection, especially in areas with limited littoral drift which eliminates the use of groins. (Artificial nourishment should not be used in areas with strong littoral currents which rapidly remove the sand.) Groins may be used in conjunction with this method to help hold the sand in place. Nourishment is also aesthetically pleasing as it preserves the beach in its natural state.

-- Groin systems are appropriate methods of shore protection in areas with ample littoral drift. If a groin system is installed where there is not ample littoral drift, sand nourishment may be required to make the system functional. The longer spacing used between groins at Sanilac 26 shows no adverse effects on the performance of the groin system. Longard tubes can be effectively used as groins; however, in sandy areas they may settle and eventually require replacement. Sandbag groins will require yearly replacement of bags. Gabions, asphalt-mastic, and timber crib groins have been stable at the Sanilac 11 site and pile groins, both timber and steel, are generally effective.

-- When site conditions require, revetments and seawalls may be utilized effectively. However, they experience accelerated destruction when overtopped by waves as shown at Michiana and Empire. Longard tubes used at Moran Township and Sanilac 11 as well as the sandbags used at Moran Township, to date, have been suitable methods of shore protection. The rock revetment installed at Tawas Point Coast Guard Station also has been successful.

-- Offshore breakwaters have traditionally been an expensive, yet effective, method. However, as shown by the breakwater system used at Pere Marquette Township, low-cost breakwaters are not suitable shore protection systems.

The data derived from this project have given insight into the possible solutions for preventing shoreline erosion. Only further years of study will provide the data necessary to properly build effective low-cost methods of shore protection. The general conclusions of two years of study presented in this paper contribute to the development of proper methods of shoreline protection from erosion damages.

TABLE 2
PROJECT DESCRIPTION

PROJECT NUMBER	PROJECT LOCATION	SITE DESCRIPTION	METHOD OF PROTECTION:	TEST CONSTRUCTION COST ¹	
				(\$ per foot)	(\$ per meter)
LAKE SUPERIOR					
1	Little Girls Point	Open coast area with 20-foot (6.1 meter) high, predominantly clay bluffs with little to no beach.	"Nami Rings" (2.5 foot by 1 foot [.8 meter by .3 meter] concrete rings weighing 265 lbs. [120.2 kg]). Part of this structure was placed on filter cloth, part on a rock foundation, the remainder was not placed on a foundation. Some of the rings were fastened together.	35	114
2	Keweenaw Peninsula	Open coast area with 15-foot (4.6 meter) sandy bluff with narrow beach.	Revetment using waste wine rock in a size smaller than normally accepted for a revetment of this type.	20	66
3	Marquette	Partially sheltered coast area with a low sand bluff, partially "protected" with broken concrete rubble, little to no beach.	Dredge sand with a large percentage of fines and a steel sheet pile groin.	*	*
4	Whitefish Township	Predominantly sheltered coast area with a low (about 3-foot [.9 meter]) sandy loam bluff, no beach.	Rock revetment with groins "tying" the revetment to the land area behind.	45	148
LAKE HURON					
5	Lakeport State Park	Open coast area with high sand bluff, low foredunes and some beach.	40-inch (101.6 cm) diameter Longard tube installed on bar to form an offshore breakwater.	25	82
6	Sanilac 26	Open coast area with 30-foot (9.1 meter) clay bluffs and no beach.	An experimental groin system with a spacing between groins of about 200 feet (61.0 meters) consisting of:		
			2 40-inch (101.6 cm) diameter Longard tubes, 100 feet (30.5 meters) long	30	98
			69-inch (175.3 cm) diameter Longard tube, 50 feet (15.2 meters) long	25	82
			Cabion baskets, 70 feet (21.3 meters) long	30	98
			Giant sandbags, 60 feet (18.3 meters) long	30	98
			Asphalt mastic, 60 feet (18.3 meters) long	45	148
			Timber crib, 50 feet (15.3 meters) long	30	98
7	Sanilac 11	Open coast area with 35-foot (10.7 meter) clay bluffs and no beach.	Seawall of 69-inch (175.3 cm) diameter Longard tube.	65	213

TABLE 2
PROJECT DESCRIPTION

PROJECT NUMBER	PROJECT LOCATION	SITE DESCRIPTION	METHOD OF PROTECTION:	TEST CONSTRUCTION COST	
				(\$ per foot)	(\$ per meter)
8	Tawas City	Sheltered sand coast area with no bluff and an existing pier (jetty) at the southwest end of the project area and a newly constructed timber pile groin at the northeast limit of the project area.	Nourishment project between a jetty and wood groin. Fill sand has a size distribution similar to the natural beach sand.	20	66
9	East Tawas	Sheltered sand coast area with no bluff.	Nourishment project using fill sand which has a size distribution similar to the natural beach sand.	15	49
10	Tawas Point Coast Guard Station	Open coast area with 10-foot (3.0 meter) sandy soil bluff, no beach.	Layered (staged) rock revetment, half "capped" with armor stone of medium size (11 to 16 inch [27.5 to 40 cm]).	50	164
LAKE MICHIGAN					
11	Michiana	Open coast area with 30-foot (9.1 meter) sand bluff. Shoreline immediately north and south of project area have seawall construction and narrow beach.	Revetment composed of rock and asphalt mastic (a European technique new to the Great Lakes).	70	230
12	Lincoln Township	Open coast area with a 20-foot (6.1 meter) sand dune and a narrow beach.	Groin system with 2 groins 240 feet (73.2 meters) on center composed of:	30	98
			40-inch (101.6 cm) diameter Longard tube, 120 feet (36.6 meters) long Timber pile, 90 feet (27.4 meters) long	50	164
13	Charles Mears State Park	Open coast area with low sandy beach area in front of high dunes. Study area is immediately north of Pentwater navigation structure	Groin system with 3 groins about 150 feet (45.7 meters) on center. Each groin is composed of gabions in beach area and giant sandbags in the water area.	*	*
14	Pere Marquette Township	Open coast area with 20-foot (6.1 meter) sand bluff and narrow beach. The Pere Marquette navigation structure (jetty) is 1 mile (1.6 km) north of the site.	3 precast reinforced concrete, zig-zag breakwaters about 70 feet (21.3 meters) long with 50-foot (15.2 meter) gaps between structures.	70	230

TABLE 2
PROJECT DESCRIPTION

PROJECT NUMBER	PROJECT LOCATION	SITE DESCRIPTION	METHOD OF PROTECTION:	TEST CONSTRUCTION COST	
				(\$ per foot)	(\$ per meter)
15	Ludington State Park	Open coast area with low, wide sand beach in front of high sand dunes.	2 steel pile groins, 125 feet (38.1 meters) on center to stabilize beach. Groins are periodically filled with sand removed from an adjacent parking area.	*	*
16	Big Sable Point	Open coast area with 10-foot (3.0 meter) sand dunes and an existing damaged seawall; no beach.	Tie backs installed on existing seawall; return and cutoff gabion groins constructed from existing seawall landward. Land area behind the seawall and between return walls and cutoff walls sand filled.	*	*
17	Empire	Open coast area with 5-foot (1.5 meter) sand bluff and little to no beach. This area has been experiencing extremely high (30 feet/yr [9.1 meters/yr]) recession rates.	40-inch (101.6 cm) diameter Longard tube placed on filter cloth parallel to the shoreline near the waterline.	30	98
18	Moran Township	Open coast area with 30-foot (9.1 meter) sand bluff and narrow beach.	3 40-inch (101.6 cm) diameter Longard tubes placed pyramid fashion (1 on top of 2) on filter cloth parallel to the shoreline near the waterline. Giant sandbags placed in 4 different stacking patterns parallel to the shoreline along the waterline.	60	197
19	Manistique	Open coast area with 5-foot (1.5 meter) sand bluff and narrow beach.	Gabion mats placed over bluff face in revetment fashion.	20	66
Note:	Cost figures given are determined over the length of shoreline the structure was designed to protect.				
*	Exact cost figures are not available.				

TABLE 3
PROJECT RESULTS THROUGH FALL, 1975 FOR SITES UTILIZING SURVEYS

PROJECT	NUMBER OF STORMS (BREAKING WAVE OF 6 FEET [1.8 METERS] OR GREATER) AT THE SITE SINCE TIME OF CONSTRUCTION (INCLUDES ALL MONTHS)	STRUCTURE CONDITION	NEARSHORE ENVIRONMENT CONDITION
Site 5, Lakeport 40-inch (101.6 cm) diameter Longard tube on bar	3	Unchanged.	Beach area has increased greatly in the vicinity of the tube (unrelated to the tube's performance) to such an extent that it is no longer a breakwater. This site is no longer part of the extended field program since the tube is not required for shore protection.
Site 6, Sanilac 26 2 40-inch (101.6 cm) diameter Longard tubes.	1	Minor differential settlement in tubes.	Sand has been trapped by the groin. Recession at top of bluff is about 10 feet (3.0 meters) in the immediate vicinity of this groin. This recession could be caused by factors other than wave attack.
69-inch (175.3 cm) diameter Longard tube	2	Unchanged.	This groin has been effectively trapping sand, particularly to the north. Top of bluff recession has been minimal.
Gabion	1	Unchanged.	Sand is being trapped, especially on north side of groin.
(Site 6 continued)			
Sandbags	2	Approximately the outer 15 feet (4.6 meters) of this structure have been lost through bag destruction.	Sand has been trapped by this structure. Top of bluff recession has been minimal.
Asphalt mastic	2	Small section (about 3 feet by 3 feet [.9 meter by .9 meter]) of groin has broken off at outer end.	Sand has been trapped by structure. Minimal top of bank recession has been recorded.
Timber crib	1	Unchanged (installed late summer 1975).	No data available.
General		Spacing between groins has been effective to date.	Some areas of localized top of bluff recession.
Site 7, Sanilac 11 69-inch (175.3 cm) diameter Longard tube	2	Structure has remained stable. The center section of the structure has lost sand.	Area of minor bluff recession.
Site 8, Tawas City Sand nourishment	1	Only minor shifting of the sand nourishment.	No change.
Site 9, East Tawas Sand nourishment	2	Totally dispersed.	No apparent effect from sand.

TABLE 3
PROJECT RESULTS THROUGH FALL, 1975 FOR SITES UTILIZING SURVEYS

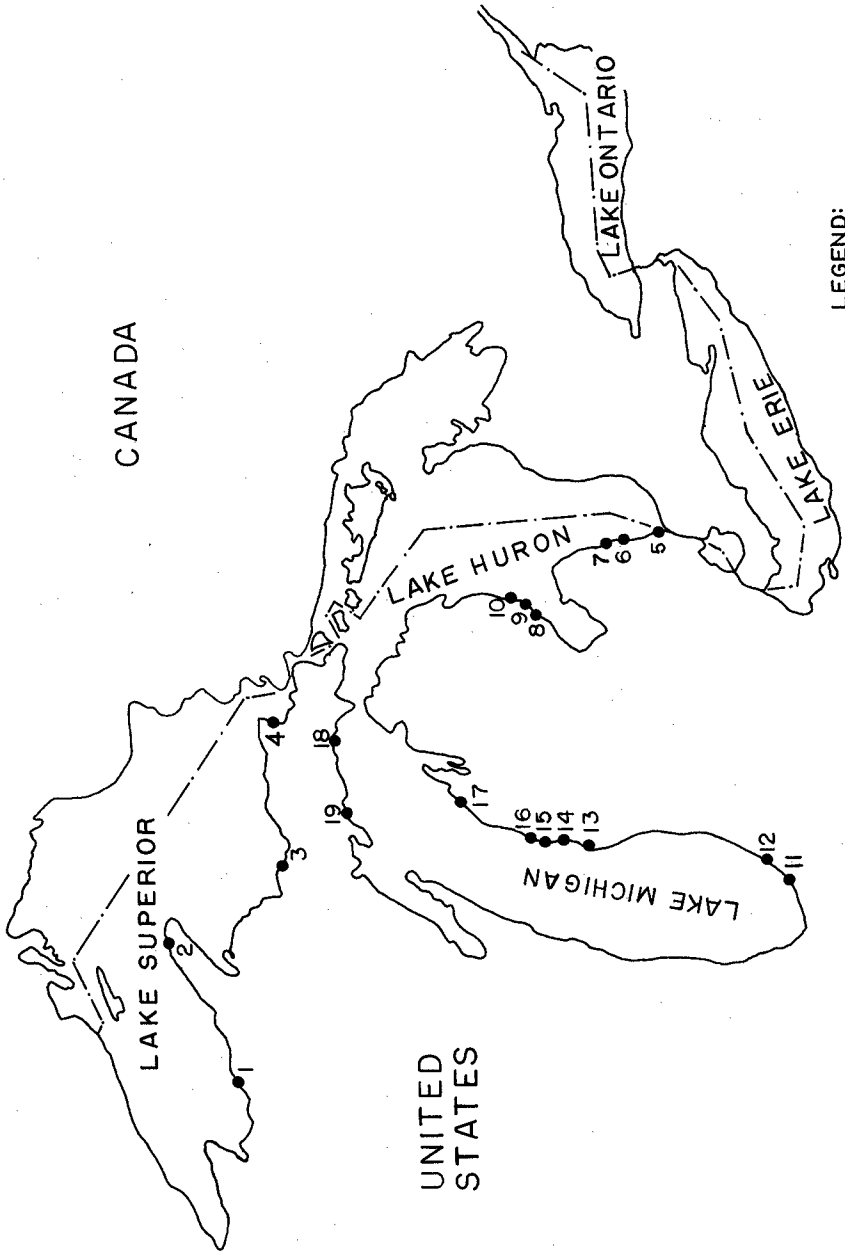

PROJECT	NUMBER OF STORMS (BREAKING WAVE OF 6 FEET [1.8 METERS] OR GREATER) AT THE SITE SINCE TIME OF CONSTRUCTION (IN- CLUDES ALL MONTHS)	STRUCTURE CONDITION	NEARSHORE ENVIRONMENT CONDITION
Site 11, Michiana Asphalt mastic revetment	5	Revetment collapsed on beach after 5 critical storms. The sand behind the revetment's slope has been flattened. Small portions of the revetment are completely destroyed.	Bluff erosion has continued. Remaining revetment is an inconvenience to bathers at this beach.
Site 12, Lincoln Township 40-inch (101.6 cm) diameter Longard tube	18	Outer portion (1/3 of tube) has been lost. The remainder of the tube has settled from 0-2 feet (0-.6 meter).	Tube has trapped and held sand. Slope on dune near tube has flattened to some extent.
Timber pile	18	Unchanged.	This groin has trapped and held sand. Slope on dune near this groin has flattened to some extent.
General			Structures have protected site by trapping sand and raising the beach profile.
Site 13, Charles Mears State Park Gabion and sandbag groins	13	Some settlement detected in all groins. One or 2 sandbags lost from each structure.	System has helped stabilize beach area with artificial nourishment added each spring.
Site 14, Pere Marquette Township Precast concrete breakwater	18	All three structures have settled about 1 foot (.3 meter). Two panels have been lost off the north end of the north section and 1 panel has been lost off the south end of the center section.	Bluff recession has continued. Bathhouse that this installation was meant to protect has been destroyed.
Site 15, Ludington State Park Steel pile groins	14	North groin had to be repaired once (lake portion pulled, straightened, and redriven).	Deep holes have scoured in the lake bottom around the outer edge of the groin. System has required periodic sand maintenance.
Site 17, Empire 40-inch (101.6 cm) diameter Longard tube	-	Destroyed within 1 month.	Rapid bluff recession has continued.
Site 18, Moran Township 40-inch (101.6 cm) diameter Longard tubes	8	Some minor differential settlement. The top tube had to be wedged in place to avoid being pushed off due to back pressure from sliding sand.	Sand bluff has flattened some.
(Site 18 continued) Sandbags	8	A number of sandbags have been lost, partly due to vandalism. Some differential settlement has been detected.	The sand bluff has slumped in some areas.

TABLE 4
PROJECT RESULTS THROUGH FALL, 1975 FOR SITES UTILIZING PHOTOGRAPHIC MONITORING ONLY

PROJECT NUMBER	PROJECT LOCATION	STRUCTURE CONDITION	NEARSHORE ENVIRONMENT CONDITION
1	Little Girls Point	Some change in revetment position due to sliding clay. Rings have filled with sand and small rock.	Some sliding of clay bluff.
2	Keweenaw Peninsula	Unchanged.	Unchanged.
3	Marquette	Groin has remained unchanged; as expected a large amount of sand has shifted.	No apparent effect from structures.
4	Whitefish Township	Unchanged.	Stable.
10	Tawas Point Coast Guard Station	Some shifting in the rocks is evident.	Unchanged.
16	Big Sable Point	(Construction problems were experienced at this site which hampered the study.) All the sand filled behind the wall has been washed out, exposing improperly installed tie backs. The south return wall which was poorly installed has failed.	In spite of these failings, the original seawall is still in place. Bluff recession has continued at a very low rate.
19	Manistee	Structure has been "paved" over and area is now a parking lot.	No longer applicable.

FIGURE 1
SITE LOCATIONS

Figure 2 Sanilac 26 April 27, 1975

The sandbag groin can be seen in the foreground with the gabion, 69-inch (175.3 cm) diameter Longard tube and the two 40-inch (101.6 cm) diameter Longard tube groins in succession behind it. The group of structures in the far background are not part of this project.

FIGURE 3

PLAN VIEW OF SANILAC 26

SANILAC TWP., MICHIGAN

Figure 4 Sanilac 11 April 27, 1975

This view shows the 69-inch (175.3 cm) diameter Longard tube used as a seawall at Sanilac 11. The very active and slumping clay bluff is evident in the photograph.

Figure 5 Michiana September 23, 1973

The revetment can be seen one month after completion of construction in the fall of 1973.

Figure 6 Michiana October 20, 1975

Large portions of the sand behind the structure have been washed out causing the structure to collapse. Despite its collapsed condition the revetment has maintained its integrity. Emergency fill operations are evident at the south end of the project near the concrete seawall. The entire beach area has been eroded as is evident by the exposed steel pile foundation beneath the concrete seawall.

Figure 7 Lincoln Township April 20, 1974

The timber pile groin, installed in the winter prior to this photograph, is evident in the foreground. Part of the Longard tube, constructed the previous fall, can be seen in the background (near the tripod). Settlement in the tube is particularly evident at the shoreline.

Figure 8. Pere Marquette Township April 29, 1974

This view shows the south and north set of panels (looking north) shortly after construction. The center panels were installed in the fall of 1973. The newer set of panels were placed at a higher elevation (with more freeboard) than the center section. As is evident, these panels were initially very effective in trapping sand.

Figure 9 Pere Marquette Township October 12, 1975

In this photograph (looking north) it is evident that the north and south sets of panels have settled considerably. Effectiveness of the structures has been reduced and the bluff behind the structures (not shown) has been considerably damaged by storms.

Figure 10 Empire November 3, 1973

This picture was taken shortly after construction was completed. The filter cloth foundation and the low sand bluff to be "protected" by the tube is evident.

Figure 11 Empire March 7, 1974

As evident in this photograph, a large portion of the structure has settled out of site. Bluff recession has continued at a high rate.

Figure 12 Moran Township November 4, 1973

The Longard tube structure and one of the stacking patterns of the sandbag structure, both used as seawalls, are shown here. The short stub groin protruding lakeward from the Longard tubes was removed. The active sand bluffs to be protected by the seawalls are evident.

Figure 13 Moran Township October 12, 1975

This is a view of the site two years later. Many sandbags have been lost and the tube has remained stable. Recession activity is evident as shown by the number of trees and vegetation scattered along the face of the bluff. This action is a result of erosion damage prior to the installation of the test projects. The shoreline in front of these structures has stabilized as well as the shoreline in the adjacent areas (no cause and effect relationship is apparent).

CHAPTER 165

LOW-COST SHORELINE PROTECTION

Billy L. Edge,¹ John G. Housley,² and George M. Watts³

ABSTRACT

As the public interest in low-cost, self-installed solutions to shoreline erosion continues to grow, the involvement of private enterprise in developing solutions intensifies. Now that low-cost devices are identified as a salable commodity as goods or services, the number of inventors, creative engineers, agronomists, and foresighted planners producing potential designs are rapidly growing. Over two hundred devices, both proven and untested devices, have been cataloged as a part of the National Shoreline Erosion Demonstration Program. This program calls for the Corps of Engineers to plan, establish, and conduct for a period of five years a shoreline erosion control development and demonstration program including physical and vegetative devices.

INTRODUCTION

There is no need to recount the tales of the thousands of miles of eroding shoreline around the United States as well as throughout the world; the National Shoreline Study adequately covers the discouraging situation around the coastline of the United States. Little else needs to be said to emphasize that without adequate protection, in the broadest sense, a very significant part of our coastline falls prey to the ravages of the sea, and, of course, to man himself. Adequate protection against these forces comes normally by constructing monumental structures, such as the San Francisco seawall (O'Shaunessy), which render the land-sea-air interface permanent. It is definitely not in the best interest of the nation to provide this degree of protection at other than very valuable property at an extremely high wave energy site.

¹Associate Professor of Civil Engineering, Clemson University, Clemson, South Carolina 29631 and Vice-Chairman Shoreline Erosion Advisory Panel.

²Civil Engineer, Planning Division, Directorate of Civil Works, Office of Chief of Engineers, U.S. Army Forrestal Building, Washington, D.C. 20314.

³Chief, Engineering Development Division, U.S. Army Coastal Engineering Research Center, Fort Belvoir, Virginia 20060.

At the opposite extreme of the cost scale is the institutional type of protection. Through appropriate legislation and other forms of institutional arrangements, loss of man-made structures along the shoreline is prevented. By restricting development to behind the third row of dunes (McHarg), man-made structures are protected from falling to the forces of the sea, at least for several years, and at the same time with adequate control the dune structure is maintained for the last line of defense. There is much to be said for this form of protection in an area that is not already fully or even overdeveloped. In the latter case it makes pitifully little sense to legislate shoreline protection. Rather, recognizing that there is little man can do to completely stop erosion, attention must be given to providing erosion protection in the form of a new beach equilibrium--a form which does not match the energy of the ocean against the inertia of a coastline but a form which enhances the resistance of the shore to erosion.

Within the context of the philosophy sketched here shoreline protection can be a reality and not a dream. Moreover, within the broad spectrum of solutions available, from laws to monuments, there is a place for low-cost protection.

Whenever major erosion threatens public property, astute elected officials generally call upon state or federal government to help solve the problem. On the other hand, when the property is private, help is seldom available and the owner is forced to provide his own defense. This requirement often results in many thousands of dollars being wasted by construction of ill-conceived projects. Sometimes the owner goes to a coastal engineer for help; but, more frequently, they design their own protection with the "good advice" of a brother-in-law, uncle, or helpful neighbor. Unfortunately, even if the private landowner does come to a coastal engineer, he seldom receives the kind of inexpensive advice for which he is looking. This is not necessarily the fault of the coastal engineer since the type of protection with which he is normally concerned is of the more glamorous, permanent, and expensive variety. So the home owner, dejected by the exorbitant costs of the traditional shore protection works, is faced with paying more than he can or is willing to afford, selling his property to an unsuspecting buyer, or developing his own solution.

More recently, significant interest has arisen in the governmental and industrial sectors to provide help for the private landowner with an eroding shoreline. Some research has been sponsored by state and federal government, although not at a level commensurate with the problem. A major demonstration and testing program has been undertaken by the Michigan Department of Natural Resources (Brater, Armstrong, and McGill, 1974, 1975). The demonstration projects are designed to provide data on various devices, methods of construction, and costs. Close evaluation of the results of this study will provide extremely useful information on effectiveness and durability of each of these shore protection devices.

Significant efforts have also been made to educate the public about not only devices suitable and available but more fundamentally about the

basic phenomena that cause erosion problems (Brater). These publications range from brochures or "roadmaps" (Arno) to thorough treatments in the language of the intended user (Habel). This self-help literature has been distributed widely in the Great Lakes area and less completely in the Atlantic, Gulf, and Pacific areas with the hope of improving on the landowners self-design.

Industry is responding to the need for low cost solutions through their own research and development which is providing the coastal engineer with many new and innovative ideas that "might" fall into the category of low cost.

Before going further, a few words of clarification are in order. It is not implied that a "low-cost" solution is acceptable or even available for most erosion situations; rather the emphasis of this paper is on eroding areas that are not necessarily amenable to the more-costly, traditional forms of control. Moreover, it must be pointed out that too often the inexpensive methods of protection are not "low-cost" at all.

To evaluate the new concepts and ideas for low-cost protection and to disseminate the results to the owners of eroding shorelines, the U.S. Congress created the National Shoreline Erosion Demonstration Program.

Section 54 of the "Shoreline Erosion Control Demonstration Act of 1974," directed the Secretary of the Army, acting through the Corps of Engineers to establish and conduct for a period of five years a national shoreline erosion control and demonstration program. The intent of the program is to develop and demonstrate to the public and technical community methods for "low-cost" shore protection. Specifically, these methods are to be developed and demonstrated in "sheltered waters." Sheltered waters are defined as those areas where the design breaking wave is less than six feet. In addition, the Act specifically calls for widespread dissemination of the results of this program.

In the following sections, proven methods and devices for low-cost protection is discussed. Next, several of the new and innovative and yet untried concepts are presented. The National Shoreline Erosion Demonstration Program is presented in terms of direction, accomplishments, and goals.

What constitutes low-cost shore protection? This question is addressed here to provide the framework needed for further discussion. Low-cost shore protection is shore protection for sheltered or inland areas which fulfills one of the following criteria:

- a. Cost less than \$50 per front foot for materials and can be constructed without the use of heavy construction equipment.
- b. Cost less than \$125 per front foot for materials plus placement using heavy construction equipment.

These cost figures are intended to provide a degree of protection to the shore for approximately a 10-year period with a minimum of maintenance assuming that a storm exceeding a 1 in 25 year severity is not encountered during the 10-year interval with the severity being measured in terms of a combination of violence and duration.

This definition now raises the question, what is a sheltered area? For the purpose of low-cost protection it is defined as follows. A "sheltered" or "inland" site is an area which falls under one or more of the following conditions:

Coastal shores. Those shores receiving wave attack from waves generated on the open or semi-open waters of the Atlantic, Gulf, Pacific, Bering Sea, or Arctic Ocean, but which waves are attenuated by refraction, diffraction or friction in such a manner that the significant wave height of waves breaking on these shores never exceeds six feet in height.

Tidewater shores. Those shores fronting on the inland tidal waters connected with the Atlantic, Gulf, Pacific, Bering Sea, or Arctic Ocean.

Great Lakes shores. All shores fronting on the Great Lakes plus the shores of all bays connected directly with one of the Great Lakes and standing at the same water levels as the parent Great Lake.

DEVICES AND METHODS WITH POTENTIAL FOR SUCCESS

This section is devoted to describing devices and methods which, if used in the field, would result with a high probability of success. This description is not intended to be all inclusive but rather to present those concepts and established devices which have a probable chance of success. Devices can be categorized as follows:

- Revetments
- Seawalls
- Bulkheads
- Breakwater
- Beach fills
- Groins
- Vegetation
- Institutional

There is one extremely important factor concerning the successful behavior of all gravity, and to some extent cantilevered, type structures in the above list. This factor involves an adequate foundation and toe (most seaward portion) protection for the structure. The successful behavior of any gravity structure whether it be semi-flexible or rigid is very much dependent on the adequacy of foundation materials on which the structure is placed. If the foundation is inadequate or under-designed, a high degree of movement of structural components can be expected with resultant failure of the integrity of the structure. A properly designed and constructed foundation for the overlying structure can result in a satisfactory performance equal to or greater than the desired life of the installation, assuming, of course, the structural components of the main element of the structure are properly designed.

Revetments

Substantial data are available to verify that a graded rip-rap type revetment can be very successful as a shore stabilization structure. Of course, the stone size distribution in the revetment, including the foundation material, must be commensurable with expected wave forces on the structure.

In geographic areas where the cost of placing suitable rip-rap material (stone) exceeds acceptable limits, consideration could be given to the placement of precast concrete armor units on a proper foundation. Most all of the presently used precast armor units are described in the CERC Shore Protection Manual. The use of precast concrete units is generally associated with large coastal structures subjected to very large wave forces. However, there are no apparent technical reasons why small precast concrete armor units, would not be equally effective in a low wave energy environment.

There are other alternative materials and approaches for construction of revetments which exhibit potential success; however, presently available performance data in regard to upper limit of stability are meager and

this lack of information is influential in establishing the relative probability of success if the structure is tested in the demonstration program. These alternatives include the precast concrete interlocking and semi-interlocking units placed on a proper foundation and appropriate toe protection provided. Also, included is a step-type revetment consisting of cribbing units which are interlocking and filled with proper graded stones, all placed on an adequate foundation with toe protection provided in front of the first step. However, one factor of concern for the crib type revetment involves a prediction of the durability of the cribbing units if low-cost constraints are adhered to for its structural make-up.

Seawalls and Bulkheads

The primary function of a seawall is to protect the area behind it from direct wave attack and the structure may or may not be subjected to backfill pressures. Bulkheads' functions are to retain backfill and are subjected to direct wave attack. The functional difference between a seawall and a bulkhead is, therefore, sometimes difficult to delineate, but for purposes of application in moderate to low wave energy environments, they may be considered to serve the same function with seawalls and, therefore, would generally be more massive than bulkheads.

There are a number of existing designs of precast concrete type seawalls, if placed on an adequate foundation, that would be promising for success. Most of these designs would require heavy equipment to handle and place the concrete segments. Promising results could also be obtained for a seawall constructed of cribbing filled with stones with the structure placed on a proper foundation and toe protection provided. However, the factor concerning structural durability of the cribbing for the seawall would be similar to that cited for the cribbed type revetment mentioned earlier.

The presently available technical guidance on bulkhead design is somewhat substantial, therefore, installation of a standard steel, concrete, or timber sheetpile bulkhead as a low-cost structure would most likely be successful. Appropriate measures to prevent excessive wave induced bottom scour in front of the sheetpile is necessary or desirable for most installations. There are alternative sheetpiling materials that would be considered for the bulkheading and depending on local environmental conditions (mainly physical). These may prove to be cost effective and exhibit a high probability of success. Examples of such materials are aluminum, asbestos, fiberglass, and many variations of synthetics. The use of lightweight steel or special additives to concrete to reduce weight but maintain strength, and thus reduce material costs of the sheetpiling, would also seem appropriate to consider.

Breakwaters

There has been limited use of breakwaters in the United States for strictly shore protection purposes. Since these structures are located offshore at depths commensurable with desired beach and shore responses, they are subjected to greater wave forces and structural components must

be stronger or larger than for those structures located in the foreshore or beach zone. An offshore breakwater of proper design will dissipate incident wave energy, thus, the shores within the "lea or shadow" of the breakwater will be protected, and in this context the overall functional behavior of the structure could be considered as promising with regard to success. There are two basic or standard techniques to constructing offshore breakwaters, both of which could be considered as resulting in a high probability of success if constructed in the demonstration programs. The first involves the use of rubble with an armor layer of stone or precast concrete units, depending on economics; and, the second involving the use of semi-interlocking precast concrete segments. Each technique requires provision for an appropriate foundation to support the super-structure, including toe protection which will remain stable under design wave forces. Relatively heavy-duty equipment and possibly certain marine plants are required for most breakwater construction and since the structure is located offshore, it is apparent that construction practices and procedures are more difficult and involved as compared to construction of a similar structure on the shore zone. This is particularly important to keep the project within the low-cost category.

Considerable attention has been given to the use of portable or floating breakwaters to attenuate wave energy. There are currently no devices of this type that do not become less efficient in wave energy attenuation as the wave length of the incident wave increases. The fact that low-cost solutions generally will be confined to sheltered waters does introduce an attraction to utilize floating breakwater devices as short wave periods would normally prevail.

Beach Fill

The use of beach fill as a low-cost structure would result in a probable chance of success provided the placed fill was of suitable size characteristics. Periodic nourishment for the initially placed fill would be required or should be anticipated. The predominance of short period waves breaking on the beach fill means that direct offshore transport will dominate. No beach recovery can be expected by onshore transport since, in general, there would be no, or minimal, occurrences of long period waves; thus, periodic nourishment to balance the losses to the offshore zone would be necessary to maintain desired project dimensions in the study area. Depending on local conditions, terminal structures (groins) may be needed at one or both ends of the eroding segment, as well as, artificial headlands.

Groins

An accurate determination of the littoral material movement of the site specific is essential to the use of groins as a low-cost structure. A moderate amount of alongshore transport of littoral materials must prevail in the area or a groin or groin system will not function properly. Assuming the prevailing littoral material transport conditions are favorable for the functional aspects of a groin system, there are several materials from which the groins can be constructed and successful results

expected. Constructing the groin of rubble has several desirable features in regard to wave energy dissipation and retention of the impounded sand. This assumes the structure has a proper foundation and distribution of stone throughout the groin cross-section. The use of steel, concrete or timber sheetpiling with stone protection around the outer end is also a well-proven and acceptable method for groin construction. Pre-fabricated segments (concrete) which have an interlocking or semi-interlocking design and founded on a proper foundation can also be structurally effective. If the material components of a crib type structure (crib units filled with stone) will be durable for the life of the structure, there is no reason to believe this type of groin would not also be effective.

If the site conditions are favorable for testing of a groin system, the most effective structure would be a rubble design. The performance of a sheetpile design with rubble placed around the outer end of the groin should be comparable to a prefabricated segmented design (interlocking or semi-interlocking) placed on proper foundation materials.

Vegetation

Very little information and guidance are presently available in regard to the effectiveness of vegetation to directly dissipate incident wave energy. Its effectiveness in a high wave energy environment is probably very limited. On the other hand, the use of vegetation to impound or retain aeolian sand in the foredune area of the coastal zone is well proven and these stabilized or created foredunes are of tremendous value in terms of shore protection.

Fairly adequate data are available on species adaptation and on establishment and maintenance on the Atlantic and Gulf Coasts. On the Great Lakes, Pacific and Alaskan coasts, considerably less is known. Although vegetation is the only generally accepted method to feasibly stabilize dunes, few quantitative estimates are available on the degree of protection provided. Dahl et al. gives a very complete literature review. Recent successes using panic grass (Panicum amarum) along the North Carolina Coast in dune stabilization is given by Seneca, Woodhouse and Broome. In addition to panic grass, American beachgrass, european beachgrass, and sea oats are some of the more successful vegetation used in dune building and stabilization.

The intertidal zone has not yet received the same degree of success. However, vegetation appears to offer considerable promise for the more protected site. Considering that many thousands of miles of shoreline are now well protected by natural marsh grass, it is obvious that the most likely technique for stabilizing the shoreline in a sheltered area is to simulate the protection provided by nature. With some assistance by man through planting sufficient numbers of plants or seeds, at the proper time, the invasion of natural marsh species can be hastened. Most of the work done in the intertidal zone has been with smooth cordgrass (Spartina alterniflora). This plant thrives well in the intertidal salt marshes of the Atlantic and Gulf Coasts. In the more brackish waters the following grasses are being considered: three-square (Scirpus Americanus), needle rush grass (Juncus roemerianus), and saltmeadow cordgrass (Spartina patens). Very little

has been written on the degree of protection that this method can provide although there is much current research in this area. Webb and Dodd show how smooth cordgrass has been used in Galveston Bay. It appears though that marsh vegetation in conjunction with some form of physical temporary protection, such as a floating breakwater, offer much opportunity for low-cost shoreline protection at a very attractive cost.

Institutional Devices

Intangible devices are much more difficult to identify except in a generic sense. Moreover, the actual cost of institutional devices are ill defined. Conceptually, the ideas that can be considered in this category include zoning, permitting, taxing and such other regulatory powers that government - local, state, and federal - can use. The institutions in themselves are indeed low-cost; however, the cost of implementing the regulation to the property owner can be quite costly. For example, if a land owner were experiencing a rapid rate of erosion he would want to quickly install some device to slow or stop the process. However, if a coastal zone authority does not permit the use of structures within fifty feet of the mean high water line then the land owner will not be allowed to protect his property and thus his cost will in no way be low. Yet, the cost to the coastal zone authority is minimal. In brief, there are few, if any, institutional devices that could qualify, to the individual homeowner, as low-cost shoreline protection.

INNOVATIVE DEVICES

As the public interest in low-cost, self-installed solutions to shoreline erosion continues to grow, the involvement of private enterprise in developing solutions intensifies. Now that low-cost devices are identified as a salable commodity as goods or services, the number of inventors, creative engineers, agronomists, and foresighted planners producing potential designs are rapidly growing. This energy has and continues to lead to very innovative designs that may be functionally and structurally successful and may be low-cost. As a part of the National Shoreline Erosion Demonstration Program, known devices and methods which have been used or tested in various degrees, or just proposed, have been tabulated. The list is limited to just those items which might be classified as low-cost. A page from that list is included as Figure 1. The devices have been categorized as shown below along with the number of devices in each category.

Revetments	37
Bulkheads and seawalls	35
Groins	39
Offshore breakwaters	24
Floating breakwaters	18
Beach fills	9
Coastal vegetation	27
Other	8

From this compilation of devices, the Shoreline Erosion Advisory Panel (which will be described later in this paper) has recommended that from this list of devices at least the following should be field tested.

- Aluminum bulkheads
- Bins or cribs (concrete, steel, aluminum, or wood)
- Gabions (rusting of mesh container a problem)
- Longard tubes (sand-filled plastic tubes)
- Nami rings (upright concrete culvert pipe)
- Interlocking concrete block (with filter cloth)
- Stone rip-rap (with gravel or plastic filters or mastic binder)
- Plastic bags (sand filled or concrete filled)
- Precast concrete sheet piling (possibly pre-stressed)
- Rubble mound groins and breakwaters
- Concrete pipe groins
- Z-wall offshore breakwaters (steel or concrete)
- Scrap tire floating breakwater
- Tethered floating mat plastic breakwaters

It was further recommended that existing installations of the following devices should be monitored.

- Sand-grabber (cinder blocks)
- Shore-protector (slat breakwater)
- Beach-builder (flap valve breakwater)

Figures 2-9 show examples of several forms of low-cost structures that have been proposed or used in the field. Some of these devices hold great promise while others do not appear as attractive.

SHORELINE EROSION CONTROL DEMONSTRATION PROGRAM

The Congress finds that because of the importance and increasing interest in the coastal and estuarine zone of the United States, the deterioration of the shoreline within this zone due to erosion, the harm to water quality and marine life from shoreline erosion, the loss of recreational potential due to such erosion, the financial loss to private and public landowners resulting from shoreline erosion, and the inability of such landowners to obtain satisfactory financial and technical assistance to combat such erosion, it is essential to develop, demonstrate, and disseminate information about low-cost means to prevent and control shoreline erosion. It is therefore the purpose of this section to authorize a program to develop and demonstrate such means to combat shoreline erosion.

Thus on March 7, 1974, the President signed into law Section 54, Public Law 251, 93rd Congress -- the Shoreline Erosion Control Demonstration Act of 1974. The Act calls for the Chief, U.S. Army Corps of Engineers, to plan, establish, and conduct for a period of five years a national shoreline erosion control demonstration and development program. The program consists of planning, constructing, maintaining, evaluating and demonstrating prototype shoreline erosion control devices, both physical and vegetative. The Act is silent on institutional devices and these are, therefore, omitted from the program.

Although the Corps of Engineers is administering the project, they are cooperating with the Department of Agriculture, vis-a-vis the Soil Conservation Service, particularly with respect to vegetative means of preventing and controlling shoreline erosion.

The actual demonstration projects developed under this program emphasize the development of low-cost erosion control devices on sheltered or inland waters. These demonstration projects are being constructed with at least two sites each on the shorelines of the Atlantic, Gulf, and Pacific Coasts, the Great Lakes, and the State of Alaska, and with six sites at serious erosion sites in the State of Delaware along Delaware Bay. These demonstration projects can be built on private or public lands as long as a non-federal sponsor can pay at least 25 percent of the construction costs and assume operation and maintenance costs upon completion of the project.

The Act directed the Chief of Engineers to establish the Shoreline Erosion Advisory Panel. The Panel is charged with providing general guidance and expert technical advice to the Chief on the establishment, conduct, and evaluation of results of the program. The Panel consists of 15 members, selected as individuals who are knowledgeable with respect to various aspects of shoreline erosion problems. Representatives from various geographical areas, institutions of higher education, professional organizations, state and local government and private organizations serve on the Panel. Specifically, the Panel is to:

- (a) advise the Chief of Engineers generally in carrying out provisions of this Act;
- (b) recommend criteria for the selection of development and demonstration sites;
- (c) recommend alternative institutional, legal, and financial arrangements necessary to effect agreements with non-Federal sponsors of project sites;
- (d) make periodic reviews of the progress of the program pursuant to this section;
- (e) recommend means by which the knowledge obtained from the project may be made readily available to the public; and
- (f) perform such functions as the Chief of Engineers may designate.

To carry out this program, Congress has authorized appropriations, over the five-year life of the program, not to exceed \$8,000,000.

A demonstration site is a shore frontage occupied by shore protection works consisting of one or more installations or devices to be monitored and evaluated under the SEAP program. The site shall include the area containing the installation or installations, plus adjacent shore fronts likely to be significantly affected by them within ten years of the date of installation. It is further recognized that three types of sites may be used.

- (a) SEAP Site - A site on which installation of protective works are initiated under the SEAP program.
- (b) Joint Site - A site bearing existing shore protection works constructed by others but which are repaired, modified, or supplemented under the SEAP program.
- (c) Existing Site - A site containing existing shore protection works or devices installed by others, but selected for study and evaluation under the SEAP program.

The Panel has developed and adopted a set of criteria for site selection evaluation which considers legal criteria, social and public relations criteria, environmental criteria, and economic criteria. The Panel has also developed and adopted a procedure for site selection; this procedure involves identifying candidate sites and ranking them in order of value as regional demonstration sites, and then matching these sites with a priority listing of methods and devices which the Panel believes worthy of testing. The result is a program of test installations scheduled as to costs and year of installation; the recommended program has been sent by the Panel to the Chief of Engineers with recommendations for construction.

The enabling Act requires that when a demonstration project is installed on non-Federal property, that part of the expense be borne by an agency or individual other than the Federal government. The Panel has prepared a set of recommendations on institutional arrangements which will be forwarded to the Chief of Engineers in October 1976. Among the questions considered in the institutional arrangements are: access to demonstration site by the interested public; liability of Federal government and land-owners for damage to other persons or other property; duration of demonstration testing at the particular site; removal of unsuccessful devices at the end of demonstration period.

The Panel has also addressed the question of monitoring the demonstration sites once the devices have been installed. As a result of its deliberations, the Panel has a draft of guidelines for use in monitoring test installations. The draft guidelines include coverage of such subjects as the proper balance between the number and type of monitoring observations against the expense of the monitoring program, and whether or not a device will be repaired or modified, and to what extent, if it is found to be failing in its intended protective action.

In accordance with the Act, the Chief of Engineers has announced the following sixteen sites (including six in Delaware Bay) where demonstration projects will be constructed.

Kotzabue, Alaska	Slaughter Beach, Delaware
Unalaklett, Alaska	Basin Bayou State Park, Florida
Alameda, California	Stuart-Jensen Causeways, Florida
Bowers, Delaware	Geneva State Park, Ohio
Broadkill Beach, Delaware	Bulls Island, South Carolina
Kitts Hummock, Delaware	Sand Point, Texas
Lewes, Delaware	Oak Harbor, Washington
Pickering Beach, Delaware	Port Wing, Wisconsin

This list includes private, local, state, and federal lands. Moreover, it includes sandy, clay, and cobble beaches, coasts with bluffs and those with dunes, beaches with moderate wave energy and beaches with low wave energy, and beaches frequented by ice. These sites are representative of the U.S. coastline.

The success of this program will do much to bring realistic, workable, low-cost shoreline protection solutions into the hands of local government and most importantly the private landowner.

ACKNOWLEDGEMENTS

The authors wish to acknowledge those members of private industry, the Soil Conservation Service, the Corps of Engineers, and especially the members of the Shoreline Erosion Advisory Panel who have significantly contributed to the concepts and activities described in this paper. This paper reflects only the views of the authors and is not intended to represent the position of any body or institution.

CHAPTER 166

RECENT APPLICATIONS OF ARTIFICIAL SEAWEED IN THE NETHERLANDS

by Henk G.H. ten Hoopen.^{*}

ABSTRACT

This paper deals with the effects and the method of laying of some recent emplaced artificial seaweed fields in the Netherlands. The weed is placed on the bottom in coastal waters to promote accretion or at least to prevent erosion along beaches and in gullies. The results of the three field trials, and some of the conditions that govern the successful application of the seaweed, which will be discussed.

INTRODUCTION

For ages measures for coastal protection, such as the construction of groynes, dikes and toe-protection of the dunes have been carried out along the sandy coasts of the Netherlands.

However, fixed structures of this kind, because of the secondary effects on the adjacent unprotected beaches, did not invariably turn out to be the ultimate solution to prevent coastal erosion. It is for this reason that other more flexible methods of coastal

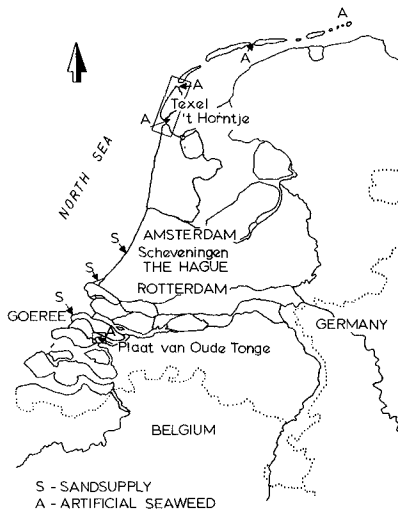

Fig. 1. Map of the Netherlands showing the sites where sand-supplies have been provided and artificial seaweed has been applied.

* Rijkswaterstaat, Den Haag, The Netherlands.

Fig. 2. Artificial seaweed.

protection such as artificial beach nourishment, have been tried out at certain locations. One of the largest trials was carried out at the west coast of the isle of Goeree (see fig. 1), where about 3.5 million m^3 of sand were placed in position (see proceedings of the 14th International Conference on Coastal Engineering). In addition to sandsupplies, tests were carried out with artificial seaweed to prevent erosion of banks in tidal waters (estuaries).

The beds of artificial seaweed consist of rows of light weight foamed polypropylene tapes (0.2 grammes/cm^3) with an anchoring system that consists of a hollow seam ($\emptyset 150 \text{ mm}$) at one end of the weed tapes filled with a heavy material such as gravel. (see fig.2). Successive anchoring tubes, each having a length of 1.5 or 2 m, are joined up lengthwise, thus forming a row. The distance between parallel rows is less or the same as the weedlength (1.5 - 2 m). When placed on the seabottom the purpose of the weed is to promote accretion. Compared with an unprotected bottom, the bottom transport of the sediment will decrease as part of the bottom shear stress will be absorbed by the seaweed. Since 1966 The Dutch Public Works Department has carried out a number of field trials along the Dutch coast. The results were quite variable, depending on local circumstances such as wave-climate and currents.

RESULTS OF SOME RECENT TRIALS WITH ARTIFICIAL SEAWEED.

Seaweed beds around the isle of Texel.

One of the Dutch Wadden islands, situated at the north-western part of the Netherlands called Texel (see fig. 1 and 3), was eroding at its south east side ('t Horntje). A deep gully,

crossing the western shallows, was developing under the influence of tidal currents. This caused damage to the eastern bank of Texel, the erosion was mainly occurring during the ebb tide. The discharge through this gully is in the order of 1000 million m^3 /tide. The velocities during low tide are more than 1m/sec. The average tidal difference is about 1.34 m. Because this location is fairly well protected from the North-Sea swell wind waves generated on the shallows prevail. These waves vary in height between 3 and 5 m. Initially fascine mattresses were laid to stop the erosion. However the erosion continued in the area adjacent

Fig. 3. Position of seaweed fields at "Texel".

to the mattresses. In 1972 it was decided to extend the area covered by mattresses with an artificial seaweed field. The first part of this trial concerned area A (see fig. 4). The weed was put down on an inclined bottom (1:5) at a depth of 5 to 15m below M.S.L. and covered an area of 80 m x 120 m. It was positioned from a pontoon and not dropped at random as was done in previous years in other areas. Because positioning according to the earlier method was not very accurate at greater depths, a more exact method was developed. An iron beam of about 30 m length on which up to

twenty anchoring tubes were laid along its length, was lowered from the pontoon. At a depth of approximately 1 m above the sea bottom the beam was tipped over and the seaweed slipped from the beam. Emplacement of the weed could be continued during the ebb or flood tide until the tidal current reached 1 m/sec. Depending on the depth of water every 3 to 7 minutes a length of about thirty meters of seaweed screen was laid. The pontoon was then moved 1.5 m in a direction opposite the tidal current and the next row was laid. In this way it took about 24 hours to cover an area of about 1000 m^2 . The results of this field trial are shown in fig. 4. Within a few weeks of putting down the weed, there was an accumulation of sand about 35 cm thickness. Till

Fig. 4. Average bottom depth in the seaweed area at 't Horntje (Texel).

about the end of 1974 the bottom in area A never scoured below the depth observed immediately prior to the emplacement of the weed. However in 1975 soundings showed a bottom depth below its position at the start of the measures early in 1972. To find out the reason for this anomaly, divers collected some samples of the artificial seaweed, which was now about four years old. Laboratory tests revealed that an increase in specific weight had occurred caused by the filling of the pores in the material by water. Due to this filling the specific weight reached a value of about four times the original value of 0.2 g/cm^3 . Growth of organic material on the weed has been negligible. However especially near the top end of the plastic tapes inorganic deposition had occurred. This was not the cause of the increase in specific weight. Further investigations are in progress to improve the material. After the laying of the weed in area A at the beginning of 1972 the adjacent area B (see fig. 4) however kept degrading. For this reason this area has also been covered in the beginning of 1974. In this instance the laying of the weed was done in a more advanced manner than used before: A $21 \times 2 \text{ m}^2$ "container beam" which could carry eighty four seaweed sections, could be lowered with the aid of a derrick mounted on a pontoon. At a distance of about 2 m above the sea-bottom part of the lower half of the beam was opened by means of a special hinged valve construction. This had the result that about one third of the total load of weed sections

In addition to the erosion problems at the south-east coast of Texel Island, the development of a gully north of Texel, just in front of a dune protection (see fig. 1,3 and 5). It was feared that a connection would develop between this gully and a deeper part of the shallows situated to the east. If this connection did develop, it was quite likely that, because of the higher stream velocities that have to be expected, the gully would extend towards the shore, causing damage to the coastal defence works. Although the conditions in this area are quite different from 't Horntje (the area is subject to strong wave attack); it was decided to lay a strip of seaweed 8 m wide perpendicular to the axis of the developing gully. The favourable results obtained with the weed elsewhere, justified this new trial. In this relatively shallow water, with a maximum depth of about 5.5 m below M.S.L., the weed was put in position in a way different from the one described before.

Fig. 6. Changes of the bottom profile in the seaweedfield Eijerlandse Gat.

carried out. Then the pontoon moved over about 1.5 m to drop another third of the load, and so on. After this the "beam" had to be refilled again above waterlevel. In this way it was possible to cover in the same time three times as much of the bottom than in the method with a single beam mentioned before. Since the laying of this weed-field, there has been sand-accumulation in location B up till the present time (see fig. 4).

Nov. 7, 1974

At shallow depth (e.g. close to the low-water line) the weed was dumped from a pontoon during high tide. At greater depths, use was made of a special pontoon equipped with eight P.V.C. tubes (diameter 35 cm) which at one end could pivot about a fixed point on the bottom (see fig. 7). After lowering the free end of the tubes to the sea-bottom, the weed is put on to the other end and slides to the bottom. The pontoon is then moved over the length of a seaweed section and the filling resumed. In this way the weed can be laid without losing time by lowering a beam, an additional advantage is the working undependent of the tide.

In the past, the depth contours in this area used to move frequently and unpredictably. Since the weed has been "planted", the gully has not developed any further (see fig. 5). It appears therefore, that the presence of the weed has had a beneficial effect. However looking at fig. 6, it is evident that the accumulation of sand in the field cannot only be caused by the weed, as at some places there is an accretion of more than 2 m which cannot possibly derive from the action of the weed. In view of the unpredictability of the bottom movement, insufficient time has elapsed to consider the evidence obtained so far as conclusive in this respect.

Fig. 7. Pontoon with the eight P.V.C. tubes in horizontal position.

Seaweed field at Plaat van Oude Tonge (Delta region).

In the Delta region, situated in the southern part of the Netherlands, the position of some old gullies has recently become very unstable as result of the closure of some estuaries. Between 1958 en 1965 the dam in the Grevelingen estuary, between Goeree and Schouwen, was built. As a consequence considerable morphological changes took place. At Plaat van Oude Tonge for instance (see fig. 1 and 8) a considerable change in direction of the gully "Krammer" occurred, which in future could result in severe damage to protective works in the neighbourhood.

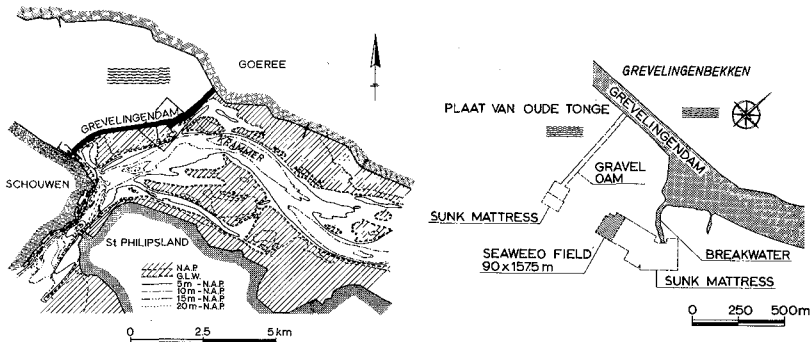

Fig. 8. Position of seaweed field at Plaat van Oude Tonge.

The axis of the gully concerned changed from N - S to NE - SW. As a consequence of the ebb-stream through the gully the Plaat van Oude Tonge eroded heavily. Since 1958 the 2.5 m below M.S.L. depth contour has moved 900 m in the direction of the Grevelingendam, and the gully increased in depth from 8m to 21 m (-M.S.L.). The slope of the western bank changed from 1:22 to 1:3.5. Measures had to be taken to prevent further erosion of this bank in front of the dam. In 1969 fascine-mattresses were placed round the end of an old breakwater over an area of 70,000 m², and 600 m to the west of this breakwater a 500 m long.

A submerged dam was constructed to keep the current as far as possible from the Grevelingendam. However in 1971 and 1972 bank-slides occurred. Extra mattresses were laid, without success

Fig. 9a and b. Profile I (see fig. 9a) before and after the laying of the weed.

however as the slides continued. Because of the similarity to the conditions at 't Horntje (same wave climate and current velocities) it was decided to "plant" a seaweed bed. This was done at the beginning of 1974.

The situation that has developed since then is shown on fig 9b and fig. 10, which show the observations from October 1972 up to Februari 1976. It is obvious that significant changes in the development of the gully and the banks, since the placing of the weed, have been occurred. Nearest the Grevelingendam erosion has come to a standstill and some accretion has taken place. Only along the edge of the weed-field (deepest part) there has been erosion because of secondary effects. The unprotected gully however has deepened considerably. Bankslides have not occurred up till the present but can be expected if the slopes along the edge are getting to steep.

CONCLUSIONS.

From the results mentioned above, it can be concluded that artificial seaweed can be applied successfully in gullies where high flow velocities occur. Accumulation is to be expected when there is little orbital motion near the bottom. However secondary effects along the edge parallel to the stream

Fig. 10. Changes of bottom profiles at Plaat van Oude Tonge after the seaweed had been put in position.

can be expected. With bigger wave heights prediction of the results is less certain. The costs of the material and of the emplacement of the weed are rather low. They amount to about one fourth of the conventional bottom protection. With investigations to improve the material proceeding it is difficult to predict what will be the lifetime of the artificial seaweed.

DESIGN PROCEDURES FOR OCEAN OUTFALLS

by

JEFFREY A. LAYTON*

ABSTRACT

This paper discusses procedures for designing ocean outfalls and offers the coastal engineer a practical design guide outlining the necessary steps required to plan, design, and construct an outfall. The design steps reviewed in this paper include site location considerations, environmental studies, outfall and diffuser hydraulics, pipe materials selection, pipe support systems design, and construction techniques.

INTRODUCTION

Wastewater disposal systems typically involve three components: collection, treatment, and disposal. The design of collection systems for domestic sewage and industrial wastes is generally a simple process. More difficult, but still relatively routine, is the design of primary and secondary treatment facilities to reduce the pollution impact of the wastewater. However, final disposal of the collected and treated wastewater effluent is not a routine design problem. Few disposal options are available; most are limited to land disposal, advanced wastewater treatment (AWT), or discharge to a water body. Land disposal is impractical in many regions due to poor soils and insufficient land availability. AWT is costly and consumes much energy in the treatment process. Effluent discharge to a water body, on the other hand, generally consumes little energy and requires little land. Further, the natural assimilative capacity of many water bodies is high enough to absorb wastewater discharges with no detrimental consequences. Because of these advantages, effluent disposal to the marine environment has become common practice.

Subaqueous effluent discharge occurs in four basic water bodies: river, lake, estuary, or ocean. Of these, the ocean is the ultimate receiving water. An outfall is a mechanism through which effluent is directly discharged to the ocean. The complex process a coastal engineer employs to design and construct an ocean outfall is described in this paper. The same process is applicable to outfalls in rivers, lakes, and estuaries.

OUTFALLS AND DIFFUSERS

An outfall is an underwater pipeline that discharges wastewater into a receiving water. Although the wastewater may have received extensive treatment, it is still desirable, and often necessary, to disperse the effluent to minimize possible impairment to the quality of the receiving waters near the point of discharge. This is accomplished by using a diffuser.

A diffuser is a section of the outfall, usually the deepest, most seaward portion, with relatively small holes or ports along its length (figure 1). These ports discharge the wastewater in numerous small quantities, as opposed to the entire flow being discharged at one point (figure 2). Diffuser ports may be

*Ocean Engineer, CH2M HILL, 1500 - 114th Avenue SE, Bellevue, Washington 98004

simple holes in the outfall pipe wall or short tubes (risers) extending from the pipe. The type of port used depends on the particular conditions of the final installation.

Figure 1
Outfall Diffuser

Figure 2
Outfall Without Diffuser

Designing an outfall diffuser system requires the same considerations as designing other types of underwater pipelines. However, the mechanism of discharging the effluent from the outfall to the receiving water requires additional design effort. The various elements of the outfall design process are discussed below.

OUTFALL DESIGN PROCESS

The design of an ocean outfall system is not a simple process. The design engineer must consider many factors to ensure that the outfall survives as a structural system in the ocean environment and also meets water quality requirements. The major components of the outfall design process are:

- Site selection
- Outfall hydraulics
- Dilution and mixing
- Diffuser port design
- Pipe design
- Pipe support systems
- Construction methods

Each of the above components must be evaluated during the design of an outfall. The design is normally phased into four elements: feasibility study, predesign, preliminary design, and final design. Each phase addresses the above outfall design components with increasing detail such that final design results in the preparation of construction plans and specifications. A flow diagram illustrating how the various design components and phases are integrated is in figure 3. Subsequent discussion will elaborate on each factor comprising the design process.

Figure 3
The Ocean Outfall Design Process

Site Selection

A discharge point for an outfall is usually located in proximity to its companion wastewater treatment plant. Therefore, the first step in the outfall site selection process is to determine the feasibility of linking the treatment plant to the nearest receiving water. This process consists of studying existing topographic maps and hydrographic charts, reviewing known literature concerning coastal processes (tides, waves, currents, geology) characteristic to the site, and obtaining available water quality data related to the proposed receiving water. If the existing information suggests that, from a construction cost and water quality viewpoint, one or more outfall routes is feasible, then additional predesign engineering studies are commenced to select a final route. If no routes are judged feasible, then relocation of the treatment plant or alternative disposal systems must be considered.

For sites judged feasible, the following outfall siting criteria are considered in detail in the predesign phase:

- Bottom topography and surf zone
- Physical oceanography
- Water quality
- Underwater soils and geology

Topography

A hydrographic survey of the general area of a proposed outfall alignment is required. An electronic recording echo-sounding device coupled with a horizontal positioning system (electronic or transit) usually produces a sufficiently accurate bottom survey. Surveys within the surf zone, however, are often difficult due to continuous wave action and often require special equipment such as helicopters to act as sounding platforms.

When reviewing the sounding data, various profiles of the bottom topography are plotted. Analysis of the profiles will reveal potential outfall routes. It is desirable to have the outfall line on a continually declining grade. This prevents potential sludge buildup in low points and accumulation of air at high points, both of which can reduce the hydraulic capacity of the outfall.

There is no ideal slope for locating the diffuser; however, a relatively flat slope is desirable. It is also desirable to have essentially equal discharge from each of the diffuser ports to facilitate equal dilutions. With a density difference between the receiving waters and the discharged effluent, a mild slope is beneficial in achieving uniform port discharge. However, a long diffuser on a steep slope can adversely modify the diffuser hydraulics. Not only will the diffuser discharge unequally from all ports, but at low flows, some ports will not flow at all.

If the topography is relatively steep, consideration must also be given to the stability of the final system. The pipeline must be secured from sliding down the slope, either slowly due to unstable soil conditions or suddenly due to natural occurrences.

Since it normally is not economically or technically feasible to significantly modify the general underwater topography of an area, the outfall must be routed and designed in accordance with the natural conditions.

Surf Zone

Penetrating the surf zone is often the most difficult and costly phase of constructing an ocean outfall. The trauma of continuous wave attack in shallow water usually limits construction to a short period during milder summer conditions. Even then, sporadic storms can shut down construction operations or damage the outfall pipe and construction equipment. Therefore, it is desirable to select outfall sites with minimum surf action. Potential sites at headlands or points of land jutting into the sea generally should be avoided because wave refraction will concentrate wave energy on these features. To minimize working in harsh conditions, surf zones extending more than about 1,000 feet offshore should be avoided if possible. Coastlines with sharp bottom dropoffs are preferable for outfall sites because the pipeline can be installed quickly in the narrow surf zone.

Physical Oceanography

Measuring water mass movements at a proposed outfall discharge site is required early in the design process. This knowledge is important because it allows the designer to predict effluent transport under all offshore current conditions. Two methods are commonly employed to measure ocean current systems: drogues and electronic current meters.

Drogues consist of a drag body positioned below the water surface with a line attached to a surface float. Movement of drogues, and therefore currents, is tracked by observing buoy movement. Current meters do not move with the water but remain fixed at a point, measuring the rate and speed of water particles as they flow past. Either system can be used to measure ocean currents, but for most ocean outfall locations both techniques are used to complement each other.

Current measurements are normally conducted over a sufficient time period to develop a comprehensive understanding of water mass movements over the outfall discharge site. This knowledge is vital so the outfall designer can predict where the effluent will be transported under all conditions. Specific monitoring periods can range from a few tidal cycles to long-term observations covering several years at sites subject to seasonal current shifts and upwelling of deep ocean waters. Careful consideration in developing a current monitoring program must be given early in the design process to allow sufficient time to conduct the studies and analyze the results.

During ocean current monitoring, physical properties of the water column, such as temperature and salinity, are also measured to calculate water density as a function of depth. Density profiles indicate the absence or presence of stratification, which can affect the dilution performance of the diffuser.

In addition to the above physical oceanographic measurements, field studies designed to measure the ocean water's natural diffusion characteristics are

often conducted. Dye studies, usually employing a fluorescent tracer such as Rhodamine WT dye, help determine the ability of a potential outfall site's receiving waters to disperse and assimilate wastewater.

Measurements of ocean wave heights and periods are also desirable for outfall sites. Knowledge of the frequency and amount of wave energy passing over the pipeline route is vital to ensure its integrity as a structural system. However, measurements of wave parameters are often difficult to obtain and designers frequently rely on wave forecasting techniques to predict design wave conditions.

Water Quality

The purpose of an outfall diffuser is to disperse effluent to minimize the pollution impact on the receiving water. No matter how efficient the diffuser is in diluting effluent with ambient seawater, some change will occur in the local marine environment around the diffuser. It is a vital element of the outfall design process to accurately predict these changes, both short-term and long-term. However, to predict water quality changes due to outfall discharges, the existing water quality conditions of the receiving water must be known.

Establishing a baseline of water quality conditions within the receiving waters of a proposed outfall often requires extensive environmental monitoring. During the site selection process, it is typically found that the potential ocean outfall site has, at best, a limited record of existing water quality data. Thus, to establish a proper data bank of predischage conditions, a water quality monitoring program is required. Baseline monitoring programs can range from a minimum of collecting one set of water samples at one location to sampling multiple stations at weekly intervals for periods of 1 to 2 years. The parameters sampled, which can also vary widely, mainly depend on composition of the effluent. The minimum parameters that should be considered for a domestic sewage outfall monitoring program are:

Water Column

Dissolved oxygen
pH
Conductivity/salinity
Temperature
Oil and grease
Fecal coliform bacteria
Nutrient content
Heavy metal content
BOD/COD

Benthic

BOD/COD
Heavy metal content
Nutrient content
Biological organisms

Location and number of sampling stations should be carefully established to maximize data acquisition while minimizing costs. Results of physical oceanographic studies should be used to establish sampling stations within the expected water transport zones. A sampling station within the immediate dilution zone of the diffuser is a minimum requirement.

Underwater Soils and Geology

Identifying the geological conditions and their uniformity along a proposed outfall alignment is important since many of the criteria considered in outfall design depend on geologic conditions and soil types. As with most underwater soils investigations, gathering soils data for outfall design is difficult and often costly. However, the investigation must be sufficient to develop design criteria and identify the existing conditions.

Marine geophysical techniques, such as reflection and seismic profiling, are commonly used to determine subbottom stratigraphy. However, interpretation of this type of data is difficult. There is no substitute for obtaining *in situ* soil samples for laboratory analysis. The best results usually are obtained from barge-mounted drilling rigs, but soil sampling with remote or diver controlled subsurface devices has been successful (Noorany, 1971).

Analysis of Site Selection Data

Upon completion of the basic studies outlined above, one particular outfall site is normally chosen as most suitable. The next step in the outfall design process is the preliminary hydraulic design of the pipeline, including diffuser dilution and mixing characteristics.

Outfall Hydraulics

The hydraulic design of an outfall results in determining design flows, selecting pipe diameters for the outfall conduit and diffuser sections, and selecting diffuser port size and spacing.

Design Flows

Outfall design flows depend upon upstream conditions. Daily flow through a domestic sewage treatment plant can vary considerably, while most industrial discharges are more constant. Massive loads to sewer collection and treatment facilities also occur during rainy periods when runoff enters the collection system either directly (combined sanitary and storm sewers) or indirectly through infiltration (leakage at pipe joints and manhole covers). During either event, flow to an outfall can be dramatically increased. If the outfall system is not properly sized, the flow will be restricted, resulting in the backup of effluent in the outfall and possible flooding of onshore facilities.

Ocean outfalls should be designed to discharge peak flows with a gravity system. However, if the hydraulic head between the ocean and the outfall headworks is minimal, discharge of design flows through the outfall may not be possible with a gravity system. Consideration must then be given to the use of pump stations. Unfortunately, pumped outfall systems present new problems--increased costs for continual maintenance of pumps and perpetual use of energy for pumping. A sometimes satisfactory solution to both problems is the combined use of gravity and pump system. During normal flows, the gravity system handles the discharge, while during peak flow periods a pumping system augments the gravity system.

Diffuser Hydraulics

In conjunction with selecting conduit size for the outfall, the diffuser system must also be designed. The size and spacing of the diffuser's ports are determined through a series of complex iterative hydraulic calculations based upon the following parameters:

- Design flows
- Pipe diameter
- Pipe slope
- Frictional resistance of pipe material
- Effluent density
- Receiving water density
- Discharge depth
- Operating head

A computer program is typically employed to solve the manifold hydraulics problem. The program takes into account the discharge characteristics of the individual port and does a numerical integration of the hydraulic conditions port by port with a trial and error optimization of port sizes considering the various factors listed above. A complete description of diffuser hydraulic design has been reported by Rawn, Bowerman, and Brooks (1961) and the basic hydraulic requirements as reported in their paper are summarized below:

Flow Distribution. The division of outflow between the various ports should be fairly uniform. For diffusers laid on a sloping sea bottom, uniform port discharge for all rates of flow is impossible. In such cases, the diffuser should be designed for uniform distribution at low to medium flows. For higher flows, the deeper ports should be allowed to discharge more flow than the average port to prevent possible clogging of the deep end of the diffuser.

Velocity in Diffusers. The flow velocity in all ports of the diffuser should be high enough to prevent gross deposition of sludge or grease. For settled sewage, minimum velocities of 2 to 3 feet per second are required.

Prevention of Seawater Intrusion. All ports should flow full to prevent intrusion of seawater into the pipe.

Dilution and Mixing

A diffuser disperses wastewater by breaking it up into a number of smaller flows and spreading it over a large area. In essence, a diffuser changes a point-source discharge into a line-source discharge. The resulting discharge plume mixes within the receiving water to produce a diluted effluent.

The processes that cause mixing and dilution when effluent is discharged by a diffuser into receiving waters are complex, but primarily involve mixing due to kinetic energy of the initial discharge velocity, mixing caused by buoyant forces due to the density difference of the effluent and receiving waters, and, finally, mixing caused by horizontal cross currents of the receiving waters (Brooks and Koh, 1965). Normally, all three of the above processes act on the discharged effluent to produce the overall mixing and dilution.

Mixing caused by the kinetic energy occurs close to the point of discharge and is primarily a function of discharge velocity. Due to the density and viscosity of water, the energy is dissipated rapidly. Dilution is generally less than two parts of seawater to one part of effluent and occurs within a few feet of the point of discharge.

When the kinetic energy is dissipated, a mixture of effluent and receiving water exists. If the density of the effluent is less than the density of the receiving water at the point of discharge, the mixture will also have a density less than the surrounding receiving waters. This difference in density creates a buoyant force that causes the effluent mixture to rise in the receiving waters. As the mixture rises, it continues to mix with, and therefore be diluted by, receiving water.

If the receiving water is of equal density at all depths, the mixture density will always be less than the density of the surrounding waters and will continue to rise and be diluted (figure 4). Under this condition, the dilution achieved is a function of port diameter, discharge velocity, relative density, and depth of discharge.

If the density of the receiving water decreases with decreasing depth, there will be a depth when the density of the rising effluent mixture is equal to the density of the surrounding receiving waters and less than the density of overlying waters. When this occurs, the effluent mixture will not rise further and is considered trapped (figure 5). In this situation, the dilution achieved is controlled by the height of rise that, in turn, is a function of the density variations of the receiving waters. Entrapment of the effluent plume below the surface is usually a desirable objective for ocean outfall design because it helps prevent possible health and aesthetic problems common to discharges rising to the water surface.

Figure 4
Effluent Plume Characteristics
for Nonstratified Water

Figure 5
Effluent Plume Characteristics
for Stratified Water

The previous discussion assumes that there are no horizontal currents in the receiving water. Horizontal currents will carry the effluent away from the point of discharge and cause rapid mixing and dilution. Port diameter, discharge velocity, and relative density will have little effect on the dilution achieved (Roberts, 1976). The velocity of the horizontal currents will control the dilution. Because the effluent is diluted and carried away rapidly, the effluent mixture will have little opportunity to rise, regardless of the density of the effluent or receiving waters.

Predicting diffuser plume characteristics is essential in outfall design. Computer programs are typically used to examine various discharge and receiving water conditions and predict height of rise and associated dilution. Baumgartner, Trent, and Byram (1971) have developed such a model which is used in outfall design.

Diffuser Port Design

Orientation

The flow direction of receiving water currents dictates the orientation of the diffuser. There are three basic diffuser orientations (figure 6):

- Current parallel to shore
- Current perpendicular to shore
- Variable current direction

The diffuser should be located perpendicular to the net current to maximize dilution. However, for currents that shift direction, "Y" shaped diffusers are employed to offer the greatest chance for keeping the diffuser perpendicular to the current.

Figure 6
Alternative Diffuser Arrangements

Port Types

The two basic types of diffuser ports are pipe wall port and riser tube (figures 7 and 8). A pipe wall port system consists of holes in the wall of the pipe, at or slightly above the pipe's spring line. To prevent the pipeline filling with bottom sediments, this type of diffuser port requires that the pipe be laid on the ocean bottom rather than buried.

Figure 7
Pipe Wall Port Diffuser

Figure 8
Riser Port Diffuser

Riser tubes are used when the diffuser pipeline must be buried (usually to prevent damage by wave action). Riser tubes project upward from the crown of the buried pipe, penetrating above the ocean bottom. The small, cross sectional area of the risers minimizes exposure to waves and current forces. However, because the riser tubes project above the bottom, they can become vulnerable to impact forces. A typical hazard common to risers--breaking of the rigid tube due to impact forces and subsequent filling of outfall pipe with bottom soils--is shown in figure 9. A satisfactory solution to this problem is the use of flexible riser tubes (figure 10). The rubber pipe wall section allows the tube to absorb impact through deflection. If the impact force is too great, the rubber section fails before the steel, allowing the pipe tube to shear off above the mud line. This type of failure minimizes the chances of filling the pipe with bottom soils and results in simple repair work.

Figure 9
Rigid Diffuser Riser

Figure 10
Flexible Diffuser Riser

Onshore/offshore and longshore drift of bottom soils must also be considered in diffuser port designs. Pipe wall ports and riser tube ports must be of sufficient height above the bottom to prevent filling of the diffuser with shifting bottom materials during low flows.

Pipe Design

Completion of the site selection process and preliminary hydraulic design results in establishing the basic outfall pipe parameters--alignment, slope, pipe length and diameter, and diffuser port sizes and spacing. The next element of the design process considers the final design of the pipeline. For ocean outfalls, the following final pipe design components must be considered:

- Foundation requirement
- Pipe forces
- Hydraulic flow properties
- Corrosion resistance
- Pipe material selection
- Pipe anchoring
- Construction methods

Foundation Requirements

Much of the actual pipe design itself depends on the soil conditions. The amount of support along the length of a pipe will influence the type of pipe that is to be used. A change in the support along a pipe will also change the type of pipe used. Some types of pipe can tolerate substantial settlement while other pipes, perhaps with closely spaced joints, would come apart if the settlement is excessive. Although soft sediments most often contribute to pipe settlement, scour and erosion from beneath a pipe can also contribute to loss of support. The support along a pipe in an ocean outfall needs to be continuous just as it does for pipes on land. Since pipes laid on rock under water may not have continuous support beneath them, the pipe may actually span two points on the rock. This can also occur in gravelly soils. Under some conditions, shifting ocean bottom materials (longshore drift) and sedimentation can contribute to the actual load on top or along the side of the pipe. In addition, consideration must be given to outfalls penetrating the surf zone where seasonal changes in beach profile will alternately scour and fill bottom materials over the pipe.

Excavation and Backfill

Outfall pipes generally need to be buried for at least part of their alignment. This requires that the conditions of excavation and backfill be evaluated. The difficulty of excavation, depth of excavation, stability of the open trench, and difficulty of actually placing the pipe in the trench all must be considered in the excavation phase. Many times the excavation must continue through a soft layer down to a firm layer. This requires that the depth of the soft layer be known and that the uniformity of the depth along the alignment be known. The disposition of the excavated material can sometimes be a problem. Most often, it will have to be loaded aboard barges and disposed of, perhaps at some distance from the excavation. It is seldom that the excavated material can also be

used for backfill. Trenches excavated in loose sands or granular material often will not stand open for a long period of time since the sides will slough and material will be brought into the trench by currents and waves. In firm granular material, the trenches generally stand open well and narrow trenches can be used. Support for the pipe along the trench is important. Uniform support is often provided by placing a layer of coarse gravel in the bottom of the trench. Unless the excavated material is exceptionally clean, backfill material will usually have to be imported. Generally, coarse granular material is used for backfilling. Any material with a majority of fines in it will generally cause turbidity problems and be unsuitable. Generally, only the larger particles will reach the trench.

Pipe Forces

Outfalls must be designed to resist both internal and external forces. The internal forces are a result of hydraulic pressure imposed on the line through flow of liquid. Operating pressures in outfalls are typically low and seldom affect the structural design of the pipe. Further, since outfalls discharge at depth, there is no requirement to design the pipe to resist the hydrostatic head of the water column above the pipe. External forces include the dynamic action of waves, force from currents, impact from foreign bodies, and overburden support.

The flow of fluid around a cylinder, such as an exposed pipeline, will induce drag forces on the pipe (Priest, 1974). See figure 11. The resultant force can displace an unanchored pipe horizontally, creating large bending and shear stress within the pipe and at its connection with the shore. If the pipe is anchored or pile supported, the horizontal drag force will then be transmitted to the pipe anchor. Close spacing of the supports may be required to prevent pipe overstress due to bending. Also, closer spacing of supports may be required to eliminate vertical pipe oscillations resulting from the resonate response of the pipe to the current.

The passage of a wave over the pipe can develop large dynamic pressures on the pipeline when it is supported above the bottom (figure 12). The pressures result from drag forces as well as inertial or impact forces caused by the moving fluid. Dynamic pressure can be minimized by locating the pipe in water deep enough so that it is not significantly influenced by the orbital motion of waves. However, the pipe should be buried in the surf zone to a depth sufficient to protect the line from damage.

Impact forces resulting from foreign objects striking the pipeline must also be considered. Impact from a ship's anchor and commercial fishing gear (figure 13) can result in severe damage to an outfall. Locating outfalls in anchorage zones or bottom trawling fishing grounds should be avoided. However, if the outfall alignment must be located in regions with a high probability of occurrences such as dragging anchors, the pipeline should be buried. The minimum pipe cover should be in excess of plow depth of the anchors.

Even though the main pipeline is protected from impact damage, the diffuser riser must extend above the mud line and become exposed. In such cases, the flexible riser systems should be considered as discussed above (figures 9 and 10).

Figure 11
Current Forces

Figure 12
Wave Forces

Impact Forces

Hydraulic Properties

An important characteristic of a pipe is its ability to transport the fluid. Various pipe materials can have substantially different frictional characteristics. Some materials, such as cast iron and steel, are subject to internal corrosion that will increase the friction and thus reduce the flow-carrying capacity over a period of time.

The range of friction factors normally applied to pipe materials commonly used for outfall construction is not sufficient to control the selection of materials or allow a reduction in outfall diameter. Since the pipeline materials cost is usually a small part of total project costs, a conservative selection of friction factors and pipe diameters is the normal procedure.

Corrosion Resistance

Saltwater can be a corrosive element for some pipe materials. The bottom sediments may also exhibit a corrosion potential so that the combination can be devastating. The technology exists to protect almost any material from excessive corrosion. The protection provided should be consistent with the design life of the facility and the protection provided associated structures. The costs for this protection are usually minimal. Therefore, corrosion is normally not a controlling factor in the selection of outfall pipe materials.

Pipe Material

A variety of pipe materials are available for ocean outfalls (table 1):

- Reinforced concrete
- Steel
- Concrete cylinder
- Corrugated metal
- Cast iron
- Ductile iron
- Fiber-reinforced plastic
- High-density polyethylene

The most common pipe material used on ocean outfalls is reinforced concrete pipe, which is a heavy and rigid pipe material that is capable of supporting large overburden loads and resisting current and wave movements. Corrosion resistance of reinforced concrete is good in the saltwater environment.

Pipe Joints

A variety of pipe joints ranging from welded to dresser couplings are available for linking outfall pipe sections together. Probably the most common is bell and spigot with a retained rubber gasket. Normally, up to 3 to 5 degrees of deflection are allowed. For greater deflections (up to 15 degrees), ball and socket joints can be used.

Outfall pipe joints are typically equipped with thrust-ties to secure the pipe joint from displacement. A bolted connection at the pipe spring line links each pipe section and restrains the joint from separating due to external forces. Stainless steel bolts are usually used in saltwater. Metallic bond straps electrically linking each pipe section together are also common features of an ocean outfall joint. Bond straps allow external electric currents to be applied to the entire pipeline to control electrolysis.

Pipe Support Systems

The wide range of pipe support systems available to the outfall designer is illustrated in figures 14 through 20. The following is a summary of each system.

Bottom Exposure. For environmental conditions with minimal current, wave, and impact potential, the outfall pipe can be laid directly on the bottom (figure 14). For this condition, only a bedding layer may be required to support the pipe. Where some current or wave action exists, an exposed outfall can be secured to the bottom with concrete anchor blocks or embedment anchors (figure 18).

Bottom Exposure With Armor. Where the pipe is subject to moderate wave attack or strong currents, it is desirable to armor a pipe laid on the bottom. Armoring usually consists of riprap and is designed in similar fashion as breakwaters (figure 15).

Buried Trench Section. Sites with heavy wave action usually require complete burial of the outfall pipe. The trench must be deep enough to ensure that scour action will not expose the pipe. Often, the pipe zone material is riprapped at the surface to reduce scouring potential (figure 16).

Table 1. CONSTRUCTION PROPERTIES OF OCEAN OUTFALL PIPE MATERIALS

Outfall Pipe Material	Composition	Range of Diameter	Nominal Length	Joint Type	Seawater Corrosion Protection	Notes
Reinforced Concrete	Concrete embedded with steel rods or fabric	12 to 120+ inches	10 feet	Bell and Spigot with thrust tie	Bond strap linking each pipe section together for induced electric currents	Very heavy and rigid pipe material; impact resistance high
Steel	Thin plates of steel welded together	Variable	Variable to 100 feet	Welded or mechanical	Pipe typically lined inside and out with mortar	Flexible pipe material; moderate impact resistance
Concrete Cylinder	Prestressed steel barrel with mortar coating and lining	12 to 40+ inches	32 feet	Bell and Spigot with thrust ties	Bond strap	Semirigid pipe material
Corrugated Metal	Rolled and bolted steel sheets, flexed or corrugated to increase stiffness	6 inches to 21 feet	12 feet	Steel band	Steel galvanized and embedded with asbestos felt, bituminous lining	May have limited use in marine environment due to corrosion potential
Cast Iron	Molded gray iron centrifugally cast on a metal mold	12 to 36+ inches	18 feet	Mechanical or ball and socket	Bond strap	Impact resistance low-- brittle failure
Ductile Iron	Chemically altered cast iron	12 to 36+ inches	18 feet	Mechanical or ball and socket	Bond strap	More resistant to impact loads than cast iron
Fiber-reinforced	Fiberglass filaments bonded by resin	12 to 60+ inches	40 feet	Bell and Spigot	None. Can carry caustic effluents	Pipe is lightweight and deflects considerably under earth loads
High-density Polyethylene	Manufactured of Polyethylene resin through a continuous extrusion process	12 to 48+ inches	Pipe can be continually extruded to any desired length	Butt fusion or mechanical joints	None required	Pipe is buoyant in seawater and flexible. Conforms easily with nonlinear bottom topography. Pipe wall easily punctured by sharp objects

Figure 20.
Floating Outfall -
Rough and Irregular Bottom

Figure 17
Shallow Trench
With Scour Mat

For some locations, scour mats can be used to eliminate the need for deep trenching. A scour mat consists of a pre-formed concrete mat that is laid over the entire exposed pipe with sufficient width to prevent undermining at its edges (figure 17).

Pile-Supported System. In some instances, the ocean bottom is composed of soft sediments, providing little, if any, bearing support for the pipe. Laying a rigid pipe material directly on the bottom in such conditions is hazardous because of potential dissimilar settlements. A common solution is the use of a pile-supported pipeline (figure 19). Piles are driven to firm bearing and a cap is attached to the pile tops. The pile caps function as a cradle for the pipe, while a tiedown strap prevents vertical pipe movements due to current-induced oscillations or positive buoyance of the pipe such as air trapped in the pipeline.

Semi-Floating Outfall. For some ocean sites, none of the previously mentioned systems is practical. An example might be a site that has minimal current action but a rough and irregular bottom (submerged coral reef). Furthermore, environmental regulations could prevent blasting a trench into the bottom. Laying the pipe directly on the bottom is not desirable because it would be damaged by sharp projections. Driving piles may be prohibitively expensive. However, floating the pipe above the bottom is a possible alternative (figure 20). A semi-floating outfall can act as a suspension bridge in reverse, keeping the pipe suspended above the problem area but below the ocean surface. Pipe material should be lightweight or, at best, buoyant. Additional buoyance chambers may be required to provide vertical uplift. Anchors and anchor cables should be sized to secure the pipe from lateral and longitudinal movements due to minor current or wave action.

Construction Methods

During the pipe design of the outfall, the designer must also consider the various construction methods available to an offshore contractor. Failure of the designer to understand outfall construction procedures can result in a difficult and costly pipe installation.

For ocean outfalls, there are three different zones that the contractor must contend with during construction: onshore, surf, and offshore. Each zone can require different construction methods. The four commonly used construction methods of outfall installation are barge lay, trestle lay, string float, and bottom pull.

With the barge lay method, the pipe is laid in relatively short lengths from a barge to the trench or bottom, similar to onshore sewer construction. The barge lay method is generally used in the offshore zone. Divers must join each pipe length to the previously installed pipe (figure 21). The cost of this method increases tremendously with increase in water depth.

The trestle lay method involves the construction of a pier through the surf zone (figure 22). The pier replaces the barge as a work platform, isolating the pipe-laying equipment from wave action. Usually steel sheeting is driven into the bottom to act as a cofferdam for the pipe trench. Pipe is laid in the trench in a similar matter as a barge lay.

CH2M HILL Photograph

Figure 22. Outfall Construction from Trestle Through Surf Zone.

Figure 23. Launching Outfall by String Float Method.

CH2M HILL Photograph

Figure 24. Offshore Tug Preparing for Bottom Pull of Outfall.

The string float method involves floating the entire pipeline into place on the surface and then sinking the line into place on the bottom (figure 23). To provide the buoyancy necessary to float the line, the pipe and diffuser are temporarily sealed while full of air. When the line is floated into place on the water surface, the air is replaced with water, causing the line to sink. The rate of submergence can be controlled by the rate of air release.

This method is most commonly used with lightweight, flexible, plastic pipes. Additional weight is added to these lines, usually by concrete ballast collars, to provide the negative buoyancy needed to sink the line and hold it in place on the bottom. The feasibility of using this method depends on many factors, including weather and water conditions. Rough water or strong currents are of particular concern.

The bottom pull method involves pulling the line into place along the ocean bottom through the surf zone and offshore areas (figure 24). Large stresses are placed on the joints and pipe and must be considered in design and materials selection. The pipe is joined onshore and pulled seaward as assembly proceeds. A specially constructed sled is used to allow the line to be pulled without damaging the pipe material. In addition to providing a means of attaching the pulling cables, the sled will also provide a grading effect on the soils. Depending on the soils and topography, additional sleds or other supports may be needed along the pipe.

All of the above construction methods will require underwater work during installation. In all cases, diver time is required for inspection of the final installation. To ensure proper monitoring of underwater construction, the use of engineering divers as inspectors rather than commercial divers is recommended (Layton, 1976).

The appropriate method of construction for an outfall line depends on many factors, primarily soils, pipe material and size, environmental conditions, depth of construction, contractor's available equipment, and final design conditions. All of these factors are involved in determining the cost of the final installation.

Perhaps the major factor relating to costs is the amount of underwater work required, particularly work performed in deep water. Difficulty, time required, and, therefore, costs increase greatly as the depth of water increases.

OUTFALL MAINTENANCE

During the design of an outfall, provisions for inspection and maintenance of the diffuser should be considered. Even carefully designed diffusers will require occasional cleaning to remove accumulated grease, slime, and grit (Rawn, Bowerman & Brooks, 1961). These accumulations can reduce flow by increasing frictional resistance. Cleaning can be accomplished by flushing or by pulling a ball through the line.

In addition to cleaning operations, an annual diving inspection of the outfall is recommended. The purpose of the inspection is to check the outfall for structural damage to pipe and diffuser risers, pipe corrosion, changes in biological activity around diffuser, and plugging of diffuser ports due to longshore drift.

Further, it is recommended that an inspection hatch be built into the end of the outfall diffuser to facilitate flushing operations and allow divers access to the outfall's interior for removing obstructions. Also, for long outfalls, several inspection hatches should be located along the conduit and diffuser sections for easy diver access.

SUMMARY

This paper discusses the major components of the complex ocean outfall design process: site selection, outfall hydraulics, dilution and mixing, diffuser port design, pipe design, pipe support systems, and construction methods. All of these components must be evaluated throughout the design process to provide a structurally sound outfall system that meets water quality requirements.

CHAPTER 168

DESIGN CONSIDERATIONS FOR THE SAND ISLAND AND BARBERS POINT OUTFALLS

Robert C. Y. Koh¹
Norman H. Brooks¹
Floyd Louis Vuillemot²

INTRODUCTION

The design and construction of a major ocean outfall and diffuser system for disposal of wastewater effluents is a complex process involving an interplay of requirements originating from various disciplines. These include, among others, considerations of physical oceanography, mixing and dispersion, treatment processes, regulatory requirements, marine geology, economics and construction. The recently completed Sand Island Outfall and the newly designed Barbers Point Outfall are both on the southern coast of the island of Oahu, Hawaii, and are designed for treated sewage effluents from the densely populated portion of the City and County of Honolulu. In this paper, some design considerations of these outfalls will be examined. The emphasis in this paper is on the hydrodynamics, although other design aspects are also discussed briefly.

The design of a large submarine outfall must consider two basic objectives. First, the design must assure the physical integrity of the structure when subjected to the sometimes violent environment. Second, the mixing, dispersion and transport of the effluent must be such that environmental degradation is acceptably small and that water quality requirements are met. In addition, the design process also includes considerations of economics, overall system compatibility, and construction.

The Sand Island Outfall was constructed in 1975-1976 while construction of the Barbers Point Outfall began in 1976. The cost of the Sand Island outfall was 13.7 million.

DESCRIPTION OF THE DESIGN

The Sand Island Outfall is 84 inches in diameter and extends 12,500 ft offshore to a depth of approximately 230 ft. The last 3384 ft of the outfall (the diffuser section) contains 282 ports on the sides of the pipe varying in diameter from 3 to 3.53 inches. The Barbers Point Ocean Outfall is 78 inches in diameter and extends 10500 ft offshore to a depth of 200 ft. The last 1752 ft of the outfall contains 146 ports varying in diameter from 3.41 to 3.74 inches. The design ranges of flow are 32 to 194 mgd for the Sand Island Outfall and 14 to 112 mgd for the Barbers Point Outfall. Figures 1 and 2 show plan views of the two outfalls.

Considerations of forces from hurricane-generated waves and seismic loadings resulted in each pipeline being buried in a trench in the ocean bottom out to a depth of approximately 70 ft where it then gradually emerges from the sea floor and rests on the bottom, being anchored and protected by armor stones. The size and gradations of the stones and the cross sections of the ballast are chosen so that they are stable under the design wave or the design earthquake.

The offshore bathymetry beyond 70 feet depth showed rock and cemented coral outcrops dotting an underwater landscape of sand and coral rubble. The alignments of the outfalls were chosen to avoid these outcrops. The bottom slopes are also quite steep. The alignments of the diffuser sections are chosen to lie essentially on a level to ensure nearly uniform flow distribution along the diffuser for the full

Fig. 2. Schematic Plan of Barbers Point Outfall.

range of discharges. The diffuser pipe sections were ballasted to prevent down-slope rolling or sliding.

The lengths and depths of diffusers for the outfalls have been designed to ensure that the sewage effluent is diluted rapidly with ambient ocean water. Typical values of dilution are on the order of a few hundred. For part of the time, particularly during the summer, the diluted effluent plumes are submerged due to the existence of density stratification in the ambient sea. In the design process, however, high dilution was considered more important than submergence of the sewage field both from environmental as well as from construction and economic considerations.

MIXING AND DISPERSION OF THE EFFLUENT IN THE OCEAN

Initial Dilution and Sewage Field Submergence

When sewage effluent is discharged through a submarine outfall diffuser, it undergoes basically three stages of turbulent mixing processes. First it rises as a buoyant plume, entraining (and mixing with) the ambient ocean water. This first phase of mixing carries the diluted effluent either to the surface or to a terminal level below the surface in the event there is sufficient ambient density stratification. The second phase of transport is that of horizontal spreading. The sewage field, being either buoyant at the surface or more homogeneous at a submerged level, tends to spread out horizontally. This second phase of the establishment of a sewage field is followed by the third phase of dynamically passive turbulent diffusion and advection in the ocean. This last phase of mixing is dependent only on the ambient ocean turbulence and currents. Proper design of an ocean outfall diffuser must take into consideration all these processes although only the first is under the direct control of the design engineer.

One of the recent advances in the technology for ocean sewage disposal is the utilization of the natural ocean density stratification to achieve submergence of the sewage field. The sewage effluent, when mixed sufficiently with the denser seawater below the pycnocline, may not reach the surface since the much diluted effluent becomes denser than the surface seawater. The probability of submergence depends not only on the diffuser design but also on the natural density stratification in the ocean at the disposal site. In particular, if there is no density stratification between the depth of the diffuser and the surface, then the sewage field can never be made to stay submerged no matter how long a diffuser is used.

Predicted dilution and submergence characteristics of the Sand Island Outfall is shown in Figure 3 for various density profiles as determined to be representative of typical conditions during the year (Figure 4). It may be noted that for a given flow, the submergence and dilution are inversely related, i.e., deep submergence is accompanied by lower dilutions. The analysis techniques used in obtaining these results are detailed in Refs. I, II, and IV. Blocking by currents were considered.

During the design process, a variety of different diffuser lengths and depths were investigated as to their performance in terms of initial dilution and sewage field submergence characteristics. For each combination of length and depth, a dilution vs. submergence graph such as shown in Figure 3 could be prepared. It is found that, as displayed in Figure 3, the dilution and submergence are interrelated. For deep submergence due to a strong ambient density gradient, the dilution obtained is low. Sometimes increasing the diffuser depth (for the same diffuser length) may actually decrease dilution if the increased depth places the diffuser in a region with stronger stratification. On the other hand, for the same diffuser depth, lengthening the diffuser always increases dilution. The choice of the diffuser design represents a compromise between achieving high dilution and submergence most of the time but without excessively deep submergence and hence too low dilution. For the case of deep submergence with attendant lower dilutions, the sewage field

Fig. 3. Dilution and Submergence Characteristics for Sand Island Outfall.

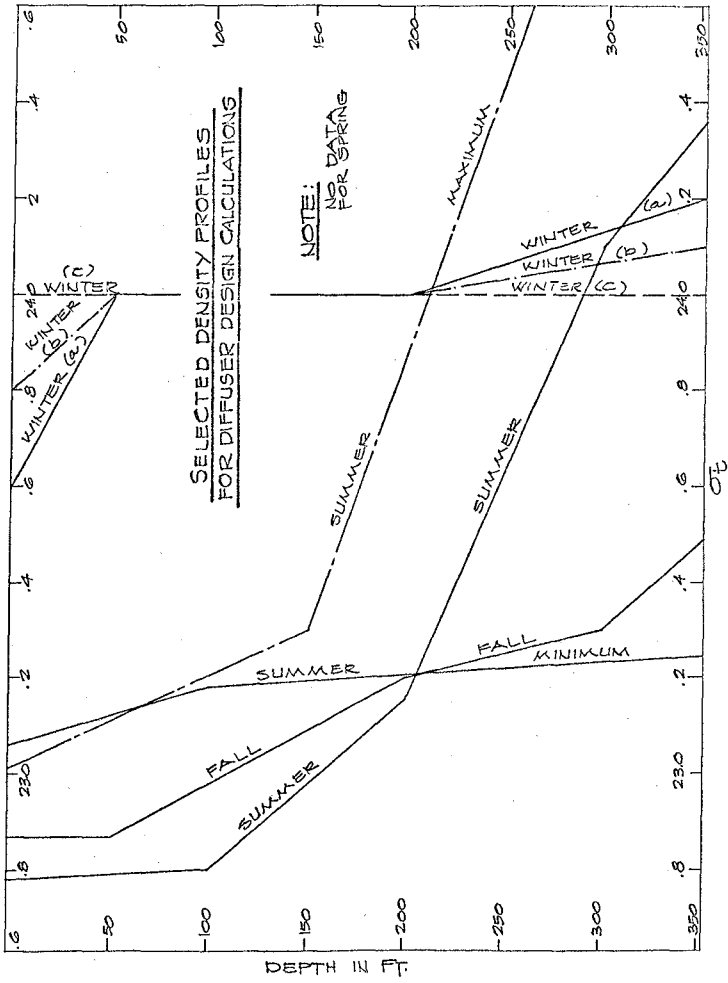

Fig. 4. Design Ocean Density Profiles for Sand Island Outfall.

would be subjected to somewhat slower natural assimilation and potentially higher impact.

Subsequent Transport and Diffusion

The advective transport of the diluted sewage effluent in the ocean environment was investigated by utilizing current meter measurements at the site in combination with statistical analyses, resulting in estimates of the probability of reaching shore as functions of time. Available ocean current data were obtained and analyzed to obtain streaklines for the sewage field advected according to the measured currents. The streaklines were then analyzed to obtain the statistics of transport to two lines designated reef line and recreation line. The reef line is a piecewise linear line which is essentially tangent to the offshore extent of the coral reef. The recreation line is displaced 1000 ft seaward of the reef line. These lines and an example segment of the streakline are shown in Figure 5 for the Sand Island Outfall location. The result of such an analysis is shown in Figure 6 where the probabilities of transport to either of the two lines are shown as a function of time of travel. It is seen that there is little chance of reaching the reef line in less than four hours. Since the bacterial dieoff rate tends to be very rapid in the tropical waters off Hawaii, health hazard due to sewage discharge from the new outfalls is very low.

During the subsequent transport of the sewage field following initial dilution, it will continue to mix with seawater by virtue of turbulent diffusion. This is generally a much less effective means of mixing for typical large plumes. For example, in four hours travel time, the additional mixing achieved by turbulent diffusion is only about a factor of two. For the Sand Island Outfall it is found that the probability of transport to shore within four hours is virtually non-existent. The probability of transport to shore in 24 hrs is no more than a few percent under tradewind conditions and only 10 to 30% during periods interspersed by Kona storms. Results for the Barbers Point Outfall are similar.

INTERNAL HYDRAULICS

The basic premise of a long multiport diffuser is to distribute the sewage effluent over a large area to ensure the availability of large quantities of diluting sea water so that the initial dilution is sufficiently high (on the order of 200 or 300 to 1). Thus it is necessary that the diffuser be designed in such a manner that effluent is discharged nearly uniformly through the many ports.

The quantity of effluent flowing in the diffuser pipe decreases along the diffuser toward the seaward end due to the continual discharge. On the other hand, the flow velocity in the pipe should be maintained sufficiently high to prevent gross deposits of grease or sludge. This fact necessitates decreasing the diffuser pipe diameter toward the seaward end and the provision of a flap gate at the end which can be opened for occasional flushing if and when required.

A hydraulically well-designed diffuser should also be such that i) the pumping head requirements be reasonable, ii) no sea water intrusion occurs, and iii) remain hydraulically insensitive to age. These considerations lead to a choice of relatively small port sizes so that the port densimetric Froude number is relatively high, and certainly larger than two; and to bell mouthed ports which minimize clogging and whose discharge coefficients are high and will remain constant.

In the hydraulic design of the San Island and Barbers Point Outfall diffusers, these requirements were all taken into consideration. In addition, the effect of the density difference between the sewage effluent and sea water, coupled with any change in elevation along the diffuser introduces density head differences which must be taken into account in the hydraulic analysis.

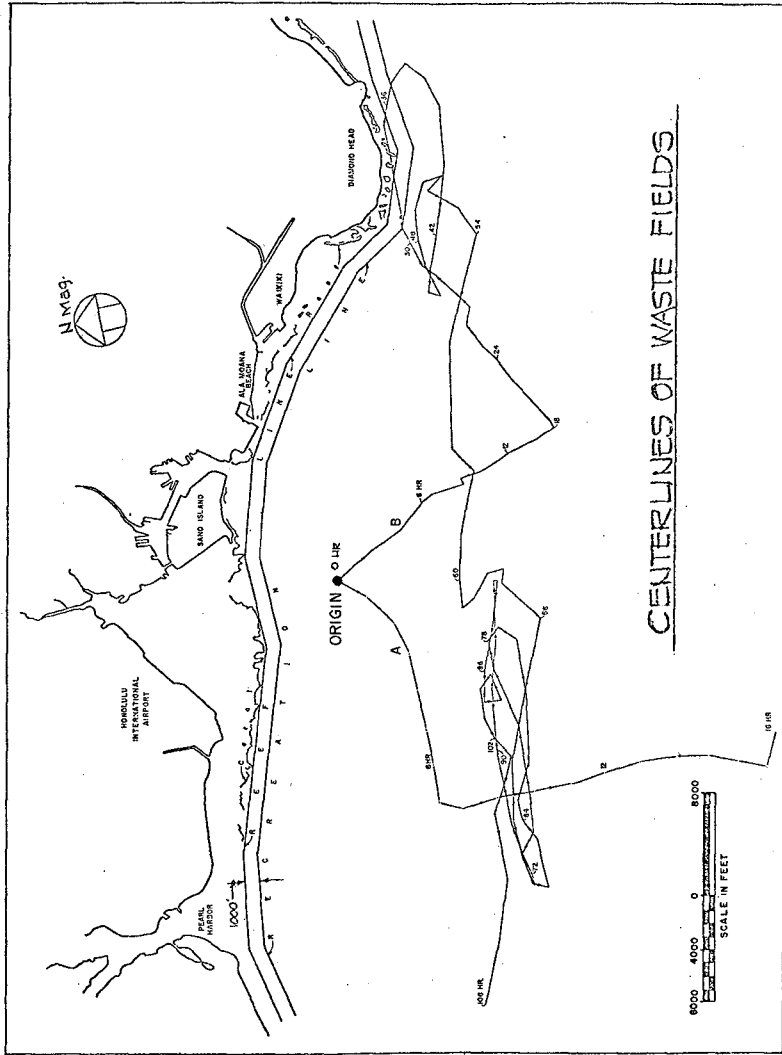

Fig. 5. Definition Sketch and Example Streaklines for Evaluation of Ocean Transport (Sand Island Outfall).

Fig. 6.

The hydraulic analysis of a multiport diffuser is basically a problem in manifold flow. The procedure for the hydraulic calculations has been documented by Rawn, Bowerman and Brooks (1951) and is used in the design. It should be noted that if the diffuser is not placed along a constant elevation, then the phenomenon of density head makes it impossible for the discharge to be uniformly distributed along the diffuser for all flows. In the particular case of the Sand Island Outfall diffuser, the design is such that the discharge is essentially uniform for medium flow rates. At high flow rates, representing the more critical case from the point of view of submergence and dilution, the deeper ports are the ones discharging more.

Figure 7 shows the distribution of port discharge in the pipe along the diffuser for the Barbers Point Outfall for a friction coefficient (Manning n) of 0.015. This is shown as an example. A range of values of the friction coefficient were evaluated in the design process.

While the diffuser pipes in the Sand Island and Barbers Point Outfalls are reduced in steps to maintain a reasonable flow velocity along the pipe, some deposition may still accumulate in the diffuser particularly towards the end. Thus the ends of these diffusers are equipped with flat gates which can be opened to let the flow flush out the system (at most only once every few years, and perhaps never). When the diffuser is operated in this manner, a significant portion of the flow is discharged through the end of the diffuser. However, the bulk of the flow still occurs through the many ports along the diffuser. Figure 8 shows the calculated velocity in the diffuser pipe for the Barbers Point Outfall diffuser when operated in the flushing mode.

OTHER DESIGN CONSIDERATIONS

It is not possible in this brief technical paper to treat all the facets in the design of a major ocean outfall structure. The reader is referred to the two design reports (Ref. I and II) for further details.

In the design process, consideration was also given to: a) geophysical factors such as nature of the ocean bottom and subbottom, and earthquake forces; b) physical factors such as storm waves, currents, and tsunami forces on the structure; c) system hydraulics and pumping requirements; d) economic factors.

The Barbers Point Outfall system also includes a 9166-ft land outfall between the Honouliuli Treatment Plant (elev. 32 ft) and the shoreline. During all but the higher flow rates, the land outfall will not flow full. The vertical alignment chosen for the land outfall consists of a hydraulically steep portion near the plant followed by a mild portion. In this way, critical flow in the land outfall is avoided. Excess energy is dissipated by friction and a hydraulic jump near the upper end of the land outfall. The chosen alignment assures that 1) the hydraulic jump is never more than a few hundred feet downstream of the change in slope, and 2) a long reach of tranquil flow exists before the pipe flows full to avoid significant air entrainment.

CONSTRUCTION OF THE SAND ISLAND OUTFALL

Construction of the Sand Island Outfall began with excavation of the 15-foot deep and 13-foot wide trench at the end of the trestle, 2,500 feet offshore and in water 20 feet deep. The contractor (Morrison-Knudsen) laid pipe downhill to the end of the diffuser. When the trestle was finished, a double bell connection was made at the end of the trestle and pipe was then laid back to the junction box on shore.

Starting from shore, the material on Sand Island was easy to dig since it was old fill material. Along the trestle, hard coral rock was encountered which made it very difficult to drive the two rows of sheet piling extending 2,500 from shore. Beyond the trestle, the bottom slopes gradually downward to where the pipe from the trench exits onto the ocean floor. This trench soil was highly variable,

Fig. 7. Distribution of Port Discharge Along Diffuser of Barbers Point Outfall.

Fig. 8. Distribution of Velocity in Pipe Along Diffuser of Barbers Point Outfall.

changing often from sand to coral of varying hardness. The contractor used 500 lb. charges of dynamite (in 25-pound sacks) repeatedly along the trench, using many charges in the process. The trench excavation was especially difficult in the deeper sectors. Beyond the trench sections, the pipe was placed directly onto the ocean bottom and the work moved quickly to completion, with rock protection being used to stabilize the pipe all the way to the flap gate at the end.

The construction site is on the leeward side of the island so the contractor had a relatively calm working area. Several Kona storms interrupted the work and, on many occasions, the summer swells from the southern hemisphere stopped work because of the difficulty of loading pipe from the pipe barges onto the pipelaying barge. The contractor had allowed 3 months of downtime for weather and sea state and used up most of it during the 18-month period of construction.

The trestle was 2,500 feet long and made of steel H-pipes and beams. High speed carriers moved on the two rails to carry cranes and supplies of sheet piles and pipe. The heavy double bell section proved very difficult to connect to the pipe spigot already in place, because of the water swells in the shallow 20-foot depth. It is interesting to note that the contractor for the Barbers Point Outfall (almost identical to this one) plans to make his connection in much deeper water where the wave forces should be minimal at the joint location.

The pipelaying barge, called the "Davy Crockett", has been used on a number of outfall jobs. It is a converted World War II Liberty Ship, rigged with large anchor winches on each quarter (see Figure 9). The large crane in the center picks up the pipes and places them in a magazine until ready for laying. It then picks one of them up with a so-called "horse", places it on the ocean bottom and pushes it home into the bell of the previous pipe. Figure 9 also shows the complex pipe placing structure, called the "horse", which can pick up a pipe section and then stand on the ocean floor with its 4 legs near the previous pipe in place. Hydraulic controls, moving in 3 dimensions, carefully insert the spigot into the bell of the previous pipe. Once in place the pipe joint is tested with hydrostatic pressure. It is then rocked into position before the horse relaxes its grip on the pipe and is withdrawn. A diving bell is located near the joint. The contractor's diver is on one side, observing the joint make-up and talking by wire line to the horse operator up on the barge. The other side of the bell has a City Inspector, also observing and reporting on the adequacy of the underwater work. In some parts of the excavated trench, the trench width was so wide that the "horse's" legs were too narrow and it had to be extensively modified to straddle the trench.

Many barge loads of heavy armor stone were put in place to protect the pipe from the 46-foot design wave which was predicted as possible during the next 50 years. The initial design called for a thick concrete blanket over the pipe throughout the trench length because large rock was not available. After the job began the local quarry operator decided to make the investment in the equipment required to produce well-graded rock in five different classes ranging in nominal diameter from 1/2-foot to 2-1/2-foot. Divers controlled the placing of rocks around and on top of the pipe in the trench. Smaller size stones were placed near the pipe. This was later topped with armor stone varying up to 2-1/2-foot nominal diameter. The armor stones are of strong basalt with a specific gravity of 2.6. The well-graded mix was not easy to achieve. The City Inspectors sampled batches of these stones at random at the quarry. Each batch was separated. Then each stone of the batch was weighed and set aside into the five weight categories to validate the gradation. It proved to be a very tedious but worthwhile specification, ensuring well-graded armor protection for the pipe.

ACKNOWLEDGMENTS

The outfalls described herein were designed by the R. M. Towill Corporation under contracts for the City and County of Honolulu. The first two authors

Fig. 9. Pipelaying Barge Used in Construction of Sand Island Outfall.

(R. C. Y. Koh and N. H. Brooks) were engaged as special hydraulics consultants by the Towill Corporation for the projects. The authors acknowledge their contributions as well as others involved in the project.

CHAPTER 169

BUOYANCY-DRIVEN GRAVITATIONAL SPREADING

by

Robert C. Y. Koh¹

Introduction

It frequently occurs in environmental fluid mechanics that a mass of less heavy fluid spreads horizontally on top of a heavier one or a more homogeneous parcel of fluid spreads within a stratified one. Examples of such phenomena include spreading of diluted sewage effluent either at the surface or in a submerged layer, the spreading of heated effluent discharged from power plants, and the spreading of oil on the surface of the sea. The general problem is rather complex, being influenced not only by the buoyancy but also by momentum, ambient turbulence and flow, surface tension, waves, wind and other complicating factors. This paper attempts to examine gravitational buoyancy-driven flow in a homogeneous otherwise motionless ambient by casting it in the form of an initial value problem. Several assumptions are made and two empirical coefficients are introduced which must be determined from experiments. Experimental data are also presented, compared with the results of the analysis and the empirical coefficients determined. Previous investigations on similar problems include Sharp (1969, 1971), Koh and Fan (1968, 1969, 1971), and Koh and Chang (1973).

Formulation of the Problem

The fluid dynamic problem which will be considered in this paper is the time dependent spreading of one fluid on top of a heavier fluid. Both the two-dimensional and the axisymmetric cases will be examined. In each geometrical configuration, both the instantaneous and the continuous discharge cases will be investigated. The derivation will be detailed only for the two-dimensional case. Results for the axisymmetric case will be presented without detailed derivations.

Consider that at time $t=0$, a mass of buoyant fluid of volume A , linear dimensions characterized by a and b and density $\rho_0 - \Delta\rho$ is released from a state of rest on the surface of a deep reservoir containing fluid of density ρ_0 (see Fig. 1). It will be assumed that there is little mixing between the two fluids and that the shape of the buoyant fluid remains similar from one instant to another while it spreads. One expects that b will increase with time and a will decrease with time. For the moment, it will be convenient to assume that the motions in the heavier fluid is insignificant.

Figure 2 shows half of the buoyant fluid mass which will be considered as a free body. Assuming for the moment that the pressure distribution is hydrostatic, the buoyancy is seen to induce a net horizontal force of

$$\frac{1}{2} g' a^2 = \frac{1}{2} g \frac{(\rho_0 - \rho) a^2}{\rho}$$

In actuality, the pressure distribution is not hydrostatic. The departure of the pressure distribution from being hydrostatic will be accounted for by a horizontal force term which resembles that for hydrodynamic form drag and will be written

$$- \frac{C_D}{2} \rho a \left(\frac{db}{dt} \right)^2$$

the negative sign to indicate that the force is in opposition to the motion. There is another horizontal force tending to retard the spreading fluid, namely,

¹Research Associate in Environmental Engineering Science, California Institute of Technology.

Figure 1. Definition Sketch.

Figure 2. Pressure Forces on Half a Spreading Element.

that on the interface between the two fluids similar to a skin friction. It will be assumed that this force is

$$- \nu C_F \frac{b}{a} \frac{db}{dt}$$

The net imbalance of these forces must be equal to the net rate of change of momentum of the free body. Thus the equation of motion is

$$\frac{d}{dt} [(C_{ab}) \frac{d}{dt} (C_g b)] = \frac{1}{2} g' a^2 - C_D \frac{g}{2} \left(\frac{db}{dt}\right)^2 - C_F \nu \frac{b}{a} \frac{db}{dt} \tag{1}$$

where C_{ab} is the cross-sectional area of the free body and $C_g b$ is the distance from the origin to the center of mass of the cross-section. These quantities C_a, C_g are coefficients which depend only on the geometrical shape of the cross-section. By the assumption of similarity in shape, they will be constants. Table 1 gives values for C_g and C_a for several shapes.

Table 1

Shape	Geometry	C_g	C_a
rectangle		1/2	1
ellipse		4/3π	π/4
truncated trapezoid		4/9	3/4

For the case of no mixing between the two fluids, the equation for conservation of mass is simply

$$C_a ab = A = \text{constant} \tag{2}$$

for the case of instantaneous release. For a continuous discharge, it is

$$C_a ab = qt \tag{3}$$

where q is the discharge rate which accounts for half of the spreading layer. It should be noted that mixing can be allowed in this formulation by properly modifying the equations. Also, an apparent mass coefficient could have been introduced on the left-hand side of the equation. Neither will be done herein for simplicity. The derivation including these effects can be found in Koh and Chang (1973).

For definiteness, the shape of the spreading layer will be taken to be elliptical so that the coefficients C_a , and C_g are $\pi/4$ and $4/3\pi$ respectively. Equation 1 then becomes, after using either (2) or (3),

$$\frac{d^2 b}{dt^2} = \frac{6}{\pi} \frac{g'A}{b^2} - \frac{3}{2} \frac{C_D}{b} \left(\frac{db}{dt}\right)^2 - \frac{3\pi^2}{16} \frac{C_F \nu}{A^2} b^2 \frac{db}{dt} \tag{4}$$

and

$$\frac{d}{dt} \left(t \frac{db}{dt} \right) = \frac{6}{\pi} g' q \frac{t^2}{b^2} - \frac{3}{2} C_D \frac{t}{b} \left(\frac{db}{dt}\right)^2 - \frac{3\pi^2}{16} \frac{C_F \nu}{q^2} \frac{b^2}{t} \frac{db}{dt} \tag{5}$$

for the instantaneous release and continuous discharge respectively.

In the axisymmetric case, defining the shape of the spreading fluid to be half an ellipsoid of revolution, the equations analogous to (1), (2) and (3) are readily deduced to be

$$\frac{d}{dt} \left\{ \frac{\pi ab^2}{16} \frac{db}{dt} \right\} = \frac{g'a^2 b}{3} - C_D \frac{ab}{4} \left(\frac{db}{dt}\right)^2 - C_F \nu \frac{b^2}{a} \frac{db}{dt} \tag{1a}$$

$$\frac{2\pi}{3} ab^2 = v \quad (2a)$$

$$\frac{2\pi}{3} ab^2 = Q_0 t \quad (3a)$$

From these equations, one can derive the equations analogous to (4) and (5) to be

$$\frac{d^2b}{dt^2} = \frac{8g'v}{\pi^2} \frac{1}{b^3} - \frac{8C_D}{\pi} \frac{1}{b} \left(\frac{db}{dt}\right)^2 - \frac{64\pi}{9v^2} C_F v b^4 \frac{db}{dt} \quad (4a)$$

and

$$\frac{d}{dt} \left[t \frac{db}{dt} \right] = \frac{8g'Q}{\pi^2} \frac{t}{b^3} - \frac{8C_D}{\pi} \frac{t}{b} \left(\frac{db}{dt}\right)^2 - \frac{64\pi}{9Q^2} C_F v \frac{b^4}{t} \frac{db}{dt} \quad (5a)$$

Equations (4), (5), (4a) and (5a) will form the basis of the investigation in the remainder of this paper.

Normalization

The equations (4), (5), (4a), and (5a) will be normalized by choosing characteristic length b_0 and characteristic time t_0 so as to make the resulting dimensionless equations as simple as possible. This leads to the choices for b_0 and t_0 as tabulated in Table 2. The dimensionless equations which result become

Table 2

	Two-dim. instantaneous	Two-dim. continuous	Axisymmetric instantaneous	Axisymmetric continuous
t_0	$\left(\frac{16A^2}{3\pi^2 v}\right)^{3/7} \left(\frac{\pi}{6g'A}\right)^{2/7}$	$\left(\frac{16q^2}{3\pi^2 v}\right) \left(\frac{\pi}{6g'q}\right)^{2/3}$	$\frac{512vq'}{9\pi v}$	$\left(\frac{\pi^2}{8g'Q}\right)^{1/2} \left(\frac{9Q^2}{64\pi v}\right)^{1/2}$
b_0	$\left(\frac{16A^2}{3\pi^2 v}\right)^{2/7} \left(\frac{6g'A}{\pi}\right)^{1/7}$	$\left(\frac{16g^2}{3\pi^2 v}\right) \left(\frac{\pi}{6g'q}\right)^{1/3}$	$\left(\frac{\pi^2}{8g'v}\right)^{1/4}$	$\left(\frac{\pi^2}{8g'Q}\right)^{1/8} \left(\frac{9Q^2}{64\pi v}\right)^{3/8}$

$$\frac{d^2\zeta}{dt^2} = \frac{1}{\zeta^2} - \frac{3}{2} C_D \frac{1}{\zeta} \left(\frac{d\zeta}{dt}\right)^2 - C_F \zeta^2 \frac{d\zeta}{dt} \quad (6)$$

$$\frac{d}{dt} \left(t \frac{d\zeta}{dt} \right) = \frac{t^2}{\zeta^2} - \frac{3}{2} C_D \frac{t}{\zeta} \left(\frac{d\zeta}{dt}\right)^2 - C_F \frac{\zeta^2}{t} \frac{d\zeta}{dt} \quad (7)$$

$$\frac{d^2\zeta}{dt^2} = \frac{1}{\zeta^3} - \frac{8C_D}{\pi} \frac{1}{\zeta} \left(\frac{d\zeta}{dt}\right)^2 - C_F \zeta^4 \frac{d\zeta}{dt} \quad (6a)$$

$$\frac{d}{dt} \left(t \frac{d\zeta}{dt} \right) = \frac{t^2}{\zeta^3} - \frac{8C_D}{\pi} \frac{t}{\zeta} \left(\frac{d\zeta}{dt}\right)^2 - C_F \frac{\zeta^4}{t} \frac{d\zeta}{dt} \quad (7a)$$

where $\zeta = b/b_0$, $t = t/t_0$, corresponding to (4), (5), (4a), and (5a) respectively. Once the solution $\zeta(t)$ is obtained, the thickness a (or dimensionless $\eta = a/a_0$,

with appropriately chosen a_0) can be obtained from the continuity equation (2), (3), (2a), and (3a).

Each of the equations (6), (7), (6a), and (7a) will give solutions in the form $\zeta(t; C_F, C_D, \zeta_0, \zeta_0')$ where the four quantities $C_F, C_D, \zeta_0, \zeta_0'$ are parameters needed to specify the solution. Here ζ_0 and ζ_0' are the values of ζ and $d\zeta/dt$ at $t=0$. It is possible to have included C_F in the normalizing factors b_0 and t_0 . This is not done to allow the effect of C_F to show up more clearly and also allow comparison with experiments to be more meaningful.

Approximate Solution for Small Time

From physical reasoning, it can be expected that for small time, the term involving C_F would be unimportant since ζ would be small. Moreover, for the instantaneous release cases (eqs. 6 and 6a), the term involving C_D would also be insignificant for small t since $d\zeta/dt$ would be small. Thus, for small t , the equations 6 and 6a can be written

$$\frac{d^2\zeta}{dt^2} = \frac{1}{\zeta^2}$$

and

$$\frac{d^2\zeta}{dt^2} = \frac{1}{\zeta^3}$$

subject to the initial conditions $\zeta(0) = \zeta_0, \zeta'(0) = 0$. The solutions can be obtained by quadratures. For example, for the continuous release case,

$$\zeta = \zeta_0 \sqrt{1 + t^2/\zeta_0^4}$$

This represents the transient start-up period. The solution for the instantaneous case is more complex and will not be displayed.

Approximate Solution for Intermediate Time

For times not too large, physical considerations again lead to the approximation of ignoring the term involving C_F in the equations (6), (7), (6a) and (7a). It is now fruitful to examine solutions of the form $\zeta = Bt^\alpha$. Substituting this into each of the equations (ignoring the C_F terms) results in the following values for α , and the resulting time dependence for ζ (width) and η (thickness).

	2-dim. inst.	2-dim. cont.	axisym. inst.	axisym. cont.
α	2/3	1	1/2	3/4
$\zeta \propto t$	$t^{2/3}$	t	$t^{1/2}$	$t^{3/4}$
$\eta \propto t$	$t^{-2/3}$	1	t^{-1}	$t^{-1/2}$

These represent the circumstance when inertia balances the buoyancy driving force.

Approximate Solution for Large Time

For large time, ζ becomes very large, thus making the term involving C_F dominant. Physically this means that the interfacial shear is the dominant resistive force. If one now balances the driving force by this term (i.e., ignore the left-hand side as well as the C_D term in equations (6), (7), (6a), and (7a)), and seek solutions of the form $\zeta = B_1 t^{\alpha_1}$, one finds

		2-dim. inst.	2-dim. cont.	axisym. inst.	axisym. cont.
$\alpha_1 =$		1/5	4/5	1/8	1/2
$\zeta \propto$	$t^{1/5}$	$t^{1/5}$	$t^{4/5}$	$t^{1/8}$	$t^{1/2}$
$\eta \propto$	$t^{-1/5}$	$t^{-1/5}$	$t^{1/5}$	$t^{-1/4}$	1

These represent the circumstance when interfacial shear balances the buoyancy driving force. It is worth noting that the behavior of η (thickness) as function of t (time) is fundamentally different between the two-dimensional and axisymmetric cases for continuous discharge. Whereas $\eta \sim t^{1/5}$ in the two-dimensional case, η tends to a constant value in the axisymmetric case. Physically, this means that the thickness will continue to grow ad infinitum in the former while it would not in the latter case.

Overall Solutions

From the above discussion it is seen that after a brief start-up period, the solution for the extent of the spreading layer can be represented in each case by a power law in time where the power changes from one value to a second value as time progresses. It should be noted that the above results could have been obtained from simple dimensional arguments. The purpose for extracting them herein is to provide more insight into the relationships among the various phenomena represented by the various terms in the equations.

In general, the equations (6), (7), (6a), (7a) including all the terms can only be solved numerically. This has been done using a fourth order Range Kutta algorithm. The results for example cases for equation (6) is shown in Figure 3.

Comparison with Experiments

The results of the analysis will now be compared with laboratory experiments. The writer wishes to acknowledge Messrs. C. Almquist, P. J. W. Roberts and J. C. Chen who actually performed these experiments. While these individuals have performed a larger number of experiments, only example runs are presented herein for comparison purposes. The experimental data used for comparison in the following are shown tabulated in Table 3.

Two-Dimensional Instantaneous Release

These experiments were performed by C. Almquist (1973) as a term project for a course in the Environmental Engineering option at California Institute of Technology. The laboratory tank used was 5 inches wide by 18 inches deep by 16 feet long. It is filled with salt water (sp. gr. ≈ 1.020). A trough at the surface at one end of the tank containing less dense dyed water in hydrostatic equilibrium with the water in the tank is released at $t = 0$ by removal of a partition (see Figure 4a). The subsequent motion of the spreading layer is then timed. The density difference and the amount of the released fluid was varied over a factor of 4 and 9 respectively resulting in a total of twenty experiments. Figure 5 shows the data for four example runs together with the predictions from equation (4). In obtaining this comparison, the initial conditions were chosen to be the values of b and db/dt (dimensional values) at the beginning of the data. The values of C_D and C_F are chosen to obtain a good fit between the prediction and the experiment. However, the same value for C_D and the same value of C_F were used in all four comparisons. This comparison indicates that the predictions are quite good. Moreover, the values for C_D and C_F (0.85 and 0.4 respectively) are what might be expected being of order unity.

Run No.	Q cc/sec	$\Delta\rho/\rho$	Depth cm
1	41.6	0.051	11.7
2	37.5	0.013	23.4
3	13.5	0.066	5.9
4	13.5	0.022	5.9
5	13.5	0.017	5.9

The same data are shown plotted in Figure 6 in non-dimensional form. The curve shown is for $C_D = 0.85$ and $C_F = 0.4$ obtained as the solution to equation (6) (in dimensionless variables). The initial start-up period is ignored in this solution hence the lack of fit for small t . It should also be pointed out that the initial conditions used in the predictive solution, as a consequence, is independent of the data. From this comparison, it is seen that the analyses does, in fact, conform to the data quite well.

Two-Dimensional Continuous Surface Release

These experiments were also performed by C. Almquist under the same circumstances in the same tank. The only difference in the procedure is in the mode of introduction of the buoyant fluid. In this case, the buoyant fluid is allowed to be discharged continuously at the surface at one end of the tank from a structure as shown in Figure 4b. The supply of the buoyant fluid is via a constant head tank. Comparison of the results of four of the experiments are shown in Figure 7 where the curve is obtained by solving equation (7) using $C_D = 0.5$, and $C_F = 5$.

Two-Dimensional Continuous Submerged Release

These experiments were performed by P. J. W. Roberts in a much larger tank than the previous experiments. The buoyant fluid is now introduced at the bottom of the tank, allowed to rise to the surface and then spread horizontally on the surface. A schematic of the experimental setup is shown in Figure 8. It should be pointed out that while equation (7) is still applicable to this case, interpretation of the coefficients C_D and C_F must be viewed somewhat differently. Whereas in the surface release case, the water depth in the tank is much larger than the thickness of the spreading layer, this is no longer true in the submerged case. More importantly, in this case, mixing occurs during the rise of the buoyant water from the discharge point at the bottom to the surface. An entrainment undercurrent is set up whose direction is opposite to that of the spreading layer. One must, therefore, expect both C_D and C_F to be larger than in the previous experiments. In the case when the entrainment is significant, one expects C_D to be larger by a factor of approximately 3 for the case when the spreading layer is approximately 1/3 of the total depth z as was observed to be the case. Comparison of these experiments with the solution to eq. (7) with $C_D = 2.5$ and $C_F = 14.5$ is shown in Figure 9 where again the data appears to confirm the analysis.

Axisymmetric Continuous Submerged Release

These experiments were performed by J. C. Chen in the same laboratory basin as the two-dimensional submerged release experiments. A 6 mm diameter round orifice is placed at the bottom of the basin. Injection is started and overhead photographs taken at discrete times to record the spread of the dyed buoyant fluid. The normalized variables ζ and t for five of these experiments are shown in Figure 10 together with the analytical results ($C_D = 0.2$, $C_F = 0.05$). The comparison is seen to be reasonable.

It should be noted here that in the submerged release cases, the buoyant discharge undergoes a certain amount of dilution before reaching the surface and spreading. Thus the value of the discharge rate is actually larger than the discharge from the orifice by a factor equal to the average dilution. The buoyancy flux, of course, is still unchanged. In plotting the experimental points in Figures 9 and 10, the discharge rates have been calculated on the basis of simple plume theory with S_a given by

$$S_a = 0.38 \frac{y(g_o' q_o)^{1/3}}{q_o}$$

Figure 6.

$$S_a = 0.16 \frac{y^{5/3} (g'_0 q_0)^{1/3}}{q_0}$$

(S_a = average dilution).

Practical Applications

It appears at first glance that the results obtained in the previous sections are of little practical value since in practice, neither two-dimensionality nor axial-symmetry obtains. It will be shown in this section how the results can be utilized to deduce some properties of the flow field which are of great practical value.

(a) Thickness of surface sewage field.

Major coastal discharges of sewage effluent into the ocean frequently employ long diffusion structures (on the order of several thousand feet long) at a depth of approximately 200 ft. Many small ports along the diffuser discharges the effluent in such a way as to approximate a long line source of effluent. It has been found experimentally that, in the event where the ocean is uniform in density and motionless, simple line plume theory gives good predictions of dilution factors (see e.g., Koh and Brooks, 1975). The centerline dilution, S_c according to that theory is simply

$$S_c = 0.38 \frac{(g'_0 q_0)^{1/3} y}{q_0} \quad (8)$$

The average dilution S_a is $\sqrt{2} S_c$. Here $(g'_0 q_0)$, q_0 , and y are the buoyancy flux and discharge per unit length, and vertical distance from the diffuser ($g'_0 = g(\rho_0 - \rho)/\rho$; g = gravitational acceleration, ρ = density of effluent, ρ_0 = density of sea water). Referring to Figure 11, there is seen to be an uncertainty in application of equation (8) in that one does not know what value of y to use. Whereas buoyant plume theory is developed for an infinite fluid, the presence of the ocean surface deflects the sewage field to spread on the surface. The value of y to be substituted into equation (8) to obtain the surface dilution should logically be $(d-a)$ where d is the depth and a the thickness of the sewage field (see Figure 11). The thickness of the surface field a will now be estimated from the results of analyses in this paper. It should first be noted that the thickness $a(t)$ defined in the two-dimensional continuous release case analyzed previously is the quantity of interest. As a function of time, it starts at zero, grows to a constant value, remains constant until interfacial shear forces become important, whereupon it grows as $t^{1/5}$ without limit. For practical problems, the $t^{1/5}$ growth is of little significance since by the time this would occur, the two-dimensionality assumption breaks down. (It may be noted that in the three-dimensional continuous release case, the thickness tends to a constant.) Given that shear is unimportant, one may write equation (5) as

$$\frac{d}{dt} \left(t \frac{db}{dt} \right) = \frac{6}{\pi} (g'q) \frac{t^2}{b^2} - \frac{3}{2} C_D \frac{t}{b} \left(\frac{db}{dt} \right)^2 \quad (9)$$

with solution

$$b = \gamma t \quad (10)$$

where

$$\gamma = \left[\frac{6}{\pi} \frac{g'q}{1 + \frac{3}{2} C_D} \right]^{1/3}$$

but

$$qt = \frac{\pi}{4} ab \quad (11)$$

Figure 11. Definition Sketch.

Figure 12. Schematic Plan View of Wastewater Plume.

so that

$$a = \frac{4q}{\pi \gamma} = \frac{4q}{\pi} \left[\frac{1 + \frac{3}{2} C_D}{\frac{6}{\pi} g'q} \right]^{1/3} \quad (12)$$

It may be seen that, in the present case, $g'q = g'_0 q_0 / 2$, and $q = S_a q_0 / 2$ where the factor 2 is to account for the fact that only half the discharge goes to either side. Noting that

$$S_a = \sqrt{2} \cdot 0.38 \frac{(g'_0 q_0)^{1/3} (d-a)}{q_0} \quad (13)$$

and substituting into equation (12) yields

$$a = \frac{4}{\pi} \frac{\sqrt{2} \cdot 0.38 (g'_0 q_0)^{1/3} (d-a)}{2} \frac{1 + \frac{3}{2} C_D}{\frac{6}{\pi} g'_0 q_0 / 2}$$

from which

$$\frac{a}{d} = \frac{\delta}{1 + \delta}$$

$$\text{where} \quad \delta = \frac{2\sqrt{2} \cdot 0.38}{\pi} \left[\frac{1 + \frac{3}{2} C_D}{\frac{3}{\pi}} \right]^{1/3} = \frac{2\sqrt{2} \cdot 0.38}{\pi} \left[\pi \left(\frac{1}{3} + \frac{C_D}{2} \right) \right]^{1/3} \quad (14)$$

From experiments (see Figure 9), $C_D = 2.5$, hence $\delta = 0.40$ and

$$\frac{a}{d} = 0.29$$

In other words, the thickness of the sewage field should be 29% of the total depth. The depth of water available for mixing is $d-a$ and is therefore 71% of the total depth. It is interesting to note that $0.71 \times \sqrt{2} \approx 1$ so that one may use the full depth d for y in equation (8) provided one interprets the result as average instead of centerline dilution.

(b) Shape of surface plume in a parallel current.

An overhead view of the spreading surface field from a long submerged diffuser might be as shown in figure 12 for the case where an ocean current of speed U flows parallel to the diffuser. Assuming that the fluid all travels at speed U , a Galilean transformation (moving with the current) indicates that $b(\frac{x}{U})$ should behave similar to $b(t)$ in the solution presented previously. For x less than L , the length of the diffuser, the continuous injection case applies while for x larger than L , the instantaneous injection case applies. For the case interfacial shear is unimportant in the region $x < L$, $b(x)$ should be proportional to x . For $x > L$, $b(x)$ should be proportional to $x^{2/3}$. For very large x , (interfacial shear becomes important), $b(x)$ should be proportional to $x^{1/5}$. Thus the horizontal extent of the surface field can be obtained by using this approximation in the case when a Galilean transformation is permitted. For low ocean current speed, the surface field would actually extend upstream and in that region, the approximation is no longer valid.

Summary and Conclusions

In this paper, the time dependent spreading of a buoyant fluid on the surface of a heavier fluid is investigated by casting the problem in the form of an initial value problem. By assuming that the shape of the spreading layer remains geometrical similar from one instant to the next, differential equations were derived for two-dimensional and axisymmetric configurations in both the instantaneous and continuous release cases. Laboratory experiments were compared with the analysis and the results were found to compare favorably. Similar analysis can also be performed for the submerged case of spreading in a density stratification.

The results of this analysis should prove of value in environmental fluid mechanics such as the spreading of wastewater or thermal effluent on the sea surface. A fundamental important finding from the analysis is that in the two-dimensional continuous release case, the thickness of the spreading layer would tend to infinity as time tends to infinity while in the axisymmetric case, the thickness tends to a constant. The extra dimension available for spreading in the three-dimensional case is apparently sufficient to prevent complete blocking of the flow (or inundation of the source). In an actual submerged discharge of wastewater from a long diffuser in an otherwise stagnant ambient, the thickness of the spreading layer could probably be represented by the value indicated by assuming $C_F = 0$ in the equation (5). This thickness is deduced to be 29% of the depth. The results of the analysis can also be applied to estimate the horizontal area covered by the surface field in the case of a parallel current.

CHAPTER 170

NEGATIVELY BUOYANT SLOT JETS

by

D. M. Shahrabani¹ and J. D. Ditmars²

Abstract

The behavior of negatively buoyant slot jets discharged from near the bottom of stagnant and flowing receiving-water environments of uniform density was studied in laboratory experiments. In particular, the locations of the maximum height of rise and maximum horizontal displacement were determined as well as the centerline dilutions at those points. Experiments in stagnant environments were conducted for discharges at angles of 30°, 45°, 60°, and 90° from the horizontal and with discharge densimetric Froude numbers of 10, 20, 30, 40 and 50. For flowing environments, discharges at angles of 45° and 90° for the same range of densimetric Froude numbers were directed into uniform currents with discharge to ambient velocity ratios of 15 and 25. The reattachment eddy formed between the jet and bottom boundary was found to have significant effects on the slot jet trajectories and dilutions. Dilutions at the maximum height of rise and maximum horizontal displacement were less than those predicted for slot jets far removed from the influence of the bottom boundary. The strictly two-dimensional discharges studied provide lower bounds on the dilutions to be expected for the cases of slots of finite length or merged multiport diffuser discharges in which the reattachment eddy is not as well developed.

Introduction

Negatively buoyant discharges are those with densities greater than the density of the receiving-water environment into which they are injected. The residual effluents from coastal desalting plants are brines which are negatively buoyant relative to the source waters. The warm surface water used to provide the heat of vaporization in LNG plants is cooled and negatively buoyant upon return to the surface waters. Industrial effluents, particularly those containing acids or acid-salts, are sometimes negatively buoyant despite having temperatures greater than those of the receiving water.

Slot jets or two-dimensional jets are created by the discharge of an effluent into a receiving-water body from a single orifice of slot

¹Pandullo, Quirk Associates, Wayne, New Jersey, USA.

²Argonne National Laboratory, Argonne, Illinois, USA (on leave from the University of Delaware, Newark, Delaware, USA).

geometry or by the lateral merging of adjacent round jets from a multiport diffuser. Negatively buoyant slot jets sink due to the gravity force acting on them. Because sites for the continuous disposal of negatively buoyant effluents are usually located offshore, near-surface discharges are not often possible, and the discharge structure is located on or near the bottom. Consequently, the effluent is discharged upward into the receiving water at some angle from the horizontal. The initial jet momentum carries the effluent upward so that mixing occurs before the gravity force brings the diluted effluent back to the bottom as indicated in Figure 1. The characteristics of a negatively buoyant slot jet of particular interest are the geometric coordinates and dilutions at the maximum height of rise of the jet and at the point of bottom impingement. The former is important to assure that the jet remains completely submerged, and the latter is of concern in the assessment of the impact on benthic communities.

The results of laboratory experiments with turbulent negatively buoyant slot jets discharged into stagnant and flowing receiving waters of uniform density are reported. For these experiments the discharge is two-dimensional; that is, the slot extends completely across the receiving-water body. Also the jet remains fully submerged below the free surface. Attention, in these experiments, was focused on the jet characteristics at the maximum height of rise and the region of bottom impingement. The applicability of the results to slot discharges of finite length and to merged jets from multiport diffusers is discussed.

Review of Round Negatively Buoyant Jet Behavior

Although no published data on the behavior of negatively buoyant slot jets are known, work has been reported on the behavior of negatively buoyant round jets in both stagnant and flowing receiving water environments of uniform density.

Turner¹ performed experiments with negatively buoyant round jets discharged vertically upward into stagnant environments and determined an expression for the maximum height of rise of such jets. Zeitoun et al.² performed similar experiments for negatively buoyant round jets discharged at a variety of angles from the horizontal and for several discharge conditions. They found that the dimensionless maximum height of rise of the jet, Y_m/D , and the centerline dilution at that point, $S(Y_m)$, could be expressed as functions of the discharge densimetric Froude number, F_r , and the discharge angle, θ_0 , as follows:

$$\frac{Y_m}{D} = C_1 F_r, \quad (1)$$

and

$$S(Y_m) = C_2 F_r, \quad (2)$$

Fig. 1. Schematic Diagram of a Negatively Buoyant Slot Jet

where

$$F_r = \frac{U_o}{\left(\frac{\Delta\rho_o}{\rho} g D\right)^{1/2}}$$

Y_m = maximum height of rise above the discharge

D = discharge diameter

$\frac{\Delta\rho_o}{\rho}$ = discharge density difference divided by a reference density

$S(Y_m)$ = centerline dilution at Y_m

C_1, C_2 = coefficients which are constant for a given angle of discharge, θ_o .

The results of the experiments of Zeitoun *et al.* for θ_o values of 30°, 45°, 60°, and 90° indicate that, for a given discharge angle and no interaction with the free surface, the maximum height of rise and the dilution at that point increase monotonically with increases in the discharge Froude number (as indicated in Eq. (1) and (2)).

Morton³ and Abraham⁴ have presented analyses of the case of a negatively buoyant round jet discharged vertically upward which employ the integral-similarity approach often used in analyses of positively buoyant jets. Predictions for this particular case are difficult to match with experimental results because the jet falls back on itself and the similarity assumption becomes tenuous. Zeitoun *et al.*² applied an integral-similarity analysis with a variable entrainment coefficient to the non-vertical discharge case and found reasonably good agreement between predictions and their experimental data for trajectories and dilutions.

Experiments on negatively buoyant round jets discharged upward into flowing environments of uniform density and velocity have been reported by Holly and Grace⁵ for a vertical discharge and by Pincince and List⁶ for a discharge inclined at 60° from the horizontal and in the direction of flow. Anderson *et al.*⁷ conducted experiments for a variety of discharge angles, discharge densimetric Froude numbers, and ratios between the discharge and crossflow velocities. The crossflow acted to bend the jet trajectory downward which resulted in a decrease in the dilution at the maximum height of rise over the equivalent case in a stagnant environment. The dilution in the region of bottom impingement, however, was found to increase due to the elongation of the trajectory over that in a stagnant case. Anderson *et al.* were able to effect agreement between an integral-similarity model and the experimental results by varying the entrainment coefficient with the discharge densimetric Froude number and velocity ratio.

Slot-Jet Experiments

The experiments for negatively buoyant slot jets in stagnant and flowing environments were conducted in a flume 5.5 m long, 0.33 m wide, and 0.46 m deep. The jet was discharged from a slot in a small (1.27 cm radius) half-cylinder mounted on the flume bottom and extending across the entire width of the flume. Slots of different opening sizes and angles to the horizontal were employed. The receiving-water depth was maintained large enough to avoid any interaction of the jet with the free surface. The receiving water flow was turbulent, in the cases of flowing environments, and the negatively buoyant jets were all turbulent with a minimum discharge Reynolds number (based on slot width) of about 2000.

The discharge effluent was a saltwater solution and the receiving water was fresh with the discharge density and flow rate adjusted to produce the densimetric Froude number desired. Since a saltwater solution was used as the effluent, conductivity probe measurements in the jet were used to infer concentrations and density and thus to determine dilution values. Dye injected into the discharge and a grid on the transparent flume wall were used for photographic records of the jet trajectory. The conductivity measurements were concentrated in the regions of the maximum height of rise and the bottom impingement of the plume. Receiving-water velocities for the flowing cases were measured with a hot-film anemometer and appeared to be quite uniform over the cross-section, except for small regions near the side and bottom boundaries.

Detailed descriptions of the experimental equipment and techniques are given in Reference 8.

Results of Slot-Jet Experiments — Stagnant Environment

Dimensional analysis of the discharge of a negatively buoyant slot jet into a stagnant environment indicates that the dimensionless trajectory coordinates, y/B and x/B , and centerline dilution, S , are functions of the slot discharge densimetric Froude number, F_s , and the angle of discharge from the horizontal, θ_0 , where,

$$F_s = \frac{U_0}{\left(\frac{\Delta\rho_0}{\rho} g B\right)^{1/2}}$$

and

B = discharge slot width.

Experiments were performed in which the Froude number had values of 10, 20, 30, 40, and 50 for each of the discharge angles of 30°, 45°, 60°, and 90°. The results of these experiments are given in terms of the maximum height of rise of the jet centerline above the discharge, Y_m , the maximum horizontal displacement of the jet centerline away from the

discharge in the region of bottom impingement, X_m , and the centerline dilutions at those points, $S(Y_m)$ and $S(X_m)$, respectively.

The data for the normalized maximum height of rise as a function of Froude number for discharge angles 45° , 60° , and 90° are shown in Figure 2. The data for $\theta_0 = 30^\circ$ are not shown as those discharges interacted so quickly with the bottom that trajectory and dilution measurements were difficult. With results similar to those for negatively buoyant round jets, the normalized maximum height of rise varied directly with the discharge Froude number. Contrary to the data of Zeitoun *et al.* for round jets, for which the $\theta_0 = 60^\circ$ case produced the largest value of the coefficient C_1 in Eq. (1), the slot jet data indicate that that coefficient increases monotonically as θ_0 increases from 0° to 90° . Figure 3 indicates that the normalized maximum horizontal displacement increases with discharge Froude number for a given θ_0 and that $\theta_0 = 45^\circ$ results in the greatest horizontal displacement.

The dissimilarity between round and slot jet behavior becomes even more apparent from the centerline dilution data. The centerline dilution at the maximum height of rise is given as a function of Froude number and discharge angle in Figure 4. The dilution increases monotonically with discharge Froude for all angles, similar to round jet experience in Eq. (2), for Froude numbers less than about 30. For discharge Froude numbers greater than about 30, the dilution at the height of maximum rise decreases with increases in Froude number. Similar behavior was found for the dilution at the maximum horizontal displacement, shown in Figure 5. The decrease of the dilution for increases in discharge Froude number appears to be due to the reattachment eddy formed between the sinking slot jet and the bottom boundary and to reentrainment by the jet. The reattachment eddy, shown schematically in Figure 6, acts to pull the jet toward the bottom because of the pressure field established and to enhance reentrainment of the discharged effluent into the jet. The entrainment of this diluted effluent, instead of fresh receiving water, decreases the dilution and decreases the local jet densimetric Froude number.

Analytical-Model Predictions for the Stagnant Case

The effects of the reattachment eddy are manifested in the attempt to predict negatively buoyant slot jet behavior with a model which ignores the presence of the bottom boundary. An integral-similarity model for an unbounded, stagnant receiving water with uniform density was employed. The governing equations were similar to those developed by Fan and Brooks⁹ for positively buoyant slot jets for the cases of the discharge conditions which existed in the experiments. The entrainment coefficient and spreading coefficient were set at 0.16 and 0.89, respectively, and the predictions were corrected for the zone of flow establishment.

Figures 7 and 8 indicate the model predictions of trajectory and dilutions at the maximum height of rise and the maximum horizontal displacement and the experimental values for these parameters for two discharges inclined at 60° from the horizontal. Both cases show that

Fig. 3. Normalized Maximum Horizontal Displacement for Stagnant Environment

Fig. 2. Normalized Maximum Height of Rise for Stagnant Environment

Fig. 4. Centerline Dilution at Y_m for Stagnant Environment

Fig. 5. Centerline Dilution at X_m for Stagnant Environment

Fig. 6. Schematic Diagram of Reattachment Eddy

Fig. 7. Comparisons of Predictions and Measurements of Trajectory and Dilution for $\theta_0 = 60^\circ$ and $F_s = 10.4$

Fig. 8. Comparison of Predictions and Measurements of Trajectory and Dilution for $\theta_0 = 60^\circ$ and $F_s = 52.4$

the experimental trajectories were shorter and lower and that the measured dilutions were lower than the predictions. The disparity between predictions and measurements becomes greater for larger discharge Froude numbers (Figure 7 versus Figure 8). Additional comparisons⁸ indicate that the model for an unbounded receiving water, in general, predicts that the dilution at the maximum height of rise is a monotonically increasing function of Froude number without the decreases in dilution found in the experimental data (Figure 2). A large discharge densimetric Froude number implies relatively large discharge momentum, and consequently, for such a case, more intense reattachment eddies than for the case of a small discharge Froude number.

The failure of the model to predict the negatively buoyant slot jet behavior is directly related to the fact that the bottom boundary and its effects on the flow are neglected in the model. Although the values of the entrainment coefficient and the spreading coefficient are not well-established for the unbounded case, sensitivity studies with variations in these parameters indicated that agreement between predictions and experimental data could not be forced. This simply confirms the fact that the proximity of the bottom boundary is the important feature governing the jet behavior.

Results of Slot-Jet Experiments — Flowing Environment

Dimensional analysis for the case of a deeply-submerged negatively buoyant slot jet in a flowing environment yields an additional governing parameter, K , the velocity ratio,

$$\text{where } K = \frac{U_o}{U_a},$$

and U_a = uniform ambient velocity.

Thus, the governing parameters for the behavior of negatively buoyant slot jets discharged into flowing environments are F_s , θ_o , and K . Experiments were performed for the cases of discharge angles of 45° and 90° for the range of F_s used for the stagnant cases (10 to 50) for K values of 15 and 25.

The normalized maximum height of rise and the normalized maximum horizontal displacement for the $\theta_o = 45^\circ$ case are shown as functions of F_s and K in Figures 9 and 10, respectively. The stagnant case ($K = \infty$) is shown for reference. Figure 9 shows that the jet is bent downward by the ambient current as expected. Figure 10 indicates that the relatively smaller ambient current ($K = 25$) acts to extend the jet downstream farther than in the stagnant case, yet the larger current ($K = 15$) apparently intensifies the reattachment eddy for $F_s > 20$ and lessens the downstream extent of the impingement. The dilutions at Y_m and X_m for $\theta_o = 45^\circ$ are shown in Figures 11 and 12, respectively. The decrease in dilution for large Froude numbers found for the stagnant case appears again in the flowing cases. The bending downward of the jet trajectory due to the

Fig. 10. Normalized Maximum Horizontal Displacement for Flowing Environment, $\theta_0 = 45^\circ$

Fig. 9. Normalized Maximum Height of Rise for Flowing Environment, $\theta_0 = 45^\circ$

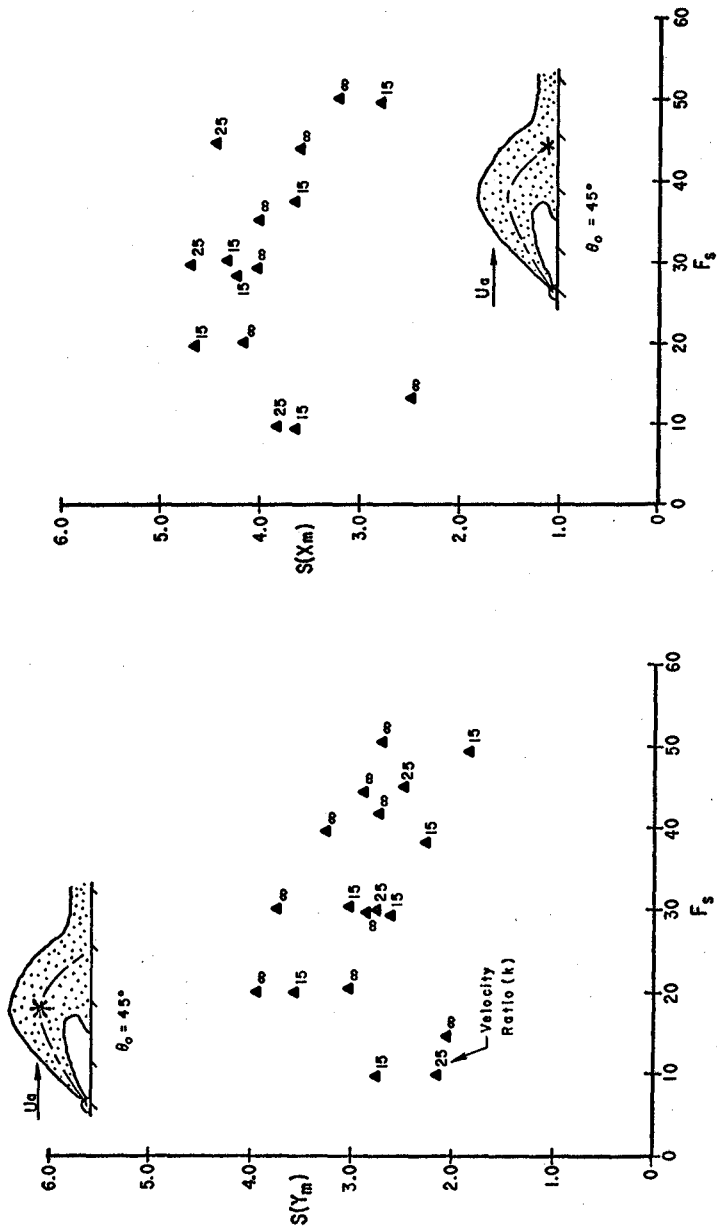

Fig. 11. Centerline Dilution at Y_m for Flowing Environment, $\theta_0 = 45^\circ$

Fig. 12. Centerline Dilution at X_m for Flowing Environment, $\theta_0 = 45^\circ$

current generally results in smaller dilutions at Y_m than in the stagnant case as shown in Figure 11 and larger dilutions at X_m due to elongation of the trajectory before bottom impingement, as shown in Figure 12. However, the data for $S(X_m)$ suggest that the higher current case ($K = 15$) may result in dilutions at X_m about equal to those for the stagnant case due to joint effects of entraining horizontal momentum from the current and of the reentrainment of dense fluid due to the reattachment eddy. Subsequently, counter to the experience with round jets in a current, where the current acted to extend the plume and to enhance mixing before bottom impingement, the slot jet in a current is greatly influenced by the reattachment eddy and enhanced downstream dilution may not be realized.

The normalized maximum height of rise and the normalized maximum horizontal displacement for the $\theta_0 = 90^\circ$ case, a vertical discharge, are shown as functions of F_s and K in Figures 13 and 14, respectively. The stagnant case does not provide the greatest Y_m/B values (Figure 13) because, in that instance, the effluent falls back on itself and, in the flowing case, the bending of the jet causes it to impinge downstream of the slot as shown in Figure 14. That difference between the stagnant and flowing cases is shown again in the dilution data at Y_m in Figure 15, where dilutions for the flowing cases are larger than for the stagnant case. Similar results are shown in Figure 16 for $S(X_m)$. One would expect that for values of K smaller than examined in these experiments (larger relative currents), the discharge would be bent over so much that dilutions at X_m would decrease below those for the stagnant case as occurred in the results for the $\theta_0 = 45^\circ$ discharge (Figure 12)

Applicability to Discharges Which Are Not Two-Dimensional

The results of this study apply strictly to the case of a slot discharge located at the bottom of the receiving water and extending completely across the receiving water (strict two-dimensionality). It has been shown that the reattachment eddy downstream of the discharge has a pronounced effect on the jet behavior. Because the existence and strength of that eddy depend on the physical situation studied, caution is necessary in the application of the results found to discharge situations which are physically different.

A slot discharge on the bottom of and extending across a river or stream clearly resembles the case studied. However, a slot discharge elevated some distance above the bottom would permit entrainment flow to the lower side of the slot and weaken or possibly eliminate the reattachment eddy. In such a case, it is expected that the integral-similarity model predictions would more readily reflect the jet behavior than the experimental results reported here. Likewise, a slot discharge of finite length, not extending entirely across the receiving water body, could induce flow inward along the axis of the slot for entrainment and diminish the strength of the eddy. The merging of adjacent round jets of a multiport diffuser to form a slot jet may also constitute a different physical situation. Although an "equivalent" slot for a multiport diffuser discharge is easily calculated, the flow between the initial round jets would probably result in a weaker reattachment eddy than would be formed had the initial discharge geometry been a slot.

Fig. 14. Normalized Maximum Horizontal Displacement for Flowing Environment, $\theta_0 = 90^\circ$

Fig. 13. Normalized Maximum Height of Rise for Flowing Environment, $\theta_0 = 90^\circ$

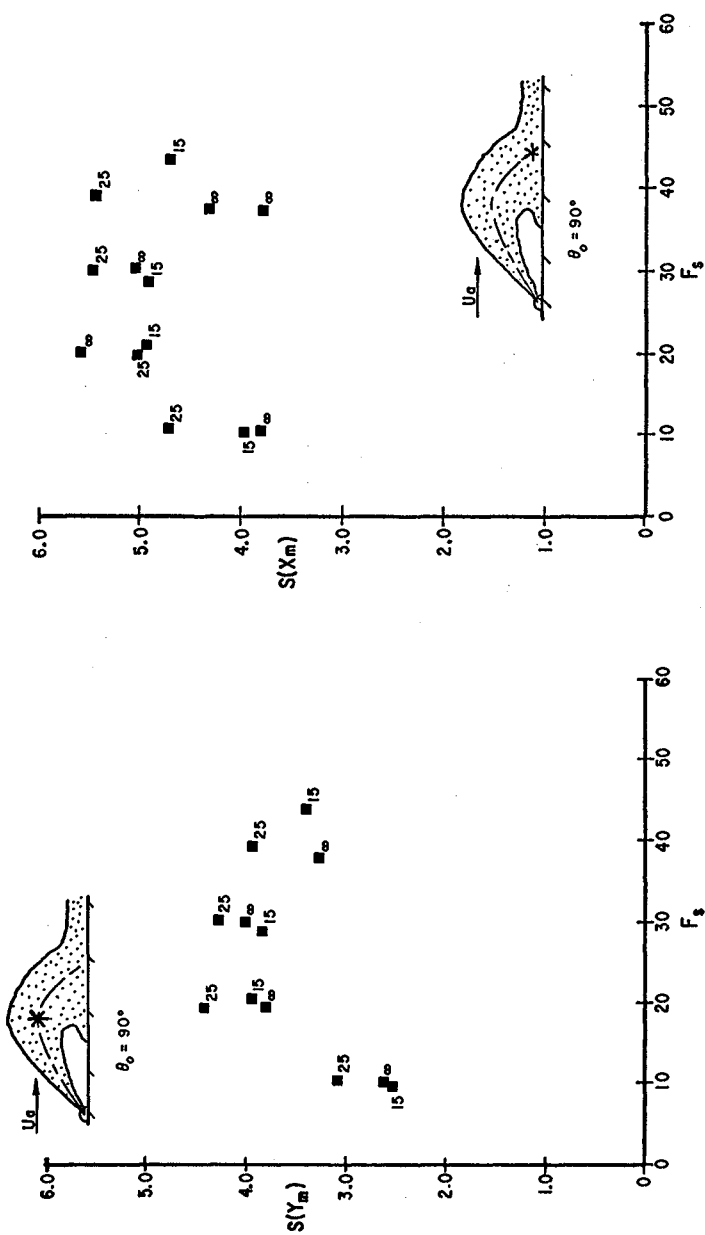

Fig. 15. Centerline Dilution at Y_m for Flowing Environment, $\theta_0 = 90^\circ$

Fig. 16. Centerline Dilution at X_m for Flowing Environment, $\theta_0 = 90^\circ$

All of the physical situations mentioned above result in the possibility that the reattachment eddy may be weakened and hence that the dilution may be increased over that predicted by the experimental data reported for this study. The sensitivity of the results to these factors and the degree to which dilution predictions can be increased remains to be studied. The results for the two-dimensional case reported here do, however, provide the lower-bound or "worst case" on the mixing to be realized from a slot or slot-like discharge of a negatively buoyant effluent. The upper bound would be that behavior predicted by the model for receiving-water environment with no boundary interference.

Conclusions

The behavior of submerged negatively buoyant slot jets discharged near the bottom of the receiving water is influenced by the reattachment eddy created between the jet and the bottom. The trajectories of such jets in stagnant and flowing environments are lower and flatter than would be predicted in the absence of the bottom boundary. Centerline dilutions at the maximum height of rise and the maximum horizontal displacement are reduced considerably relative to predictions for the unbounded case. Contrary to experience with negatively buoyant round jets discharged near the bottom, the dilution at the maximum height of rise for a given discharge angle does not increase monotonically with increases in the discharge densimetric Froude number. The existence of the reattachment eddy in the slot discharge case results in the dilution at that point decreasing for Froude numbers greater than about 30. The strictly two-dimensional case studied provides a lower bound for dilution and trajectory predictions for cases of discharges from finite-length slots and discharges from multiport diffusers which merge to form slots.

CHAPTER 171

GUIDELINES FOR THE DESIGN OF AIR BUBBLE SYSTEMS

By

Nabil Ismail*, Graduate Student
Hydraulic Division, University of California
Berkeley, California, U.S.A.

ABSTRACT

Based on a literature review of theoretical and experimental work on air-bubble systems, guidelines for the ideal design of submerged distributors discharging air into water are presented.

A comprehensive study of gas-liquid dispersions was carried out to find out the effect of physical properties, distributor arrangement, and the air flow rate, on the flow pattern within the jet. This review revealed that the distributor arrangement largely influences the characteristics of the dispersion within the zone of flow establishment. Also, upon analyzing the experimental results of air-water systems, it was found that the zone of flow establishment extends to greater distances of the water depth than that in the case of one-phase turbulent plumes. Furthermore, the experimental results showed that the efficiency of air bubble plumes can be increased by the proper design of the distributor.

Recommendations for the distributor design are given, which include, diameter of orifices and their spacings, pressure drop across orifices, number of manifolds, and the maximum air flow rate.

*On a Study Leave from Civil Engn. Dept., Alexandria University, Alexandria, A. R. Egypt.

INTRODUCTION

Air-bubble systems have been used extensively for a variety of purposes, such as pneumatic breakwaters, prevention of ice formation, as barriers against salt water intrusion in rivers and locks, as barriers to reduce silt intrusion into estuaries, for stopping the spreading of oil spills on the water surface, for reduction of under water explosion waves, and for agitation, mixing, cooling, in process industries.

Based on the results of both small and large scale tests, and prototype tests, applied for use as pneumatic breakwaters, there has been a controversy for the past 30 years among investigators of the effect of the air distribution system on the efficiency of bubble systems. In addition, despite the wide range of practical applications, no theory has been developed to give a satisfactory description of the hydrodynamics of air-bubble systems. However, with a better understanding of the physical mechanism of this kind of plumes, there is some hope that the behavior of the air-bubble systems may be analyzed sufficiently well for design purposes.

Therefore, the fundamentals of disintegration of gas jets into liquids, and the subsequent upward motion have received consideration in the present work. This together with analyzing the previous theoretical and experimental work, provide us with some guidelines for the proper design of these bubble systems and necessary information to improve the present theoretical models.

DISINTEGRATION OF GAS JETS INTO LIQUIDS

In the range of air flow rates employed in most of the practical applications, the air issuing from a nozzle or an orifice quickly expands according to the sudden pressure drop across the nozzle, and eventually breaks up due to the instability of the jet. In other words, the continuous air stream disintegrates into series of closely spaced large irregular bubbles after it has travelled some distance from the air source. These irregular bubbles finally disintegrate into smaller ones and begin to rise through the water column. Normally, coalescence of bubbles occurs between bubbles of different sizes, and bubbles, during their rise, might coalesce depending upon their size distribution. Fig. 1 shows the disintegration of an air jet into water of depth 4.5 ft.

The flow pattern of one-phase turbulent jets can be divided into distinct zones. The boundary between the zones of flow establishment and established flow, can be defined

After Abdel-Aal (1)

Fig. (1). Dynamic Behavior of The Air-Water Jet

in the terms of the variation in the velocity and concentration. The extent of the ZFE either for the velocity or for the concentration is just few times the width of the slot.

In the case of a two-phase jet it is rather difficult to determine such boundaries between the different zones of the air-bubble flow. Generally the lateral spreading of the bubbly flow is less than that of the plume. With respect to the air stream, the flow can be divided into the following zones.

(a) Zone of Flow Establishment (ZFE): This zone can be subdivided:

- i) the initial zone where the air stream is still stable at the end of this zone, the air disintegrates into closely spaced large bubbles.
- ii) the transition zone, where the irregular large bubbles break up into discrete bubbles of various sizes.

and (b) Zone of Established Flow (ZEF): Regarding the gross behavior of the jet, all the previous experimental studies reveal that the center-line velocity reaches an almost constant value, and the velocity profiles become similar, with respect to a virtual source, at some distance above the air source. This defines the region of the jet, where the flow becomes fully developed. In this region, the air-water stream will rise with a velocity which depends on the bubble size distribution and concentration. All the previous experimental work indicates that this distance is comparable to the submergence of the air source which distinguishes this kind of jets from one-phase turbulent jets. Figure 2 shows a typical velocity traverses in a rising air-water jet.

In this kind of turbulent jet, most of the kinetic energy of the air leaving the manifold is rapidly dissipated in the turbulent shearing of the liquid and generation of new surface area (1). Therefore, it is a good assumption to consider that only the potential energy of the bubbles, which is converted to the kinetic energy of the water jet. This is evident, as is shown in Fig. 3. The momentum flux increases due to the buoyancy terms which grow logarithmically with distance above the air source (12 and 13).

Most of the conventional theoretical treatments of one-phase turbulent jets and plumes have considered only the main region of the jet, on the assumption that the extension of the zone of flow establishment is very small compared to the submergence of the jet. The integral technique, used in these treatments has been applied recently, by Cederwall and Ditmars (8), to study the gross behavior of air-bubble plumes over the whole depth of the air-source submergence. The predictions of their model do not represent well the

After Kobus (13)

Fig. (4) Extent of Initial Region

actual behavior of the plume. However, a more satisfactory model necessitates a full knowledge of the complex details of the flow conditions in the zone of flow establishment to provide a proper mathematical formulation.

ZONE OF FLOW ESTABLISHMENT

Figure 4 shows the experimental results of Kobus (13) regarding the extent of the zone of flow establishment. It seems from this figure that the length of this zone is proportional to both the air flow rate per orifice and the pressure drop across the orifices. This would suggest that such correlation from these results could be applied to the case of multiple orifice pipe if the individual jets do not merge before disintegration. This could exist if the spacing between orifices is equal to the mean jet diameter at the point of disintegration.

Silberman (21) derived an equation which gives the mean jet diameter, J , by the end of the initial zone which he verified experimentally.

$$J = \left(\frac{q_1}{0.81 \pi^2 g} \right)^{1/5} \quad \text{in ft} \dots (1)$$

where q_1 = the volumetric air flow rate measured at the pressure and temperature in the liquid at the orifice ft^3/sec .

g = the acceleration of gravity ft/sec^2 .

ZONE OF ESTABLISHED FLOW

All the previous theoretical work such as that of Kurihara (14), Charlton (9), Ismail (12), Cederwall and Ditmars (8), have revealed that the potential energy of bubbles is more effectively used for generating an air-water jet by minimizing the relative velocity between the two-phases. In the following, the fundamentals of the bubble-liquid interaction are presented in order to reveal the effect of the various factors such as the physical properties, distributor design, and gas flow rate on the relative velocity of the air stream. The review can be generally classified into two parts. The first is concerned with the disintegration of the air jet while the second deals with the motion of the bubble stream.

Bubble Formation

Leibson et al (15), and Abdel-Aal (1) described in detail the complex breakup of the air-jet in the turbulent region. The turbulent region, where most of the applications of air-bubble systems exist is when the orifice Reynolds number, R_{eo} , exceeds 2100.

The experimental results of Leibson et al, for the case of single orifices, are shown in Fig. 5. This figure shows that as turbulence becomes fully developed (i.e., $2,100 < R_{eo} < 10,000$) the effect of orifice size and Reynolds number on the bubble diameter could be expressed as:

$$d_b = 0.18 d_0^{1/2} R_{eo}^{1/3} \quad \text{in inches} \quad \dots \quad (2)$$

where d_0 is the orifice diameter in inches. This correlation falls closely to the experimental results of Davidson (10) for the same flow conditions. The results also indicate that there is no noticeable effect of orifice diameter d_0 on the bubble size, d_{bvs} , in the fully turbulent region. The bubble size d_{bvs} is defined as the diameter of a bubble whose ratio of volume to surface is equivalent to that of the bubble size distribution. For the air-water system, Leibson et al obtained the following experimental equation which fits the data for orifice Reynolds number greater than 10,000:

$$d_{bvs} = 0.28 (R_{eo})^{-0.05} \quad \text{in inches} \quad \dots \quad (3)$$

It is important to notice that these results give the bubble size just after jet disintegration. Therefore by increasing the air flow rate within the turbulent region, the bubble size is expected to increase by the end of the transition zone, due to the coalescence of bubbles caused by their increasing proximity (7).

For the case of multiple orifices, the mean bubble size after jet disintegration is given by Calderband (7) for turbulent conditions ($R_{eo} > 2,100$) as

$$d_b = 0.713 (R_{eo})^{-0.05} \quad \text{in inches} \quad \dots \quad (4)$$

This equation is comparable with Leibson's equation for single orifices in the fully developed turbulent regime. These results agree with the findings of Rennie and Evans (20), which are shown on Fig. (6).

After Leibson(15)

FIG. (5) BOTTOM-ENTRANCE FLOW MEAN BUBBLE DIAMETER VERSUS ORIFICE REYNOLDS NUMBER.

After Rennie and Evans (20)

FIG. (6) BUBBLE DIAMETER AGAINST ORIFICE REYNOLDS NUMBER.

In addition to the previous mentioned effect of high gas flow rates on the proximity of bubble, which could be shown in the experimental results of Silberman (Fig. 7), there is another factor affecting coalescence. Normally coalescence of bubbles occurs between bubbles of different sizes. At low gas rates and intensities of turbulence the ranges of bubble sizes normally encountered is not very great. By increasing the gas flow rate or the pressure drop across orifices, turbulence will increase and the size distribution will spread, thus increasing the rate of coalescence. Therefore, in situations where it is desired to attain maximum interfacial area, it is advantageous not to exceed the orifice Reynolds number greater than 10,000.

In this respect Silberman (21) derived an equation by which the size of the largest bubble formed from jets may be predicted and he confirmed it by experiments: the mean bubble diameter is given by

$$d_{bl} = 1.41 \left(\frac{q_1^2}{g} \right)^{1/5} \quad \text{in ft. ...} \quad (5)$$

where q_1 is the volumetric air flow rate evaluated at the orifice in $\text{ft}^3/\text{sec.}$, and g is the acceleration of gravity.

The above equation still holds for the case of multiple orifices as long as the individual jets do not merge before disintegration. It is worthwhile to show the effect of distributing the same air flow rate over many orifices on the mean bubble size. This effect is shown when comparing the bubble sizes in Fig. 7-b and Fig. 8 where the size in the latter figure is smaller due to the decrease of the air flow rate per orifice.

In case where porous pipes are used, the size of bubbles produced depends upon both the size of the pores and the pressure drop across them. For every type of porous pipes, the manufacturer suggests a working limit for gas flow rate (18), after which serious coalescence will occur. Table 1 gives this limiting gas flow rate for various types of porous pipes.

Bubble Motion

In the zone of established flow the rise of bubble swarms is more complicated than the case of single bubbles. This is caused by the interaction of bubbles among themselves. However the motion of single bubbles in stagnant water still provides an instructive conceptual picture of the motion of bubble streams (11).

After Perry [18]

Therefore the fundamentals of bubble-liquid motion in stagnant water have been collected together on Fig. 8, which shows the various factors affecting the related aspects of bubble motion (12).

These aspects include the shape of the bubble, its rise path, the drag exerted by the liquid on it, and its rise velocity.

The effect of turbulence on the relative bubble velocity of rise is not yet well defined. The only available data (5) is shown in Fig. 9. This figure shows that for a bubble size larger than 0.3 cm the relative velocity remains relatively constant at approximately 25 to 27 cm/sec., until an equivalent diameter of about 0.9 cm is reached beyond which the slip velocity slightly increases.

DISCUSSION

In the various applications of air-bubble systems there are two descriptions of efficiency which can be applied to an air-water jet. For mixing purposes, the interest is the mass transport capacity of the system, and the efficiency is represented by the ratio of total entrained water to the air flow rate. For pneumatic breakwaters, the criteria of the wave stopping power is the energy of the surface current, and the efficiency is measured by the ratio of the kinetic energy of the surface current to the potential energy available in the air jet leaving the manifold.

The air-bubble systems have proved to be a very efficient means of entrainment water. Table 2 lists entrainment ratios for a wide-world experimental work. On the other hand pneumatic breakwaters have been demonstrated by model tests and full scale tests in U.S.A., England, Japan, and Germany, to be only feasible to attenuate seas of length/water depth up to 5 and periods up to 5 sec. (12). For swell the Japanese experience suggests using parallel multiple air distributors, spaced four times their submergence, when there is an adequate air supply, which imposes limitations for using air-bubble systems to attenuate swell (14).

Kurihara (14) 1958	8.3 ms	13 lit/sec/m	50
Kurihara	162 ms	20 lit/sec/m	110

In order to reduce the power requirements of operating pneumatic breakwaters, researchers all over the world have investigated the effect of the distributor arrangements on the efficiency of the system. However, there has been a controversy for the last 30 years among the researchers upon this effect.

Bulson (6) reported that when the same quantity of air passed through a variety of orifice diameter and spacings, there was no significant difference in the velocity profile across the jet. Also, he found that results for a single manifold were not noticeably different from those when two or more adjacent manifolds were delivering the same total quantity of air. When using porous pipe as air distributor he found no significant difference in the resulting surface current velocity.

Kurihara (14) attributed the high efficiency obtained in the Japanese experiments to having a very fine dispersion. The air distribution system used in their experiments either in the full scale tests or model tests was distinguished by having a large number of holes. Both a single pipe and a

ladder type of pipe were used. The latter was used to attenuate shallow water waves.

On the contrary, the experiments of the U.S. Army (25) showed that a single discharge manifold produces greater efficiency than do multiple manifolds separated by some distance.

The experimental results of Kobus (13) did not show any effects of the distributor arrangements on the jet-pattern.

In fact Bulson's data do not agree with his conclusions. His data are extrapolated to calculate the values of entrainment and energy efficiencies. This led to the conclusion that there is a positive effect of the distributor arrangements on the efficiency of air-bubble jet, even the range of variation in the arrangements was small. Bulson* agreed about the results of analyzing his data. The reason behind the lower performance he obtained than that of the Japanese experiments is due that the air flow rate per orifice is very large, which resulted in the formation of large air slugs. Also the pressure drop across orifices was very high, which had an adverse effect on the efficiency. This excessive pressure drop is the reason for the low velocity performance in the experimental work of Kobus (13).

On the other hand, decreasing the pressure drop across the orifices resulted in a high efficiency as the experimental results of both Kurihara and the U.S. Army showed.

Regarding the disappointing results which Bulson obtained, when using porous pipes, the type of porous pipe used in his experiments was not the proper one for discharging the high air flow rate employed in his experiments.

For those investigators who used multiple manifolds in order to attain a higher efficiency, the low efficiency obtained in some of their experiments had resulted from the improper design of the spacing between manifolds. This led to a low concentration of the air bubbles within the plume.

CONCLUSIONS

It is concluded that in order to obtain the best efficiency of an air bubble sytem: for a given air flow rate

*Special correspondence with P. S. Bulson, M.E.E., Christchurch, England, 1971.

i) The air flow rate should be distributed over a large number of orifices. This number is determined by calculating the air flow rate per orifice based on the designed maximum bubble size in the dispersion.

ii) The diameter of the orifices should be designed in a way that the orifice Reynolds number is in the fully turbulent region (10000), also the pressure in the manifold should be just sufficient to cause the air to be released.

iii) The minimum spacing between orifices should be equal to the mean jet diameter at the point of air disintegration, to allow disintegration before merging of the individual jets without serious coalescence.

iv) If the above conditions cannot be satisfied by using one manifold, different manifolds could be used. The spacing between them should be designed by model tests in order to achieve an optimum value of air concentration.

v) Porous pipes are preferable provided that we are working within their maximum air flow rate. The maximum limit of using them can reach up to $990 \text{ ft}^3/\text{ft}^2/\text{min}$ which makes the porous pipes utilizable for practical applications.

ACKNOWLEDGMENTS

This paper extends work which was done in 1971 at the Civil Engr. Dept., Alexandria Univ. Egypt. The author is greatly indebted to Professor H. Hammad and Professor I. Ebeido for their interest and continual guidance throughout that work. The valuable discussions of Professor A. El-Taweel, Chemical Engr. Dept., at that time made possible the completion of that work.

I would like to thank Professor R. L. Wiegel, Hydraulic Div., Univ. of Calif., Berkeley, for his critical review and comments on this paper.

CHAPTER 172

COASTAL ENVIRONMENT AND A NUCLEAR POWER PLANT

by

RALPH A. DE LA PARRA

ENGINEER, SOUTHERN CALIFORNIA EDISON COMPANY

INTRODUCTION

Regulatory requirements and social constraints make it necessary to evaluate the environmental effects of a project and to incorporate into the design features to minimize adverse environmental impacts. This paper presents a case history of efforts to meet these requirements for a coastal power plant in southern California.

Southern California Edison Company and San Diego Gas & Electric Company are jointly now constructing two additional units to the existing San Onofre Nuclear Generating Station. Being added are Units 2 and 3. The site, about 84 acres (34 ha.), is located within Camp Pendleton, a United States Marine Corps Base, about halfway between San Diego and Los Angeles, California.

The site (See Figure 1) is situated on the edge of a narrow coastal plain that extends from the coastline to a range of low hills, two miles inland, that have a maximum elevation of 1,725 feet (525 m) above sea level. The plain terminates at the beach in a line of wave-straightened cliffs, extending 60 to 80 feet (18 to 24m) above a narrow sandy beach. Numerous ravines are cut into the cliffs as a result of erosion by storm runoff from the coastal plain.

Oceanographic features at the San Onofre site include a sandy bottom which slopes gradually to a depth of 60 feet (18 m) at about 10,000 feet (3,000 m) offshore. Mean maximum summer surface water temperature is about 73°F (23°C). During the fall and winter the water column is usually thermally homogeneous with a minimum temperature of approximately 56°F (13°C).

Ocean currents at the site are chiefly tidally induced, although large scale low velocity circulation patterns are generally present. Very near to the southern California coast, local currents are influenced primarily by a combination of wind, tide, and local topography. The total current is ordinarily the sum of components due to wind, tide, and perhaps large-scale ocean circulations. Speed of the total current measured at San Onofre typically ranges from 0.10 to 1.75 knots, but averages 0.2 knots.

San Onofre, Units 2 and 3 are being constructed southeast of, and immediately adjacent to existing Unit 1. Both the existing and the units under construction generate electrical power by using pressurized water nuclear reactors. Unit 1 has a capacity of 450 MWe and began commercial operation in 1968. Units 2 and 3 will each have a rated electrical output of 1,100 MWe. Commercial operation of Unit 2 is scheduled to begin in October 1981, and Unit 3 in January of 1983.

San Onofre Nuclear Generating
Station Units 2&3
Construction Site

August 2, 1976

Figure 1

Both the existing and the proposed units use sea water in a once through system for cooling the main condensers. Each of the new units will have a completely separate once through cooling system with a flow rate of 1,850 cfs (3,100 m³/min). The temperature rise of the seawater across the condensers is approximately 20°F (11°C).

EFFLUENT LIMITATIONS

Under the Environmental Protection Agency's (EPA) effluent guidelines and standards for steam electric power generating facilities, Units 2 and 3 are classified as "generating units" and are subject to a "no discharge of heat" limitation. The EPA has approved an exception to the "no discharge of heat" limitation for Units 2 and 3 on the basis that insufficient land is available to construct a recirculating cooling system (cooling towers). Because of this exception, the thermal components of the discharges from Units 2 and 3 are subject only to regulation by the "Water Quality Control Plan for Control of Temperature in the Coastal and Interstate Waters and Enclosed Bays and Estuaries of California" (Thermal Plan). Under the Thermal Plan the applicable guidelines are as follows:

- (1) The temperature of the discharge shall not average more than 20°F (11.1°C) above that of the incoming ocean water.
- (2) The discharge of elevated temperature waste shall not result in increases in the natural water temperature exceeding 4°F (2.2°C) at (a) the shoreline, (b) the surface of any ocean substrate, or (c) the ocean surface beyond 1000 feet from the discharge system. The surface temperature limitation shall be maintained at least 50% of the duration of any complete tidal cycle.

Southern California Edison Company requested and the California Regional Water Quality Control Board, San Diego Region, granted an exception to the specific water quality objectives of the Thermal Plan for the purpose of heat treatment to control marine fouling organisms in the cooling water system. The State Water Resources Control Board conditionally approved the exception to the Thermal Plan for heat treatment purposes contingent upon the Company completing studies which would permit the Regional Board to set precise limits on the frequency, temperature, and duration of heat treatments. These studies are described under "Environmental Impact of Plant Operation" below.

The Thermal Plan requires that exceptions be granted only in accordance with Section 316(a) of the Federal Water Pollution Control Act of 1972 and subsequent federal regulations. Section 316(a) requires the discharger to demonstrate that the proposal would assure the protection of aquatic communities in the receiving waters. EPA has approved the scope of the heat treatment studies being conducted for the State of California as being consistent with the requirements of 316(a) and as therefore being acceptable as a 316(a) demonstration.

A problem involved in measuring the thermal dispersion from a coastal power plant is that there could be significant natural temperature

variability. At San Onofre, temporal variations in the ocean surface temperature of the order of 2°F can occur over a period of several minutes, and fluctuations over 5 days or so can be as great as 10°F .¹ Spatial variations in ocean surface temperatures of 2°F and greater are numerous over distances of just a few miles.

A paper in the Journal of Geophysical Research² presented the results of time series analyses of several years of coastal ocean temperature records. The records were analyzed using digital filtering, covariance and spectral analysis. The low-frequency component of the temperature signal showed a strong seasonal component in southern California. A period of midwinter warming was apparent in southern California. Intermediate frequency components showed strong correlations in southern California with the presence of distinct and substantial temperature events occurring almost simultaneously over distances of the order of 125 miles (200 km). High-frequency components have a large standard deviation in summer (1.4°F) and a low standard deviation in winter (0.7°F). These components are uncorrelated at stations even a few miles apart.

DESIGN FEATURES TO COMPLY WITH ENVIRONMENTAL REQUIREMENTS

A plan of the offshore circulating water system for Units 2 and 3 is shown in Figure 2. Both of the cooling water intakes will be located about 3,100 feet (945 m) offshore at a depth of about 30 feet (9 m). The outfall for Unit 2 will extend approximately 8,200 feet (2,500 meters) and for Unit 3 approximately 5,900 feet (1,800 meters) from the shoreline. The intake and discharge conduits will utilize 18 foot (5.5 m) ID reinforced concrete pipe.

Each discharge utilizes a diffuser system designed to provide the necessary dilution to meet the California thermal regulatory requirements given above. Each discharge structure consists of a diffuser about 2,500 feet (760 m) in length containing 63 discharge nozzles, or diffuser ports, at the seaward end of the discharge conduit. The diffuser ports will be spaced approximately 40 feet (12 m) apart and will have a nominal throat diameter of approximately 2 feet (0.6 m). The nozzles, shown in Figure 3, will be oriented at a vertical angle of 20° above the horizontal and are aligned to direct the discharge offshore alternately at angles of 25° to the right and 25° to the left of the diffuser section centerline.

Figure 3

Physical model studies at the California Institute of Technology were used to develop the diffuser design³. A number of different experimental investigations were performed in the course of developing the conceptual design for Units 2 and 3 discharge diffusers. Final confirming tests were conducted in order to provide a model evaluation of the system as finally designed.

The physical model studies predicted a surface delta T not greater than 2.5°F (1.4°C), 1000 feet (300 m) from the diffusers under the most adverse current conditions. The area studied was approximately 2×1.7 miles (3.2×2.7 km). The smallest delta T isotherm definable completely within the area studied was the 1.5°F (0.8°C) isotherm. The 1.5°F (0.8°C) delta T is about the lowest isotherm that can be measured with accuracy in the field because of the ambient surface temperature variations that exist at San Onofre.

The diffuser design produces a general offshore drift, one result of which is to minimize if not completely negate the problems of reentrainment and recirculation. The offshore drift is superimposed on the longshore current. When the tide reverses, this technique provides greater protection against reentrainment of previously discharged water into the plume.

The intake of fish at offshore intake structures is an unavoidable consequence of using seawater for cooling. Past developments have significantly reduced the number of fish entrapped. Continuing studies have resulted in incorporation into the circulating water system design, some unique features to further reduce fish mortality.

The cooling water intake structures for all coastal power plants in the Southern California Edison Company system utilize a velocity cap to reduce fish entrainment. The velocity cap (See Figure 4) is a concrete slab horizontally suspended by columns above the vertical intake pipe. The use of a velocity cap is based on modeling and prototype studies conducted by the Company in the late 1950's⁴ The velocity cap forces water to enter as a horizontal flow rather than a vertical flow. The studies demonstrated that fish are better able to detect, or resist, a vertical flow than a horizontal flow and could therefore avoid being entrained into the cooling water intake structure. The intake of fishes was reduced 90% at stations fitted with the the prototype velocity cap.

Figure 4.- CONVENTIONAL INTAKE STRUCTURE 4a WITHOUT VELOCITY CAP & 4b WITH VELOCITY CAP

Since the cooling water requirement for San Onofre, Units 2 and 3, is much greater than other plants, it was deemed necessary to develop further means of reducing fish mortality. In 1972, the Company sponsored additional studies to minimize fish entrainment at offshore intake structures and to safely remove fish already entrained into the generating stations' screen wells⁵.

San Onofre Units 2&3

Figure 5

These later studies resulted in a slightly modified velocity cap design for San Onofre, Units 2 and 3, Figure 5. The Units 2 and 3 velocity cap design provides a lip extending out about 8 feet (2.5 m) from the vertical riser and a lower intake velocity.

SAN ONOFRE SCREEN WELL CONCEPT

Figure 6

This geometry provides a uniform flow profile across the entrance. Water enters the structure at a velocity of approximately 1.7 feet per second (1/2 m per second) through the circumferential opening.

The fish conservation studies done in 1972 also resulted in a fish conservation system being incorporated into the design of the circulating water system for Units 2 and 3. A plan of the screen wells is shown in Figure 6. Each unit's screen well has a guiding system, fish collecting chamber and fish elevator. The screen well incorporates a system of traveling bar racks and screens to prevent large objects from entering the pump well. It was found that the design most effective for conserving fish was a concept that set the screen well at an angle to the flow stream. The first line of trash removal, trash bars, is positioned at an angle to the flow. Tests showed that all species of fish could be guided with trash bars at right angles to the frame and the frame set at an angle of 30° or less to the flow.

Fish that have entered the circulating water system are guided into the fish collecting chamber, a still water area, shown in Figure 7. A constant flow of water enters the chamber and flows through the screens at the back of the chamber, but fish are prevented from going further. Fish hover over the fish elevator bucket at the bottom of this chamber. The elevator (Figure 8) is a bucket which is periodically raised carrying fish, in water, out of the structure and deposits them into a gravity-flow sluicing channel. A common 4 foot (1.2 m) ID fish return conduit returns entrapped fish, unharmed, to the ocean. The velocity in the fish return conduit is about 5.3

**FISH BY-PASS
AND HOLDING CHAMBER**

Figure 7

feet per second (1.6m per second). Only one fish return conduit is required to serve both units, since each system will operate only a few times per day.

The fish outfall, shown in Figure 9, is in about 15 feet (5 m) of water and is approximately 2000 feet (610 m) offshore. The plan view of the circulating water system, in Figure 2, shows the location of the fish outfall. It is estimated that the fish conservation system, together with the velocity cap will reduce fish loss by more than 99%.

CONSTRUCTION

Site preparation for Units 2 and 3 began in the first quarter of 1974. As of August 1, 1976, construction of this facility was approximately 22% complete. In connection with site preparation for the new units, approximately 2,350,000 cubic yards (1,795,400 cubic meters) of spoil material was excavated from the bluffs. The surface terrace deposit material was disposed of at designated inland sites. The remaining material excavated from the underlying, very dense, fine to coarse sand, consisting of approximately 350,000 cubic yards (267,400 cubic meters), was deposited along the beach in front of the plant site to be redistributed by natural wave action for replenishment of the beaches in the area.

Figure 1 shows an offshore pad, constructed to serve as a laydown area and to allow the construction of the shore portion of the circulating water system and its interface with the offshore conduits, in the dry. The pad is about 1000 feet (300 m) long and extends

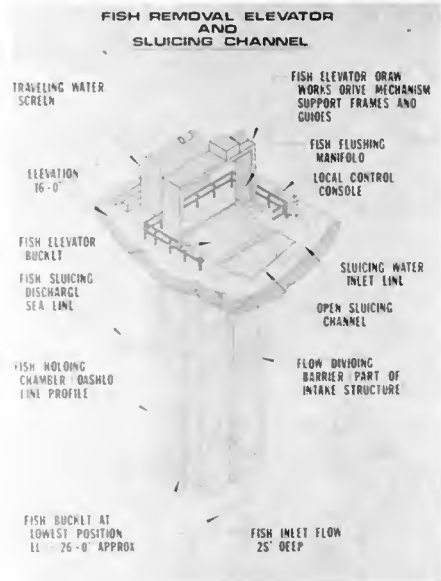

Figure 8

FISH OUTFALL STRUCTURE

Figure 9

about 300 feet (90 m) offshore. It was constructed by depositing sand from the site excavation offshore, and then driving sheetpiling around the area. One can see that the pad acts as a groin and sand has built up on the northerly end. After the construction is complete the sheetpile wall will be removed and the shoreline will revert back to its normal configuration.

This was the same method used for the construction of Unit 1. From our experience with Unit 1, it is estimated that the shoreline will regain its original alignment with a somewhat wider beach within two years and within 5 years will be back to its original location.

Figure 10 is an artist rendering of the offshore conduit construction. A tressel will be utilized out to about 3000 feet (900 m) offshore, from there a jack-up barge will be used. The dimensions of this barge are about 100 x 300 feet (30 x 90 m). The 18 foot (5.5 m) ID pipe will be layed in 24 foot (7.3 m) sections, buried beneath the ocean bottom, with approximately a 4 foot (1.2 m) cover.

ENVIRONMENTAL IMPACT OF CONSTRUCTION

Extensive environmental monitoring is being conducted during construction to measure the effects of this activity. The monitoring programs include periodic examination of local beaches, intertidal cobble beds, established benthic stations and local kelp beds. The

Laying of 18' ID Cooling Water
Conduits Offshore of San Onofre

Figure 10

monitoring programs are designed to monitor mainly the effects of the construction dewatering discharge into the ocean, the offshore conduit construction and the disposal of sand on the beach. The programs include the following: (1) Water samples of the discharge into the ocean from the construction dewatering and hydrotesting operations are taken and analyzed weekly; (2) Aerial photographs are taken to record the areal extent of visual turbidity present in the ocean and to record placement of sand spoil on the beach; (3) Monthly, beach profiles are taken and bi-monthly intertidal cobble beds in the area are surveyed to determine the amount of inundation, and subsequent re-exposure, of the rocky substrate from sand disposal and from natural conditions; (4) Quarterly, marine biologists conduct intertidal, benthic and local kelp bed surveys.

To date, no irreversible effect upon the local biota can be attributed to the construction activity.

ENVIRONMENTAL IMPACT OF PLANT OPERATION

Heat treatment is the method used by the Southern California Edison Company for the control of fouling organisms within the offshore conduits. Coastal power plants presently heat treat approximately every 5 to 6 weeks by raising the temperature of the discharge to approximately 115° to 125°F (46° to 52°C). Presently, a study, as mentioned above under "Effluent Limitations", is being conducted to determine the optimum mode of heat treatment to control fouling organisms while minimizing adverse effect on marine life. This study consists of the following:

- (1) Fouling organism temperature tolerance and growth rate studies.
- (2) Data collection on fish and macroinvertebrates lost during heat treatment operation at Unit 1.
- (3) Receiving water plankton study.
- (4) Heat treatment plankton mortality study.
- (5) Investigations of alternate methods for controlling marine fouling.
- (6) Heat treatment thermal plume assessment.
- (7) Report on method to minimize nekton entrainment.

These studies will permit the Regional Water Quality Control Board to set precise limits on the frequency, temperature, and duration of heat treatments. The heat treatment study is in progress and will continue through December of 1978. Preliminary data indicates that it may be possible to reduce the frequency, temperature and/or duration of the heat treatments, while still providing protection against excessive marine fouling growth.

An evaluation of the effect on the marine environment of operation of San Onofre Unit 1, and predictions of the effect from Units 2 and 3, is made possible by the San Onofre Unit 1 marine monitoring program in existence since 1963. The monitoring program includes both oceanographic and marine biological studies, and is independent of the monitoring being done for the construction. This program, conducted by consultants, is presently being carried out for Southern California Edison Company, by the Lockheed Ocean Laboratory of San Diego, California. An analysis of the environmental monitoring programs and the predicted thermal addition, show that there will be no adverse effects on the environment from the thermal discharge of Units 2 and 3 and that protection of the beneficial uses of the receiving waters at San Onofre is assured.

In addition to the above monitoring programs, a completely independent program is required as part of the permit process for San Onofre, Units 2 and 3 by the California Coastal Zone Conservation Commission. This program, as were the ones previously mentioned, is an extensive study of the marine environment in order to predict and eventually measure the effects of the proposed new generating units. This work, presently in progress, emphasizes the zooplankton and larval organisms, as well as evaluates compliance with regulatory requirements of state and federal water quality agencies.

It was specified that the California Coastal Zone Conservation Commission program should be designed and conducted under the direction of an independent Marine Review Committee consisting of 3 persons with professional experience in marine biology; one to be chosen by Southern California Edison Company, one to be chosen by opponents of the project, and one to be chosen by the Commission.

The Marine Review Committee program plan has been developed around two elements. The first is a comprehensive definition of the marine ecosystem as it now exists offshore in the vicinity of San Onofre. The second is the development of a predictive model that will utilize data from a special biological program, along with data from the operation of San Onofre Unit 1, to predict the perturbations that will be caused by Unit 2 and 3.

The special biological program has been developed to cover the main ecological elements of the offshore communities and to emphasize those groups that were expected to be the impacted most by plant operation. The biological program covers 6 major study areas:

- (1) Determination of the area of ocean affected by the power plant cooling water intake system.
- (2) Fish population dynamics as influenced by the cooling water system.
- (3) Thermal effects on the structure of benthic ocean communities.
- (4) Fish entrapment.

- (5) Planktonic organisms entrainment into the intake.
- (6) Development of mathematical models using data from the above elements to identify important relationships, test hypothesis, and redirect the program.

Results have not yet been obtained from these studies. The cost of these independent studies will be borne entirely by Southern California Edison and San Diego Gas & Electric Companies.

CONCLUSION

The greatest impact of "borrowing" ocean water for power plant cooling purposes occurs in altering the marine ecosystem immediately around the cooling system's intake and discharge structures. One of the principal environmental concerns in the design of intake systems is possible entrainment of marine organisms. In the design of discharge systems, acceptable limitations of waste heat additions to the receiving water bodies and the rapid dissipation of heat at the discharge outfall should be the main considerations. These considerations and efforts to mitigate adverse effects to the coastal environment have resulted in some unique design features for Units 2 and 3.

Marine monitoring programs, which are part of the project, provide ongoing surveys of the effect of all phases of plant construction and operation. Monitoring programs concerned with temperature dispersion and ecosystem changes indicate that the San Onofre, Units 2 and 3, outfall structures will have little impact upon the San Onofre area. The information obtained can be applied to the siting and design of future power facilities, and will serve as a contribution to basic biological and oceanographic research.

San Onofre Nuclear Generating Station Units 2 and 3 will make it possible to meet the growing public and industrial demand for power, while meeting the legal and social constraints related to environmental concerns.

CHAPTER 173

FIELD STUDIES OF SUBMERGED-DIFFUSER THERMAL PLUMES WITH COMPARISONS TO PREDICTIVE MODEL RESULTS

by

A. A. Frigo, R. A. Paddock, and J. D. Ditmars*

Abstract

Thermal plumes from submerged discharges of cooling water from two power plants on Lake Michigan were studied. The system for the acquisition of water temperatures and ambient conditions permitted the three-dimensional structure of the plumes to be determined. The Zion Nuclear Power Station has two submerged discharges structures separated by only 94 m. Under conditions of flow from both structures, interaction between the two plumes resulted in larger thermal fields than would be predicted by the superposition of single non-interacting plumes. Maximum temperatures in the near-field region of the plume compared favorably with mathematical model predictions. A comparison of physical-model predictions for the plume at the D. C. Cook Nuclear Plant with prototype measurements indicated good agreement in the near-field region, but differences in the far-field occurred as similitude was not preserved there.

Introduction

Submerged discharges and multiport diffusers are finding wider use as means of disposing of waste heat from once-through condenser cooling-water systems for power plants. These discharges appear to be superseding surface shoreline discharges for large power plant applications. A reason for employing submerged discharges is that they may create greater initial dilution of the effluent than surface discharges.

The Federal Water Pollution Control Act of 1972 targets heat as a pollutant and hence prohibits its discharge into navigable waterways such as the Great Lakes. However, Section 316(a) of the Act allows for rescinding the no-discharge requirement when it can be demonstrated that the discharge of waste heat will not result in damage to the aquatic environment. It authorizes, on a case-by-case basis, the easing of any thermal limitation that is more stringent than necessary "to assure the protection and propagation of a balanced, indigenous population of shellfish, fish, and wildlife" in the receiving water. This may mean that the surface temperature rise and the extent of the plume will have to be limited — hence the use of high-velocity submerged discharges. One of

*Energy and Environmental Systems Division, Argonne National Laboratory, Argonne, Illinois, 60439, USA.

the requirements for obtaining a 316(a) exemption will probably be a prediction of the spatial and temporal characteristics of the thermal plume from a power plant. Before a plant begins operation, analytical and physical (hydraulic) models must be used for prediction. After operation has begun, actual prototype field measurements can be made.

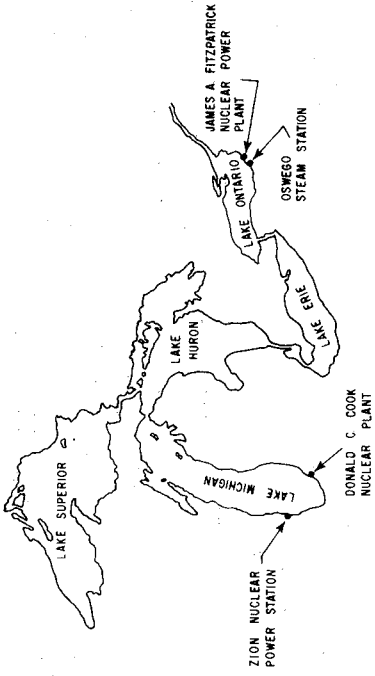

Few predictive models have been verified at prototype scales, and little is known regarding the limitations and applicability of many models. The evaluation of predictive techniques, through prototype-model comparison, is one of the main objectives of the program of which a portion is discussed in this paper.

Argonne National Laboratory (ANL) has been studying the effects of power-plant waste-heat discharges into the Great Lakes since 1970. The initial effort involved the study of thermal plumes from power plants employing shoreline surface discharges. A review of analytical and physical modeling techniques for predicting the fate of waste heat in large lakes was carried out.¹ In addition, a review of available prototype data on thermal plumes was conducted.² This review indicated a paucity of field data describing these plumes under various environmental conditions. Because it was clear that detailed field data of good quality were needed to evaluate the various predictive techniques, ANL began an extensive field program to measure the physical phenomena related to surface shoreline waste-heat discharges into the Great Lakes. Approximately 75 sets of thermal-plume data along with related physical parameters such as lake currents, ambient diffusivities, and meteorological conditions were measured at six different discharge sites on Lake Michigan.^{3,4,5} The results of the thermal-plume measurements were analyzed and compared with model predictions. This four-year effort culminated in a comprehensive critical evaluation of mathematical modeling techniques for surface discharges in which many models were examined and eleven of the most promising models were reviewed in detail.⁶

In response to recent interest in high-velocity submerged discharges, ANL began a study of the physical aspects of these discharges similar to the program carried out for surface discharges. Again, there is a lack of detailed prototype data of good quality for thermal plumes from submerged discharges. This study includes field measurements of the three-dimensional structure of thermal plumes from submerged discharges on the Great Lakes and an evaluation of physical and mathematical models for submerged discharges.

Field studies have been conducted at four power plants with submerged discharges located on the Great Lakes. The power plants being studied include the Zion Nuclear Power Station and Donald C. Cook Nuclear Plant on Lake Michigan and the Oswego Steam Station Unit 5 and James A. FitzPatrick Nuclear Power Plant on Lake Ontario (Fig. 1). Ten sets of thermal-plume data have been collected at the Zion site, nine sets at Donald C. Cook site, three sets at the Oswego Unit 5 site, and four sets at the James A. FitzPatrick site. In addition to thermal-plume temperature data, related information such as limnological, meteorological, and plant operating data have been collected for the times of the thermal-plume surveys. Results of some of the surveys at the Zion and Donald C. Cook plants are discussed in References 7 and 8, respectively.

Fig. 3. Schematic Diagram of Data Acquisition System

In this paper, the equipment and techniques used by ANL to collect and handle thermal-plume and related data are discussed. In addition, some results are presented for the case of two adjacent submerged discharges with thermal plumes which effect each other. Comparisons are made between ANL prototype data and pre-operational mathematical- and physical-model predictions.

Field Measurements and Data Handling System

A measurement and data-acquisition system for relatively rapid measurement of the three-dimensional temperature structure of thermal plumes from submerged discharges was developed at ANL. The system was designed for use aboard a small (7.5 m) boat (Fig. 2). The acquisition system (Fig. 3) was interfaced with seven thermistors, a navigational ranging system, a depth sounder, and a real-time boat-position plotting system. The thermistors were mounted at 0.5-m intervals on a 3-m long aluminum bar with streamlined cross section which is towed through the water from the boat. Temperature data at seven depths along with water-depth data are recorded by the system as a function of time and boat position on both paper tape and magnetic-tape cassettes. In addition, the aluminum bar can be replaced with a towed thermistor chain which was developed to allow the measurement of water temperatures in water columns of depths to 10 m. The sampling time interval is variable; typically, data were acquired at eight-second intervals. The data acquisition system allows the collection of data at approximately 1000 points over a linear distance of 10 km in one hour. The real-time plotting system permits the boat operator to know the boat location at any time and, therefore, to adjust the boat's course so as to map completely and in varying detail the study area. The plume data, originally recorded on the magnetic-tape cassettes, are transcribed onto computer-compatible magnetic tapes. These tapes, along with calibration data, are used by a computer program to produce plots of the water temperature and bathymetry as a function of position for each of the depths of measurement. Isotherms and plume centerlines for each level are then drawn by hand on these plots. Figures 5 and 6 are examples of plume isotherm plots at the surface obtained using these techniques. In addition to horizontal plots, vertical cross sections through the plume can also be obtained. The small dots in the figures are the actual temperature values at the location indicated and hence also represent the boat path. The temperature values accompanying the bold dots are representative temperatures corresponding to particular locations.

An ambient water temperature survey is conducted before each plume mapping. Upcurrent from the power plant, the boat is moved from a location offshore to a location as close to the shoreline as possible along a line perpendicular to the shoreline. Ambient water temperatures at the surface and six depths are recorded at about 100 locations during this survey. Ambient lake currents are measured from the boat at fixed locations with a ducted-impeller current meter. In addition, for the duration of the field study, current speed and direction are measured along with lake temperatures at a fixed position and depth by an in-situ current meter/thermograph package. These data are recorded by digital, cassette tape recorder. Wind speed and direction, air temperature, relative humidity, and lake surface conditions are monitored during each thermal-plume field study. Plant operating data and records of wind

speed and direction and air temperature from utility meteorological stations are obtained from the utility records. In addition, thermographs which have been calibrated along with the ANL data acquisition system, are installed in the plant to measure cooling water intake and discharge temperatures to insure temperature data consistency.

Measurements at the Zion Nuclear Power Station

The Zion station is located in northeastern Illinois on the western shore of Lake Michigan about 5.1 km south of the Illinois-Wisconsin state line (Fig. 1). It consists of two units (Unit 1 to the south, Unit 2 to the north) employing pressurized water reactors. Each unit is capable of a gross generating capacity of 1100 MWe. Each unit has its own discharge structure located 232 m from shore, about 47 m on either side of the plant centerline, in about 4.5 m of water (Fig. 4a.). Each discharge structure consists of a rectangular box with 14 ports on the offshore and outboard edges. The ports are 0.9 m high and 1.6 m wide and are oriented at 45° to the box centerline. The discharge flow rate at full power operation is about 50 m³/s for each unit and the average velocity at the outlet ports is 2.4 m/s. The nominal temperature rise of the cooling water is 11 C°.

Plumes were surveyed at the Zion site on ten occasions. On eight occasions cooling water was discharged from only one discharge structure. In most cases, the ambient current was approximately shore-parallel, and thus was either in the direction of the discharge or in a direction opposite to the discharge. An example of the surface isotherms for a single discharge in the direction of the ambient current is shown in Fig. 5. Subsurface isotherms also indicate the same general orientation of the plume. The surface isotherms for a single discharge opposed to the ambient current are shown in Fig. 6. The plume is bent in the direction of the ambient current in the far field, and the near-field surface dilutions are decreased below those for the case of discharge in the direction of the ambient current. Again, subsurface isotherms indicate that the plume far field has been bent in the direction of the ambient current. The case of discharges from both units, one plume with and the other plume opposed to the ambient current, is shown in Fig. 7. While two plumes can be distinguished on this surface isotherm plot, the far-field region is a combination of plumes from both discharges.

One basis for describing and comparing thermal plumes is an isotherm-surface-area plot. The area refers to the surface area enclosed within an isotherm of particular temperature or normalized temperature. The isotherms here are characterized by the excess-temperature ratio, θ/θ_0 , that is, the ratio of the difference between the actual isotherm temperature and the ambient water temperature and the difference between the discharge and ambient water temperatures. Figure 8 shows the results from the surveys at the Zion site for single discharges opposed to the ambient current, and for discharges from both units. The envelope about each average line reflects the range of values determined from the measurements. This scatter appears due to variations in discharge conditions and ambient current magnitude and direction which resulted in variation in values of the discharge densimetric Froude number, F_s , and velocity ratio, K , where,

K Range	83 - 100	10 - 111	38 - 45

Single discharges opposite to the ambient-current direction result in larger areas for given isotherm excess-temperature ratios than single discharges in the direction of the ambient current. In the case of discharges from both units (double discharge), Fig. 8 indicates that the plume of the discharge opposed to the ambient current has an isotherm-area relationship similar to that of a single discharge opposed to the current. However, that plume of the pair, with the discharge in the direction of the ambient current, has larger surface areas associated with a given isotherm than a single discharge with the ambient current. It appears that interaction or interference between the adjacent discharge plumes is responsible for the increased areas or decreased dilution in the downcurrent plume of the pair. Entrainment of the heated water from the upcurrent plume into the second plume and thus the blocking of cool ambient water on the upcurrent side results in increased temperature elevations in the downcurrent plume over those experienced by a single discharge in the direction of the ambient current.

The degree of interaction between the plumes in the case of discharges from both units at the Zion site is manifested further by the following comparison. Consider a prediction of the isotherm-area relation for the double-discharge situation at the Zion site which neglects any interaction between the two discharges. In such a case, the total surface area associated with a given excess-temperature-ratio isotherm would be the sum of the corresponding areas for two single-discharge plumes, one discharged with the ambient current and one discharged opposite to the ambient current. A comparison of measured total surface areas for double plumes and the areas resulting from the linear super-

position of single-plume areas is reflected in the ratio, R , shown as function of θ/θ_0 in Fig. 9. If the superposition were valid and interactions were thus negligible, the ratio, R , would be 1.0. However, as shown in Fig. 9, measurements of double plumes indicated far-field areas as much as ten times larger than simple superposition would predict. The ranges in R values for a given value of θ/θ_0 reflect the envelopes of results, and the dots represent mean values.

The double-discharge measurements at the Zion site point out an interesting feature of the design and evaluation scenarios associated with the environmental assessment of thermal discharges. The often postulated idea that the critical situation for surface temperature fields occurs under conditions of small or zero ambient currents appears valid at the Zion site for single discharges but not for double discharges. Relatively small ambient currents appear to result in significant interaction between plumes for the double-discharge case with increases in surface areas affected over those which would be predicted for two non-interacting plumes discharged into a stagnant environment.

Predictive mathematical models applied to the thermal plumes at the Zion site are of two types: a site specific model developed by Pritchard and general models for thermal discharges in shallow water developed at MIT.

Pritchard⁹ made predictions of plume temperatures and geometry for full power operation prior to construction based on a model similar to an earlier model for surface discharges. This modeling effort considered the case of no ambient lake currents and no significant interaction between plumes. Subsequently, on the basis of field observations, the model was modified and refined to include the case of bending of the plume into shallow water by currents.^{10,11} Predictions for this case reflect the effects of reduced entrainment from below the plume, recirculation of heated water through the cooling water intake, and reentrainment of heated plume water following a current reversal. Direct comparison between the Pritchard single plume predictions and the ANL field measurements is not possible as the predictions are for seasonal "worst cases." However, a comparison of the isotherm-area predictions for the fall/spring cases of bent and unbent plumes with the average of the ANL data for single discharge against the current indicates good agreement for $\theta/\theta_0 < 0.5$ and conservative predictions for $\theta/\theta_0 > 0.5$.

No general models for submerged discharge are strictly applicable to the Zion site and discharge geometry. Integral-similarity models for buoyant plumes, such as those reported by Fan and Brooks,¹² are not appropriate for the shallow submergence (depth is only 4.2 slot widths) of the Zion discharge structure. Adams¹³ studied the behavior of horizontal thermal discharges from long, multiport diffusers into shallow water with current directed over the discharge. This model accounts for the acceleration of the flow downstream from the diffuser due to the addition of the discharge momentum and predicts the dilution of the discharge in a well-mixed region downstream of the discharge. Although the proximity of the Zion discharge structure to the shoreline does not conform strictly to the idealized unbounded flow field of the model and the well-mixed region geometry is not predicted by the model, dilution predictions in the well-mixed region were found to be about 1.45 (or

$\theta/\theta_0 = 0.7$) for single discharge conditions at the Zion site. Jirka and Harleman¹⁴ provided a more detailed study of submerged diffuser discharges in shallow water based on a two-dimensional analysis of a long slot-type discharge in a channel with no ambient currents. Several regimes of flow were found possible depending on the hydraulics of the heated water flow on the surface away from diffuser and the entrainment flow on the bottom toward the diffuser. The range of parameters for the horizontal Zion discharge result in the prediction of a flow instability or "full-mixing" region near the diffuser. The uniform vertical temperatures measured at the Zion site in the near-field region confirm that this is approximately the case there. The Jirka-Harleman model gave predictions of the discharge dilution in this "full-mixing" region to be about 1.8 (or $\theta/\theta_0 = 0.6$) for single-discharge conditions at the Zion site.

Although the models of Adams and of Jirka and Harleman are not strictly applicable to the Zion discharge and although temperature measurements do not indicate the extensive, well-defined "full-mixing" region postulated for the models, comparisons of model predictions were made with near-field surface centerline temperatures for eight single plumes measured by ANL. The location of the point of the highest surface temperature on the centerline occurred between 40 and 100 m from the discharge with an average of 70 m, and the corresponding surface excess-temperature ratios ranged from 0.49 to 0.73 with an average of 0.59. There is remarkably good agreement with the model predictions. However, the fact that vertically well-mixed conditions actually exist in the near-field region is probably the primary factor responsible for the good agreement with the effects of finite diffuser length and boundary geometry being of secondary importance.

In addition to preoperational mathematical-model predictions of the thermal-plume characteristics at the Zion site, physical model studies were performed.¹⁵ These studies employed an undistorted model with geometric scale reduction of 1:25 and Froude and densimetric Froude number similitude. The model boundaries appeared to influence the model results significantly. Comparison of model predictions for single discharges, with and against the ambient current, with the ANL field measurements in terms of centerline temperatures and isotherm-area plots indicate that the model results underestimate the initial near-field dilutions.

Detailed discussion of the comparisons between the field data from the Zion site and the predictions of plume characteristics from mathematical and physical modeling techniques is found in Ref. 7.

Measurements at the Donald C. Cook Nuclear Plant

The Donald C. Cook Nuclear Plant is located near Bridgman, Michigan on the southeastern shore of Lake Michigan, about 18 km south of Benton Harbor (Fig. 1). The two D. C. Cook nuclear reactors are nearly identical, pressurized-water units. Each is capable of a gross generating capacity of 1090 MWe. During 1975, only Unit 1 was operational. The Unit 1 discharge structure is located 365 m offshore, in about 5.7 m of water. The cooling-water discharge from Unit 1 is through two horizontal slots each 9.1 m wide by 0.6 m high, about 0.5 m above the

lake bottom (Fig. 4b). One slot is directed offshore while the other is set at 70° to the offshore direction. The discharge flow rate is $48 \text{ m}^3/\text{s}$ and the average discharge velocity is about 4.3 m/s . The nominal temperature rise for the condenser cooling water is about 12 C° .

Plumes were surveyed at the D. C. Cook site on nine occasions during the spring and summer of 1975 by ANL. Comparisons of field data with model predictions require careful examination of all prototype data over a range of conditions. However, as an example, a limited portion of the available data for plumes at the D. C. Cook site is presented here.

Preoperational physical-model studies were undertaken by Alden Research Laboratories¹⁶ for prediction of the characteristics of the thermal plumes due to the discharges from both of the proposed units of the D. C. Cook plant. An undistorted hydraulic model with geometric scale reduction of 1:75 was employed and resulted in an area modeled which extended about 2300 m along the shoreline and about 1100 m offshore. Temperatures and velocities were scaled to preserve both Froude and densimetric Froude numbers. Near-surface temperatures in the model were measured using a fixed grid of 137 thermocouples for a variety of submerged discharge designs and of discharge and ambient receiving water conditions. Examples of the model-study predictions of near-surface isotherms for the case of cooling-water discharge from the final design Unit 1 slots only are shown in Figs. 10 and 11.¹⁷ These figures indicate, in prototype dimensions, the excess-temperature-ratio isotherms for the case of a constant temperature ambient receiving water, uniform, shore-parallel ambient currents in a northerly direction, and maximum cooling-water flows with full-power-generation discharge temperatures about 11.7 C° above ambient water temperature. The magnitude of the ambient current is 6.1 cm/s for the case shown in Fig. 10 and 15.2 cm/s for the case in Fig. 11.

Comparison of prototype data with the physical-model results requires that dynamically similar conditions be found among the prototype surveys. In regard to the near-field dilution of the plume, that requires that the same densimetric Froude number, F_s , and velocity ratio, K , exist. For the model cases reported above, the densimetric Froude number is about 27 for both cases and the velocity ratios are 65 and 26 for Figs. 10 and 11, respectively. For the small relative discharge submergence (water depth to slot width) of 8.5 and large densimetric Froude number, laboratory experiments and analysis¹⁴ indicate that "full mixing" conditions may exist in the near-field region, similar to those found at the Zion site discussed above. The physical-model studies for the D. C. Cook discharge show a vertically well-mixed region in the near field for the range of conditions investigated. Prototype temperature measurements confirm the existence of this near-field feature. Analysis, and to a degree laboratory experiments,¹⁴ indicate that the dilution of the discharge in the near-field "full mixing" region is independent of densimetric Froude and is dependent primarily on the relative submergence. Since scaling of the relative submergence is assured by geometric similitude between model and prototype, dilutions in "full-mixing" regions in the near field should be comparable in model and prototype for cases of similar ambient-current direction and velocity ratio, K . Plume characteristics in the intermediate and far-field regions, however, are not likely to scale so simply. In the

Fig. 10. Surface Excess Temperature Ratio Isotherms From Physical-model Study for D. C. Cook Unit 1 with an Ambient Current of 6.1 cm/s

Fig. 11. Surface Excess Temperature Ratio Isotherms from Physical-model Study for D. C. Cook Unit 1 with an Ambient Current of 15.2 cm/s

intermediate region, beyond the "full-mixing" region, preservation of local densimetric Froude number is probably important to produce proper gravitational spreading in the surface region. However, in the intermediate and in the far-field regions interfacial friction should also be scaled properly, and it is not clear that that is possible in an undistorted model of this scale.¹⁸ Moreover, the far-field mixing is primarily governed by ambient mixing processes which may not be scaled properly in the model. Thus, complete similitude between a single model and prototype plume temperatures is unlikely over the range of regimes from the near field to the far field. For the undistorted model studies conducted, the comparison between model predictions and prototype measurements is most appropriate in the near-field region.

An example of prototype surface-temperature measurements at the D. C. Cook site made under conditions providing a degree of similarity is shown in Fig. 12. The ambient lake temperature was uniform, and a plant power generation at about 80% of capacity resulted in a discharge-temperature elevation of 7.4 C° above ambient. The depth-averaged ambient current (measured upcurrent and offshore of the discharge) had a magnitude of 5.8 cm/s and was directed at about 40° from north or about 20° from being shore-parallel as in the model studies. These conditions produce a discharge densimetric Froude number of about 54 and a velocity ratio of about 75. The Froude number associated with the prototype case is about twice as large as that for the model tests mentioned above. However, the prototype Froude number is large enough to indicate "full-mixing" conditions in the near-field region, and such conditions are observed in the near-field temperature data. Thus, as argued above, near-field mixing should be independent of the exact value of densimetric Froude number, and, for similar values of velocity ratio, model and prototype similarity should exist. Comparison of Figs. 10 and 12 indicates reasonable agreement between the near-field surface excess-temperature ratios ($\theta/\theta_0 > 0.27$). However, the general surface-isotherm pattern of the prototype resembles that for the model case with larger ambient current ($K = 26$) shown in Fig. 11. The offshore isotherms in the prototype case are more closely spaced than in either model case and do not indicate the proximity to the intake structures shown in the model case of $K = 65$ (Fig. 10). The comparison between prototype and model plume centerline excess-temperature ratios is shown in Fig. 13. Isotherm-area plots for the prototype and model cases are given in Fig. 14. The agreement for these gross plume characteristics is good, although the prototype data indicate slightly larger centerline temperatures and areas.

Several explanations are possible for the differences between the model and prototype surface-isotherm patterns. The prototype ambient lake current in the vicinity of the discharge did not appear to be shore-parallel as in the model study. The current had a component in the onshore direction. Moreover, the wind was from the west in an onshore direction and, with the current, may have contributed to the close spacing of the prototype offshore isotherms. This effect is not, however, realized on the inshore side of the plume. The difference in power generation levels, as manifested by lower discharge temperature excess in the prototype case, may not be significant in the near-field region but certainly affects the intermediate- and far-field spreading. Since these regions of the model plumes contain larger temperature

Fig. 12. Surface Excess Temperature Ratio Isotherms from ANL Field Measurements at D. C. Cook: May 14, 1975, 1158-1318 hr CDT. Ambient Current = 5.8 cm/s.

Fig. 14. Comparison of Isotherm Areas from Physical-model and Prototype Data for D. C. Cook Unit 1

excesses than the prototype plume, larger lateral gravitational spreading would be expected in the model cases than in the prototype case. The offshore, far-field region of the model may also be affected by the presence of the model boundary. The offshore model boundary is indicated by the end of the offshore isotherms in Figs. 10 and 11. Its proximity to the plume may result in reduced transport of heat in the downcurrent direction and an increase in temperature in that region.

Evaluation of a physical-model prediction on the basis of a single prototype condition, dynamically similar or not, is hardly proper. The comparison presented is for the purpose of demonstrating the problems associated with such model and prototype comparisons. A comprehensive evaluation requires a set of such comparisons for all the prototype data obtained.

Conclusions

The examples of comparisons between model predictions and prototype measurements demonstrate that while predictions of maximum near-field temperatures may be reasonably good for these cases, prediction of other plume characteristics is not so straight-forward. The cases considered have been relatively simple; that is, ambient receiving-water stratification and ambient current shear have been negligible. Measurements at the Zion site indicated that the direction of the ambient current was an important parameter governing plume dilution and extent. The interaction between plumes from the two discharges at the Zion site resulted in heated surface areas as much as ten times larger than would be predicted by models assuming the superposition of two independent discharges. The example of temperature measurements at the D. C. Cook site indicates the difficulty of obtaining dynamic similarity for comparisons between physical models and prototype cases. The need for prototype measurements at submerged discharge sites is clear. Evaluation of predictive mathematical and physical models requires detailed measurements of the temperature field produced as well as carefully monitoring of ambient conditions. Comparisons between model predictions and prototype measurements require a reconciliation of the idealizations necessary for model predictions and the complex nature of the prototype conditions and an appreciation of the capabilities and limitations of the modeling techniques. Only continued comparisons of model predictions with carefully gathered and interpreted prototype data will enhance the value of either technique for design or environmental assessment.

Acknowledgments

The work reported has been carried out at Argonne National Laboratory for the U.S. Energy Research and Development Administration under Contract No. W-31-109-Eng-38. The assistance of utility personnel at the Zion and D. C. Cook plants is gratefully acknowledged. C. Tome, L. Van Loon, W. Orvosh, and D. L. McCown of ANL were active participants in the development of equipment and the collection and handling of the field data.

CHAPTER 174

THERMAL DISCHARGES: PROTOTYPE vs. HYDRAULIC MODEL

Gary C. Parker*
C. S. Fang*
Albert Y. Kuo*

ABSTRACT

Data on physical parameters in the James River around the condenser cooling water discharge of the Surry Nuclear Power Plant, taken prior to and during plant operation, were analyzed to determine the physical effects of the thermal discharge on the area and to compare the prototype distribution of excess temperature to predictions based on hydraulic model experiments.

The results of this investigation indicated that the increase in water temperatures due to the thermal discharge did not represent a significant alteration of the physical environment outside the mixing zone. The thermal discharge experienced turbulent mixing and entrainment near the out-fall and temperatures decreased rapidly in this region.

Field data on temperature distributions around the discharge, when compared to predictions based on hydraulic model experiments, indicate that the model predictions were conservative.

INTRODUCTION

The generation of electrical energy from a steam source results in an energy loss as described by the laws of thermodynamics. The thermal energy not utilized is rejected from the process in the form of heat transferred to the water circulating through the condensers of a power station. This heat is ultimately transferred to the atmosphere by conduction and evaporative cooling either in closed-cycle systems, e.g. cooling towers, or in once-through systems, from the surface of the receiving water body.

Decisions dealing with methods for transferring the rejected heat to the atmosphere must be based upon a thorough understanding of hydro-thermal dynamics and the effects of excess temperature on indigenous populations of aquatic life.

*Scientists, Virginia Institute of Marine Science,
Gloucester Point, Virginia U.S.A.

The Virginia Institute of Marine Science has been conducting a hydrothermal monitoring program since 1971 at the site of the VEPCO Nuclear Power Plant on the James River (Fig. 1).

The objectives of this investigation have been:

- 1) Compare pre- and post-plant operation data to determine the physical effects of the thermal discharge on the survey area.
- 2) Compare field results with predictions of temperature distributions made with the James River hydraulic model to determine the applicability of the hydraulic model to field temperature predictions.

The Surry Nuclear Power Plant consists of two 788 MW nuclear reactors, the first of which began commercial operation in December 1972, the second in March 1973. The power plant uses the once-through cooling method. Water is drawn into the intake canal on the downstream side of Hog Point, pumped through the condensers and out through the discharge structure into the James River estuary, upstream from Hog Point. The shoreline distance between intake and discharge points is about 9.17 km and the intake canal is about 2.74 km long.

Each unit requires 52,987 liters/second of river water to supply condensing and service water needs. The maximum temperature rise through the condensers is 8.3°C.

FIELD STUDY RESULTS

A detailed description of the study sampling program was given by Parker and Fang (1975) and Fang and Parker (1976). A moving boat sampling scheme was used. The parameters measured were water temperature at depths of 0.15, 0.9 and 1.8 m, air temperature at 0.9 and 1.8 m above the water surface and dew point temperature. These data, along with salinity and dissolved oxygen samples taken at fixed stations and meteorological data from nearby Ft. Eustis, were deemed sufficient to identify natural variations in river conditions and to isolate thermal effects of the heated water discharge.

AREA WITHIN ISOTHERMS

After isothermal plots of a survey run were drawn, a planimeter was used to measure the area within the isotherms

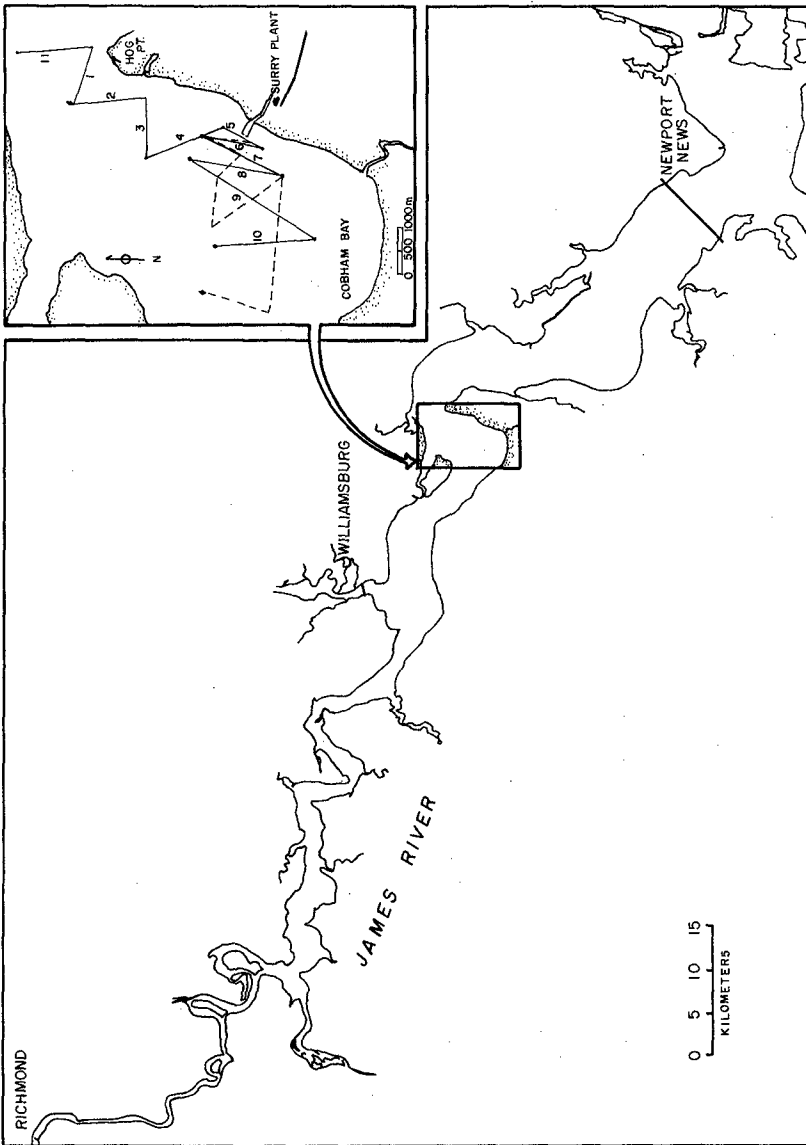

Figure 1. Location of the Surry Nuclear Power Station Site Inset: 1975 transects (solid), 1974 (dashed). Transects 11, 1, 2, 3, 4 same for both years.

which were "closed" around the outfall.

A graph of the area within excess temperature isotherms as a function of fractional excess temperature, Figure 2, indicates that the area (A) within the isotherms generally increases logarithmically with decreasing fractional excess temperature (θ/θ_0). An approximation to a straight line fit to the data is represented by the line:

$$A = (5.6 \times 10^6)e^{-6.8 (\theta/\theta_0)}$$

The data plotted in Figure 2 represent data for plumes with plant operation at greater than 90% capacity. When the data are separated into low and high slack water plumes, as shown in Figure 2, it appears that the low slack water plumes were slightly larger than high slack plumes, although the differences were not significant.

The area data from 1975 indicate as a rough estimate that as the value of θ/θ_0 approaches zero, the area within the excess temperature isotherm, θ , approaches $5.6 \times 10^6 \text{m}^2$, which represents the maximum surface area affected by the plume.

CENTERLINE TEMPERATURE DECAY

In 1975, plume centerline temperature decay was determined from isothermal plots for ten selected survey runs in August and September. The selection process was based upon the ease of determining plume centerlines from the isothermal plots. Plume centerlines were drawn subjectively, and distance and temperature along the centerline were recorded.

A graphical presentation of the data, Figure 3 indicates an exponential centerline temperature decay approximately represented by the equation:

$$\theta/\theta_0 = e^{-.0002d}$$

where d is the distance along the plume centerline. Fractional excess temperatures at centerline distances less than 45 m from the outfall show much less variation than those at greater distances.

The graph indicates that generally θ/θ_0 reaches a value of 0.5 within 1050 m of the outfall, indicating that a major portion of initial plume mixing with ambient water occurs within 1050 m from the outfall.

Figure 2. Area within excess temperature isotherm versus fractional excess temperature (θ/θ_0), 1975 data.

Figure 3. Plume centerline temperature decay, August and September 1975 data.

VERTICAL TEMPERATURE STRATIFICATION

Figure 4 shows a portion of the isothermal plot for August 21, 1975, at high slack water. On this date the plant power production was 1487 MW, winds were SE at 11-12.8 kph. Four transects, AA', BB', B'C, and DD', have been shown in vertical cross section to the maximum sample depth of 1.8 m in Figure 5.

Transects AA' and BB' show a maximum stratification of approximately 1.1°C over 1.8 m. Transect B'C, across the mouth of the outfall, shows a hot core of 37.8°C water at 0.9 m depth at the outfall. The maximum stratification along this transect is approximately 2.8°C over the 1.8 m depth. The plot of transect B'C also shows a sharp temperature gradient on the downstream (B') side of the plume, with a more gradual gradient on the upstream side. Transect DD', 365 m offshore and parallel to B'C, shows that plume temperatures at the centerline have dropped to 35°C. The strongest areas of stratification are on the extreme upstream (D') and downstream (D) ends of the transect. Figure 4 shows that these regions are near sharp temperature gradients at the surface. In these regions the temperature gradient is a maximum 3.3°C over 1.8 m of depth.

COMPARISON OF AREAS WITHIN ISOTHERMS

Areas within excess temperature isotherms for August 1974 and 1975 are compared in Figure 6. Water temperatures are generally at their peak during August, and as mentioned previously, August 1975 power production was continuously higher than 90% of capacity. These factors suggest that August 1975 data would represent conditions under maximum temperature loading for the river. The figure indicates that excess temperature isotherms enclosed larger areas during 1975 than during 1974 and that the differences were greater for low values of fractional excess temperature. The line drawn in Figure 6 shows an approximate best fit line for the 1975 area data; this line represents an approximation for the isotherm area versus fractional excess temperature relationship under equilibrium conditions at the Surry plant. The equation for the line shown in Figure 6 is given by:

$$A = (8.2 \times 10^6) e^{-7.2(\theta/\theta_0)}$$

where A is the area within fractional excess temperature θ/θ_0 . This equation and the line representing it were not calculated mathematically and are given only as approximations. An exact equation for such a relationship obviously does not exist and for this reason, approximations were deemed

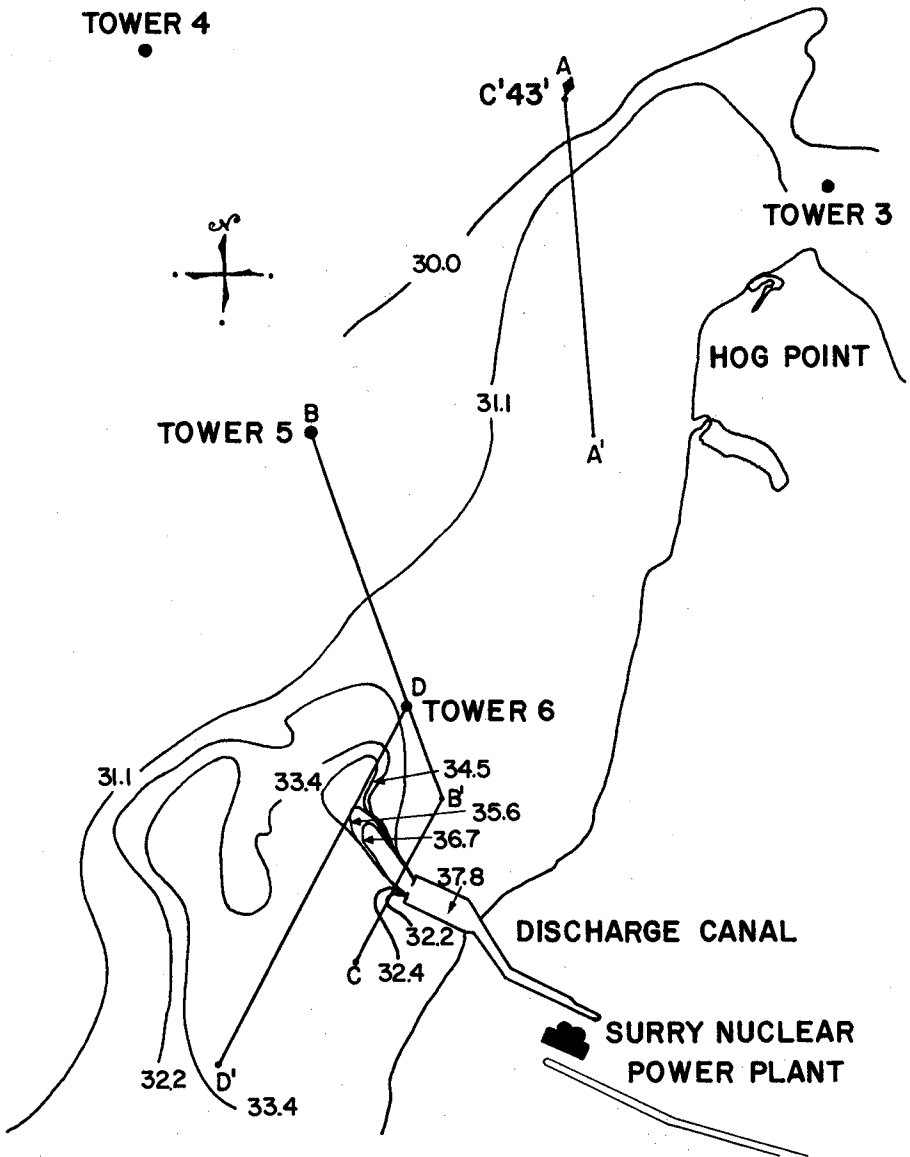

Figure 4. Thermal plume on August 21, 1975.

Figure 5. Vertical sections AA', BB', B'C, DD'.

Figure 6. Comparison of areas within excess temperature isotherms for August 1974 and August 1975, power production greater than 1400 MW.

sufficient for the analysis. The equation indicates that as θ/θ_0 approaches zero, the area within the excess temperature approaches 8.2×10^6 square meters. This area represents the maximum area affected by the thermal discharge under equilibrium conditions, with close to maximum (>90%) power production.

HYDRAULIC MODEL PREDICTIONS

Studies conducted by Carpenter and Pritchard (1967) on the hydraulic model of the James River estuary resulted in predictions of excess temperature distributions resulting from the discharge of waste heat by the Surry Nuclear Power Station. One purpose of the present study was to compare these predictions to actual temperature distributions observed in the field in order to determine the reliability of hydraulic modeling as a method of predicting the effects of thermal discharges into an estuary.

The hydraulic model of the James River estuary, located at the U. S. Army Corps of Engineers Waterways Experiment Station, Vicksburg, Mississippi, covers the tidal waterway from Richmond to the mouth and has a horizontal scale of 1:1000, and a vertical scale of 1:100.

Two separate sets of experiments were run on the hydraulic model. In the first set the model was run for a total of 475 tidal cycles, corresponding to approximately 246 days of prototype time. During this set of experiments the river discharge at Richmond was at a simulated 56.6 cms. In the second set of experiments, river discharge at Richmond was at 169.9 cms and the model was run for a total of 784 tidal cycles.

During both sets of experiments a model thermal plant, releasing a simulated 12×10^9 BTU-hr⁻¹ of waste heat into the river, was operating at a location corresponding to the Surry Nuclear Power Plant site.

Temperatures in the model were measured using a rapid response thermistor head mounted on a trolley which ran across the model on a 4.9 meter unit beam. The beam could be moved to the desired transect and the thermistor sensor run across the model to obtain a plot of temperature versus lateral distance made on a strip chart recorder.

The hydraulic model was designed to reproduce the prototype velocity and salinity distribution. The relative pattern of excess temperature should be the same for model and prototype; however, the model was subject to different heat exchange coefficients than prevailed in the natural

environment. It was, therefore, necessary to adjust the excess temperature distributions observed in the model to take into account the difference in the surface exchange coefficients between the model conditions and prototype conditions.

The correction procedure used by Carpenter and Pritchard was:

$$(A_{\theta})_p / (A_{\theta})_m = 1, \theta \geq 0.5 \theta_0$$

$$(A_{\theta})_p / (A_{\theta})_m = 0.9 \frac{\gamma_m}{\gamma_p}, \theta \leq 0.15 \theta_0$$

where $(A_{\theta})_p$ and $(A_{\theta})_m$ were areas within excess temperature isotherm θ for the prototype and model, respectively, and γ_m and γ_p were the heat exchange coefficients for the model and prototype, respectively. The initial excess temperature at the discharge canal (θ_0) determines the regions in which the two relationships were applied. For $0.15\theta_0 < \theta < 0.5\theta_0$, the relationship was assumed to have a linear variation between the two given ratios.

The results of these experiments were presented as a series of excess temperature isothermal plots. Figure 7 shows two of these plots, for high slack water (tidal hour 0), and for slack water (tidal hour 6).

For comparison purposes, prototype data had to be selected so that heat rejection was as close as possible to the modeled heat rejection. As mentioned previously, hydraulic model tests were run for 56.6 and 169.9 cms river discharges at Richmond. This factor should also be taken into account for the comparisons, but it was considered secondary when compared to heat rejection. The prototype data which had the maximum heat rejection also had river discharges in the range 56.6-198.2 cms so that differences between model and prototype due to river discharge differences were minimal. This conclusion is justified since it has been previously shown that river discharge has little direct effect on tidal currents and excess temperature except for periods of extreme river discharge.

The average values of ambient water temperature, wind speed, and heat rejection for the prototype data selected for comparison with the model were 27.6°C, 9.8 kph, 11.2×10^9 BTU-hr⁻¹ respectively. These values are relatively close to the modeled values of 26.7°C, 8.0 kph, and 12.0×10^9 BTU-hr⁻¹. For the purposes of this investigation, the

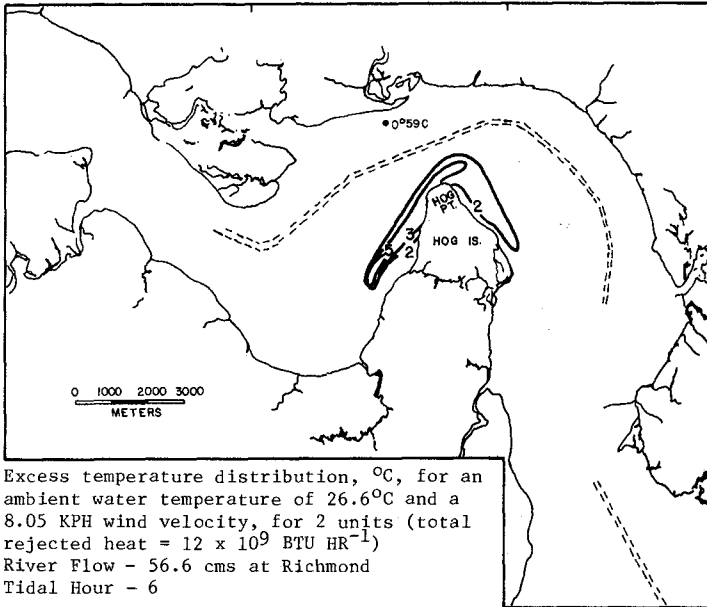

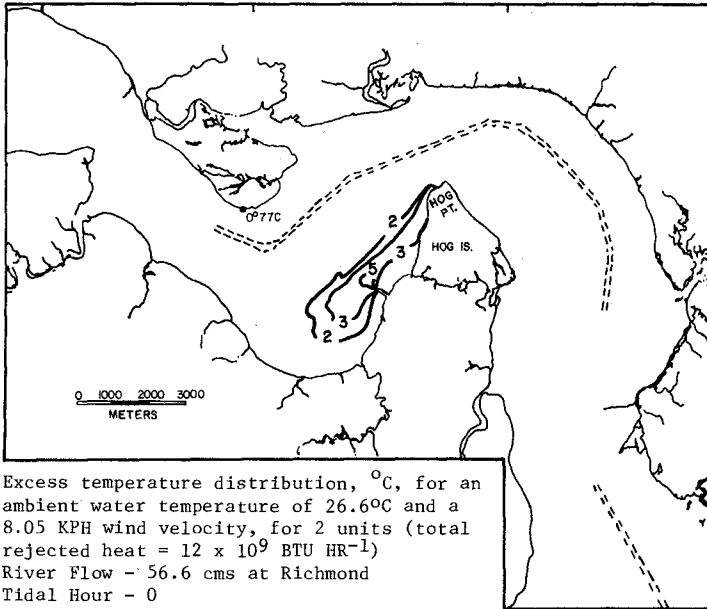

Figure 7. Typical excess temperature isotherms as predicted by the hydraulic model (from Carpenter and Pritchard, 1967).

effects of the differences between ambient water temperature and wind speed for the model and the prototype are considered negligible when compared to the effects due to the difference in rejected heat.

Areas within each excess temperature isotherm were determined from isothermal plots of the appropriate survey runs in 1973 through 1975 using a compensating polar planimeter. These areas, along with the areas within the excess temperature isotherms presented in the results of Carpenter and Pritchard's report, were plotted and are shown in Figure 8.

The figure indicates that the lower limit of the model data approximately coincides with the upper limit of the prototype data. There are only a few data points which lie above the lower limit of the model data. To determine whether the difference between the model and prototype data was statistically significant, the means and 95 percent confidence intervals of the means were calculated for the area within the 2.0°C, 3.0°C, and 5°C excess temperature isotherms in both model and prototype. In the prototype the area within the 2°C and 3°C isotherms were obtained by linear interpolation between the area within next higher and next lower whole degree isotherms.

The means of the area and the 95 percent confidence interval of these means are presented in Figure 9. The fact that the confidence intervals do not overlap for any of the model and prototype data indicates that the differences between the data were significant. The model enclosed areas were significantly greater than the corresponding prototype enclosed areas in all three cases. For the 2°C excess temperature isotherm, the model predictions were greater than prototype data by a factor of five, while for the other two isotherms, model predictions were greater than prototype data by an order of magnitude or more.

The prototype data indicate that the excess heat dissipated more rapidly than was predicted by the hydraulic model. The model predictions for the area with the 2°C excess temperature isotherms were more accurate than those for the higher excess temperatures. Qualitatively, the temperature distributions in the field, as a function of tidal phase, were similar to those predicted by the model.

Lower heat rejection in the prototype was partially responsible for the smaller areas within each excess temperature isotherm. Heat rejection on the days compared with the hydraulic model predictions were from 8-14 percent lower than the modeled heat rejection. It is assumed that at full plant capacity the areas in the prototype would be

Figure 8. Comparison of areas within a given excess temperature isotherm for the hydraulic model and the prototype.

Figure 9. Comparison of mean areas and 95 percent confidence intervals for the hydraulic model and the prototype.

10-20 percent larger, which is probably an over-estimation, the differences between the model predictions and the prototype would still be significant.

Carpenter and Pritchard assumed that in the near field region, which they define as $\theta > 0.5\theta_0$, cooling has had little time to act. To reflect this, the correlation factor applied to this area, $(A_\theta)_p / (A_\theta)_m$, had a value of unity. With an average value of θ_0 of approximately 6.7°C , the field data indicate that for values of $\theta > .50\theta_0$, the ratio $(A_\theta)_p / (A_\theta)_m$ had a value of approximately 0.1.

For the region removed from the outfall, with values of $\theta < 0.15\theta_0$, Carpenter and Pritchard applied the correction factor $(A_\theta)_p / (A_\theta)_m = 0.9 (\gamma_m / \gamma_p)$. The field data indicate that the ratio $(A_\theta)_p / (A_\theta)_m$ had a value of 0.2 for values of $\theta = .33\theta_0$. Since the field data were compared to the corrected model results, the actual correction factor should have been of the form

$$(A_\theta)_p / 0.9 \left(\frac{\gamma_m}{\gamma_p} \right) (A_\theta)_m = 0.2$$

which reduces to

$$(A_\theta)_p / (A_\theta)_m = 0.18 \left(\frac{\gamma_m}{\gamma_p} \right)$$

It would appear, then, that a more accurate set of correction factors than those used by Carpenter and Pritchard have the form

$$(A_\theta)_p / (A_\theta)_m = 0.1, \quad \theta > 0.50\theta_0$$

$$(A_\theta)_p / (A_\theta)_m = 0.18 \left(\frac{\gamma_m}{\gamma_p} \right), \quad \theta < 0.33\theta_0$$

with a linear variation for intermediate values of θ .

The inability of the hydraulic model to predict the areas within the higher excess temperature isotherms to the same order of magnitude was most probably due to scale distortion. In a discussion of hydraulic modeling, Silberman and Stefan (1970) indicate that it is necessary to model three regions: near field, the joining region, and far field, in order to completely model a given plume. In the near field region near the outfall, entrainment of ambient fluid is the major process to be modeled. In the

joining region, entrainment is still important, but buoyancy, surface cooling, and convection are also important. Surface cooling, dispersion, and convection are the most significant processes in the far field. The different physical phenomena involved within each region mean that in most situations these regions cannot be combined in one hydraulic model.

One of the most important considerations when modeling parts of the plume separately is the placement of the proper boundary condition on the separate models. As an example, in a far field model, the initial thickness and momentum of the plume are determined by the end conditions in the joining region.

Carpenter and Pritchard (1967) have attempted to model all three regions of the thermal plume using a distorted model. The model does not accurately model entrainment in the near field and joining region. Field data indicate that the heat dissipation was higher in the near field than predicted by the model, indicating that entrainment was lower in the model than in the prototype. The correction factors used by Carpenter and Pritchard did not account for this entrainment in the near field, which resulted in predictions which were factors of five to ten time greater than the observed field conditions. The modified correction factors, derived from field data and model comparisons, can be applied to other sites or to other hydraulic models, provided that the discharge geometries and velocities are similar and the hydraulic model has the same scale distortion.

ACKNOWLEDGEMENTS

Funding for the study which was provided by the U. S. Energy Research and Development Administration is greatly appreciated.

CHAPTER 175

FLOW FIELD NEAR AN OCEAN THERMAL ENERGY CONVERSION PLANT

by

D. M. Sheppard⁽¹⁾, G. M. Powell⁽²⁾, I. B. Chou⁽³⁾

The flow field in the vicinity of an Ocean Thermal Energy Conversion (OTEC) Plant is extremely complex. The plants will normally be located in an area of relatively high surface currents and the location must also be such that a large temperature difference exists between the lower layers and the surface. Locations that demonstrate this characteristic can in many cases be modeled as a two layer fluid as shown in Figure 1. A number of different designs for the OTEC plants are being considered, but they all have one thing in common, a large vertical cold water pipe. This pipe extends from near the surface to some point in the cold water layer (see Figure 1). In some designs this pipe is as large as 40 m in diameter and 460 m in length.

Having such a large object penetrating the interface between the two temperature layers in the presence of a shear flow can significantly alter the character of the interface. The highly turbulent wake downstream from the pipe can drastically effect the mixing across this density interface.

A conventional heat engine cycle is used in the plant with the high temperature source being the water in the upper layers and the low temperature reservoir being the water from the lower depths. Since the temperature difference is small for this type of plant (20° max.), vast quantities of both high and low temperature water must be used. The intake and discharge for the warm water as well as the cold water discharge will be in the upper layer; the intake for the cold water will be in the lower layer at or near the end of the cold water pipe.

The flow problem is thus one of a vertical cylinder in a two layer stratified shear flow with sources and sinks located along the cylinder.

Since the integrity of the temperature profile is of the upmost importance to the successful operation of the plant, an understanding of the flow field is essential. In addition, the possible alterations

of the environment could be significant especially if a number of OTEC plants are located in the same area. This paper addresses itself to only part of this problem and even then only illustrates the need for more work. The part considered deals with the wake downstream from a cylinder in a two-layer stratified shear flow. A physical model of a typical cold water pipe was placed in a stratified flow facility and measurements were made just above the interface in the wake region.

The mixing across a density interface (thermocline) is believed to be a function of the turbulent energy present at or near the interface (Long). Although this subject is not completely understood at this time, the work of Long¹, Kato and Phillips² and others indicates that the erosion velocity U_e is proportional to U_1^3 where U_1 is the RMS of the turbulent velocity fluctuations near the interface. This relationship should hold provided the other parameters such as the density jump across the interface and the turbulent length scales remain constant. In the undisturbed ocean, the primary source of turbulence is the air-sea interaction at the surface. The intensity of the turbulence decreases with depth. This is perhaps the reason for the depth limits on the thermocline. The introduction of a source of turbulence at or near the thermocline can, as this paper shows, have a significant effect on the level of turbulent energy in this region.

It is difficult, if not impossible, to model all the significant dimensionless groups for a problem such as this. The groups that are of primary importance here are 1) interfacial Froude number, $\frac{\Delta V}{\sqrt{\frac{\Delta \rho}{\rho_2} gh}}$,

2) pipe diameter to interface thickness ratio, $\frac{D}{h}$, and 3) Reynolds number based on the pipe diameter, $\frac{VD}{\nu}$, where ΔV is the difference in the mean

velocities between the upper and lower layers, $\Delta \rho$ the difference in mass density between the upper and lower layers, g the gravitational acceleration, h the thickness of the interface, ρ_2 the mass density of the lower layer, D the diameter of the pipe, V the velocity of the upper layer and ν the kinematic viscosity of the water. The first two groups were held constant for the model and prototype, but this was not possible in the case of Reynolds number. In fact, the Reynolds numbers for the prototype and model were quite different, approximately 10^6 for the prototype and approximately 10 for the model. This must be kept in mind when drawing conclusions about the prototype from the experimental results.

The experiments were performed in a stratified flow facility 24.5 m long, 1.22 m high and .61 m wide (for a complete description of the facility see Ref. 3). Sodium chloride was used as the stratifying agent for these experiments. The lower .61 m of the tank was filled with salt water (dyed red to aid in the flow visualization) and the upper .61 m filled with fresh water. Specific gravity and Brunt Väisälä frequency profiles are shown in Figures 2 and 3. A pump in the 30 cm diameter pipe connecting the ends of the tank is used to circulate the upper layer and create the shear flow velocity profile shown in Figure 4. Salt water was continuously

added at the bottom of the tank and fresh water drawn from the top during the experiments to maintain the interface at approximately the same location. A crosswire hot film probe for measuring y and z components of the velocity and velocity fluctuations, a high resolution electrical conductivity probe for measuring mass density and a glass beaded thermistor for measuring temperature. Were attached to a vertically and horizontally traversing probe support. The four transducer outputs plus a signal giving the location of the probes were digitized and recorded on magnetic tape. The data was reduced on an IBM 370 Mod 65 computer.

The experimental procedure was as follows: The pump was started and allowed to run for approximately one and one-half hours so that the flow could reach an equilibrium condition. A constant speed vertical traverse was made to obtain a mass density profile and locate the position of the interface. A stepped vertical traverse was then made to obtain a time averaged velocity profile. Next the probes were placed approximately 1 cm above the interface and turbulence measurements were made. The cylinder was then put in place and turbulence data taken at the positions shown in the definition sketch.

Constant speed traverse were also made during and at the completion of the turbulence measurements to precisely locate the interface.

The results are given in Table 1 and Figures 5-9. The erosion velocity (velocity at which the interface recedes) is believed to vary as the cube of the RMS velocity near the interface¹. Figure 5 is a graph of the ratio of the erosion velocity with the cylinder to the erosion velocity without the cylinder at the cross sections of the wake shown in Figure 1.

Although more data points are needed to obtain a complete picture the results clearly indicate a substantial increase in the turbulent energy present at the interface. The vastly increased mixing was visible to the eye and was recorded on movie film (shown at conference). Energy density spectra for the horizontal and vertical components of velocity are shown both without (Figures 6 and 7) and with (Figures 8 and 9) the cylinders. Note the overall higher turbulent energy level in the wake. The vortex shedding frequency is also clearly visible in Figures 8 and 9. It should be pointed out again that the Reynolds number based on the pipe diameter for the model is much lower than for the prototype. At higher Reynolds numbers, however, the turbulent energy will undoubtedly be higher and thus the mixing in the wake of the prototype would be ever greater.

No attempts to integrate the erosion velocity over the wake region was made since with the large difference in Reynolds numbers the results cannot be directly applied to the prototype. The results do however indicate that this problem should be investigated further.

CHAPTER 176

ADAPTABILITY OF PREDICTION METHOD OF HYDRAULIC MODEL EXPERIMENT FOR THERMAL DIFFUSION

1) 2)

By Masanobu Kato and Akira Wada

1. INTRODUCTION

In formation processes of the region of water temperature rise caused by the cooling water discharge from thermal and nuclear power stations located on the site facing the ocean, flow of discharged cooling water itself, current and turbulence existing in the sea region play an important role.

Their motions are predominant in the horizontal direction in the sea region. The horizontal scale of thermal extent is, therefore, extremely larger than the vertical scale of thermal extent.

Therefore, whenever the diffusion experiments of discharged warm water in the far field are conducted by hydraulic model method, the model which has a difference in the geometrical reduced rate between the horizontal and vertical directions, what is called, the distorted model must be used, so that the effects of the viscosity and the surface tension on the experimental model can be avoided.

In such a model, the horizontal scale is determined by the relation between the size of the experimental water basin and the surface area of the sea region to be reproduced.

But, there is no clear method of choosing the vertical scale, though there are some suggestions about it.

For example, the similarity of the $4/3$ power law of the diffusion coefficient gives a relation between the vertical scale and the horizontal scale of the hydraulic model.

On the other hand, the similarity of the surface heat exchange coefficient gives another relation between the vertical scale and the horizontal scale of hydraulic model if the surface heat exchange coefficients of hydraulic model and prototype are not same.

Therefore, it is better to give some allowance in the determination of the vertical scale of the hydraulic model within the range where the reproducibility of the diffusion phenomena can be conserved.

To clarify sure the relations between the distortion rate and the reproducibility of the phenomena in the model, experiments on the diffusion of discharged warm water were conducted by using three kinds of tidal hydraulic models having different distortion rates.

1), 2) Ocean Environment Section, Hydraulic Department,
Central Research Institute of Electric Power Industry
Abiko Chiba, Japan.

The selected site as prototype is Takasago Point located in the north-eastern part of Harima of the Seto Inland Sea in Japan, where the semi-diurnal tidal current is predominant and two thermal power stations in operation are located adjacently.

In this paper the loci of tidal current, the horizontal turbulence of meso-scale and far field temperature distributions obtained in the three hydraulic models having different distortion rates are compared with those of field measurements in prototype.

From these results, same problems of adaptability for the technique of distorted hydraulic model experiment for predicting the diffusion extent of thermal discharge are discussed.

2. RESULTS OF PROTOTYPE INVESTIGATIONS

The selected site as prototype is Takasago Point located in the north-eastern part of Harima of the Seto Inland Sea, where are two thermal power stations in operation adjacently.

Figure 1 shows the site map of Takasago Point.

One is Takasago Thermal Power Station of Kansai Electric Power Company (total output 900 MW, maximum volume of cooling water 33.5 m³/sec.) and the warmed cooling water is discharged into the sea region in front of the power station.

The other is Takasago Thermal Power Station of Electric Source Development Company (total output 500 MW, maximum volume of cooling water 21.8 m³/sec.) and the warmed cooling water is discharged into the inlet beside the power station.

The temperature rise of the discharged cooling water from both power stations is about 7°C above the ambient sea water temperature.

To examine the characteristics of flow in this sea region, the auto-correlations and the energy spectra of the flow observed for 15 days running at 3 m below the sea surface in the 1 km and 3 km offing of the outlet are calculated.

Figure 2 shows the autocorrelation coefficients of the flow which were observed at station - 2 in Takasago Site.

The autocorrelation of the flow velocity which is parallel to coast oscillates periodically and its period of the oscillation is nearly equal to the period of the semi-diurnal tidal current.

Figure 3 shows the energy spectra of the flow which were observed at station - 2 in Takasago Site.

The energy spectrum of the flow velocity which is parallel to coast has a maximum energy concentration at the frequency equivalent to the period of the semi-diurnal tidal current.

Judging from these figures, it is evident that the semi-diurnal tidal current is predominant in this sea region. It runs north-westward during flood tide and south-eastward during ebb tide.

The amplitude of the semi-diurnal tidal current is about 30 cm/sec. during spring tides.

The actual measurement of the discharged warm water diffusion range in the sea region near Takasago Power Station was carried out by Kansai Electric Power Co., Ltd. from January 22nd to February 3rd, 1972, and also by Water Temperature Survey Corporation from February 15th to 22nd, 1973.

The field surveys were conducted at the time of the spring tide both in 1972 and in 1973; and the amplitude of the semi-diurnal current was

approximately 30 cm/sec.

The environmental water temperature in the sea region was about between 9°C to 11°C and the marine condition was mild.

According to the results of the actual measurement, the area of 1°C rise above ambient sea water temperature extended about 2 - 2.5 km along the coast on both sides from the outlet and extended about 2 km toward the offing from the outlet.

The area of 2°C rise above ambient sea water temperature extended about 1 - 1.5 km along the coast on both sides from the outlet and extended about 1 km toward the offing from the outlet.

3. SIMILITUDE RULE OF HYDRAULIC MODEL EXPERIMENT

(1) Diffusion Process of Discharged Warm Water in the Coastal Sea Region

Although the diffusion phenomenon of discharged warm water is extremely complicated and the factors which affect the diffusion process are various and numerous, the main process can generally be considered as follows:

In the sea region near the outlet, the main process is the entrained mixing between the discharged warm water and ambient water.

The discharged warm water itself flows toward to offing through the process of mixing, and gradually the flow and turbulence of the discharged warm water become smaller than those in the sea region.

In this sea region, the diffusion process affected by the flow and turbulence of the sea controls the formation process of the water temperature distribution. Accordingly, for the purpose of predicting the diffusion of discharged warm water on the basis of the hydraulic model experiment, it is essential to make actual measurement investigations into the diffusion characteristics in the coastal sea region and to verify each factor which controls the diffusion phenomena in each case, and finally to discover the similitude rules for reproducing these factors on the model.

(2) Near Field

In the hydraulic experiment on the water temperature distribution formed in the sea region near the outlet, the entrained mixing phenomena should be reproduced in the model.

Under the condition that we should correspond the internal Froude number of the model with that of the prototype, this phenomenon can be expected to be reproduced.

This condition gives following equations. m means the model and p means the prototype,

$$\begin{aligned}
 F_{ip} = F_{im} &= \frac{U_{op}}{\sqrt{\frac{\rho_{sp} - \rho_{op}}{\rho_{op}} \cdot g \cdot h_{op}}} \\
 &= \frac{U_{om}}{\sqrt{\frac{\rho_{sm} - \rho_{om}}{\rho_{om}} \cdot g \cdot h_{om}}} \dots\dots\dots (1)
 \end{aligned}$$

where

- Fi : internal Froude number
- Uo : outfall velocity
- ρ_s : density of the environmental water
- ρ_o : density of the discharged water
- g : acceleration of gravity
- ho : depth at the outlet

In the hydraulic model where the Froude Similitude Rule is applied, the next relation can be obtained.

$$\frac{\rho_{sp}}{\rho_{op}} = \frac{\rho_{sm}}{\rho_{om}} \dots\dots\dots (2)$$

That is to say, the equation described above shows the condition that we should correspond the environmental water density and the discharged water density of the prototype with those of the model.

However, as it is difficult to grasp the three dimensional phenomena concerning the entrained phenomena near the outlet, more detailed examination of the similitude rule for reproducing the phenomena is considered necessary.

(3) Far Field

In this sea region, the flow and turbulence of the sea play an important role in the formation process of water temperature distribution.

This process is also affected by the heat exchange process between the atmosphere and the sea surface.

The average flow conditions such as the current trace and the topographical current are supposed to be very important factors which play a main role as the advective effects to change the diffusion pattern of the discharged warm water.

After integrating the equation of motion in the vertical direction, neglecting the stress which acts on the water surface and taking into consideration of the stress acting on the sea bed expressed by the help of the friction coefficient, the following relations to reproduce the average flow conditions may be obtained.

$$\frac{U_p}{U_m} = \frac{V_p}{V_m} = \left(\frac{Z_p}{Z_m}\right)^{1/2} \dots\dots\dots (3)$$

$$\frac{t_p}{t_m} = \left(\frac{X_p}{X_m}\right) \left(\frac{Z_p}{Z_m}\right)^{-1/2} \dots\dots\dots (4)$$

$$\frac{C_p}{C_m} = \left(\frac{X_p}{X_m}\right)^{-1} \left(\frac{Z_p}{Z_m}\right) \dots\dots\dots (5)$$

where,

- U, V : vertically averaged velocities in X and Y directions
- t : time

C : friction coefficient
 X, Z : length scales in horizontal and vertical directions.

The equations (3) and (4) can be transferred to the following equation.

$$\frac{U_p}{\sqrt{g Z_p}} = \frac{U_m}{\sqrt{g Z_m}} = Fr \dots\dots\dots (6)$$

where,

Fr : Froude number.

The equation (6) shows the similitude rule of Froude.

It is considered that the average flow condition such as the tidal current trace or the topographical flow can be reproduced by corresponding the Froude number of the model with that of the prototype.

On the other hand, the mechanism and characteristics of the turbulence which play a very important role in the diffusion process in the sea region can be obtained by statistically analyzing the results of long term continuous observation on the flow velocity fluctuations. They can be clearly expressed in the autocorrelation functions and the energy spectrum functions.

According to the results that were obtained using the distorted model on the reproducibility of the horizontal turbulence which exists in the tidal current, it is shown that the statistical characteristics and mechanism of the horizontal turbulence which are expressed in the autocorrelation and the energy spectrum can almost be reproduced in the model by applying the similitude rule of Froude. However, as far as the reproducibility of horizontal turbulence is concerned, it seems that some restrictions are given by the Reynolds number and topographical features at the site to be investigated for the experiment.

Accordingly, in order to reproduce the diffusion process in the sea region far from the outlet on the model, it is necessary to adopt the similitude rule of Froude, and it is also important to check the reproducibility of the average flow condition and the horizontal turbulence by comparing the results of the model with those of the actual measurements in prototype.

The heat balance between the atmosphere and the sea surface is determined by the short wave radiant energy coming from the sun and the sky, the long wave radiant energy from the atmosphere and the water surface, the transfer of the sensible heat energy and the latent heat energy, and by the additional heat energy caused by the discharge of warm water.

The factors which affect the surface heat exchange are the wind velocity, the water temperature, the atmospheric temperature, the humidity, the cloudiness and so on.

The rate of the surface heat exchange is usually expressed by introducing the surface heat exchange coefficient.

The relation of the surface heat exchange coefficient ratio can

be obtained from the equation of thermal diffusion which is integrated in the vertical direction and from the similitude rule of Froude, as follows.

$$\frac{K_{Tp}}{K_{Tm}} = \left(\frac{X_p}{X_m}\right)^{-1} \left(\frac{Z_p}{Z_m}\right)^{3/2} \dots\dots\dots (7)$$

where, K_T : surface heat exchange coefficient

This relation shows that the model must be given distortion if the surface heat exchange coefficient of the model is the same as that of the prototype. Actually however, the former is different from the latter and the coefficient heat exchange in the model is generally presumed to be smaller than that in the prototype because no consideration is given to the effects of the wind.

If a correct coefficient of the heat exchange in the model as well as in the prototype is obtained, the equation (7) provides a means of determining the distortion ratio. However, it is very difficult at the present stage to apply the similitude condition regarding the effect of heat balance in the hydraulic experiment because of difficulty in obtaining the coefficient of surface heat exchange.

4. EXPERIMENTAL METHOD AND MODELING RATIO

The diffusion basin used for the hydraulic model experiment is 20 m x 10 m x 1 m, and the tide production equipment is installed at the end of the basin. This air pressure system can produce the change of the water level and the flow in the model basin by alternating the air pressure in the air-tight chamber. (See Figure 4)

Water temperature, current speed and their variations in the basin were measured by using thermistors and a supersonic currentmeter connected to a data-logger.

The average flow conditions such as the loci of tidal current were measured by photographing the movements of float in the basin from the upper part.

The horizontal length ratio was chosen as 1/1,000 to reproduce the prototype area of 15 km along the coast by 6 km offshore in the experimental basin.

The vertical length ratio was chosen as 1/50, 1/100 and 1/200, so three models having different distortion rates were constructed.

The relations between the values of the prototype (P) and the values of three models (m) are shown in the following table.

Table 1. Summary of Modeling Ratios for the Experiment

		Case I	Case II	Case III
Horizontal length	$X_p/X_m = Y_p/Y_m$	1000	1000	1000
Vertical length	Z_p/Z_m	200	100	50
Distortion rate	$(X_p/X_m)/(Z_p/Z_m)$	5	10	20
Horizontal velocity	$U_p/U_m = V_p/V_m$	14.14	10	7.07
Flow rate	$Q_p/Q_m = (X_p/X_m)(Z_p/Z_m)^{3/2}$	2.83×10^6	10^6	3.54×10^6
Time	$t_p/t_m = (X_p/X_m)(Z_p/Z_m)^{-1/2}$	70.71	100	141.42

5. EXPERIMENTAL RESULTS

(1) Reproducibilities of Average Flow Conditions and Horizontal Turbulence

Before the experiment of the thermal diffusion, the reproducibility of the average flow conditions such as the loci of tidal current and the reproducibility of the horizontal turbulence of meso-scale which play an important role in the diffusion phenomena in the sea were examined.

Figure 5 shows the loci of tidal current during ebb tide obtained in three models having different distortion rates.

In this figure, the experimental results are indicated as the values of the prototype values, and they are compared with the loci of tidal current obtained in the field surveys.

From this figure, it is considered that the average flow conditions such as the tidal current trace obtained in three models having different distortion rates are not influenced so remarkably by the variation in distortion rate, and it is also confirmed that the results of the field surveys are reproduced in these models.

The average flow conditions at the time of flood tide are also reproduced in the models.

S. Hayami et al²⁾ proposed the similitude to give the distortion rate for the model of tidal current, considering the bottom friction in the laminar flow regime, as follows.

$$\frac{C_p(\text{Rep})^{1/2}}{1.328} \cdot \left(\frac{X_p}{X_m}\right)^{1/2} = \left(\frac{Z_p}{Z_m}\right)^{5/4} \dots\dots\dots (8)$$

They conducted the hydraulic model experiments by the use of three models of horizontal length ratio 1/500, distortion rates of 2, 4 and 8.

From the experimental results, they concluded that the flow patterns of the field surveys were reproduced better in the model having distortion rate of 2, which satisfied the relation of equation (8).

But it is considered to be difficult to determine the distortion rate using the relation of equation (8), owing to the fact that the value of the Reynolds number varies with space and time.

Judging from the results of author's experiments and the previous works done by others, it may be concluded that the average flow conditions, such as the loci of tidal current, can be reproduced in the distorted Froude model not influenced so remarkably by the variation in distortion rate.

But careful attention must be paid to the fact that large distortion rate makes the flow in the model basin three dimensional.

The characteristics and mechanism of the horizontal turbulence are represented remarkably by the energy spectrum which can be obtained by statistic analysis of the results of long term continuous observation of fluctuations in flow velocity.

For the purpose of examining the reproducibility of the horizontal turbulence, long term continuous measurements of fluctuations in flow velocity were conducted at the same point as the field survey spot.

The energy spectrum of fluctuations in flow velocity obtained by the experiments performed in the tidal hydraulic models having three different kinds of distortion rates is shown in Fig. 6. The point of measurement is St. 2 shown in Fig. 1.

The energy spectrum shown in this figure is obtained by excluding the oscillating current component in the model which corresponds to the semidiurnal current component. And in the case of the prototype, the spectrum is obtained by excluding the semidiurnal current and the diurnal current. The values of the model are indicated as the values of the prototype according to the similitude rule of Froude.

The energy spectra of the flow parallel to coast show the same energy level as the level of the prototype in both high and low frequency ranges.

But the energy spectrum obtained in the model of distortion rate of 20 shows a larger peak at the frequency equivalent to the period of 6 hours in comparison with those of other two models and prototype.

On the other hand, the energy spectra of the flow normal to coast obtained in three models having different distortion rate are about the same as those of prototype in the high frequency range, but in the low frequency range the energy levels of spectra obtained in two models of distortion rate of 5 and 20 are lower than that of prototype.

Due to the results mentioned above, it has been recognized that the horizontal turbulence having a fluctuation period of less than several hours can be reproduced in the model without being remarkably influenced by the difference in distortion rate. But as far as the horizontal turbulence having a long fluctuation period is concerned, the energy level of the flow normal to coast is lower than the level of the prototype, and the isotropy in the horizontal direction is lost by the effects of the distortion rate of the model, the topographical characteristics of the investigated site, the scale of the experiment and so forth.

(2) Reproducibilities of Diffusion Phenomena of Discharged Warm Water

After examining the reproducibilities of the average flow conditions

like the tidal current trace and the horizontal turbulence, experiments on the diffusion of discharged warm water were conducted.

From the experimental results, the reproducibility of diffusion phenomena and the effect of distortion on the reproducibility were examined.

The diffusion patterns of discharged warm water obtained in the tidal hydraulic models alternate in accordance with change of the tidal current.

The range of water temperature rise spreads toward the north-western sea region during flood tide and it spreads toward the south-eastern sea region during ebb tide.

As regards the diffusion patterns of discharged warm water at each tidal time obtained both in the hydraulic model and prototype, some similar diffusion patterns are recognized, but many different kinds of diffusion patterns are also recognized.

This is due to the fact that the natural phenomena are extremely complicated and have lots of random characteristics. On the other hand, the model keeps the so-called regularity comparatively well as it is simplified in order to reproduce the main factors in the diffusion process of the prototype.

Also it is due to the fact that there is no simultaneity between the data of the field survey because it takes a long time to measure one diffusion pattern.

Accordingly, in examining the reproducibility of diffusion phenomena by comparing the experimental results with the field survey results, it is more reasonable to compare the diffusion range as the envelope of all the patterns than to compare the each individual diffusion patterns.

Figure 7 shows the comparison between the actual measurement results of 1°C and 2°C rise in the surface layer and the enveloped range of 1°C and 2°C in the surface layer obtained in the hydraulic experiments conducted under the conditions corresponding to the conditions at the time of the actual measurement.

From the experimental results on diffusion area of the discharged warm water obtained in the two models with distortion rate of 5 and 10, there was no remarkable difference between them. The diffusion areas of the actual measurements in prototype were reproduced in each experimental result.

On the other hand, as far as the diffusion area of the discharged warm water obtained in the model with distortion rate of 20 is concerned, it was found that the variation in the distortion rate gives greater effects on the reproducibility of diffusion phenomena as compared with the results obtained in other two models and in the field surveys.

It is considered that these results are attribute to the fact that the flow volume of the discharged warm water in the model experiment increases as the distortion rate in the model becomes larger.

In order to determine the flow volume of the discharged warm water in the model having a large distortion rate, therefore, it is not enough to apply Froude similarity rule only.

H. Higuchi et al ³⁾ proposed the similitude to give the distortion rate for the model of turbulent diffusion considering the 4/3 power law of the horizontal diffusion coefficient, as follows.

$$\frac{Z_p}{Z_m} = \left(\frac{X_p}{X_m}\right)^{2/3} \dots\dots\dots (9)$$

This relation requires a distorted model having distortion rate of 10 if the horizontal length ratio is chosen as 1/1000.

But as far as the results of author's experiments are concerned, the diffusion phenomena of discharged warm water are reproduced even in the model having distortion rate of 5 which does not satisfy the relation of equation (9).

6. CONCLUSIONS

Judging from above mentioned results, in order to conduct the diffusion experiment of discharged warm water by using the distorted hydraulic model applying Froude similarity rule, the distortion rate of model should be smaller than 10 within the range where the effects of the viscosity and the surface tension can be neglected.

CHAPTER 177

HORIZONTAL DIFFUSION IN TIDAL MODELS AND SCALING CRITEREA FOR THERMAL-HYDRAULIC MODEL TESTS

by
Gerd Flügge^{†)}

INTRODUCTION

Near Brokdorf at the lower Elbe river (West Germany) a nuclear power plant is projected. The electric energy output shall be 1300 MWe; therefore the waste heat output will be about 2600 MWe. The maximum allowed temperature rise in the condenser amounts to 10 K. Accordingly the cooling water discharge is about $61 \text{ m}^3/\text{s}$ in case of the provided once through cooling.

For the purpose of the mixing and spreading of the discharged cooling water by

mean tidal conditions and storm-tide conditions

model tests have been carried out at the Franzius-Institut of the Technical University of Hannover.

SCALING CRITEREA FOR THERMAL-HYDRAULIC MODEL TESTS

With regard to the environmental impact and ecological aspects the temperature distribution has to be determined.

Therefore the whole far-field region is reproduced in the distorted model with a vertical scale of 1:100 and a horizontal scale of 1:300.

The scales of the far-field model were selected with regard to the reproduction of the turbulent diffusion and with re-

†) Dipl.-Ing., Scientific Assistant, Franzius-Institut of the Technical University of Hannover, Germany

gard to the heat exchange at the water surface due to the following scaling criteria for the heat exchange

$$k_r = \frac{K_N}{K_M} = \frac{\lambda_V^{1.5}}{\lambda_H} \quad (\text{as outlined in reference (3)})$$

where K is the heat exchange coefficient in $W/m^2 \cdot K$ and λ_V the vertical scale and λ_H the horizontal scale.

In the laboratory (without wind effects) heat exchange coefficient K_M of about $15 W/m^2 \cdot K$ were measured. For the German estuarine areas one assumes significant mean low heat exchange coefficients of about $50 W/m^2 \cdot K$, hence the value of k_r in the above mentioned model study is 3.33.

In regard to the reproduction of the turbulent diffusion in the model the Reynolds number should be large enough to satisfy that the turbulence is sufficiently well developed.

The scale of the Reynolds number r is given by this relationship

$$r = \frac{Re_N}{Re_M} = \lambda_V^{1.5}$$

where λ_V is the vertical scale, index N indicates prototyp dimension and index M model dimension.

A special near-field model was built for the purpose of cooling water discharge currents, the waste heat recirculation, the dilution and dispersion influenced by the outlet design.

In the near-field region physical effects such as buoyancy, density currents, stratified flows, jet-diffusion and the advective and diffusive heat transport processes are predominant. Therefore a scale of 1:50 and no distortion were selected for the near-field model.

Figure 1

Figure 1 shows the characteristic values for the water depth (tidal level), the current velocity and the Reynolds number as a function of time. On the left hand the prototype dimension and on the right side the values for the undistorted near-field model with a scale of 1:50 and the three times distorted far-field model are represented.

The diagram shows that only during a short time before and after slack tide the Reynolds number of onethousandfivehundred is not satisfied. The dotted line belongs to the far-field model.

DIFFUSION AND TURBULENCE PHENOMENA IN TIDAL MODELS

The model tests showed a characteristic behavior of the horizontal diffusion coefficient D_z during the tidal cycle (Fig. 2).

During the well developed tidal current the horizontal diffusion coefficient is nearly constant. But a short time before and a short time after slack tide the horizontal diffusion coefficient becomes a maximum.

This result leads to the question: What kind of physical effects induces this behavior of the horizontal diffusion?

Theoretical considerations lead to the following statement:

The turbulence is mainly generated through large eddies, the energy of which is a function of the mean flow velocity. The large eddies transfer their energy to smaller eddies until the eddies become so small that they are dissipated by viscosity effects (1).

In turbulence theory distinction is made between:

Figure 2

$$\text{integral scale } \Lambda \quad (\text{a macro scale}) \quad \Lambda :: L \quad (1)$$

$$\text{Taylor scale } \lambda \quad (\text{a micro scale}) \quad \lambda :: v \frac{\sqrt{u'^2}}{\epsilon} \quad (2)$$

$$\text{Kolmogoroff scale } \eta \quad (\text{a micro scale}) \quad \eta :: \left(\frac{v^3}{\epsilon}\right)^{1/4} \quad (3)$$

where L : characteristic dimension of length (for example: water depth)

ϵ : energy dissipation per unit mass and unit time

v : coefficient of cinematic viscosity

u' : turbulent velocity fluctuation

The turbulent energy induced by the bottom shear in the fluid motion per unit mass amounts to:

$$E :: \frac{\tau_b \cdot L^2 u}{\rho L^3} :: \frac{f_b \cdot u^3}{L} \quad (4)$$

where τ_b = bottom shear stress ($\tau_b = \frac{1}{8} f_b \cdot \rho \cdot u^2$)
 f_b = bottom shear coefficient

Assuming that a state of equilibrium exists between induced turbulent energy and energy dissipation.

$$E = \epsilon \quad (5)$$

From this condition, we derive (Abraham (2)) the following relationship between the Reynolds number and the scales of turbulence:

$$\frac{\eta}{L} :: Re^{-3/4} \quad (6)$$

$$\frac{\lambda}{L} :: Re^{-1/2} \quad (7)$$

where the Reynolds number is defined as follows:

$$Re = \frac{\bar{u}L}{v}$$

Equation 6 and 7 lead to the following conclusion:

With decreasing Reynolds numbers the size of the eddies which are dissipated by viscosity (Kolmogoroff scale, Eq. 6) increases. The size of eddies of which only a small fraction is dissipated by viscosity (Taylor scale, Eq. 7) increases also with decreasing Reynolds numbers.

These theoretical arguments lead to the statement, that - a short time before and a short time after slack tide, when the horizontal diffusion coefficient D_z increases, the turbulence spectrum of the flow contains mainly large eddies.

Therefore the next step of research was to investigate the behavior of the turbulence spectrum during the tidal cycle - in both models.

Figure 3 shows in the upper diagram the characteristic current velocity as a function of the tidal process and the turbulence spectra at the marked points of time in the upper diagram. The full-line represents the results of the undistorted model, scaled 1:50, and the dotted line represents the results of the distorted model, scaled 1:100/1:300.

The ordinate indicates the velocity fluctuation.

Diagram A points out, that a short time after low water slack the turbulence is not fully developed - in both models. The frequency is smaller than two Hertz, that means only large eddies exist.

At time B the turbulence spectrum in the near-field model is more developed.

That means the turbulence spectrum contains also small eddies. The predominant eddy size is indicated by the maximum of the

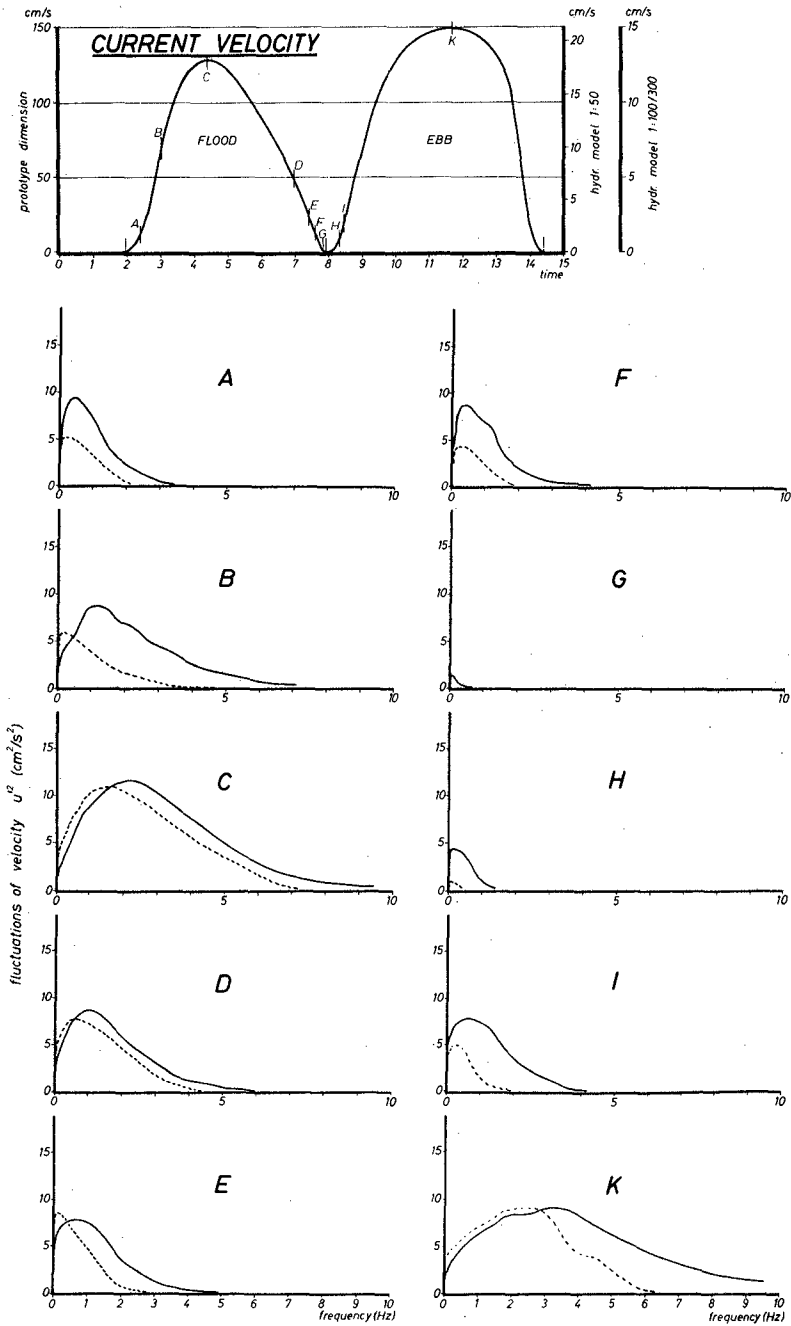

Figure 3

curve. The dotted line shows that - at the same tidal point - in the distorted model the turbulence is not well developed. Only a small fraction of small eddies represented by the higher frequency exists.

At C the turbulence is fully developed. In both models the spectrum has nearly the same shape. In comparison to B the fraction of large eddies decreases; but the fraction of small eddies increases. The total of turbulence intensity - with other words the integral of the curve - becomes a maximum.

At D the turbulence intensity decreases. Mainly the small eddies are filtered out by viscosity effects - or with other words the range of higher frequencies is dissipated. The range of low frequencies has not changed importantly.

At E and F the intensity of turbulence decreases more and more. One can observe that the smaller eddies, that means the range of the higher frequencies of the spectrum, in this case from four to two Hertz, are filtered out. With other words the size of the existing eddies becomes more and more uniform.

At G that means at slack tide there is no turbulence in the far-field model (1:100/300). In the near-field model only a very small fraction with low intensity of turbulence exists.

At H the development of the turbulence has started again. But at this time only a small intensity of turbulence exists. Only large eddies - indicated by low frequencies - are generated.

At I one can confirm a further development of the turbulence spectrum. The spectrum contains mainly large eddies with frequencies to about two Hertz.

At K a fully developed turbulence spectrum exists. In comparison to G, H, I one can confirm that at first the larger eddies are generated and with increasing intensity more and more smaller eddies are produced until the turbulence is fully developed - as shown in diagram K.

CONCLUSION

The statement, that the maximum of the horizontal diffusion coefficient D_z a short time before and a short time after slack tide is caused by the effects of turbulence - that means the turbulence spectrum becomes more and more uniform containing only large eddies - seems to be verified by the investigations in both models.

As well known the turbulence is of a statistically manner.

Therefore the transportation process is also a statistically process - and one can imagine, that the efficiency of the transport process is also influenced by the rate of uniformity of the eddy size.

And in regard to the mentioned behavior of the horizontal diffusion coefficient, it seems that the increase of the eddy size and the uniformity of the eddies after my opinion cause this phenomenon. But to get sure information about this effect and about the magnitude of this effect for prototype conditions field investigations about the variation of the turbulence spectrum during the whole tidal cycle will be done as soon as possible.

CHAPTER 178

DYNAMICS OF A LONGITUDINALLY STRATIFIED ESTUARY

by

Jorg Imberger*

1. Introduction.

A partially stratified estuary is defined as one which possesses a quite definite longitudinal salinity gradient from the mouth to the head of the estuary, but only a very weak vertical or transverse salinity structure. For an estuary to exhibit such characteristics it must possess a source of fresh water near the head of the estuary, sufficient vertical mixing to overcome the potential energy associated with such a fresh water inflow and be very much longer than its width to reduce transverse variations.

If the estuary is very shallow (a few meters) then wind generated turbulence is often sufficient to eliminate most or all the vertical structure. Deeper, or very sheltered, estuaries require additional strong tidal shears to break up the vertical density gradients. However, in both cases the mixing is usually not sufficient to completely homogenize the estuary longitudinally and it is found that these estuaries display a near linear salinity gradient along the principle axis of the estuary throughout most of the spring and summer months.

Such a density gradient drives a gravitational circulation within the estuary which leads to a net transport of salt from the sea mouth to the head of the estuary. Two dimensional theories (see for instance Rattray and Mitsuda (1974)) have been established, but in general these greatly underestimate the longitudinal transport found in such estuaries and three dimensional circulation effects must be considered.

Fischer (1972) was the first to recognise this fact and he carried out a first order analysis which pointed to a greatly increased longitudinal dispersion. However, Fischer (1972) carried out his analysis only to first order, not explaining how the transverse pressure field, set up by the first order velocity field convecting the longitudinal density gradient, is balanced. It is the purpose of this paper to give a rigorous foundation to Fischer's (1972) hypothesis that it is the transverse variations in velocity which yield the greatest contribution to any longitudinal transport of the density or any passive pollutant. Furthermore, the presented theory is applied to a local Western Australian estuary which is ideally suited for such a comparison complying strictly to the assumptions of the theory.

In order to facilitate the theoretical work the experimental apparatus described in Imberger (1974) was modified and used to visualize the flow. An insulated, completely enclosed perspex tank possessing a triangular section and containing water was heated

*Senior Lecturer, Departments of Mathematics and Mechanical Engineering, University of Western Australia, Nedlands, 6009, W.A.

at one end and cooled at the other. The dimensions of the tank were 2.58 meters long, 0.45 meters wide and 0.05 meters deep at one side and of zero depth at the other. The flow was visualized by the thymol blue technique and the temperature was measured with small thermistors.

The motion was in general difficult to quantify because of its three dimensional nature. However, two features were common to all the motions observed. Firstly, in the central sections of the tank, away from the end walls, the motion was confined to vertical planes, parallel to the longitudinal axis. The warm fluid at the top flowed towards the cold end and the colder undercurrent flowed towards the warmer end wall. In the shallow sections the net flow was towards the cold end wall, while in the deeper parts the net flow was towards the warmer end wall. Secondly, the temperature structure was approximately independent of the transverse coordinate and dependent only on the distance along the longitudinal axis and the depth below the upper surface.

Hence, the experiments indicated that the dominant force balance of such a flow is

$$\epsilon_z \frac{\partial^3 u}{\partial z^3} + \frac{g}{\rho_0} \frac{\partial \rho}{\partial x} = 0, \text{ where } u \text{ is}$$

the longitudinal velocity, ρ is the density, ρ_0 is a reference density, ϵ_z is the vertical mixing coefficient for vorticity, g is the acceleration due to gravity and x and z are the horizontal and vertical coordinates. This balance yields a scale for the velocity u in terms of the longitudinal density gradient $\frac{\partial \rho}{\partial x}$ and a non-dimensionalizing of the full flow equations, based on this force balance, is shown in section 2 to admit a consistent perturbation solution very similar to that described by Cormack, Leal and Imberger (1974).

2. Gravitational circulation in a triangular shaped basin

Consider half of an idealized estuary as shown in figure 1, filled with water which is kept in motion by a longitudinally applied buoyancy flux. The basin is assumed to possess a cover in contact with the water. This is not an essential assumption and a non-conducting free surface could be treated just as easily. The result with regard to the final mass transport is quite insensitive to this boundary condition, yet the pressure field is simplified reducing the algebra somewhat. All sides and top surfaces are considered to be non-conducting and the emphasis will be on investigating the flow in the central sections of the basin where the flow is essentially in the vertical plane. The end regions where the flow is turned are neglected.

From the experiments described in the introduction the following scales are apparent;

$$\text{Density: } \frac{\rho - \rho_0}{\rho_0} = O(\Delta\rho),$$

$$\text{Horizontal length: } x = O(L)$$

$$\text{Transverse length: } y = O(B)$$

$$\text{Vertical length: } z = O(H)$$

$$\text{Horizontal velocity: } u = O\left(\frac{Gr \epsilon_z}{L}\right)$$

$$\text{Transverse velocity: } v = O\left(\frac{B Gr \epsilon_z}{L^2}\right)$$

$$\text{Vertical velocity: } w = O\left(\frac{H Gr \epsilon_z}{L^2}\right),$$

where $\Delta\rho$ is the applied density variation, Gr is the effective Grashoff number $g\Delta\rho H^3/\epsilon_z^2$, ϵ_z the vertical vorticity diffusion coefficient assumed to be constant and g is the acceleration due to gravity.

This suggests introducing the non-dimensional variables:

$$u^* = \frac{u}{\frac{Gr \epsilon_z}{L}}; \quad v^* = \frac{v}{\frac{B Gr \epsilon_z}{L^2}}; \quad w^* = \frac{w}{\frac{H Gr \epsilon_z}{L^2}}; \quad p^* = \frac{p}{\frac{\epsilon_z^2 \rho_0 Gr}{H^2}}$$

$$\theta^* = -\frac{\rho - \rho_0}{\rho_0 \Delta\rho}; \quad x^* = \frac{x}{L}; \quad y^* = \frac{y}{B}; \quad z^* = \frac{z}{H}$$

Interest here centres on very shallow, long estuaries with aspect ratios

$$A_1 = \frac{H}{L}, \quad A_2 = \frac{H}{B} \quad \text{and} \quad A_3 = \frac{B}{L}$$

all being very small. However, for a perturbation scheme to be applicable, these must be ordered. The most realistic limit is obtained by setting

$$A_2 = A, \quad A_1 = \alpha A^2 \quad \text{and} \quad A_3 = \alpha A \quad \text{where}$$

α is the ratio B^2/LH as $H \rightarrow 0, L \rightarrow \infty$. The Boussinesque approximation to the full equations of motion for the mean components of the velocity may thus be written:

$$\alpha^2 A^4 \text{Gr}(u u_x + v u_y + w u_z) = -p_x + \lambda \alpha^2 u_{xx} + \lambda \Lambda^2 u_{yy} + u_{zz}, \quad (1)$$

$$\alpha^4 A^6 \text{Gr}(u v_x + v v_y + w v_z) = -p_y + \alpha^4 \lambda \Lambda^6 v_{xx} + \alpha^2 \lambda A^4 v_{yy} + \alpha^2 A^2 v_{zz}, \quad (2)$$

$$\alpha^4 A^8 \text{Gr}(u w_x + v w_y + w w_z) = -p_z + \theta + \alpha^4 \lambda A^8 w_{xx} + \alpha \lambda^2 A^6 w_{yy} + \alpha^2 A^4 w_{zz}, \quad (3)$$

$$\alpha^2 A^4 \text{GrPr}(u \theta_x + v \theta_y + w \theta_z) = \lambda \alpha^2 A^4 \theta_{xx} + \lambda^2 A^2 \theta_{yy} + \theta_{zz}, \quad (4)$$

$$u_x + v_y + w_z = 0, \quad (5)$$

where $\lambda = \frac{\epsilon_y}{\epsilon_z} = \frac{\epsilon_x}{\epsilon_z}$, $\text{Pr} = \frac{\epsilon_z}{\kappa_z}$ and all asterisks have been dropped.

The scaling has captured the dominant physical processes and an appropriate solution may be sought in the form,

$$\phi(\underline{x}; \Lambda) = \phi_0 + A^2 \phi_2 + \Lambda^4 \phi_4 + \dots, \quad (6)$$

where ϕ represents the variables u, v, w and p .

Substituting this expansion into the above and expanding terms leads to:

$$O(\Lambda^0): \quad p_{0x} - u_{0zz} = 0, \quad (7)$$

$$p_{0y} = 0, \quad (8)$$

$$p_{0z} - \theta_0 = 0, \quad (9)$$

$$\theta_{0zz} = 0, \quad (10)$$

$$u_{0x} + v_{0y} + w_{0z} = 0, \quad (11)$$

$$O(\Lambda^2): \quad p_{2x} - u_{2zz} = \lambda u_{0yy}, \quad (12)$$

$$p_{2y} = \alpha^2 v_{0zz},$$

$$p_{2z} - \theta_2 = 0,$$

$$\theta_{2zz} = -\lambda \theta_{0yy},$$

$$u_{2x} + v_{2y} + w_{2z} = 0,$$

$$O(A^4): \quad p_{4x} - u_{4zz} = -Gr\alpha^2 (u_{00x} + v_{00y} + w_{00z}) + \lambda\alpha^2 u_{0xx} + \lambda u_{2yy}, \quad (17)$$

$$p_{4y} = \lambda\alpha^2 v_{0yy} + \alpha^2 v_{2zz}, \quad (18)$$

$$p_{4z} - \theta_4 = \alpha^2 w_{0zz}, \quad (19)$$

$$\theta_{4zz} = \alpha^2 PrGr (u_{00x} + v_{00y} + w_{00z}) - \lambda\alpha^2 \theta_{0xx} - \lambda\theta_{2yy}, \quad (20)$$

$$u_{4x} + v_{4y} + w_{4z} = 0. \quad (21)$$

The solution to the problem may now be carried out in stages. Consider the zeroth order problem.

Equation (10) implies

$$\theta_0 = f_1(x,y)z + f_0(x,y),$$

but at $z = 0$, $\theta_{0z} = 0$ which requires that $f_1 = 0$.

Also equation (9) together with equation (8) prohibit f_0 to be a function of y . Hence

$$f_0 = f_0(x), \quad (22)$$

where f_0 must be determined from higher order equations and the end boundary conditions.

Eliminating the pressure from equations (9) and (7) yields

$$u_{0zzz} = f_{0x}, \quad (23)$$

which allows u_0 to be determined

$$u_0(y,z) = \frac{h^3}{12} f_{0x} \left(\frac{2z^3}{h^3} + \frac{3z^2}{h^2} + \frac{z}{h} \right) - \frac{6U_0}{h} \left(\frac{z^2}{h^2} + \frac{z}{h} \right), \quad (24)$$

where h is the local depth equal to $-y$ and U_0 is the net volume flux towards the lighter end of the basin. This may be determined from equations (8) and (7) which require

$$u_{0zzy} = 0. \quad (25)$$

The total net flux over the triangular section shall be assumed to be zero, thus substituting equation (24) into equation (25) leads to

$$U_0(y) = \frac{1}{30} \frac{\partial f_0}{\partial x} y^3 \left(1 + \frac{5}{4} y\right) \quad (26)$$

Equation (15) and the no flux boundary at $z = 0$ require that

$$\theta_2 = f_2(x, y), \quad (27)$$

where $f_2(x, y)$ must still be determined.

Integrating equation (20) from $-h$ to zero with respect to z yields

$$-\theta_{4z}(z = -h) = \alpha^2 \text{PrGrf} U_{0x} U_{0x} - 2\alpha^2 f_{0xx} h - \lambda \theta_{2yy} h, \quad (28)$$

which is only possible if

$$f_0 = kx, \text{ where } k \text{ is a}$$

constant - determined by the flow in the end regions. For the two dimensional analogue Cormack, Leal and Imberger (1974) solved the end regions to show that k could itself be expanded in a power series of A . Here k will be taken as experimental data since the three dimensional motion in end regions where the flow turns is far too complex to solve in closed form.

The heat flux $\theta_{4z}(z = -h)$ is strictly non-zero since

Phillips (1970) type boundary layer always exist at a sloping wall in a stratified fluid. However, the heat flux necessary to drive such a layer at small angles is very small, certainly not an appreciable proportion of the flux convected by U_0 and θ_{4z} may thus in the first instance be set to zero at

$z = -h$. If desired a wall boundary layer could be added with small modifications resulting to the main flow.

Setting $\theta_{2y}(y = -1) = 0$ and $\theta_2(y = -\frac{4}{5}) = 0$ completely determines the second order temperature field.

$$\theta_2(y) = -\frac{\alpha^2 \text{PrGr} k^2}{1440\lambda} (3y^5 + 4y^4 + y + 0.1446) \quad (29)$$

Eliminating the pressure from equations (13) and (14) and substituting equation (29) into the resulting equation yields,

$$v_0(y, z) = -\frac{\text{PrGr} k^2}{288\alpha^2} \left(\frac{y^4}{4} + \frac{4}{15} y^3 + \frac{1}{60} \right) (2z^3 - 3z^2y + zy^2) \quad (30)$$

Equation (11) allows a streamfunction $\psi_0(x, y)$ to be defined such that

$$v_0 = \psi_{0z} \quad \text{and} \quad w = -\psi_{0y}$$

From equation (30) ψ_0 may thus be determined

$$\psi_0(y, z) = -\frac{\text{PrGr} k^2}{576 \alpha^2} z^2 (y - z)^2 \left(\frac{y^4}{4} + \frac{4}{15} y^3 + \frac{1}{60} \right). \quad (31)$$

The flow represented by equation (31) is depicted in figure 2 and it consists of two opposing eddies.

Eliminating the pressure from equations (12) and (14) and substituting for u_0 allows u_2 to be determined.

$$u(x, z, y) = \frac{k}{36} (2z^3 - 3z^2y + 2y^2) + \frac{6U_2(x, y)}{y^3} (z^2 - zy) \quad (32)$$

and U_2 may be determined from equations (12) and (13):

$$U_2(y) = \frac{ky^3}{72} \left(y + \frac{4}{5} \right). \quad (33)$$

Finally, substituting u_0 , θ_0 and θ_2 into equation (20) allows the determination of the 4th order temperature field:

$$\theta_4(z, y) = \frac{\alpha^2 \text{PrGr} k^2}{24} \left\{ \left(\frac{z^5}{5} - \frac{z^4 y}{2} + \frac{z^3 y^2}{3} - \frac{y^5}{60} \right) + \frac{z^2}{2} \left(y + \frac{4}{5} \right) (z - y)^2 \right\}, \quad (34)$$

where the integration constant has been chosen so that $\theta_4 = 0$, $z = \frac{1}{2}y$ and $y = -\frac{4}{5}$.

The quantities so far determined allow the mass transfer to be computed correct to $O(A^4)$. Higher order terms may however easily be derived.

3. Longitudinal mass transfer

The convective mass transfer in the x direction is given by

$$\begin{aligned}
 q &= \int_{-B}^0 \int_{-h}^0 \theta u \, dz \, dy = \frac{HBGr\epsilon_z \Delta\rho}{L} \int_{-1}^0 \int_y^0 \theta^* u^* \, dz^* \, dy^* \\
 &= \frac{HBGr\epsilon_z \Delta\rho}{L} \int_{-1}^0 \int_y^0 \{ (\theta^* u^*)^2 + (\theta^* u^*)^4 \} \, dz^* \, dy^* \quad (35)
 \end{aligned}$$

Substituting from section 2 for $\theta_0, u_0, \theta_2, u_2$ and θ_4 and carrying out the integration yields

$$q = - HB D k^3, \quad (36)$$

where

$$D = \frac{\kappa_z \Delta\rho}{L} \frac{\alpha^2 Pr^2 Gr^2 A^2}{\lambda} \{ 1.286 \times 10^{-7} + 6.81 \times 10^{-5} A^2 \lambda + \}.$$

So far the flow has been considered steady, but since there is a net flux from the estuary mouth to the head of the estuary the salinity will build up there. In line with Taylor's (1954) argument it will be assumed that the time scale of this change is large compared to the flow establishment time. Furthermore, if it is also assumed (again following Taylor (1954) that the gradients of $f_0(x)$ are small enough for the above theory to hold, at least, locally, then a mass balance, averaged across any cross-section yields the relationship

$$\frac{dq}{dx} = - \frac{HB}{2} \frac{\partial \theta_0}{\partial t}. \quad (37)$$

Substituting equation (36) into (37) yields an equation for $\theta_0(x)$

$$\frac{\partial \theta_0}{\partial t} = 6D \left(\frac{d\theta_0}{dx} \right)^2 \frac{d^2 \theta_0}{dx^2}, \quad (38)$$

which may be viewed to the equivalent to Taylor's (1954) mean diffusion equation, the only difference being that the tracer here is the salinity itself which also drives the motion. The exact analogy for the two dimensional flow is discussed in more detail in Imberger (1974).

The exact solution of equation (38) is difficult to obtain for a bounded domain $0 < x < L$. For comparison with experimental work it is sufficient to note that equation (38) admits a self similar valid in the unbounded domain

$$\theta = \theta \left(\frac{x^2}{\sqrt{DE}} \right), \quad (39)$$

yielding a time scale for salinity adjustments at the end of an enclosed estuary of the order of

$$T = \left(1.3 \times 10^7 \frac{\Delta\rho L^2 \lambda}{\kappa_z Pr^2 Gr^2 A^2} \right)^{1/3}. \quad (40)$$

4. Application to the Harvey Estuary

The Harvey estuary situated about 80 km south of Perth is a long, shallow coastal lagoon, behind and parallel with the late Pleistocene dunes. Fig. 3 shows the general bathymetry of the basin and indicates the suitability of the Harvey for testing the above theory. The principle axis of the basin is oriented along the direction of the major wind system which blew consistently from the south with a mean velocity of between 6 and 10 km/hr for most of the study period.

The measurements were initiated in July 1974 when the fresh water inflow for the season was at its maximum. The stations at which the salinity and temperature were measured are indicated on fig. 3 and the actual values recorded are listed in table 1. All measurements were recorded from a small dinghy with a standard induction salinometer.

Figure 4 shows the average salinity plotted against distance from station 140 for the period July to April. The fresh water inflow had ceased almost completely by October 1974. Table 2 shows that the variations with depth are indeed small past station 150 consistent with the assumption of a well stirred lagoon. Table 2 lists the comparison of the experimental findings with those predicted from the above theory. All the assumed values of constants are shown and it is seen that the response time for salinity variations at the southern extreme (station 180 and 190) due to applied changes at Station 140 are predicted quite well. Careful probing of the deepest depressions along the central trough showed evidence of pools of saltier water (usually 1 or 2‰ higher) of about 5 to 10 cm thickness underlying the well mixed water above. This indicates that the 1.5 meter depth is on the limit of wind mixing and salt replenishment by salt wedge underflow does take place on the more calm days. It was very difficult to estimate the magnitude of the contribution to the salt transport by this later mechanism as little is known about the entrainment across a density interface under surface waves. However, the lateral extent was no more than 300 meters i.e. 1/10 of the width. Assuming a fully active layer

of thickness $h_0 = 5$ cm with a velocity $(\Delta\rho gh_0)^{1/2} = 0.02$ m sec⁻¹ and a salinity gradient $\Delta\rho/L = 5.5 \times 10^{-8}$ leads to a flux of $O(h_0^2 u_0) = 8.75 \times 10^{-9}$ compared to 1.9×10^{-6} m²sec⁻¹ for the slow circulation mechanism.

4. Acknowledgement

The author would like to thank Mr. Ron Black, Western Australian Institute of Technology, for helping in the collection of the physical data.

CHAPTER 179

INTERFACIAL INSTABILITY IN STRATIFIED FLOW

by

Richard H. French*

I. INTRODUCTION

When heated water from a thermal power plant is discharged onto the free surface of an estuary or river, a density stratified flow consisting of superposed layers of hot and cold water is established. Such a flow is characterized by an initially stable interface at which there is zero velocity difference and a decaying density difference. Since it is known that after the density difference has decayed sufficiently the interface will be destroyed by turbulent eddies generated at the bottom boundary, it is pertinent to inquire if the point of interfacial stability can be easily located. It is the purpose of this paper to examine the question of interfacial stability in the presence of boundary generated turbulence and in the absence of interfacial shear.

Although the problem of interfacial stability has been previously investigated, scant attention has been given to the case of a two layer flow without shear in the presence of boundary generated turbulence. Keulegan (1949) investigated a turbulent current of fresh water moving over a quiescent pool of saline water. He concluded that the stability of the interface could be adequately described by a single dimensionless parameter, the "Keulegan" number:

$$K'_U = \frac{\bar{u}^3}{\nu g \frac{\Delta\rho}{\bar{\rho}}} \quad (1)$$

where \bar{u} is the mean velocity of the upper layer and since the lower layer was at rest, \bar{u} is also the velocity difference across the interface, ν the kinematic viscosity of the lower fluid, $\Delta\rho$ the density difference across the interface, $\bar{\rho}$ the density of the upper, flowing fluid, and g the local acceleration of gravity. Interfacial instability was defined as the point at which the rate of mixing suddenly increased; the critical value of K'_U was found to be 180.

Maxwell, et al (1975) studied arrested thermal wedges and arrested cold water intrusions. They concluded that for arrested thermal wedges an increase in bed roughness caused a corresponding increase in the interfacial friction factor; but in the case of arrested cold water intrusions changes in bed roughness had no effect on the interfacial friction factor. Although others have investigated the problem of interfacial instability; e.g., Sherenkov (1971) and

*Assistant Professor, Hydraulic and Water Resources Engineering, Vanderbilt University, Nashville, Tennessee.

Plate and Friederick (1975), the results have not been conclusive.

In the case of Keulegan's investigation, the critical value of K' should not be viewed as a constant; rather, it is a variable dependent not only on fluid viscosity but also on the turbulence present in the two fluids. Turner (1973, p. 118) has indicated that boundary generated turbulence may cause an interface to become wavy; a condition which leads to interfacial instability at values of K' substantially lower than Keulegan's critical value. Plate and Friederick (1975) have noted that field data demonstrates that in some cases buoyant plumes from thermal power plants are not observed upstream of the outlets even though the densimetric Froude number for the flow is less than one. Destruction of the interface by boundary generated turbulence could account for these observations.

The conclusions of Maxwell, et al (1975) verifies the conclusions of Turner (1973, p. 116-118) regarding the mechanisms of mixing in stratified flows. For an arrested thermal wedge, the mixing is controlled by turbulence generated at the bottom boundary, while in the case of an arrested cold water intrusion, the lower layer is stationary relative to the bottom and no turbulence is generated at the boundary. In the former case, boundary generated roughness is important while in the latter case it is unimportant.

Although these previous investigations have aided in understanding the mechanisms of turbulence generation in layered, stratified flow, they have dealt with arrested wedges rather than the environmentally important case of discontinuous vertical density profiles and continuous vertical velocity profiles. In this case, there is no shear at the interface, and interfacial stability is dependent on the stratification and the turbulence generated at the bottom boundary. In the particular case of a decaying density difference across the interface, an interface which is initially stable may at some point become unstable; and, presently, the literature offers no practical criterion for determining the point of instability.

II. EXPERIMENTS

The experiments for this research were performed in a glass flume 12.2 meters long, 1.2 meters deep, and 0.4 meters wide at the Richmond Field Station of The University of California, Berkeley. The experimental apparatus is shown schematically in Figure 1. The upstream end of the flume was connected to a mixing chamber into which fresh and saline water were injected by diffuser pipes. At the downstream end, there was a vertical slotted weir.

Saline water was injected at the entrance beneath the splitter plate by a 15.2 cm. diffuser pipe which was connected to a constant head tank. This water, which originated in San Francisco Bay, was first pumped to a holding pond (capacity 378 cubic meters), and from the holding pond to the constant head tank. The maximum sustainable saline water flow rate was 0.028 m³/s. Fresh water, supplied by a 10.0 cm. city water main to the fresh water constant head tank, was injected above the splitter plate by a diffuser identical to the one used for the saline water. The maximum sustainable fresh water flow rate was 0.071 m³/s. Within the mixing chamber directional vanes and fine mesh screening were used to damp initial turbulence. Additionally, the walls of the chamber and contracting

Figure 1: Experimental Apparatus

section were brought to glass like smoothness by repeated applications of epoxy paint.

Once a steady flow was established, the fresh water layer was dyed at the flume entrance to identify the position of the interface. At Station 30, ten meters downstream of the flume entrance, a visual determination of interfacial stability was made, and the results were documented by photographing the interface. The photographs were taken with a Hasselblad 500 EL camera using a Zeiss Distagon wide angle lens ($f = 50$ mm.). In addition, vertical salinity and velocity data were gathered at Station 30, and the water surface slope was determined.

Velocities were measured by a pitot-static tube connected to a PACE P7D differential pressure transducer, and the amplified signal of the transducer was recorded on a strip chart for later analysis. A vacuum system attached to the pitot-static tube was used to collect water samples, and the conductivities of these water samples were determined with a Beckman RC-19 conductivity bridge. The conductivities were converted to salinities by interpolation in a table relating temperature and conductivity to salinity, Tiphane (1962); the salinities were converted to densities by the empirical formulas of Eckart (1958).

The bottom boundary shear velocity, u_* , which was considered a direct measure of the turbulence generated at the bottom boundary, was computed by

$$u_* = \sqrt{gRS_f} \quad (2)$$

where R is the hydraulic radius and S_f the slope of the energy grade line. Since the bottom of the flume was horizontal, S_f was taken as the slope of the free surface. Although the sides of the flume were glass, the bottom was roughened by placing angular stones, approximately $2.5 \times 1.2 \times 1.2$ cm, by hand in a single layer of uniform surface height. The value of u_* calculated by Equation (2) was adjusted by the method of Vanoni and Brooks (1957) to account for the fact that the boundary roughness was not uniform; i.e., while the bottom boundary was hydraulically rough, the side walls were hydraulically smooth.

A wide range of depths and salinities were used; the input salinity was limited to a maximum of 20 ‰, because the source of the saline water was San Francisco Bay which never became more saline. The minimum salinity was 2 ‰ because at lower salinities the mixing was so strong that the flow quickly became homogeneous.

III. EXPERIMENTAL RESULTS

Before describing the experimental results, three terms must be defined in the context of this research.

Stable Interface (Figure 2): A density interface between two homogeneous fluids of different densities across which little or no mixing takes place. In Figure 2, the interface is seen as a sharp line crossed by no noticeable eddies. In this situation, the interface will remain sharp, and the flow will remain layered.

Figure 2: Stable Interface

Figure 3: Unstable Interface

Figure 4: Transition Interface

Unstable Interface (Figure 3): This term specifies a density interface across which there is active mixing. In Figure 3, there are large, violent eddies crossing the interface in both directions; and after a finite period of time, the sharp interface will be destroyed and a continuous system of stratification established.

Transition Interface (Figure 4): This term specifies the case where the interface can be considered neither stable nor unstable. In Figure 4, although there are eddies crossing the interface, they are neither as large nor as violent as those in Figure 3; and it is not clear that the turbulence is of sufficient magnitude to completely destroy the interface.

It was assumed that in a stratified, two layer flow where the turbulence was primarily generated at the bottom boundary the stability of the interface was a function of $(u_*, \bar{u}, D, g \frac{\Delta\rho}{\rho}, \nu)$ where u_* is the corrected bottom boundary shear velocity, \bar{u} the average velocity of the flow, D the total depth of flow, g the acceleration of gravity, $\frac{\Delta\rho}{\rho}$ the maximum change in density across the flow, $\bar{\rho}$ the average density of the flow, and ν the kinematic viscosity of the flow. From this array of variables, the Buckingham Π - theorem states that three dimensionless groups can be formed:

$$R_0 = \frac{g \frac{\Delta\rho}{\rho} D}{u_*^2} \tag{3}$$

$$K_u = \frac{\nu g \frac{\Delta\rho}{\rho}}{\bar{u}^3} \tag{4}$$

and

$$\frac{u_*}{\bar{u}} \tag{5}$$

R_0 is the ratio of the fractional change in buoyancy across the flow and the depth of flow to the turbulent energy generated at the bottom boundary. As defined by Equation (4), the Keulegan number, K_u , is the inverse product of a Reynolds number, $RR = \frac{\bar{u}D}{\nu}$, and a densimetric Froude number, $FF_D^2 = \frac{\bar{u}^2}{g \frac{\Delta\rho}{\rho} D}$; i.e.,

$$K_u = \frac{1}{RR FF_D^2} \tag{6}$$

The experimental data are tabulated in Table 1. It should be noted that in most cases the friction factor associated with the bottom, f_b , was substantially larger than the friction factor associated with the glass walls, f_w . It is also noted that f_b varied over a wide range of values, apparently as a function of the Reynolds number; however, the correlation between f_b and R is very low. Thus, it is hypothesized that the variation in f_b must be either due to random experimental error or the effects of the stratification.

Interfacial stability is plotted in Figure 5 as a function of R_b and K_u . In this figure, the "line" delineating the zone of unstable interfaces from the zone of stable interfaces -- the line is the zone of transition interfaces -- is well-defined and slopes downward from left to right. In addition, three points extracted from field data gathered by Motz and Benedict (1971) downstream from the Widows Creek (Alabama) Steam Plant are plotted. The first point is near the point where the thermal plume enters the Tennessee River, and the third point is approximately one mile downstream. Point one clearly represents either a stable or transitional interface and at point three sufficient heat has been lost that the interface is unstable.

Figure 6 demonstrates the dependence of the results on the parameter $\frac{u^*}{\bar{u}}$; i.e., the data plotted in Figure 5 consists of a family of curves with a separate curve for each value of $\frac{u^*}{\bar{u}}$. In Figure 6, small values of $\frac{u^*}{\bar{u}}$ are seen to correspond to relatively large values of K_u , and large values of $\frac{u^*}{\bar{u}}$ correspond to small values of K_u . Thus, the zone of transition interfaces is a band intersecting the $\frac{u^*}{\bar{u}}$ curves.

IV. CONCLUSION

When the bottom boundary is the primary source of turbulence, Figure 5 demonstrates that it is possible to classify the stability of density interfaces between homogeneous fluids on the basis of two dimensionless parameters, R_b and K_u . This system includes the densimetric Froude number, which has previously been the sole criteria of interfacial instability, and a term which accounts for the generation of turbulence at the bottom boundary. Field verification of the results presented here is presently being sought, and it is hoped that once this is accomplished these results will be of use in analyzing the effects of non-conservative stratifying agents discharged into the environment.

CHAPTER 180

NUMERICAL MODELING OF DISPERSION IN STRATIFIED WATERS

by

George C. Christodoulou¹

Jerome J. Connor²

ABSTRACT

A numerical model is developed for the quantitative description of the dispersion process in a two-layer system which represents an approximation for a natural coastal water body during the summer season when a distinct thermocline usually exists. The formulation is based on the convection-diffusion equation, vertically integrated between the layer boundaries. Layer velocities and thicknesses are assumed to be obtained from a separate hydrodynamic model. The quantification of the physical processes of entrainment and mixing through the density interface as well as the horizontal dispersion mechanisms is discussed.

The finite element method is chosen for numerical implementation because of its flexibility in grid layout and easier handling of spatial and temporal variability. Triangular elements with linear interpolation functions are used for the spatial discretization, while a simple implicit iterative scheme based on the trapezoidal rule is employed for time integration. The method is shown to be unconditionally stable, for an arbitrary grid and both one- and two-layer problems, when there is no iteration and the parameters are constant. General convergence criteria required by the iteration procedure are developed and expressed in terms of the basic parameters of the problem and are subsequently confirmed by numerical experiments. Verification of the model is performed by comparison with analytical solutions derived for counterflow conditions. Finally the model is applied to a particle dispersion experiment carried out recently in the Massachusetts Bay and comparisons with field data are presented.

INTRODUCTION

Coastal dispersion problems have received considerable attention in recent years, due to the rapid growth in the development of the coastal zone and the increasing concern for the impact on the coastal environment. Mathematical models of the hydrodynamic processes involved have been developed in the past based on the assumption that flow parameters and concentrations are approximately uniform over the water column, resulting in a depth-averaged treatment of the problem. This approach is justified to some extent by the characteristic shallowness of coastal water bodies, as compared to their horizontal dimensions. However, the assumption of uniformity is no longer valid during the summer season, when a significant stratification usually exists.

The presence of a strong thermocline suggests the idealization of the flow field as a two-layer system. This is the simplest stratified case and it is felt that it has to be studied prior to proceeding to a multilayer approach, for understanding the fundamental physical behavior of dispersion in a layered system. Multilayer or quasi-three dimensional models of the transport of constituents are presently being incorporated into large multipurpose computer codes [1, 8, 9] utilizing finite difference techniques. Such models will require difficult and costly verification studies and extensive field data (especially boundary conditions) for their proper application to a given area. A simpler two-layer model needs less "tuning" and is much more economical, while still providing a good approximation to the actual conditions when a distinct thermocline exists.

In this paper, problems associated with properly describing the dispersion of matter in a two-layer system are investigated. First, the mathematical formulation is presented and the modeling of the physical processes involved is discussed. Then, the details of the finite element method are examined and, in particular, its stability requirements in this class of problems are established. Lastly, the applicability of the numerical model to real world problems is addressed.

MATHEMATICAL FORMULATION

The present model is intended to describe the dispersion of an arbitrary constituent, possessing vertical mobility, in a two-layer coastal water body of variable bottom topography and boundary geometry. The velocity field in both layers as well as the layer thicknesses will be assumed known, presumably

obtainable through a separate hydrodynamic model. By uncoupling the hydrodynamic and dispersion models, the same flow pattern can be used to investigate very economically the spreading of several different substances and to experiment with different source locations, loading strategies, parameter values, etc. However, this can only be done provided that the constituent of interest does not affect significantly the flow field or the density structure.

The mass balance of a constituent is expressed by the 3-D convection-diffusion equation:

$$\frac{\partial c}{\partial t} = - \frac{\partial}{\partial x} (uc+q_x) - \frac{\partial}{\partial y} (vc+q_y) - \frac{\partial}{\partial z} ((w-w_s)c+q_z) + p \tag{1}$$

where

- u, v, w are the water velocities in the x,y,z directions
- w_s is the particle settling velocity, positive downward
- q_x,q_y,q_z are diffusive fluxes in the x,y,z directions
- p represents generation or decay of the constituent

Integrating between the layer boundaries (Figure 1) and using Leibnitz's rule, one obtains for the top layer

$$\begin{aligned} \frac{\partial c}{\partial t} \int_{-h_1}^{\eta} cdz = & - \frac{\partial}{\partial x} \int_{-h_1}^{\eta} (uc+q_x) dz - \frac{\partial}{\partial x} \int_{-h_1}^{\eta} (vc+q_y) + \int_{-b_1}^{\eta} pdz \\ & + [c(\frac{D\eta}{Dt} - w+w_s) - q_s]_{\eta} + [c(\frac{Dh_1}{Dt} + w-w_s) - q_i]_{-h_1} \end{aligned}$$

Figure 1: The Two-Layer Idealization

The terms in brackets represent fluxes through the free surface and interface, respectively. The kinematic condition at the surface requires

$$\left[\frac{D\eta}{Dt} - w \right]_{\eta} = 0$$

However, the interface, defined as the position of steepest density gradient, is not necessarily a material surface. We may write in general

$$\left[w + \frac{Dh_1}{Dt} \right]_{-h_1} = w_e$$

and refer to the relative velocity, w_e , of the water particles with respect to the layer boundary as "entrainment" velocity. This is considered positive when directed upward, indicating net water motion from the bottom to the top layer. The other component, q_i , of the interfacial transport is a diffusive flux and can be expressed in terms of the difference in concentration between the layers. Approximating the concentration at the interface as the average value of the two layers, the overall transfer is expressed as:

$$Q_{21} = (w_e - w_s) c_{-h_1} - q_i = (w_e - w_s) \frac{c_1 + c_2}{2} + \alpha(c_2 - c_1) \quad (2)$$

In large water bodies, the erosion of the quiescent lower layer by the upper layer, moving under the influence of wind or other driving mechanism, is explained by the one-way transport of water toward the turbulent layer.

In coastal areas, both layers are quite turbulent and possess velocities of the same order of magnitude, hence water exchange both ways through the interface should be anticipated. Denoting the respective volumetric rates per unit area by m_{21} and m_{12} (Figure 2), the net transfer of material is:

$$Q_{21} = m_{21}c_2 - m_{12}c_1 \quad (3)$$

By comparing Equations (2) and (3) it is evident that

$$w_e = m_{21} - m_{12} \quad (4a)$$

$$\alpha = (m_{21} + m_{12})/2 \quad (4b)$$

Several experimental and theoretical investigations in 1-D two-layer systems have been carried out in the past mostly with one layer quiescent, as reviewed in [3, 15, 11]. The one-way rate of transport, usually measured by the thickening of the moving layer, has been expressed with different velocity and length scales so that at first only a qualitative agreement between them is evident. Upon careful examination, however, it may be seen [5] that a rather general expression in terms of the mean flow characteristics can be given, as follows:

$$m_{ji} = \frac{10^{-3} U_i}{Ri_o} \quad i, j = 1, 2 \quad (5)$$

where the overall Richardson number for a 2-D flow is defined as

$$Ri_o = \frac{g \frac{\Delta \rho}{\rho} H}{(\bar{u}_i - \bar{u}_j)^2}$$

where H is the average layer thickness, i.e., half the depth.

Figure 2: Schematization of Interfacial Transport

We introduce now the following notation

$$C_1 = \int_{-h_1}^{\eta} c dz = \bar{c}_1 H_1$$

$$u = \bar{u} + u'', v = \bar{v} + v'', c = \bar{c} + c''$$

where the overbar denotes layer average value and the double prime spatial deviation from that average. Then, Equation 2 takes the form

$$\frac{\partial C_1}{\partial t} + \frac{\partial}{\partial x} (\bar{u}_1 C_1) + \frac{\partial}{\partial y} (\bar{v}_1 C_1) = - \frac{\partial}{\partial x} Q_{x_1} - \frac{\partial}{\partial y} Q_{y_1} + P_1 \tag{6}$$

where P_1 includes source, decay and interfacial flux terms, and the total dispersive fluxes Q_{x_1}, Q_{y_1} are approximated as follows:

$$Q_{x_1} = - \int_{-h_1}^{\eta} (u'' c'' + q_x) dz = H_1 (E_{xx_1} \frac{\partial \bar{c}_1}{\partial x} + E_{xy_1} \frac{\partial \bar{c}_1}{\partial y}) \tag{7a}$$

$$Q_{y_1} = - \int_{-h_1}^{\eta} (v'' c'' + q_y) dz = H_1 (E_{yx_1} \frac{\partial \bar{c}_1}{\partial x} + E_{yy_1} \frac{\partial \bar{c}_1}{\partial y}) \tag{7b}$$

The dispersion coefficients

$$\underline{E} = \begin{bmatrix} E_{xx} & E_{xy} \\ E_{yx} & E_{yy} \end{bmatrix} = \underline{E}^d + \underline{\epsilon}$$

comprise a second order tensor consisting of a shear-dispersion part and an eddy diffusivity part. The analogy of the effective horizontal spreading due to nonuniformity of the velocity profile to the turbulent diffusion process has

been shown initially by G.I. Taylor [14] for flow through a pipe and later by Elder [7] for flow in an open channel. By extending their arguments to the case where both u and v velocity components are present, one may prove the validity of Eqs.(7a, b) with shear dispersion coefficients given by [5]:

$$E_{xx}^d = \frac{1}{H} \int_0^H \frac{1}{\epsilon_x} \left[\int_0^H u'' d\zeta \right]^2 dz \quad (8a)$$

$$E_{yy}^d = \frac{1}{H} \int_0^H \frac{1}{\epsilon_z} \left[\int_0^H v'' d\zeta \right]^2 dz \quad (8b)$$

$$E_{xy}^d = E_{yx}^d = \frac{1}{H} \int_0^H \frac{1}{\epsilon_z} \left[\int_0^H u'' d\zeta \right] \left[\int_0^H v'' d\zeta \right] dz \quad (8c)$$

where ϵ_z is the vertical eddy diffusion coefficient.

The horizontal turbulent diffusion term accounts for mixing due to horizontal eddies. Based on the theory of locally isotropic turbulence, the well-known 4/3 law is derived. According to [12]

$$\epsilon = b e^{1/3} L^{4/3} \quad (9)$$

where

e is the rate of energy input

L is a length scale and

b is a numerical constant of order 0.1.

As the cloud size increases, larger scale motions are being incorporated into the diffusion term, explaining the length dependence of the diffusion coefficient. It should be clear, however, that this depends on the detail of specification of the advection processes. In the case that the velocity field is specified at certain grid points and the cloud increases beyond the level of discretization, internal mixing is now (partly) described by the advection terms, and hence the length scale of Equation (3) should be related to the grid size.

An alternative expression for ϵ , based on mixing length arguments, is [2,6]:

$$\epsilon = L^2 \sqrt{\phi} \quad (10)$$

where

$$\phi = 2 \left(\frac{\partial \bar{u}}{\partial x} \right)^2 + 2 \left(\frac{\partial \bar{v}}{\partial y} \right)^2 + \left(\frac{\partial \bar{u}}{\partial y} + \frac{\partial \bar{v}}{\partial x} \right)^2$$

This has the advantage of using the readily available mean velocity gradients instead of the energy input. According to [6], the sub-grid scale eddy coefficient is modeled by a length scale an order of magnitude smaller than

the grid size. However, the resolution of the flow field description associated with spatial averaging in the hydrodynamic model employed has to be taken into account and the coefficient increased accordingly.

THE FINITE ELEMENT METHOD

For each layer, the governing equation has the form (6). The boundary conditions are (Figure 3)

- 1) Essential, i.e., the concentration is specified on the boundary segment S_c : $C = C^*$
- 2) Natural, i.e., the normal concentration gradient, or, equivalently, the normal dispersion flux, is specified on the boundary segment S_q :

$$Q_n = Q_n^*$$

Figure 3: Solution Field and Boundary Conditions

In seeking an approximate solution, the partial differential equation and the flux boundary condition are multiplied by a weighting function (w) and the residual R over the domain is required to vanish:

$$R = \iint_A \left\{ \frac{\partial C}{\partial t} + \frac{\partial(\bar{u}C)}{\partial x} + \frac{\partial(\bar{v}C)}{\partial y} + \frac{\partial}{\partial x} Q_x + \frac{\partial}{\partial y} Q_y - P \right\} w dA + \int_{S_q} (Q_n^* - Q_n) w dS = 0 \quad (11)$$

Employing partial integration, this is rewritten as

$$R = \iint_A \left[\left\{ \frac{\partial C}{\partial t} + \frac{\partial}{\partial x}(\bar{u}C) + \frac{\partial}{\partial y}(\bar{v}C) - P \right\} w - Q_x \frac{\partial w}{\partial x} - Q_y \frac{\partial w}{\partial y} \right] dA + \int_{S_q} Q_n^* w dS = 0 \quad (12)$$

It should be mentioned that the trial function C is required to satisfy the essential boundary condition and the weighting function to satisfy the homogeneous form, i.e., $w = 0$ on S_c .

Expression (12) is called the symmetrical weak form and involves only first derivatives of both trial and test functions, which can therefore be chosen from the same solution space. In the finite element method the domain is subdivided into elements and the total residual is evaluated as the sum of element residuals. By introducing interpolation functions within each element, the continuous problem is transformed to a discrete one, with the concentrations at the nodal points as unknowns. Triangular elements with linear interpolation functions are used herein, as in the one layer model [10]. Setting

$$C = \underline{N} \underline{C}^e \quad w = \Delta C = \underline{N} \Delta \underline{C}^e$$

the element residual becomes:

$$\underline{R}^e = (\Delta \underline{C}^e)^T \left(\underline{M}^e \frac{d \underline{C}^e}{dt} - \underline{P}^e \right) + (\Delta \underline{C}^e)^T \underline{F}^{be} \quad (13)$$

where

$$\underline{M}^e = \iint_A \underline{N}^T \underline{N} dA \quad (14a)$$

$$\underline{P}^e = \iint_A \left[\underline{N}^T \left(P - \frac{\partial}{\partial x} (\bar{u}C) - \frac{\partial}{\partial y} (\bar{u}C) + \frac{\partial \underline{N}^T}{\partial x} Q_x + \frac{\partial \underline{N}^T}{\partial y} Q_y \right) \right] dA \quad (14b)$$

$$\underline{F}^{be} = \int_{S_q} \underline{N}^{bT} Q_n^* dS \quad (14c)$$

Carrying out the summation over all elements for each layer results in:

$$\underline{R} = \sum_e \underline{R}^e = (\Delta C)^T (\underline{M} \dot{C} - \underline{P} + \underline{F}^b) = 0$$

and since ΔC is arbitrary,

$$\underline{M} \dot{C} = \underline{P} - \underline{F}^b = \hat{\underline{P}} \quad (15)$$

This constitutes a set of linear ordinary differential equations and is integrated by using an implicit iterative trapezoidal scheme, as follows:

$$\underline{C}_{1,t+\Delta t}^{(i+1)} = \underline{C}_{1,t} + \frac{\Delta t}{2} \underline{M}^{-1} (\hat{\underline{P}}_{1,t+\Delta t}^{(i)} + \hat{\underline{P}}_{1,t}^{(i)}) \quad (16a)$$

$$\underline{C}_{2,t+\Delta t}^{(i+1)} = \underline{C}_{2,t} + \frac{\Delta t}{2} \underline{M}^{-1} (\hat{\underline{P}}_{2,t+\Delta t}^{(i)} + \hat{\underline{P}}_{2,t}^{(i)}) \quad (16b)$$

Since the geometrical matrix \underline{M} is time-invariant it has to be inverted only once. By lumping all other terms in the $\hat{\underline{P}}$ vector, maximum flexibility in handling time variability of any or all of the relevant parameters and loadings is achieved. In addition, any non-linear relations of the various terms to the concentrations can be readily handled in this way. In practice, the iteration

continues until either the change in concentration between current and previous values is below a specified tolerance or the number of iterations reaches an imposed upper limit.

STABILITY ANALYSIS

Expanding the \hat{P} vector leads to the following form of the matrix equation for each layer

$$\tilde{M}\tilde{C} + \tilde{A}\tilde{C} + \tilde{K}\tilde{C} + \tilde{D}\tilde{C} = \tilde{S} \quad (17)$$

where \tilde{A} is associated with advection, \tilde{K} with dispersion, \tilde{D} with decay and \tilde{S} includes sources and boundary conditions. The trapezoidal integration rule is expressed as follows

$$\begin{aligned} \left[\tilde{M} + \frac{\Delta t}{2}(\tilde{A} + \tilde{K} + \tilde{D}) \right] \tilde{C}_{n+1} &= \left[\tilde{M} - \frac{\Delta t}{2}(\tilde{A} + \tilde{K} + \tilde{D}) \right] \tilde{C}_n \\ &+ \frac{\Delta t}{2}(\tilde{S}_n + \tilde{S}_{n+1}) \end{aligned} \quad (18)$$

To investigate the stability of the scheme, we consider the homogeneous case, i.e., $\tilde{S}_n = \tilde{S}_{n+1} = 0$, and assume the various matrices are constant over the time step. We note that the geometrical, decay, and dispersion matrices, being composed of individual symmetric positive definite sub-matrices, also have these properties. Continuity considerations and the compatibility of inter-element velocity expansions [5], leads to:

$$\tilde{A}\tilde{C} = -\tilde{A}^T\tilde{C} + \int_{S_q} u_n N^b N^b dS \tilde{C}^b \quad (19)$$

where the superscript b denotes boundary quantity and u_n is the velocity normal to the boundary (positive outwards). Writing the advection matrix as the sum of a symmetric and a skew-symmetric part

$$\tilde{A} = \tilde{A}_s + \tilde{A}_{ss}$$

it is seen that the former usually vanishes since normally S_q refers to land boundaries where the normal velocity is zero.

By writing

$$\tilde{C}_{n+1} = a \tilde{C}_n \quad (20)$$

where a is the amplification matrix, one may set

$$\tilde{C}_n = \lambda^n \phi \quad (21)$$

where λ is an eigenvalue of a .

The necessary condition for stability is

$$||a|| < 1 \text{ or } |\lambda| < 1$$

Substituting (21) into the homogeneous form of (18), premultiplying by $\tilde{\Phi}^T$ and noting that, according to the above discussion

$$\begin{aligned}\tilde{\Phi}^T \tilde{M} \tilde{\Phi} &= m > 0 \\ \tilde{\Phi}^T \tilde{K} \tilde{\Phi} &= \kappa > 0 \\ \tilde{\Phi}^T \tilde{D} \tilde{\Phi} &= d > 0 \\ \tilde{\Phi}^T \tilde{A} \tilde{\Phi} &= ia_{ss}\end{aligned}$$

we obtain for λ

$$\lambda \left\{ m + \frac{\Delta t}{2} (\kappa + d + ia_{ss}) \right\} = m - \frac{\Delta t}{2} (\kappa + d + ia_{ss})$$

or,

$$\lambda^2 = \frac{\left[m - \frac{\Delta t}{2} (\kappa + d) \right]^2 + a_{ss}^2}{\left[m + \frac{\Delta t}{2} (\kappa + d) \right]^2 + a_{ss}^2} < 1 \quad (22)$$

This indicates that the scheme is unconditionally stable for an arbitrary grid.

However, the time step is always limited by the desired detail of description of the time variability of inputs or parameters of the problem. When the matrices \tilde{K} , \tilde{D} , \tilde{A} are actually variable, it becomes uneconomical to form and invert matrices of the form $\tilde{M} + \frac{\Delta t}{2} (\tilde{A} + \tilde{K} + \tilde{D})$ every time-step. This is a basic reason for resorting to the iteration procedure discussed earlier, which may be written in expanded form:

$$\tilde{C}_{n+1}^{(i+1)} = \left[\tilde{M} - \frac{\Delta t}{2} (\tilde{A} + \tilde{K} + \tilde{D}) \right] \tilde{C}_n - \frac{\Delta t}{2} (\tilde{A} + \tilde{K} + \tilde{D}) \tilde{C}_{n+1}^{(i)} \quad (23)$$

For convergence of the iteration, however, a restriction on the time step is required. The general sufficient condition

$$\left| \left| \tilde{M}^{-1} \frac{\Delta t}{2} (\tilde{A} + \tilde{K} + \tilde{D}) \right| \right| < 1 \quad (24)$$

leads to

$$\Delta t < \frac{2}{\left| \left| \tilde{M}^{-1} (\tilde{A} + \tilde{K} + \tilde{D}) \right| \right|}$$

or, the more restrictive condition:

$$\Delta t < \frac{2}{\left| \left| \tilde{M}^{-1} \tilde{A} \right| \right| + \left| \left| \tilde{M}^{-1} \tilde{K} \right| \right| + \left| \left| \tilde{M}^{-1} \tilde{D} \right| \right|} \quad (25)$$

Unfortunately, (25) is not practical in this form, since one does not have an explicit relation between the time step and the parameters of the problem. An approximation to it can be obtained by considering a single element only, forming the matrices and evaluating their norms, i.e., their eigenvalues. For uniform velocity U , isotropic dispersion E and decay rate k , the resulting expression for an equilateral triangle of size Δs is [5]:

$$\Delta t < \frac{1}{\sqrt{\frac{3}{2}} \frac{U}{\Delta s} + \frac{8E}{\Delta s^2} + \frac{k}{2}} \quad (26)$$

This was obtained using the average eigenvalue of the $\underline{M}^{-1}\underline{K}$ matrix. The same result is arrived at for a right triangle, when the flow is parallel to one of the legs of the right angle, of size Δs . The conclusions reached at the element level can be conservatively generalized for the whole domain, provided the "worst case" element is considered.

A similar analysis for the two-layer problem shows that the time integration scheme is again unconditionally stable, with no iteration. The latter requires a restriction on the time step analogous to (25). Another term has now to be added in the denominator to account for interfacial mixing, i.e., $||\underline{M}^{-1}\underline{E}||$. Evaluating this term for a single triangle results in the addition of $\alpha'/2$ in the denominator of (26), where α' is the interfacial mixing rate normalized by the layer thicknesses. This term is usually small and consequently the time step is essentially governed by the "worst" layer.

Experimental confirmation of condition (26) was attempted by means of test runs carried out in the 1-D grid shown in Figure 5. The contribution of the decay term was of the order of 1% and thus neglected. For each run, a point was plotted on the plane of the non-dimensional coordinates $(U\Delta t/\Delta s, E\Delta t/\Delta s^2)$. These points are shown in Figure 4 along with the theoretical bound (26). The symbols used are defined in Table 1. It is seen that runs corresponding to points within the "safe" area always converge well, while outside the theoretical boundary more or less significant errors are present, eventually leading to instability a little further outside. Further, the line $E/U\Delta s = 1/2$ is seen to exactly separate runs with and without significant upstream negatives and spatial oscillations due to the approximation of steep concentration gradients. This condition, analogous to finite difference schemes, was derived theoretically [5] and earlier empirically [10]. Thus, accuracy considerations actually reduce the acceptable area to a fraction of the safe region for iteration convergence. Additional runs, carried out in 2-D test grids, as well as grids of natural water bodies, compiled in [5], show the theoretical limit to be still approximately valid.

VERIFICATION AND APPLICATIONS

To test the correctness of the model structure, comparisons with analytical solutions are desirable. However, the availability of analytical solutions is restricted to very simple flow conditions. In Figure 6, the numerical model is compared with the solution for an instantaneous point source in the top layer of a 1-D counterflow. A unit load is distributed between the three nodes at $x = 0$

Figure 4 Comparison of Theoretical Bound on the Time Step with 1-D Runs

Table 1
Definition of Symbols used in Figure 4

Symbol	Error after 10 Iterations	Negatives as Percent of Peak	Remarks
o	< 1%	< 10%	Good, smooth solution
●	< 1%	> 10%	Iteration converges well, but result exhibits oscillations
Δ	< 10%	< 10%	Iteration error goes down rapidly as time proceeds
▲	< 10%	> 10%	
+	> 10%	< 10%	It. Error does not always decrease rapidly (some may eventually blow up)
x	> 10%	> 10%	
⊙	—	—	Blows up

of the grid of Figure 5, and the results adjusted to yield values per unit width of the channel. A unit depth is assumed for each layer. Zero concentration is specified at the ends of the grid and zero flux is prescribed along the side boundaries. The parameters used are

$$\begin{aligned}U_1 &= -U_2 = 0.05 \text{ m/sec} \\E_1 &= E_2 = 0.01 \text{ m}^2/\text{sec} \\ \alpha &= 5 \times 10^{-4} \text{ m/sec} \\ \kappa &= 0\end{aligned}$$

It may be observed from Figure 6 that the lower layer concentrations are two orders of magnitude smaller than those of the top layer. This supports to some extent the treatment of the interface as a barrier. However, it may not hold for longer time periods and is certainly not valid for substances possessing vertical mobility. Irrespective of that, it should be clear that a great advantage of the two-layer treatment is the more detailed description of the velocity field. In this particular counterflow case the depth-average velocity is zero, implying a stationary peak of the depth-averaged concentration distribution located at the origin. As shown in Figure 6, this is far from the actual depth-averaged concentration distribution of the two-layer system. Further verification studies can be found in [5].

To establish confidence in the predictive capability of the model and the degree of its applicability under natural conditions, further verification, consisting of comparisons to real-world cases, is necessary. For this purpose a dispersion experiment was carried out by M.I.T., sponsored by the Boston Edison Co., in the vicinity of the Pilgrim Nuclear Power Station (PNPS) on the Massachusetts coast (Figure 7) in August 1975. Five hundred pounds of small fluorescent sphalerite (ZnS) particles were introduced into the water and their motion subsequently monitored for 5 days by boat and by helicopter. Also, two current meter stations had been installed prior to the experiment as indicated in Figure 7 by dots.

The finite element grid used was the same as in the previous applications of one-layer models to the Bay. The value of the dispersion coefficient, $30 \text{ m}^2/\text{sec}$, and the difference in tidal amplitude between the ends of the open boundary, were kept the same as established for the one-layer models [13]. The circulation model used to obtain velocity inputs is that of Wang and Connor [16]. Since it requires both layers to extend over the whole domain, some nodal depths had to be increased

Figure 5 One-dimensional Finite Element Test Grid

Figure 6 1-D Distribution at $t=10$ sec. after an Instantaneous Injection

to at least 15 m in order to avoid intersection of the interface with the bottom. The position of the interface was set at 8 meters as initial condition, consistent with available information [4]. However, much more detailed data are needed for the specification of interface motion along the ocean boundary. In view of lack of such data at present, the interface was assumed to be linear along the boundary and various cases, e.g. remaining fixed over the tidal cycle or moving with the same amplitude as the free surface, were examined. Actual time-varying wind data were used in the computations.

Figure 7 Mass. Bay Finite Element Grid and Location of the MIT Experiment

The experimental results were reduced to layer-average concentrations by averaging together samples taken above and below the thermocline to yield a single representative value for each layer. The resulting plots, in particles/lt, are shown in Figures 8 and 9 corresponding to 2 and 3 days after the dumping took place. The plume is seen to move slowly to the southeast, approximately parallel to the shore and later extending to the east.

In the dispersion simulations the shaded triangle was loaded over a period of three timesteps. The area of the triangle is quite large in comparison to the actual source and as a consequence one should expect unrealistically large plume areas for short times. The interfacial mixing rate is set at 10^{-5} m/sec and the settling velocity at 7.3×10^{-5} m/sec, based on an average particle size of 7 microns. The computed concentrations 2 and 3 days after the injection are shown in Figures 10 and 11. Taking into account the initial spreading of the source, good qualitative agreement with respect to the size and location of the plume as well as the peak values is observed.

CONCLUSION

The objective of this study was to investigate the problem of dispersion in coastal water bodies under conditions of strong stratification. The two-layer idealization was adopted as a useful extreme case and, at the same time, the easiest to handle mathematically. The ability of the two-layer treatment to handle transport between the layers is important, whether or not the constituent of interest has some vertical mobility, in providing a refined picture of the distribution over the depth. A further advantage of the two-layer formulation, evident from both ideal and real-world applications, lies in the more detailed description of the velocity field. However, the sensitivity of the results to variations in the flow field points out the necessity for using realistic current input.

Additional fundamental research is needed for better understanding the turbulent mixing processes in stratified environments. Also, field monitoring programs are required to provide reliable inputs, primarily on the behavior of the interface along open boundaries of the domain under consideration. It is believed that the present two-layer model, providing an extreme-case picture of the response of the physical system, can be a useful tool in coastal dispersion studies.

CHAPTER 181

DETERMINATION OF THE INTERFACIAL EDDY DIFFUSION COEFFICIENT OF A HIGHLY STRATIFIED ESTUARY

by

Yu - Hwa Wang*

INTRODUCTION

Estuaries may be sequentially classified into highly stratified, moderately mixed and vertically homogeneous. An important difference between moderately stratified or vertically homogeneous estuaries, and highly stratified estuaries (salt wedges) is that, in the former, tidal currents are sufficient to cause turbulent mixing of fresh water and sea water over the full depth of the estuary. In the latter, a distinct interface or interfacial layer exists which separates the two nearly homogeneous layers. The vertical advection of salt in this two-layer flow is the dominant process in maintaining the salt balance. This paper presents an analytical model describing this process. Experiments have been conducted in the laboratory to compare with the developed theory.

A large number of publications concerning estuarine dynamics are available for moderately mixed and vertically homogeneous estuaries. Relatively little information, however, is available for highly stratified estuaries. In an earlier work Keulegan (1949) defined the critical velocity of the upper layer at which the entrainment of the salt water layer starts. A summary of Keulegan's work may be found in Chapter 11 of the book, "Estuary and Coastal Hydrodynamics" edited by Ippen (1966). Recently Partheniades *et. al.* (1975) reviewed Schijf-Schonfeld's analytical work and Keulegan's experimental data with regard to the length, shape and shear stresses of a saline wedge. Wang (1975) compared his laboratory measurements of interfacial stresses with Lock's Theory.

THEORETICAL DEVELOPMENT

For a steady, incompressible, viscous, two-layer, stably stratified estuarial type flow, the governing equations are:

$$u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = \nu \frac{\partial^2 u}{\partial y^2} \quad \text{Bottom Layer (1)}$$

*Assistant Professor of Coastal Engineering, University of Florida, Gainesville, Florida, 32611

$$u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = v_2 \frac{\partial^2 u}{\partial y^2} \quad \text{Top Layer (2)}$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad \text{Continuity (3)}$$

The salt balance equation is:

$$u \frac{\partial c}{\partial x} + v \frac{\partial c}{\partial y} = E \frac{\partial^2 c}{\partial y^2} \quad (4)$$

The symbols and coordinates are referred to in the following sketch. V is the velocity in the y -direction and E the eddy diffusion coefficient. Subscripts 1 and 2 refer to the bottom and top layers.

Figure 1. Definition Sketch

From laboratory observation, a highly stratified estuarial flow can be maintained if the flow of both layers are fairly uniform. However, this does not exclude turbulence from the vicinity of the interface due to the instability of the interface and the breaking of interfacial wavelets (Browand and Wang, 1972; Rumer, 1974; Wang 1975). It seems justified to assume self-similarity of velocity profiles such that:

$$\frac{u}{U_1} = \phi \left(\frac{y}{\delta_1} \right) = \phi (\eta_1) \quad (5)$$

where ϕ is a function to be determined, and δ_1 is a vertical length scale such as the thickness of the viscous layer at the interface. This self-similarity assumption is analogous to the case of approximate self-similarity of the velocity profiles in turbulent wakes and boundary layers discussed by Townsend (1956). The observed self-similarity of concentration profiles facilitates the integration of the salt balance equation (4).

With equation (5), the interfacial shear stress is given by:

$$\tau_1 = \mu_1 \left(\frac{\partial u}{\partial y} \right)_{y \rightarrow 0} = \frac{\mu_1}{\delta_1} U_1 \phi_1' \quad (6)$$

the interfacial friction factor is defined as (Lock 1951)

$$f_1 = \frac{\tau_1}{\rho_1 U_1^2} \sqrt{\frac{U_1 x}{v_1}} \quad (7)$$

Eliminating τ_1 between equation (6) and (7), we have

$$\left. \frac{\partial u}{\partial y} \right|_{y \rightarrow 0} = \frac{1}{\mu_1} \left(f_1 \rho_1 U_1^2 \sqrt{\frac{v_1 x}{U_1}} \right) \quad (8)$$

Let

$$\eta_1 = \phi_1 \left(\frac{y}{\delta_1} \right) = y \sqrt{\frac{U_1}{v_1 x}}$$

integrating equation (8) and applying the condition

$$u \rightarrow u_1 \text{ when } y \rightarrow 0-$$

We obtain

$$u = f_1 U_1 \eta_1 + u_1 \tag{9}$$

The continuity equation (3) implies

$$v = \int \left(- \frac{\partial u}{\partial x} \right) dy = \frac{1}{4} f_1 U_1 \eta_1^2 \sqrt{\frac{v}{U_1 x}} \tag{10}$$

substituting (9) and (10) into the salt balance equation (4) and applying the chain rule we have

$$\frac{\partial^2 c}{\partial \eta^2} + \frac{v}{E} \left(f_1 \frac{\eta^2}{4} + \frac{u_1}{U_1} \frac{\eta}{2} \right) \frac{\partial c}{\partial \eta} = 0 \tag{11}$$

Let

$$P = \frac{\partial c}{\partial \eta}, \quad P = \frac{\partial^2 c}{\partial \eta^2}$$

the equation (11) may be solved,

$$P = A_0 \text{ Exp} \left[-f_1 \frac{1}{4} \frac{v}{E} \frac{\eta^3}{3} - \frac{u_1}{U_1} \frac{v}{E} \frac{\eta^2}{4} \right]$$

Integrating to get

$$C = A_0 \int_0^\eta e^{-\left(f_1 \frac{1}{4} \frac{v}{E} \frac{\xi^3}{3} + \frac{u_1}{U_1} \frac{v}{E} \frac{\xi^2}{4} \right)} d\xi + A_1 \tag{12}$$

Near the interface

$$\xi < 1 \text{ and } f_i \ll 1.$$

Therefore,

$$\left| f_i \frac{1}{4} \frac{v}{E} \frac{\xi^3}{3} \right| \ll \left| \frac{u_i}{U_1} \frac{v}{E} \frac{\xi^2}{4} \right|$$

Neglecting the cubic term, we have

$$C = A_0 \int_0^\eta e^{-\left(\frac{u_i}{U_1} \frac{v}{E} \frac{\xi^2}{4} \right) \beta \xi} + A_1. \quad (13)$$

The conditions are:

$$C(\eta = -\infty) = C_1 \text{ implies } A_1 = C_1$$

$$C(\eta = +\infty) = A_0 \int_0^\eta e^{-\beta \xi^2} \beta \xi + C_1 = A_0 \sqrt{\frac{\pi}{\beta}} + C_1$$

Where

$$\beta = \frac{1}{4} \frac{u_i}{U_1} \frac{v}{E}$$

Then,

$$A_0 = -(C_1 - C_2) \sqrt{\frac{\beta}{\pi}}$$

Substituting β , A_0 and A_1 into equation (13), we obtain the concentration distribution

$$C = -(C_1 - C_2) \sqrt{\frac{\beta}{\pi}} \int_0^\eta e^{-\beta \xi^2} d\xi + C_1 \quad (14)$$

The concentration gradient at the interface is obtained by differentiating equation (14) with respect to y .

$$\frac{\partial C}{\partial y} \Big|_{y \rightarrow 0} = -(C_1 - C_2) \sqrt{\frac{u_1}{4\pi E \chi}} \quad (15)$$

For a given station from the river mouth, E is ready to be determined if the concentration gradient and velocity at the interface are known.

EXPERIMENTAL RESULTS AND DISCUSSION

Two streams of salt water of different concentrations $C_1 > C_2$, are brought to the open channel entrance to form a two-layer type flow field. The velocities of both layers are adjusted by control valves. For a given concentration difference $\Delta C = C_1 - C_2$, the degree of mixing at the interface is proportional to the velocity differential $\Delta U = U_1 - U_2$. For this experiment, the ΔU is maintained in such a way that the interface is sharp. The bottom layer is dyed red for visual observations. A standard TSI hot-film probe is used for velocity measurement. Variations in electrical conductivity is used to detect the variations in concentration. Both hot-film sensor and conductivity probes are mounted together in the same probe holder. The velocity profile and concentration profile at various x -stations are obtained simultaneously by traveling these two probes slowly across the interface. The interfacial velocity u_1 and the concentration gradients are obtained from the velocity and density profiles.

The theoretical concentration distribution is compared to the measured profile in Figure (2). The theory gives a less steep slope at the interface than was actually measured. The discrepancy may be explained as the following:

In the process of integration a common vertical scale length is used. This means the theory is developed under the consideration that viscous layer thickness δ_u and diffusion layer thickness δ_ρ is of the same order of magnitude

$$\frac{\delta_u}{\delta_\rho} \approx 1$$

A close examination of the measured data reveals that in the experiment

$$\frac{\delta_u}{\delta_\rho} \gg 1$$

The viscous layer thickness δ_u is plotted against longitudinal x-axis in Figure (3), and the diffusion layer thickness δ_ρ versus x is shown in Figure (4).

For a given x-station, equation (15) indicates that the eddy diffusion coefficient E is inversely proportional to the square of the concentration gradient at the interface. For this experiment run,

$$\frac{E_{\text{theory}}}{E_{\text{measured}}} = 6.2$$

It may be concluded that the relative size of the viscous layer thickness and diffusion layer thickness is important in determining the eddy diffusion coefficient. The developed theory herein predicts concentration distribution and eddy diffusion coefficient E for $\delta_u = \delta_\rho$. The theory gives larger E values and less steep slopes of the concentrations profile at the interface when $\delta_u > \delta_\rho$, smaller E values and steeper concentration profile slopes at the interface when $\delta_u < \delta_\rho$.

CHAPTER 182

FRICITION AT THE INTERFACE OF TWO-LAYERED FLOWS

by

Nobuyuki Tamai

Associate Professor
Department of Civil Engineering
University of Tokyo, Tokyo, Japan

ABSTRACT

Viscous perturbed velocity field induced by interfacial waves is solved to the first order in terms of wave amplitude for sharply stratified flows described in a curvilinear coordinate system assuming that the external velocity is uniform and constant along the interface. A new type of formula for the interfacial friction coefficient is proposed based on the theoretical result on viscous dissipation in the boundary layer along the interface. The interfacial friction coefficient is supposed to be inversely proportional to the square root of the product of the Reynolds number of a moving layer and the densimetric Froude number to the fifth. The new formula agrees with observed data better than the best empirical law does especially in the range of large Reynolds number. It is found out, however, that the proportional constant may be affected by stability of the two-layered flow system concerned.

INTRODUCTION

The behavior of saline wedges is directly concerned with the municipal, industrial or agricultural utilization of estuarine waters. The form of the interface and the length of arrested saline wedges have been analyzed by the one-dimensional scheme as the case of varied flows in open channels. However, we have to estimate the value of the interfacial friction coefficient from the bulk hydraulic parameters to perform the prediction in a closed calculation scheme.

One of remarkable flow patterns observed in a two-layered flow system is the generation of interfacial waves and its existence for a relatively wide range of flow conditions. Therefore, the flow regime changes from laminar to turbulent via stable transition zone with interfacial waves. When a whole flow system reaches turbulent condition we have another flow pattern, that is, well mixed estuaries which have density gradient not in vertical direction but in horizontal direction. Although the

flow regime in the upper layer (fresh water) is turbulent, the flow regime near the interface is considered in the transition zone due to the suppression of turbulence by the sharp density gradient. In this analysis mixing between two layers is assumed very weak or none. If there exists moderate mixing between two layers, it is supposed that the density distribution may change and the thickness of the mixed zone will develop along the interface. In this case the flow system develops to a different condition from what was assumed initially. Thus we are concerned especially with the case of abrupt interface with stable infinitesimal interfacial waves at the interface as the first approximation of the fresh-salt interface.

Theoretical approaches are classified into two types. One is to consider the energy dissipation of the formation of interfacial waves. This way of approach was initiated by Keulegan (1949) for inviscid fluids. He derived an expression for the interfacial friction coefficient assuming that the dissipation took on the same value as for surface waves in contact with air. He also formulated the additional shearing resistance due to the mixing. Since the liquid crossing the interface is initially at rest and after crossing the interface it acquires the velocity of the current, the current must suffer momentum loss.

Shi-igai (1965) extended the Keulegan's approach to a fresh-salt two-layered flow system. He expressed the flow field by means of the velocity potential. However, interfacial waves were considered to suffer from viscous dissipation. Thus, a virtual shear flow was considered in his analysis. Summarizing the characteristics of interfacial waves, he proposed that the interfacial friction coefficient was inversely proportional to ψ where $\psi = R_e F_d^2$. Here R_e is the Reynolds number of a moving layer and F_d is the densimetric Froude number.

Hamada (1966) calculated the dissipation of infinitesimal waves formed on the interface of viscous stratified fluids. He utilized the theoretical results of the Rayleigh-Taylor instability problem. His final result is summarized that the interfacial friction coefficient is inversely proportional to the square root of ψ . However, the theory is built up on the basis of no external flow field, which disagrees with the real situation of salt-water wedges.

Another theoretical approach treats with skin friction and momentum loss due to entrainment of fluid particles from a stationary layer. If we consider the laminar condition for a stationary saline wedge, we can theoretically derive a velocity distribution for both layers and calculate shearing stress of the type of skin friction. In the laminar flow the interfacial friction coefficient is inversely proportional to the Reynolds number of a flowing layer.

Valembois (1963) considered the shearing stress at the interface as the sum of a laminar part and a turbulent part. The turbulent part is expressed by the mixing velocity across the interface. Although he obtained the order of magnitude of these components by utilizing four among forty six experimental data of Lofquist (1960), he did not mention the general behavior of the mixing velocity any further.

Recently Pedersen (1972) investigated the mechanism of entrainment in two-layer stratified flows. With the use of the momentum and work energy equations, both with respect to the net entrainment, the interfacial friction coefficient is found to be equal to the non-dimensional entrainment velocity. The details of the entrainment velocity, however, remained vague with respect to hydraulic parameters of a flowing layer since the

interfacial friction coefficient appeared to be a minor objective in his paper.

As was briefly reviewed there are several components which contribute to the friction at the interface of a stratified flow. Referring to the proposed functional relationship it is said that when the Reynolds number is very large and the stratification is stable, which is encountered in saline wedges in estuaries, the magnitude of laminar friction is much smaller than that of the friction due to interfacial wave formation. In addition, as long as we consider a two-layered flow system the mixing between two layers remains weak. Therefore, it is supposed that the friction due to the mixing does not play a dominant role in sharply stratified flows with which we are concerned in this paper. The objective of this paper is to construct a more advanced theory on the interfacial friction under the existence of interfacial waves. Main flow is divided into two parts, that is, an inviscid part and a viscous perturbed part so as to improve previous theories. Then, boundary layer along the wavy interface is analyzed and the interfacial friction coefficient is derived from viscous dissipation in the boundary layer.

THEORETICAL CONSIDERATIONS

The definition sketch of a two-dimensional two-layered flow system is given in Fig. 1. The coordinate system (x, y) is a moving frame with the celerity of interfacial waves, c . We have stable infinitesimal interfacial waves at the interface. The velocity distribution in the upper layer is assumed uniform. This is because the flow of the upper layer is considered turbulent, though the flow regime near the interface is in the transition due to the suppression of turbulence by the density difference. Since the relative importance of skin friction with the resistance due to interfacial waves diminishes as the Reynolds number becomes high, the velocity distribution is not essential in this analysis. The salt-water layer is assumed stationary. If we consider this motion as a relative motion, the situation is general.

The coordinate system (x, y) is transformed into a curvilinear coordinate system (ξ, η) by utilizing a conformal mapping.

$$\zeta = \xi + i\eta = z - ia e^{ikz} \quad (1)$$

Fig. 1. Definition sketch of a two-layered flow

where $z=x+iy$, a is the amplitude of an infinitesimal interfacial wave, and k is the wave number. From Eq. (1) we obtain

$$\xi = x + a e^{-ky} \sin kx, \quad \eta = y - a e^{-ky} \cos kx \quad (2)$$

Jacobian of the transformation is calculated as

$$J = 1 + 2ak e^{-ky} \cos kx + O(a^2) \quad (3)$$

The interface is expressed by $\eta=0$ if we neglect the effect of the order of a^2 .

The vorticity transport equation for a steady motion is expressed by

$$\mathbf{u} \cdot \nabla \boldsymbol{\omega} - \boldsymbol{\omega} \cdot \nabla \mathbf{u} = \nu \nabla^2 \boldsymbol{\omega} - \nabla(1/\rho) \wedge \nabla p \quad (4)$$

where \mathbf{u} and $\boldsymbol{\omega}$ are velocity and vorticity vectors, respectively, ν the kinetic viscosity of the fluid, ρ the density of the fluid, p the pressure, ∇ a gradient operator, \cdot inner product, and \wedge vector product. Equation of continuity for an incompressible fluid is explained by

$$\nabla \cdot \mathbf{u} = 0 \quad (5)$$

Equation (5) is an exact expression for the equation of continuity even in the case of slight density variation due to a solute and is a passable expression to the first order approximation under the density variation caused by both temperature and concentration (Yih, 1965). The equation of continuity in the curvilinear coordinate transformed by Eq. (1) is

$$J \left\{ \frac{\partial}{\partial \xi} (J^{-1/2} u) + \frac{\partial}{\partial \eta} (J^{-1/2} v) \right\} = 0 \quad (6)$$

where u and v are ξ and η components of velocity, respectively. Equation (6) is satisfied by the stream function, X , defined by

$$u = J^{1/2} \frac{\partial X}{\partial \eta}, \quad v = -J^{1/2} \frac{\partial X}{\partial \xi} \quad (7)$$

In a two-dimensional problem vorticity has just one component perpendicular to ξ - η plane. Therefore we can treat vorticity as a scalar denoting $|\boldsymbol{\omega}| = \omega$. Further, the second term of the left-hand side of Eq. (4) vanishes in case of a two-dimensional problem. Because a sharply stratified flow is considered in this analysis, density gradient and pressure gradient are parallel each other. Therefore, the second term of the right-hand side of Eq. (4) also vanishes in this case. Equation (4) is thus rewritten as in Eq. (8).

$$-J^{1/2} \frac{\partial X}{\partial \xi} \cdot J^{1/2} \frac{\partial \omega}{\partial \eta} + J^{1/2} \frac{\partial X}{\partial \eta} \cdot J^{1/2} \frac{\partial \omega}{\partial \xi} = \nu J D^2 \omega \quad (8)$$

where $\omega = -J D^2 X$ and $D^2 = \partial^2 / \partial \xi^2 + \partial^2 / \partial \eta^2$.

Now perturbation method is applied to solve Eq. (8). Stream function defined in Eq. (7) is expanded in power series as shown in the next equation.

$$X = X_0 + \epsilon X_1 + \epsilon^2 X_2 + \dots \quad (9)$$

where the suffix of X stands for the order of a perturbed representation and $\epsilon = ak$. We assume the external flow is inviscid. Therefore, X_0 is obtained by the inviscid theory. X_1 is composed of a wave component, X_{1w} , which is also calculated by the inviscid theory and a viscous component, X_{1v} . Substitution of Eq. (9) into the definition of vorticity yields

$$\begin{aligned} \omega &= -JD^2X = \omega_0 + \epsilon\omega_1 + \epsilon^2\omega_2 + \dots \\ &= -(1 + 2\epsilon e^{-k\eta} \cos k\xi + O(\epsilon^2)) \cdot (D^2X_0 + \epsilon D^2X_1 + \epsilon^2 D^2X_2 + \dots) \\ &= -\epsilon D^2X_1 - \epsilon^2 (D^2X_2 + 2e^{-k\eta} \cos k\xi \cdot D^2X_1) + O(\epsilon^3) \end{aligned} \quad (10)$$

Since X_0 is derived from the inviscid theory, it provides irrotational motion. Thus the perturbed expression for vorticity begins with the first order in terms of ϵ .

The equation in ϵ is obtained as follows by substitution of Eqs. (9) and (10) into Eq. (8).

$$-\frac{\partial X_0}{\partial \xi} \frac{\partial}{\partial \eta} D^2X_1 + \frac{\partial X_0}{\partial \eta} \frac{\partial}{\partial \xi} D^2X_1 = \nu D^2(D^2X_1) \quad (11)$$

According to the Kelvin-Helmholtz problem, the inviscid solution of the stream function is given by

$$\begin{aligned} \Psi &= (U_1 - c)y + \frac{(U_1 - c)a}{\sinh kh_1} \sinh k(y - h_1) \cos kx \\ &= (U_1 - c)\eta + (U_1 - c)ae^{-k\eta} \cos k\xi + \frac{(U_1 - c)a}{\sinh kh_1} \sinh k(\eta - h_1) \cos k\xi \\ &\quad + O(a^2) \end{aligned}$$

where Ψ is the stream function, U_1 the velocity of the upper layer, and h_1 the depth of the upper layer. The stream function defined by Eq. (9) is thus obtained up to the order of ϵ as

$$\begin{aligned} X_0 &= (U_1 - c)\eta \\ \left\{ \begin{aligned} X_1 &= \frac{1}{k}(U_1 - c)e^{-k\eta} \cos k\xi + \frac{U_1 - c}{k \sinh kh_1} \sinh k(\eta - h_1) \cos k\xi + X_{1w} \\ &= X_{1w} + X_{1v} \end{aligned} \right. \end{aligned} \quad (12)$$

Following Eq. (12) we obtain $\partial X_0 / \partial \xi = 0$. Therefore, we can simplify Eq. (11) further as

$$(U_1 - c) \frac{\partial \omega_1}{\partial \xi} = \nu D^2 \omega_1 \quad (13)$$

In addition length scale along the interface is considered much larger than that of the direction perpendicular to the interface. Hence $\partial / \partial \xi \ll \partial / \partial \eta$ and $\partial^2 / \partial \xi^2 \ll \partial^2 / \partial \eta^2$ may hold to reduce the governing equation as in the following expression.

$$(U_1 - c) \frac{\partial \omega_1}{\partial \xi} = \nu \frac{\partial^2 \omega_1}{\partial \eta^2} \quad (14)$$

where $\omega_1 = -\partial u_1 / \partial \eta$. Here u_1 is the first order component of perturbed velocity.

Now the velocity component along the interface is developed in power series through Eq. (7).

$$\begin{aligned} u &= u_0 + \epsilon u_1 + \epsilon^2 u_2 + \dots \\ &= \frac{\partial X_0}{\partial \eta} + \epsilon \left\{ \frac{\partial X_1}{\partial \eta} + (U_1 - c) e^{-k\eta} \cos k\xi \right\} + O(\epsilon^2) \end{aligned} \quad (15)$$

Boundary conditions under which Eq. (14) is to be solved are determined as follows. As was previously mentioned the interface is expressed by $\eta=0$ to the order of ϵ . Fundamental scheme on the velocity of this paper is that we allow velocity gap in the external flow but we impose no-slip condition for perturbation velocities. Therefore, we have

$$u_1 = 0 \quad \text{at } \eta = 0, \quad u_1 = \frac{\partial X_{1W}}{\partial \eta} \quad \text{at } \eta = \infty$$

The second condition shows that viscous effect vanishes as the distance from the interface increases. If we denote wavy and viscous parts in the perturbed velocity separately, we obtain the following expression from Eqs. (12)₃ and (15)₂.

$$\begin{cases} u_1 = u_{1W} + u_{1V} + (U_1 - c) e^{-k\eta} \cos k\xi \\ u_{1W} = \partial X_{1W} / \partial \eta, \quad u_{1V} = \partial X_{1V} / \partial \eta \end{cases} \quad (16)$$

Thus we obtain the boundary conditions in terms of the first order viscous perturbed velocity, u_{1V} .

$$\begin{cases} u_{1V} = (U_1 - c) \coth kh_1 \cos k\xi & \text{at } \eta = 0 \\ u_{1V} = 0 & \text{at } \eta = \infty \end{cases} \quad (17)$$

The governing equation (14) is again rewritten in terms of u_{1V} .

$$(U_1 - c) \frac{\partial^2 u_{1V}}{\partial \xi \partial \eta} = \nu \frac{\partial^3 u_{1V}}{\partial \eta^3} \quad (18)$$

Integration with respect to η produces Eq. (19).

$$(U_1 - c) \frac{\partial u_{1V}}{\partial \xi} = \nu \frac{\partial^2 u_{1V}}{\partial \eta^2} + H(\xi) \quad (19)$$

Integration constant $H(\xi)$ is considered pressure gradient referring to a momentum equation.

The solution to Eq. (19) is obtained with boundary conditions of Eq. (17) for the case of $H(\xi)$ equals zero, which represents constant external velocity. This is the case that the interface is parallel to the water surface and would be the first approximation even for the case of slightly inclined interface.

$$u_{1v} = (c-U_1) \coth kh_1 e^{-\beta\eta} \cos(k\xi + \beta\eta) \quad (20)$$

where

$$\beta = \sqrt{(c-U_1)k/2\nu} \quad (21)$$

Vorticity is thus calculated up to the first order.

$$\begin{aligned} \omega &= \varepsilon\omega_1 = -\varepsilon\partial u_1/\partial\eta \\ &= \beta(c-U_1)ak \coth kh_1 e^{-\beta\eta} \{\cos(k\xi + \beta\eta) + \sin(k\xi + \beta\eta)\} \end{aligned} \quad (22)$$

In order to obtain a real value for β in Eq. (21), the condition $c \geq U_1$ must be hold. The interfacial wave propagating downstream satisfies this condition. A more detailed description will be given as follows. Let us denote $\Delta\rho = \rho_2 - \rho_1$ and $g' = g \cdot \Delta\rho / \rho_1$, where $\Delta\rho$ is the density difference between upper and lower layers and g is the acceleration of gravity. For the case of a stationary lower layer and of a slight density difference, which is treated in this paper, the condition $c \geq U_1$ can be rewritten on use of the inviscid theory as

$$g' \geq kU_1^2 \coth kh_2 \quad (23)$$

where h_2 is the thickness of the lower layer. For long waves we can approximately express $\coth kh_2 = 1/kh_2$. Thus Eq. (23) reduces to

$$(1/F_d^2)(h_2/h_1) \geq 1 \quad (24)$$

where

$$F_d = \frac{U_1}{\sqrt{\frac{\Delta\rho}{\rho_1} gh_1}} \quad (25)$$

is the densimetric Froude number. The value of F_d is less than unity in density currents like as saline wedges. Therefore, the condition of Eq.(24) is ordinarily satisfied unless the thickness of the lower layer is extremely small. For deep water waves we can put approximately $\coth kh_2 = 1$. Then we obtain the relationship for the wave length λ

$$\lambda \geq 2\pi h_1 \cdot F_d^2 \quad (26)$$

Equation (26) shows that interfacial waves whose wave length is shorter than that given by Eq. (26) are unstable. Since we can expect to have real values for β for usual hydraulic conditions as shown in Eqs. (24) and (26), we can accept Eq. (22) as a basis for further investigation.

Viscous energy dissipation is generated in the boundary layer, the thickness of which is the order of $1/\beta$, along the interface. In this analysis the boundary layer is only considered along the upper surface of the interface. This may be acceptable under the assumptions adopted in this analysis that the lower layer is stationary, the density profile is discontinuous at the interface and the amplitude of interfacial waves is infinitesimal. The mean energy dissipation per unit area is given by

$$\dot{E} = -\mu \int_0^{\delta} \overline{\omega^2} d\eta \quad (27)$$

where δ is the thickness of the boundary layer and overbar denotes the

average over a wave length. Substituting Eq. (22) into Eq. (27) we obtain

$$\dot{E} = -(1/2)\mu\beta(c-U_1)^2 a^2 k^2 \coth^2 kh_1 \quad (28)$$

where the outer edge of the boundary layer is approximated by $\eta=\infty$.

This energy dissipation must be fed by the mean flow of the upper layer. The resistance stress to the upper layer, τ , is thus obtained by dividing the rate of energy dissipation by the mean flow velocity of the upper layer and turning the sign following the definition of the resistance stress.

$$\tau = -\dot{E}/U_1 \quad (29)$$

Interfacial friction coefficient, f_i , defined by

$$\tau = (1/2) f_i \rho U_1^2 \quad (30)$$

is then obtained on use of Eqs. (28), (29), and (30).

$$f_i = \frac{1}{\sqrt{2}} R_e^{-1/2} \left(\frac{c}{U_1} - 1\right)^{5/2} (kh_1)^{1/2} a^2 k^2 \coth^2 kh_1 \quad (31)$$

where

$$R_e = \frac{U_1 h_1}{\nu} \quad (32)$$

is the Reynolds number of the upper layer. It is noted that in this analysis the energy dissipation is not caused by the maintenance of interfacial waves but by the viscous perturbed velocity field which is induced by the presence of interfacial waves.

It is found out that the interfacial friction coefficient is inversely proportional to the square root of the Reynolds number of the moving layer. In order to study the dependence on the densimetric Froude number we have to specify the magnitude of interfacial wave celerity which is obtained by the inviscid theory.

$$c = \frac{U_1 \coth kh_1 + \{g'(\coth kh_1 + \coth kh_2)/k - U_1^2 \coth kh_1 \coth kh_2\}^{1/2}}{\coth kh_1 + \coth kh_2} \quad (33)$$

For a real value of β only plus sign of the square root is considered. This expression can be simplified in two extreme cases of long waves and deep water waves. Further analysis on the frictional coefficient is developed for these cases.

(a) *The case of long waves:* We can put approximately $\coth kh_1 = 1/kh_1$, and $\coth kh_2 = 1/kh_2$. From Eq. (33) we obtain

$$\frac{c}{U_1} = \frac{h_2 + \{F_d^{-2} h_2 (h_1 + h_2) - h_1 h_2\}^{1/2}}{h_1 + h_2}$$

(i) $h_2 \gg h_1$

In this case Eq. (31) reduces to

$$f_i = 0.707 (R_e F_d^5)^{-1/2} (kh_1)^{1/2} a^2 k^2 \coth^2 kh_1 \quad (34)$$

(ii) $h_2 \approx h_1$

In this case Eq. (31) is rewritten as

$$f_i = 0.125 R_e^{-1/2} (\sqrt{2F_d^{-2}-1} - 1)^{5/2} (kh_1)^{1/2} a^2 k^2 \coth^2 kh_1 \quad (35)$$

For very small values of F_d , Eq. (35) reduces to the same type of formula as Eq. (34).

$$f_i = 0.297 (R_e F_d^5)^{-1/2} (kh_1)^{1/2} a^2 k^2 \coth^2 kh_1 \quad (36)$$

(b) *The case of deep water waves:* In this case $\coth kh_1$ and $\coth kh_2$ are approximated to be unity. From Eq. (33) we obtain

$$c/U_1 = (1/2) \{ 1 + \sqrt{\lambda / (\pi h_1 F_d^2)} - 1 \}$$

Substitution of the above expression into Eq. (31) yields

$$f_i = 0.125 R_e^{-1/2} \{ \sqrt{\lambda / (\pi h_1 F_d^2)} - 1 \}^{5/2} (kh_1)^{1/2} a^2 k^2 \coth^2 kh_1 \quad (37)$$

A few remarks on Eq. (37) are added. For the shortest waves that satisfies Eq. (26) f_i reduces to zero. In that case the celerity of the interfacial wave is identical to the mean flow velocity. Thus the upper layer does not suffer from the energy dissipation. The longest wave that satisfies the deep water condition is written as $\lambda = 2h_1$. For this wave we can simplify Eq. (37). If we assume the densimetric Froude number F_d is much smaller than unity, Eq. (37) gives the relationship $f_i \propto (R_e F_d^5)^{-1/2}$.

COMPARISON WITH MEASURED DATA AND DISCUSSION

There have been several experimental works and field observations on saline wedges. Reported data of the interfacial friction coefficient are rearranged on the light of a newly developed formula. Referring to Eqs. (34), (35) and (37), the frictional coefficient depends on the wave characteristics even in specified cases. However, none has been reported explicitly about the wave length, the amplitude, and the celerity of interfacial waves. Therefore whichever formula we choose, certain magnitude of scattering of data around the estimated relationship will be inevitable.

Previous formulae claim the type of relationship

$$f_i = \alpha \psi^{-n} \quad (38)$$

where α and n are constants and $\psi = R_e F_d^2$. Because no observational result explains the amplitude and the wave length of interfacial waves as mentioned above, we have to simplify Eq. (31) in order to compare the theoretical result with reported data. The newly derived formula is approximated as in Eq. (39) excluding the effect of the characteristics of interfacial waves.

$$f_i = m (R_e F_d^5)^{-1/2} \quad (39)$$

where m is a proportional constant. This type of formula is chosen in connection with Eqs. (34), (35) and (37). Note that for very small F_d Eqs. (35) and (37) reduces to the same type of relation as Eq. (34).

The observed data are shown in Fig. 2 in the relationship between f_i and $R_e F_d^5$. Detailed values of f_i , R_e , and F_d of each data are listed in Table 1. A full line in Fig. 2 shows Eq. (39) in which $m=0.085$. The au-

thor's experiment (Tamai, 1964) was performed in a flume 15cm wide and 420 cm long and interfacial profiles of stationary saline wedges were recorded for a bottom slope of 1.27/100. Values of the interfacial friction coefficient were selected to produce the best fit interfacial profile by the numerical integration of a one-dimensional open channel equation for two-layered flows. The determined interfacial friction coefficient is thus considered the average value over the interface. The Reynolds number of the upper layer remains constant even for an inclined interface because of the constant discharge per unit width. The representative depth of the upper layer to calculate F_d is chosen at the mid-point of intruded saline wedges.

Lofquist (1960) performed his experiment in a horizontal flume 23.3cm wide and 30m long. In his experiment a heavier salt-water layer moved underneath a stationary fresh-water layer. Mean shear stress with respect to width at the interface were calculated from the slope of the interface, bed shear stress, and velocity gradient. Although friction coefficient is given with respect to the maximum velocity in the paper, the conversion to the definition of Eq. (30) is available utilizing the listed quantities.

Nakamura and Abe (1970) observed the behavior of a saline wedge in the Kuzuryu River. Values of the interfacial friction coefficient were calculated by the equation

$$f_i = 2 F_d^{-2} \frac{h_1}{h_1+h_2} \left\{ -(1-F_d^2) \frac{\Delta h_1}{\Delta x} + \frac{U_1^2}{(\Delta \rho / \rho_1) g B} \frac{\Delta B}{\Delta x} \right\} \quad (40)$$

Here we assume a stationary lower layer and B is the width of a channel. Symbol Δ explains finite difference in the marked quantities and x is a coordinate axis taken to the direction of fresh-water flow. It is noted that the resulted interfacial friction coefficient through Eq. (40) is considered a local value at a certain position in two-layered flows.

Suga and Takahashi (1971) performed a field observation in the Tone River and experiments in two flumes. One is 80cm wide and 100m long and the other is 30cm wide and 30m long. Values of the interfacial friction coefficient were computed by Eq. (40). Other data reported previously cannot be rearranged in Fig. 2 because the data are tabulated only with the value of ψ which is the sole parameter in the existing formula, Eq. (38). Thus the value of R_e and F_d cannot be obtained separately.

In f_i versus ψ diagram the best fit empirical formula was the case that $\alpha=0.2$ and $n=1/2$ in Eq. (38). But the value of n to explain the trend of the data measured in the Tone River that is one of the largest rivers in Japan is about 6/5. Therefore, the empirical formula fails to explain the behavior of the interfacial friction coefficient in the largest range of ψ . The trend of the data obtained in the Tone River which are indicated in solid circles in Fig. 2 seems to follow a line

$$f_i = 0.025 (R_e F_d^5)^{-1/2} \quad (41)$$

The trend agrees with what the new formula, Eq. (39), predicts, though the magnitude of coefficient is different from other groups of data.

Generally speaking scattering around the solid line

$$f_i = 0.085 (R_e F_d^5)^{-1/2} \quad (42)$$

in Fig. 2 is smaller than that shown in f_i versus ψ diagram by previously proposed formulae. The data reported by Lofquist (1960) illustrated by sol-

Fig. 2. Interfacial friction coefficient vs. $Re F_d^5$

id reversed triangles in Fig. 2 behave differently from others. Previously only four cases in forty six of Lofquist's experimental results were reported by Valembos(1963). Present analysis revealed that the different relationship held for a set of all forty six data. The magnitude of the interfacial friction coefficient remains almost unchanged regardless of the value of the abscissa. This is partly because Lofquist performed his experiments with a moving denser fluid while a lighter upper layer remained stationary and therefore the results might be affected more strongly by bottom shear. Although the trend is not so clear as Lofquist's data, the data obtained in the Kuzuryu River expressed by open circles in Fig. 2 shows nearly the same feature.

The measured data follow the trend explained by Eq. (42) on the whole. As mentioned above, however, there is a more appropriate formula like Eq. (41) for a special group of data. The variety of the magnitude of coefficients of the derived formulae is discussed from the standpoint of the stability of a two-layered flow system. Equation (43) is an interpretation of the reciprocal of the Keulegan number by Turner(1973).

$$\theta = \left(\frac{\rho U_1^2}{\Delta \rho g \delta} \right) \left(\frac{U_1 x}{v} \right)^{1/2} \quad (43)$$

Here δ denotes the thickness of the boundary layer and x is the length of contact of two layers along the interface. In field observation like the case of the Tone River the length of the contact of interface measured from the saline wedge toe may be much larger than that encountered in experimental flumes. Thus the Keulegan number observed in natural streams is expected much smaller than the critical value if it exists at all. Therefore, the stability of field data may be higher than that obtained in experiments.

The amplitude of the lowest internal mode obtained by Phillips(1969) is expressed for $n \ll N_m$ by

$$a^2 k^2 = \left(\frac{N_m}{n} \right)^{-2} J^{-1}$$

where n is the frequency of an internal wave mode, N_m the maximum Brunt-Väisälä frequency ($N \equiv \{-(g/\rho)(\partial \rho / \partial y)\}^{1/2}$), J the local Richardson number. Substitution of this expression into the derived relationship, Eq. (34), yields

$$f_1 = 0.707 (R_e F_d^5)^{-1/2} (kh_1)^{-3/2} (n/N_m)^2 J^{-1} \quad (44)$$

This suggests that the higher the stability of a two-layered flow system is, the lesser the magnitude of the interfacial friction coefficient will be, which explains the feature of the observed data qualitatively.

One more comment on the field data is added. Values of the interfacial friction coefficient were calculated by Eq. (40) which was applicable only to steady motions. Since tidal motion affects the behavior of saline wedges continuously, we would have measured various hydraulic quantities under unsteady conditions in reality. This discrepancy from the assumed condition may explain the scattering of field data.

CONCLUSIONS

An advanced theory on the interfacial friction of sharply stratified two-layered flows is developed. Because the magnitude of laminar friction is much smaller than that of the friction due to interfacial wave formation in case of the large Reynolds number, the theory is formulated under the existence of interfacial waves. The solution to a governing equation is obtained to the first order in terms of wave amplitude by perturbation method. No-slip condition is imposed for the first order solution and external flow velocity is assumed uniform and constant. In this theory it is considered that the energy dissipation is caused by the viscous perturbation velocity field which is induced by the presence of interfacial waves.

Based on the theoretical result a new type of formula for the interfacial friction coefficient is proposed discarding the detailed properties of interfacial waves which have not been reported in available form. It is said that the agreement between the proposed relationship, that is, f_i is proportional to $(ReF_d^3)^{-1/2}$, and the observed data is better than that demonstrated by the best empirical formula, $f_i \propto (ReF_d^2)^{-1/2}$. Scattering of data may be attributed to the stability of two-layered flows. It is pointed out that the proportional constant in the new formula decreases its magnitude as the stability increases.

This study has explained the hydrodynamic feature of the interfacial friction coefficient under the existence of interfacial waves with no mixing between two layers. In order to determine the more detailed feature of the derived expression, it is still needed to obtain reliable data from which we can specify the interfacial wave characteristics and to develop a more refined theory which can take account of the effect of viscosity even in the zeroth order principal velocity or of the acceleration of the external flow.

ACKNOWLEDGMENTS

The author wishes to express his gratitude to Professor Tosio Iwasaki at Tohoku University for his promotion and valuable suggestions to this study. Cordial assistance offered by Mr. Hiroshi Nakamura of Central Research Institute of Electric Power Industry and by Mr. Kyoza Suga of Public Works Research Institute is also appreciated. Rearrangement of field data would not have been performed without their cooperation of providing the details of their observation data.

CHAPTER 183

TIDAL RESPONSE OF TWO-LAYER FLOW AT A RIVER MOUTH

by

Shizuo Yoshida*

and

Masakazu Kashiwamura**

ABSTRACT

This paper describes various features of tidal effects on the behavior of a salt wedge and on the mechanism of mixing between the salt water and the fresh water in the vicinity of a river mouth. The studies have been performed through experiments, field observations and theoretical considerations. The condition upon which the fresh water begins to show an intermittent flow-pattern owing to an increase of the tidal action, and the criterion of a transition of the mixing type from negligible into intense, were obtained, with two dimensionless parameters λ and θ . The former parameter λ is given by $\lambda = A_0/U_0 T_0$, in which T_0 is the tidal period, A_0 is the tidal amplitude of the sea level, and U_0 is the temporal mean velocity of the fresh water at the river mouth. The latter parameter θ is the so-called Keulegan number. Besides, it came evident that a tidal motion of the salt wedge couldn't be understood without a consideration of the internal wave inside the mouth, which were induced by the tide, in addition to a direct effect of the tide.

1. Introduction

Since early times, in Japan, river mouths have been utilized in many ways, for example, as fishery ports, navigation harbors, suppliers of water for irrigation and industries, etc. The river mouth, in this meaning, is considered to be an important base for all industries. Recently, with a growth of utilization of the river mouths, a serious problem has attracted public attention. It is water pollution. Saline pollution owing to the salt wedge has widely been known from old times, as a main difficulty to agriculture, chemical industries and to citizens' lives. Nowadays, in addition, sewage poured from citizens' lives, and waste from industries have come a new matter of the utmost concern, since they give a damage to coastal fisheries, and its results rebound to human life again, as a danger against human health.

* Research Assistant, Department of Engineering Science, Hokkaido University, Sapporo, Japan.

** Professor of Engineering Science, Hokkaido University, Sapporo, Japan.

To solve those problems, studies on the two-layer flow at a river mouth have an important role. Prediction of a length or a form of the salt wedge, control technique of its length¹⁾, an estimate of the area of river water expanding over the sea, outflow patterns varying with a degree of river discharge^{2),3),4),5)} etc. are those of already revealed to a certain degree, which have greatly served to increase a correct comprehension on mechanics of the problems. Most of them, however, have been investigated under a tideless condition, and many studies concerning the tidal effect are, at present, left unsolved yet. Needless to say, there have been many studies related to a tidal estuary, but most of them are directed to established types of mixing, namely, intense mixing or moderate mixing, where tidal variations of flow, level and saline concentration, from time to time, are usually ignored, and instead, temporal mean values are important.

The present authors intend, hereby, to describe a fine mechanism of the two-layer flow which varies in response to the tide. They deal, first, with an equipment for experiments and a method of measurements, which were adopted in the study, in Section 2, next, with a relationship between outflow patterns of the fresh water and the tide in Section 3, third, with a periodical motion of the salt wedge due to the tide in Section 4, and finally, with a problem of tidal mixing between the fresh water and the salt water, and also with a contribution of the tide to a transition from the negligible mixing type into the intense mixing type in Section 5.

2. Experimental Equipment

In order to observe the whole behavior of the two-layer flow which extends widely from the upstream of a river to the open sea, an equipment was designed as shown in Fig. 1, so as to consist of a large water vessel and a long straight channel which connects to the vessel at right angles. The vessel and the channel correspond to the sea and a river, respectively. Since they are made of transparent acrylic acid resin, for the purpose of marking dye in water being observable from outside. A tide generator is specially devised so that the water level may follow any curve of hydrographs. Its block diagram is shown in Fig. 2. Salt water in the vessel is separated by a wide vinyl sheet on the bottom, from water which is pumped in and out from below to change the water level. Thus, the salt water is moved bodily up and down, and is kept undisturbed.

As a movie camera is insufficient to observe the whole behavior of the salt wedge, another optical method is additionally adopted. The diagram of the optical system is shown in Fig. 1. Light pulses emitted from a xenon lamp intermittently at constant intervals, are made parallel by a concave mirror, and reflected perpendicularly at many plane mirrors which are lined up along the channel. Many light beams thus divided penetrate the channel transversely, pass through narrow slits of 0.3 mm in width, which are attached on the other side of the channel, and arrive at a long sheet of photosensitive paper, which moves along the channel by 0.3 mm, synchronously with every arrival of pulses. Since light is reflected or refracted at the water surface and the interface, both levels are exposed on the sheet, from time to time. Thus, a tidal change of the surface and the interface can be obtained at 10 cm intervals along the channel. The behavior of the two-layer flow outside the mouth are caught with a 8 mm movie camera, by the aid of fluorescein sodium liquid as a tracer.

Figure 1.

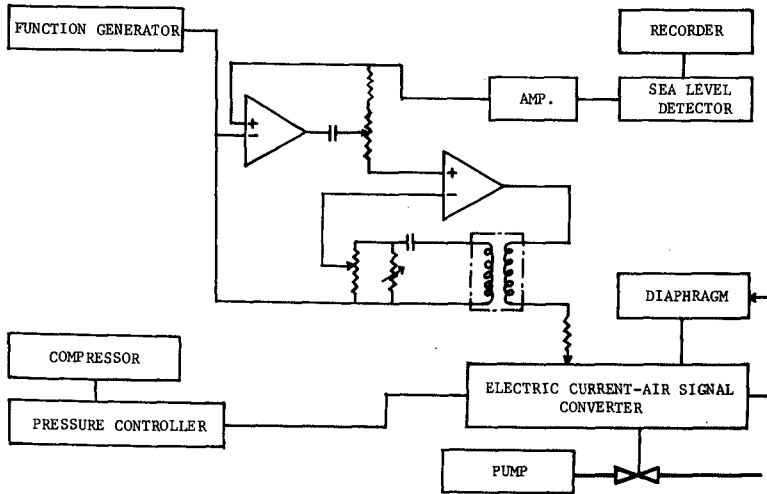

Figure 2

3. Tidal Change of Flow Pattern

An appearance of outflow pattern varies depending on only the amount of a river discharge, if it is assumed tideless. When the discharge grows, the outflow pattern approaches an extreme type called the E pattern, which resembles a turbulent jet of homogeneous fluid. On the other hand, if the discharge falls off, it reaches the other extreme type called the A pattern, whose stream lines extend slowly in all directions over the sea without turbulence. According to experiments, three transitional types lie between those extreme two, and they are called the B, C and D patterns. All patterns are shown in Fig. 3 (1), and they can be classified with two parameters, which are the Keulegan number θ and the Reynolds number R respectively, where $\theta = (\nu \epsilon g)^{1/3} / U_0$ and $R = U_0 b / \nu$. The symbol b is a cross-sectional mean velocity of the fresh water at the mouth, ν is a kinematic viscosity, and $\epsilon = (\rho_2 - \rho_1) / \rho_2$, where ρ_1 and ρ_2 are densities of the fresh water and the salt water respectively. The classification is shown in Fig. 3 (2).

When the tide exists, every pattern varies from time to time. At a flood tide, it has a trend to approach the A pattern, and at the ebb tide, it changes toward the E pattern. A degree of the tidal range dominates a change of the pattern. According to experiments, if an amplitude of the tide level is small, or a tidal period is long enough, the change is small, and the fresh water always flows out from the mouth over the whole tidal period. However, when the amplitude grows up excessively, or the tidal period decreases below a certain value, the fresh water sometimes stops or flows upstream at the flood. If it develops extremely, the fresh water, which has flown out at the ebb, cannot return into the river even at the flood, and it produces a special pattern, an "intermittent flow", every tidal cycle. In such a case, mixing of the fresh water and the salt water develops, and an adoption of the two-layer theory becomes impossible.

Two examples are shown in Figs. 4 and 5, which are those transferred from movie films. The former one is photographed on condition that the discharge is $6.70 \text{ cm}^3/\text{s}$, the tide amplitude is 1.70 cm , the tide period is 1380 sec and $\epsilon = 0.018$. If tideless, the upper values are those of the B, or C pattern, whose condition is $\theta R^{0.137} = 0.673$. However, the tide lets the fresh water change its flow pattern from time to time. Under the above condition, the upstream flow doesn't occur even at the flood. According to tidal hours, the flow pattern varies in such a manner that it shows the pattern C at the high and low waters, B at the flood, and E at the ebb. Fig. 5 is another example under condition that the discharge is $2.89 \text{ cm}^3/\text{s}$, the amplitude is 2.29 cm , the tidal period is 360 sec and $\epsilon = 0.020$. If tideless, the flow pattern belongs to B somewhat close to A with a relationship, $\theta R^{0.137} = 0.849$. Compared with the former case, in this case, the discharge and the period are so small that the tidal effect is strong. At every hour of the tide, the pattern shows A or B at the high and low waters, D at the ebb and an upstream flowing pattern at the flood, when the surface at the mouth is occupied by the salt water, namely, this type is an intermittent flow.

Other experimental results are all situated between those two cases, where sometimes the fresh water stops at the ebb, or sometimes the fresh water flows upstream in a type different from the intermittent flow.

Next, a criterion, upon which above various types occur, will be

Figure 3(1).

R	Reynolds number	1213

Figure 4.

Figure 5.

Figure 6.

discussed. Since a condition on which the fresh water flows upstream seems to arise, when the tidal current exceeds a temporal mean velocity of the fresh water, the ratio of both velocities will be a dimensionless parameter which dominates this problem. An intensity of the tidal current can be regarded as a function of A_0/T_0 , where A_0 is the amplitude of the tidal level and T_0 is the period. Therefore, the ratio λ , which is represented by $\lambda = A_0/U_0T_0$, should be a parameter required. In addition, the velocity U_0 of the fresh water is so deeply related to the two-layer flow system itself, that this problem seems to have a relation also to the Keulegan number θ .

Thus, by using those two parameters λ and θ , various patterns are classified as follows.

- $\lambda\theta < 1.22 \times 10^{-4}$: The fresh water always flows out, over the whole tidal period.
- $\lambda\theta = 1.22 \times 10^{-4}$: The fresh water stops at the flood.
- $1.22 \times 10^{-4} < \lambda\theta < 1.63 \times 10^{-4}$: The fresh water flows backward into the river, at the flood, but it is no intermittent flow.
- $\lambda\theta = 1.63 \times 10^{-4}$: The salt water covers the surface temporarily in the vicinity of the mouth, at the flood.
- $\lambda\theta > 1.63 \times 10^{-4}$: The intermittent flow occurs.

Those conditions are shown in Fig. 6. The value of U_0 is evaluated from the equation $U_0 = (egQ/b)^{1/3}$, which is derived from two equations, $Q = bh_1U_0$ and $U_0^2/egh = 1$, where Q and h_1 are temporal mean values of the discharge and a depth of the fresh water at the mouth, respectively. There arises a question whether the conditions thus obtained from experiments are valid for natural rivers or not. This will be discussed again in Section 5, with some theoretical consideration.

4. Tidal Change of Two-Layer Flow and Its Propagation

Problems of a stationary two-layer flow inside the river mouth are more or less related to those of the salt wedge. A prediction of a form of the salt wedge plays an important part for solving problems of this kind, and it is possible from the theory after Schijf-Schönfeld, by using a coefficient of interfacial resistance. Physical properties of the interfacial resistance have not fully been revealed yet, but studies on those are growing through experiments and field observations, along a definite line to relate the resistance with a certain parameter ψ , which is composed of the Reynolds number R and the interfacial Froude number F_1 , as $\psi = RF_1^2$.

Studies on the dynamical behavior of the two-layer flow which is under the tidal effect have been also developed in some degree mainly through field observations. For example, a front of the salt wedge is formed steep at the high water and is flattened at the low water; The surface level moves with not always the same phase with that of the interface; the salt wedge advances at the flood and retreats at the ebb, while the fresh water continuously flows down over the whole period, etc. Those are nowadays well-known facts, though fairly empirical.

The authors conducted a series of experiments with high accuracy on those problems, and also made field observations to test experimental

Figure 7(1).

Figure 7(2).

Figure 7(3).

Figure 7(4).

Figure 7(5).

results.

(a) Results of Model Experiments and Analyses

First, a change of the vertical distribution of velocity due to the tide is examined. Figs. 7 (1), (2), (3) and (4) show some examples. Observational points are 2.75 m upstream from the mouth, in cases of (1) and (2), and 1.3 m in (3) and (4). The discharge of the fresh water increases, in order, from (1) to (4). Fig. 8 shows a tidal change of salt concentration in the surface water (in electrical conductivity, $\mu\text{g}/\text{cm}$) at the mouth, at various values of discharge. Fig. 9 shows the same at different places inside the mouth. Throughout experiments, the tidal change of the level is given to move sinusoidally. If the discharge is small, for example, $Q = 1.91 \text{ cm}^3/\text{s}$ in Fig. 8, the salt water occupies the surface for some distance from the mouth at the flood, and it suggests an intermittent flow. This case belongs to a condition of the intermittent flow, $\lambda\theta > 1.63 \times 10^{-4}$, and the shape of the fresh water is sketched as shown in Fig. 10. When the discharge increases, the intermittent or upstream types disappear and the fresh water flows down every tidal hour, but on the other hand, the salt water beneath the fresh water, moves upstream and downstream according to the tidal hours. Such a case has frequently been experienced in field observations as shown in Fig. 7(5). However, the change of the interfacial level is more remarkable in field than in experiment.

As described above, the level, interface, velocity and salinity, change periodically with the tide at every point along the channel, and it suggests that those variations may propagate along the channel. Observations at two points, one of which is 50 cm upstream from the mouth and the other 350 cm, provide some properties of those propagations. Two examples are shown in Figs. 11 and 12. Experiments were performed with dye as a tracer and a movie camera. Fig. 11 is an example of no discharge, when the tidal periods are 33.3 sec and 100 sec. Both curves are different in phase with each other, where an exactly opposite trend can be found. This is because of that the case of 33.3 sec is resonant with the proper period of the channel which is 31.9 sec. According to a detailed observation at the upstream point, a change of velocity and level is observed always to have a phase difference $\pi/2$, the former being ahead of the latter. This fact is understood from a consideration that there occurs a cooscillating tide in the channel caused by the tide outside. Fig. 12 shows an example with the discharge $12.0 \text{ cm}^3/\text{s}$. The approximate behavior is almost the same with that of no discharge, since the amount of the discharge is relatively small. In those two examples, the effect of the external wave which is caused by the tide is dominant on the motion of water inside the channel, where the interface between the fresh water and the salt water moves at the same phase with the water surface.

The tidal current induced in the channel is next examined theoretically, in order to compare the observed results with it. If the channel has a constant depth and its length is small compared to the wave length of the external wave, equations of motion and continuity are given at the first approximation for an inviscid two-layer flow, as follows.

$$h_1 \frac{\partial u_1}{\partial x} + \frac{\partial}{\partial t} (\eta_1 - \eta_2) = 0 \quad (1)$$

Figure 8.

Figure 9.

Figure 10.

Figure 11.

Figure 12.

$$h_2 \frac{\partial u_2}{\partial x} + \frac{\partial \eta_2}{\partial t} = 0 \quad (2)$$

$$\frac{\partial u_1}{\partial t} = -g \frac{\partial \eta_1}{\partial x} \quad (3)$$

$$\frac{\partial u_2}{\partial t} = -g \frac{\rho_1}{\rho_2} \frac{\partial \eta_1}{\partial x} - \epsilon g \frac{\partial \eta_2}{\partial x} \quad (4)$$

where t is time, x is a coordinate along the channel from the mouth, η_1 and η_2 are vertical deviations of the surface and the interface from their temporal mean values, h and u are depth and velocity at each layer, and subscripts 1 and 2 represent the upper and the lower layers. By combining four equations, the next form of u is derived.

$$\frac{\partial^4 u_1}{\partial t^4} - g (h_1 + h_2) \frac{\partial^4 u_1}{\partial t^2 \partial x^2} + \epsilon g^2 h_1 h_2 \frac{\partial^4 u_1}{\partial x^4} = 0 \quad (5)$$

By introducing new symbols C_s as a velocity of the external wave, and C_i as the internal wave, such as $C_s^2 = g (h_1 + h_2)$, and $C_i^2 = \epsilon g h_1 h_2 / (h_1 + h_2)$, a general solution, $u_1 = f(mx + \sigma t) + F(mx - \sigma t)$ is obtained from Eq. (5) under the condition $\epsilon \ll 1$, where $\sigma/m = C_{s,i}$ which represents both C_s and C_i together. Similarly u_2 , η_1 and η_2 are given in the same form with u_1 .

$$\eta_1 = \eta_{10} \cos (mx - \sigma t) \quad (6-1)$$

$$\eta_2 = \left(1 - \frac{gh_1}{C_{s,i}^2}\right) \eta_{10} \cos (mx - \sigma t) \quad (6-2)$$

$$u_1 = \frac{g}{C_{s,i}} \eta_{10} \cos (mx - \sigma t) \quad (6-3)$$

$$u_2 = \frac{C_{s,i}}{h_2} \left(1 - \frac{gh_1}{C_{s,i}^2}\right) \eta_{10} \cos (mx - \sigma t) \quad (6-4)$$

Since the upper end of the channel exists, it can be assumed that the velocity $u = 0$ at $x = \ell$ which is the distance from the mouth. Furthermore, putting the tide level $\eta_1 = \eta_{10} \cos (\sigma t + \epsilon)$ outside the mouth, solutions are given as follows.

$$\eta_1 = \eta_{10} \frac{\cos \{m(x - \ell)\}}{\cos m\ell} \cos (\sigma t + \epsilon) \quad (7-1)$$

$$\eta_2 = \left(1 - \frac{gh_1}{C_{s,i}^2}\right) \eta_{10} \frac{\cos \{m(x - \ell)\}}{\cos m} \cos (\sigma t + \epsilon) \quad (7-2)$$

$$u_1 = \frac{g}{C_{s,i}} \eta_{10} \frac{\sin \{m(x - \ell)\}}{\cos m\ell} \sin (\sigma t + \epsilon) \quad (7-3)$$

$$u_2 = \frac{C_{s,i}}{h_2} \left(1 - \frac{gh_1}{C_{s,i}^2}\right) \eta_{10} \frac{\sin \{m(x - \ell)\}}{\cos m\ell} \sin (\sigma t + \epsilon) \quad (7-4)$$

Figure 15(1).

Figure 15(2).

Substituting experimental values which are shown in Fig. 12, as $\eta_{10} = 0.2$ cm, $T = 100$ sec and $l = 450$ cm, into Eq. (7-3), the value, $u_{10} \neq u_{20} = 1.36$ cm/s is found. This value is consistent well with the cross-sectional mean velocity, 1.2 cm/s, which is calculated from the lateral velocity distribution. Besides, the phase difference of the velocity and the level which has already been described as $\pi/2$, is also explained by those equations.

As pointed out like those, changes of the level and the velocity owing to the tide with the period 100 sec, coincide with those estimated from Eq. (7-3), where the propagation is based on the external wave. This fact, however, is not always true, because the interface grows remarkable with a distance from the mouth, and also with an increase of the tidal period. Such an example is shown in Fig. 13. These pictures are obtained through the technique by using the light-beam system which has already been described in Section 2. Since a propagation of the surface level is very fast, owing to its dependence on the external wave, the time difference cannot be detected at any station, but on the other hand, the interface is recognized to delay with a distance from the mouth. This means that the interface is affected more strongly by the internal wave. The experiments were made under condition that $Q = 9.67$ cm³/s, $\epsilon = 0.0067$, $\eta_{10} = 1.0$ cm, $T = 1623$ cm and a time interval of every exposure is 8.92 sec.

In order to investigate how the phase difference of the surface and the interface is related to the tidal period, experiments were repeated in a direction toward a decision of the time delay δ of the interface behind the surface, at various points along the channel. The results are shown in Fig. 14, in which $Q = 10$ cm³/s and $\eta_{10} = 0.27$ cm. From this figure, it can be understood that an increase of δ is approximately linear against x . Its gradient δ_i has a trend to grow steep with an increase of the tidal period. This means that a change of the interface propagates upstream with a certain velocity which depends on the tidal period. The velocity V is estimated undoubtedly as the reciprocal of δ_i . The dependency of V on the tidal period is seen also in Figs. 15 (1) and (2), in which the discharge or the tide amplitude is taken as a parameter, where the amplitude is very small compared with the whole depth.

From those results, it is found that V is exceedingly large at the period of 100 sec and the phase difference between the surface and the interface is negligible, but it decreases with a growth of the tidal period, and finally it converges to a certain small value. Those final values become to be independent of the tide amplitude, but they depend on only the discharge. Convergent values are very close to those calculated from the following equation which gives the velocity of an internal wave.

$$C_i = - \frac{U_2 h_1 + U_1 h_2}{h_1 + h_2} + \sqrt{g \frac{h_1 h_2}{h_1 + h_2} - \frac{(U_1 - U_2)^2 h_1 h_2}{(h_1 + h_2)^2}} \quad (8)$$

This coincidence proves that a change of the interface brought by the tide has a property of the internal gravity wave.

In conclusion, a short period of the tide produces only the external wave at both the surface and the interface, but a sufficiently long period of the tide causes the external wave at the surface and the internal wave

Figure 16.

Figure 17.

at the interface. There is no theory sufficient to explain all those phenomena in detail yet, but it is not only interesting but also important for a study on the salt wedge. Under the condition of a long period, it must be noticed that a velocity of the flow in the salt layer also propagates with the velocity of the internal wave, although a velocity of the fresh water shows that of the external wave. Then, the surface level rises and falls almost simultaneously everywhere along the channel, nevertheless, the interface delays in time behind the surface, with an increase of the distance, because a propagation of the velocity of the salt water is very slow. In an extreme case, when the surface rises, the interface at a certain point may sometimes fall. It is possible that the origin of the internal wave is situated at some place inside the river mouth, from paying attention to Fig. 14. Needless to say, the occurrence of the internal wave is due to the tide, but the mechanism in what manner the tide passes through the mouth is still unknown and it belongs to the future study. If the tidal period is short enough, the effect of the internal wave disappears inside the mouth, and the interface rises and falls simultaneously at any point, as shown in Fig. 14.

(b) Field Observation of the Two-Layer Flow and Analyses

Figs. 16 and 17 show examples of field observation, at two stations along the Teshio River in Hokkaido. One is 0.5 km upstream from the mouth, and the other is 5.1 km. Observations at both stations were made at every one hour over the whole period of 25 hours. Since the Japan Sea to which the Teshio River opens, has a small tidal range of about 30 cm at its maximum, the length of the salt wedge is little affected by the tide. The relationship between the length and the river discharge is shown in Fig. 18. In the case of Fig. 16, as the discharge is about $90 \text{ m}^3/\text{s}$, the length of the salt wedge is estimated about 15 km. In Fig. 17, the length is expected 22 km, since the discharge is $44 \text{ m}^3/\text{s}$. According to the hydrograph obtained at the station of 18.3 km from the mouth, the change of the water level coincides with the tide, except flood days. This means that the external wave caused by the tide can travel for a great distance along the river without decay.

The surface level, interface velocity, water temperature and electrical conductivity were observed. It is noticeable that the change of the velocity contains irregular components whose periods are smaller than the tide, at the lower station. It seems to have been caused by the stormy weather which produces a seiche with a long period. After eliminating those components, the careful comparison of tidal components of the level, interface and velocity with each other, will lead to understanding that they are waves rather progressive towards upstream, than standing waves which have been discussed in the preceding section. This is evident from the fact that there is no reflection from the upstream of the river and the tide is caught without decay even at a very far station upstream from the river mouth.

In such a case, Proudman's solutions seems to be adoptable. The velocity is calculated from Eq. (6) as $u_{10} = 10.7 \text{ cm/s}$. This is very close to the cross-sectionally averaged value 13 cm/s , while the value at the center of the flow is 20 cm/s , as shown in Fig. 13. As described like those, since all the changes are thought progressive, there can be a phase difference at two stations upper and lower. However, the external wave is estimated as 7 m/s in velocity and its travel time is only 11 minutes over the distance of 4.6 km between both stations.

Figure 18.

Figure 20.

Figure 19(1).

Figure 19(2).

Therefore, the time difference of the surface level is not detected between the two stations. For the purpose of finding of the detailed relationship between the surface and interface levels, enlarged figures are shown in Figs. 19 (1) and (2), in which the interface is defined as a level of 30,000 $\mu\text{S}/\text{cm}$ in electrical conductivity. A representative type of the vertical distribution of electrical conductivity which corresponds to density, is shown in Fig. 20. The time difference of the surface level and the interface is negligible at the lower station, but not at the upper station as easily expected. There are 3-4 hours in Fig. 19 (1) and 2.5-3 hours in Fig. 19 (2). They are approximately the same with values of the internal wave which passes through two stations, where the former is calculated 3.1 hours and the latter 2.7 hours by using Eq. (8).

From all those experienced in field observation, the tidal effect at the Teshio River can be regarded as the same with that experienced in the experiment of a long tidal period which has already been described. It must be stressed again that the velocity change in the salt layer propagates with a velocity of the internal wave also in field observations. However, the velocity of the fresh water doesn't seem, for the present, to have a property of propagation of the internal wave.

There are many other important problems unsolved. For example, the case in which the tidal range becomes comparable with the water depth; a problem of the degree of a change of the interface level, which is much larger in field than in experiment, etc. are belonging to future studies.

5. Tidal Mixing of Two Layers

In a case of a negligible tide, mixing of the two-layer flow is thought to occur by interfacial instability and turbulence, caused by an increase of the relative velocity of the two layers. In such a case, the salt wedge has another phenomenon. The increase of the relative velocity brings a retreat of the salt wedge and finally pushes it out from the river mouth into the sea. From those two facts, it is understandable that if the salt wedge exists inside the river, mixing of two layers is always weak or negligible. Therefore, the existence of various types of mixing has been, hitherto, considered to depend on the tidal effect. The intense mixing type of a density current inside a river mouth or an estuary is, for instance, possible only in a case of the great range of tide.

In order to test this point of view, the authors repeated experiments with various degrees of the tidal range. However, contrary to expectation, there occurred no intense mixing, nor moderate mixing but always a type of distinctly separated two-layer flow, at any large value of the tidal range. As has already been described, the channel used in the experiments has a smooth bed and smooth sides, since it is made of acrylic resin. According to another experiment in which roughness is given to the bed, flow patterns change completely and mixing occurs even with a relatively small tidal range.

Examples are shown in Figs. 21 (a), (b), (c) and (d), whose conditions are, $T = 200$ sec, $Q = 10$ cm^3/s , $\epsilon = 0.0067$ and the total depth is 4 cm. The roughness is given with rectangular wooden pieces having a square cross-section of 6 mm \times 6 mm and every spacing is 10 cm in distance. Figs. from (a) to (d) are photographed at the flood, where the amplitudes of the tidal range are $\eta_{10} = 4.9$ mm, 8.4 mm, 17.3 mm and 20.7 mm,

Figure 21(a).

Figure 21(b).

Figure 21(c).

Figure 21(d).

Figure 22.

respectively. The interface is distinct and straight horizontally in Fig. (a). Lee waves occur in Fig. (b), and the interface begins to break down in Fig. (c), in which many vortices produced behind wooden pieces move with the current, gradually growing and disturbing the interface, and finally break the interface in such a manner that vortices drag down the interface into themselves, and cause mixing of the two layers. A type of fully developed mixing is found in Fig. (d), which is that of the so-called intense mixing. In the case of Fig. (d), however, the interface has a trend to restore its original two-layer type at the ebb time. Therefore, in order to keep the intense type over the whole period, a larger amplitude is necessary.

As thus described, mixing is deeply dependent on the roughness of the channel and a strength of the tidal current. The degree of mixing is classified with two parameters λ and θ , which have already been used in the classifications of outflow pattern, as shown in Fig. 22. Although experiments are not so plentiful enough to derive the conclusion yet, within the limited range of values of θ , breaking of the interface occurs, when $\lambda\theta \geq 6 \times 10^{-4}$, and a transition to the intense mixing type is found, when $\lambda\theta \geq 9 \times 10^{-4}$. But the observational results in field are not so coincident with those values, that another new parameter should be introduced, instead of λ . According to field measurements, since the tidal current depends rather on a velocity of the external wave, than on the tidal period, another parameter such as $\lambda_U = KgA_0/C_S U_0$ was tried to take into account, but at present it is not successful. Unification of the results, both in field and experiment, by discovering a reasonable parameter, is an important problem for further study.

CHAPTER 184

EVALUATION OF AIR-SEA INTERFACE HEAT FLUX

ROBERT L. STREET¹, M.ASCE
A. WOODRUFF MILLER, JR.²

ABSTRACT

A theoretical analysis, laboratory experiments, and the routine availability of infrared remote sensors for boat, airplane or satellite use are combined to provide a simple method for evaluating the total heat flux through the air-water interface under nighttime field conditions in which the water surface is rough; all indications are that the technique can be extended to other conditions as well. To evaluate this flux all that is required is the local windspeed, the water surface temperature, a subsurface temperature, and the character of the sea surface. Conversely, the theory can also be applied to predict temperature differences across the interface if the heat transfer can be otherwise established.

INTRODUCTION

Rejection to the atmosphere is the ultimate fate of the heat released by thermal power plants. The probable development of off-shore nuclear plants and the existing coastal power plants make necessary an understanding of and a means of evaluating the effects of ocean waves and the wind on the total heat transfer and/or temperature gradients across the air-sea interface. This transfer is important to local ocean thermal conditions and as an input to the development of local climatology.

The key to estimating interface transfer is knowledge of the temperature structure in the aqueous boundary layer just beneath the air-

water interface. Saunders (1967) said, "For some decades it has been known that the surface is generally cooler than the subsurface water with the major temperature variation concentrated in the uppermost millimeters." He also noted, "When used from a near surface position, radiometers afford a unique tool for determining the magnitude of this surface anomaly, and ... it seems likely that they will become indispensable in field experiments where the transfer of heat, moisture and momentum are measured." Following this Hasse (1971) considered the heat flow through the surface. Disregarding initially the short wave radiation due to the sun, he developed a theoretical analysis, based on the diffusivity relationship of Reichardt, for the vertical transfer of heat in the aqueous boundary layer that is required to balance the heat loss (or gain) at the surface through evaporation, sensible heat transfer and effective back radiation. He then provided a theoretical relationship including the influence of the sun.

Using the insight provided by Saunders and Hasse, we have extended the latter's theoretical analysis, used our own laboratory experiments, and presumed the routine availability of infrared remote sensors for boat, airplane or satellite use to provide a simple method for evaluating the total heat flux through the air-water interface under *nighttime* field conditions in which the water surface is rough; all indications are that the technique can be extended to other conditions as well. To evaluate this flux all that is required is the local windspeed, the water surface temperature, a subsurface temperature, and the character of the sea surface. Conversely, the theory can also be applied to predict temperature differences across the interface if the heat transfer can be otherwise established.

The work of Scarpace and Green (1973) at Wisconsin gives a good illustration of the applicability of such a theory. Airborne thermal imagery (infrared radiometry) was used on thermal plumes. The imagery was supported by simultaneous data taken from boats. They reported:

The scanner is virtually impossible to calibrate from the air. It also gives no information on subsurface temperatures. Thus an intensive ground truth effort is essential to providing both accurate data and supporting information.

While the plane was overhead (sometimes shortly before and after), two or three surface craft measured underwater temperatures with Whitney resistance thermometers, while [a 40 ft R/V boat] made several passes over a predetermined course marked by 20 buoys. The PRT-5 [radiometer] was mounted on the bow.

Application of the method discussed below would either yield the heat transfer from the Scarpace and Green data or, combined with meteorological and wave data, obviate the need for either the subsurface or the PRT-5 data as ground truth.

BASIC THEORY

As mentioned above both Saunders and Hasse developed theories for the heat transfer and temperature difference relationship in the aqueous boundary layer. Saunders' theory was applicable across the so-called thermal sublayer where molecular effects are dominant, while Hasse's theory applies across a specific depth of the layer (as does ours). Interestingly the attempts to verify Saunders' theory have been made through experiments more relevant to Hasse's and our theories, leading to a diversity of results for Saunders' transfer coefficient λ .

Hasse (1971) suggests treating the flux Q_T in the aqueous surface layer in differential form as (Fig. 1)

$$Q_T = -\rho_w c_{p_w} K \frac{\partial T}{\partial z} \quad (1)$$

where $K = K(z)$ is the *effective* thermal diffusivity, T is the water temperature, ρ_w is the density of water, c_{p_w} is the heat capacity of water, and z is measured positive downward from the surface. If $\partial T/\partial x$ is essentially zero, and we speak of a steady mean flow so $\partial T/\partial t \equiv 0$, then

$$Q_T = -\rho_w c_{p_w} K \frac{dT}{dz} \quad (2)$$

In the surface layer Q_T is constant below the level of back radiation and in the absence of solar (incoming) radiation. We ignore the temperature effects on ρ_w and c_{p_w} across the thermal layers. Then,

$$\frac{dT}{dz} = -\left(\frac{Q_T}{\rho_w c_{p_w}}\right) \frac{1}{K(z)} \quad (3)$$

The key parameters of the problem are summarized as follows (see Fig. 1):

- h = mean surface roughness (wave) height
- k' = Kármán constant = 0.40
- Pr = molecular Prandtl number = ν_w/κ_w
- $U_{*w} = (\tau_o/\rho_w)^{\frac{1}{2}}$ = friction velocity in water
- z_b = depth of "bulk" water temperature measurement
- z_s = radiometer optical depth ($z_s \approx 140 \mu\text{m}$ for our experiments, while $z_s \approx 20 \mu\text{m}$ for a PRT-5)

- δ_t = thermal sublayer thickness
 δ_T = thermal layer matching thickness (i.e., the point at which the temperature profile becomes logarithmic)
 δ_v = viscous sublayer thickness
 κ_w = thermal diffusivity of water
 ν_w = kinematic viscosity of water
 τ_o = surface shear stress

We also define a set of nondimensional (Reynolds) numbers:

$$\begin{aligned}
 h^+ &= U_{*w} h / \nu_w; & z_b^+ &= U_{*w} z_b / \nu_w; & z_s^+ &= U_{*w} z_s / \nu_w; \\
 \delta_T^+ &= U_{*w} \delta_T / \nu_w; & \delta_t^+ &= U_{*w} \delta_t / \nu_w; & \delta_v^+ &= U_{*w} \delta_v / \nu_w
 \end{aligned}
 \tag{4}$$

Yaglom and Kader (1974) discussed the flow over and heat transfer from rough surfaces. They defined the functional form of the eddy viscosities and eddy diffusivities in the surface layers; we employ their formulations here. We also let $\Delta T_t = T_s - T_b$ where T_s and T_b are the "surface" and bulk water temperatures and the heat transfer coefficient becomes

$$\frac{1}{C_H} = \frac{\rho_w c_p U_{*w} \Delta T_t}{Q_T}
 \tag{5}$$

The immediate objective of our work was to obtain an explicit relationship between $1/C_H$ and the parameters of the flow. Our goals then were *first* to use our results from a laboratory experiment employing an infrared radiometer to relate δ_v^+ to h^+ for rough flows and *second* to employ this relation to predict $1/C_H$ for any rough flow. The experiments were run in the Stanford Wind, Water-Wave Research facility (Fig. 2).

The key to the analysis is prescription of $K(z)$. We have developed expressions based on Yaglom and Kader's analysis for fully rough wall flows, i.e., for $h^+ > 100$. Thus,

$$\epsilon_H = a_H' \nu_w (h^+)^{-3/2} (z^+)^3
 \tag{6}$$

$$\epsilon_M = a_M' \nu_w (h^+)^{-3/2} (z^+)^3
 \tag{7}$$

near the rough wall, where ϵ_H and ϵ_M are the eddy diffusivities for heat and momentum, respectively, and a_H' and a_M' are supposed constant for any given boundary geometry.

For the layers shown in Fig. 1 we must have

$$\text{a. at } z^+ = \delta_t^+ : \epsilon_H = a_H^+ \nu_w (h^+)^{-3/2} \quad (\delta_t^+)^3 = \kappa \quad (8)$$

$$\text{b. at } z^+ = \delta_v^+ : \epsilon_M = a_M^+ \nu_w (h^+)^{-3/2} \quad (\delta_v^+)^3 = \nu \quad (9)$$

$$\text{c. at } z^+ = \delta_T^+ : \epsilon_H = a_H^+ \nu_w (h^+)^{-3/2} \quad (\delta_T^+)^3 = k^+ \nu \delta_T^+ \quad (10)$$

Thus we require $\epsilon_H = \kappa$ at the edge of the thermal sublayer, $\epsilon_M = \nu$ at the edge of the viscous sublayer, and $\epsilon_H = k^+ U_{*w} z$ as a matching condition so the eddy diffusivity given by the cubic estimate matches that of the logarithmic layer (cf., Sec. 3.2, Kader and Yaglom, 1972). Using Eqs. (8-10) and other arguments (see, Street and Miller, 1976), we were able to conclude, first, that the classic relation

$$\delta_t^+ / \delta_v^+ = Pr^{-1/3} \quad (11)$$

is still valid, and, second, that

$$\delta_v^+ = k^{-1/3} \delta_T^{+2/3} \quad (12)$$

or

$$\delta_T^+ = 0.63 (\delta_v^+)^{1.5} \quad (12)$$

It follows that, if $K(z) = \kappa + \epsilon_H$, then

$$\text{a. in } z_s \leq z \leq \delta_T^+ : K(z) = \kappa [1 + (z^+ / \delta_T^+)^3] \quad (13a)$$

$$\text{b. in } \delta_T^+ \leq z \leq z_b : K(z) = \kappa (1 + 0.4 Pr z^+) \quad (13b)$$

Therefore, our basic equation (Eq. 3) can be integrated to give

$$\int_{T_s}^{T_b} dT = \left(\frac{-Q_T}{\rho_w c_p} \right) \int_{z_s}^{z_b} \frac{dz}{K(z)} \quad (14)$$

which leads to

$$\frac{1}{C_H} = \frac{\text{Pr}\delta_t^+}{3} \left[\frac{1}{2} \ln \left\{ \frac{(\delta_t^{+2} - \delta_t^+ z_s^+ + z_s^{+2})(\delta_t^+ + \delta_T^+)^2}{(\delta_t^{+2} - \delta_t^+ \delta_T^+ + \delta_T^{+2})(\delta_t^+ + z_s^+)^2} \right\} + (3)^{\frac{1}{2}} \left\{ \tan^{-1} \left(\frac{2\delta_T^+ - \delta_t^+}{(3)^{\frac{1}{2}}\delta_t^+} \right) - \tan^{-1} \left(\frac{2z_s^+ - \delta_t^+}{(3)^{\frac{1}{2}}\delta_t^+} \right) \right\} \right] \quad (15)$$

$$+ 2.5 \ln \left\{ \frac{1 + 0.4 \text{Pr}z_b^+}{1 + 0.4 \text{Pr}\delta_T^+} \right\}$$

EVALUATION OF RELATION BETWEEN δ_v^+ AND h^+

The data of Miller, et al. (1975) were used, together with Eq. (15), by Street and Miller (1976) to obtain an estimate of the relation between δ_v^+ and h^+ . Indeed Yaglom and Kader (1974) hypothesize (in effect) that

$$\delta_v^+ = a^+ (h^+)^{\frac{1}{2}} \quad (16)$$

Thus, we sought the constant a^+ for rough flows ($h^+ > 100$).

To establish a^+ we used 23 cases of wind-generated waves in the Stanford laboratory facility (Fig. 2) with water to air temperature differences of about 2.5, 5.0 and 7.5°C at fetches of 9.5 and 14.5 m (Miller, et al., 1975). The water surface temperatures were measured to $\pm 0.01^\circ\text{C}$ with an infrared radiometer employing an indium antimonide detector with a wave length range of 1.5 to 5.5 μm and an optical depth z_s of about 140 μm . (Extracting the surface temperature involved special calibration and computational techniques and consideration of the wave-length dependent, water and air, optical properties within the detector band width; details can be found in Miller, et al., 1975.) The thermal layer temperature difference ΔT_t was defined as the bulk water temperature T_b measured 100 mm below the mean interface minus the average temperature at $z = z_s = 140 \mu\text{m}$. The parameters used in calculating surface temperature and wave height were monitored continuously. Other parameters, such as mean free-stream air velocity, temperature and humidity, were obtained also. They formed the basis for calculating the total heat transfer and surface roughness Reynolds numbers h^+ through use of data collected by previous investigators in the Stanford channel.

From our experiments we derived the key result that $a^+ = 0.37$ so

$$\delta_v^+ = 0.37(h^+)^{\frac{1}{2}} \quad (17)$$

Thus, Yaglom and Kader's conjecture for rough solid surfaces applies as well to mobile surfaces and

$$\delta_v^+ = 0[(h^+)^{\frac{1}{2}}] \quad (18)$$

We also have from Eq. (11)

$$\delta_t^+ = 0.37(\text{Pr}^{-1/3})(h^+)^{1/2} \quad (19)$$

FIELD USE

The statistical distribution of wave heights in both laboratory and field is known to be a Rayleigh distribution. In addition, the similarity theory of Yaglom and Kader (1974) which underlies Eqs. (17) and (19) should not be scale dependent, a^+ being supposed to vary only with surface shape. Accordingly, we believe that Eqs. (17) and (19) should be valid in the field as well as in the laboratory, except perhaps in the presence of long-wave swell which should be subtracted before computing h^+ for the remaining sea (defined here as freshly generated waves).

Given that δ_v^+ and δ_t^+ are known via Eqs. (17) and (19) as functions of h^+ and Pr , we may use Eq. 15 with a minimum of measurements to obtain C_H . When C_H is known we can predict Q_T by measuring U_{*w} , the sea surface physical characteristics, the surface temperature (with an infrared radiometer to obtain T_s and, hence, ρ_w and c_{pw}) and the bulk water temperature T_b (in any convenient manner).

One possible approach to obtain U_{*w} and the necessary sea surface characteristics is as follows. Hsu (1974) shows that the dynamic roughness z_o of a water surface can be expressed as

$$z_o = \frac{1}{2} \frac{H}{(C/U_{*a})^2} \quad (20)$$

where H is the dominant wave height, C is its phase velocity and U_{*a} is the friction velocity in the atmospheric constant-flux layer. Using the results of Kondo, et al. (1973), Kondo (1975) determines that the mean surface roughness height h is given by

$$h = 30 z_o \quad (21)$$

for completely rough flow above the sea (established to occur when $U_{10} \geq 8 \text{ m}\cdot\text{s}^{-1}$ where U_{10} is the windspeed at 10 metres elevation). Of course, h can be measured directly also. Kondo (1975) also shows that the drag coefficient

$$C_D = (U_{*a}/U_{10})^2 = 10^{-3}(1.2 + 0.025 U_{10}) \quad (22)$$

for $U_{10} \geq 8 \text{ m}\cdot\text{s}^{-1}$. Applying the assumption of stress continuity across the interface yields

$$U_{*w} = (\rho_a/\rho_w)^{\frac{1}{2}} U_{*a} \quad (23)$$

where ρ_a is the air density. Given U_{10} and the temperatures in air and water, U_{*w} is found by the combination of Eqs. (23) and (22).

Hasse (1971), Saunders (1967), and others have followed the concept of stress continuity across the interface, according to Eq. (23). Wu₂ (1975) points out clearly that the fraction of the momentum flux $\rho_a U_{*a}^2$ from the air which goes to drift currents ranges from about 0.6 to 0.8 in the rough flow regime, the remaining flux going to wave generation. In a rough boundary case where eddying is driven by the drift current boundary layer flow and the random water wave motion together it is not entirely clear whether one should use U_{*w} or some fraction thereof as the reference velocity (the fraction ranging apparently from $\sqrt{0.6} \approx 0.8$ to $\sqrt{0.8} \approx 0.9$). We feel that, pending further evidence, the use of U_{*w} is best.

Thus, Eqs. (15), (17), (19), (21-23), and (12) are the needed set for prediction of the heat flux and temperature difference relationships for a given wind and sea state. Given basic physical data one can either predict ΔT_t from known Q_T or predict Q_T from known ΔT_t .

AN APPLICATION

An example illustrates the variation of parameters. Assume that T_b is 20°C so ν_w , ρ_w , c_{pw} and $Pr = 7.1$ are known. Take $T_{air} = 15^\circ\text{C}$ so ρ_a is known and assume $U_{*a} = 0.381$ (equivalent to $U_{10} = 10 \text{ m/s}$, for example). We employ a PRT-5 radiometer so $z_s = 20 \mu\text{m}$ and measure the bulk temperature at one of 3 depths, viz., $z_b = \delta_T$, $z_b = 1 \text{ cm}$ and $z_b = 10 \text{ cm}$.

Under these conditions $h^+ = (1.3 \times 10^4)h$ so $h^+ > 100$ when $h > 3/4 \text{ cm}$. One finds, for example,

$$z_s^+ = 0.27 (\delta_v^+ \geq 3.7, \delta_t^+ \geq 1.9 \text{ and}$$

$$\delta_T^+ \geq 4.5 \text{ for } h^+ \geq 100)$$

$$z_b^+ = \delta_T^+, 133 \text{ or } 1330$$

In Fig. 3 we show δ_v^+ and δ_t^+ as functions of h . As expected $\delta_t^+ \approx \frac{1}{2} \delta_v^+$ and both are proportional to \sqrt{h} . Figure 4 shows the inverse transfer coefficient C_H^{-1} as a function of h and z_b . As δ_T represents the point of transition to the fully turbulent, logarithmic temperature profile, $z_b = \delta_T$ corresponds to neglecting any temperature variation between δ_T and the actual measurement point for bulk temperature. As Saunders' theory neglects even the variation between $z = \delta_t$ and $z = \delta_T$, it is clear that comparison of laboratory or field measurements to Saunders' theory is moot because we cannot measure at $z = \delta_t$ which lies between the surface roughness. From this figure we see that neglecting the temperature variation in the logarithmic zone leads to an error of between 10 and 50 percent for $z_b = 10$ cm.

The final figure (Fig. 5) shows ΔT_t , i.e., the surface temperature depression for a typical field heat transfer value with all the previous assumptions in effect. Clearly a 1 to 2°C depression over 10 cm is worth considering.

The next step in our efforts will be to carry out the straightforward extension of our theory to daytime (significant solar radiation) conditions and to transition rough and smooth flow conditions.

CHAPTER 185

STATE ESTIMATION OF ESTUARINE CIRCULATION AND WATER QUALITY BY NUMERICAL SIMULATION AND OBSERVATION

J. J. Leendertse; S. K. Liu

The Rand Corporation, Santa Monica, CA, U.S.A.

SUMMARY

This paper describes a hindcast of post-rainstorm coliform bacteria distributions in Jamaica Bay made by use of a water-quality simulation model of that bay and models of the surrounding drainage basins on the basis of tide, wind, and rainfall data. That hindcast is then compared with coliform estimates obtained by field sampling.

Although the investigators did not have access to the results of the field sampling until the hindcast was completed, the estimates obtained by simulation agree well with the estimates from field data. It is concluded that the models used here are capable of making predictions for engineering assessments.

INTRODUCTION

The City of New York is presently working to terminate the discharge of untreated combined sewer overflows after rainstorms by constructing Auxiliary Water Pollution Control Facilities (AWPCFs) around the periphery of Jamaica Bay (Fig. 1). The completion of this plan, together with ongoing upgrading of existing Water Pollution Control Facilities (WPCFs), would open the possibility of extensive use of the area for recreational purposes. Being within the City limits, it is ideally suited for that purpose.

Control of water pollution is generally a difficult task; extensive engineering analysis is required prior to committing large amounts of capital for the construction of facilities. The problems of analysis are compounded in this case, where water pollution control must be applied to the large intermittent discharges of relatively short duration caused by rainstorms.

For the optimal design of a control system as a whole and the auxiliary plants which are part of that system, the quality and quantity of the overflows, as well as the impact of each of the overflows upon the water quality in the bay, must be determined for rainstorms of different intensity and duration.

To optimize the design of AWPCFs with respect to required storage and treatment characteristics, it is particularly important to know the drainage basins' responses to rainstorms in quantity and quality of overflow, since overdesign would make the installations much more expensive to build and underdesign would impair the system's effectiveness. The tools for such assessments have been developed in a previous study [1]. Models of the different drainage basins around the bay are now available, and water-quality distributions can be computed by means of a two-dimensional model of the bay [2-7].

Figure 2 presents an overview of the Jamaica Bay urban estuarine water-quality simulation system. This figure shows the boundaries of several major drainage systems, together with the results of the water-quality simulation model for the bay itself.

The area around the bay is generally residential, with a large population. In certain areas there are more than 100 housing units per acre. However, along the northwestern shore of the bay much open undeveloped space still exists. These areas can be noted easily in the aerial photograph of the bay (Fig. 1), which is on the same scale as Fig. 2. It will also be noted that the islands in the bay are not developed except the Broad Channel community along the north-south connection through the bay.

Two airports are situated near the bay. A runway of John F. Kennedy International Airport extends onto a marshy island in the bay. The boundaries of the drainage basins near Kennedy Airport are not known exactly, but their storm-water discharges into the bay are accounted for and the discharge points are shown. Similarly, we accounted for a major storm-water discharge from a large, densely populated area west of the bay, namely, the Mill Basin separate system.

The effectiveness of the drainage basin models and the water-quality simulation model was evaluated by the observation, simulation, and state estimation of coliform distributions in Jamaica Bay resulting from a rainstorm during the period from May

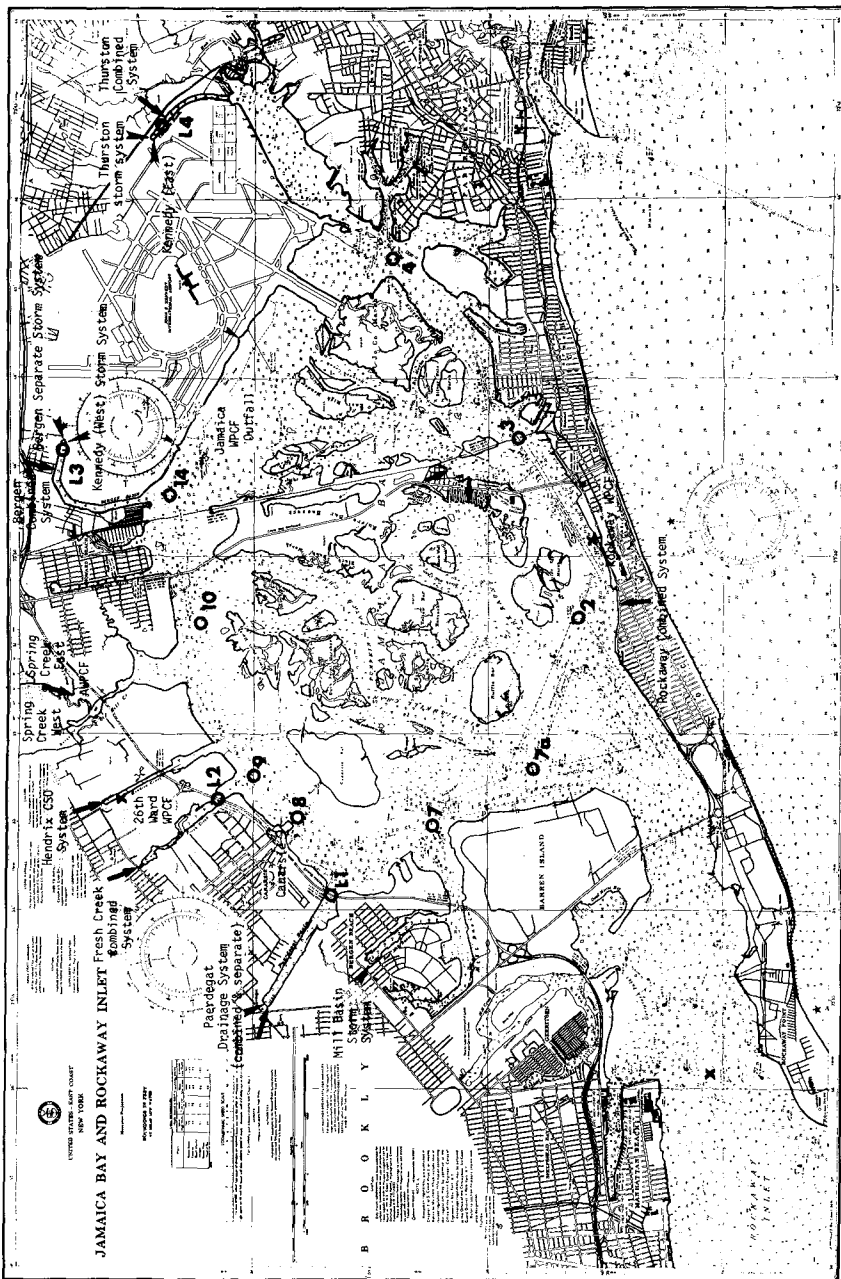

Fig. 3--Location of field sampling stations and the major discharges into Jamaica Bay

31 to June 3, 1972. This evaluation is presented in Ref. 7. In that experiment the results obtained by estimation agree well with those obtained by field measurement.

Because these predictive tools are important to the optimal design of the control system and its components, another evaluation was made based upon very extensive field measurements made by City personnel in the period of June 13 to June 17, 1973. To obtain from these models predictions completely unbiased by knowledge of observed water-quality data in the bay, the data from the observations were retained by the City until the predictions were completed. The present paper describes the results of this second evaluation experiment, in which state estimates obtained from field measurements were compared with estimates obtained from simulations.

DRAINAGE BASIN SIMULATIONS

The peripheral drainage areas of Jamaica Bay are served by nine major sanitary storm combined systems with a total drainage area of approximately 17,700 acres. An additional 19,000 acres of peripheral drainage areas have storm water systems which are separate from the sanitary system. These drainage systems, together with their points of discharge, are shown in Figs. 2 and 3. To simulate the water quality of the bay, the quantity and quality of discharge from these drainage areas during and after the storm must be determined.

These data were obtained by models for each of the drainage basins. Models were used because it is not physically possible to measure the quantity and quality of the time-varying overflows from each of the drainage systems simultaneously. Also, the City intends to use these drainage basin models for the real-time control of AWPCF operation after rainfall, as described in Ref. 1.

Consequently, the applicability of these models was proved in the experiment described here by predicting the time histories of the discharges and coliform concentrations from rainfall data. Thus, if the predictions made with the drainage basin model provided adequate input for the water-quality simulation and if the state estimates of coliform in the bay obtained by simulation agreed well with those obtained by observation, both types of models would be verified* and the models would be then considered suitable for use in prediction and control.

The drainage basin models use response functions which relate the overflow to the rainfall after taking into account depression storage of the rain and infiltration into the ground. For five of these basin models, the response functions were derived from extensive data sets of rainfall and the resulting overflow. These data, measured in 1970 and 1971 during a field study of water quality in the bay and inputs into the bay, were made available to us by the City. In determining the response functions from these data sets, we made extensive use of cross-spectral analysis, as described in Ref. 1. For those basins where these data were not available, response functions of a basin with similar hydrological and waste loading characteristics were used with modifications for the size of the basin.

* In a strict sense, compensating features do exist for these two types of models; they originate mainly from the time variability in the runoff quality estimates and the estimation of diffusive transport in the bay model. These characteristic compensating components would have equal probability of realization in future prediction when both models are used together. The expected variability of prediction should be similar to that determined from the present experiment.

To prepare the drainage system inputs of the water-quality simulation, the digitized rainfall data were first converted into effective net rainfall by estimating the system's imperviousness parameter and the depression storage. Then, for the free-flow system (i.e., no tidal influence downstream), the computed overflow hydrographs were obtained by means of numerical convolution of effective net rainfall and response functions.

For the downstream-controlled system, the time-varying overflow discharges were determined from the effective rainfall by a procedure which takes into account the water levels on each side of the tide gates in the overflow structure and the storage and flow characteristics of the sewer system. Determining these downstream-controlled discharges is much more complicated than for the free-flow discharges, since the former may have a delay of several hours for part or all of the discharged quantity when the tide gates close during high water.

The time histories of the bacterial concentration in each of the CSOs were computed from a formula that incorporates the basic mechanisms of surface washing, conduit dilution, and bottom scouring from within the system[1]. For the separate storm water systems, the quality of the discharge was based upon field data monitoring during a summer season, and a mean value of 70,000 MPN/ml was estimated.

A typical result of a drainage basin simulation is presented in Fig. 4. The hyetograph and the overflow, the response kernel, the overflow hydrograph, and the pollutograph are shown for the Thurston combined system.

The hyetograph is expressed in terms of inches per hour per unit area. The resulting system overflow is presented in the same graph in the same units for easy comparison. It will be noted that the total rainfall quantity is much larger than the overflow, since there is considerable loss from infiltration into the ground, especially within a large cemetery situated in the middle of this drainage area. Furthermore, part of this precipitation was handled by the WPCF as intercepted flow.

The location (+) of the rain gauge and the overflow (0) are indicated in the insert map on the hyetograph. The location of overflow as indicated refers to the location of the discharge in the two-dimensional model, not necessarily the actual geographical location due to the schematization. The zero reference for the elapsed time in this figure is at noon, June 13, 1973.

The rainfall intensity for this drainage basin was obtained from the rain gauge at John F. Kennedy International Airport.

The coordinates of the response kernel are expressed in terms of cubic feet per second per inch. This unit was selected so that digitized rainfall data sensed from the tilting-bucket rain gauge (volume increments per 10 min) network installed in the drainage systems can be used directly to produce overflow discharges in cubic feet per second (cfs) through a simple machine computation.

The peak of the response kernel occurs at a time of one hour. As the rainfall intensity is strongly peaked, the overflow hydrograph also shows a peak, but at an elapsed time which is one hour later than the occurrence of the peak of the rainfall intensity.

The overflow hydrograph is also presented in cfs. The pollutograph shows the time history of coliform concentration on the overflow in MPN/ml.

THE SIMULATIONS

The water-quality simulation was carried out for four calendar days from 0000 hr of June 13, 1973 through 2400 hr of June 16, 1973, with $T = 0$ at 0000 hr of June 13, which is approximately 14 hr before the beginning of the rainstorm. The time step of the simulation was 1 min ($\Delta t = 60$ sec). A coliform disappearance rate of 2.65×10^{-5} /sec, which corresponds to a 90-percent decay in concentration per day, was used throughout the simulation; this is the same as previously used. All the other parameters required for the simulation were kept the same as for the simulations of the previous rainstorm which was used for verification, as reported in Ref. 7.

The first simulation run which was made without the geostrophic boundary correction as described earlier caused some perturbations in the velocity field near the entrance. However, these local perturbations did not appear to influence the interior of the model.

In preparing the graphical outputs of the spatial distributions of coliform after the briefing, we noted that part of the records were lost because of a bad computer graphics tape. Also, from reviewing the drainage basin inflow time histories, we noted that several small values of inflow from the Rockaway CSO were inserted by mistake at the first hour of the second simulation day when the values should have been zero. For these reasons and because of our intention to try the geostrophic boundary correction, we made another simulation run without using any additional field information.

As mentioned earlier, this correction was made in anticipation of using this boundary information not only for this experiment, but also for a future investigation of the influence of a planned hurricane barrier in Rockaway Inlet. The major portion of the graphical results presented herein is from the second simulation. Charts with spatial distributions of velocities, mass transports, and coliform were obtained at time intervals of 124 min (2 lunar hr); a typical example of the velocity distribution is shown in Fig. 5. The following basic information is given in this chart, which represents the situation at 2235 min from the beginning of the simulation:

1. Clock time and date.
2. Wind speed (kn) and direction.
3. Locations and names of eighteen peripheral inputs, indicated by (O).
4. Tidal and wind-induced current velocity vector (2 ft/sec corresponding to a grid) on every point of the computation in each direction.
5. Current velocity and tide stage at eighteen stations throughout the bay. The value to the left of these current stations marked by (x) is the local velocity, the value to the right is the local water level.
6. Contours of equal velocity, with the values of the isolines indicated in the lower right corner of the chart. The lowest contour is at 0.2 ft/sec.

To relate the flow field to the tide stage, we also show in the figure a graph of the computed tide at Rockaway near the boundary of the model. The tide stage is indicated by a small arrow on the tide curve.

The velocities in Grassy Bay in the northeastern part of Jamaica Bay are very low: only in part do the vertically-averaged velocities exceed 0.2 ft/sec. If the veloc-

ies are a little smaller than 0.2 ft/sec, the vectors are not plotted, since their direction cannot be determined from the graphical output. The velocities in the inlet are the highest, exceeding 2 ft/sec.

Figure 6 shows, for the same time, the transports in cfs per ft width. The basic information on the chart is very similar to that of the velocities in Fig. 5. In this graph the isocontours of the transports are shown, as well as the transport vectors. Since the transports also reflect the depth, the figure shows more clearly the flow in the bay during the incoming flood tide. As water flows out of the channels onto the tidal flats, the transport intensities decrease towards the northeast. It will be noted that at this time the wildlife refuge in the center of the bay is filled to a large extent by flow in a northeasterly direction, through the so-called Pumpkin Patch Channel.

Grassy Bay is filled by the flood flow from the south as well as from the west. In order to study the flow pattern in this bay in more detail, the transport vectors in the bay were enlarged five times in comparison with the vector intensities in the remainder of the figure. The flow, through the deep channel which enters from the south, generates eddies in Grassy Bay, apparently by a kind of jet effect.

Figure 7 shows another typical result of the simulation. This graph shows the isocontours of the coliform concentrations as well as the velocity vectors and the area flooded at that time. This is shown by a dot (·) at the water-level point which participates in the computation at the time of plotting.

The condition represented by this figure shows that the marshes in the bay are only partially flooded. In contrast to figures shown in previous publications, the velocity vectors in all the graphs are now located at the point where the water depth is inserted. The vector is suppressed, however, if the velocity is smaller than 0.2 ft/sec. This method presents the submerged areas more clearly.

In this figure, the state estimates of coliform and water level are shown at the locations at which bay samples were obtained. The location at which this numerical data is presented is indicated by (x). The numerical value on the left of the mark in this case is the coliform concentration in 1000 MPN/ml, whereas the values on the right are water levels. The coliform estimate shown can assist in finding the values of the coliform contours.

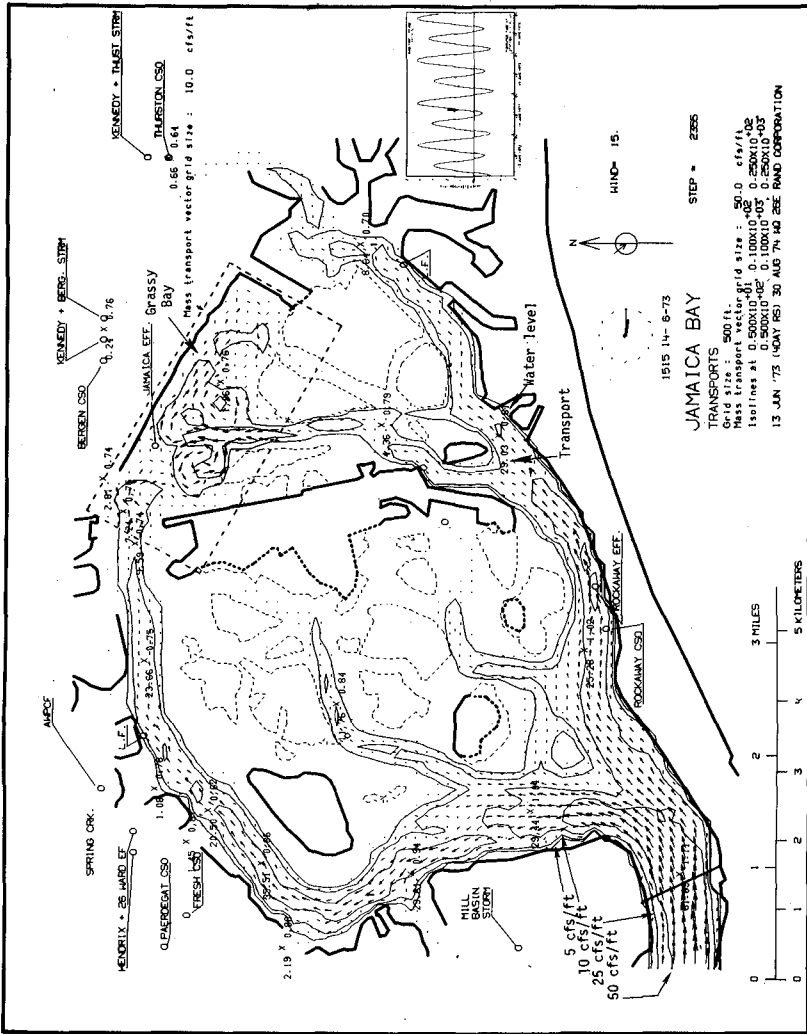

Fig. 6--Hindcasted transport distributions in Jamaica Bay on June 14, 1973 at 15 hr 15 min

STATE ESTIMATES OF COLIFORM FROM SIMULATION AND OBSERVATION

At thirteen stations in the bay, samples were taken which can be compared with the state estimates from the simulation. These comparisons are shown in Figs. 8 through 10

In these figures the 90-percent confidence interval is shown for the observations as well as for the computed estimates. The upper limit shown is the upper 95-percent confidence limit, and the lower is the lower 95-percent confidence limit. Thus, in a statistical sense, we have 90-percent confidence that the computed and observed estimates are within the interval of the limits shown. The interval of the observed coliform concentrations is determined by the nature of biological tests made. The interval of the computed estimates is the same as the number of tests used to determine the characteristics of the drainage basin model, and the confidence interval can be carried over from the drainage basin model results into the water-quality simulation.

Since animal life is present nearly everywhere in the bay, small randomly distributed coliform loads are being applied to the system continuously. Because the results of extensive coliform surveys made a few years ago indicated that these sources give a background level of about 10 MPN/ml, this value was added to the results of the simulation presented herein.

In Fig. 8 the observed coliform estimates agree well with the estimate by simulation; only two observed estimates are outside the confidence band of the simulation. These values are somewhat suspect, since these high values occur at about the same time at each station and thus have likely been processed in the same manner.

In Fig. 9 also only a very few observations are outside the confidence band. Generally we underestimated some high values in the second day of the simulation. An underestimate is quite well possible near discharges, since we are computing with averages in a 500×500 ft² area, which averages can be lower than observed if steep gradients are present.

In Fig. 10 as well only a few observations are outside the confidence limit.

A time-independent plot of the observed and the computed coliform concentration is presented in Fig. 11. In this diagram the ordinate represents the observed values, whereas the abscissa represents the computed values. The solid line across the diagram represents the location of all values in the hypothetical case that we were able to exactly predict computed values for and make error-free field observations. The six values denoted by cross hatches (+) indicate the discrepancies in the Paerdegat Basin as described earlier.

The model and the field sampling are far from being free of error, but we are able to indicate confidence bands. The confidence band representing the testing variability of the observed samples is delineated by dashed lines. Thus, according to the nature of the laboratory test, there is approximately a 10-percent probability that the actual number of bacteria in a given sample lies outside of these limits. Approximately the same confidence band also exists for the computed estimates, which are represented by a horizontal range of limits. This probabilistic behavior of the computed values is inherited from the water-quality inputs derived from the

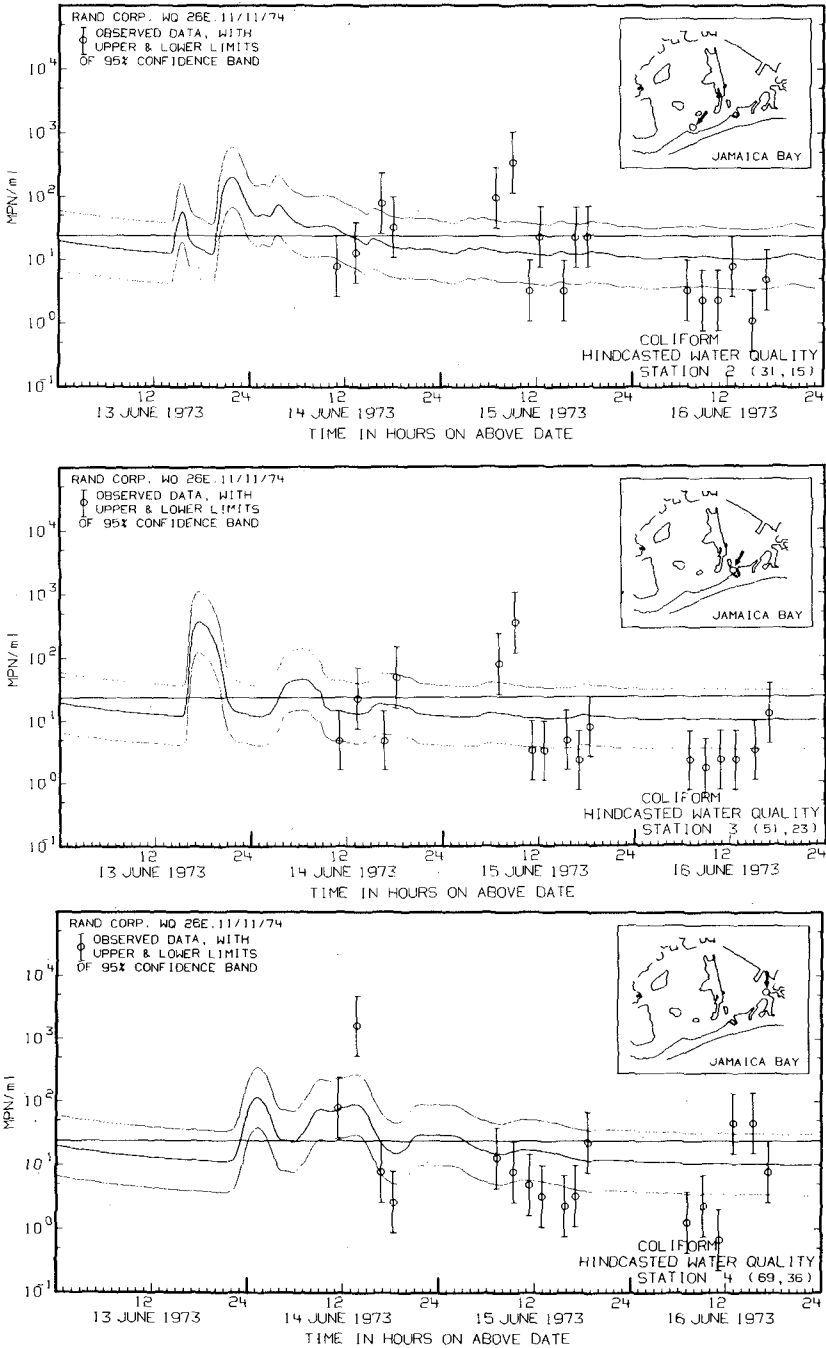

Fig. 8--Hindcasted coliform concentration histories and observed values at three stations in the southern part of Jamaica Bay

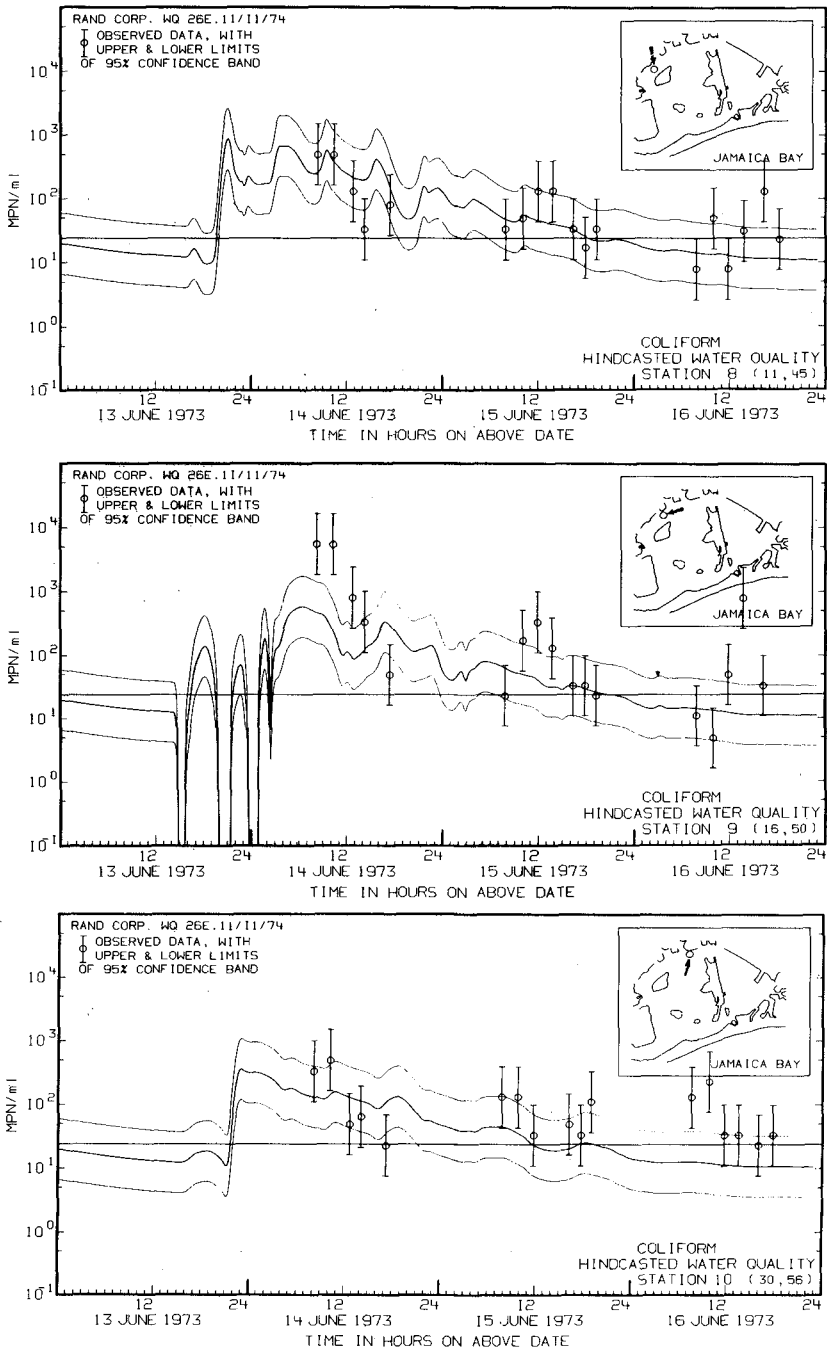

Fig. 9--Hindcasted coliform concentration histories and observed values at three stations in the northern part of Jamaica Bay, New York

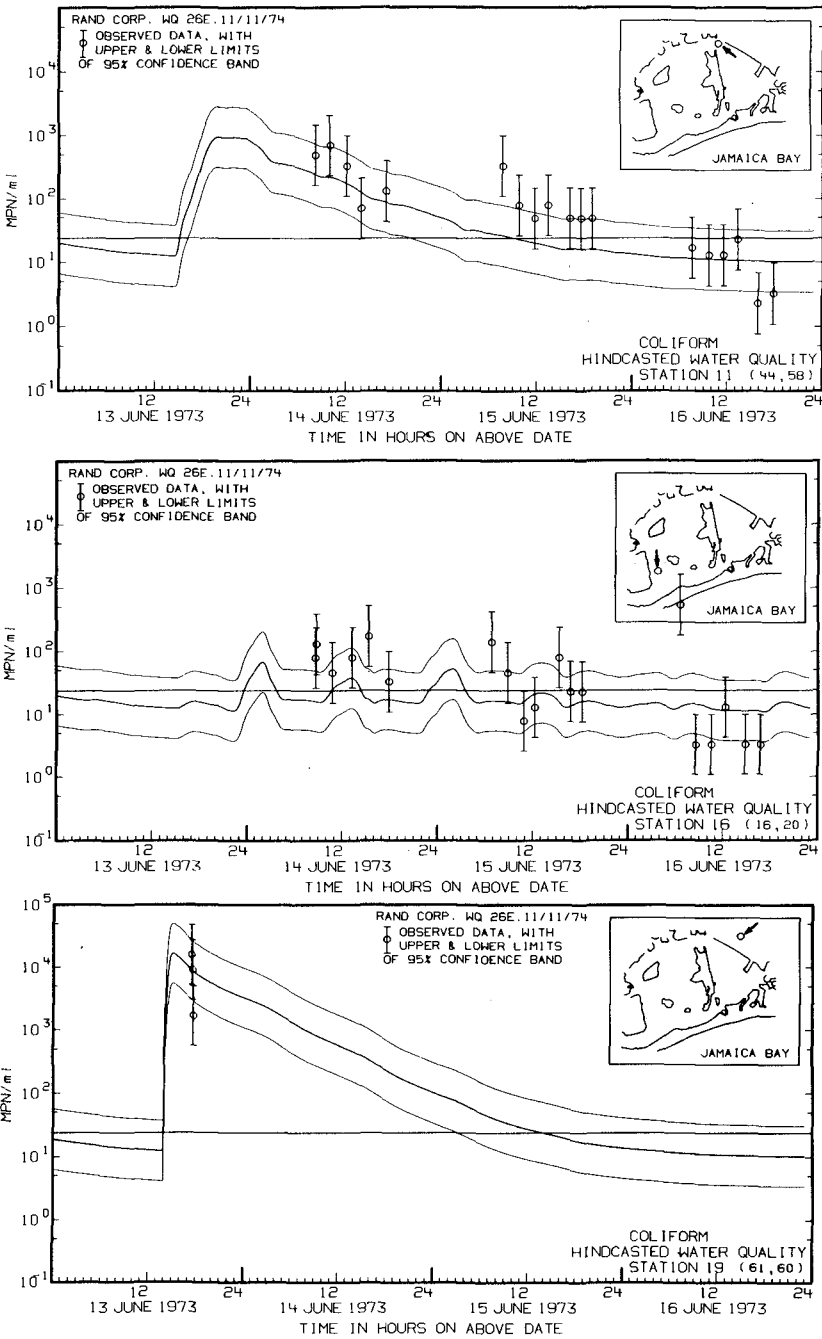

Fig. 10--Hindcasted coliform concentration histories and observed values at three stations in the western and northeastern part of Jamaica Bay, New York

peripheral drainage models and applied to this two-dimensional hydrodynamic computation of the bay water quality. Because the former derived its coliform prediction functions using observed coliform estimates, it is subject to a testing variability similar to that mentioned for the observed samples in the bay. The other error sources which contribute to the total deviation between the computed and the observed values are as follows:

- The resolvability of the rain gauge network.
- The prediction of overflow quantity.
- The time of discharge of the estimated overflow within the drainage system.
- The intercepted flow to the WPCF for the particular day and time.
- The computation of the flow in the water-quality model.
- The estimated parameters governing the diffusion and advection in the water-quality model.
- The sampling location in the field, especially in the vicinity of a discharge point where a sharp gradient exists.
- The resolvability of the grid system for representing computed estimates in the model.

In Fig. 11, no computed values lower than 10 MPN/ml are shown because of the assumption that a uniformly distributed background level of 10 MPN/ml exists in the bay. This value appears to overestimate the stations in the southernmost channel along the Rockaway peninsula, as indicated by the number of coliform observations lower than 10 MPN/ml.

It is apparent from the comparisons presented here and in the previous report that the models are able to make predictions quite well within the confidence bands. In the time-independent comparison (Fig. 11) it appears that only a small percentage (approximately 10 percent) is outside the expectation range. Thus, if other simulations are made, one would expect the results to be similar.

CONCLUSIONS

From the comparison of coliform estimates from observations in Jamaica Bay and the estimates obtained by simulation, it can be concluded that coliform density distributions in the bay, as well as discharges in the bay, can be predicted with confidence. Consequently, the models used in this investigation are capable of making predictions for engineering assessments.

Fig. 11--Observed versus computed coliform state estimates with their confidence bands

ACKNOWLEDGMENTS

We appreciate greatly the action taken by Mr. Martin Lang, First Deputy Administrator of the Environmental Protection Administration of New York City, which resulted in the stringent test of the predictive capability of water quality in Jamaica Bay described in this report.

We also want to acknowledge the cooperation of Mr. Norman Nash, First Deputy Commissioner, and Mr. William Pressman of the Department of Water Pollution Control. The field studies used in this investigation were made by Messrs. S. Arella, M. Singer, and H. Innerfeld of the Department. During the study period Mr. Charles Samowitz was Commissioner of Water Resources.

The many graphs in this report were prepared by Ms. M. Lakatos and Ms. G. Burkholz. Our colleague Mr. A. Nelson made the simulations.

The development of the programs used in the data analysis is sponsored by the U.S. Geological Survey of the Department of the Interior and by the Data Processing Division of the Netherlands Rijkswaterstaat.

CHAPTER 186

NUMERICAL MODELLING - AN AID TO ASSESSING FIELD DATA

H.P. Riedel¹ and F.L. Wilkinson²

ABSTRACT

After the completion of 5 years of field measurements, complemented by extensive numerical modelling in 1974, the hydraulics of Cockburn Sound, Western Australia, are now understood in enough detail to allow the rate of exchange of water between the Sound and the ocean to be determined. Flow patterns in Cockburn Sound tend to be complicated by the superimposition of many driving influences, the most important being wind, but by using the output of a numerical model most of these patterns are predictable.

Current magnitudes within Cockburn Sound have not reduced so that the rate of dispersion of effluents released by the industrial complex on the eastern side of the Sound has not changed. However, flow rates through the southern entrance to Cockburn Sound have been reduced to between 30 to 45% of the rates which occurred prior to the causeway construction. This means that the mean discharge rate is now 570 m³/sec through the causeway bridges compared to a rate of about 1500 m³/sec before the causeway construction.

1. INTRODUCTION

The hydraulic and environmental conditions in Cockburn Sound, Western Australia (see locality map, Fig. 1), an area with a very small tidal range, have been the subject of intensive investigation since 1969 in order to assess the effect on Cockburn Sound currents of constructing a causeway, with two bridge openings, between Garden Island and the mainland. The causeway was constructed in the period 1971-1973 so that field data has been collected before, during and after completion of the project. However, because of the complexity of the driving forces which control currents in Cockburn Sound, much of the data collected before the start of 1974 appeared contradictory and there was still a large degree of uncertainty in the interpretation of the field data.

In 1972 some exploratory numerical modelling was conducted using 'System 21 - Jupiter', a general purpose system for studying two dimensional nearly horizontal flows which has been adequately described in the literature by Abbott et al (1). From these early numerical modelling runs, it appeared that the incomplete picture provided by the field data could be improved by detailed numerical modelling. Consequently, extensive numerical modelling of currents due to ocean currents, wind and tide were carried out both for currents caused by individual driving forces and for selected combinations of driving forces during July-August 1974.

1, 2 Maritime Works Branch,
Australian Government Department of Construction.

In all, 26 modelling runs were executed in order to compare water movements in Cockburn Sound before and after the causeway construction, in particular in areas where field measurements had given rise to ambiguities.

2. FACTORS CAUSING CURRENTS IN COCKBURN SOUND

Currents in Cockburn Sound are caused by the combination of several driving forces which may be sub-divided into primary and secondary groups. The available information shows that water exchange between Cockburn Sound and the ocean is predominantly governed by wind induced currents within Cockburn Sound and by oceanic currents moving north or south along the West Australian coast. Secondary influences are tides, surges during storms, long waves and short period waves. The current patterns and magnitudes are also largely influenced by bottom topography.

The magnitude of wind induced currents in an open body of water are typically up to 3% of the wind velocity. When considering wind effects on an enclosed or semi-enclosed body of water with a complex bottom topography, the cause and effect relationship between the wind and the water becomes quite complex. Consequently, the water current cannot be inferred directly from the wind velocity and must either be directly measured or theoretically determined by the use of modelling.

The oceanic current is derived from the West Australian current which is a large scale current present in deep water off the West Australian coast. See Neumann (2) for a more complete description. It is partially driven by other currents circulating in the Indian Ocean and is part of a larger oceanic system which is the result of a balance between geostrophic, inertial and prevailing wind driven currents. The oceanic current is then modified locally by :

- (i) the effect of wind systems along the West Australian coast;
- (ii) the intensity and rate of movement of atmospheric pressure systems;
- (iii) nearshore bottom topography

to yield currents at the boundaries of Cockburn Sound.

Either of the primary currents may dominate the flow field and mask the effect of any other current. Generally, ocean currents tend to be persistent, their time scale being of the order of days and many explanations of observed water movements must make reference to this parameter for a satisfactory interpretation of the data. Wind induced currents are relatively easy to detect and can easily be correlated with wind data. Many of the observed flow rates and patterns can easily be explained in terms of wind induced currents, especially when the velocity field is predicted from a numerical model. However, for short duration strong winds there have been instances where current directions are observed opposite to the wind direction due to the predominance of the ocean current, or the presence of a seiche of 2-3 hours period. The natural frequency of seiching for Cockburn Sound in the north-south direction is $2\frac{1}{2}$ hours.

Tidal currents are of small magnitude because of the small diurnal tidal range, however, the exchange of water between Cockburn Sound and the ocean caused by the tide is basically steady from day to day resulting in about 3% of the volume of Cockburn Sound being exchanged daily.

Currents induced by long and short period waves affect small scale water circulation rather than gross exchange. These currents are most noticeable in the shallow Southern Flats area, particularly at the bridge openings while in the bulk of the Sound they are often not detected.

With the construction of the causeway, current patterns and magnitudes have changed, significant changes being confined mainly to areas within 1500 metres of the causeway.

3. FIELD MEASUREMENTS

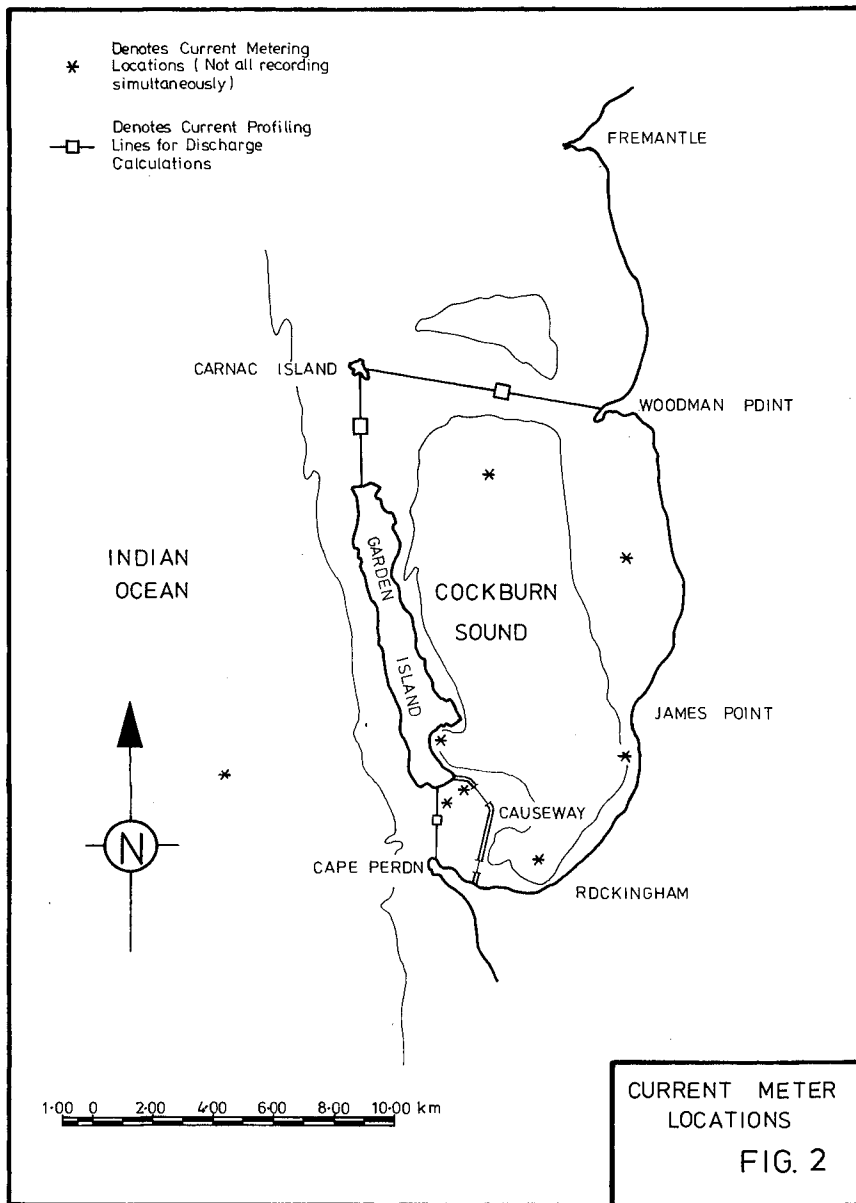

These measurements consist of

(a) Current Metering, which has been in progress for the full duration of the field measurements with current meters placed at the locations shown in Fig. 2 at various stages of the study. Unfortunately, conventional off the shelf meters, as used in this study, generally have two restrictions on their use. They have a threshold velocity of about 4 cm/sec so that they usually do not respond to the low velocities present in the deep waters of the Sound, and they tend to oscillate and give unreliable results if waves are present with periods greater than about 5 seconds. Consequently, most of the useable data has been confined to current measurements made across the Garden Island to Cape Peron gap.

These measurements were made in 1969-70 before the causeway and in 1974-75 after the causeway construction and form the basis for the quantitative assessment of discharges through the southern entrance to Cockburn Sound.

(b) Salinity-Temperature Metering, which was used at one metre depth intervals for about 30 points throughout Cockburn Sound. Measurements were conducted twice daily for periods up to 10 days in an attempt to track the motion of discrete bodies of water labelled by their salinity/temperature characteristics. Flushing rates estimated using this method were sometimes 5 times the rate estimated by other methods and indicated practically unchanged flushing rates before and after the causeway construction. The unchanged apparent flushing rates between 1971 and 1973 may be explained by current magnitudes after the causeway construction remaining constant through the intensification of a large scale circulation in the centre of Cockburn Sound. This occurred even though the nett discharge through the entrances to Cockburn Sound had changed significantly. Data using salinity metering has been ignored for any quantitative analysis, and no further data was collected after 1973.

(c) Float Drogue Tracking, which was used extensively up until 1974 with most of the tracking concentrated along the causeway route and within 1500 metres of the causeway. The main problem with the float drogues was wind drag on that portion of the float above the water surface. Also there is a partial integrating effect because of drag on the float as well as on the drogue vanes. Considering these factors the float drogues can only be expected to yield qualitative data in Cockburn Sound which is an extremely windy area.

(d) Dye Tracking, which consisted of instantaneously releasing a quantity (about 10 kg) of Fluoroscetin or Rhodamine B and then tracking the dye patch from aerial photos and/or by a fluorometer mounted in a runabout. It was attempted to obtain quantitative data but the information was only used for descriptive purposes because of problems with instrument operation.

(e) Tidal data. Tide records are available continuously for the port of Fremantle and, as would be expected, short term tide recordings taken within Cockburn Sound correlate well with the Fremantle data. The predominating feature of the West Australian coast in the vicinity of Fremantle is the very small, diurnal tidal range. The tidal range rarely exceeds 0.6 metres and tidal velocities tend to be negligible in water depths greater than 5 metres. The average tidal range is 0.4 metres which results in about 3% of the volume of water in Cockburn Sound being exchanged daily by this mode.

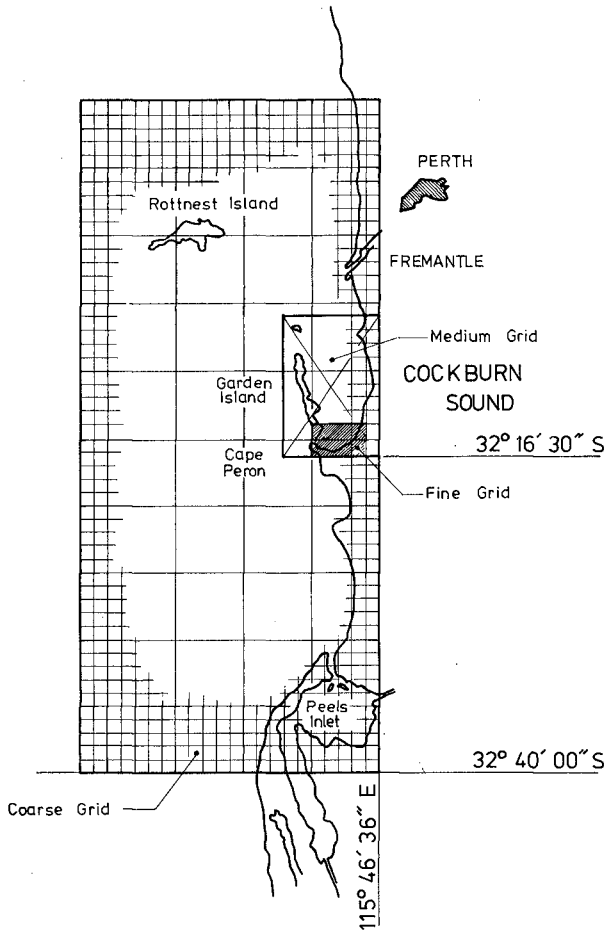

(f) Meteorological data. Wind and barometric pressure records were available from the Fremantle Port Authority and again the difference between observations of these parameters at Fremantle and within Cockburn Sound was negligible, except for a time lag in the wind, in particular in the arrival of the sea breeze. The wind data was necessary in estimating the component of water currents caused by wind shear and the barometric data usually explained any discrepancy between the predicted and observed tidal heights. It is also thought that the passage of intense pressure systems will induce seiching and water currents because of the 'inverted barometer' effect but it is difficult to isolate this phenomena when there are so many other driving influences present.

The overall picture presented by the collection of the above field data up to December 1973 was one of uncertainty and clarification was required, and it was thought that numerical modelling would be the method most likely to succeed.

4. THE NUMERICAL MODEL

Numerical modelling studies were made using System 21 'Jupiter', a computational system consisting of a set of computer routines with back up documentation which is used to construct a numerical model of any region of two dimensional nearly horizontal flow when presented with the hydrography of the region and operates the model from given initial and boundary conditions, wind velocities, atmospheric pressure differences, tidal-tractive forces, latitude and other external conditions as required. It provides output in the form of velocity and water surface level plots for selected regions on the complete computation field. A detailed description of the model may be found in Ref. (1)

In all, 26 computer runs were made using 3 different grid sizes with boundary conditions chosen to represent the most commonly occurring current generators. A very coarse grid (C) of 1 nautical mile spacing was used (Fig. 3) to include a sufficient ocean area so that the penetration of the oceanic current into Cockburn Sound could be reliably reproduced. Runs 1-4 were run on the coarse grid and were used as boundary conditions for medium grid runs involving the oceanic current. For these runs an oceanic current of 20 cm/sec was modelled for a real time duration of 13 hrs which was the time required to reach a steady condition.

MODEL GRIDS

Coarse Grid Spacing = 1 Nautical Mile

FIG. 3

A grid with a spacing of $1/3$ nautical mile, termed a medium grid (M), was used for most of the study to predict flow patterns and water throughput for Cockburn Sound. Run numbers 5-22 were based on the medium grid and covered all the commonly occurring wind, oceanic and tidal conditions affecting Cockburn Sound. The wind applied in runs 5-14 was increased linearly from 0 to 20 knots over a period of 3 hours and then held constant for the next 3 hours by which time a steady state had been reached.

In order to obtain a clear pattern of velocity vectors for tidal flows, runs Nos. 15 and 16, an extreme tide range of 0.8 m was modelled rather than the mean range of 0.4 m. A full diurnal tidal cycle was modelled and the only affect of the causeway was to push the null point of the tide within Cockburn Sound further south. As expected the tidal range did not change.

Runs 17 to 20 used a hot start from runs 1 to 4 respectively, ie. the boundary conditions at the edge of the medium grid were obtained from the steady condition of the coarse grid and held constant for 3 hours in order to let the medium grid runs reach a steady state. Then a SW or NW wind is applied in the same way as for runs 5 to 8.

Runs 21 and 22 on the medium grid were used to simulate a sea breeze pattern which is a common occurrence at Cockburn Sound during summer. The sea breeze cycle consists of an overnight land breeze from the NE followed by a change of the wind to the SW during the day.

Runs 25 and 26 were made on a fine grid (F) with a spacing of $1/9$ nautical mile and only covered the area in the vicinity of the causeway. This grid was not used to predict discharges but was used to look closely at seiching and other oscillations which may have been induced by varying boundary conditions arising from the influence of the sea-breeze.

Table 1 lists the modelling runs. By combinations or superposition of the results from the 26 runs it is possible to estimate the currents for any physically occurring situation. The only significant limitation in using the model is that it is depth integrated and so only gives velocities averaged over the depth at any point. This means that where wind shear is the driving force which moves the surface water roughly in the direction of the wind to a depth of, say, 10 metres, there may be a return current below this depth in order to satisfy continuity, but the numerical model effectively gives the average of these two components which may not resemble either of them. It is in this type of situation where discrepancies between field observed currents and numerically computed currents is most likely to occur. However, in shallow water areas the model will give a representative indication of the currents. The model is however, directly useful for estimating gross rates of water exchange as the depth averaged velocities relate directly to water transport or "flux".

TABLE 1 - MODEL RUNS

5. COMPARISON OF FIELD DATA WITH NUMERICAL MODELLING SOLUTIONS

Comparison of field data with the numerical modelling solutions was divided into two categories - comparison of flow patterns on a qualitative basis as is possible with float drogue data, and comparison of measured discharges through the southern opening to Cockburn Sound. Both types of comparison can only be attempted in situation where wind controls the flow and wind fields are similar in the model and in the field. Direct comparison of oceanic current model runs with field information is not possible because this current was not measured successfully in the field. All the field data gathered at times for which there are model solutions with comparable wind fields are presented in the comparisons and any poor correlations can usually be explained by seiching, the oceanic current or tidal currents.

5.1 Flow Patterns

Float drogue measurements were made over a period of four years during which float tracks were obtained for all wind directions. However, in order to compare these current measurements with the model output it was considered that the wind should average at least 5 m/sec and not change in direction by more than 45° for a 6 hour duration. Six hours was chosen because in this time a wind induced current would approach a steady state condition.

The general type of results obtained are shown for the case of a SW wind, the most common weather condition, in Figs 4 and 5, which show flow patterns before and after the causeway construction respectively. Comparisons for other wind conditions give similar agreement but because of space limitations the results for only two other weather conditions will be shown.

It is emphasised that the current pattern comparison is qualitative only and the current depicted by the float drogue paths show direction only and are not scaled. A quantitative comparison is not valid because the float drogue usually measures a surface current whereas the model calculates a current averaged over the whole depth and additionally there is a wind drag on the float which usually results in the velocity of the float drogue being higher than that of the water current. From a combination of these two effects the current magnitudes of the float drogues are on an average approximately 50% greater than the currents estimated by the comparable numerical model. However, the current directions taken by the float drogues were reproduced remarkably well by the models.

Fig. 4 shows the comparison between observed float drogue tracks and model predictions prior to the causeway construction. Each arrow shows the average path of 10 to 20 float drogues released at one time over a length of about 200 metres at the start of the arrow and excellent agreement occurs between the measurements and predictions except for days 2, 7 and 10.

The appearance of a possible eddy in track No. 7 is probably caused by the causeway construction having proceeded to the trestle bridge and flows in the Rockingham area could follow the post-causeway predictions which do show eddies in this area. The movement of float drogues on days 2 and 10 are not in agreement with the model prediction, possibly because on day 2 the wind was SSW to SW and on day 10 it was WSW to SW.

Since the causeway construction there were 15 occasions on which winds exceeded 5 m/sec from the SW during which float drogue measurements were made and these observations are shown in Fig. 5. Of these tracks only those of days 1 and 10 do not agree with the model predictions. Both these tracks exhibit obvious wind drag effects on the float and could illustrate a surface flow in the direction of the wind whereas the net flow as depicted by the model is slightly against the wind.

Fig. 6 shows the comparison between observed float drogue tracks and model predictions after the causeway construction for a NW wind and Fig. 7 shows a similar comparison for a N wind. Both these examples are presented because they show float drogue tracks which were difficult to understand without the model output. Figs. 6 & 7 show how each float drogue group follows the vector plot as depicted by the model. Yet using the float drogues alone it would not be possible to deduce the current patterns.

CURRENT PATTERNS SW WIND FIG. 5

5.2 Discharge Rates

Current magnitudes within Cockburn Sound and net discharges through Cockburn Sound are the most important factors controlling the ability of the Sound to adequately dissipate pollutants. A knowledge of these factors would also allow the determination of the most suitable discharge points for effluents into Cockburn Sound.

Discharges through Cockburn Sound have been measured both before and since the causeway construction. This information has been augmented by discharge calculations under similar conditions using numerical modelling. In general terms the following sections will show that current magnitudes in the bulk of the Sound are not reduced significantly but the net discharge of water through Cockburn Sound has been reduced on the average to 30-45% of the discharge which occurred before construction of the causeway.

5.2.1 Measured discharge rates before and after the causeway construction

Field measurements in the form of twice daily current profiles were made at approximately two week intervals across the gap between Cape Peron and Collie Head for a period of 14 months during 1969-70. Measured discharge rates averaged over the two profiles taken on each day varied from 3300 m³/sec out of the Sound to 2400 m³/sec into the Sound via the southern entrance. The average magnitude of the flow rate over the 28 sets of readings taken during the 14 months was 1500 m³/sec.

Since July 1974 there have been regular current profile measurements under both of the causeway bridges and the range of discharge rates, averaged over a day's observations, up to January 1976 was 2700 m³/sec out of the Sound to 780 m³/sec into the Sound. It needs to be noted that the observation of 2700 m³/sec is double the rate of the next highest observation which in turn is 50% greater than the 3rd highest flow rate observed. In comparison, there were 6 observations of flow rates above 2,300 m³/sec prior to the causeway construction. Consequently a true comparison of flow rates can only be obtained by comparing means rather than extremes. The average magnitude of the flow rate over 33 sets of readings was 570 m³/sec, which is 38% of that occurring before the causeway was constructed.

The range of field measurements is shown in Figs. 8 and 9.

5.2.2 Discharge rates computed by the model before and after the causeway construction

The basic numerical model output which was used in the assessment of currents and discharges was the steady state solution reached after the application of a 20 knot wind from the direction of interest. A steady state condition was reached approximately 6 hours (prototype time) after the start of the wind. For the model runs where the forcing function was not steady such as for tidal runs, runs where a wind is superimposed on an oceanic current or sea breeze runs, the output was analysed at about one hourly intervals because a steady state condition did not exist. Table 2 compares the discharge through the southern opening with the causeway and without the causeway for each of the model runs.

TABLE 2

Boundary Condition	Discharge (m ³ /sec)		Discharge with causeway Discharge w/o causeway %
	w/o causeway	with causeway	
20 knot N wind	+ 2410	+ 946	39
20 knot E wind	+ 1835	+ 780	42
20 knot S wind	- 2590	- 1020	39
20 knot SW wind	- 2780	- 1125	40
20 knot NW wind	+ 754	+ 240	32
NE wind	+ 2657	+ 725	26
N to S oceanic current	+ 3070	+ 1057	34
N to S oceanic current & sea breeze	+ 1062	+ 389	37
S to N oceanic current	- 2583	- 896	35
S to N oceanic current & NW wind	- 2126	- 779	37
Sinusoidal tide	varying		Range 29% - 40%

Table 2 shows that the numerical model predicts that on an average, weighted for frequency of occurrence of conditions, the discharge through the southern opening to Cockburn Sound has been reduced to 38% of the flow occurring before the causeway construction. This ties in closely with the discharge measurements reported in 5.2.1.

5.2.3 Comparison of measured and computed discharges.

In the comparison of measured and computed discharges as shown in the scatter diagrams of Figs. 8 and 9 it has been assumed that the relationship between wind speed and current is linear and that each of the measured currents is purely attributable to the wind blowing during the previous 6 hours. Consequently, there is quite a wide scatter on both diagrams, with the scatter reflecting the effects of the oceanic current, seiching and tidal flows. The redeeming feature in the scatter is that current magnitudes predicted by the model and those measured in the field correspond both before and after the causeway construction. It may be concluded that the model gives a good representation of net discharge through the southern entrance to Cockburn Sound and that if the magnitudes of the currents resulting from seiching and from the oceanic influence could be measured, and corrected for, the data points would exhibit less scatter.

5.2.4 Currents in the Bulk of Cockburn Sound

Inspection of the vector plots from the numerical model results shows that current magnitudes have not changed noticeably within Cockburn Sound for all runs except those involving the oceanic current. In some cases the extra constriction at the southern entrance has resulted in an intensified eddy in the centre of the Sound resulting in current magnitudes greater than those occurring prior to the causeway construction. See Cases 1, 3 and 5 of Table 3. An exception is the oceanic current which does not cause eddy formations because it is controlled by a simple head difference between the two ends of the Sound. In this case currents are reduced to 1/3 of the magnitude occurring prior to the cause, (cases 6 and 8). Usually the oceanic current does not occur on its own but is accompanied by a wind induced current so that generally currents have not changed in magnitude appreciably after the causeway construction, cases 7 and 9.

TABLE 3

Case	Boundary Condition	Gross Discharge across Section Between Sulphur Bay and Alcoa (m ³ /sec)	
		w/o causeway	with causeway
1	20 knot N wind	2840	3960
2	20 knot E wind	1890	1010
3	20 knot S wind	2730	3850
4	20 knot SW wind	2740	2310
5	20 knot NW wind	3230	3600
6	N to S oceanic current	3070	1060
7	N to S oceanic current and SW sea breeze	4550	4030
8	S to N oceanic current	2400	930
9	S to N oceanic current and NW wind	5770	4790

The only field data verification for currents in the bulk of Cockburn Sound comes from the salinity/temperature measurements which indicated that the rate of movement of bodies of water described by their salinity had not changed as a result of the causeway construction.

6. CONCLUSIONS

(i) For large bodies of water where wind generated currents greatly influence the flow, only sufficient field data should be obtained to determine the driving forces and then numerical modelling can be used as an effective tool in explaining and determining details of the flow field. More field data may then be desirable to confirm features of the flow highlighted by the model.

(ii) The exchange of water between Cockburn Sound and the Indian Ocean has been reduced to 30-45% of the exchange which occurred prior to the causeway construction. This figure is validated both by field data and numerical modelling.

(iii) Current magnitudes in the bulk of Cockburn Sound have remained nearly constant compared to those occurring before the causeway construction. Thus the rate of mixing or dispersion of effluents within the Sound has not changed significantly.

ACKNOWLEDGEMENTS

It is desired to express appreciation to Mr. Warwick-Smith, Secretary of the Australian Government Department of Construction, for permission to publish this paper. Nevertheless, the opinions expressed herein are those of the authors.

CHAPTER 187

WIND-DRIVEN CIRCULATION OF SAGINAW BAY

James H. Saylor¹ and Larry J. Danek²

ABSTRACT

A combination of Lagrangian measurements and fixed current meter moorings were used during the summer of 1974 and the winter of 1974-75 to determine the circulation patterns of Saginaw Bay. Because the bay is shallow, the water responds rapidly to wind changes. Distinct circulation patterns were determined for southwest and northeast winds. These directions parallel the major axis of the bay and were the prevailing wind directions during the study. A typical exchange rate between the inner and outer bay during moderate winds aligned with the bay axis is $3700 \text{ m}^3 \text{ s}^{-1}$. If sustained, this flushing rate would completely exchange the water of the inner bay in about 26.5 days. However, winds perpendicular to the axis of the bay cause little water to be exchanged and the residence time of water in the bay is much longer. Comparison of measured currents with the results of an independently-developed numerical model for the bay indicates there is good agreement between the observations and the simulation of the circulation in the shallow inner bay. Agreement is poor in the deeper outer bay, where specification of proper boundary conditions at the open mouth of the bay is important for meaningful model simulations. Ice cover during winter shields the water surface from wind stress. Currents are sluggish and driven almost entirely from interactions with the lake-scale circulation of Lake Huron.

INTRODUCTION

Saginaw Bay is a large and important embayment on the southwestern coast of Lake Huron, centered close to $44^{\circ}00'N$ latitude and $83^{\circ}20'W$ longitude (Figure 1). The mouth of Saginaw Bay (from Point Aux Barques to Au Sable Point) is 42 km wide with an average depth of 27 m. The bay's narrowest constriction is between Sand Point and Point Lookout, with a width of 20 km and a mean depth of only 4 m. A line between these two points forms an approximate boundary between the outer bay (mean depth 16 m) and the much shallower inner bay (mean depth 4.5 m). The bay is 83 km long with its major axis aligned 40° east of north. An important feature of the bay is the relatively deep channel that runs through the inner bay. It is aligned nearly parallel with the major axis of the bay and has a maximum depth of about 14 m.

²NALCO Environmental Sciences, Northbrook, Illinois.

Figure 1. Location map of Saginaw Bay. Current meter moorings were placed at stations numbered 1 - 9, and wind speed and direction was recorded at the Gravelly Shoal Light.

The currents of Saginaw Bay and the character of Saginaw Bay-Lake Huron interactions are important because of the heavy load of pollutants entering Lake Huron through the bay. The Saginaw River drains an area of over 16,000 km² and discharges the wastes of the industrialized cities of Midland, Bay City, and Saginaw, Michigan. It is the largest tributary source of undesirable materials discharged to Lake Huron. A long residence time and the pattern of water mass movement within Saginaw Bay have adversely impacted parts of the bay. Several other rivers flow into the bay, but their combined discharge is small compared to that of the Saginaw River.

Because the inner reaches of Saginaw Bay are shallow and tidal amplitudes are negligible, currents in the inner bay are closely related to the wind. The outer bay, although also influenced by the local winds, interacts strongly with the large-scale circulation of Lake Huron. Several qualitative studies have been conducted on the circulation of Lake Huron and Saginaw Bay. Harrington (1895) and Johnson (1958) performed drift bottle studies on the lake and bay, and Ayers et al. (1956) used a dynamic height method developed for fresh water to determine the circulation in Lake Huron. Beeton et al. (1967) used chemical distributions to trace the water movements in the bay. These studies were in agreement in that all indicated currents in the bay were strongly dependent on local winds and were highly variable. A more recent study by Allender (1975) used a numerical model to simulate the circulation. This paper presents the results of a study using both Lagrangian and Eulerian current measuring techniques to determine the circulation patterns of the bay. Also presented are representative current speeds and volume transports for various wind conditions and a comparison of these results with the results of Allender's numerical model.

METHOD

Eighteen Geodyne model A-100 film recording current meters were installed in Saginaw Bay during May, 1974, and operated through October, 1974. As many as three of these Savonius rotor current meters were attached to an anchored line and suspended in the water column by a subsurface float. A small surface float attached to the end of a ground line 30 to 40 m in length was used to mark the location of the moorings and to aid in the recovery of the meters. Several of the meters failed because of mechanical and electrical problems leaving some holes in the planned sampling grid. Locations and depths of the meters are given in Figure 1 and Table 1. Each current meter sampled the velocity for a 50 s interval every 30 min and accumulated over 7200 data points for the duration of the study.

Drogues were tracked for three 2-week sessions, one session each in June, August, and October of 1974. The drogues consisted of a surface bouy plus a subsurface panel. The bouy was made from a pneumatic float and a radar reflector that extended 1.5 m above the water surface. The panel, a sheet metal current cross with a cross-sectional area of 1.86 m^2 , could be set to any desired depth in the water column. During this study the panels were set only at depths of 2 or 5 m and used almost exclusively in the shallow water of the inner bay where the use of moored current meters was impractical. The drogues were followed with a small tending vessel and sequentially positioned by radar with reference to anchored radar reflectors deployed at the site of each released drogue.

Wind speed and direction were measured at the Gravelly Shoal Light near Point Lookout. Data were continuously recorded on a strip chart by the use of a Bendix wind recording system and later digitized as hourly averages. The sensor location was approximately 23 m above the water surface. As the distance to the nearest point of land was 4.5 km, local interferences were minimal.

During the winter of 1974-75 an extensive study of currents and water

temperatures was performed in Lake Huron to determine the large-scale circulation of the lake. In this study many current meter moorings were placed along the west shore of Lake Huron and in the mouth of the bay. The moorings were in place from November, 1974 to May, 1975 and consisted of AMF Vector Averaging Current Meters, again of Savonius rotor design. Thus, the mouth of Saginaw Bay was instrumented for a period of almost one year, although a short gap in the records at the end of October and early November, 1974 exists. The entire bay is usually nearly isothermal so that the water mass is essentially homogeneous. Only during early summer in the deeper water at the mouth of the bay was any density stratification of significance observed.

RESULTS

Drogues

Since most of the inner bay was too shallow for current meter moorings, the drogue studies were concentrated in that area. During 25 days on the bay, 117 drogues were tracked for an average interval of 5 hr each. The

average speed for the drogues was 6.7 cm s^{-1} , while the highest speed measured was over 30 cm s^{-1} ; however the speeds in several areas of the bay varied considerably from the average. Near Point Lookout, where the channel has its narrowest constriction, the average speed was 10 cm s^{-1} . Water flow balancing the wind-driven transport in the shallow water southeast of the channel is funneled through this constriction causing the higher average speed. On the other hand, water in the southeast corner of the bay was nearly stagnant, with speeds of less than 4 cm s^{-1} . This is the same area where the highest ion concentrations were reported by Beeton et al. (1967). In the central part of the inner bay the speeds were typically slower in the channel (average speed 6.2 cm s^{-1}) than in the shallow water areas on either side (average speed 8.8 cm s^{-1}). There was no appreciable difference between the average speeds measured at 2 and 5 m depths.

As it was not possible to do a synoptic survey of the entire bay, the drogue data were compiled to present on one chart observations made during similar wind conditions in various parts of the bay thus providing a reasonably accurate picture of the circulation of the inner bay for certain wind directions. Transects for 7 days during which the wind was out of the southwest are shown in Figure 2. The drogue tracks show that the water in the

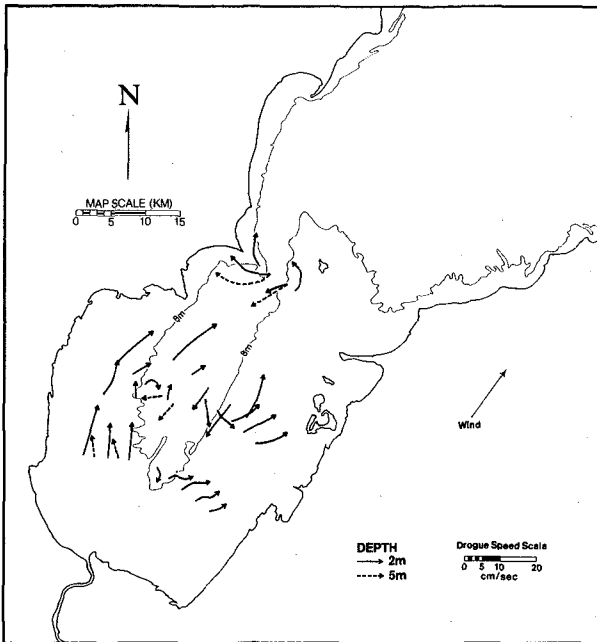

Figure 2. Compilation of drogue tracks observed during southwest wind.

inner bay generally moves to the northeast with the wind, except in the channel, where there is a counterflow to the southwest. The current in the southwest section of the bay, combined with the return flow in the channel, forms a crude clockwise gyre in that region, whereas the current in the shallow southeast area follows the shoreline and flows into the outer bay between Charity Island and Oak Point. Part of the water from the southeastern region of the inner bay also flows northeastward west of Charity Island, a part of this water may be recycled to the inner bay by the return flow southwestward in the channel. The flow distribution near Point Lookout shows that the return flow is confined to a rather narrow stream, with northeastward flow in the shallow water to each side. The drogue trajectories show that the return flow is still well defined further into the bay, although the apparent path of the flow does meander somewhat because of slightly different wind conditions during the separate days of observations.

On the day that drogues were deployed across the channel near Point Lookout, the wind was out of the southwest with an average speed of 5.8 m s^{-1} . Drogue panels set at 2 and 5 m made it possible to estimate the vertical profile of horizontal velocity and to compute the volume water entering the inner bay through the channel. The estimated transport was $3700 \text{ m}^3 \text{ s}^{-1}$ or 37 times the average flow of the Saginaw River. Since the volume of the inner bay was about $8.5 \times 10^9 \text{ m}^3$ during the time of the study, it would take only 26.5 days for this flow to replace the inner bay water.

On several days the wind changed rather abruptly during the drogue experiments presenting an opportunity to examine the response of the bay to sudden wind changes and to determine the time required for the return flow in the channel to develop. The response for a wind changing to one out of the southwest is that in all areas of the inner bay the water initially flows with the wind; after approximately 8 hr a return flow develops in the central channel. Of course residual currents and the intensity of the wind affect the circulation and the lag time before a return flow develops and a new equilibrium state is established, but this response time is typical for a moderate southwest wind. This result also agrees well with previous work on the bay (Johnson, 1958, and Allender, 1975). The current speed averaged about 3% of the wind speed in shallow water where the currents flow with the wind.

During the Lagrangian current studies the wind was usually out of the southwest, but there were a few occasions of northeast winds. The transects from these days indicate that water enters the inner bay between Charity Island and Oak Point and flows to the southwest in the shallow areas of the bay. The results also show a countercurrent in the channel flowing to the northeast, but there was insufficient data to estimate a volume exchange rate. With flow to the southwest on either side of the channel and a counterflow to the northeast in the channel, the circulation pattern is just reversed from that observed for a southwest wind.

Current meters

Since the largest part of the inner bay was too shallow for current meter moorings, most of the meters were deployed in the outer bay. Histograms of current direction were used to display the summer data. The

histograms were constructed by sorting the current direction into 40° sectors. The percentage of data points that fell into each sector was computed and the average speed for each sector was calculated (percentages of less than 5% are not shown). The average speeds were divided into three categories, low (less than 8 cm s^{-1}), medium (8 to 15 cm s^{-1}), and high (greater than 15 cm s^{-1}), and the results are displayed on the histograms. A similar histogram of wind data was computed, giving the direction toward which the wind was blowing (that is, to be consistent the oceanographic convention was also used for the wind direction so that a wind out of the north was plotted in the south sector).

Since the currents are so highly dependent on the local winds, the nature of the bay circulation during several well-defined meteorological events was examined. Histograms of current direction were computed for periods when the wind was relatively constant for at least two days. Since the two predominant wind directions during the summer of 1974 were out of the southwest and out of the northeast, the response of the bay to winds from these directions was analyzed.

The wind was constant out of the northeast on 22-27 June. Histograms computed for that period are shown in Figure 3. The results of this episode, which are typical of several episodes of northeast wind examined, show that the flow is characterized by a counterclockwise gyre in the outer bay; water enters the bay at the northern edge of the bay mouth, flushes through the outer bay in one large counterclockwise loop, and flows back into Lake Huron along the southern part of the bay mouth. Meter 9A suggests that a return flow has developed in the channel even that far into the bay, although the return current isn't as well defined as that for a southwest wind. An illustration of this flow pattern, combined with the circulation derived from the drogue results for a northeast wind in the inner bay, is shown in Figure 4. The vectors on the Figure represent a qualitative vertically averaged circulation pattern, with the length of the arrows proportional to flow intensity.

The wind was constant out of the southwest on 3-5 October (Figure 5). The histograms from this episode, which are similar to others computed for a southwest wind, are markedly different than those calculated for a northeast wind. The flow from Lake Huron enters the bay through the southern parts of the bay mouth, circulates through the outer bay in a clockwise direction, and flows out along the edge. Meter 9A shows the prominent return flow in the channel noted in the drogue studies. This circulation pattern, together with the flow pattern determined from the drogue studies for a southwest wind, is illustrated in Figure 6. The flow past station 5 is usually toward the southwest under both wind conditions, influenced more by the gross circulation and geometry of the bay than by the direct influence of the local winds. This site is in the zone of the return flow in the channel during southwest wind and in the inflow to Saginaw Bay from Lake Huron during northeast wind. Histograms computed for the entire length of the summer current meter records revealed a high variability of flow, with the current direction for some of the meters almost equally distributed around the compass. The meter at site 9, though, showed a dominant flow to the southwest because the prevailing winds during the summer were from the southwest. Wind from directions not nearly parallel to the bay axis drives a local circulation in the inner bay, but does not appear to cause much exchange of water with the outer bay.

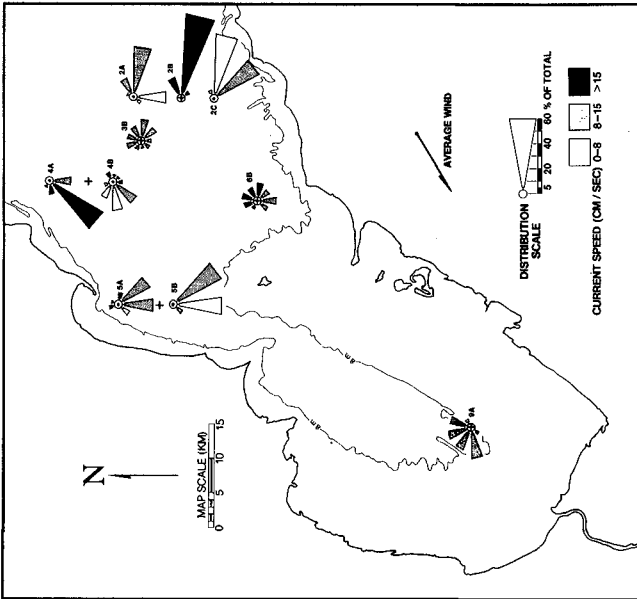

Figure 3. Current direction histograms during northeast wind, 22-27 June, 1974.

Figure 6. The circulation of Saginaw Bay driven by southwest wind.

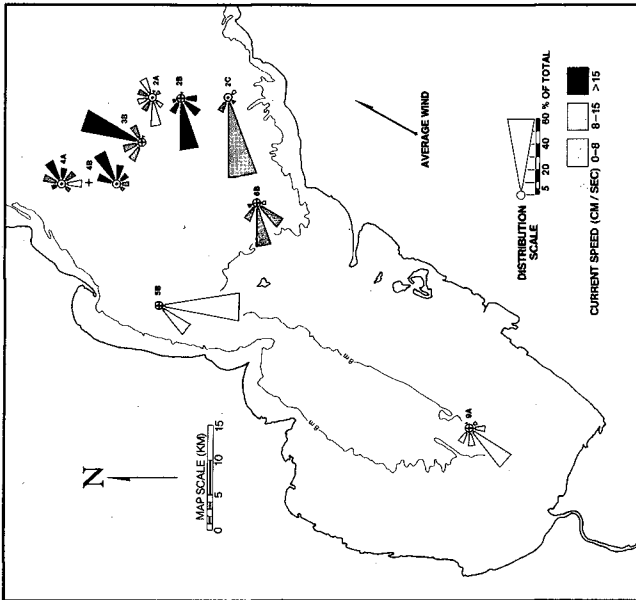

Figure 5. Current direction histograms during southwest wind, 3-5 October, 1974.

Winter current meters confirmed the same nature of outer bay circulation. Winter studies of Lake Huron have shown that southward flow along the west coast of the lake is the dominant feature of lake circulation. The rest of the lake responds to this flow in the form of one large cyclonic cell, returning water northward along the eastern coast. This persistent southward flow across the mouth of Saginaw Bay interacts strongly with the outer bay and plays a major role in determining its flow characteristics. Figure 7 shows an episode of lake scale current flow during moderate northerly winds in November of 1974. Current roses of water transport past each current meter are shown at the 15 m level. Wind run roses for this episode as recorded at five stations around the perimeter of the lake are shown in usual meteorological fashion here, being wind from the north and northeast at 5 to 6 m s^{-1} . This episode shows, as noted earlier for the summer studies, that north to northeasterly wind drives a counterclockwise loop of Lake Huron water through the outer bay. The average current speeds in the outer bay were 15 to 20 cm s^{-1} during this episode.

Ice cover during its peak development in winter covers the entire surface of Saginaw Bay, extending lakeward past all four current meter moorings placed in the mouth of the bay. Figure 8 shows another episode of wind similar to that of the November case, but during extensive lake ice cover. With ice extending from 10 to 15 km lakeward from the outer bay current meters, the currents in the bay are entirely different in character. Lake Huron retains its cyclonic flow pattern, but under the ice the bay mouth circulation loses its distinctive character. Flow is weak with average current speeds of a few cm s^{-1} . Thus, even the driving force of lake current interactions is lost during extensive winter ice cover, and the bay circulation must be very disorganized and sluggish.

MODEL COMPARISON

Allender (1975) simulated the bay using a finite difference method to solve the linear barotropic equations for two-dimensional motion. Because the development of such a model requires the specification of boundary conditions at the mouth of the bay, he examined water level records from within Saginaw Bay and from Lake Huron near the bay mouth and determined the dominant periods of oscillation of the surface stage. He then specified as boundary conditions periodic functions of the velocity field at the open boundary between Saginaw Bay and Lake Huron at periods of the observed dominant surface oscillations. The intensity of the flow field was adjusted to yield water surface oscillations with amplitudes near those observed on the bay. Figure 9 shows the circulation he calculated for a southwest wind, and Figure 10 shows the flow pattern driven by a northeast wind. A comparison of these results with the results of the field studies shows that there is very good agreement between the flow patterns in the inner bay. Both results show a distinct current in the channel flowing into the wind and flow in shallow water with the wind. The agreement in the outer bay for similar wind conditions is not close, however. The differences between the model and field study circulations are due to the strong influence of Lake Huron currents on the flow in the outer bay, effects which were not included in model development.

 T = 10.0 hours
 → = .40 m²/sec

Figure 9. Currents in Saginaw Bay driven by a southwest wind with weak boundary forcing at periods of 3.3 and 2.0 hr (from Allender, 1975).

Spectral analyses of the current meter recordings reveal no significant periodic components in the flow field near the periods specified in model development, although during the density stratified season strong inertial period current flows are prominent near the bay-lake boundary. The dominant interaction between the bay and Lake Huron is controlled by the southward flowing coastal current structure in the lake, so that more realistic model development would necessarily include the dynamical effects of this interaction. Of course, the interaction of the lake and bay cannot be described without detailed field investigation, and the results of these surveys were not available for Allender's work.

SUMMARY

Currents in Saginaw Bay are quite variable and dependent on the local winds. The inner bay is especially susceptible to wind changes, but the circulation patterns developed are predictable for winds from the southwest or northeast, as a stable pattern develops within about 8 hr after a wind shift. Since wind from directions just slightly different than these cause only small perturbations to the flow field, as revealed during several of the drogue tracking intervals, it is felt that the two circulation charts are representative of wind from the southwest and northeast quadrants.

Winds blowing transverse to the longitudinal axis of the bay also cause the circulation pattern to change quickly. The flow pattern is more complex than when the wind is nearly parallel to the axis of the bay, but not enough data were collected under these wind conditions to determine a detailed circulation pattern. The outer bay responds less rapidly to wind changes and the current patterns are strongly influenced by currents in Lake Huron. The dominant southward flowing current along the west shore of Lake Huron frequently flushes through the outer bay. A northeast wind causes part of this current to flow through the outer bay in a counterclockwise loop, whereas the current flows past the mouth of the bay during southwest wind and drives a large clockwise eddy in the outer bay. The existence of such an eddy was suggested by Ayers et al. (1956). Ice cover during winter shields the water surface from wind stress and the bay circulation is very sluggish. Even the outer reaches of Saginaw Bay are decoupled from strong interaction with the currents flowing in Lake Huron as the ice fields grow lakeward of the bay mouth.

The comparison of results of this field study with those of a numerical model developed for the same area demonstrates the usefulness and validity of such modeling techniques. The agreement of the model with the actual data is excellent in the shallow water of the inner bay. However, the comparison also illustrates the importance and difficulty of prescribing proper boundary conditions at the open mouth of the bay. The model agrees well with the data far from the bay mouth, but breaks down near the open boundary. The choice of realistic boundary conditions is essential for the prediction of meaningful flow patterns, especially in this region where currents in Lake Huron are so important in influencing the circulation.

CHAPTER 188

PREDICTION OF POLLUTANT DISTRIBUTION IN ESTUARIES*

A. Y. Kuo and J. P. Jacobson
Department of Physical Oceanography and Hydraulics
Virginia Institute of Marine Science
Gloucester Point, Virginia 23062

ABSTRACT

A method was developed for predicting the distribution of sewage constituents which would result from a proposed sewage outfall in estuaries or coastal seas. The method is based on the mathematical relationship between the solutions of the mass-balance equations with and without a decay term and on the assumption that both the dispersion and decaying processes are linear, acting independently. The application of the method requires dye dispersion experiments and a numerical model employing the results of the experiments. This approach makes it possible to predict the concentration field of sewage constituents with differing decay rates by using tracer release experiment employing a conservative tracer.

The method has been applied to assess the environmental impact of a proposed sewage outfall in Hampton Roads, Virginia. Two dye dispersion experiments were performed, one a continuous release over a flood tide cycle and the other over an ebb tide cycle. Horizontal distributions of dye were measured at subsequent slack waters before flood and ebb. The results were used to predict the concentration fields of total nitrogen, total phosphorus, coliform bacteria, biochemical oxygen demand, dissolved oxygen deficit and chlorine residuals, which would result from the proposed sewage outfall.

INTRODUCTION

The dilution and mixing of sewage with receiving water may be considered a two-stage process. The first stage is the initial jet mixing. This initial mixing of the sewage jet with receiving water produces a broad field of diluted sewage. The second stage of mixing is the dispersion of sewage due to natural flow field as the diluted sewage field drifts with the ambient currents.

Models for the first stage, jet mixing, have been studied extensively (Fan, 1967; Fan and Brooks, 1969). These models are capable of delineating the concentration distribution of sewage constituents within the mixing zone.

* Virginia Institute of Marine Science Contribution No. 788.

The layout of diffuser ports, jet momentum, ambient currents and density difference are important parameters affecting the details of the mixing zone.

The second stage of mixing is dominated by the currents and turbulent characteristics of the receiving water. The far field distribution of sewage constituents outside the mixing zone is relatively insensitive to initial mixing. The ideal models for this stage of mixing are based on the equations of motion, continuity and mass balance of sewage constituents (Tracor, 1970). These models calculate the hydrodynamic characteristics, such as currents, density variations, turbulence of receiving water body and use them as inputs to the mass balance equation to calculate the concentration distribution. Due to the amount of field data required for the formulation and verification of this kind of model, it is not always feasible to resort to them for problem solving. Simple models based on the solutions of point or line source in a steady uniform flow field have been developed (Brooks, 1959; Csanady, 1973). The extension of these simple models to an estuarine environment where the flow field is non-uniform and oscillatory, is not straightforward. A purely analytical approach has yet to be developed.

The experimental approach of tracer release has been employed to delineate the far field distribution of pollutant discharge into a water body. Pritchard and Carter (1965) developed a method to estimate the concentration distribution of a nonconservative substance from that of a conservative substance which may be obtained with a field experiment. Their method is based on an empirical relationship that the concentration field of a continuous point source approaches its steady state with an exponential function of time. This paper describes a new approach using the concentration field of a conservative tracer to predict those of sewage constituents discharged from a proposed sewage outfall. This method makes it possible to describe the concentration fields of nonconservative substances without a large field effort to measure or calculate parameters, such as velocity field and dispersion coefficient, which are necessary for solving the mass-balance equation.

THEORETICAL BACKGROUND AND APPROACH

The concentration distribution of a sewage constituent in a receiving water body may be described by the mass balance equation

$$\frac{\partial c}{\partial t} + u \frac{\partial c}{\partial x} + v \frac{\partial c}{\partial y} + w \frac{\partial c}{\partial z} = \frac{\partial}{\partial x} (e_x \frac{\partial c}{\partial x}) + \frac{\partial}{\partial y} (e_y \frac{\partial c}{\partial y}) + \frac{\partial}{\partial z} (e_z \frac{\partial c}{\partial z}) - kc + S(x, y, z, t) \quad (1)$$

where

c is the concentration of sewage constituent,
 t is time,
 x, y, z are three orthogonal coordinates,
 u, v, w are velocity components,
 e_x, e_y, e_z are turbulent diffusion coefficients,
 k is decay rate,
 $S(x, y, z, t)$ is source or sink.

As it was stated previously, an ideal model would be the one based on the solution of equation (1) with the velocity components, turbulent diffusion coefficients, decay rate, and source as input parameters. The velocity field and diffusion coefficients have to be solved with a hydrodynamic model or measured in the field. Because of the efforts involved, developing such a model is often unfeasible.

An alternative way of obtaining the concentration distribution of a sewage constituent is to introduce a tracer at the proposed outfall location and measure the resulting concentration distribution. The release of the tracer should last long enough such that an equilibrium condition is achieved. Furthermore, different tracers have to be used to simulate sewage constituents of different decay rates. This direct experimental method is unfeasible in practice because

- 1) for each group of sewage constituents with a different decay rate, a tracer-release experiment has to be done,
- 2) tracers of a given decay rate cannot always be found.

The approach described here is to construct a simple model based on the relationship of concentration distributions between decaying and non-decaying substances. The experimental results of a non-decaying tracer provide the input data of the model and the concentration distributions of decaying substances are calculated.

The Model for a Steady Flow Field

If $N_0(x, y, z, t, t')$ and $N(x, y, z, t, t')$ are the concentration distributions, at time t , resulting from an instantaneous release at time $t = t'$ of non-decaying and decaying substances respectively, then

$$N(x, y, z, t, t') = N_0(x, y, z, t, t') \exp\{-k(t-t')\} \quad (2)$$

where k is the first order decay rate. In a steady flow field, the functions N and N_0 depend on $t - t'$, while they are independent of the time of release t' , therefore

$$N_0(x, y, z, t, t') = N_0(x, y, z, t-t') \quad (3)$$

and

$$N(x, y, z, t, t') = N(x, y, z, t-t') \quad (4)$$

If a tracer is introduced continuously at a constant rate (unit mass per unit time) for an infinitely long time, an equilibrium concentration field will be reached with

$$C_\infty(x, y, z) = \int_{-\infty}^t N(x, y, z, t-t') dt' \quad (5)$$

Let $\tau = t-t'$, equation (5) may be transformed into

$$C_\infty(x, y, z) = \int_0^\infty N(x, y, z, \tau) d\tau \quad (6)$$

and, substituting equations (2) and (3), it may also be obtained that

$$C_\infty(x, y, z) = \int_0^\infty N_0(x, y, z, \tau) \exp(-k\tau) d\tau \quad (7)$$

Mathematically, equation (7) states that the equilibrium concentration field of decaying substances may be calculated from the results of the tracer release experiment with a non-decaying tracer.

However, it is technically impossible to monitor continuously the history of a time-varying concentration field, $N_0(x, y, z, \tau)$. The continuous release of a tracer may be regarded as a succession of piece-wise continuous release of duration T . Equation (5) may be written as

$$C_\infty(x, y, z) = \sum_{n=1}^{\infty} \int_{t-nT}^{t-(n-1)T} N(x, y, z, t-t') dt' \quad (8)$$

Similarly, equations (6) and (7) become

$$C_{\infty}(x,y,z) = \sum_{n=1}^{\infty} \int_{(n-1)T}^{nT} N(x,y,z,\tau) d\tau \quad (9)$$

and

$$C_{\infty}(x,y,z) = \sum_{n=1}^{\infty} \int_{(n-1)T}^{nT} N_0(x,y,z,\tau) \exp(-k\tau) d\tau \quad (10)$$

If the time interval T is small compared with the time scale of decay, i.e. $1/k$, the decaying factor, $\exp(-k\tau)$, may be approximated by a constant $\exp(-\frac{2n-1}{2} kT)$ with an error less than $(kT)^3$, and equation (10) becomes

$$\begin{aligned} C_{\infty}(x,y,z) &= \sum_{n=1}^{\infty} \int_{(n-1)T}^{nT} N_0(x,y,z,\tau) d\tau \cdot \exp(-\frac{2n-1}{2} kT) \\ &= \sum_{n=1}^{\infty} C_{On}(x,y,z) \exp(-\frac{2n-1}{2} kT) \end{aligned} \quad (11)$$

where

$$C_{On}(x,y,z) = \int_{(n-1)T}^{nT} N_0(x,y,z,\tau) d\tau,$$

has a physical meaning as the concentration field resulting from a continuous release of a non-decaying substance over a time interval from nT to $(n-1)T$ in the past. Thus, the series C_{On} may be obtained from a field experiment in which a tracer is continuously released over a time period T and the concentration fields are measured at subsequent time instants $T, 2T, 3T, \dots, nT$ after the beginning of release. Equation (11) may then be used to calculate the equilibrium concentration field of any sewage constituent with decay rate k .

Extension of the Model to Tidal Estuaries

In the case of a non-steady flow field, the functions $N_0(x,y,z,t,t')$ and $N(x,y,z,t,t')$ not only depend on $t-t'$, but also on t' , the time when the tracers are introduced. The analysis in the previous section cannot be applied. However, the model may be easily extended to a tidal estuary if the flow field in the estuary is assumed periodic.

In estuaries where the tidal propagation dominates the flow field, the advective velocities u, v, w and diffusion

coefficients e_x , e_y , e_z are periodic functions of time. The period of fluctuation, one tidal cycle, may be used as the time unit and functions $N_0(x,y,z,n,n')$ and $N(x,y,z,n,n')$ may be defined as the concentration fields at a particular phase of the n^{th} tidal cycle resulting from instantaneous release at any phase of the n^{th} cycle. Because of periodicity, N_0 and N depend only on $n-n'$, while being independent of n' , thus

$$N_0(x,y,z,n,n') = N_0(x,y,z,n-n') \quad (12)$$

$$N(x,y,z,n,n') = N(x,y,z,n-n') \quad (13)$$

Therefore, the analysis of the previous section is still applicable if the time duration of a piece-wise continuous tracer release T equals a tidal cycle.

Equation (11) gives the equilibrium concentration at a particular phase of tide when the concentration fields are measured at that phase of successive tidal cycles. Of the concentration fields varying with phase of tide, the most significant ones are those at slack water before ebb (SBE) or high water slack and at slack water before flood (SBF) or low water slack because they are the extremes of the tidal excursion.

Let a non-decaying tracer be released continuously over a tidal cycle starting at slack water before ebb and let

$CH_n(x,y,z)$ be the measured concentration field at the n^{th} SBE after release begins,

$CL_n(x,y,z)$ be the measured concentration field at the n^{th} SBF after release begins,

then, according to equation (11), the equilibrium concentration field at SBE may be expressed as

$$CH(x,y,z) = \sum_{n=1}^{\infty} CH_n(x,y,z) \exp\left(-\frac{2n-1}{2} kT\right) \quad (14)$$

Since the concentration fields CL_n are not measured at the same tidal phase when the tracer-release begins or ends, the decaying factor of equation (11) has to be modified. The first concentration field CL_1 is measured at a time when the tracer has been released for only half of the tidal cycle. The average decaying factor is $\exp\left(-\frac{1}{4} kT\right)$. For $n \geq 2$, the

concentration fields CL_n are measured at $(n-1)$ tidal cycles after the mid-time of tracer release. The decaying factor is $\exp\{-(n-1)kT\}$. Therefore, equation (11) is modified to

$$CL(x,y,z) = CL_1(x,y,z)\exp(-\frac{1}{4}kT) + \sum_{n=2}^{\infty} CL_n(x,y,z)\exp\{-(n-1)kT\} \quad (15)$$

In deriving equation (11), the decaying factor $\exp(-k\tau)$ is approximated by a constant $\exp(-\frac{2n-1}{2}kT)$ over the time interval $t = (n-1)T$ to $t = nT$. The error introduced by this approximation may be reduced by shortening the duration of continuous tracer release T . For a tidal estuary, this may be easily achieved by separating the tracer-release into two parts: one continuous release over ebb tide and another continuous release over flood tide. Successive concentration fields at SBE and SBF are measured for both releases and constant decay factors applied to each of the measured concentration fields.

Let

$CHF_n(x,y,z)$ be the concentration field of flood tide release, measured at the n^{th} SBE,

$CHE_n(x,y,z)$ be the concentration field of ebb tide release, measured at the n^{th} SBE,

$CLF_n(x,y,z)$ be the concentration field of flood tide release, measured at the n^{th} SBF,

$CLE_n(x,y,z)$ be the concentration field of ebb tide release, measured at the n^{th} SBF.

then, for a non-decaying substance, the CH_n and CL_n in equations (14) and (15) may be expressed as

$$CH_n = CHF_n + CHE_n \quad (16)$$

$$CL_n = \begin{cases} CLF_{n-1} + CLE_n & n \geq 2 \\ CLE_n & n = 1 \end{cases} \quad (17)$$

The asymmetry of indices in equation (17) arises from the fact that CL_n is the concentration field at slack water before flood while the continuous tracer release is assumed to be from SBE to SBE.

For a decaying substance, different decaying factors are applied to the two parts of CH_n and CL_n , and equations (14) and (15) become

$$CH(x, y, z) = \sum_{n=1}^{\infty} CHF_n(x, y, z) \exp \left\{ - \left(\frac{2n-1}{2} - \frac{1}{4} \right) kT \right\} \\ + \sum_{n=1}^{\infty} CHE_n(x, y, z) \exp \left\{ - \left(\frac{2n-1}{2} + \frac{1}{4} \right) kT \right\} \quad (18)$$

$$CL(x, y, z) = \sum_{n=1}^{\infty} CLF_n(x, y, z) \exp \left\{ - \left(\frac{2n-1}{2} + \frac{1}{4} \right) kT \right\} \\ + \sum_{n=1}^{\infty} CLE_n(x, y, z) \exp \left\{ - \left(\frac{2n-1}{2} - \frac{1}{4} \right) kT \right\} \quad (19)$$

The adjustment of $\frac{1}{4} kT$ and $-\frac{1}{4} kT$ for the decaying factors of concentration fields of half-tidal cycle tracer releases improves the accuracy over a continuous full tidal cycle release.

FIELD EXPERIMENT

The model was used to study the proposed Nansemond Sewage Treatment Plant to be located on the south shore of the James River near the mouth of the Nansemond River. The outfall for this plant would be in Hampton Roads at a point roughly 12,000 feet (3,658 meters) from shore and a depth of 20 to 25 feet (6.1 to 7.6 meters), as shown in figure 1. The depth in Hampton Roads is much smaller than the horizontal dimensions of the water body. Vertical mixing by tidal currents is strong so that, at a location outside of the zone of initial mixing, the vertical variation of water constituent concentrations is negligible when compared with horizontal variations. The vertical homogeneity is especially true in late summer when the density stratification is weak and when the water quality problem is severe. Therefore, the horizontal distribution of concentration fields were measured in the tracer release experiments and vertical homogeneity was assumed. Vertical distribution of dye was measured at several locations during the field experiment and they confirmed the vertical homogeneity.

During the summer of 1974, two dye studies were conducted in Hampton Roads to simulate the release of pollutants during the flood and ebb cycles separately. The dispersion and transport of the dye, Rhodamine WT, were

Figure 1. The location map of Hampton Roads and proposed Nansemond STP Outfall.

followed for a period of about four days in each experiment. Two moving boats equipped with flow-through fluorometers and Hastings-Raydist navigation units traversed the study area at slack waters before ebb and flood (SBE and SBF). Each boat moved from shore to shore in a zigzag fashion following the period of slack water as it progressed upriver. The near surface (1 ft. or 30.5 cm below surface) dye concentration was monitored continuously and location coordinates were recorded every ten seconds. The data from these cruises were transferred to a chart of the area and contours of equal dye concentration were drawn by hand.

The dispersion and transport of the dye can be seen in figure 2 which shows some samples of dye clouds following the ebb cycle release. No data are presented within the area labeled Initial Mixing Zone, since within that area, there was a significant vertical variation in dye concentration. Outside that area, the concentration was nearly uniform with depth. The initial plume at the first SBF is about six miles long but less than one mile wide (figure 2a). At the following SBE, one complete tidal cycle after the dye release began, the dye cloud reaches from shore to shore, as shown in figure 2b. The dye has been dispersed over a broad area, and the complex pattern of currents in Hampton Roads has broken the dye cloud into several patches. At the second SBF, figure 2c, the dye cloud has been further dispersed and moved downriver. By the fourth SBF, figure 2d, the dye has been dispersed over a large area so that the concentrations are quite low. Much of the dye has left the James and gone into Chesapeake Bay. Similar patterns were found for the dye clouds of the flood cycle release, samples of which are shown in figure 3.

Data from the contours for the various slack waters for both flood and ebb releases were digitized for input to the computer. An 8.5 mile (13.7 kilometer) by 7 mile (11.3 kilometer) grid with 0.1 mile (0.161 kilometer) grid spacing was constructed and dye concentrations at each grid point were tabulated and read into the computer. Due to limited manpower and difficulties surveying at night in an area with a large volume of shipping, it was not possible to sample on every slack tide. Therefore an interpolation procedure was needed to provide the missing data. Values for the dye concentration one tidal cycle prior to and one tidal cycle after the slack with missing data were used to calculate the interim value (Kuo and Jacobson, 1975). Once this procedure had been accomplished, the summation process in equations (18) and (19) was completed and the equilibrium values were printed out on the grid points. This printout was then contoured and the equilibrium distributions were obtained.

Figure 4 shows the equilibrium concentration fields resulting from a continuous point source of 800 lb/day (363 kg/day). Equations (18) and (19) allow the simulation of the dispersion of nonconservative substances as well as conservative substances. In the figure one can compare the equilibrium concentration distributions for a conservative substance and one with a decay rate of 0.30 per day.

RESULTS

Using the designed effluent loadings of the proposed sewage treatment plant and the dye distribution data from the field experiment, the model was used to predict the distribution of total nitrogen, total phosphorus, biochemical oxygen demand, dissolved oxygen deficit, residual chlorine and coliform bacteria in Hampton Roads. The following are the designed average effluent loadings:

flow	:	16 MGD (0.702 m ³ /sec)
BOD ₅	:	4000 lb/day (1814 kg/day)
total nitrogen	:	25 mg/l (as N)
total phosphorus	:	10 mg/l (as P)
residual chlorine	:	2 ppm
fecal coliform	:	70/100 ml

In the simulation, total nitrogen and total phosphorus were assumed to be conservative substances. The predicted maximum concentrations of total nitrogen and total phosphorus are 40 µg/l and 25 µg/l respectively. Throughout Hampton Roads, concentrations are generally less than 10 µg/l for total nitrogen and 5 µg/l for total phosphorus. The dissolved oxygen deficit was estimated from the equilibrium relationship between reaeration and biochemical oxygen demand (both carbonaceous and nitrogenous). It was concluded that the DO deficit would be of the order of 0.1 mg/l in general, with a maximum of 0.4 mg/l near the initial mixing zone.

The toxicity of residual chlorine resulting from disinfection of treated wastewaters to estuarine organisms has recently been shown to vary widely with the species and the life history stage. For some organisms, e.g. oyster and clam larvae, 48 hours LC50 (50% lethal concentrations) as low as 0.001 ppm have been found (Roberts et al. 1975). In light of these findings and the fact that the James River estuary is the largest producer of seed oysters in Virginia the model was also used to estimate the potential impact of chlorine disinfection on sensitive species in the estuary. This was accomplished by applying the decay rate for chlorine and monochloramine to the field data of dye concentrations. The decay constant utilized was that determined by Bender, et al. (1975) who showed the decay of both chlorine and monochloramine to be approximately first order with $k = 0.05 \text{ hr}^{-1}$. Figures 5a and 5b show the predicted residual chlorine

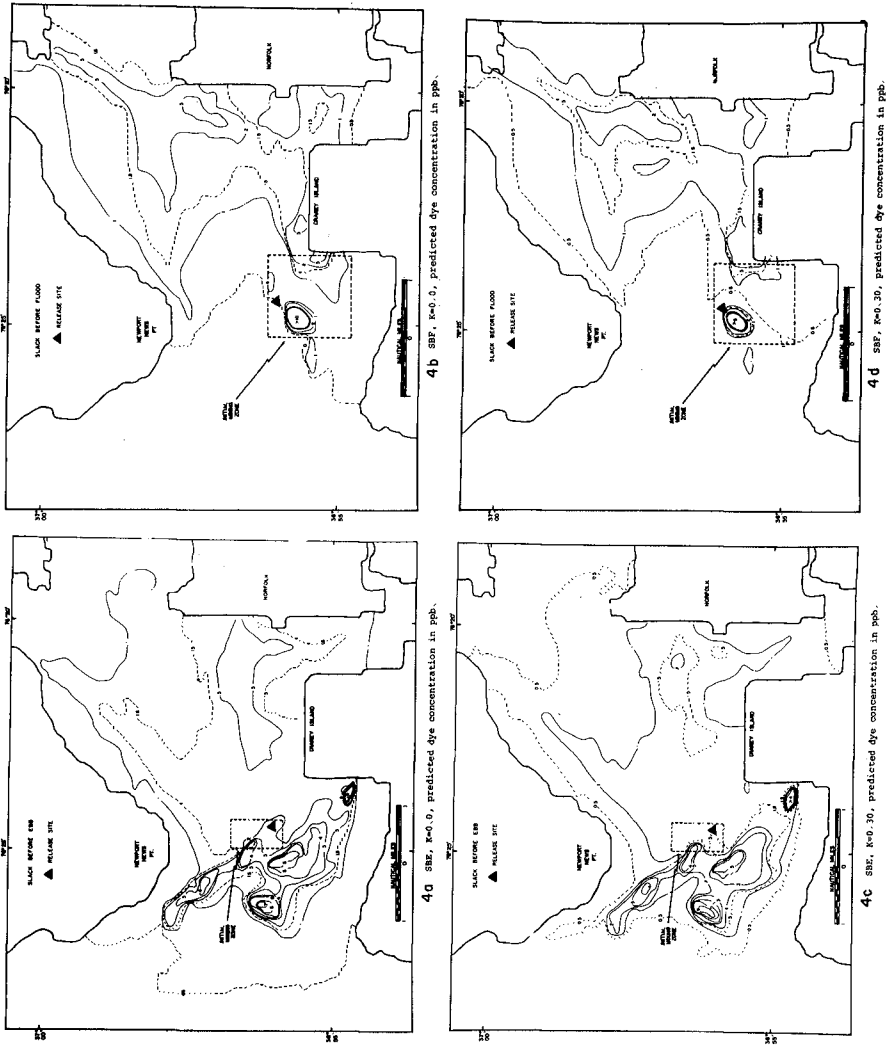

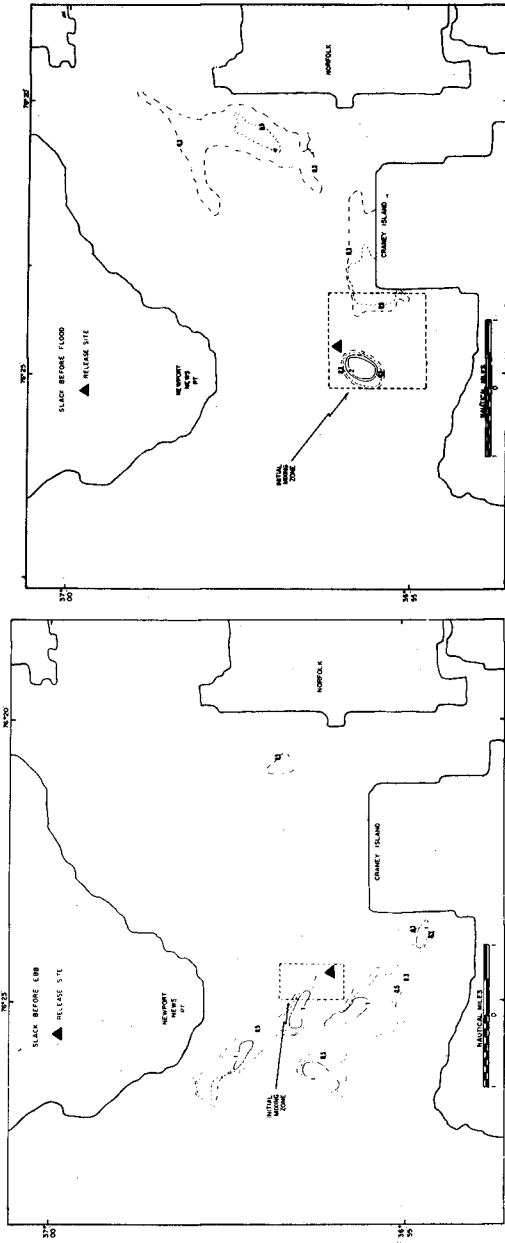

Figure 4. Equilibrium dye distributions from a continuous point source.

Figure 5. Concentration fields of residual chlorine.

distributions in the estuary at SBE and SBF respectively. As can be readily seen from inspection of figure 5a, considerable risk to oyster and clam larvae entrained in or passing through this segment seems likely.

Although not directly detrimental to marine organisms, the presence of coliform organisms above given levels in estuarine water is used by public health officials as an indicator of fecal contamination. If coliforms or fecal coliforms exceed accepted limits in a given segment of water the area is restricted for shellfish harvesting, thereby incurring an economic loss of valuable resources without actual damage to the shellfish population.

The model was used to predict the increase in ambient coliform concentrations as the result of proposed effluent loadings. The maximum bacteria level allowable in the effluent was set at 70 fecal coliforms per 100 milliliter of water. The model predicted that the maximum increase in ambient coliform levels was less than 1 per 100 ml. It was concluded that coliform loadings at this rate would not have a detrimental effect from the standpoint of shellfish closures. However, to cover the contingency of a breakdown in normal chlorinating procedures at a sewage treatment plant, an area around a sewage outfall was always designated that no shellfish might be taken within it. The model was used to simulate the coliform distribution which would result from the discharge of unchlorinated secondary effluent (3×10^5 fecal coliform/100 ml) for some specified length of time to simulate the discharge of unchlorinated effluent for finite duration. The summation in equations (18) and (19) was carried out to the first few terms corresponding to the duration of the point source. Figures 6a and 6b show the concentration distributions resulting from chlorination breakdown of half a tidal cycle.

DISCUSSION

The method presented in this paper has three elements: determining the dispersion and transport of a conservative substance released in a water body, some measure of the rate of decay or transformation of the wastewater constituents, and a set of mathematical procedures to combine this information and predict the distribution of nonconservative substances. All three elements will introduce some error. The effluent distributions which have been predicted appear reasonable to the oceanographers who have studied the tidal circulation in this region.

It is possible to note several limitations of the method. First, the determination of the physical dispersion and transport is time and site specific. That is, the results do not apply to other outfall locations nor do they

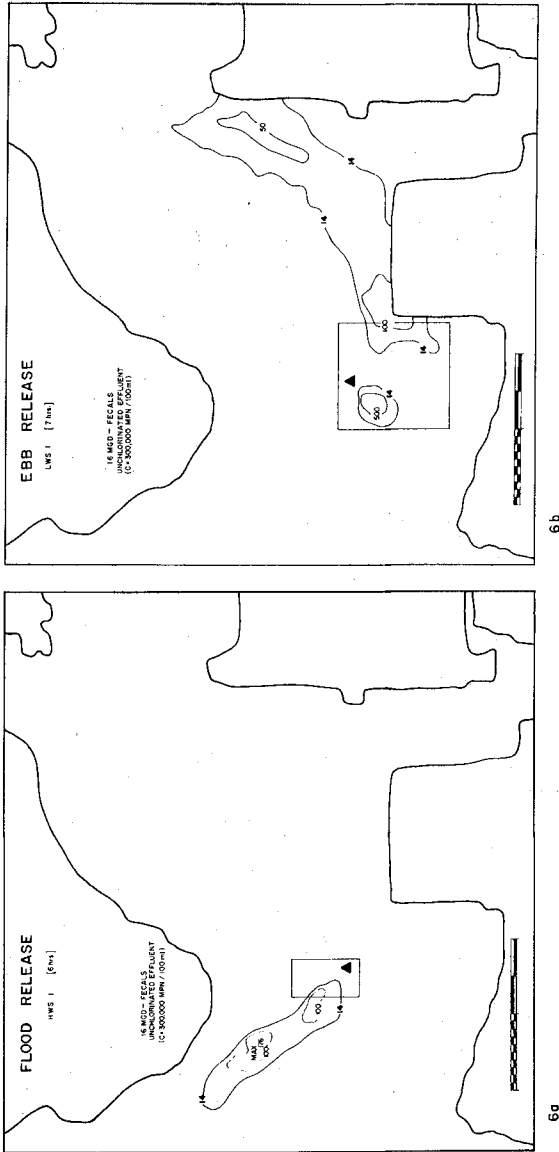

Figure 6. Fecal coliform distributions resulting from unchlorinated sewage.

necessarily apply to other times if the meteorological and hydrographic conditions have changed. An obvious example is that the results of the dye studies conducted in Hampton Roads during the summer of 1974 would not give good predictions for extreme events such as floods or hurricanes. It is not known to what extent the results will be modified when the estuary exhibits strong vertical salinity stratification, as occurs most winters and springs, but it is believed that the results will differ only slightly. If a hydraulic model is available for the water body under investigation, the tests could be repeated for different hydrographic conditions. The results then could be used to give the predictions for the corresponding conditions in the real world.

The rate of decay depends on many biological, geological and chemical processes and it is not always possible to determine a single rate of transformation which will be widely applicable. Therefore, values should be used which underestimate the rate of decay, and therefore provide conservative predictions since the residence time and concentrations will be over-estimated. The errors introduced by the mathematical manipulations are believed to be smaller than those introduced by the other two steps.

ACKNOWLEDGEMENTS

Many thanks are due to our colleagues, especially to Mr. E. P. Ruzecki for his capable supervision of the field study, and to Drs. C. S. Fang and B. J. Neilson for their suggestions and criticism.

This model was developed under the Cooperative State Agencies Program. The continuing support of the Virginia State Water Control Board is appreciated. The application of the model as described herein was supported by Hampton Roads Sanitation District Commission through McGaughy, Marshall & McMillan-Hazen and Sawyer: A Joint Venture. They are appreciated for the financial support and encouragement.

CHAPTER 189

NUMERICAL MODEL FOR DENSITY CURRENTS IN ESTUARIES

Karsten Fischer*

1. Introduction

In the estuarine mixing areas of salt water and fresh water the vertical stream velocity profile generally is strongly affected by the baroclinic forces, giving rise to upstream currents near the bottom. Such reverse currents occur not only in stratified estuaries, but also in estuaries of the well-mixed type [1], and they may cause problems like strong shoaling areas, salt intrusion, or difficulties when disposing wastes or dredged material [3]. The contributions of the salinity variations to the tidal motion are comparable to the contributions from the fresh water upland discharge [1]. For well-mixed estuaries with negligible fresh water discharge, the tidal velocities and water elevations may be obtained from numerical vertically averaged models or from physical homogeneous-flow models, but for all other conditions or desired results one has to use numerical vertically discretized models or physical inhomogeneous-flow models. As numerical and physical models have different properties and deficiencies, they may be used complementarily rather than concurrently [4], the farfield regime apparently becoming the domain of numerical models.

The increased public and scientific interest in water quality problems led to the development and application of baroclinic numerical tidal models [5, 6]. The present paper is concerned with the question, how well the action of baroclinic forces can be represented by numerical techniques. As a test example, the salt wedge problems is tackled. Studies on salt wedges by means of physical models have been very successful [1, 7], but mathematical approaches were confined to analytical solutions for the stationary salt wedge [8 - 10] and simple geometric boundaries only. The numerical approach is free from these restrictions, giving a solution of the complete equations of motion, continuity, and convection-diffusion simultaneously.

The main difficulty for the numerical model lies in the solution of the convection equation. The usual methods to solve the convection equation (like Forward Time / Centered Space, Upstream Differences, Lax-Wendroff, ADI, Leapfrog, or Galerkin-Finite Elements) break down when the convection of fairly sharp density jumps is to be calculated, as is the case for the salt wedge. Strong artificial diffusivity, mass losses, violations of the second law of thermodynamics or even unstable solutions are encountered. The numerical errors can be reduced considerably by using higher order difference approximations [11] at

*

Research Scientist, Sonderforschungsbereich 79, Technische Universität Hannover, F.R. Germany

the expense of higher numerical effort and more complicated boundary conditions, or by using a floating (Lagrangian) grid formulation; however, shearing and circulating flow forces the programmer to interpolate back to a fixed (Eulerian) grid from time to time, so that the advantage of the Lagrangian formulation in part gets lost, while the full numerical effort remains. In the baroclinic numerical model, errors in the convective solution may distort the whole model because of the faulty baroclinic forces (arising from a faulty density distribution) which act in the equations of motion. The question is, whether the numerical smoothing of sharp density jumps still allows for an adequate solution of the dynamics.

In the present paper, a new method for solving the convection equation is described, where the above mentioned numerical errors are reduced drastically. The numerical solution is compared to a semi-analytic one, ensuring the quality of the numerical method. A few exemplary calculations, showing the influence of bottom friction, barriers, and tidal motion on the shape of the salt wedge, demonstrate the versatility of the numerical model.

2. Numerical Method

Figure 1 shows the schematic salt wedge and the geometry used in the present investigation. We take a channel of constant depth a and length S , open at both ends. The lateral (y -) dependence is neglected. The freshwater discharge Q enters from the right. The salt wedge is formed by the sharp density jump between salt water (density ρ_1) and fresh water (density ρ_0) at $z = -t$, the thickness of the wedge over the bottom is r .

Figure 1. Salt wedge - schematic for definition of parameters.

The numerical solution is based on the following equations:
the equation of motion

$$\frac{\partial u}{\partial t} + \frac{1}{\rho} \frac{\partial p}{\partial x} - A \frac{\partial^2 u}{\partial z^2} = 0 \quad (1)$$

the hydrostatic pressure equation

$$\frac{\partial p}{\partial z} + \rho g = 0 \quad (2)$$

the continuity equation for incompressible flow

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0 \quad (3)$$

and the convection equation

$$\frac{\partial c}{\partial t} + u \frac{\partial c}{\partial x} + w \frac{\partial c}{\partial z} = 0 \quad (4)$$

where the concentration c is related to the density ρ by

$$c = \frac{\rho - \rho_0}{\rho} \quad (5)$$

u and w are the velocities in the x - and z -direction, respectively. p is the pressure, g the gravitational acceleration, ρ the density, and A the vertical eddy viscosity coefficient. In (1), the convective terms have been neglected in order to make an analytic solution possible which is needed for the comparison purpose. Eq. (1) still contains the terms responsible for tidal motion and salt wedge formation, and major effects from the convective terms should only be expected near the tip of the salt wedge where the velocity gradient is large. It will be shown that this is the region where the numerical errors are largest, but the comparison to experimental salt wedge profiles is good, so the neglect of the convective terms can be justified. In eq. (4) the diffusion terms were neglected for the same reason, i.e. the desired analytical solution works with two fluid layers of different density as depicted in fig. 1, while diffusion would create a continuous vertical density profile. For the numerical model, a certain amount of numerical diffusivity cannot be avoided, and an additional physical diffusion term would make the comparisons even more difficult.

For the numerical solution of the dynamic equations (1-3) the scheme of Suendermann [12] was used. The linearized equations are solved by an explicit leap - frog method, whereby the z -dependency of the velocity u is treated implicitly. The time-step of this procedure is limited by the step size along the x -axis through the Courant stability criterion.

For the numerical solution of the convection equation, a newly developed method was applied [13]. For simplicity, the method is explained for the one-dimensional case. The spatial density distribution is represented by Hermite interpolation functions; at the computational grid points, the density value ρ_j and its local gradient $(\frac{\partial \rho}{\partial x})_j$ are defined as time-dependent variables. For example, the density representation between grid points 0 and 1 is given by

$$\rho(x) = \rho_0 a(x) + \rho_1 b(x) + \left(\frac{\partial \rho}{\partial x}\right)_0 c(x) + \left(\frac{\partial \rho}{\partial x}\right)_1 d(x) \quad (6)$$

with the Hermite interpolation polynomials

$$\begin{aligned} a(x) &= 2x^3 - 3x^2 + 1 & b(x) &= -2x^3 + 3x^2 \\ c(x) &= x^3 - 2x^2 + x & d(x) &= x^3 - x^2 \end{aligned} \quad (7)$$

This representation has the following properties

$$\rho(0) = \rho_0, \rho(1) = \rho_1, \frac{\partial \rho}{\partial x}(0) = \left(\frac{\partial \rho}{\partial x}\right)_0, \frac{\partial \rho}{\partial x}(1) = \left(\frac{\partial \rho}{\partial x}\right)_1$$

The convection equation

$$\frac{\partial \rho}{\partial t} = -u \frac{\partial \rho}{\partial x} \quad (8)$$

is converted to the explicit difference equation

$$\rho_j^{n+1} = \rho_j^n - u_j \Delta t \left(\frac{\partial \rho}{\partial x}\right)_j^n \quad (9)$$

with j the spatial index and n the time-index, Δt is the time step.

For the gradient variables, another marching equation is needed. This equation is obtained from eq. (8) by spatial differentiation:

$$\frac{\partial}{\partial t} \left(\frac{\partial \rho}{\partial x}\right) = -u \frac{\partial^2 \rho}{\partial x^2} - \frac{\partial u}{\partial x} \frac{\partial \rho}{\partial x} \quad (10)$$

and transformed to the difference equation

$$\begin{aligned} \left(\frac{\partial \rho}{\partial x}\right)_j^{n+1} &= \left(\frac{\partial \rho}{\partial x}\right)_j^n - \frac{u_j \Delta t}{\Delta x} \left\{ \begin{aligned} &\frac{6}{\Delta x}(\rho_{j-1}^n - \rho_j^n) + 4 \left(\frac{\partial \rho}{\partial x}\right)_j^n + 2 \left(\frac{\partial \rho}{\partial x}\right)_{j-1}^n \\ &\frac{6}{\Delta x}(\rho_{j+1}^n - \rho_j^n) - 4 \left(\frac{\partial \rho}{\partial x}\right)_j^n - 2 \left(\frac{\partial \rho}{\partial x}\right)_{j+1}^n \end{aligned} \right\} \\ &\quad - \frac{u_{j+1} - u_{j-1}}{2 \Delta x} \left(\frac{\partial \rho}{\partial x}\right)_j^n \end{aligned} \quad (11)$$

where Δx is the spatial step size. The second term in the right-hand side of eq. (11) models the term $\frac{\partial^2 \rho}{\partial x^2}$ and is obtained from the evaluation of the second derivative of eq. (6), letting $x \rightarrow 0$; upstream differences are taken in eq. (11), where the upper line holds for $u_i > 0$, the lower line for $u_i < 0$. The third term on the r-h-s of eq. (11) is a spatial nonlinear term and was omitted in the calculations because of its destabilizing behaviour. It was found that eqs (9) and (11) together are linearly unstable, but stability could be achieved by a small correction to eq. (9). Instead of eq. (8), the form

$$\frac{\partial \rho}{\partial t} = -u \frac{\partial \rho}{\partial x} + \frac{u^2 \Delta t}{2} \frac{\partial^2 \rho}{\partial x^2} \tag{12}$$

was evaluated, where the corrective second term could immediately be taken from eq. (11).

The accuracy of the above described convective solution method is compared to several other methods in figure 2.

Figure 2. Numerical solution for convection of density spot.
 a) Initial, b) final density distribution (exact),
 c) present method, d) upstream differencing,
 e) forward time-centered space, f) Fromm's method.

As test example, the convection of a narrow density spot (initial width = $1 \cdot \Delta x$) over a distance $24 \cdot \Delta x$ was calculated by iterating over 240 time steps. The best approximation to the exact final density distribution is given by the present

method, which is even superior to the higher order method of Fromm [11]. The unstable character of the Forward Time-Centered Space method results in the strongly oscillating curve, while the Upstream Differencing scheme displays the strong numerical damping. Many other methods like Leapfrog, Lax-Windroff, Finite Elements or Flux-Corrected Transport can be shown to be inferior to the method of Fromm [13]; the present method gives comparatively very good results, uses simple boundary conditions and needs little numerical effort, only some more core space is needed for storing the gradient values.

In two dimensions, a second expression analogous to eq. (11) has to be evaluated numerically. The calculation can be done by fractional time steps, scanning through the coordinate directions successively, or by computing and adding the contributions from both coordinates simultaneously; the latter method was used here.

3. Semi - Analytic Solution to the Stationary Salt Wedge

Omitting the partial time derivative in eq. (1), a quadratic z -dependency of the velocity u can be obtained for each density layer (see fig. 1) separately, by integration. The non-slip condition is applied at the bottom:

$$u(-a) = 0 \quad (13)$$

The total flow across r is zero:

$$\int_{-a}^{-t} u(z) dz = 0 \quad (14)$$

Introducing the "baroclinic water level" k :

$$k(x) = h(x) - c q(x), \quad (15)$$

one gets for the velocity in the lower saline layer

$$u(z) = \frac{g}{6A} \frac{\partial k}{\partial x} \{ 3z^2 + 2(2a + t)z + a(a + 2t) \} \quad (16)$$

For the upper layer, the following two conditions are applied:

- 1.) the velocity $u(z)$ must be continuous at the interface $z = -t$.
- 2.) The total fresh water flow across q has the given constant value Q :

$$\int_{-t}^h u(z) dz = Q \quad (17)$$

For the velocity in the upper layer one gets

$$\begin{aligned}
 u(z) = & \frac{g}{2A} \frac{\partial h}{\partial x} z^2 + \frac{1}{3} \left\{ \frac{g}{A} \frac{\partial h}{\partial x} (2t - h) - \frac{g}{A} \frac{\partial k}{\partial x} \frac{r^2}{q} + \frac{6Q}{q^2} \right\} z \\
 & + \frac{1}{6} \left\{ \frac{g}{A} \frac{\partial h}{\partial x} t (t - 2h) + \frac{g}{A} \frac{\partial k}{\partial x} \frac{r^2}{q} (h - t) + \frac{12Q}{q^2} t \right\}
 \end{aligned} \quad (18)$$

For the calculation of the wedge shape $t(x)$ and the surface $h(x)$ two conditions are needed. They are obtained by considering the tangential forces:

1.) the stress at the surface is zero

$$\left. \frac{\partial u}{\partial z} \right|_{z=h} = 0 \quad (19)$$

2.) the stress at the interface is continuous

$$\left. \frac{\partial u}{\partial z} \right|_{z=-t-0} = \left. \frac{\partial u}{\partial z} \right|_{z=-t+0} \quad (20)$$

Inserting (16) in (20) and (18) in (19) and (20), one gets

$$\frac{\partial t}{\partial x} = \frac{1}{c} \frac{\partial h}{\partial x} \left(\frac{3}{2} \frac{h+t}{a-t} + 1 - c \right) \quad (21)$$

$$\frac{\partial h}{\partial x} = - \frac{12QA}{g(h+t)^2(4h+3a+t)} \quad (22)$$

This system of nonlinear, first - order differential equations was solved (to an arbitrary degree of accuracy) by numerical methods, and the solution is referred to as semi - analytic.

Dimensional analysis of (21) and (22) shows that x scales with a^4 while t and h scale with a , thereby establishing an affine relationship. Integrating (21) over the length L of the salt wedge gives the proportionality

$$L \sim \frac{gc}{QA} a^4 \quad (23)$$

where the remaining constant depends only on the relative depth of the salt wedge at the river mouth. Introducing the densimetric Froude- and Reynolds-numbers

$$Fr = \frac{Q}{\sqrt{cga^3}} \quad , \quad Re = \frac{\sqrt{cga^3}}{A}$$

one has

$$L \sim \frac{Re}{Fr} a \quad (24)$$

while the corresponding results of Keulegan [7] read

$$L \sim \frac{Re^{\frac{1}{4}}}{Fr^{\frac{5}{2}}} a \quad (25)$$

for natural rivers and

$$L \sim \frac{Re^{\frac{1}{2}}}{Fr^{\frac{5}{2}}} a \quad (26)$$

for hydraulic model flumes.

The difference in the results may arise from the simplifications in our theory, especially the constant eddy viscosity A and the non-slip condition (13).

4. Numerical Results

The computer code developed for the calculations permits the choice of variable step sizes in the vertical direction, variable bottom friction and bottom topography, and wind stresses at the surface. At the open boundaries upstream and downstream, the density distribution was kept fixed during the calculation. Care was taken that the salt wedge did not reach the upstream boundary. Since the buoyancy forces had been omitted in the initial differential equations, the hydrodynamically stable stratification had to be readjusted by averaging when a higher density value occurred above lower density values.

The fresh water discharge Q was taken as a dependent variable. As upstream and downstream boundary conditions the water levels were kept fixed. Stationary solutions were obtained after 10 000 time steps ($\hat{=}$ 4 weeks model time). The uniqueness of the solution was checked by starting from various density distributions; up to some minor differences in the velocity distribution, the same results were obtained in every case. More details of the calculations can be found in [14].

The following parameters were used throughout the calculations:

- Channel length $s = 36$ km, height $a = 13.7$ m
- Salt wedge thickness at the downstream end = 6.8 m, concentration = 3‰
- Eddy viscosity coefficient $A = 10^{-3} \text{ m}^2/\text{s}$
- Water levels upstream 4.7 cm, downstream 0.0 cm.

Figure 3. Stationary salt wedge profiles and water levels

Figure 3 shows the stationary salt wedges, computed by the various methods. For the present numerical method called "Hermite-interpolation", the 1.5% - isohaline was plotted as salt wedge boundary. The comparison to the semi-analytic curve called "exact" is good, major differences occur only at the tip of the wedge (where the neglect of the convective terms may play a significant role). It should be noted, however, that the wedge thickness in this region is comparable to the vertical grid spacing, as indicated in the figure. For comparison, another numerical solution is shown where the convection equation was solved by "upstream differencing". From this one can conclude that only the numerical high-precision solution of the convection equation leads to reasonable results in the field of highly stratified estuaries. The differences in the water level are less important, as shown in the upper part of the figure.

At $x = 9$ km, the vertical density profiles of the three different solutions are shown in figure 4.

Figure 4. Vertical density profiles of stationary salt wedges from fig. 3. at $x = 9$ km

The sharp density jump of the exact representation is reproduced fairly well by the "Hermite-interpolation" method, while the "upstream differencing" - result shows a very long tail extending towards the channel surface.

All of the following numerical results are obtained with the method of "Hermite-interpolation". Figure 5 shows the changes in the shape of the salt wedge, when the density profile at the river mouth is altered.

Figure 5. Vertical salinity profiles at river mouth $x = 0$ and corresponding salt wedges

From this figure one can see that little changes in the river mouth density cause substantial changes in the wedge length. This high sensibility of the baroclinic model will make the calibration of parameters in a realistic calculation easier, and it might be interesting to observe such an effect in natura.

Figure 6 shows the influence of bottom friction on the salt wedge shape; the dimensionless friction coefficient R is defined by the Taylor formula for the bottom stress

$$\tau = R u_b |u_b| \quad (27)$$

where u_b is the bottom velocity. With decreasing bottom friction the length of the salt wedge increases. One could have thought of an increased fresh water discharge (because of the decreased bottom friction) and a corresponding shortening of the salt wedge length (see eq. 23), but the opposite is true.

Figure 6. Influence of bottom friction R on salt wedge profile

The influence of a bottom barrier on the salt wedge form is demonstrated in fig. 7

Figure 7. Influence of bottom barrier on salt wedge profile
a) without barrier, b) with barrier

As can be seen in the figure, a barrier height d which is about $1/3$ of the undisturbed salt wedge height, is fully sufficient to prevent the salt wedge from spreading out upstream. This result is contrary to Keulegan's [7] statement that the barrier must be as high as the salt wedge. The problem can be elucidated by considering the velocity distribution eq. 16. For the lower two thirds of the wedge height r , the fluid moves upstream. No salt water can be transported upstream across a barrier of height $d = 2r/3$, because the transport velocity above this level is downstream. In addition, the velocity profile near the bottom is changed by a barrier, so that a barrier height of only $r/3$ prohibits salt intrusion.

As a first instationary calculation, a tidal wave was superimposed on the fresh-water discharge. The data for the calculation are:

	upstream	downstream
- average water levels:	5.3 cm	0 cm
- tidal amplitude:	102.8 cm	102.8 cm
- tidal phase shift:	25.0 deg.	0 deg.
- salt wedge thickness:		7.0 m

The calculation was carried out until periodic conditions were obtained. Figure 8 shows the salt wedges at high and low water. The difference in length is not large, but the

Figure 8. Salt wedge under tidal excitation. a) minimal, b) maximal salt water intrusion into the estuary

difference in salt wedge volume is. The constant height of the salt wedge at the downstream end is an unrealistic boundary condition and should be replaced by a tidally varying one. An indication of a computational instability was found near the tip of the wedge where the concentration at a single grid point was slowly but steadily increasing during the tidal periods. This effect can certainly be removed by more realistic boundary conditions and shall be further observed.

Finally, in order to show the relation of the present calculations to experimental data, the semi-analytic salt wedge curve is compared to Keulegan's [7] affine curve in figure 9.

Figure 9. Comparison of semi-analytic salt wedge (full line) to experimental data. Dotted line: Keulegan's salt wedge [7], fitted to critical flow conditions at river mouth
Circles: Keulegan's salt wedge, fitted to present results
Dashed line: Water surface

Taking the point of critical flow in the fresh water layer as "river mouth",

$$t_c = \sqrt[3]{\frac{Q^2}{cg}} \quad (28)$$

the dotted curve, taken from Keulegan's table [7], should be compared to that piece of the semi-analytic solution curve covering the same x - interval. The comparison is rather bad, however, the relation (28) is based on homogeneous flow in both fluid layers and not very well justified experimentally [7]. Relaxing this condition and fitting Keulegan's curve (circles in fig. 9) to the present one, a very good comparison is obtained; the empirical critical depth for this case is

$$t_c \approx \frac{Q}{\sqrt{cga}} \quad (29)$$

In conclusion, the present numerical model appears to be well suited to calculate the hydrodynamics of highly stratified estuaries. Of course, the numerical problems in calculating partially mixed estuaries are comparatively small. The results of such a calculation are given in figure 10.

Figure 10. Horizontal velocities (arrows) and salinities (numbers) in a well - mixed estuary (stationary). Dashed line separates regions of upstream and downstream currents.

For this calculation, a horizontal and a vertical diffusion term were added to the density transport equation (4). The diffusion coefficients were taken as large as allowed by stability conditions for an explicit difference scheme. At the boundaries fully mixed conditions were prescribed (numbers indicate density values). The partial stratification in the interior had developed dynamically. The combined effects of longitudinal stratification and sloping bottom lead to a zone of upstream current velocity, indicated in the lower

left part of the figure. This upstream current apparently exists independently from the degree of vertical stratification in the estuary, but only caused by the longitudinal stratification. The tip of the upstream current zone or equally the tip of the salt wedge are known to be the areas of maximum shoaling [3]. In consequence, for longitudinally stratified estuaries no information about the sediment transport can be obtained from measurements of surface velocities or calculations with vertically averaged numerical models, and this seems to hold for vertically stratified and mixed estuaries as well.

5. Summary and Conclusions

A numerical model for density currents in estuaries was presented, combining a classical solution scheme for the dynamical equations with a new solution scheme for the transport equation. The effects of baroclinic forces caused by density differences were studied in a two-dimensional x-z-model, and the results for a stationary salt wedge were shown to be in good agreement with a semi-analytic solution and experimental data. The uniqueness of the numerical solution was checked by varying the initial and boundary conditions. The influence of bottom friction, a bottom barrier, and tidal motions were studied; and the stationary solution for a well - mixed estuary was obtained.

It was found that the accuracy of the results for stratified estuaries depends mainly on the quality of the convective solution scheme, and that the present method of "Hermite-interpolation" gives satisfactory results in every case. As a practical aspect, it was found that bottom barriers for preventing salt intrusion into estuaries need not be as high as the undisturbed salt wedge. For realistic calculations, the time - dependency of water levels and vertical density profiles at the open ends of the estuary must be known from measurements.

CHAPTER 190

ENERGY DISSIPATION IN TIDAL ESTUARIES

by

Hans-Werner Partenscky ¹⁾

and

Günther Barg ²⁾

INTRODUCTION

In this study, the method for damped co-oscillating tides is used to evaluate damping and energy dissipation characteristics for various estuaries of different geometry and depth.

Of special interest are the damping and energy dissipation characteristics of the German tidal rivers such as Elbe, Weser and Ems in comparison with North-American tidal estuaries, since the former are characterized by deep navigation channels and relatively flat wadden areas at their lateral boundaries.

Harleman and Ippen have applied a mathematical model for co-oscillating tides to the Bay of Fundy and the Delaware estuary. This model gives information about the damping behaviour and energy distribution in the tidal estuaries.

Both of the above mentioned estuaries represent special cases since the geometric form of the Bay of Fundy allows it to be approximately represented as a rectangular chanal of constant width and depth, whereas for the Delaware Estuary one can assume a constant depth of water. Partenscky has applied an extended form of this model to the St. Lawrence Estuary.

The method of co-oscillating tides has now also been used in a mathematical model for the German tidal rivers such as Elbe, Weser and Ems. This method takes into account the influence of geometry and depth on the tidal motion and also the damping of the tidal wave due to friction and partial reflection. Data from gauges situated along the estuaries are needed as initial input for the calculation of the damping coefficient and the phase change. The wave amplitude and the time of highwater must be known from these stations.

2) Dipl.-Ing., Research Assistant, Franzius-Institute, Technical University of Hannover, Germany

DESCRIPTION OF THE GERMAN TIDAL RIVERS ELBE, WESER AND EMS

Fig. 1 shows a plan view of the German tidal rivers Elbe and Weser. Both rivers flow into the German Bay. The third mentioned river, the Ems, is a much smaller tidal river and not a so important navigation channel as Weser or Elbe. It flows more westwards near the boundary to the Netherlands into the Dollart. All three German tidal rivers have relatively flat wadden areas at their lateral boundaries.

The Elbe River is the largest German tidal river, it stretches from the mouth at Cuxhaven to the weir at Geesthacht. The width at the mouth is about 3300 m and the mean water depth is nearly 11 m.

The tidal estuary of the Weser River extends from Bremerhaven to the weir at Hemelingen. That is a distance of about 70 km. The harbour of Bremen is located nearly 5 km seaward from the weir of Hemelingen. 65 km downstream of Bremen at the bend near Bremerhaven the tidal river has a width of 1100 m and a mean water depth of 8 m.

In all three German tidal rivers the semidiurnal component is dominant, hence the tidal period is constant to 12.42 hours.

The cross-sections of the German tidal rivers are bounded upstream by weirs, so that one can assume total reflection of the tidal wave at these points.

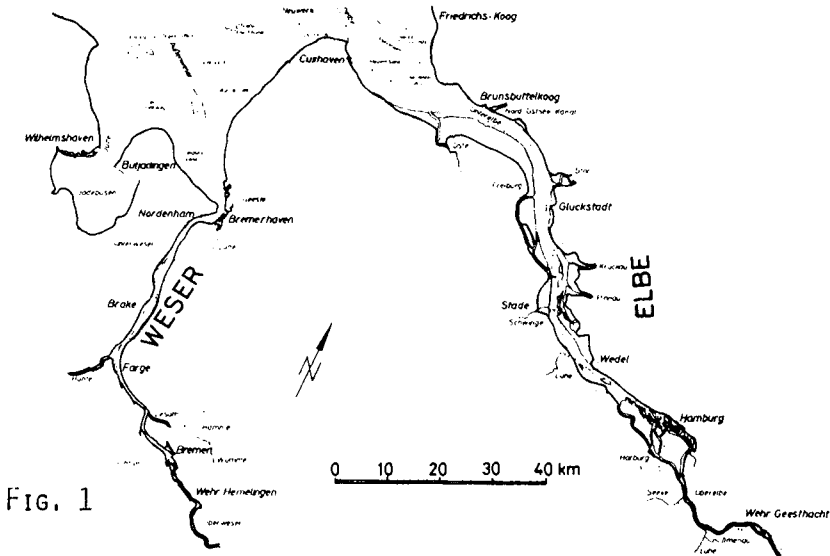

Fig. 1

ENERGY DISSIPATION AND DAMPING PARAMETERS.

Extensive prototype measurements at the Weser river are carried out by the Franzius-Institut to determine the influence of heat rejection of nuclear power plants on water quality parameters such as temperature and oxygen level. In this case, measurements in different cross sections of the river upstream and downstream of the cooling water intake over a stretch of about 40 km are carried out.

In order to examine the mixing process of seawater and freshwater in this area, it is useful to determine the longitudinal salinity distribution by conductivity measurements or chemical analysis. For given boundary conditions such as tidal motion and geometry of the estuary the longitudinal salinity distribution is a function of the freshwater discharge.

The stratification parameter $\beta = G/J$ is a useful parameter for this calculation, where G is the energy transported by the tidal wave with respect to the water mass of the examined area. J is the potential energy that the freshwater gains by increasing salinity.

Fig. 2 Energy flux

The energy flux of a tidal wave is given by $P = E_{\text{tot}} \cdot c$ with

$$c = L/T = \frac{\sigma}{k}$$

To determine the resulting energy flux for a cross section at a point x , one must split the observed tidal wave into an incoming and a reflected component (Fig. 2).

For a cross section at $x > 0$ the resulting energy flux is

$$P_{Rx} = P_{x1} - P_{x2}$$

At the point of total reflection $P_{x1} = P_{x2}$ and there is of course no longitudinal energy transport.

The loss in potential and kinetic energy of the tidal wave between the river mouth and a point between the river mouth and the weir is $\Delta P_x = P_{RL} - P_{Rx}$.

Let ΔP_x be the wave energy transformed into heat by friction and turbulence, then we get the relative loss of energy G_x as the transformed energy related to the water mass in the segment $l - x$.

For the cross section with total reflection we get the energy dissipation $G_o = P_{RL}/M$.

Fig. 3 Energy dissipation

An analysis of the energy dissipation with respect to G_o for all three examined German tidal rivers shows pronounced differences in the plotted curves. At the smallest tidal river, the Ems, the energy ratio G_x/G_o increases towards the mouth to 1,65. For the Weser, which is completely transformed into a navigation channel from the mouth up to the weir, the value is about 1,0. Contrarily

to the Ems, the Elbe River shows a decrease in the ratio towards the river mouth to 0,65.

To demonstrate these relationships, the resulting energy flux and the corresponding water mass in which the energy flux takes place are shown for the three tidal rivers as functions of distance in the diagram of Fig. 4. At $x=1$, i.e. at the seaward end of the examined tidal river the values of the energy flux and the water mass are assumed to be 100 %.

Fig. 4 Energy flux and water mass

With these assumptions, it can be clearly seen from the plots, that

$$\begin{array}{ll} \text{for } P_{Rx} < M_x & \text{it follows that } G_x/G_0 > 1 \\ P_{Rx} > M_x & G_x/G_0 < 1 \\ P_{Rx} = M_x & G_x/G_0 = 1 \end{array}$$

For the Weser River, the curve of water mass is almost identical to the curve for the energy flux. Accordingly, the energy ratio G_x/G_0 is about 1,0.

The variation is roughly only 10 % in the lower Weser and the energy dissipation can be assumed to be constant in the brackwater zone of the Weser.

The value G_x was used for tests to describe the longitudinal salinity distribution in the brackish area of the lower Weser.

The damping of the tidal wave is characterized by the damping coefficient μ which is important for the energy dissipation.

Referring to HARLEMAN and IPPEN, the equation for the damping coefficient was found by solving the equation for the local time of high water and the equation for the local amplitude of high water.

With application of Green's Law the local amplitude of high water is given by:

$$\eta_{xH} = a_o \left(\frac{b_o}{b_x}\right)^{1/2} \left(\frac{h_o}{h_x}\right)^{1/4} \left[e^{\mu x} \cos(\sigma t_H + kx) + e^{-\mu x} \cos(\sigma t_H - kx) \right]$$

and the corresponding time of high water is then:

$$\sigma t_H = \tan^{-1} (-\tan kx \cdot \tan \mu x)$$

For the damping coefficient follows then:

$$\cosh^2 \mu x = \frac{1}{2} \left[(N+1) + \sqrt{(N+1)^2 - 4 N \cos^2 \sigma t_H} \right]$$

$$\text{where } N = \frac{\eta_{xH}^2}{\eta_{oH}^2} \cdot \left(\frac{b_o}{b_x}\right)^{-1} \cdot \left(\frac{h_o}{h_x}\right)^{-1/2}$$

The reflected component of the resulting wave can be estimated from the value of μx . The component of the reflected wave is negligible as μx becomes very large. One arrives at an approximation of a progressive tidal wave without reflection.

In the case of no friction and total reflection at the closed end of the estuary, we get $\mu x = 0$ and the phase lag of the entrance of highwater $\sigma t_H = 0$.

In the study of real estuaries one finds values between these limits (Fig. 5).

Since the validity of Green's law is not satisfied in the German tidal rivers, the damping coefficient includes effects of friction, geometry and partial reflection of wave energy from the side walls of the estuary.

In comparison to the Elbe and Ems, the Weser River has the

smallest damping coefficient but the local change of this value is greater than for example in the lower part of the Elbe River as shown in Fig. 5.

Fig. 5 Damping Parameter

The increase in the energy flux also shows this tendency.

Let the energy flux be 100 % at the river mouth and 0 % at the weir of these three rivers, then the decrease in energy flux from the river mouth to the point of reflection is greatest with the Ems and smallest in the Elbe. The energy flux at the half distance from the mouth to the weir is 10 % for the Ems ($x = 26 \text{ km}$), 27 % for the Weser ($x = 34 \text{ km}$) and 36 % for the Elbe ($x = 70 \text{ km}$) of the initial value at the river mouth.

In general, it can be stated that the greater the change in the damping coefficient, the greater the relative decrease of the energy flux will be.

In comparison with the North American tidal estuaries (such as Bay of Fundy, Delaware Estuary and St. Lawrence) the German tidal rivers Elbe, Weser and Ems are much smaller in size.

The examined estuaries can be classified in three general types:

- Estuaries of nearly rectangular geometry in plan view having an approximately constant water depth (Example: Bay of Fundy).
- Estuaries whose widths vary exponentially, whereas the mean water depth remains approximately constant (Examples: Delaware Estuary and Weser Estuary).
- Estuaries featuring an exponentially varying width and a continuous decrease in water depth towards the head of the estuary (Examples: St. Lawrence Estuary and Elbe Estuary).

Comparison of the damping behaviour and energy dissipation has been made in Figure 6 between the three North American and the three German estuaries.

Fig. 6 Phase change and damping parameter

From the diagramm it is evident that the three North American tidal estuaries show smaller damping parameters at points equidistant from the reflection point than German tidal estuaries. This can be readily explained by the fact, that in the North American tidal estuaries due to their size the friction and geometry affect is of smaller importance than in the shallower and narrower German tidal rivers.

Only the mean water depth of the Delaware Estuary is nearly the same as the water depth of the German tidal rivers.

This relationship also can be seen from the plotted damping parameter versus distance x . The comparison is made for a distance of only 150 km seaward the point of total reflection, because all German tidal rivers are shorter.

The Bay of Fundy shows nearly no change of it very small

damping parameter with respect to the distance.
In the St. Lawrence Estuary there is a slope at the first 75 km and then the curve progress horizontal.

Only the Delaware Estuary shows nearly the same change of μx with respect to the distance x as the German tidal rivers Elbe and Weser.

CHAPTER 191

ALGORITHM FOR VERTICAL DIFFUSION

Søren Peter Kjeldsen**)

ABSTRACT

A mathematical method and a computer algorithm is developed for the case of one-dimensional vertical mixing for an estuary with rather small advection. In the case under consideration varies the diffusion coefficients both with time and depth, and the case is therefore closer to actual estuaries than earlier computing methods that applies constant coefficients. Model experiments with a small grid oscillation with high frequencies in two fluids with different densities were performed to test the algorithm. Reynolds number for turbulence was near $1.6 \cdot 10^4$.

The results showed that the ratio between the stabilizing Brunt-Väisälä frequency and the agitating cyclic frequency was a governing parameter for the system, and dimensionless diffusion coefficients could be expressed as a function of this parameter.

INTRODUCTION

Pollution problems in the sea and in the adjacent estuaries play an important role in coastal engineering and demands more and more sophisticated computational technique to be solved in a satisfactory way.

This paper deals with the case where two fluids with different densities are found in an estuary, with very small advection. After initial mixing in outlets and jets has occurred a more calm phase will be found where a light fluid is overlying a more dense fluid, and vertical mixing is due only to local turbulence.

This situation is common in many cases where the coastal engineer is involved such as:

**) Senior research engineer, River and Harbour Laboratory at the Norwegian Institute of Technology, Trondheim, Norway.

- 1) Thermal power plants with density differences between heated water and cooler recipient water.
- 2) Water power plants with density differences between fresh water in the mountains and salt water in the recipient.
- 3) Outlets that belong to the municipal sewage system.
- 4) Outlets and rivers containing different kinds of sediments in suspension.

Figure 1 shows a typical Norwegian fjord. The advection that occurs here is mainly wind driven. (See H. Rye, 1973 [1]). The algorithm presented here can also be extended to include advection and treat a case like this, as outlined below.

Figure 1. Site for collection of field data. Romsdalsfjord, Norway.

MATHEMATICAL ANALYSIS

Let us now consider the one-dimensional case without advection. The problem under consideration is shown in Figure 2. A salinity profile varying with depth is slowly mixed due to local turbulence. In the case under consideration no current is acting and all diffusion is vertical.

Figure 2. Definition of the problem.

The general equation for this situation is:

$$\frac{\partial s}{\partial t} = \frac{\partial}{\partial x} (D \cdot \frac{\partial s}{\partial x}) \quad (1)$$

D is the diffusion coefficient varying both with time and depth, x is the vertical co-ordinate, t is the time co-ordinate and s is the concentration of substance; here salinity (in other cases this could be heat or concentration of particles in suspension).

The boundary conditions for this situation are that the salt flux through the surface is zero, and that the time derivative of salinity integrated over the whole volume is zero as no material is transferred to the system from outside the control volume. (Eq. (2) and (3).)

$$FLUX_{x=h} = D \cdot \frac{\partial s}{\partial x} = 0 \quad (2)$$

$$\int_0^h \frac{\partial s}{\partial t} \cdot dx = 0 \quad (3)$$

Integration of the general equation with respect to x for a certain time kept constant gives

$$\int_0^x \frac{\partial s}{\partial t} \cdot dx = D \cdot \frac{\partial s}{\partial x} + CONSTANT \quad (4)$$

An integration constant appears here on the right side. This constant can be determined as shown in eq. (5) where the integration is taken over the whole volume.

$$CONSTANT = \int_0^h \frac{\partial s}{\partial t} \cdot dx - [D \cdot \frac{\partial s}{\partial x}]_{x=h} = 0 \quad (5)$$

The last term is the flux through the surface which is known to be zero, and the first term is also zero due to continuity. Thus the integration constant in eq. (4) is determined to be zero. The diffusion coefficient can then be found as the integral on the left hand side divided with the salinity gradient. Eq. (6) thus shows the determination of the diffusion coefficient for a certain time t_1 and a certain depth x_1 .

$$[D]_{x=x_1, t=t_1} = \frac{[\int_0^{x_1} \frac{\partial s}{\partial t} \cdot dx]_{t=t_1}}{[\frac{\partial s}{\partial x}]_{x=x_1, t=t_1}} \quad (6)$$

This result is now transferred to an algorithm for computer work.

Figure 3 shows the flow sheet of the computer version of the algorithm. The input is recorded density profiles. They are written out for each series or test.

AN ALGORITHM FOR VERTICAL DIFFUSION

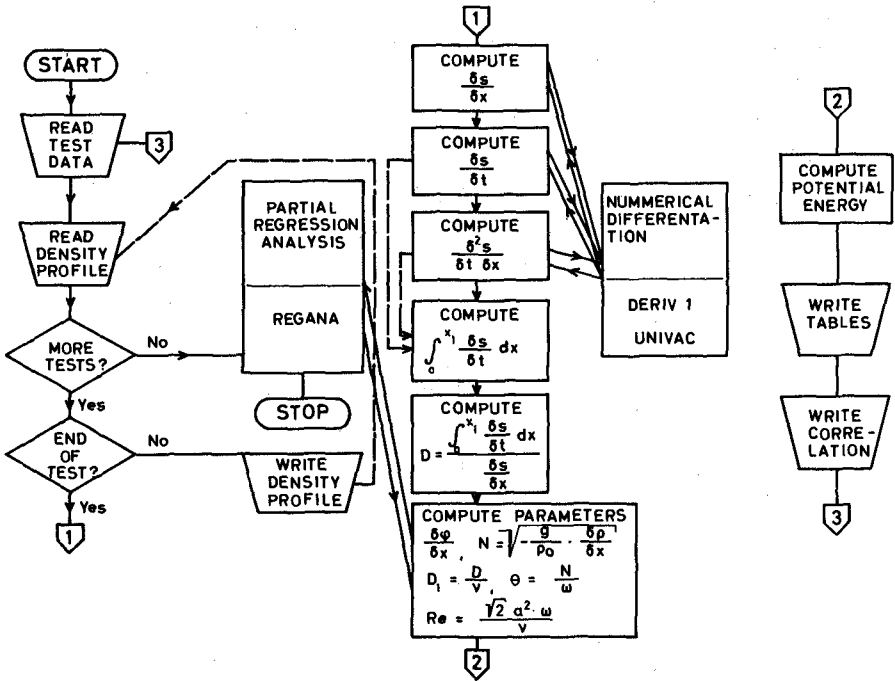

Figure 3. Flow diagram for algorithm.

A vital part of the programme is shown in two boxes, viz. a routine for numerical differentiation and a routine for a partial regression analysis. When a series of recordings is ended the computational part of the programme is called. This computes all the derivatives shown. Further, the programme uses a routine for numerical integration in which the input is both the salinity gradient with respect to time and the second derivative of salinity with respect to time and depth. From this the integral is found, and division with the local salinity gradient then gives the diffusion coefficients. Further, a special part of the programme computes all parameters that are considered necessary for the analysis of diffusion, such as density gradient, Brunt-Väisälä frequency, dimensionless diffusion coefficient, and Reynolds number for turbulence. The programme then goes on and computes potential energy and writes all parameters in tables.

Finally the regression analysis is called and it is then possible to investigate if there is any correlation between diffusion coefficients and selected density or turbulence parameters. This programme gives the final correlations directly. It takes density profiles as input and it gives the final correlation between diffusion coefficients and selected parameters immediately as output. It should, therefore, be an effective tool for research work in this field.

MODEL EXPERIMENTS

Experimental laboratory data for vertical mixing were used to test the algorithm. These were obtained in a small test tank that contained a layer of fresh water overlying a layer of salt water. A fine mesh grid was installed in the test tank and this could oscillate with different frequencies and amplitudes and thus generate the necessary turbulence. Two types of fine mesh grid were used, one with horizontal nets and one with vertical nets. Water samples could be extracted from the test tank through small tubes and the salinity was then determined with a conductivity meter. The temperature was kept constant during the tests. The test arrangement is shown in Figure 4.

FIG. 4. MODEL ARRANGEMENT

RESULTS

Figure 5 shows a typical test result, after 2 minutes testing. The density profile is mixed to some extent. The Brunt-Väisälä frequency is the reference parameter for the density profile that is considered most important. It is defined by the equation:

$$N = \sqrt{-\frac{g}{\rho_0} \cdot \frac{\partial \rho}{\partial x}} \quad (7)$$

where g is the acceleration of gravity, ρ_0 is the local density and $\partial \rho / \partial x$ the density gradient. It can be derived from the density profile. It shows a clear maximum in a certain level. 2π divided by this frequency is the lowest period with which internal waves can exist, and the distribution of the Brunt-Väisälä frequency is thus one of the most important dynamical characteristics of an estuary. Corresponding with this we can here see the computed vertical diffusion coefficient from the algorithm. It has a local minimum where the Brunt-Väisälä frequency has its maximum, and it has two local tops. This illustrates the inverse proportionality between these two parameters.

Figure 5. Test result after 2 minutes mixing.

Figure 6 shows a correlation between the diffusion coefficient and the squared Brunt-Väisälä frequency in one of the tests. The figure contains 154 points taken at different times during the 6 minutes test period. There is a considerable scatter. Still the partial regression analysis showed an inverse proportionality between the two parameters with a multiple correlation coefficient 0.94.

Fig. 6. Diffusion coefficient as a function of Brunt-Väisälä frequency.

Table 1 gives the equations for similar obtained correlations for all five performed tests.

TABLE 1
REGRESSION ANALYSIS NO 2

Level of significance to enter variable : 4.0
 Level of significance to delete variable : 4.0
 Minimum (residual variance/observed variance): 10^{-4}

Run	Correlation between D and N ²	Number of observations	Multiple corr. coefficient	Residual error	Anti-log residual error
No	Equation	m	r _{ij}	S _r	S _r ' = e ^{S_r'/0.4343}
7	$D = \frac{8.989 \cdot 10^{-2}}{(N^2)^{0.9928}}$	66	0.9535	0.5147	3.271
8	$D = \frac{4.957 \cdot 10^{-1}}{(N^2)^{0.9852}}$	33	0.9924	0.2886	1.944
9	$D = \frac{1.247 \cdot 10^{-1}}{(N^2)^{0.9551}}$	66	0.9630	0.4035	2.532
11	$D = \frac{2.572 \cdot 10^{-1}}{(N^2)^{0.9008}}$	66	0.9423	0.5620	3.648
12	$D = \frac{1.597 \cdot 10^{-1}}{(N^2)^{0.9604}}$	154	0.9414	0.4525	2.834

D = cm²/sec
 N = sec⁻¹

The power in the equation for the squared Brunt-Väisälä frequency is in the first test 0.99 obtained for 66 points. In the second test the power was 0.99 obtained for 33 points. In the following tests the power was 0.96 for 66 points and 0.90 for 66 points respectively, and in the last test the power was 0.96 for 154 points. Altogether 385 points were recorded and correlation coefficients varied between 0.94 and 0.99 as shown in the table.

The power for the squared Brunt-Väisälä frequency was thus in all cases found to be a little less than one.

Fig. 7 further illustrates that and shows the calculated best fit obtained from the regression analysis for all 5 tests performed, and the correlation coefficients. Further it is indicated that two types of grids, one horizontal and one vertical are used with different oscillating frequencies, and it is observed that the diffusion coefficient for both types of grids increases with increasing oscillation frequency.

Fig. 7. Results of regression analysis. Diffusion coefficients as functions of Brunt-Väisälä frequencies.

The next step is then to relate the obtained results to the turbulence that acted in the test tank.

DESCRIPTION OF TURBULENCE

It is well known that if u denotes the velocity fluctuation in the turbulence then the scalar energy spectrum is given by equation (8) where κ is the wave number.

$$\overline{u^2} = 2 \int_0^{\infty} E(\kappa) d\kappa \quad (8)$$

We can then form a Reynolds number consisting of the root-mean-square of the velocity fluctuations multiplied by a characteristic length scale for the eddies l and divided by the kinematic viscosity (Eq. (8)).

$$Re = \frac{(\overline{u^2})^{1/2} \cdot l}{\nu} \quad (9)$$

Unfortunately it was not possible to make direct measurements of the turbulence when the tests were performed. A first estimate of the turbulence parameters is therefore extracted from the sinusoidal oscillation of the agitating grid. In

Fig. 8 one of the bars-in the grid is shown in the mean position and in positions with maximum amplitudes, where the velocity is zero. The streamlines according to potential flow theory are also shown for the case where the oscillating velocity is maximum.

OSCILLATING CYLINDER

Fig. 8. Oscillating cylinder.

It is believed that it is the streamlines in this situation that dominate the flow pattern, as the velocity becomes smaller and the circles decrease near the amplitude maximum. Therefore as a first estimate the characteristic length of the eddies l is taken to twice the amplitude, a .

$$l = 2a \quad (10)$$

The validity of this approach to the macro-length scale is dependent on the Reynolds numbers for the oscillating cylinder. It will not be possible to obtain a better estimate without access to experimental data. Eddie shedding will occur from the back-side of the cylinder, but l is defined as the maximum length in which velocities can be correlated and it is therefore equation (10) and not the scale of the smaller eddies that is the best approximation for the scale of turbulence.

Further as a first approximation to the root mean square of the turbulent fluctuations the root mean square of grid velocity is taken as outlined in equation (11). ω is here the cyclic frequency in the oscillation. This is a reasonable first estimation as the added mass coefficient for an accelerated cylinder is near to one.

$$\overline{(u^2)}^{\frac{1}{2}} = \left[\frac{1}{T} \int_0^T a^2 \omega^2 \sin^2 (\omega t) dt \right]^{\frac{1}{2}} = \frac{\sqrt{2}}{2} a \omega \quad (11)$$

It is now possible to form the characteristic Reynolds numbers describing the turbulence. When the result for the root mean square of the velocity fluctuations and the characteristic length scale is set into equation (8) we obtain:

$$Re = \frac{\overline{(u^2)}^{\frac{1}{2}} \cdot l}{\nu} = \frac{\sqrt{2} a^2 \omega}{\nu} \quad (12)$$

In the experiments this Reynolds number was varied from $1 \cdot 10^4$ to $1.6 \cdot 10^4$, which indicates that a well developed turbulence was obtained.

It is possible to obtain a dimensionless parameter that describes the process, simply by forming the ratio between the stability frequency (the Brunt-Väisälä frequency N) and the agitating cyclic frequency ω .

$$\theta = \frac{N}{\omega} \quad (13)$$

All data for diffusion coefficients obtained in 3 different tests with the horizontal grid and with 3 different agitating frequencies were then correlated with this dimensionless number and presented in a dimensionless form, so that the ratio between diffusion coefficient and the kinematic viscosity is given. The result is shown in Fig. 9.

Fig. 9. Diffusion coefficients as a function of the ratio between stabilizing and agitating frequencies.

All data in the 3 different tests, 165 altogether, correlated with a multiple correlation frequency 0.82 and the equation obtained was:

$$\frac{D}{\nu} = \frac{2.25 \cdot 10^5}{\theta^{1.87}} = \frac{\text{CONSTANT}}{(N/\omega)^{1.87}} \quad (14)$$

The ratio between the diffusion coefficient and the kinematic viscosity can thus be expressed as a constant divided by the frequency ratio to the power 1.87.

A typical order of magnitude for the diffusion coefficients involved here is $10 \text{ cm}^2/\text{sec}$.

EXTENSION TO CASE INCLUDING ADVECTION

The general equation for three-dimensional diffusion with varying diffusion coefficients is:

$$\frac{\partial s}{\partial t} + U_x \frac{\partial s}{\partial x} + U_y \frac{\partial s}{\partial y} + U_z \frac{\partial s}{\partial z} = \frac{\partial}{\partial x} (D_x \cdot \frac{\partial s}{\partial x}) + \frac{\partial}{\partial y} (D_y \cdot \frac{\partial s}{\partial y}) + \frac{\partial}{\partial z} (D_z \cdot \frac{\partial s}{\partial z}) \quad (15)$$

Here x is the vertical coordinate while y and z are horizontal coordinates. If advection in one direction dominates, as in the case in many estuaries with wind driven circulation, we obtain:

$$\frac{\partial s}{\partial t} + U_y \frac{\partial s}{\partial y} = \frac{\partial}{\partial x} (D_x \frac{\partial s}{\partial x}) \quad (16)$$

Horizontal diffusion terms might be included here on the left side as a constant or as a function of space coordinates. For the vertical diffusion coefficient we can then obtain:

$$D_x = \frac{\int_0^x \frac{\partial s}{\partial t} dx + \int_0^x U_y \frac{\partial s}{\partial y} \cdot dx}{\frac{\partial s}{\partial x}} \quad (17)$$

If the current velocity is recorded the algorithm can then be extended and operated for a case with advection.

Field data in the form of density profiles, current profiles and wind, tide and wave recordings have already been collected from a typical Norwegian fjord which has been found suitable for further studies. This is the Romsdalsfjord earlier mentioned and shown in Fig. 1.

Use of the algorithm on the field data obtained here is in progress.

CONCLUSION

The purpose of this project was to develop a mathematical method that is able to treat the case of vertical diffusion with a diffusion coefficient varying with time and dept.

This was done and a computer programme was developed for the one-dimensional case without advection.

Model experiments were performed to test the algorithm. The results from these showed that the ratio between the stabilizing Brunt-Väisälä frequency and the agitating cyclic frequency was a governing parameter for the system and dimensionless diffusion coefficients could be expressed as a function of this parameter.

The algorithm can easily be extended to include advection, and is therefore usefull also for the treatment of field data in more complex situations.

This extension can be made step by step, and might include more and more terms in the general equation for diffusion in space and time with variable diffusion coefficients.

Further knowledge concerning development and decay of turbulence in the presence of a density profile is urgently needed.

ACKNOWLEDGEMENT

The author would like to epress his gratitude to Dr. T. Carstens, Head of Research at VHL, who suggested the experiments and gave advice on the paper. "Konsesjonsavgiftsfondet", The Fund of Licence Fees, The Norwegian Water Resources and Electricity Board sponsored the project.

CHAPTER 192

DISPERSIVE TRANSPORT IN RIVER AND TIDAL FLOWS

by

R. B. Taylor¹

ABSTRACT

Analytical results are presented which describe the mechanisms of longitudinal dispersive mass transport in rectangular channels of finite and infinite widths for both unidirectional (river) and oscillatory (tidal) flow regimes. Emphasis is placed upon the discussion of results and the characteristics of longitudinal dispersive mass transport revealed by the analytical treatment. Expressions presented for the dispersion coefficient were obtained from solutions to four sets of boundary value problems for the velocity and concentration variation components u'' and c'' . Examination of these expressions reveals that in oscillatory flow the dispersive mass transport is described by a type of resonant interaction between the period of oscillation and the time scales of vertical and lateral mixing. The analysis also shows that for oscillatory flow regimes the effect of lateral shear becomes negligible for very wide channels and the three dimensional solution collapses to the two dimensional case in which vertical shear and mixing effects dominate. It is shown analytically that this is not the case in unidirectional flows. For this case the lateral shear and mixing effects dominate the corresponding vertical effects and dispersive mass transport increases without bound with increasing channel widths.

INTRODUCTION

Previous efforts (Bowden 1965; Holley et al. 1970; Fukuoka 1973) to describe the mechanism of dispersive mass transport in oscillatory flows have generally assumed that it is reasonable to describe this process through comparison by analogy to a similar process in a steady unidirectional flow. As will be seen from the results presented here, this assumption is misleading and can lead to erroneous results and conclusions. This is due to the fact that the dispersion process in oscillatory flow behaves quite differently from the corresponding process in unidirectional flow. Thus, unless the basic characteristics of dispersion are clearly understood for both types of flows, the interpretation of results can vary greatly depending upon the basis used for the comparison.

¹Florida Coastal Engineers, Inc., Jacksonville, Florida

The mechanisms of dispersion in unidirectional flow are better understood. The most useful analytical treatment of this problem and the one which appears to provide the best results was developed by Fischer (1967). However, to apply Fischer's results one must have a detailed knowledge of the variations in the velocity field within the flow cross section. Moreover, his analysis assumes that the vertical effects of viscosity and diffusivity are small when compared to the same effects acting laterally across the channel. While this seems reasonable and has provided good results, it does not provide an analytical basis for examining those conditions under which either the vertical or lateral effects would play a dominant role in the dispersion process. Results presented in this paper allow for this comparison and are generally supportive of Fischer's work.

STATEMENT OF THE PROBLEM

The approach used to obtain expressions for the longitudinal dispersion coefficient generally follows the methodology devised by Taylor (1953) and applied later by others which defines the dispersive flux as the correlation over space and/or time of the velocity and concentration cross-sectional variation components by means of the following relationships:

$$-E_L \frac{\partial \bar{c}}{\partial \xi} = \overline{u'' c''} \quad (\text{unidirectional flow}) \quad (1)$$

$$- \langle E_X \rangle_T \frac{\partial \bar{c}}{\partial \xi} = \langle \overline{u'' c''} \rangle_T \quad (\text{oscillatory flow}) \quad (2)$$

where the overbar denotes the spatial average of the variable over the flow cross section, and the notation $\langle \rangle_T$ denotes an average over the period of oscillation, T. The variables u'' and c'' are defined by:

$$u'' = u - \bar{u} \quad (3)$$

$$c'' = c - \bar{c} \quad (4)$$

where u and c are the velocity and concentration variables, and \bar{u} and \bar{c} are the corresponding cross-sectional mean values. In carrying out the analysis, strict adherence to the use of companion solutions to the equation of motion and the transport diffusion equation was followed to obtain solutions for u'' and c'' which most nearly reflected the kinematic structure of the flow field of the particular problem being investigated. This is particularly important for the case of oscillatory flow regimes where, as illustrated by Figure 1b, flow reversals occur in the lower momentum regions of the channel which significantly affect u'' during portions of the tidal cycle. These phenomena have been preserved here and represent a departure from the work of previous investigators in which temporal phase differences in the velocity field over the flow cross section have not been included (Holly and Harleman 1965; Okubo 1967; Holley, *et al.* 1970; Fukuoka 1973).

$$-E_L \frac{\partial \bar{c}}{\partial \bar{t}} = \overline{u''c''}$$

FIGURE 1 - DESCRIPTIVE FLOW REGIMES AND ASSOCIATED DISPERSIVE MASS TRANSPORT RELATIONSHIPS

Expressions for the longitudinal dispersion coefficient were developed for the four combinations of flow and channel geometries previously mentioned. The analytical procedure was begun by solving the prescribed equation of motion for the velocity u for the particular flow regime and channel geometry under consideration. From this, an expression for u'' was obtained which in turn was used to force the companion form of the transport diffusion equation. Solutions to the transport diffusion equation then yielded expressions for the concentration variation component, c'' . Expressions for the longitudinal dispersion coefficient were obtained from Equations (1) and (2) by averaging the product $\text{Re}(u'') \cdot \text{Re}(c'')$ over the flow cross section, and for oscillatory flow by averaging again over the period of oscillation.

Boundary Value Problem Formulation

Several assumptions must be introduced to obtain forms of the governing equations that can be solved in a reasonable manner. These are described as follows:

- (a) The Boussinesq approximation is applied to the viscous terms in the equation of motion and the eddy viscosity coefficients, $\bar{\epsilon}_y$ and $\bar{\epsilon}_z$, are introduced. These coefficients are considered to be constant and equal to their spatial and temporal mean where appropriate.
- (b) Eddy diffusivity coefficients, \bar{K}_z and \bar{K}_y , are used to formulate the turbulent diffusion terms in the transport diffusion equation in a manner similar to that described for the viscous terms.
- (c) For purposes of the simplification of results and physical interpretation it is assumed that the eddy coefficients of viscosity and diffusivity are of equal magnitude. Thus, $\bar{K}_z = \bar{\epsilon}_z$, and $\bar{K}_y = \bar{\epsilon}_y$.
- (d) For steady unidirectional flow the pressure field is independent of time. If the flow is uniform then it can be assumed that

$$\frac{1}{\rho} \frac{\partial p}{\partial x} = K \quad (5)$$

where K is constant.

- (e) For oscillatory flow the pressure field is assumed to be temporally periodic, thus

$$\frac{1}{\rho} \frac{\partial p}{\partial x} = K e^{i\sigma t} \quad (6)$$

where σ is the angular frequency of oscillation and t is time.

(f) The velocity and concentration variables in oscillatory flow are assumed to be temporally periodic and of the form

$$u = u_s e^{i\sigma t} \quad (7)$$

$$c'' = c_s'' e^{i\sigma t} \quad (8)$$

where u_s and c_s'' are complex variables of the spatial coordinates defining position within the flow cross section. This formulation allows for temporal phase differences of u'' and c'' within the flow cross section.

The forms of the transport diffusion equations presented in all four boundary value problems are consistent with those used by previous investigators (Taylor 1953, 1954; Fischer 1967; Bowden 1965; Holley, et al., 1970) in which the concentration variable is viewed from a Lagrangian frame of reference traveling with the cross-sectional mean velocity. This transformation is accomplished by the introduction of the variable ξ defined as follows:

$$\xi = x - \bar{u}t \quad (\text{unidirectional flow}) \quad (9)$$

$$\xi = x - \int_0^t u(t') dt' \quad (\text{oscillatory flow}) \quad (10)$$

The first two sets of boundary value problems (BVP #1 and BVP #2) describe the dynamics of fluid motion and the transport diffusion of a substance in which only the vertical effects of shear and eddy diffusivity are considered. As shown by Figure 2, the x coordinate has been chosen to act along the principal flow axis while the z coordinate is defined positive upward from the channel bed. The two dimensional shear flow cases examined by these two boundary value problems incorporate essentially the same boundary conditions. For the equations of fluid motion the conditions of no-slip at the channel bed and zero shear at the free surface are applied; whereas for the transport diffusion equation the conditions of zero Fickian flux across the free surface and channel bed are used.

The boundary value problem formulations for three dimensional steady unidirectional and oscillatory flow regimes are presented by boundary value problems 3 and 4 (BVP #3 and BVP #4). Figure 3 illustrates the coordinate system used in these formulations. The origin has been located at the center of a rectangular region of height $2h$ and width w . The open rectangular channel is mathematically represented by the lower half of the full section shown in Figure 3. Selection of the coordinate system in this manner preserves the symmetry of the problem about the origin and, as will be shown later, correctly predicts the same dispersive mass transport for equal degrees of skewness in channel geometry in either the vertical or lateral directions. Equations (15) through (18) are of the same form as those presented for the two dimensional cases in BVP #1 and BVP #2 with additional terms included to account for the lateral effects of turbulent shear and diffusivity. Boundary conditions

$$\underline{\text{TDE}} : \bar{K}_z \frac{\partial^2 c''}{\partial z^2} + \bar{K}_y \frac{\partial^2 c''}{\partial y^2} = u'' \frac{\partial \bar{c}}{\partial \xi} \quad (16)$$

$$\frac{\partial c''}{\partial z} = 0; z = \pm h$$

$$\frac{\partial c''}{\partial y} = 0; y = \pm w/2$$

BVP#4 : Three Dimensional Oscillatory Flow

$$\underline{\text{EOM}} : \bar{\epsilon}_z \frac{\partial^2 u_s}{\partial z^2} + \bar{\epsilon}_y \frac{\partial^2 u_s}{\partial y^2} - i\sigma u_s = K \quad (17)$$

$$u = 0; z = \pm h, y = \pm w/2$$

$$\underline{\text{TDE}} : \bar{K}_z \frac{\partial^2 c_s''}{\partial z^2} + \bar{K}_y \frac{\partial^2 c_s''}{\partial y^2} - i\sigma c_s'' = u_s'' \frac{\partial \bar{c}}{\partial \xi} \quad (18)$$

$$\frac{\partial c_s''}{\partial z} = 0; z = \pm h$$

$$\frac{\partial c_s''}{\partial y} = 0; y = \pm w/2$$

used include the conditions of no slip and zero Fickian flux at the sides of the full rectangular section.

Dispersion Coefficient Solutions

Solutions obtained for u'' and c'' from BVP #1 through BVP #4 were used as previously discussed to develop the corresponding expressions for the longitudinal dispersion coefficient. The reader is referred to Taylor (1974) for the detailed development of these expressions.

To simplify the expressions obtained, several mixing time scales were introduced. These are defined as follows:

- a. Vertical Mixing Time, $T_{cz} = h^2/\bar{K}_z$
- b. Lateral Mixing Time, $T_{cy} = w^2/4\bar{K}_y$
- c. Non-Dimensional Vertical Mixing Time, $T'_z = T_{cz}/T$
- d. Non-Dimensional Lateral Mixing Time, $T'_y = T_{cy}/T$
- e. Relative Mixing Time, $T'_c = T_{cz}/T_{cy}$

where T is defined as the period of flow oscillation.

The solution of Equations (11) and (12) for the case of two dimensional steady unidirectional flow is straightforward. The expression obtained for the longitudinal dispersion coefficient is given as

$$E_L = \frac{8u_{\max}^2 T_{cz}}{945} \quad (19)$$

where u_{\max} denotes the maximum cross-sectional velocity. Equation (19) has been expressed as a function of u_{\max} by maximizing the solution for u as a function of the pressure gradient modulus, K . This provides a relationship between u_{\max} and K that can be used to express the dispersion coefficient solutions in terms of the more useful parameter u_{\max} .

Except for the numerical constants, the expression given by Equation (19) is identical to that obtained by Taylor (1953) for steady flow in a circular tube. By itself it is of passing interest only. However, for comparative purposes later in this paper, it is noted from Equation (19) that in two dimensional unidirectional flow, the dispersive mass transport increases proportionally with increasing vertical mixing time.

For the case of oscillatory two dimensional shear flow, the solution of Equation (13) for the velocity has been known and documented for some time (Lamb 1945; Segall 1971). To obtain a solution for c''_s , the velocity variation

component was expanded in a Fourier cosine series, and a Fourier cosine series form of the solution for c_S'' in Equation (14) was correspondingly assumed. The assumed form for c_S'' and the expanded series form for u_S'' were then substituted into Equation (14) and the Fourier coefficients for c_S'' were solved for. Expressions obtained for u'' and c'' were then integrated over the flow cross section, and time-averaged over the period of oscillation to obtain the dispersive mass transport. This produced the following expression for the longitudinal dispersion coefficient as a function of u_{\max} , the temporal and spatial maximum of the velocity:

$$\langle E_X \rangle_T = \pi u_{\max}^2 T \frac{T^2}{Z} \frac{(\cosh 2 \sqrt{\pi T^1} \frac{Z}{Z} - \cos 2 \sqrt{\pi T^1} \frac{Z}{Z})}{(\cosh \sqrt{\pi T^1} \frac{Z}{Z} - \cos \sqrt{\pi T^1} \frac{Z}{Z})^2} \sum_{n=1}^{\infty} \frac{(n\pi)^2}{[(n\pi)^4 + (2\pi T^1 \frac{Z}{Z})^2]^2} \quad (20)$$

It should be noted that Equation (20) incorporates the effects of an oscillatory velocity shear profile which allows for temporal phase differences of the flow over the water column. It also demonstrates the dependence of the dispersion mechanism on both the vertical mixing time scale and the period of oscillation. Although this dual dependence has been pointed out by previous investigators (Okubo 1967; Holley *et al.*, 1970; Segall and Gidlund 1972; Fukuoka, 1973) the fundamental way in which these two time scales govern dispersive mass transport has not been identified. This will be discussed in the following section.

Equation (20) has also been expressed as a function of the pressure gradient modulus, K , and the excursion length of a surface particle during one-half of a period of oscillation. The reader is referred to Taylor (1974) for the development of these expressions. Results obtained from these, however, will be used later for discussion purposes.

Solutions for the longitudinal dispersion coefficient in three dimensional unidirectional and oscillatory flows were obtained by assuming double Fourier cosine series forms for u and c'' . Arguments of the cosine functions were selected to satisfy both the boundary conditions stated for BVP #3 and BVP #4 and the physical requirements of no-slip, zero shear stress and zero diffusive flux at the appropriate boundaries and points of the rectangular half-section corresponding to the open channel cross section. The remaining portions of the solution techniques used are similar to those described previously for the two dimensional shear flow cases. To obtain the dispersive mass transport, the product of the real parts of u'' and c'' were integrated over the full rectangular section shown in Figure 3 and the result divided by 2 to provide the actual dispersive mass transport in the rectangular open channel.

The expression thus obtained for the longitudinal dispersion coefficient as a function of u_{\max} for the three dimensional steady unidirectional flow case is stated in nondimensional form as

$$E_L' = \frac{E_L}{u_{\max}^2 T_{CZ}} \quad (21)$$

$$E_L' = \frac{64}{\pi^4 \phi'^2} \sum_{\ell=0}^{\infty} \sum_{k=0}^{\infty} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \sum_{p=0}^{\infty} \sum_{q=0}^{\infty} \frac{\mu_{\ell k}}{\delta(\ell, k, m, n, p, q) R_{mn} R_{pq} R_{\ell k}} \quad (22)$$

where,

$$\delta(\ell, k, m, n, p, q) = [(2p+1)^2 - (2\ell)^2][(2q+1)^2 - (2k)^2][(2m+1)^2 - (2\ell)^2][(2n+1)^2 - (2k)^2]$$

$$R_{mn} = \left[\frac{(2m+1)\pi}{2} \right]^2 + T_C' \left[\frac{(2n+1)\pi}{2} \right]^2$$

$$R_{pq} = R_{mn} \text{ with } p \text{ replacing } m \text{ and } q \text{ replacing } n$$

$$R_{\ell k} = [(\ell\pi)^2 + T_C' (k\pi)^2]$$

$$\phi' = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{(-1)^{m+n}}{(2m+1)(2n+1)R_{mn}}$$

$$\mu_{\ell k} = \begin{cases} 1 & k \neq 0, \ell \neq 0 \\ \frac{1}{2} & k = 0, \text{ or } \ell = 0 \\ 0 & k = \ell = 0 \end{cases}$$

The non-dimensional form of the longitudinal dispersion coefficient obtained for the three dimensional oscillatory flow case (BVP #4) is presented on the following page as Equation (23). It is noted from an inspection of Equations (22) and (23) that:

(a) Dispersive mass transport in channels of finite width for both oscillatory and unidirectional flows is a function of both the vertical and lateral time scales of turbulent mixing through the variable T_C' .

Solution for Three Dimensional Oscillatory Flow (BVP #4)

$$E'_X = \frac{\langle E_X \rangle}{u_{max}^2 T} = \frac{32T_1^2}{\pi^4 \psi^2} \sum_{\ell=0}^{\infty} \sum_{k=0}^{\infty} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \sum_{p=0}^{\infty} \sum_{q=0}^{\infty} \frac{\mu_{\ell,k} \{ [r_2(\ell,k) - (2\pi T_1^2)^2]^2 \cos \lambda + (2\pi T_1^2) \sin \lambda \}}{\delta'(\ell,k,m,n,p,q) r_1^2(m,n) r_1^2(p,q) r_2(\ell,k)} \quad (23)$$

where,

$$\delta'(\ell,k,m,n,p,q) = [(2p+1)^2 - (2\ell)^2][2q+1)^2 - (2k)^2][2m+1)^2 - (2n)^2] - (2k)^2$$

$$r_1(m,n) = \{ [\frac{(2m+1)\pi}{2}]^2 + T_1^2 [\frac{(2n+1)\pi}{2}]^2 \}^2 + (2\pi T_1^2)^2 \quad \alpha_1(m,n) = \tan^{-1} \frac{2\pi T_1^2}{[\frac{(2m+1)\pi}{2}]^2 + T_1^2 [\frac{(2n+1)\pi}{2}]^2}$$

$r_1(p,q) = r_1(m,n)$ with p replacing m and q replacing n

$$r_2(\ell,k) = \{ (\ell\pi)^2 + T_1^2 (k\pi)^2 \}^2 + (2\pi T_1^2)^2$$

$$\lambda = \alpha_1(m,n) - \alpha_1(p,q)$$

$$\mu_{\ell,k} = \begin{cases} 1, & k \neq 0, \quad \ell \neq 0 \\ \frac{1}{2}, & k = 0 \text{ or } \ell = 0 \\ 0, & k = \ell = 0 \end{cases}$$

$\alpha_1(p,q) = \alpha_1(m,n)$ with p replacing m and q replacing n

$$\psi^2 = \left\{ \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{(-1)^{m+n} [r_1(m,n) - (2\pi T_1^2)^2]^2}{(2m+1)(2n+1)r_1(m,n)} \right\}^2$$

$$+ \left\{ 2\pi T_1^2 \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{(-1)^{m+n}}{(2m+1)(2n+1)r_1(m,n)} \right\}^2$$

(b) The dispersive mass transport for the three dimensional oscillatory flow case is also a function of the period of oscillation through the variables T and T'_z .

DISCUSSION OF RESULTS

Two Dimensional Oscillatory Flow

Bowden (1965) was the first investigator to look at longitudinal dispersive mass transport in oscillatory flow. He found that for the case in which the period of oscillation is infinitely long the longitudinal dispersion coefficient is one-half the value of the same coefficient for a corresponding unidirectional flow having the same surface velocity, the same shear profile, and the same vertical eddy diffusivity. Okubo (1967) and Holley, *et al.* (1970) extended Bowden's work and demonstrated that the dispersion process in oscillatory flows was functionally dependent on both the time scale of vertical mixing and the period of oscillation. The manner in which Holley, *et al.* interpreted their results stimulated much of the interest in the work presented here, and will therefore be discussed for illustrative and comparative purposes.

Holley, *et al.* assumed a linear oscillatory profile for the spatial component of velocity of the form

$$u'' = \alpha z \sin \sigma t \quad (24)$$

where α is a constant, z is the vertical coordinate, and σ is the angular frequency of oscillation, $2\pi/T$. Proceeding in the same manner as described here, they then used this expression for u'' to obtain solutions for c'' and the longitudinal dispersion coefficient corresponding to the general case of two dimensional oscillatory flow, and the special case in which the period of oscillation is infinitely long. The dispersion coefficient for the infinitely long period of oscillation, E_∞ , was then used as the basis for comparison of the dispersion processes in oscillatory and unidirectional flows. This was accomplished by plotting the ratio of the dispersion coefficient for oscillatory flow divided by E_∞ versus the non-dimensional time T' defined as $1/T'_z$ as used here. This produced the results as shown by curve ① in Figure 4. The ordinate variable used in Figure 4 is normalized by the corresponding dispersion coefficient for unidirectional flow, E_L , which is exactly double the value of E_∞ . The results of Holley, *et al.* were adjusted accordingly.

For comparison purposes Figure 4 includes results obtained from the present work as shown by curves ② and ③. Curve ③ plots the ratio of Equation (20) divided by Equation (19) while curve ② plots the ratio of the corresponding forms of Equations (20) and (19) expressed as functions of the pressure gradient modulus, K .

The results depicted in Figure 4 demonstrate the fact that the relative magnitudes of the dispersion coefficients for oscillatory and unidirectional

flow vary considerably depending upon how one chooses to make the comparison. All three curves shown approach the limiting value of one-half for large periods of oscillation which agrees with the findings of Okubo (1967) and Bowden (1965). However, as T' decreases the curves begin to diverge considerably. The agreement between the results of Holley, *et al.* (1970) and the u_{\max} normalization of the results presented here is good for large values of T' . However, it becomes increasingly worse as T' decreases. The close agreement for large values of T' is not surprising since both curves ① and ③ were developed by requiring the surface amplitude of the velocity in the oscillatory flow field to be equal to the velocity at the surface in the unidirectional flow field. The divergence of the two curves with decreasing values of T' results from the use of a truly oscillatory velocity profile in the present work as compared to the one assumed by Holley, *et al.* in which the velocity remains temporally in phase over the water column. Thus, as the period of oscillation decreases the effect of inertial forces increases thereby increasing the effects of flow reversals over the water column on the dispersive mass transport.

Curve ② in Figure 4 serves to illustrate the dramatic difference in behavior of the dispersion process when one chooses to compare the oscillatory and unidirectional cases by requiring both flow regimes to have the same pressure gradient modulus, K . For unidirectional flow the pressure gradient and viscous forces are in equilibrium so as to produce a constant unidirectional shear flow for the dispersive transport of substance. In oscillatory flow, however, the pressure gradient is in constant balance with the time varying inertial and friction forces. As the period of oscillation decreases, the inertial effects become very large such that in the limiting case little or no flow would be induced. This results in little or no dispersive transport.

The dramatic difference in the behavior of the velocity and pressure gradient normalized solutions raises the question of whether or not a plot such as Figure 4 is the most meaningful method of illustrating the characteristics of dispersive mass transport in oscillatory flow. It also suggests that the non-dimensionalization of the oscillatory dispersion coefficient by the corresponding unidirectional flow coefficient may in fact mask the fundamental behavior characteristics of the dispersion process in oscillatory flow. This is shown to be true by plotting separately the expressions obtained for E_L and $\langle E_X \rangle_T$ versus T_{CZ} , the vertical mixing time. Figure 5 presents such a plot. In this figure, the longitudinal dispersion coefficient, $\langle E_X \rangle_T$, as given by Equation (20) is plotted versus the vertical mixing time, T_{CZ} , for four periods of oscillation ranging from 22,526 to 223,560 seconds and a u_{\max} of 1 ft./sec. Also plotted is the solution for the unidirectional flow coefficient, E_L , as given by Equation (19). This figure clearly shows the significantly different behavior of E_L and $\langle E_X \rangle_T$. The unidirectional flow coefficient varies directly with the vertical mixing time which for little or no turbulent mixing over the water column allows the shear flow to transport higher concentrations of substance far downstream. The behavior of the oscillatory flow coefficient, however, is governed by a type of resonant interaction between the period of oscillation and the vertical mixing time. As the period

FIGURE 5 - COMPARISON OF DISPERSION PROCESSES AS A FUNCTION OF T_{cz}

FIGURE 4 - NON-DIMENSIONAL DISPERSION COEFFICIENT $\langle E_x \rangle_T / E_L$, AS A FUNCTION OF T'

of oscillation is increased, the resonant peak shifts to the right and likewise increases until the limiting case is reached where the peak is infinitely large and the values predicted for $\langle E_x \rangle_T$ are exactly one-half those predicted for the unidirectional flow coefficient, E_L . The resonant characteristic of $\langle E_x \rangle_T$ also explains the abrupt decrease in the ratio of $\langle E_x \rangle_T / E_L$ as exhibited by the curves in Figure 4.

The physical reasoning behind the resonant behavior of $\langle E_x \rangle_T$ is surprisingly simple. Consider first the case where the period of oscillation is much greater than the vertical mixing time. In this situation, the rate of vertical mixing is so rapid that there is no time for the velocity shear profile to transport the substance longitudinally before it loses its identity through vertical mixing. Thus, the oscillatory and unidirectional flow dispersive processes behave in a similar manner and both are small. This corresponds to conditions found in the extreme left regions in Figure 5. If T is held constant and T_{cz} is allowed to increase, the oscillatory shear profile is then able to transport the substance farther downstream before excessive mixing occurs; thereby increasing the dispersive transport. Thus, the oscillatory case continues to behave in the same manner as the unidirectional case. This continues to be true until the optimum ratio between the period of oscillation and the vertical mixing time is reached. At this point, the dispersive mass transport in the oscillatory flow regime has reached its maximum. If, however, the vertical mixing time is increased beyond this point, the oscillatory nature of the flow begins to become a factor and the longitudinal dispersion is decreased. This trend continues as T_{cz} is increased further until the limiting case is reached in which there is little or no vertical mixing taking place during one or more periods of oscillation. For this situation an elemental volume initially residing in the water column at elevation z , and containing an initial concentration c , would remain at this elevation thus being transported over the closed pathline of flow, and returned to its initial position with no longitudinal dispersion having occurred. By comparison, in a unidirectional flow with little or no vertical mixing, the longitudinal dispersion would be very large.

Thus, it is seen that for an oscillatory flow regime, the longitudinal dispersive mass transport becomes small for both $T \ll T_{cz}$ and $T \gg T_{cz}$; whereas for a unidirectional flow the longitudinal dispersive mass transport varies directly with T_{cz} .

The family of curves implied by Figure 5 was collapsed into one summarizing curve by expressing $\langle E_x \rangle_T$ as given by Equation (20) in the following non-dimensional form:

$$E'_x = \frac{\langle E_x \rangle_T}{u_{\max}^2 T} \quad (25)$$

It is noted that the form of E'_x follows naturally from Equation (20). A

plot of E'_x versus the non-dimensional vertical mixing time T'_z is shown by Figure 6. As indicated, the maximum value of the longitudinal dispersion coefficient occurs when the vertical mixing time, T_{cz} , is 1.58 times the period of oscillation, T .

Three Dimensional Oscillatory Flow

The non dimensional form of the solution for the longitudinal dispersion coefficient in three dimensional oscillatory flow, as given by Equation (23), is plotted versus T'_z in Figure 7 for several values of the relative mixing time, T'_c . As stated earlier, the relative mixing time is defined as the ratio of the vertical mixing time scale to the lateral mixing time scale. Thus, small values of T'_c are indicative of a very wide shallow channel, whereas $T'_c = 1$ would represent a channel whose width is twice its depth provided $\bar{K}_z = \bar{K}_y$. T'_c can therefore be considered as a measure of the relative effects of vertical and lateral shear for a given width-to-depth ratio, and vertical and lateral eddy diffusivities. Values of T'_c ranging from 1×10^{-6} to 1 were used to develop the curves shown in Figure 7.

It is seen from Figure 7 that when both the vertical and lateral effects of shear and turbulent mixing are considered, the dispersion process in oscillatory flow is described by an infinite number of resonant curves as compared to the single curve presented in Figure 6 when only vertical effects are considered. The effect of varying T'_c causes changes in the shape of the curve, the maximum value of E'_x achieved, and the value of T'_z at which this maximum occurs.

The innermost curve shown in Figure 7 is identified by $T'_{c \leq} \times 10^{-6}$ on the left hand side of the peak and by $T'_c \leq 0.001$ on the right. A comparison of this curve and the one shown in Figure 6 shows that the general shapes of the two curves are nearly identical with both peaks occurring at $T'_z = 1.58$. The peak value of E'_x in Figure 6 is 3.27×10^{-3} whereas for the limiting curve in Figure 7 it is 3.07×10^{-3} or 6 percent below the value shown for the two dimensional case. Differences in these two curves are attributed to the number of terms used to generate Figure 7. Because the solution for E'_x as given by Equation (23) contains six infinite summations nested in series, some limitations were necessary in carrying out the required computations. By varying the upper bound on each of the sums, it was demonstrated that the solution converges upward to its limiting value. The convergence occurs reasonably rapidly; however, above an upper limit of 10 terms for each sum the rate of convergence is slowed considerably. The results presented here were computed using an upper bound of 10 on each sum; therefore, each value of E'_x includes approximately 1.2×10^6 terms. Notwithstanding this obvious

FIGURE 6 - E'_x AS A FUNCTION OF T'_z FOR TWO DIMENSIONAL OSCILLATORY SHEAR FLOW

FIGURE 7 - E'_x AS A FUNCTION OF T'_z AND T'_c FOR THREE DIMENSIONAL OSCILLATORY SHEAR FLOW

limitation, it appears that the three dimensional solution for E'_x approaches the two dimensional solution for E'_x in the limit as $T'_c \rightarrow 0$.

Before passing, it is worthy to note the mathematical and physical symmetry of the dispersion process described by Equation (23). If T'_c had been inversely defined as T_{cy}/T_{cz} , Equation (23) would be of the same form with T'_y replacing T'_z everywhere, and the newly defined T'_c multiplying all complementary terms in r_1 , r_2 , and α_1 . This form of the solution would predict the same value of E'_x as the original formulation provided that u_{max} and T were the same, and that the new T'_y equaled the old T'_z and the new T'_c equaled the old T'_c . Stated another way, for the same u_{max} and T , a channel whose half-width was twice its depth would produce the same dispersive mass transport as a channel whose depth was twice its half-width provided that the ratio K_y/K_z for the first case equaled K_z/K_y in the second case. One way to show the symmetry of the solution about $T'_c = 1$ is by means of a plot such as Figure 8 in which isolines of E'_x are shown for channel geometries skewed in both width and depth. The lower half of this figure corresponds to geometries in which $w/2h > 1$ whereas the upper half corresponds to geometries in which $w/2h < 1$, provided that $K_z = K_y$.

Three Dimensional Steady Unidirectional Flow

Values for E'_L obtained from Equation (22) are plotted versus T'_c in Figure 9. In performing the computations, a summation limit of 12 was used on each of the six infinite summations included in the solution. By adjusting this value in a manner similar to that discussed for the oscillatory case, it was concluded that the solution as presented in Figure 9 is near that given by the infinite summations.

It is seen from Figure 9 that the longitudinal dispersion coefficient becomes very large with increasing channel widths. By comparison, if the definition of E'_L given by Equation (21) is applied to the two dimensional solution for E_L given by Equation (19) the result is

$$E_L = \frac{8}{945} = \text{constant} \quad (26)$$

This is shown in Figure 9 by the dotted line. The difference between the behavior of the two solutions is dramatic and for unidirectional flows supports Fischer's theory regarding the dominant effect of lateral shear on longitudinal dispersion in wide channels. It is apparent that the longitudinal dispersion for the three dimensional case increases without bound as the width of the

- Maximum Value of $E'_x = 354 \times 10^{-5}$ occurring at $T'_c = 0.25$ and $T'_z = 1.95$

FIGURE 8 - SYMMETRIC DISPLAY OF ISOLINES OF $E'_x \times 10^5$ IN THREE DIMENSIONAL OSCILLATORY SHEAR FLOW

FIGURE 9 - E'_L AS A FUNCTION OF T'_c FOR TWO AND THREE DIMENSIONAL UNIDIRECTIONAL SHEAR FLOW

channel is increased correspondingly, whereas the longitudinal dispersion predicted for the two dimensional case remains independent of changes in the channel width.

The fact that the three dimensional solution does not approach the two dimensional solution in the limit as $T_c' \rightarrow 0$ is not surprising if one considers the physical characteristics of the unidirectional flow regime and the mathematical formulations of the two cases examined. The three dimensional problem has by definition a lateral shear effect which, no matter how wide the channel, is forever present. Conversely, the two dimensional problem by definition has no such effect. Thus, the presence of this shear coupled with a unidirectional flow and a long time scale of lateral mixing must produce a significantly higher longitudinal dispersive mass transport than would be produced in the case where the lateral effect is non-existent. This phenomena does not apply to the oscillatory flow case because of the completely different nature of the flow regime. In that situation, the oscillatory characteristics of the flow negate the effects of a large lateral mixing time by periodically transporting the water mass across a fixed point of reference rather than transporting it far downstream as in unidirectional flow.

It is noted that the solution given by Equation (22) is symmetrical about $T_c = 1$ in exactly the same manner as discussed for the three dimensional oscillatory flow case. Thus, the discussion presented applies equally to those channels whose geometries are skewed in depth rather than width provided the conditions previously discussed are satisfied. This, of course, would not include the period of oscillation, T .

SUMMARY AND CONCLUSIONS

Analytical expressions for the longitudinal dispersion coefficient have been presented for four cases of shear flows, namely:

- a. Unidirectional flow in an infinitely wide rectangular channel
- b. Oscillatory flow in an infinitely wide rectangular channel
- c. Unidirectional flow in a rectangular channel of finite width
- d. Oscillatory flow in a rectangular channel of finite width

Examination of these results shows that in oscillatory flow regimes the dispersion process is governed by a type of resonant interaction between the period of oscillation and the time scales of transverse mixing over the flow cross section. For two dimensional oscillatory flows in which lateral effects are not considered, this interaction is confined to the period of oscillation and the time scale of vertical mixing. The dispersion coefficient was found to reach its maximum value for this case when the vertical mixing time is 1.58 times the period of oscillation. For the case of three dimensional oscillatory flows in which both the vertical and lateral effects of shear and

turbulent mixing are considered, it was found that the inclusion of the lateral effects affected the shape of the resonant curve, the maximum value of the dispersion coefficient achieved, and the value of T_z^2 at which the maximum occurred. It was also shown that the three dimensional solution for the dispersion coefficient in oscillatory flow approaches the two dimensional solution in the limit for wide channels.

The solution presented for the dispersion coefficient in three dimensional unidirectional flow was shown to predict increasing dispersive mass transport as the channel width was increased correspondingly. Thus, the three dimensional solution does not collapse in the limit to the two dimensional case as was found for oscillatory flow. This behavior supports Fischer's (1967) theory regarding the dominant effect of lateral shear on longitudinal dispersion in wide channels.

ACKNOWLEDGEMENTS

The author would like to thank Robert G. Dean who, as his doctoral studies advisor, provided many hours of encouragement and scientific insight for the work presented.

CHAPTER 193

TIDAL STREAM FLOW SOLVED BY GALERKIN TECHNIQUE

By L. H. Smith & R. T. Cheng

Water Resources Division
U.S. Geological Survey

I. The Problem

The total discharges in a tidally influenced stream reach are known to be related to the stages (water levels) at the ends of the reach. The discharge-stage relationships can be derived from the conservation principles of mass and momentum under a few simplifying assumptions. Solutions of the governing equations with appropriate boundary and initial conditions give spatial and temporal variations of the flow in the reach. Practically, the most needed information are the instantaneous discharges, which, in many instances, provide guidance for water resources management decision making. Unfortunately, measuring the instantaneous discharge in a tidal reach is often difficult, tedious and costly. However, measuring the stages of a tidal reach is relatively simple, inexpensive and is done routinely. To determine discharges from measured water levels has been the subject of the present study.

The governing conservation equations of momentum and mass when written for unidirectional, constant density, transient flow are, respectively,

$$L_1(u, Z) = \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + g \frac{\partial Z}{\partial x} + G |u| u + (q/A)u = 0, \quad (1)$$

$$L_2(u, Z) = \frac{\partial Z}{\partial t} + u \frac{\partial Z}{\partial x} + (A/B) \frac{\partial u}{\partial x} + (S_0 + \frac{\partial A}{\partial x}/B)u - (q/B) = 0, \quad (2)$$

where

A = channel cross-sectional area

B = width of channel cross-section at water surface

g = gravitational acceleration,

G = $gn^2 / (1.49^2 R^{4/3})$, n being Manning's coefficient,

q = lateral inflow per unit length of channel,

R = hydraulic radius of a cross-section,

S_0 = slope of the channel bottom,

t = time,

u = average water velocity for cross-sectional area A,

x = direction of flow,

Z = elevation of water surface,

as indicated in Figure 1.

Figure 1. Schematic Diagram of a Tidal Reach

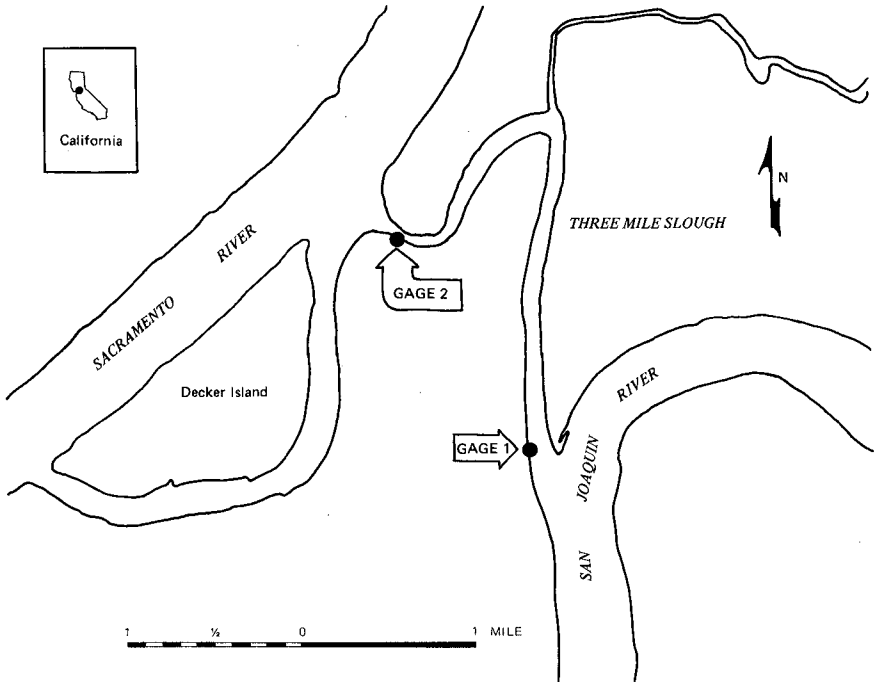

Figure 2. Plane View of Three-mile Slough, California

These equations assume that the flow is relatively uniform in any cross-section of the reach so that an average velocity u can be used to characterize the total discharge by Au . Though the cross-sectional area is treated as a variable, we further assume that A can be schematized by stacked trapezoids and that a linear representation of variation of A along the stream is sufficient. Stoker (1957), Chow (1959), Dronkers (1964) and Baltzer and Lai (1968) provide derivations and further discussion of these equations. The governing equations are coupled, nonlinear partial differential equations of hyperbolic type, which with specified water stages as the boundary conditions at ends of a channel segment, and initial conditions specified within the channel segment, form an initial-boundary value problem without known analytical solution.

Resorting to numerical techniques, Baltzer and Lai (1968) have considered the power series method, the implicit finite-difference method, and the method of characteristics to construct solutions of the discharges. Of these methods, the method of characteristics appears to produce the most accurate solutions. Recently, many classical variational techniques have attracted attention of researchers in relation to finite element methods, and use of the finite element methods in solid mechanics has been very fruitful.

Applications of the finite element techniques to hyperbolic equations are not yet numerous. Wang, et al. (1972) considered the one-dimensional primitive shallow water equation using cubic Hermite basis functions. Smith (1975) demonstrated that a Galerkin-finite element solution using linear basis functions compared favorably with those obtained by Baltzer and Lai (1968). Following a similar approach, a finite element solution of the Saint-Venant equation using linear basis functions was presented by Cooley and Moin (1976). They found that a stage boundary condition at each end of a channel segment must be implemented with the aid of the characteristic equations.

In this study we illustrate the use of cubic Hermite polynomials as basis functions in formulating a Galerkin-finite element solution to Eqs. (1) and (2). We explore the use of explicit and implicit time-differencing schemes. For a field case we compare measured discharges with discharges computed by the solution algorithm using measured stages as boundary values.

II. Galerkin-Finite Element Method

A. Galerkin Procedure

A general way to construct a finite element solution to a set of partial differential equations (such as (1) and (2)) is to employ the method of weighted residuals (Finlayson, 1972). For an M -th order approximate solution \bar{u} and \bar{Z} for the dependent variables u and Z , we write

$$\bar{u}(x,t) = \sum_{i=1}^M a_i(t) \psi_i(x), \text{ and} \quad (3)$$

$$\bar{Z}(x,t) = \sum_{i=1}^M b_i(t) \psi_i(x), \quad (4)$$

where ψ_i , $i=1,2,\dots, M$ are a carefully selected family of linearly independent functions called basis functions. If residual functions R_1 and R_2 are defined as

$$R_1(x,t) = L_1(\bar{u}, \bar{Z}), \text{ and}$$

$$R_2(x,t) = L_2(\bar{u}, \bar{Z}),$$

the method of weighted residuals obtains \bar{u} and \bar{Z} by making integrals of the residuals R_1 and R_2 vanish over the entire domain of interest with respect to certain weighting functions W_i , $i=1,2,\dots, M$. In other words,

$$\int_0^L R_1(x,t) W_i(x) dx = 0, \text{ and} \quad (5)$$

$$\int_0^L R_2(x,t) W_i(x) dx = 0, \quad (6)$$

for $i=1,2,\dots, M$, where L is the length of the entire channel segment of interest. When the weighting functions are defined and the integrals are evaluated, Eqs. (5) and (6) become a system of $2M$ simultaneous, ordinary differential equations of a_i 's and b_i 's, $i=1,2,\dots, M$. The Galerkin procedure assumes that $W_i = \psi_i$, and the classical Galerkin procedure is equivalent to the scheme of eigenfunction expansion for solution of boundary value problems. In finite element applications the basis functions ψ_i are neither complete nor orthogonal, so that the Galerkin procedure only implies that the weighted-averaged residuals are zero over the domain with respect to the basis functions.

Following the Galerkin procedure, and using Eqs. (1) - (4), Eqs. (5) and (6) can be written in matrix form as

$$[T] \frac{d\{a\}}{dt} + [P(a)]\{a\} + g [S]\{b\} + [Q(G|u| + q/A)]\{a\} = 0, \quad (7)$$

$$[T] \frac{d\{b\}}{dt} + [P(a)]\{b\} + [P(A/B)]\{a\} + [Q(S_0 + \frac{\partial A}{\partial x}/B)]\{a\} - [T]\{A/B\} = 0, \quad (8)$$

where

{ } = a column vector of dimension M ,

$$[T] = \int_0^L \psi_i \psi_j dx, \quad (9)$$

$$[S] = \int_0^L \psi_i \frac{\partial \psi_j}{\partial x} dx, \text{ and} \quad (10)$$

$$[P(f)] = \sum_{k=1}^M f_k U_{ijk}, \quad (11)$$

$$[Q(f)] = \sum_{k=1}^M f_k V_{ijk} \quad (12)$$

in which

$$U_{ijk} = \int_0^L \psi_i \frac{\partial \psi_j}{\partial x} \psi_k dx, \quad (13)$$

$$V_{ijk} = \int_0^L \psi_i \psi_j \psi_k dx, \text{ and} \quad (14)$$

for a given function $f(x)$ we write

$$f(x) = \sum_{k=1}^m f_k \psi_k(x). \quad (15)$$

Calculations for f_k are straightforward and clear when defined in terms of $\psi_k(x)$. Appendix I gives expressions for the above integrals in which $\psi_k(x)$ are cubic Hermite polynomials. In terms of local coordinates, the integrals defining the coefficient matrices have been evaluated explicitly. Appendix II contains specific entries for these matrices.

Application of the Galerkin-finite element procedure to the conservation equations produces the 2M - coupled, nonlinear, ordinary differential equations, Eqs. (7) and (8). In this study both the explicit and implicit finite-difference schemes have been used in the temporal space.

B. Explicit Time-differencing

Of the explicit time-differencing schemes, predictor-corrector schemes are well-suited for solving Eqs. (7) and (8). A fourth order Haming's modified predictor-corrector formula (Ralston and Wilf, 1960) has been employed in this study for which stages and discharges and their time-derivatives at three consecutive, equally-spaced times are used to predict their values at a fourth time. The time derivatives of the stages and discharges at the fourth time can thus be evaluated by Eqs. (7) and (8), and the processes repeated. A Runge-Kutta formula must be used up to the fourth time step to start the fourth order predictor-corrector. This integration scheme is explicit and requires relatively small time steps to maintain numerical stability. Because of its explicit nature, specification of stages at end boundaries must be implemented with the aid of characteristic equations (Cooley and Moin, 1976).

C. Implicit Time-differencing

Alternatively, in many applications an implicit Crank-Nicholson time differencing scheme which is numerically stable is preferred. Before applying a Crank-Nicholson scheme, we employ the quasi-linearization procedure to the governing equations, Eqs. (1) and (2).

1. Method of Quasi-linearization

As shown above the Galerkin procedure is general. When applied to nonlinear partial differential equations it only results in a system of nonlinear ordinary differential equations. The question of nonlinearity is dealt with by first linearizing the governing equations and introducing an iteration upon them. The Galerkin procedure is then applied to the linearized system to construct numerical solutions for each step of the iteration. This is plausible, and the following nonlinear terms are approximated by

$$u \frac{\partial u}{\partial x} \cong u^{(n)} \frac{\partial u^{(n+1)}}{\partial x} + u^{(n+1)} \frac{\partial u^{(n)}}{\partial x} - u^{(n)} \frac{\partial u^{(n)}}{\partial x} \tag{16}$$

$$u \frac{\partial Z}{\partial x} \cong u^{(n)} \frac{\partial Z^{(n+1)}}{\partial x} + u^{(n+1)} \frac{\partial Z^{(n)}}{\partial x} - u^{(n)} \frac{\partial Z^{(n)}}{\partial x} \tag{17}$$

where the superscript indicates the order of the iteration. When the $(n + 1)$ -th order solutions are sought, the n -th order solutions are known functions. Thus, Eqs. (16) and (17) are linear with respect to the $(n + 1)$ -th order solutions. Normally, the previous time solutions of u and Z are taken as the zeroth order solutions. It can be demonstrated that the quasi-linearization is but the extension of Newton's method to functional space. If convergence can be reached, the iteration converges at a quadratic rate (Bellman and Kalaba, 1965). Some nonlinearities in Eqs. (1) and (2) are weak and may be treated by a time delayed approximation. Thus Eqs. (1) and (2) become

$$\tilde{L}_1(u, Z) = \frac{\partial u}{\partial t} + u^{(n)} \frac{\partial u}{\partial x} + u \frac{\partial u^{(n)}}{\partial x} + g \frac{\partial Z}{\partial x} + G |u^{(o)}| u \tag{18}$$

$$- u^{(n)} \frac{\partial u^{(n)}}{\partial x} + (q/A) u = 0, \tag{19}$$

$$\tilde{L}_2(u, Z) = \frac{\partial Z}{\partial t} + u^{(n)} \frac{\partial Z}{\partial x} + u \frac{\partial Z^{(n)}}{\partial x} + \left[\frac{A}{B} \right]^{(o)} \frac{\partial u}{\partial x}$$

$$+ \left[S_o + \frac{\partial A}{\partial x} / B \right]^{(o)} u - \left[q/B \right] = 0,$$

where \tilde{L}_1 and \tilde{L}_2 are linear operators in which the superscript $(n + 1)$ is dropped for clarity, and terms with superscript (o) are treated with the time-delayed approximation.

By applying the Galerkin procedure, Eqs. (18) and (19) become, in matrix form,

$$[T] \frac{d\{a\}}{dt} + [P(\underline{a}^{(n)})] \{a\} + [P(\underline{a})] \{a\}^{(n)} + g [S] \{b\} \tag{20}$$

$$+ [Q [G | u| + q/A]^{(o)}] \{a\} - [P [\underline{a}^{(n)}]] \{a^{(n)}\} = 0,$$

$$[T] \frac{d\{b\}}{dt} + [P [\underline{a}^{(n)}]] \{b\} + [P (\underline{a})] \{b^{(n)}\} + [P [A^{(o)}/B]] \{a\} \tag{21}$$

$$+ [Q [S_o + \frac{\partial A}{\partial x} / B]^{(o)}] \{a\} - [T] \{q/B\} = 0,$$

in which the matrices $[T]$, $[S]$, $[P]$, and $[Q]$ are defined previously in Eqs. (9)-(12). Eqs. (20) and (21) are coupled, linear ordinary differential equations. At a particular time iterative solutions are obtained until $|\{a\} - \{a\}^{(n)}|$ and $|\{b\} - \{b\}^{(n)}|$ are less than a specified tolerance before further increment of time. Experience suggests that this criterion can usually be met within one or two quasi-linear iterations.

2. Crank-Nicholson Time-differencing Scheme

The Crank-Nicholson scheme is now applied to integrate Eqs. (20) and (21).

$$\text{Since } [P(a)]\{b\} = [P^*(b)]\{a\} \quad (22)$$

$$\text{where } [P^*(b)] = \sum_{j=1}^m U_{ijk} b_j$$

Eqs. (20) and (21) can be assembled such that they appear as

$$[C] \frac{d\{\xi\}}{dt} + [D]\{\xi\} = \{F\} \quad (23)$$

where the vector $\{\xi\}$ has dimension $2M$ and $\xi_{2i-1} = a_i$ and $\xi_{2i} = b_i$.

Using a finite-difference expression for $\frac{d}{dt}\{\xi\}$, we write Eq. (23) in the form

$$\left([C] + [D] / 2 \right) \left(\{\xi\}^+ - \{\xi\}^- \right) = \{F\} - [D]\{\xi\}^- / 2 \quad (24)$$

where $\{\xi\} = \{\xi(t_0)\}$ and $\{\xi\}^+ = \{\xi(t_0 + \Delta t)\}$.

The difference of the present and past $\{\xi\}$, i.e. $\{\xi\}^+ - \{\xi\}^-$, is actually solved to minimize possible round-off errors that could have been incurred in the computations. Because of the properties of the functions $\psi_i(x)$, the coefficient matrix $([C] + [D] / 2)$ is banded and diagonally dominant. An extended Cholesky algorithm (Tewarson, 1973) satisfactorily solves Eq. (24).

In summary, using an implicit time-difference scheme, we have (1) quasi-linearized the nonlinear partial differential equations, (2) applied the Galerkin procedure in the space domain, (3) integrated the resultant ordinary differential equations with respect to time by the Crank-Nicholson finite difference scheme.

III. A Case Study

Three-mile Slough, which is located about 40 miles northeast of San Francisco in the delta region of California's central valley, provides an interesting example of tide-induced, unsteady, open-channel flow. The slough is actually a channel approximately three miles in length connecting the Sacramento and San Joaquin Rivers, Fig. 2.

The long-period tidal waves propagate inland through Golden Gate, San Francisco Bay, San Pablo Bay, Carquinez Strait, Suisan Bay, and on. At the confluence of the San Joaquin River with the Sacramento River near the city of Pittsburgh, the waves divide and continue to propagate upstream in the separate river channels. Because of lesser distance above the confluence and because of greater channel depth, a translatory wave crest passes the Sacramento River end of Three-mile Slough from 30 to 45 minutes before the corresponding wave crest reaches the slough's San Joaquin River end. As a result, Three-mile Slough exhibits continuously and rapidly varying flow through each tidal cycle. Moreover, the direction of flow alternates with the passage of each successive wave. Because of the high degree of unsteadiness and alternating direction of the flow, this tidal reach was deemed desirable for trial evaluation of the discharge computation process.

In 1959, Water Resources Division of the U.S.G.S. conducted an extensive field investigation in this tidal reach. Two tidal gages were installed at the San Joaquin and at the Sacramento River ends to record water levels at 15-minute intervals. A field survey was also conducted to help establish its cross-sectional properties. During the months of July and August, 1959, gates blocked all the diversionary channels, and several sets of discharge measurements were made using current meters. These data were used to evaluate the computational schemes suggested in the present study.

Using the measured stage records at the ends of the Three-mile Slough (See Fig. 2) as inputs, the computations have been carried out by both the predictor-corrector and Crank-Nicholson schemes for several values of Manning coefficient. Figure 3 is a plot of measured and computed discharges obtained by the predictor-corrector scheme for three different Manning values. A Manning value of 0.038 gives a best over-all fit for this scheme. Since the discharge ranges between +35,000 cfs (ft^3/sec) to -35,000 cfs, it is quite likely that the Manning n value should have been treated as a function of the discharge. We have not included this feature in the present study, although implementation of a variable n in the model is plausible. For a Manning coefficient of 0.038, Figure 4 compares the computed discharges for the predictor-corrector and quasi-linearization schemes to those computed by the predictor-corrector scheme with linear basis functions. The predictor-corrector schemes both were run with a 1-minute time-step, and the Crank-Nicholson (quasi-linearization) scheme with a 5-minute time-step. The deviation of the quasi-linearization scheme is attributable to the different manner in which it handles the friction term. For a reach with channel geometry as regular and length as short as Three-mile Slough, there is little difference in the discharges computed using the Hermite and linear basis functions. All of the schemes compute discharges within 5 percent of the measured values.

IV. Discussion

In this study numerical solutions to the governing equation of a tidal reach have been constructed using a Galerkin-finite element approximation in space and finite-difference approximation in time. The computer algorithms have been successfully tested in a case study at Three-mile Slough, California, where a complete reversal of flow takes place in every semi-diurnal tidal cycle. The predictor-corrector

Figure 3. Comparison of the Computed and Measured Discharges at Sacramento River for Various Values of Manning Coefficient

Figure 4. Discharges at Sacramento River Computed by Various Numerical Schemes

solution computes accurate discharges but requires use of the characteristic equations to implement the boundary conditions, and small time-steps to maintain numerical stability. The implicit Crank-Nicholson and quasi-linearization scheme has neither of these requirements. Although it requires longer computer time per time step, it permits the use of larger time steps. The total computer time requirements for the implicit and explicit methods are comparable. Good agreement between the measured and computed discharges suggests further applications of the present model to realistic field problems.

Appendix I. Spatial Integration with Hermite Basis Functions

To facilitate easy application of the Galerkin procedure, we first partition the domain $[0, L]$ into N elements, i.e.,

$$0 = x_0 < x_1 < x_2 < \dots < x_n = L,$$

where the i -th element spans $[x_{i-1}, x_i]$. The local coordinates L_1 and L_2 are introduced such that any point x on the line element $[x_1, x_2]$ can be expressed as

$$x = L_1(x) x_1 + L_2(x) x_2 \quad (\text{I-1})$$

where

$$L_1(x) = \frac{x_2 - x}{x_2 - x_1}, \quad L_2(x) = \frac{x - x_1}{x_2 - x_1}$$

The functions L_1 and L_2 , known as the natural or local coordinates, are simply ratios of length when measured from x_2 and x_1 respectively, and satisfy

$$L_1 + L_2 = 1. \quad (\text{I-2})$$

Utilization of the properties of local coordinates significantly simplifies evaluation of integrals over the elements. General quadratures in terms of the local coordinates can be derived easily (Eisenberg and Malvern, 1973). For one-dimensional problems, we redefine, for the i -th element,

$$L_{i,1}(x) = \frac{x_i - x}{x_i - x_{i-1}}, \quad L_{i,2}(x) = \frac{x - x_{i-1}}{x_i - x_{i-1}}, \quad (\text{I-3})$$

then

$$\int_{x_{i-1}}^{x_i} L_{i,1}^\alpha L_{i,2}^\beta dx = \frac{\alpha! \beta! L_i}{(\alpha + \beta + 1)!}, \quad \text{where } L_i = x_i - x_{i-1}.$$

The cubic Hermit polynomials can be defined in natural coordinates as

$$\psi_{2i-1}(x) = \begin{cases} -2 L_{i,2}^3 + 3 L_{i,2}^2 & \text{if } x_{i-1} \leq x \leq x_i \\ 2 L_{i+1,2}^3 - 3 L_{i+1,2}^2 + 1 & \text{if } x_i \leq x \leq x_{i+1} \\ 0 & \text{otherwise,} \end{cases} \quad (I-4)$$

$$\psi_{2i}(x) = \begin{cases} L_{i,2}^2 L_{i,1} L_i & \text{if } x_{i-1} \leq x \leq x_i \\ L_{i+1,1}^2 L_{i,2} L_{i+1} & \text{if } x_i \leq x \leq x_{i+1} \\ 0 & \text{otherwise.} \end{cases} \quad (I-5)$$

The functions $\psi_{2i-1}(x)$ and $\psi_{2i}(x)$ are sketched in Fig. 5 for the sub-regions $[x_{i-1}, x_i]$ and $[x_i, x_{i+1}]$, or the i -th and $(i+1)$ -th elements.

Note that $\psi_{2i-1}(x_i) = 1$, $\psi_{2i}(x_i) = 0$, $\frac{d\psi_{2i-1}}{dx}(x_i) = 0$, and $\frac{d\psi_{2i}}{dx}(x_i) = 1$. (I-6)

These imply in Eqs. (3) and (4) of section II A that

$$\begin{aligned} a_{2i-1}(t) &= u(x_i, t), & a_{2i}(t) &= \left. \frac{\partial u}{\partial x} \right|_{x=x_i}, \\ b_{2i-1}(t) &= Z(x_i, t), & b_{2i}(t) &= \left. \frac{\partial Z}{\partial x} \right|_{x=x_i}. \end{aligned} \quad (I-7)$$

Thus \bar{u} and \bar{Z} are interpolation expressions for the functions u and Z in terms of their values and spatial gradients at the x_i . The $C^{(1)}$ -interpolating functions ψ_i constitute a basis for the set of $C^{(1)}$ -elements in one-dimensional problems (Strang and Fix, 1973). The numerical solutions are the discrete solutions of velocity and stage at each node, u_i and Z_i and their spatial gradients, $\frac{du_i}{dx}$ and $\frac{dZ_i}{dx}$.

Therefore, $C^{(1)}$ elements provide continuous approximate u , z , $\frac{du}{dx}$ and $\frac{dZ}{dx}$ but piecewise continuous second order derivatives.

Figure 5. The Cubic Hermite Polynomial Shape Functions for i -th and $(i+1)$ -th Elements

Integrals defining the coefficient matrices, Eqs. (9)-(14), can now be examined. For example,

$$[T] = \sum_0^L \psi_i \psi_j dx = \sum_{k=1}^n \int_{x_{k-1}}^{x_k} \psi_i \psi_j dx. \quad (I-8)$$

Note that unless $i, j = 2k - 1, 2k, 2k + 1,$ or $2k + 2,$

$$\int_{x_{k-1}}^{x_k} \psi_i \psi_j dx = 0.$$

Therefore the elemental contribution to $[T]$ from $[x_{k-1}, x_k]$ can be given as

$$[T]^{(k)} = \frac{L_k}{420} \begin{bmatrix} \frac{156}{L_k} & 22 & \frac{54}{L_k} & -13 \\ 22 & 4 L_k & 13 & -3 L_k \\ \frac{54}{L_k} & 13 & \frac{156}{L_k} & -22 \\ -13 & -3 L_k & -22 & 4 L_k \end{bmatrix} \quad (I-9)$$

where the first through the fourth column and row represent rows and columns from $(2k-1)$ to $(2k+2)$ in the global (over-all) matrix. This recurrence formula constitutes the basic algorithm of the finite element method. The global matrix $[T]$ is formed by adding the elemental contributions to the proper rows and columns. Likewise, elemental

contributions of $[S]^{(k)}, [u_{ij}^{(k)}]_1, [v_{ij}^{(k)}]_1$ have been calculated and their values are given in Appendix II.

Appendix II. Elemental Contributions of Coefficient Matrices.

$$[S]^{(k)} = \int_{x_{k-1}}^{x_k} \psi_i \frac{d\psi_i}{dx} dx = \frac{1}{60} \begin{bmatrix} -30 & -6 L_k & -30 & 6 L_k \\ 6 L_k & 0 & -6 L_k & L_k^2 \\ 30 & 6 L_k & 30 & -6 L_k \\ -6 L_k & -L_k & 6 L_k & 0 \end{bmatrix}$$

CHAPTER 194

MODEL VERIFICATION FOR TIDAL CONSTITUENTS

By

R. W. Whalin,¹ F. C. Perry,² and D. L. Durham³

ABSTRACT

Installation and operation of an automated model data acquisition and control system have made it possible to make a quantum advance in the accuracy and time required for verification of tidal inlet (or estuary) hydraulic models. The flexible sampling rate (usually about 200 samples per model tidal cycle for each gage) and digital recording of these data make them ideal for harmonic analysis and comparison with prototype data defining the coefficients and phase for each tidal constituent at various key locations within the tidal lagoon and at an open-ocean station removed from the immediate influence of the tidal inlet. The concept used is to force the model with the M_2 tidal constituent with the amplitude being correct at the ocean tide gage. A harmonic analysis is performed at all other gage locations corresponding to the prototype measurements, and the amplitude and phase (relative to the ocean tide gage) are calculated and compared with the prototype data. Investigation of the relative phases between various gages quickly shows those areas where either more or less model roughness is required. It is reasonable to expect to be able to have all phases for the M_2 constituent verified within 1 degree. Tidal elevations can almost always be expected to be verified to within a maximum deviation of ± 0.1 ft in both tidal height and mean tide level. Upon verification of the M_2 constituent, which practically insures that the proper channel roughness is obtained, a progressive tide can be constructed; and it should be attempted to perform a verification for a 14.765-day (synoptic period for M_2 and S_2 components) progressive tide at east coast locations using the prototype measurements of tidal velocities for the final verification data. Should additional roughness be necessary, it will almost always be on the mud flats or marsh areas. Computations are made to illustrate the energy transfer from the M_2 constituent to higher order harmonics as the wave propagates from the ocean to the back of the estuary, and it is shown that this energy transfer is, at worst, the same order of magnitude in both the model and prototype.

The concept ventured in this paper has been applied to verification of the Murrells Inlet, South Carolina, hydraulic model. Model scales were 1:60 vertical and 1:200 horizontal (a distortion ratio of 3-1/3:1).

Major conclusions are that verification based on the M_2 constituent is feasible and was quite successful in the Murrells Inlet, South Carolina, model, and it is postulated that a method similar to that contained in this paper should be used for the verification of numerical models.

INTRODUCTION

Design, construction, and operation of hydraulic models of tidal inlets in order to evaluate the effects of planned improvements to inlet-estuary systems are common problems undertaken in the Wave Dynamics Division. Usually the improvement consists of either proposed jetty construction to stabilize and maintain some project depth in an entrance channel or lengthening of existing jetties with an associated deepening of the entrance channel to accommodate larger and deeper-draft vessels. This type of problem has been common during the past 20 years and is anticipated to continue for the foreseeable future since there are about 340 navigable tidal inlets and river entrances along the east, Gulf, and west coasts of the continental United States.

Tidal inlet models are practically always distorted out of necessity for various reasons which will be mentioned but not discussed. Many times tidal inlets are large and the bathymetry includes flood and ebb tidal deltas which are quite shallow leading to large model energy attenuation and viscous friction scale effects on waves. These effects can be minimized through distortion and at the same time decrease model costs. It is extremely desirable to reproduce the entire tidal estuary for reasons which follow. Inclusion of the tidal estuary in the model results in the flexibility to study the effects of proposed improvements on the tidal prism, tidal circulation, tidal flushing, and salinity of the estuary. In addition, inclusion of the estuary should result in the correct nonlinear energy transfer from various tidal constituents to higher order harmonics. Deletion of a major portion of the estuary leaves reproduction of this phenomenon considerably more uncertain, although its importance is not well established but should perhaps be investigated on a case-by-case basis.

This paper focuses attention on the problem of model verification and reports on an attempt to verify a model by using the elevation and phase of the M_2 tidal constituent for the principal verification tool. A progressive tide was subsequently used in the final phase of verification. The model being used was of Murrells Inlet, South Carolina; and since this was a project study (not a research study), there are several experimental tests which should be conducted to supplement the knowledge gained in this investigation. These areas are pointed out and will, hopefully, be the subject of future research.

HYDRAULIC MODEL OF MURRELLS INLET, SOUTH CAROLINA, USA

This section gives a brief discussion of model design, instrumentation, and the automated data acquisition system used in the model study. Verification by tidal constituent is practically impossible without an automated data acquisition system which was an integral part of this model study.

Model Design

Murrells Inlet, South Carolina, is an unimproved inlet, Figure 1, with an existing main channel of only about -4.0 ft mlw which meanders and is not stable. The estuary is actually a well-mixed tidal lagoon of ocean salinity with no source of fresh water inflow except for surface runoff from rainfall. Figure 2 illustrates the model layout showing the head bay, wave generator locations, and locations of prototype and model tide gages and velocity ranges. Vertical scale of the model is 1:60 and horizontal scale is 1:200 resulting in a distortion of 3-1/3.

An interesting point to designers of hydraulic models is that a portion of the model bathymetry (seaward of the -22 ft mlw contour) is artificial in order to compensate for refraction due to bathymetric variations seaward of this contour which could not feasibly be installed in the model because of the extremely large distance seaward. This is a typical problem along the east and Gulf Coast of the United States. This represents the first use (at the Waterways Experiment Station) of an artificial bathymetry to correct for refraction seaward of the model limits and will be the subject of a future paper. A thorough discussion of this appears in the final report (Perry, 1976) to be published near the end of this calendar year. The artificial bathymetry was chosen to yield the approximate prototype energy distribution and wave direction at the -22 ft mlw contour from all wave directions of interest in the model study.

Instrumentation

The principal information required in the verification process is tidal elevation data. Various types of tidal height sensors are in use; however, the Murrells Inlet model used a "bubbler system" or gage which measures small hydrostatic pressure changes associated with changes in model tidal elevations. The "bubbler system" consists of a high precision pressure transducer, a scanivalve device for sequencing input ports, and 48 pressure inputs. Durham *et al.* (1976) gives a thorough discussion of the model sensors. Wave gages also were installed in the model but are not discussed here since those data were not essential to the verification process. Velocities of tidal currents were measured with miniature Price-type current meters and with two electromagnetic velocity meters. Most data were acquired with the miniature Price meters, but the electromagnetic current meters seem to be quite promising for future model use.

Data Acquisition

An automated data acquisition and control system (acronym ADACS) has been designed, procured, installed, and is operational on wave and tidal inlet models at WES. Durham, *et al.* (1976) describes the system. The principal functions of ADACS are to provide automated acquisition of wave and tide data in a format compatible for digital reduction and analyses and automated control of model sensor calibration and of wave and tide generators.

Figure 1. Murrells Inlet, South Carolina.

MURRELLS INLET
MODEL LAYOUT

SCALES IN FEET

Figure 2. Model Layout.

Tidal elevation data for a programmed tide condition are collected from a specified number of tide sensors, digitized and recorded on magnetic tape or disc for future analysis. A flexible sampling scheme is used and is only limited in sampling rate by the scanivalve multiplexing rate. The sampling scheme used for this study consisted of the following (a) increment the scanivalve to the first data channel, (b) delay a specified time interval (usually 0.5 sec) to allow input pressure stabilization, (c) collect a specified number of samples (10 in this case), (d) average the voltage samples, (e) store the discrete sample in memory, (f) increment to the next channel, (g) repeat the above procedure, and (h) continue sequentially through the remaining channels. Using input parameters, the minicomputer calculates (1) the required timing interval between scanivalve multiplexing scans to provide the correct sampling rate, (2) the delay interval at each channel, and (3) the number of voltage samples to be digitized and averaged and initializes counters for determining completion of tidal tests. In addition, it provides an analog command signal through the digital to analog converter to the tide generator and lags the beginning of data acquisition by a specified number of tide cycles after starting the generator.

Due to thermal effects (zero drift) on the transducer output over a tidal test of 2-3 hours duration, the pressure transducer is calibrated prior to and at selected time intervals during each tidal test to provide accurate, update calibration data for scaling voltage (pressure) to tidal elevations. Durham et al. (1976) give a complete discussion of the calibration procedure.

A limited number of channels of tidal velocity can be measured by miniature, electromagnetic current meters which are monitored by ADACS. The collection of tidal velocities using ADACS has not been fully implemented at this time and is pending the completion of transducer evaluation which should be within the next year. Until such time, the majority of tidal velocity measurements are obtained manually by using a modified version of the miniature Price meters.

In addition to tide data, most tidal inlet studies require wave information. Generation and acquisition of wave data at specific tidal phases (normally high, low, and mean tide levels) are provided by ADACS. While controlling the tide generator and collecting tidal data, ADACS uses in-core timers to determine the occurrence of specified tidal phases at which times (1) the wave generators are turned on, (2) wave data at a specified sampling rate for a predetermined number of wave periods are collected at various locations in the model, (3) the completion of wave test for that tidal phase is detected, (4) the wave generators are turned off, and (5) in-core timers initialized to determine the next specified tidal phase for wave tests. These wave tests are performed normally during the middle cycle of a three-cycle tidal test. The instrumentation and procedure for collecting wave data are the same as described in Durham and Greer (1975).

At completion of the acquisition mode, the calibration, wave, and tide data have been recorded in binary form on magnetic tape or disc. Schematically, the automated procedures for analyzing tidal data are as follow:

1. Program Initialization

- (1) Input test parameters and option flags.
- (2) Read and decode data tape or disc file.
- (3) Demultiplex data files and scale data.

II. Tidal Data Analyses

- (1) Harmonic analysis using Least Squares techniques.
 - (a) Amplitude and phases of tidal constituents.
 - (b) Relative phases between gages.
- (2) Analyses of residual variances.
 - (a) Original versus Least Square estimate.
 - (b) Prototype tide versus model tide.
 - (c) Model base test versus model plans.
- (3) Graphic output of above results.

In addition to the above automated procedures, manual and photographic techniques are employed in tidal models to study general patterns of tidal circulation and to qualitatively define littoral transport and deposition patterns. Analyses of wave data are discussed by Durham and Greer (1975) and are basically auto-spectral and cross-spectral analyses, statistical analyses for wave heights and periods of wave signals at selected locations throughout the model, and computation of response functions or amplification factors from wave energy within the harbor or tidal inlet relative to incoming wave energy.

PROTOTYPE DATA

Model verification can be no better than the prototype data available for verification. Recent improvements and advances in acquisition of hydraulic model data (ADACS) have resulted in the situation where model data are almost invariably more accurate than the prototype data. The method of verification discussed in this paper was selected subsequent to collection of the prototype data (of course after evaluation of these data to ascertain their adequacy for such an approach). As a result the tidal elevation data are completely satisfactory, but the velocity data are not adequate to extract components of the various tidal constituents. Nonetheless, they are satisfactory for velocity verification during a portion of the progressive tide. The verification method described makes primary use of tidal elevation data.

Tidal Elevations

Prototype data on tidal elevations were obtained at seven locations in the tidal lagoon and one location on the open coast north of the

inlet. The gages were installed, operated, and analyzed by personnel of National Ocean Survey (NOS) of the National Oceanographic and Atmospheric Administration for a period of approximately 6 months. Gage locations are shown in Figure 2, and results of the NOS analysis of these data for the tidal constituents at the open-coast gage are shown in Table 1. As indicated in Table 1, the Murrells Inlet tidal regime is dominated by the principal lunar semidiurnal constituent M_2 . The M_2 variance represents approximately 90 percent of the tidal variance in Murrells Inlet.

Tidal Velocities

Prototype tidal velocities were measured for a 14-hr period on 1 May 1974 at the ranges illustrated in Figure 2. Depending on the channel width and depth, currents were measured every 30 minutes for 1 to 3 stations (marked by buoys) on each range at 1 to 3 water depths per station (surface, mid-depth, and bottom). Bottom and surface measurements were 3 ft above the bottom and 3 ft below the surface, respectively. Price current meters were used with a direct readout on boat for both speed and direction. A hand-operated winch was installed on the boat for raising and lowering the current meters. These velocity data are summarized in their entirety in Perry (1976).

Bathymetry

Bathymetric data required for model construction were obtained by the U. S. Army Engineer District, Charleston, and consisted of a survey of the offshore area at 500-ft intervals normal to the shore established baseline out to the 30-ft contour where the topography was taken directly

from existing C&GS survey charts. The channels also were surveyed. Aerial photography (color infrared and black and white) was obtained at low water (while the gages were installed) from which the preceding high water line could be clearly distinguished. Spot elevations in the tidal lagoon also were obtained after inspection of the aerial photography in order to insure a good tie in between the prototype survey with the aerial photography.

MODEL VERIFICATION

Upon completion of construction of the Murrells Inlet hydraulic model the ADACS described previously had just been installed and became operational for Wave Dynamics Division models of harbors and tidal inlets. Availability of this new capability for acquisition and analysis of large quantities of model data led to the plan to attempt verification of Murrells Inlet model by using the M_2 tidal constituent and proceeding to use a progressive tide.

Procedure

In the past, verification of tidal inlet and estuary models has consisted of first matching model and prototype tide curves (recorded on a strip chart) at key locations within the estuary and on the open coast. This matching process was either performed by visual means or by a least squares analysis of a discrete (but relatively small) number of points during a tidal cycle. Adjustments in model roughness are made primarily on the basis of the tidal amplitude comparison but also considering the phase if there is an obvious disparity between model and prototype curves. It is difficult to visually detect relatively small phase differences if the relative phase of the tidal constituents is not known for either the model or prototype curves. Subsequent to verification of the tidal elevations, a tidal velocity verification is conducted where additional model friction adjustments are made. In the past, prototype data usually consist of a tide curve for several days (almost never an analysis of the amplitude and phase of the tidal constituents and their harmonics) and 13 or 25 hrs of velocity data at several stations along pertinent ranges in the inlet and estuary.

Upon considering the capabilities of the newly operational ADACS and the availability of prototype data on the amplitude and phase of the tidal constituents, it became apparent that we had the opportunity to possibly improve our model verification procedure with no increase in model testing cost (and potentially a decrease in future model testing costs). Considering the previous verification procedure, it was hypothesized that the time usually spent in velocity verification was probably really performing model roughness adjustments in order to make the tidal phases (model to prototype) agree. The basis for this hypothesis was that it is difficult to detect up to a 30-minute variation in phase when model and prototype data only consist of strip chart information which must be digitized and compared. Furthermore, the usual prototype velocity data consist of discrete velocity measurements every 20 to 30 minutes. A 5 to 20 minute variation in phase can, in some instances, make a large difference in velocity fields, especially at some critical

locations near channel intersections and large flooding marshes. Therefore, it was concluded that any new verification procedure should focus on adjustments in model roughness to verify both tidal amplitudes and phases throughout the estuary as closely as possible.

The desired verification procedure can be summarized as follows:

- a. Adjust the tide generator to reproduce M_2 , M_4 , M_6 , and M_8 at the open-coast gage.
- b. Calculate the amplitude and phase of M_2 at each gage in the inlet and estuary and tabulate the phases relative to the open-coast gage and relative to adjacent gages in the estuary and compare these calculations with one another. Also calculate the mean tide level at all gages and compare with that for the prototype.
- c. Readjust model roughness (preferably between two gages only), conduct another test, and again calculate the amplitude and relative phases at all gages for the M_2 constituent.
- d. Repeat Step c until a satisfactory verification has been achieved.
- e. Construct a progressive tide and perform a velocity verification for that portion of the progressive tide for which prototype data are available. This should be near the middle of the model progressive tide.

It should be noted that the desired procedure described above was not precisely followed due to various reasons such as problems with the tide controller and time constraints on the project schedule. Actually the tide generator was adjusted to reproduce the M_2 component at the open-ocean gage; however, the energy in M_4 , M_6 , and M_8 was not reproduced for this gage. Consequently, the energy in the overtides is not precisely what it should be; however, it is the correct order of magnitude. This will be discussed later in the paper in connection with energy transfer to higher order harmonics. The remainder of the procedure described above was followed. For emphasis, the parameter used to estimate the distribution (horizontal) of roughness elements is the relative phase of the M_2 tidal constituent and the mean tide level at different locations along a tidal channel relative to some reference location in the channel.

Elevation of the prototype tide at a specific location can be represented by

$$h(t) = H_0 + \sum_{i=1}^N f_i H_i \cos [\alpha_i t + (V_0 + \mu)_i - \kappa_i]$$

The harmonic analysis performed by NOS provided H_0 , and H_i , and κ_i for each tide gage. Other coefficients f_i , α_i , $(V_0 + \mu)_i$ can be obtained from tables (Schureman, 1940). The above equation can be rewritten in the form

$$h(t) = H_0 + \sum_{i=1}^N A_i \cos(\omega_i t + \phi_i)$$

which is used for model control and analyses of the hydraulic model data. A harmonic function composed of M_2 , M_4 , M_6 , and M_8 was used as the initial command signal to the model tide generator, and tidal heights were recorded simultaneously at all model tide gages. The model tidal elevation can be represented as

$$h_M(t) = \hat{h}_M(t) + \varepsilon(t) \equiv a_0 + \sum_{i=1}^N [a_i \cos(\omega_i t) + b_i \sin(\omega_i t)] + \varepsilon(t)$$

where $\hat{h}_M(t)$ is the calculated tidal elevation represented by a harmonic series of known frequencies and $\varepsilon(t)$ is noise. Since the noise level is unknown, the method of least squares is used to solve for the unknown coefficients (amplitudes and phases) for the M_2 , M_4 , M_6 , and M_8 tidal constituents by minimizing the variance of the sum of the squared difference between the measured model tidal elevation and the assumed form for the model tidal elevation.

Therefore, the harmonic coefficients for the model tidal height at each tide gage can be used to calculate the phases of the tidal constituents at each gage relative to tidal Gage 8 on the open ocean and the differences in the model and prototype relative phases can be determined.

The above procedure should, in principle, lead to an excellent verification including that for tidal velocities. It was decided to attempt to verify the tidal amplitudes within ± 0.1 ft and the phase of M_2 within ± 1.0 degree.

It appeared that the primary problem which might not be solved by the M_2 verification procedure enumerated above would be the situation where a spring tide caused a considerable amount of flow to occur over relatively flat marsh areas which might have little or no flow over them for the M_2 constituent of smaller amplitude. If such were the case, there would have been a lack of adjustment of model roughness in these areas. A minor problem somewhat analogous also could occur for a neap tide if there were too much roughness in relatively shallow channels. However, for tidal regimes dominated by M_2 variance, this procedure with emphasis placed on mean tide level verification as well as the M_2 constituent throughout the inlet should minimize this problem.

Consequently, the velocity data, practically always taken during a spring tide (if only one set is acquired), should be used for this final verification using a progressive tide in the model and making velocity measurements at the stage corresponding to that for which prototype data are available. Since the progressive tide should run for 15 or 30 days, depending on the location, this test will be quite long in the model and should be performed after all other verification tests.

Verification for the M_2 Constituent

Since this was the first time such a verification procedure was

attempted, it required more tests than originally contemplated to verify the M₂ constituent. However, the total time for verification was normal or less than that for similar models using the usual procedure. A total of 73 test runs were made leading up to the verified condition. This number included all runs, some of which were made to determine optimum sump water level and to repair the model tide generator which malfunctioned twice during the process. When testing was ongoing, two tests were conducted per day. Total elapsed time from initiation to completion of verification was about 4 months. With hindsight, it appears that 6-8 weeks might be sufficient on a similar future model study.

Tables 2, 3, 4, and 5 show some results of the M₂ constituent verification procedure after Runs 1, 36, and 73. Run No. 1 represents the first test, No. 36 an intermediate test, and No. 73 the verified condition.

For Run No. 1, Table 2 shows all model tidal amplitudes are too high (most by 0.3 ft) and Table 3 indicates the tide reaches all estuary gages too fast (relative to Gage 8 the phase differences range from about 6 degrees to 18 degrees). Table 4 shows there is about the correct amount of roughness between Gage 4 and 7, there is too much roughness or something is restricting the flow too much between Gages 6 and 7, there is too little roughness elsewhere, and the most roughness should be added between Gages 1 and 2 (a little but not much is needed between Gages 2 and 3). Actually there was an error in molding the channel between Gages 6 and 7, which did not allow enough flow through the channel. Table 5 illustrates that the mean tide level is too high everywhere except at Gage 3. It is readily apparent that an enormous amount of information has been gained by merely looking at Tables 2 through 5 for Run No. 1.

7	2.676	3.012	+0.336	2.523	-0.153	2.762	+0.086
8	2.344	2.557	+0.213	2.128	-0.216	2.365	+0.021

For Run No. 36, Table 2 shows that all tidal amplitudes are still too high but within 0.1 ft of the prototype, and Table 3 indicates the tide still reaches all gages except No. 4 too fast (relative to Gage 8), however, the largest phase difference has been reduced to 3 degrees. Table 5 shows more roughness is needed between all gages, but the most is needed between Gages 1 and 2 and 4 and 6. Table 5 illustrates that the mean tide level is too low at all model gages and by nearly 0.5 ft at Gage 4.

For Run No. 73, the verified condition, Table 2 shows that all model tidal amplitudes are less than the prototype but by only a few hundredths of a foot (the largest difference is 0.07 ft). Table 3 also indicates that about half of the phase differences are positive and half negative (relative to Gage 8) with the largest being 1 degree. Table 4 shows that the largest phase difference is 1.17 degrees and that is between Gages 7 and 8. Table 5 illustrates that the mean model tide level is larger than the prototype at about half the gages and smaller at the other half. The largest difference in the mean tide level is 0.086 ft. Figures 3 and 4 illustrate model and prototype tide curves for M₂ at Run No. 1 and Run No. 73 for Gage 8 and Gage 2, respectively.

To summarize the M₂ constituent verification, we have been successful in verifying the M₂ tidal amplitude to within +0.1 ft, the mean tide level

to within ± 0.1 ft, and the phase of the M_2 constituent to within 1 degree relative to the phase at the open-ocean gage. This is considered to be an excellent M_2 constituent verification.

Verification for Progressive Tide

Due to the lack of prototype constituent velocity data, this portion of the verification was limited. A 15-day progressive tide consisting of the M_2 , S_2 , and their overtide constituents was generated in the model and velocities were measured at the 4 ranges for which prototype data were available. The velocity verification was considered adequate, and no adjustments in model roughness were made or additional verification tests conducted. Figure 5 illustrates a sample of the velocity verification.

DISCUSSION OF OTHER PERTINENT DATA

A brief discussion follows on the significance of other data acquired during the verification processes of the model study. Although these data have not been analyzed to glean their full potential some interesting and quite important information has been obtained.

Energy Transfer to Higher Order Harmonics

Table 6 shows a comparison of the model and prototype amplitudes for M_2 , and its overtides M_4 , M_6 , and M_8 . Gage 8 is the open-ocean gage and the model and prototype M_2 amplitudes are identical for all practical purposes. Unfortunately, sufficient time was not available to adjust the amplitudes of the overtides (M_4 , M_6 , and M_8) to coincide with the prototype data at Gage 8. However, the information contained in Table 6 is interesting and can be quite informative. The difference between amplitudes of the overtides in the estuary (Gages 1 to 7) and the open coast (Gage 8) represents a nonlinear transfer of energy from the principal lunar component M_2 to its harmonics M_4 , M_6 , and M_8 . Obviously this is occurring at a non-negligible rate in the prototype. It has often been questioned whether or not such nonlinear energy transfers occur in hydraulic models and to what degree. Unfortunately, this question cannot be answered completely from the data contained in Table 6 since the energy in M_4 , M_6 , and M_8 was not precisely adjusted at Gage 8. However, it is obvious that nonlinear energy transfer is occurring in the model and in more or less the correct proportion. Thus, the information in Table 6 is interpreted as preliminary confirmation that such nonlinear effects are occurring in approximate similitude (at least within the correct order of magnitude) in the hydraulic model. Several additional model tests should be conducted to confirm this indication and to unequivocally determine the relative degree of similitude of these nonlinear energy transfers.

FIGURE 5. VERIFICATION OF MODEL VELOCITIES - MID-DEPTH

Table 6: ENERGY IN HIGHER ORDER HARMONICS (RUN NO. 73)

Gage	M_2 ft		M_4 ft (10^{-2})		M_6 ft (10^{-2})		M_8 ft (10^{-3})

8	2.4020	2.40	1.06	3.54	0.65	1.02	10.9	5.93

Energy in Other Harmonics

A plot of the residual energy as a function of frequency was performed for each gage after each test in order to insure that a large residual energy was not present or that energy was not showing up in some characteristic frequency band which might be indicative of a malfunctioning tide control, sump, or pump, or perhaps an undesirable model resonance. No such problems were detected and the residual energy was always low.

NUMERICAL MODEL IMPLICATIONS

It is believed that results of this study have wide-ranging implications, in particular for numerical models. Recent advances (Butler and Raney, 1976) in numerical modeling of inlet-estuarine systems have finally made numerical modeling of well-mixed systems a viable engineering tool for the early stages of an inlet or estuarine improvement plan. While still having resolution disadvantages relative to a physical model, a numerical model may be a viable alternative in the planning stage to evaluate the relative adequacy of numerous plans while a physical model may and probably should be used as the principal tool for final design.

Since numerical models must be verified in much the same manner as physical models, it is hypothesized that the M_2 constituent verification is a superior method of numerical model verification. This brings many interesting numerical experiments immediately to mind. For instance, will the numerical model predict the nonlinear energy transfer to higher order harmonics as well as the physical model? Will the velocity verification, which is critical to numerical models, be essentially disposed of upon verification of both the amplitude and phase of the M_2 constituent?

It will be practically impossible to verify the numerical model (even the much faster implicit model of Butler and Raney, 1976) for a progressive tide due to computer time and cost limitations. However, the next generation of computers should solve this limitation. While advances in numerical modeling are taking place quite fast, more serious applications work is needed for them to realize their full potential and to complement physical hydraulic model studies to the fullest possible extent.

RECOMMENDATIONS FOR ADDITIONAL RESEARCH

Information emanating from the study reported herein has perhaps led to more questions than answers; however, it is believed a new set of questions have been raised and that our knowledge of model verification has advanced accordingly. As a result of the work performed, the following recommendations for additional research are made:

- a. Additional prototype velocity data should be collected at Murrells Inlet to define the velocity constituents. These data would form the basis for further physical model and numerical model verification experiments.
- b. Investigate the velocity constituent verification in the physical model of Murrells Inlet using both the M_2 tide and a progressive tide.
- c. Attempt to verify a numerical model for Murrells Inlet (Butler and Raney, 1976, appears to be the most applicable model) by use of the M_2 tidal constituent.
- d. Perform more physical model experiments specifically designed to investigate nonlinear phenomena occurring. In particular, adjust the model to open-coast gage and analyze the nonlinear energy transfer in model and prototype.
- e. Perform detailed numerical model experiments of the nonlinear phenomena present comparing these findings with both the physical model data and the prototype data.
- f. It may be possible to experimentally relate and quantify the number of roughness elements needed to relative phase lags.

CONCLUSIONS

The following conclusions are formulated as a result of this study:

- a. It is feasible to verify a physical hydraulic model by using tidal constituents.
- b. Verification by the M_2 constituent can be expected to be achieved within ± 0.1 ft in amplitude, within ± 0.1 ft in mean tide level, and ± 1 degree in phase.
- c. Verification by the M_2 constituent should be followed by verification for a spring tide to insure correct marsh and overbank roughness and a check for a neap tide condition would be wise. It is preferable to perform this verification with a progressive tide of at least 15 days duration which contains 1 spring and 1 neap tide.
- d. Prototype verification data collection should be designed to define the principal tidal constituents and their overtides for both the tidal elevation stations and the tidal velocity stations (i.e. a month of record is required as a minimum).

CHAPTER 195

Finite Element Model for Estuaries with Inter-Tidal Flats

Bruno Herrling*

Abstract

This paper deals with finite element formulations for the numerical computation of two-dimensional incompressible long-period shallow water waves. The described mathematical model is used to reproduce the dynamic situation occurring at the tidal propagation in estuaries. Areas which fall dry and wet again within a tidal cycle - so called inter-tidal flats - are taken into account.

Introduction

Since more than ten years the finite element method has been applied with considerable success in structural mechanics. In the last years the method was also used in fluid mechanics. Investigators like Grotkop [1], Connor, Wang [2], Davis, Taylor [3] and other made use of it to compute shallow water waves. But up to now inter-tidal flats - that are areas which fall dry and wet again within a tidal cycle - were not considered in these models. Only some investigators like for example Ramming [4] and Apelt, Gout, Szewczyk [5] took these areas into account using the finite difference method.

In the south eastern part of the North Sea in Europe many inter-tidal flats extend in front of the coast line. Without considering a natural phenomenon like that the hydrodynamic situation near these areas could be predicted only incompletely by a mathematical model. Therefore calculation algorithms for inter-tidal flat elements and for normal ones were developed, which are coupled in one mathematical model. The coupling is useful for saving computing time because only for elements of the first type much effort has to be made to include the permanent changing geometry of the area.

Basic Differential Equations

For the present problem two vertically averaged, horizontal velocities v_i ($i=0,1$) defined in a Cartesian coordinate system and the height of water level h (see Fig.1) are introduced as unknown parameters. The differential equations for this two-

* Dipl.-Ing., Scientific Assistant, Chair of Fluid Mechanics
Technical University Hannover, W.Germany

Fig.1 Definition Sketch Described in a Vertical Section

dimensional problem are obtained from the three-dimensional form of the continuity equation and the equations of motion by integrating over the depth (see e.g. Dronkers [6]). The vertically integrated equations received in this way are the continuity equation

$$h_{,t} + q_{i,i} - q^* = 0 \quad (1)$$

and the equations of motion (2)

$$v_{i,t} + v_j v_{i,j} + gh_{,i} + \frac{\lambda \sqrt{v_j v_j}}{a+h} v_i - \Omega \epsilon_{ij} v_j + \frac{1}{\rho} p_{0,i} - \frac{\mu_w \sqrt{W_j W_j}}{a+h} W_i = 0$$

with $i, j = 0, 1$ to be summed. In the continuity equation the flux per length q_i will be replaced by the relation

$$q_i = (a+h) v_i \quad (3)$$

later. q^* is the inflow in the area of computation and will be specified afterwards.

In the equations of motion there are special terms for bottom friction, Coriolis force, atmospheric pressure and wind force as usual - g signifies the acceleration due to the gravity, λ a dimensionless friction parameter, Ω the Coriolis parameter, which is a function of the latitude, ϵ_{ij} an alternating tensor, ρ the density of the water, p_0 the atmospheric pressure, μ_w a dimensionless wind friction parameter and W_i are components of the wind velocity.

In the equations (), $_{,i}$ and (), $_{,t}$ mean partial differentiations with respect to the coordinates x_i and to the time t .

Besides the friction term there are two further non-linear terms in the basic equations. For these the following linea-

rizations are realized:

$$q_i = (a + \bar{h}) v_i + (h - \bar{h}) \bar{v}_i \quad (4)$$

$$v_j v_{i,j} = \bar{v}_j v_{i,j} + v_j \bar{v}_{i,j} - \bar{v}_j \bar{v}_{i,j} \quad (5)$$

\bar{h} and \bar{v}_i are e.g. in time extrapolated values or values from the last step of iteration, when an iteration within each time step is used, or initial values of the time step when no better values are available.

Boundary conditions are the hydrographs of the water level or of the flux across the boundaries (see Fig.2):

$$h - \hat{h} = 0 \quad \text{on } S_h \quad (6)$$

$$q_i n_i + \hat{q} = 0 \quad \text{on } S_q \quad (7)$$

\hat{h} signifies a prescribed water level and \hat{q} a flux normal to the boundaries; \hat{q} is positive when the water flows in the area of computation. On closed boundaries \hat{q} is equal to zero.

Fig.2 Designation of Boundaries

Finite Element Analysis

Because there exists no functional approach for the problem the method of weighted residuals is used and is the basic for

the application of the finite element method (see e.g. Zienkiewicz [7]). The domain of computation is subdivided into finite elements. For the integration of the weighted differential equations elements in space and time are chosen with linear shape functions θ_E and τ_T as described in Fig.3. In time the differential

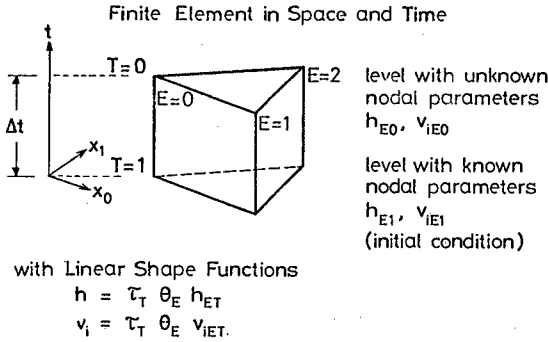

Fig.3 Discretization and Shape Functions

equations are solved in a stepwise manner as usual. The weighting functions

$$\delta h = \bar{\tau}_0 \theta_E \delta h_{E0}$$

and

$$\delta v_i = \bar{\tau}_0 \theta_E \delta v_{iE0}$$

are functions of space and time; δh_{E0} and δv_{iE0} are arbitrary values. In the present model the functions in space θ_E are identical with the shape functions (Galerkin method) though

in conformity with a new publication from Gärtner [8] better ones could be used. In time special weighting functions $\bar{\tau}_0$ (see Fig.4) are chosen to reduce the numerical damping. With

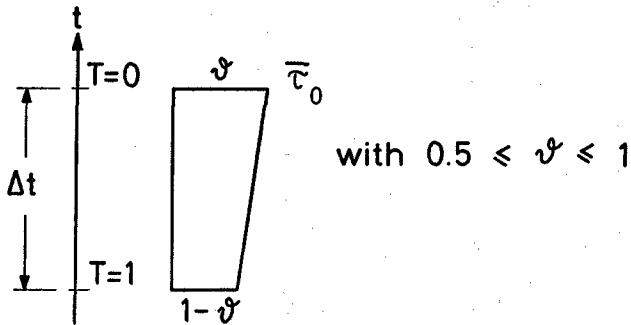

Fig.4 Weighting Function in Time

$\psi = 0.5$ the Crank-Nicolson time integrating factors are received and with $\psi = 1$ the method of Galerkin is again employed. The best value is near 0.5.

The continuity equation (1) is weighted with respect to δh

$$\iint_{At} \delta h (h_t + q_{i,i}) dt dA - \iint_{At} \delta h q dt dA - \int_t \delta h_K Q_K dt = 0 \quad (8)$$

Instead of q^* an areal distributed mass inflow q and a point source of mass inflow Q_K at node K of the system are introduced. After integrating by parts and insertion of the boundary conditions (7) on S_q equation (8) gets the form (9)

$$\iint_{At} \delta h h_t dt dA - \iint_{At} \delta h_{,i} q_i dt dA = \iint_{S_q t} \delta h \hat{q} dt ds + \iint_{At} \delta h q dt dA + \int_t \delta h_K Q_K dt$$

and finally after substitution of q_i and linearization according to (4)

$$\begin{aligned} \iint_{At} [\delta h h_t - \delta h_{,i} ([a+\bar{h}]v_i + [h-\bar{h}]\bar{v}_i)] dt dA = & \iint_{S_q t} \delta h \hat{q} dt ds + \iint_{At} \delta h q dt dA \\ & + \int_t \delta h_K Q_K dt \end{aligned} \quad (10)$$

The equations of motion (2) are weighted with respect to δv_i

$$\int_{\Delta t} \int_A \delta v_i [v_{i,t} + v_j v_{i,j} + gh_{,i} + \frac{\lambda \sqrt{v_j v_j}}{a+h} v_i - \Omega \epsilon_{ij} v_j + \frac{1}{\rho} p_{o,i} - \frac{\mu_w \sqrt{W_j W_j}}{a+h} W_i] dt dA = 0. \quad (11)$$

After the linearization (5) these equations receive the shape

$$\int_{\Delta t} \int_A \delta v_i [v_{i,t} + \bar{v}_j v_{i,j} + v_j \bar{v}_{i,j} - \bar{v}_j \bar{v}_{i,j} + gh_{,i} + \frac{\lambda \sqrt{\bar{v}_j \bar{v}_j}}{a+h} v_i - \Omega \epsilon_{ij} v_j + \frac{1}{\rho} p_{o,i} - \frac{\mu_w \sqrt{W_j W_j}}{a+h} W_i] dt dA = 0. \quad (12)$$

The integration of the weighted equations (10) and (12) is carried out in time t over a time interval Δt because of the stepwise solution algorithm and in space strictly speaking over the whole area A of the computation. As the finite element technique is used the integration in space can be reduced to an element area A_e . This leads to matrix equations of an element existing of nine equations with nine unknown parameters. As the integration have to be performed over the whole area A the matrix equations of all elements are added. So the big set of equations is received which have to be calculated in each time step.

The boundary condition (6) is inserted in the whole set of equations by erasing of lines and columns as usual in the finite element technique.

Area of Inter-Tidal Flats

Two basic problems appear when computing areas of inter-tidal flats in a mathematical model: First the difficulty to describe the physical situation near the changing water-land boundary (water boundary) and second the organizing problem when the boundaries of the mathematical model start to wander because some areas fall dry.

The author proposes the following procedure in principle for the solution of these problems:

- The discretization in space remains constant.
- Elements with at least one dry node in the end of a time step are approximately removed from the area of computation.
- In the partly flooded elements only the remaining volume of water is considered and is fixed as a function of the water level in the flooded nodes.

By these simplifications the dynamic is not exactly represented in the direct reach of the water boundary but the continuity is guaranteed. As this area is very small in comparison with the remaining model and the water depth mostly low the defect will be unimportant. On the other hand thus the whole organization of the program seems to be mastered in a

reasonable time.

To perform the proposed solution some postulated conditions have to be fulfilled:

- The boundaries of the flooded area are described by boundary integrals.
- In special nodes of the system an exactly defined mass inflow or outflow of water can be realized.
- An iteration is practicable within each time step to correct the actual boundary of computation and to improve the assumed volume of water in the partly flooded elements.
- A relaxation can be used to accelerate the iteration.
- For a better starting-point of the iteration the height of water level is extrapolated in the time direction with application of the least squares method.

In the following the procedure will be explained in detail. For the computation of a new time step there exist defined initial conditions of all parameters from the last time step. By an extrapolation in time with consideration of several known time levels the water level can be roughly predicted in all nodes.

Thus elements can be found which have three dry nodes at the end of a time step; these are dry elements (Fig.5). Further

Fig.5 Various Boundaries in the Area of Inter-Tidal Flats

there are elements with one or two dry nodes, the so called partly flooded elements. All the other ones are flooded elements and these constitute the remaining mathematical model. The boundary between the flooded and the partly flooded elements - the actual boundary of computation - is described by boundary integrals. The actual water boundary is found by a horizontal extrapolation of the water level in adjacent flooded elements and is used to compute the remaining water volume (Fig.6). The difference of the water volume between

Fig.6 Partly Flooded Elements

the initial and the new state in the partly flooded and dry elements is given as a point source of mass inflow or outflow in or out of the remaining dynamic model in the same time step. By this the partly flooded elements effect the dynamic behaviour and correct the continuity in the flooded area. After computing the element matrices of the flooded elements and solving the set of equations the new water levels and velocities are received. These differ from the extrapolated values in general. By an iteration within the same time step the water levels are improved and by this the actual boundary of computation and the assumed volume of water in the partly flooded elements. The iteration is accelerated by a relaxation.

Numerical Computation

The program system MECCA (Modular Element Concept for Continuum Analysis) is used for the numerical computation. The modular constructed system (Fig.7) performs the always recurrent operations as being found in the finite element technique for boundary value problems or like in this case for initial and boundary value problems. MECCA manages organization problems such as input and output, data storage on disk packs, assembling and solving the set of equations and a graphic representation of the results. The input and partly the control over the sequence of program modules is managed by a problem oriented language (Fig.8). A special data organization (Fig.9) is prepared for the storage of the big and complex data sets.

The differential equations describing a physical process and the characteristics of an element are specified in a separate element program (Fig.7,8) which is linked to special modules

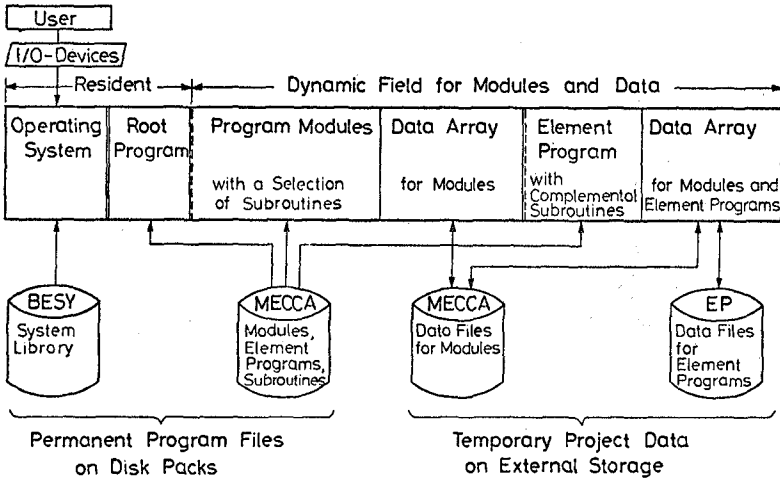

Fig.7 Allocation of the Computer by the Program System MECCA

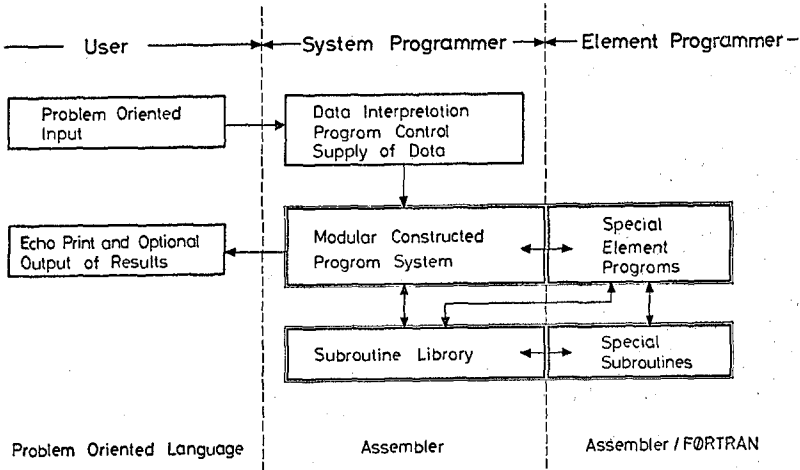

Fig.8 Schematic Organization of the Program System MECCA

of MECCA. Thus the possibility exists to couple different types of elements - in this case inter-tidal flat elements and normal ones - using common parameters in the connection nodes.

A first publication of MECCA happened by Beyer [9] and Herrling, Pfeiffer [10].

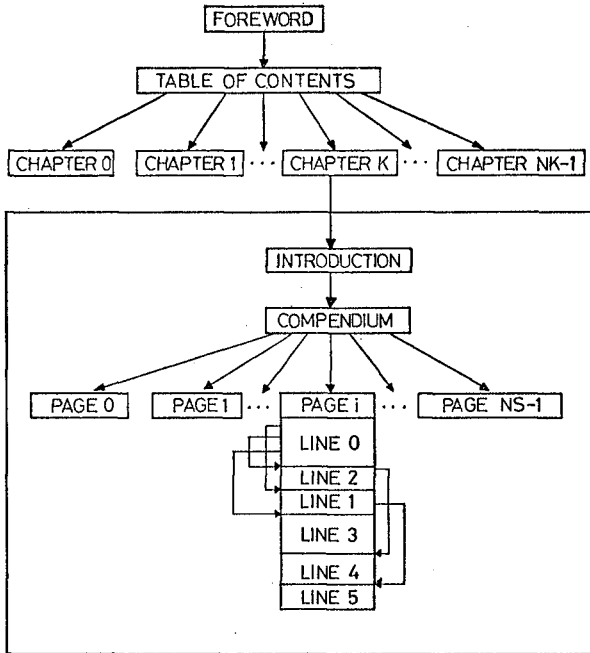

Fig.9 Set-up of a Data File

Numerical Results

The usefulness of the presented method is demonstrated by two examples: First a test of continuity is carried out in a basin falling dry partly, and in a second test the program is employed to the tide situation in the exterior Jade.

For the test of continuity a sloping basin has been chosen with a finite element network and a distribution of depth as shown in Fig.10. Three boundaries of the basin are closed and the other one is open. On this boundary the time dependent flux \hat{q} is described (see Fig.11). The discharge is so propor-

Fig.10 FE Network and Distribution of Depth

tioned that the water volume goes down for 1m in the whole basin.

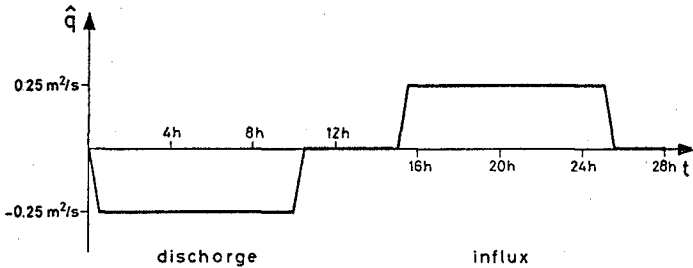

Fig.11 Prescribed Flux across the Boundary

In Fig.12 to 15 the numerical results are shown at different times. The time step Δt amounts to 30 minutes and 0.003 is the value of the friction coefficient.

As a second example the time dependent distribution of water levels and velocities in the exterior Jade (Fig.16) has been computed. The Jade is a German estuary in the south eastern part of the North Sea.

Fig.16 Topology of the Exterior Jade

Fig.17 shows the very coarse network of elements and Fig.18 the distribution of depth in the model. In this mathematical model two different types of elements are used (Fig.19). Boundary conditions are prescribed water levels at the open ends of the model (Fig.20). The friction coefficient has the value 0.003 and the time step amounts to 10 minutes. Fig.21 and 22 demonstrate the distribution of velocities and the areas of dry and partly flooded elements.

Conclusion

The numerical results have shown that the new method is qualified to analyze the dynamic of estuaries with inter-tidal flats. In the mathematical model the dynamic behaviour is correct and the continuity of the water masses is guaranteed. The author hopes that he has provided a further contribution for a wide future application of the in hydrodynamics more and more advanced method of finite elements by the new opportunity to consider areas of inter-tidal flats in a mathematical model.

Acknowledgement

This investigation was supported by the Sonderforschungsbereich 79 (SFB 79) 'Wasserforschung im Küstenbereich' in Hannover, W.Germany. Moreover the author wants to thank Mr. J. Claussen for his support to realize the program [11] and to compute the numerical results and Dipl.-Ing. H. Hennlich for preparing the element network of the exterior Jade.

CHAPTER 196

Calibration of Branched Estuary Models

by

James P. Bennett¹

INTRODUCTION

Unsteady flow models of one-dimensional channels or of channel networks are commonly calibrated using a combination of stage (water surface elevation) and discharge observations. In tidally influenced areas these observations may extend in time over several tidal cycles. Where there is an important mean flow discharge such as in a river harbor, observations must be repeated for a number of representative mean flow conditions.

Stage observations are commonly collected using recorders coupled to water surface floats mounted at various points on the channel banks. The initial costs of purchasing the recorders, installing them, and in the leveling necessary to determine datum are the primary expenses involved in collecting stage observations. For these observations the cost per observation decreases as the number increases.

In tidally influenced channels, accurate one-dimensional instantaneous discharge measurements are difficult if not impossible to obtain because of the rapidly changing flow velocity. In many locations, discharge measurements cannot be made throughout a tidal cycle because of safety restrictions. Finally, with respect to stage information, the cost of collecting discharge information can be extremely high. In addition, the cost per observation does not decrease with the number of observations.

With respect to the boundary conditions used to drive them, there are two main classes of unsteady flow models, the stage-stage models and the discharge-stage models. The former are driven by inputs of stage at all important external boundary points. The primary purpose of the stage-stage model is to determine the time history, or an average value of downstream discharge. Discharge-stage models are driven upstream by steady or time-variable observed or hypothetical discharges and downstream by observed or hypothetical stages. This type of model is used primarily in conjunction with solute transport models in predicting the location and concentration of dissolved substances, as in dissolved oxygen modeling.

¹U.S. Geological Survey, Reston, Va.

In light of the difficulty, danger, and relative expense of collecting discharge measurements, as compared to stage observations the question arises how best to locate in space and time the minimum number of discharge measurements required to calibrate an unsteady flow model. In fact, it should be asked if situations arise wherein unsteady flow models can be adequately calibrated without any discharge measurements. This paper is presented to discuss these questions. Illustrations are presented using field data collected to calibrate both stage-stage and discharge-stage flow models.

THEORY

Unsteady Flow Computation

The conservation of mass equation for a segment of one-dimensional open channel with no distributed inflow is

$$\frac{\partial A}{\partial t} + U \frac{\partial A}{\partial x} + A \frac{\partial U}{\partial x} = 0 \quad (1)$$

Wherein the independent variables are x downstream distance and t , time. The dependent variables are cross-sectional area, A , and downstream velocity U . The conservation of momentum equation is

$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + g \left(\frac{\partial H}{\partial x} + S_f \right) = 0 \quad (2)$$

Wherein g is the gravitational constant, S_f is the friction slope and H is the stage. Cross-sectional area is expressed as a function of H and x . In (2) friction slope is expressed using Chezy's formulation

$$S_f = \frac{U^2}{C^2 D} \quad (3)$$

Wherein C is Chezy's discharge coefficient, the hydraulic depth, D , is A/T and T is the channel top width corresponding to a particular water surface elevation.

One of the most efficient schemes for solving the nonlinear hyperbolic partial differential equations 1 and 2 is Strelkoff's (1970) linear implicit technique presented here as modified by Bennett (1975). In this formulation, the following space-time convention is used,

and (1) becomes

$$\begin{aligned} & \frac{1}{2\Delta t} \left[T_{i+1}^j (H_{i+1}^{j+1} - H_{i+1}^j) + T_i^j (H_i^{j+1} - H_i^j) \right] \\ & + \frac{(U_{i+1}^j + U_i^j)}{2\Delta x_{i+1}} \left[(A_{i+1}^j - A_i^j) + T_{i+1}^j (H_i^{j+1} - H_i^{j+1}) - T_i^j (H_i^{j+1} - H_i^j) \right] \\ & + \frac{(A_{i+1}^j + A_i^j)}{2\Delta x_{i+1}} \left[U_{i+1}^{j+1} - U_i^{j+1} \right] = 0 \end{aligned} \quad (4)$$

while (2) becomes

$$\begin{aligned} & \frac{1}{2\Delta t} (U_{i+1}^{j+1} - U_{i+1}^j + U_i^{j+1} - U_i^j) + \frac{(U_{i+1}^j + U_i^j)}{2\Delta x_{i+1}} (U_{i+1}^{j+1} - U_i^{j+1}) + \\ & g \left[\frac{(H_{i+1}^{j+1} - H_i^{j+1})}{x_{i+1}} + \frac{1}{2} \left((S_f^j)_{i+1}^j + (S_f^j)_i^j + \left(\frac{\partial S_f}{\partial U} \right)_{i+1}^j (U_{i+1}^{j+1} - U_{i+1}^j) \right. \right. \\ & \left. \left. + \left(\frac{\partial S_f}{\partial U} \right)_i^j (U_i^{j+1} - U_i^j) + \left(\frac{\partial S_f}{\partial y} \right)_{i+1}^j (y_{i+1}^{j+1} - y_{i+1}^j) + \left(\frac{\partial S_f}{\partial y} \right)_i^j (y_i^{j+1} - y_i^j) \right) \right] = 0 \end{aligned} \quad (5)$$

Bennett (1975) lists the advantages and disadvantages of the linear implicit formulation in solving the single reach unsteady flow problem. He also describes a general model which allows the efficient extension of the linear implicit technique to the computation of unsteady flows in networks of open channels. This model uses a coding system referenced to the end cross-sections of channel segments intersecting at interior junctions to inform the solution algorithm to apply interior boundary conditions and thus carry the implicit formulation from one channel segment to another. Specific techniques are introduced to reduce the core storage required and to expedite the inversion of the resulting sparse, wide-banded coefficient matrix. The calculations described in the remainder of this paper were made using the general model.

Calibration

Calibration of a mathematical model is the process of adjusting model parameters to obtain best-fit of model predictions to a set or sets of observations. The best-fit criterion is the objective function, a single unique function of differences between observations and the corresponding predictions. "Best-fit" is achieved when the objective function is minimized. The parameter values producing this minimum comprise the optimum parameter set.

A number of automatic optimization routines have been used to derive optimum parameters for unsteady flow models. Becker and Yeh (1972) and (1973) use the influence coefficient algorithm. A modification of their scheme was used by Bennett (1975) and is incorporated into the general model discussed above. Yih and Davidson (1975) found the Marquardt algorithm to be the most efficient in obtaining longitudinal dispersion coefficients. The main disadvantage in the use of these routines is the large number of complete simulation runs that must be made before the optimum is reached. In unsteady flow simulation this can become quite expensive.

The most commonly used objective function is the mean square error, the average of the squares of difference between observations and predictions. The square root of the mean square error, the RMS (Root Mean Square Error) is used in this paper. It has the advantage of being expressed in the same units as the original predictions and observations, and is, therefore, more easily comparable to the values of the individual variables themselves. When the observation consists of two or more noncommensurable quantities such as a stage and discharge it becomes difficult to define the objective function to give the correct weight to each type of observation. In this case some normalizing function should be used to commensurate the contributions of the two types of observations to the objective function. The definitions of the normalizing functions of course, influence the final result of the calibration; they, therefore, must be defined with great care. Becker and Yeh (1972) use velocity and depth errors directly in their objective function. For the shallow flows that they worked with this places about equal weight on both types of observations, however, for deeper flows it would emphasize the depth. Bennett (1975) used the average value of depth to normalize errors in stage and the average absolute value of discharge to normalize errors in discharge. This scheme probably places too much weight on discharge.

In this paper we want to investigate the possibility of calibrating the two basic types of unsteady flow models using stage data alone. We will therefore work primarily with the RMS of stage errors. However, we will continuously monitor the RMS of discharge deviations to determine the effectiveness of our techniques.

THE STAGE-STAGE PROBLEM

Three Mile Slough

The data chosen to illustrate the stage-stage problem was collected jointly by the U.S. Geological Survey and the California Department of Water Resources in July and August, 1959. As shown in Figure 1 Three Mile Slough is the first connecting channel upstream of the confluence of the Sacramento and the San Joaquin Rivers. It is a natural channel which has been stabilized and diked.

Figure 1. Three Mile Slough, a stage-stage problem.

At the two ends of the Slough the water surfaces in the rivers oscillate independently because of different travel times for tidal transients moving up the rivers from San Francisco Bay. Because of the independence of the water surface elevations at the two ends of the channel and because it is a relatively small channel connecting the two larger bodies of water, Three Mile Slough provides a classical example of the stage-stage problem.

There are seventeen sets of cross section descriptions available over the 3.2 mile length of the Slough, nine were used in the mathematical model. The side channel is a 2,300 foot segment of Seven Mile Slough presently closed off at the end away from Three Mile Slough. The only cross sectional properties available for Seven Mile Slough are average width and depth. These were used in the mathematical model. Little attention was paid to Seven Mile Slough during data collection because it was observed that this channel had little influence on the discharge picture in Three Mile Slough. Simulation results confirm this observation.

The tidal oscillations in the Sacramento and San Joaquin Rivers at the ends of Three Mile Slough were recorded digitally from direct reading floats at 15-minute intervals. The discharge observations used were obtained by summing the instantaneous contributions of individual discharge hydrographs for each of about twenty subsections at each end of the Slough. The individual hydrographs were prepared from standard discharge measurements made from boats. Each subsection was gaged about every 45 minutes.

Numerical Experiments

The investigation of the stage-stage problem, essentially a sensitivity analysis, was conducted as follows: (1) Fourier series were fit to the driving stages at the Sacramento (arbitrarily chosen as the upstream end of the Slough) and at the San Joaquin for a tidal day of twenty five hours. This was done, first, because it expedited interpolation between the observed stages, as stability conditions required a computation time interval on the order of six minutes rather than the fifteen minutes used in recording the data. Second, the analytical expressions for the driving stages allowed them to be shifted in time by any arbitrary increment, permitting the investigation of the influence of phase errors. The Fourier series stages were seldom as much as two-hundredths of a foot different than the original observations.

The mathematical model driven by the Fourier series stages was calibrated against upstream and downstream observed discharge by adjusting Chezy's C. The absence of intermediate discharge observations precluded the use of different C values for the three channel segments comprising the mathematical model. The optimum parameter value is $C = 75 \text{ ft}^{3/2}/\text{sec}$. and the corresponding value of the normalized RMS discharge error is .123 (12 percent).

For use as observations in the sensitivity analysis the calibrated model was used to compute stages at river miles .66, 1.26 (the intersections of Three Mile and Seven Mile Sloughs) and 2.44 measured upstream to downstream. This error-free numerically generated set of stage observations was used to perform the sensitivity analysis of a typical stage-stage unsteady flow model subjected to perturbations of its parameters and boundary conditions. Note that because of rounding the hypothetical observations to the nearest 0.01 ft, the normalized stage RMS errors for the error free data set is .00015 (0.015 percent). Again, because actual observations of discharge, were used, this corresponds to a normalized error of 0.123 in this variable.

The Discharge Coefficient

The effect of varying the Chezy discharge coefficient C on normalized RMS stage error and normalized RMS discharge error is shown in figure 2. For the stage error, the largest quantity given on figure 2 represents an RMS error of only 0.01 ft (to the nearest hundredth) at each of the three observation stations. The stage errors are systematic, that is the water surface elevation for C values not equal to $75 \text{ ft}^{3/2}/\text{sec}$. are always slightly lower than for this value. Figure 3 shows for the extreme cases of $C = 60 \text{ ft}^{3/2}/\text{sec}$. and $C = 90 \text{ ft}^{3/2}/\text{sec}$, the influence of the variations on the discharge at the Sacramento River end of the slough. When C is greater than $75 \text{ ft}^{3/2}/\text{sec}$. the amplitude of the discharge fluctuation is noticeably larger than for this value, while for a lesser, the amplitude is less. A similar pattern is observed at the San Joaquin end.

Figure 2. Effect of variation of Chezy C on normalized stage and discharge errors.

Figure 3. Observed and predicted discharge hydrographs for extreme values of Chezy C.

Using the error free stage observation set in performing the present sensitivity analysis has provided the answer to one of the questions posed earlier; namely, is it possible to calibrate a stage-stage model using stage observations alone. The answer is no, because while for the nonoptimum C values the deviation of stage from that observed for $C = 75 \text{ ft}^2/\text{sec}$ is systematic, it is too small to be observed in a real stage record collected in the field.

Figure 3 makes it possible to answer another of the questions posed in the introduction namely, where best in space and time to place discharge measurements to make the best use of them. In calibrating a stage-stage model the best positions in time are at the two extremes of positive and negative discharge to define the amplitude of the discharge fluctuation. At least two positive and two negative peaks should be observed for each mean flow condition of interest. At least in a reach as short as Three Mile Slough, the spacial location of the discharge measurements is unimportant and measurements at one cross section should be sufficient.

At this point the main questions posed concerning the calibration of a stage-stage model using a bias-free data set have been answered. The remaining topics in this section concern the influences of errors in the calibration data on the final product and describe how to detect these errors using auxiliary stage observations.

Cross-Sectional Area

The effect of variation of cross-sectional area on normalized RMS discharge error is shown on figure 4. The area ratio of this figure is a multiplicative factor applied in simulation to the true values of area and top-width of a cross section at any stage. At least for the magnitudes shown in figure 4, cross-sectional area has no discernable effect on the RMS stage error. Therefore, errors in cross-sectional area cannot be detected from stage records in the stage-stage problem.

Figure 4. Effect of errors in cross-sectional area on discharge.

Decreasing the cross sectional area has the same quantitative effect on predicted discharge as decreasing the discharge coefficient, it increases the frictional resistance. Therefore, the amplitude of discharge fluctuation decreases as cross sectional area decreases. As can be seen from figure 4 for the same amount of area variation, the effect is more severe as the area decreases than as it increases. For relatively small errors in cross sectional area, say up to 20 percent a stage-stage model can probably be calibrated successfully. The C values will simply be erroneous and compensate for the errors in the cross sectional area. The section on discharge-stage models contains a discussion of the advantageous use of such compensating "errors" in calibrating a discharge-stage model.

Gage Datum

Assuming the intermediate gages are to correct datum, an error in the datum in one of the driving gages is distributed essentially linearly along the segment of channel between the driving gages. The error is easy to see because it appears as a vertical displacement between the observed and predicted water surface elevations at the intermediate gages. An approximate value for the error can easily be recovered by a simple linear extrapolation. Under normal operating conditions three to five hundredths of a foot should be detectable.

The effect of a positive datum shift at the upstream gage on the calculated tidal-cycle average downstream discharges for the simulation period are shown in table 1.

Table 1. Effects of datum shifts on downstream discharge.

Description	Average downstream discharge (cfs)	Steady uniform discharge (cfs)
Datum Shift		
" " = .05 ft	1572	6888
" " = .1 ft	3052	9741
" " = .2 ft	6116	13775

Also given in the table is a predicted approximate value for the steady-uniform flow in Three Mile Slough for $C = 75 \text{ ft}^{3/2}/\text{sec}$ where the amount of fall is equal to the datum shift. The unsteady nature of the flow causes the predicted average value to be less than that for steady uniform flow. The predicted average downstream discharge increases linearly with datum shift, rather than with the square root of it as does the steady-uniform flow discharge. This is probably an isolated occurrence because, of course, as shift increases average fall increases and tends to become dominant in determining the average value of discharge. As this happens the square root relationship has to come fully into effect.

The average value of 810 cfs for an observed downstream discharge seems large in comparison to the predicted value of 94 at zero shift. However, it should be kept in mind that 810 is somewhat less than two and one-half percent of the average of the absolute values of the observed discharges. This is well within measurement error for a single discharge measurement and surprisingly small when one considers the combined hydrograph technique that had to be used to convert the time-distributed measurements into the instantaneous values shown.

Driving Stage Timing

Errors in timing of driving stage gages can be caused by different speeds of the clocks driving the recorders, a missed punch, or erroneous starting or finishing times. They can be damaging because small errors are difficult to detect and, although it is apparently not so in the case illustrated here, small timing errors in driving stage can sometimes result in large errors in predicted discharge.

Figure 5 shows the effects of various time shifts of the stage record of the San Joaquin-gage on the normalized RMS stage error and normalized RMS discharge error. Figure 6 shows the effect of twelve minute shift on the records produced at the three intermediate stations.

Figure 5. Effect of time phase shift of downstream gage on predicted stage and discharge.

Figure 6. Effect of 12 minute time phase shift on predicted water surface elevations at the intermediate observation stations.

As can be seen from figure 6 the time shift is approximately linearly distributed amongst the auxiliary stations. If we can make the big assumption that the clocks on the intermediate recorders are accurate, the approximate value of the shift should be recoverable by linear extrapolation. For a real field situation where we can't be certain about the intermediate clocks either, but with conditions similar to the ones illustrated here it should at least be possible to discern a shift as small as six minutes.

Figure 5 shows a minimum in the normalized RMS discharge error at a value of time shift somewhere around five minutes. This indicates, first, that there was probably an undetected timing error of about this magnitude in the original stage records. It indicates, second, that this technique; that is, the construction of hypothetical shift versus normalized discharge error graphs, is a viable alternative to inspection of the intermediate stage records for finding possible timing errors.

In this example the increase in the normalized RMS discharge error is not significant until the time shift becomes something between 12 and 18 minutes that is between two and three times the time computation step and around fifteen times the Courant time step. That this magnitude of shift is permissible should not, however, be taken as a general conclusion because a number of factors such as the rapidity with which the driving stages change, the phase difference between them, and the length of the reach being modeled determine the allowable value before serious errors result.

THE DISCHARGE - STAGE PROBLEM Portland Harbor

The data selected to illustrate the discharge-stage problem comes from Portland Harbor, Oregon. As shown in figure 7, Portland Harbor consists of the lower 26 miles of the Willamette River from Willamette Falls to the Columbia River, the 21 miles of Multnomah Channel, and 56 miles of the Columbia River from Bonneville Dam to Columbia City Oregon. Forty-nine cross sections in seven different channel reaches provided an adequate representation of harbor geometry for use in the simulation model. Input boundary conditions for running the model consist of the mean flow discharges for the Columbia River at Bonneville and for the Willamette River at Willamette Falls and the Columbia River stage at Columbia City.

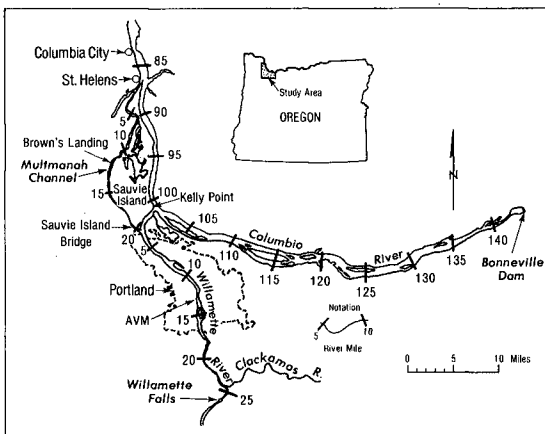

Figure 7. Portland Harbor, Oregon.

Cross section properties were obtained from recent soundings corrected to Columbia River datum and transcribed on a photomosaic of the Harbor by the Portland District of the U.S. Army Corps of Engineers. Calibration data were collected during four short term intensive data collection periods characterizing a range of mean flow conditions on the two rivers. Referring to figure 7, measured discharges were available at the Acoustic Velocity Meter (AVM), Willamette River mile (RM) 1, and Sauvie Island Bridge. Observed water surface elevations were available at the AVM, Kelly Point, St. Helens, and the Vancouver Interstate bridge (Vancouver). The discharge at the AVM was obtained at hourly intervals from the calibrated acoustic flow meter, at RM 1 by boat measurement, and at Sauvie Island Bridge by bridge measurement, all by standard U.S. Geological Survey techniques. The water surface elevations were obtained from floats and recorded digitally at 15 minute intervals. Bennett (1975) describes this data set in greater detail.

Calibration Procedure

Bennett (1975) gives calibration curves for Chezy C versus characteristic discharge drawn for the seven segments of the Portland Harbor model. The calibration curves were derived from the data set described here and another set which covered a wider range of discharges but consisted only of observations of stage and discharge at the AVM. In his study Bennett (1975) used the influence coefficient algorithm, an automatic optimization routine, to minimize an objective function which consisted of discharge prediction error normalized by local absolute mean discharge and water surface elevation prediction error normalized by local mean depth. In contrast the object of the present study is to calibrate the model manually as though only stage information were available. The results of using the two calibration procedures will be compared in some detail, however, first it is necessary to describe the manual calibration procedure used.

The first step in the manual calibration procedure is the adjustment of the mean value of stage and the RMS stage error at Kelly Point by varying the Chezy coefficient C in the two channel segments of the Columbia River between Columbia City and Kelly Point. This can be done essentially independent of Multnomah Channel because the stage at Kelly Point is primarily dependent on the much larger discharge of the Columbia River. For a predominantly unidirectional flow, aid in determining the amount of adjustment of the discharge coefficient required can be obtained by multiplying S_f by the length of reach and expanding the friction loss term as the first four terms in a power series in Chezy discharge coefficient. The resulting cubic equation in ΔC the required increment in the discharge coefficient, can be easily solved by synthetic division or Newton iteration.

For constant discharge, decreasing C has the effect of increasing the average predicted stage. A similar effect can be achieved by decreasing the cross-sectional area. Controlling the predicted stage by varying cross-sectional area has the advantage that C is left free, to a certain extent, to control the amplitude of the water surface elevation fluctuations. For the simulations reported here, the cross sectional-area of the Columbia River from Kelly Point to Columbia City was reduced by ten percent to allow

C to be large enough to force the amplitude of the stage fluctuations to that observed. This may be considered a questionable procedure because cross-sectional area is obtained from physical measurements made in the field. However, it should be realized that the cross sections used are at best random samples of those in the channel segments and as such may not be truly representative of the average conditions. Additionally, the field measurements may be inaccurate or incomplete, therefore, it is reasonable to permit small changes in cross-sectional properties to expedite calibration.

The second step in the manual calibration procedure is the adjustment of the predicted stage at the AVM and Vancouver by varying the C's in the Willamette and in the Columbia above Kelly Point. Calibration for these two stages can proceed simultaneously yet independently because the water surface elevations at these two locations are functions of the independent discharge in the two rivers and of the stage at Kelly Point which has been established in the previous calibration step. Because of the large natural cross sectional areas in the Willamette below Willamette Falls, the stage at the AVM is insensitive to discharge coefficient for the lower discharges. For these discharges it is determined almost entirely by the water surface elevation at Kelly Point.

The final step in the manual calibration procedure was an attempt to minimize the RMS stage error at St. Helens by varying the discharge coefficient in Multnomah Channel. The results of this, however, were not necessarily good in terms of discharge prediction because calibration of Multnomah Channel is essentially a stage-stage problem. The water surface elevation at St. Helens is determined by those at Columbia City and Kelly Point independent of the discharge coefficient value in the Channel. The entire calibration process described here was completed for each data set in less than fifteen simulation runs, a considerable savings compared to the fifty to seventy-five required for the automatic optimization procedure described by Bennett (1975).

Results

For the four data sets, table 2 gives the component prediction RMS errors and the corresponding normalized RMS errors for simulations using the optimum parameters resulting from the calibration procedure described above. In the table, these errors are compared to the corresponding ones resulting from simulations using the optimum parameters derived in the study by Bennett (1975). As might be expected the normalized stage RMS errors for all four data sets are smaller for the parameters derived using the above procedure while the normalized RMS discharge errors are all larger.

Whether or not the increase in accuracy of discharge prediction evidenced by the earlier technique as compared to the one described here is sufficient to merit the additional cost of collection of the necessary discharge data is a question that has to be answered based on the purposes for which the model will be used. To add perspective, typical model behavior for the

parameters derived from the two calibration procedures is shown by the stage hydrographs of figure 8 and the discharge hydrographs of figure 9. The hydrographs were computed using boundary conditions and optimum parameters for the data set of 5-31-73. Casual inspection detects little difference between the agreement of either set of predictions with the observed data.

Figure 8. Predicted and observed stage hydrographs at Kelly Point for 5/31/73. Solid line curve reproduced from Bennett (1975).

Figure 9. Predicted and observed discharge hydrographs at River Mile 1 for 5/31/73. Solid line curve reproduced from Bennett (1975).

Besides the accuracy of stage and discharge estimation another point which must be considered is the consistency of the parameter estimates obtained from the various data sets. Table 3 shows the C values for each of the seven channel segments of the harbor model. For the first three

Table 3. Channel segment discharge coefficients in $\text{ft}^{1/2}/\text{sec}$.

Channel segments Description	Date			
	5/31/75	8/1/73	12/5/73	6/12/74

Columbia: Vancouver to Willamette	195	200	96	120
Columbia: Willamette to Multnomah Channel	102	102	102	95
Columbia: Multnomah Channel to Columbia City	102	102	102	95

segments the values are the same for all data sets. The C value for the fourth segment was not adjusted in calibration because of lack of stage data above Vancouver. The optimum C value for the fifth segment behaves erratically in a fashion which can not be explained. Finally, the C values for the 6th and 7th segments are essentially constant. This is much more consistent behavior than demonstrated by the optimum C values obtained by Bennett (1975).

The reasons for the consistent behavior bear some discussion. First the AVM stages are not sensitive to C at the lower discharges, therefore, the C values for the first two segments are essentially set by the 12/5/76 data set. Second, Multnomah Channel is really a stage-stage problem, and should be fine-tuned using discharge information. This is beyond the scope of the technique being investigated. Third, the C values in the lower Columbia apparently decrease slightly, but only slightly with increasing discharge. Finally, as mentioned above, no explanation has been found for the behavior of C values in the short segment of the Columbia from Vancouver to the Willamette.

As explained earlier the model's intended use dictates acceptable prediction accuracy. However, Table 2 and figures 8 and 9 indicate that, with the possible exception of Multnomah Channel, the Portland Harbor model could have been calibrated acceptably for most purposes in the complete absence of discharge measurements. Whether or not detailed information concerning Multnomah Channel behavior is important in the final study will dictate how much attention should be paid to its calibration. If its behavior must be predicted accurately Multnomah Channel should be calibrated as in the stage-stage problem; that is, with discharge information collected at the extremes of ebb and flood flow.

Conclusions

Calibration of a stage-stage model requires the use of observed discharge. The best time for making the required discharge measurements is near the peaks of maximum and minimum downstream flow. Like variations in the Chezy discharge coefficient, errors in cross-sectional area can not be detected using auxiliary stage observation stations. On the other hand, gage datum discrepancies on the order of 0.05 ft and timing errors in one of the driving stage records on the order of 6 to 12 min. can be detected by comparing the predicted and observed stage records from such stations.

In most water quality modeling situations, discharge-stage models can be satisfactorily calibrated using only stage observations. The data used should cover as nearly as possible the range of mean flow discharges to be encountered in prediction.

CHAPTER 197

MOVABLE BED TIDAL INLET MODELS

by

Subhash C. Jain¹

and

John F. Kennedy²

INTRODUCTION

Stabilization of tidal inlets is a major engineering problem that is frequently encountered in the development of harbors. The planning, design, and modification of these inlets under the dynamic conditions that generally characterize their surroundings is, at best, a complex and uncertain undertaking. Prediction of the sedimentary response of an existing inlet to artificial improvements and to changing environmental conditions, or of a new inlet to the expected ambient conditions, and the optimization of the layout in order to minimize undesirable accretion or erosion are major elements in the design of tidal inlets. Because of the complexity of the problem, movable bed hydraulic models often are employed, despite the questions that surround their validity, to investigate these responses and to guide designs. The success of a movable bed hydraulic model depends upon the proper choice of similitude conditions and modeling criteria. Unfortunately, the conditions of similitude still are not well defined, as many of the phenomena constituent to the processes involved are yet to be elucidated adequately and formulated. Moreover, it is not possible to satisfy simultaneously all of the similitude conditions that arise. The required grain size and density of the model bed material, the current exaggeration that may be required, the effects of geometric distortion, etc. cannot be determined by straightforward computations. These must be chosen to obtain the most favorable balance between all relevant phenomena. The criteria of similitude generally are specified by experimenters who have previous experience with this type of model. The execution of a model studies of this type is, therefore, largely an "art" and entails major elements of subjectivity.

The Iowa Institute of Hydraulic Research, under contract to Coastal Engineering Research Center, U.S. Army Corps of Engineers, is presently (1976) conducting a study to evaluate the reliability and effectiveness of movable bed, tidal inlet, hydraulic models as predictors of prototype behavior. The main emphasis of this study is on comparison of model predictions with observations made in the prototypes, and evaluation of model performance in the light of: (i) the criteria of similitude adopted; (ii) the sedimentary material and instrumentation utilized in the models; (iii) the experimental procedure followed; (iv) the quality of the prototype data utilized in verification of the models; and (v) the degree and accuracy of model verification. The scope of this study is limited to those models in which the area of interest is composed entirely of movable material and not of just a thin erodible layer placed over a fixed bathymetry. In the United States these model studies

² Director, Inst. of Hyd. Res., Univ. of Iowa, Iowa City, Iowa USA

have been conducted only by Waterways Experiment Station (WES), U.S. Army Corps of Engineers, Vicksburg, Mississippi.

SIMILITUDE CONDITIONS - WHY?

Is it always necessary to satisfy certain dynamic similitude conditions in a coastal mobile bed model? It is generally possible to find by a trial and error procedure a combination of waves and currents in the model which will produce the known bed configuration and transport sediment at the desired rate to a certain scale. Why not then use the empirical approach; i.e., the trial and error procedure? To answer this question let us examine what L.F. Vernon-Harcourt (1892) reported long ago on movable bed technology. According to him, a model can be used successfully to predict the possible effects of proposed modification: (a) if the originally existing conditions can be reproduced in the model; and (b) if, moreover, by placing regulating works in the model, the changes that were brought about by the training works actually built can be reproduced. The first of these conditions, i.e., the satisfactory reproduction of the originally existing conditions, may be obtained using a suitable combination of waves and currents, determined by trial and error, in the model. There is, however, no guarantee that satisfactory reproduction would be obtained using the same combination of waves and currents when the constructed works are placed in the model; i.e. that condition (b) will be satisfied. This dilemma was encountered in a model study reported by Reinalda (1960). In his study, the model results were compared with the prototype data for the period before and after the construction of groynes along the coast in the vicinity of the Thyboron channel on the east coast of Denmark. The horizontal and vertical scales of the model were 1:250 and 1:40, respectively. Ground Bakelite with mean diameter of 1.8 mm and a density of 1350 kg/m³ was used as sediment. The waves and currents were reproduced according to the Froude law. The sedimentological time scale was determined by comparing the rates of recession of the coastlines in the model and the prototype. Groynes were built in the model at locations and times at which prototype groynes were installed. The relationship between the sedimentological time scale in the model and the prototype time scale for both pre- and post-construction periods is shown in figure 1. For the period from 1874 to 1890 (before the construction of groynes) one year in the prototype corresponds to about 0.5 hours in the model, while after 1920 (following construction of groynes) one year in the prototype corresponds to roughly 2 hours in the model. The model, therefore, over-predicted the effectiveness of the groynes on the rate of recession of the shore-line by a factor of 4. Although the groynes in the model reduced the rate of recession of the shoreline as observed in the prototype, the rate of sediment transport in the model was not accurately reproduced in the model. It might have been possible, after numerous attempts, to find another combination of waves and currents which would have yielded the same time scale for both pre- and post-construction periods (although the probability of doing so is very small). But such a trial and error procedure is very time consuming and expensive. It can be applied only in those cases in which extensive prototype detailed data are available for comparison and model calibration.

The empirical approach, therefore, can be applied only in very few cases and with limited expectation of success. It follows that the realization of a satisfactory model can be achieved only by satisfying certain similitude conditions at the outset. As mentioned in the introduction, these conditions of similitude are still not well defined. A certain amount of experimentation to determine proper combinations of waves and currents and to calibrate each model will continue to be required to reproduce the prototype conditions satisfactorily, even if one has satisfied similitude requirements to the extent possible. But the refined procedure will certainly reduce the time required for model calibration. Moreover, the results from such models can be used with more confidence.

SIMILITUDE RELATIONS

Over the past several years many papers (Bijker, 1967; Fan and Le Méhauté, 1969; Yalin, 1971; Migniot, 1972; Kamphuis, 1975) have been written on similitude requirements for mobile bed coastal models. Dimensional analysis generally has been used to derive the nondimensional quantities which must assume equal values in model and prototype for similitude to attain. Any dependent property, A, of the flow may be expressed in terms of the independent variables by the following relationship:

$$A = f[H, L(\text{or } T_w), \sigma_w, \theta, T_t, d, U, \rho, \nu, \rho_s, D, \sigma_g, X, g] \quad (1)$$

in which

H = wave height	}	Wave parameters
L = wave length		
T_w = wave period		
σ_w = parameter to describe the distribution of wave heights and periods		
θ = wave direction		
T_t = tide period	}	Tide and current parameters
d = flow depth		
U = current velocity		
ρ = density of water	}	fluid parameters
ν = kinematic viscosity of water		
ρ_s = density of sediment particles	}	sediment parameters
D = diameter of sediment particles		
σ_g = parameter to describe the size distribution of sediment particles		
X = some characteristic horizontal dimension		
g = acceleration due to gravity		

Equation 1 may be expressed in dimensionless form as

$$\pi_A = \phi_A \left\{ \frac{H}{d}, \frac{L}{d}, \sigma_w, \sigma, \frac{T U}{X}, \frac{Ud}{v}, \frac{\rho_s}{\rho}, \frac{d}{D}, \sigma_g, \frac{d}{X}, \frac{U^2}{gd} \right\} \quad (2)$$

which is so general as to be of practically of little practical use without simplification. It can be said at the outset, however, that it is neither possible nor essential to have the values of all the dimensionless quantities appearing in (2) equal in model and prototype. There is general accord (Fan and Le Méhauté, 1969; Yalin, 1971; Migniot, 1972; Kamphius, 1975) that the waves should be scaled according to the Froude law, with the scales for wave length and wave height equal to the vertical geometric scale. This condition insures proper wave breaking and refraction in the model (provided the model bottom topography is correct by modelled), but the wave reflection and diffraction are not reproduced correctly (because the wavelength is not scaled according to the horizontal length scale). Normally the currents also should be simulated according to Froude law. But the correct simulation of shear velocity, as discussed below, requires a certain exaggeration of the current velocity. The parameters σ_w and θ can be satisfactorily simulated in the model if the wave machine is able automatically to produce a continuous succession of irregular waves of different heights, periods, and directions. Though it is possible to simulate σ_w (by a crushing and sieving process), it is normally disregarded. It remains to simulate the other four nondimensional parameters: Reynolds number, $Re = \frac{Ud}{v}$; density ratio, ρ_s/ρ ; ratio of flow depth to sediment size, d/D ; and model distortion, d/X .

Froude similitude permits dynamically scaled representation of the mean hydraulic flow in the model but does not take into consideration the motion of the sediment. In order to define a suitable model bed material (sediment size and density) and a model distortion which will reproduce sediment motion in the model which is similar to that in the prototype, let us examine how the various sediment transport mechanisms are related to the dimensionless variables. It should be mentioned that the nondimensional parameters given in (2) are not unique. It is possible, at least in principle, to express these nondimensional variables in an infinite number of alternate forms. The form of the dimensionless parameters which should have the same values both in prototype and model to achieve similitude is not obtained by dimensional analysis alone, but requires also consideration of the physical processes involved.

For the satisfactory simulation of sediment motion in a tidal inlet movable bed model, it is desirable that the following conditions be satisfied in the model:

1. The general shape of the beach be conserved.
2. The condition of incipient entrainment of the sediment be correctly simulated
3. The rate of sediment transport be correctly reproduced.

It should be stressed that it may be neither possible nor necessary in some cases to satisfy all these conditions. It is hoped that the results of the study involving comparison between model and prototype which currently (1976) is underway at Iowa will determine which of these conditions must be fulfilled for acceptable similitude to be achieved. Unfortunately, the relationships among the various nondimensional variables which arise in the aforementioned

conditions are not well formulated. Past investigators have used different relations and thus proposed different similitude conditions; these are summarized in a recent report by Kamphuis (1975). The following discussion is based upon the present state of knowledge of the roles of three conditions stated above.

Equilibrium Beach Profiles. A generally reliable relationship which will define the equilibrium beach profile in terms of independent variables has not been developed to date. Noda (1972) recently proposed some scale relations for equilibrium beach profiles, but Collins and Chesnutt (1975) concluded on the basis of their laboratory experiments that Noda's model laws predict only the shape of the foreshore region, and its general use was not recommended by them. Until a better relationship for the equilibrium beach profile is obtained, it is recommended that preliminary experiments in a two-dimensional wave tank be conducted to determine beach profiles using the selected model bed material and vertical and horizontal scales, for some characteristic model wave conditions. If the actual scale distortion of the resulting equilibrium beach does not agree that imposed in the wave tank experiments, it is necessary to adjust the imposed value of distortion until the values do agree.

Incipient Entrainment of Sediment. Presently only very limited experimental data are available on initiation of sediment motion by the combined action of waves and currents. The experimental information on initiation of sediment by currents or waves alone suggests that the initiation of sediment motion due to both waves and currents may be expressed by a relation similar to that of Shields (Vanoni, 1975) for steady unidirectional flows. The criterion for the incipient entrainment of sediment under the action of waves and currents can be expressed as

$$F_{*C} = f(R_{*C}) \quad (3)$$

where

$$R_{*C} = \frac{U_{*C} D}{\nu}$$

and

$$F_{*C} = \frac{U_{*C}}{\sqrt{g\gamma' D}}$$

in which U_{*C} is the critical shear velocity, $\gamma' = \frac{\gamma_s - \gamma}{\gamma}$ is the apparent specific weight of the submerged sediment, and γ and γ_s are specific weights of the fluid and sediment, respectively. Both F_{*C} and R_{*C} are based on shear velocity, U_{*C} , which is a dependent variable. Equation 3 is not a suitable basis for a similitude condition unless U_{*C} is known for the model and the prototype. Valembois (1960) expressed Shields' relation in the modified form

$$G = f(R_{*C}) \quad (4)$$

where $G = \frac{\gamma' g D^3}{\nu^2}$, the so-called grain parameter, is obtained by dividing F_{*C} by $(R_{*C})^2$. It is proposed here, for want of a better alternative, that for the simulation of incipient entrainment of sediment, the value of grain parameter, G , should be equal in model and prototype. This gives the following similitude condition:

$$\lambda_Y, \lambda_D^3 = \lambda_V^2 \quad (5)$$

in which λ represents the scaling factor (value in model/value in prototype) for the quantity symbolized by its suffix. It is assumed that λ_g is unity.

Sediment Transport. Experimental data on sediment transport under the combined action of waves and current are also very limited. Recently Lin (1972) conducted some tests in a model basin to study sediment transport due to inlet currents and waves approaching the shoreline at an angle of 10° . He used dimensional analysis and his experimental results to express the sediment transport rate as a function of Froude number, bottom shear stress, friction factor, and wave steepness. Another experimental study on sediment transport by currents and waves was conducted by Bijker (1967). He expressed the rate of sediment transport by the following relation:

$$\frac{q_s}{U_*^3 D} = 1.95 e^{-0.33 \frac{\gamma' g D}{\mu U_*^2}} \quad (6)$$

in which q_s is the volumetric sediment transport rate per unit width, U_* = shear velocity based on total shear stress due to both waves and currents, and μ is a "ripple factor". For correct simulation of the sediment transport in the model, the value of $\frac{\gamma' g D}{\mu U_*^2}$ should be the same both in the model and the prototype, i.e.,

$$\lambda_Y, \lambda_D = \lambda_\mu \lambda_{U_*}^2 \quad (7)$$

The scale of shear velocity can be written

$$\lambda_U = \lambda_{U_*} \lambda_C \quad (8)$$

where C is bed resistance coefficient. Assuming $\lambda_\mu \approx 1$, as found by Bijker (1967) in his experiments, the similitude condition^u for sediment transport becomes

$$\lambda_U = (\lambda_Y, \lambda_D)^{1/2} \lambda_C \quad (9)$$

Using (5), (8), and (9) it can be shown that

$$\lambda_{R_*} = 1 \quad (10)$$

where $R_* = \frac{U_* D}{\nu}$; that is if (5) and (9) are satisfied, then (10) is also satisfied. Equation 7 for $\lambda_\mu \approx 1$ reduces to the similitude condition that the particle Froude number based on the total shear velocity must be the same both in the model and the prototype.

STUDIES CONDUCTED AT WES

Through 1975 WES had conducted seven movable bed model studies of tidal inlets. Each study was conducted on an *ad hoc* basis, in that no general similitude requirements or modeling criteria were followed. The waves and currents required to produce satisfactory bed configurations were obtained by a trial and error procedure. Wave heights were exaggerated as much as possible without causing wave breaking to occur at entirely wrong locations. Two prototype hydrographic surveys conducted some time apart were used for model verification and calibration. A model distortion of five was adopted in all model studies. Sands with mean diameters ranging from 0.2 mm to 0.25 mm was used as a model bed materials in all models except the Galveston Harbor Entrance Model, in which coal with specific gravity of 1.4 and a median diameter of 1.4 mm was utilized. The WES studies have utilized plunger-type wave generators, which are adjusted manually to generate regular waves of desired height and period. In all model studies, waves were generated from one or more fixed directions. The bed configurations in the model were recorded manually using sounding rods graduated to 1 ft (prototype). Tides were produced using automatic tide generators.

For the verification of the movable bed models, fill and scour maps, both for prototype and model, were prepared and compared. In some studies the dredging volumes also were used in the model verification. If the general pattern of fill and scour in the model was similar to that in the prototype, the model was considered to have been satisfactorily verified. This "eye-ball" comparison of the scour and fill patterns involves, of course, a strong element of subjectivity.

A PROPOSAL FOR QUANTIFICATION OF MODEL VERIFICATION

It would be very useful to have a quantitative measure of the performance of movable bed tidal models. Some of the quantitative indicators being considered in the Iowa study are the following.

Let S_j be the total amount of scour and F_j be the total amount of fill over the j th profile during a given time Δt (see figure 2). Let Q_j be equal to $(S_j - F_j)$; thus Q_j is a measure of the net sediment transport across the j th profile in the given time. It is also a measure of the average depth change over the j th profile.

The degree to which the change in bed elevation along at a given profile or at a given point in the model is related to that in the prototype can be expressed by the correlation coefficients

$$R_S = \frac{1}{N-1} \sum_{j=1}^N \frac{(S_{jm} - \bar{S}_{jm})(S_{jp} - \bar{S}_{jp})}{\sigma_{Sm} \sigma_{Sp}} \quad (11)$$

$$R_F = \frac{1}{N-1} \sum_{j=1}^N \frac{(F_{jm} - \bar{F}_{jm})(F_{jp} - \bar{F}_{jp})}{\sigma_{Fm} \sigma_{Fp}} \quad (12)$$

$$R_Q = \frac{1}{N-1} \sum_{j=1}^N \frac{(Q_{jm} - \bar{Q}_{jm})(Q_{jp} - \bar{Q}_{jp})}{\sigma_{Qm} \sigma_{Qp}} \quad (13)$$

and

$$R_D = \frac{1}{\sum_{j=1}^N M_j - 1} \sum_{j=1}^N \sum_{i=1}^{M_j} \frac{(D_{ij} - \bar{D}_{ij})_m (D_{ij} - \bar{D}_{ij})_p}{\sigma_{Dm} \sigma_{Dp}} \quad (14)$$

in which D_{ij} is the change in the bottom elevation at a point (i,j) within the given time interval (figure 2), σ is the standard deviation of the quantity symbolized by the subscript, the overbar denotes the average value, and the suffixes m and p denote model and prototype, respectively,

If the model results were in perfect agreement with the prototype data, the correlation coefficients in (11) thru (14) would be unity. This would be too much to expect from a model with a high value of R_D , but the values of the other correlation coefficients in (11), (12), and (13) must be high (approaching unity) before a reasonable verification of the model can be said to have been achieved.

A CONCLUDING REMARK

In conclusion the writers take this opportunity to invite identification of other model prototype studies and other methods of analysis that could be used in the Iowa investigation of tidal inlet models.

CHAPTER 198

CHURCHILL RIVER SALT-WATER TIDAL MODEL

by

Bruce D. Pratte*

1. BACKGROUND

The Port of Churchill is located just inside the mouth of the Churchill River, on the western shore of Hudson Bay (Fig. 1, Photo 1). Each shipping season, about 25×10^6 bushels of grain are shipped to Europe and Britain. The Port opens just after mid-July when Hudson Strait and Bay become relatively clear of ice. However, it is forced to close 3 months later by ice forming upstream in the rapids, sweeping down as slush ice at ebb tide, jamming between the ships and the dock and breaking mooring lines. Since the route to Europe is shorter and therefore the laid-in cost of the grain slightly less than from other Canadian ports, there is a demand to extend the operating season at Churchill. A feasibility study and field survey in 1965 by Dick (Refs. 1, 2) showed that the Port could remain open about 2 weeks longer than the present October 23 closing if the slush ice could be kept out of the harbour. To this end, the National Harbours Board in 1974 commissioned the Hydraulics Laboratory of the National Research Council of Canada to do an hydraulic model study of the harbour and estuary.

2. OBJECT OF STUDY

The sponsor of the study required that various structures be examined for protecting the ships in the harbour from the current of slush ice, principally at ebb tide. Since the structure will be permanent, it must also not have detrimental effects during the rest of the year with regard to flow patterns and velocities and sedimentation. Although maintenance dredging is not a major problem in the harbour at present, averaging about 8,300 yd³ per year, the season is so short that it would be undesirable if excessive dredging were caused by implementation of one of the schemes. Ideally, the structure should produce a quiet harbour so that loading and turning of the ships can go on without the present concern for the high outflow ebb velocities at the dock.

Fig. 2 shows the extent of the area modelled, and how the dock is situated on the outside of a bend in the flow. The most obvious structure would be a deflector just upstream of the dock, and various deflectors formed a large part of the model investigation. Another, but considerably more expensive scheme is a dam from the dock over to Cackle's Point, incorporating a section with a weir with crest elevation above the extreme tidal highwater. In addition to excluding the slush ice from the harbour, it could serve as a causeway to the west shore of the river, opening it up for development and access to historic Fort Prince of Wales.

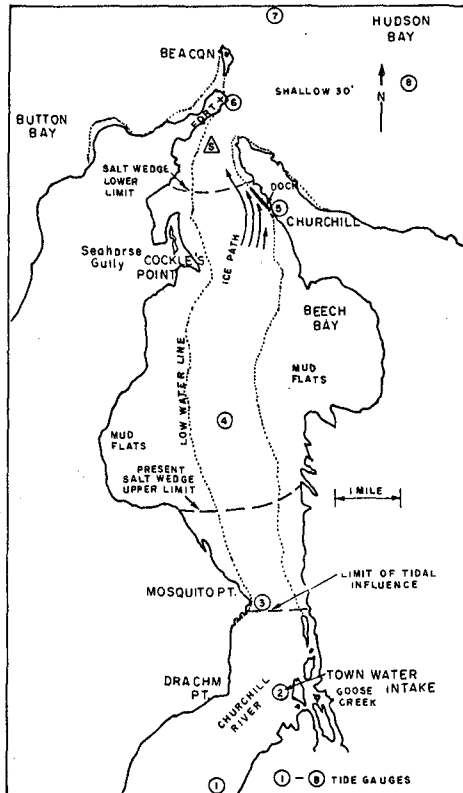

Fig. 2. Extent of Model

Since the river several hundred miles upstream is soon being partially diverted into the Nelson River system for power development, the freshwater discharge will be reduced in the harbour area from a present mean around 50,000 cfs down to about 20,000 cfs. However, there is the possibility of it going as low as say 2,000 cfs in the fall, so that the 1% salt-water limit of intrusion will move up the river past Mosquito Point. This will require relocating the town's fresh water intake pipe, presently at Goose Creek, Fig. 2, further upstream. The model was also expected to show how far upstream the salt will penetrate at extreme high tides and very low river discharges.

3. THE MODEL

To study all the required objectives, the model in Fig. 2 and Photo 2 was constructed of concrete over sand. It is 185 ft long, 55 ft wide, and extends the equivalent of 3

miles into Hudson Bay as the seaward salt water tidal boundary. The upstream end of the model is above the tidal limit and supplies a constant freshwater inflow by means of a head tank and vee-notch weir.

Photo 2. Churchill Tidal Model with Supply Manifold in Foreground, and a Dam Past the Dock.

3.1 Model Scales

Prototype/model length scales are $L_p/L_m = 400/1$ horizontal, $d_p/d_m = 50/1$ vertical, giving a vertical exaggeration or distortion of 8. This is necessary to achieve sufficient depth and turbulent flow in the shallow reaches of the river.

From the Froude (Fr) law for scaling of free surface flow phenomena, one derives the following relations:

$$\text{since } Fr_m = Fr_p, \quad V_m/\sqrt{gd_m} = V_p/\sqrt{gd_p},$$

$$\text{the velocity scale is } T_p/T_m = \frac{L_p}{L_m} \times \sqrt{\frac{gd_m}{gd_p}} = 56.5685;$$

(Thus a 12.4 hour tide cycle requires 13.1 minutes on the model.)

$$\text{The discharge scale is } Q_p/Q_m = \frac{V_p L_p d_p}{V_m L_m d_m} = 141,421.$$

Finally, the salt concentration, salinity or density is modelled in a 1/1 ratio, so that it is the same in model

and prototype, namely 28% out in Hudson Bay near the tidal boundary. Because the harbour is in an area of density stratification where a fresher surface layer at times flows in quite different directions to the bottom seawater layer, it was necessary that the model be a salt-water one, with freshwater river discharge. This of course gives rise to considerably more complex model control, and measurement and calibration of velocity and density.

3.2 Model Control

A large sump is kept up to seawater salinity by a Robertshaw pneumatic controller which causes a small amount of saturated brine, obtained from a pit of dissolving rock salt, to be injected into the intake of the 6 cfs seawater pump. A Schlumberger Solartron density meter monitors the density of a continuously sampled portion of the flow leaving the pump. This instrument works on the principle of the change in frequency of an oscillating pair of tubes through which the fluid travels, and senses extremely small changes in fluid density. Any deviation from the controller's set-point density causes the appropriate amount of brine to be injected. The brine is needed to make up for the dilution of the seawater caused by the steady freshwater river inflow.

The main seawater flow then enters a large head tank before flowing by gravity into the Hudson Bay end through a 32 feet long, 1 foot diameter manifold pipe. The 5 cfs inflow is constant. Tidal control is effected by a drain valve located in the corner of the model such that the flow drains toward it in the same direction as in the prototype. The valve is controlled by an on-line EAI-640 computer which compares the historical tide curve desired, to the level sensed by a floating water level sensor in Hudson Bay. Any error results in a signal to the valve to open (lower) or close (raise the water level). In addition to control of the tide, the computer also records for off-line plots and printouts, the water levels and velocities from gauges on the model to allow comparisons of different test conditions.

A 10 feet long weir near the valve follows the tidal water level. The overflow from this weir is set to twice the freshwater inflow rate, and passes through a 3-way 4 inch valve. When the tide is rising, this valve drains into the seawater sump. However, on falling tide when Hudson Bay gets a skin of fresher water from the river flow, this valve opens so as to bypass the "fresher" weir overflow down the sewer. Thus, the sump level is not filled up or degraded in salinity quite so much by the fresher water during a test.

3.3 Instrumentation

There are eight tide gauges located along the model. A glass ball float is attached to a stem which is free to move up and down inside a DCDT (direct-current differential transformer). Outputs of up to ± 3 volts D.C. are sensed by the computer and converted to water levels by a calibration equation. Five velocity meters are located in the estuary, and each incorporates a DCDT mounted horizontally, and has a 2 x 4 cm drag plate in the water suspended from thin frictionless straps (Photo 3). Movement of the plate by fluid drag causes the stem or core to move freely inside the DCDT. This meter is sensitive enough to measure velocities, both upstream and downstream, down to about 1 cm/sec, and up to 30 cm/sec. One disadvantage of the meter is that it must be carefully levelled, and therefore is not suited for traversing through the flow depth.

A newly developed velocity meter was also used. It comprises a very sensitive strain-gauged Kistler transducer, connected by a rod to a flat circular cylinder drag body. Velocities coming from any direction in the horizontal plane can be sensed by this instrument, and the resultant vector obtained from computer analysis of the output of the x and y axis strain gauges. This instrument was located where the flow direction swings appreciably as the tide changes, in the center of the estuary between the dock and Cockle's Point.

Photo 3. Drag-Plate Velocity Meter

Photo 4. Traversing "Salinity" Probe

Vertical velocity profiles were very difficult to obtain since the velocities were often low and the sensitive levelled drag-body velocity meters could not be traversed. Even miniature Kent and Ott laboratory-type propellor meters were not adequate. Therefore, a dye injection system was devised, which involved timing a puff of dye (injected normal to the flow direction) past a ruler located at the same depth. This system worked very well, and allowed vertical traverses. However, by the time velocities were measured at say 10 depths, the tide cycle was quite different than when starting the traverse. Therefore, several tide cycles had to be repeated in order to get enough measurements at different levels at the same point in the tide cycle.

Vertical salinity profiles in the model test locations were made by traversing a specially developed conductivity probe which continuously sucks a tiny sample of the water through a fixed volume past platinized electrodes, Photo 4. This instrument is similar to that constructed by the Delft Hydraulic Laboratory. A motorized traversing rig moves the probe through the full range of the depth at about 1 cm/sec. Response is very good although electrical calibration in standard solutions of "known conductivity" must be made frequently. Temperature is also monitored to allow conversion of conductivity to salinity by standard equations. Again, several tide cycles of testing were needed before enough points were available to plot a near instantaneous vertical salinity profile. This of course assumes the tides and salinity distributions repeat very well from cycle to cycle in the model.

To measure the 1‰ salinity penetration upstream towards Mosquito Point, a small Beckman conductivity probe was used.

4. MODEL CALIBRATION

In August 1974, temporary tide gauges were installed on the Churchill River at 4 and 2, Fig. 1, in addition to the long-time permanent gauge at the dock. A survey of elevations at 3 and 1 allowed their levels also to be tied in to these tide gauges. In 1965, Dick (2) made a field survey of prototype vertical velocity and salinity profiles at various locations near the harbour and estuary entrance. Also, penetration of the 1‰ salt-water limit was found to be about as shown on Fig. 1 at high tide. Mosquito Point, near 3 is a region of very rapidly flowing water, with large 5 to 8 feet diameter boulders on the bottom in less than 8 feet of water. At low tide and average river flow of about 50,000 cfs, the salt limit is pushed down just past the dock. There is a very strong density gradient seaward of this point with a fresher layer on the surface moving rapidly (5 fps) out to sea, and a nearly stagnant sea

water layer underneath trying to move up the estuary as a wedge. Surface movement of ice and of drogue bodies was observed or tracked by theodolite, giving vector paths as sketched in Fig. 1 approaching at about 30° to the dock.

Model calibration involved placing 2 cm wide stainless steel strips vertically into holes in the concrete bed of the model in the area from the entrance up to Cackle's Point, and coarse gravel in the shallow areas further up-stream. By trial, a distribution of this bed roughness was found which forced the model to reproduce the correct tide curves at each station. Due to the vertical distortion, $d_p/d_m = 8/1$, the deeper areas are exaggerated and tend to attract more flow in the model than would occur in the real river. Therefore, roughness was concentrated more in these deeper areas to create velocities in the various locations where measurements were available. The roughness of course has no effect at high water slack, but is very effective on falling or rising tide when velocities and head losses become significant.

Fig. 3 shows a comparison of model and prototype vertical velocity (from dye timing) and salinity profiles at 2.2 hours after low tide at location s, Fig. 1. The tide is rising and the seawater is flooding in beneath the fresher layer on top which even at this time is still ebbing seaward. By about 3 hours after low water, the surface layer itself will turn and start to be backed up into the estuary. The salinity profiles show the very marked stratified gradient at this station, in the estuary entrance, of 25‰ in the lower 35 feet and nearly fresh above. The thick lower layer

Fig. 3. Comparison of Model (x) and Prototype (o) 2.2 Hours after Low Tide

forces the freshwater layer to flow seaward at high velocity throughout the 2.5 hour period just after low water. This phenomena is of importance to the surface clearing of ice, as is the time, speed and duration of movement of the lower layer with respect to suspended sediment transport. Only with a salt-and-fresh water model can these effects be properly simulated.

Photographs of the movement of surface floats (styrofoam, paper punchings, or wood pieces) were also used in calibration of the model, and in testing various flow diverting structures. A Haselblad 500 EL camera mounted above the harbour area was computer-controlled to take a 5 second exposure at times of interest in the tide cycle, such as at maximum flood and ebb tide, and high and low water. Just after the shutter opened, an external blade was triggered to briefly cover the lens, producing a break in the streaks which the particles create on the film. This break is near the end of the streak where the particle came from. There are white strings 30 inches apart, or 1,000 feet prototype, stretched across the model just above the water surface, which allows one to scale off the length of each 5 second streak in the photograph, and determine the particle's velocity, direction and sense.

Velocity of the lower layer was measured by the current meters, but frequently dye was used to show flow direction and to colour the lower salt-water layer to observe its penetration up the dredged navigation channel, into the harbour, and further upstream. In fact, at low tide, the seawater layer was dyed just downstream of the dock, and the dye front observed to penetrate up to the same limit towards Mosquito Point as shown in Fig. 1 from the prototype observations of Dick. This dye limit corresponded well with that measured using the Beckman conductivity cell at the same spot but without dye.

Since an indication of any large changes which various structures might create in the bottom sediment movement was also required, gilsonite, bakelite, and fine crushed walnut shells (shelblast) were tried as tracers. The walnut shells were found most useful for a qualitative idea of likely bed erosion and deposition areas. Although no tracer studies were made in the prototype, it is known from a few bed samples Dick obtained, that the harbour area deposits are mostly medium to coarse sand of 0.4 to 0.9 mm median grain diameter, felt to come from up river, plus some fine, silty grey mud of 0.075 mm size. This mud may come from the photographically evident littoral drift zone around Button Bay, and be carried on flood tide up the estuary to settle out on the mud flats, and eventually in the harbour itself. Ignoring the cohesive effects of the silts, the sand may be expected to move as bed load for bed velocities greater than 0.5 to 0.8 fps.

5. TEST RESULTS

Since many tests were made, and since the results are proprietary information of the sponsor, only a few illustrative results of the investigation will be given here by permission. These results should not be considered as representing the sponsor's opinions or recommendations.

5.1 Deflector Upstream of Dock

Various configurations were tried, varying the length, angle to the flow, and tip curvature to lessen scour. Photos 5 and 6 show the ebb flow from left to right past the dock without and with a deflector. The deflector shown is a 1,200 feet long rubble mound structure. It provides adequate protection in the entire harbour area at ebb tide with the slush ice kept out, and with only a very weak clockwise re-circulating eddy present.

Photo 5. Surface Ebb Flow
Past Dock

Photo 6. Harbour Protection
with Deflector

At flood tide most of the returning ice flows up the shallow west side of the estuary across from the harbour, since that side then is on the outside of the bend for flood flow. Any ice trapped in the harbour on ebb tide was not packed in between deflector and dock on flood tide. Rather, the bottom seawater layer moves into the deep harbour area, locally raising the nearly stagnant freshwater layer on top and causing a superelevation so that the surface "ice" moves out around the deflector. This phenomena was unexpected, but indeed welcome since in the model, even a northwest wind failed to overcome the strong clearing effect. In the prototype, however, freezing cohesion of the real ice could alter this behaviour somewhat, and some small tugboat action might be needed to break up any persistent ice cover which forms.

Sediment placed in the harbour tended to stay there. However, walnut shells placed at A upstream of the deflector at ebb tide was vigorously moved northwest on the bed, at about 30° to the direction of the surface currents, Fig. 4. As the tide approached low water, the deflected flow slowed down, and was attracted more towards the deeper harbour, and a small number of walnut shells moved along the outer edge of the harbour at B, a few depositing in the downstream corner of the harbour at C and in the approach channel at D. Approximately 90% of the particles placed across the river section at A, simulating the sand bed-load coming down the river, were strongly moved out the narrow deep entrance mouth into Hudson Bay, not to return on flood tides. The few particles at D were carried up into the harbour on the next flood tide, and settled out in there in the areas hatched. Particles placed at E were cleared out by the strong bottom seawater currents at flood tide. Obviously

Fig. 4. Effect of Deflector on Ebb Bed Particle Movement Compared to Surface Flow Velocity Meter Locations Also Shown

sedimentation will be more of a problem in the harbour if this deflector were build, if indeed there is significant sediment coming down the river, a factor not yet well determined.

It is also expected that deposition of some sand, but mostly mud, will occur on the upstream side of the deflector, as shown by dye simulating any suspended silts brought in from Hudson Bay in the salt water layer.

5.2 Dam With Weir and Causeway

The second idea investigated was a dam extending the deflector over to Cockle's Point. Placement of a weir was tested for best results in the harbour. Photo 7 shows one scheme with a 2,600 feet long weir near the middle of the section. The crest elevation of +10 feet above mean water level was 0.4 foot above the highest recorded tide in the harbour of September 7, 1967, which had a 9.6 feet high water and a -6.9 feet low water. The weir length was chosen to pass the maximum expected flood flow of 100,000 cfs with a 5 feet head, giving a dammed level upstream of +15 feet, the highest suggested before significant flooding would occur.

Photo 7. Dam and Weir Upstream of Dock

The advantages of the dam were found to be as follows. First, the slush ice formed in the rapids becomes a static ice cover in the deep wide nearly-stagnant lake created by the dam. Therefore, no ice problem occurred in the harbour area, which in any case was protected from the direct weir overflow. Next, the harbour velocities were lowered, with mostly seawater of very low velocity moving slowly back and forth to fill the much reduced tidal prism between dam and Hudson Bay. Third, river-borne sediment was trapped in the lake, and did not get past the dam. The lake created by the dam was non-tidal and fresh, forming a

steady recreational area all year round, plus giving ready access to fresh water for the Port and town of Churchill. Finally, a roadway may be constructed on top of the dam and weir to provide safe access for development of the west shore and for tourism.

The disadvantages of the dam were found to be: firstly, extremely high cost due to material and equipment availability and overall size (almost 8,000 feet long); definite possibility of suspended material settling out due to the low velocities in the harbour area even though the surface freshwater layer from the weir is always moving seaward even at flood tide (except when river discharges are very low). The tests showed that at flows of 10,000 and 24,000 cfs, the tidal inflow near the bed predominates in duration over its outflow, allowing more time for littoral drift sediments to be brought in and deposit in the harbour. Thus, increased dredging is forecast, although conditions for dredging would be easier. The river is blocked to navigation, although small boats would likely be kept above the dam in any case. Some flooding of the area between the dam and Goose Creek will occur at flood flows nearing 100,000 cfs, requiring dykes and building relocations. Certain yearly maintenance costs would be incurred, and finally the harbour would not clear of ice until a few days later than normal.

5.3 Reduction of River Flow by Diversion

The Churchill River will soon have much of its flow diverted into the Nelson River several hundred miles upstream for power development. The effect of severely reduced flows on conditions in the harbour was investigated. Fig. 5 shows the drag-plate current meter velocities over two semi-diurnal tide cycles, for two test conditions, one with present average river flow of 50,000 cfs, and the other for an admittedly very small discharge of only 2,500 cfs. These two tests demonstrate the effect of a reduction in river flow. First, although not shown here, the high water levels at the dock are influenced mainly by Hudson Bay, and so were found to be almost the same. The low water, however, is about 0.6 foot lower with the small flow since only a small slope is then required to get this amount of freshwater out to Hudson Bay. Water levels further upriver are lowered dramatically, by over 4 feet at gauge 1, Fig. 2, so that the river becomes much narrower and shallower. The velocity meters located as in Fig. 4, showed interesting behaviour. Meter 51 was in the entrance in the surface layer and meter 59 was directly below it near the bed. With the 50,000 cfs flow, there was a 2.5 hour lag between the time the bottom seawater (59) began to move as inflow and the time when the surface layer (51) finally reversed also. However, with the 2,500 cfs river flow, the surface layer is so thin that virtually the whole flow from top to bottom

reverses direction at the same time. The tidal prism of the estuary which at high flows is filled by river and tide, will then be mainly filled by inflow from Hudson Bay. Thus inflow times will be longer and the velocities higher, and outflows will be shorter. The end result will be more time for littoral drift sediments to be carried into the estuary, and less time to be cleared out. On the favourable side of the question of reduced river discharges is the fact that less river flow will bring down less sand and sediments. In addition, less ice should be produced in the rapids by the smaller river cross-section. These two factors may well more than compensate for the increased siltation expected from Hudson Bay. The best recommendation now is to wait and see if the results of the diversion bear out the predictions from the model tests.

Fig. 5. Two Semi-Diurnal Tide Cycles Giving Velocities for 50,000 cfs (—) and 2,500 cfs (---) River Discharges

6. DISCUSSION

The purpose in presenting this model study is to encourage the use of salinity models in the study of flow phenomena where density effects are involved. Although not inexpensive to operate because of salt use, the model control and data acquisition by on-line computer was most effective in keeping testing to a minimum. Use of plastic pipe and concrete is recommended where possible to avoid corrosion problems. Even rusting, however, requires years before

significant damage occurs, and by then the equipment has certainly paid for itself in allowing better knowledge to be gained than from all-fresh water tests. Instruments made of type 316 stainless steel were found to resist corrosion very well.

The results of a few of the schemes tested on the model to improve conditions in Churchill harbour, particularly under ice-run conditions were described along with their advantages and drawbacks. Obviously no scheme was perfect, but at least the results should allow a better appraisal of the merits of each when the time comes to implement one at Churchill.

CHAPTER 199

Analysis of Time Conditions for Hybrid Tidal Models

Klaus-Peter Holz*

Summary

Hybrid models for the investigation of tidal waves in rivers and estuaries are a combination of mathematical and hydraulic models, which are coupled under real-time conditions. The coupling procedure cannot be performed without some time delay which mainly depends on the time needed for the computation of the mathematical model and for the control operations on the instrumentation. An analysis of their influence on the accuracy of a hybrid model is given and experimental results from a feasibility study are presented.

Introduction

During recent years great advances have been made in the field of numerical models. Simple models which start from the assumption of vertically averaged velocities have quite often been applied for the simulation of far-field processes in tidal waters. They are of good economics and high physical reliability and have thus become standard tools for coastal engineers. However, when detailed three-dimensional investigations have to be performed, often mathematical models are less reliable than physical models are. This is due to the fact that only few numerical models of this type [1,2,3] are in use and still only few experience on the choice of physical coefficients is available. Furthermore the computational expense grows considerably. So it is reasonable to stick to physical models for three-dimensional investigations, which should be performed at the largest scale possible. However, a small section of an estuary can be modeled then only. For this the boundary conditions have to be known which often makes a separate investigation necessary. This can be per-

*Dr.-Ing., Universitätsdozent, Technische Universität Hannover

formed by setting up a physical model of the whole estuary at a much smaller scale. This technique would be rather expensive. A second approach can be made by using a far-field numerical model. However, now the near-field section has to be included into the computation which starts from the assumption of vertically averaged velocities. A considerable error may result from this simplification, which should not be allowed for. It can be avoided by a new investigation technique, in which the near-field section of the model is realized hydraulically and the outer area of the model, for which the far-field assumptions are valid, is set up numerically. Both models are coupled under real-time conditions and thus integrated into one new formulation, which we call a hybrid model. The three-dimensional physical model interacts dynamically with the two-dimensional numerically simulated part and vice versa. So no special boundary conditions have to be controlled on the physical model part. The only prescribed conditions are those for the outer mathematically simulated part.

The coupling technique between the hydraulic and numerical model follows the strategy of correcting the water-levels and the discharges on the boundary between both models within small fixed time-intervals, thus guaranteeing continuous condition between both models. The practical applicability of hybrid models depends on the computing time needed for the numerical model and on the time needed for performing the control operations on the instrumentation. These time-elements have to be analysed carefully. This will be done by some theoretical considerations and experimentally in a feasibility study which was run for an one-dimensional open channel system.

Hybrid Model

The hybrid model technique will be tested in principle for a rectangular straight channel of about 25m length. The tank is closed at one end and a sinus-shaped variation of the water-level is controlled at the other end (Fig.1).

The channel may be regarded as a hydraulic model of a system. For our investigations the model has to be reformulated in a hybrid way. It is cut into two parts (Fig.1) now, one of which still is a hydraulic model, whereas the other part is simulated numerically on a computer. As with respect to geometry and boundary conditions no changes have been made, the time history of the water-levels must remain the same for any station in the hydraulic model as well as for the hybrid formulation. A comparison between measured values in both model tests gives some idea on the accuracy and reliability of the hybrid approach.

Fig. 1 Feasibility Study

The coupling procedure between the numerical and the physical model part is run on the same computer as the numerical model is (Fig.1). Within fixed time-intervals which we call the coupling intervals Δt , the water-level is measured at the coupling point in the hydraulic model and given as boundary condition to the mathematical model. Now the computation is performed for one time-step, which is equal to the coupling interval. The numerical model is thus updated from the time level of the last measurement to that for which the boundary condition is valid. The computed discharge is then given for control to a pump-system on the hydraulic part (Fig.1). If this procedure works within very small intervals, continuous water-levels and discharge on either side of the coupling point can be expected. Practically, however, the coupling interval cannot be made arbitrary small as within each interval some time must be spent on the computation of the numerical model and some further time for setting the pump-system to the computed discharge values. These time-elements determine not only the frequency of the coupling procedure but they also represent a time-delay between measuring and having the pump set to the computed new position. So they strongly influence the behaviour of the hybrid model which is seen from Fig. 2, in which a comparison is made between water-levels h and discharges q measured in the complete hydraulic model and the corresponding values h^* and q^* in a hybrid for-

Fig. 2 Coupling Procedure

mulation.

The left side of Fig.2 shows a situation when the delay is assumed to be nearly zero. The coupling procedure starts by measuring a water-level h^* and gives this as boundary condition to the numerical model. This now computes a discharge q^* which will be bigger than the corresponding q in the hydraulic model if h^* was measured higher than h . When now q^* is controlled on the pump it causes the water-level to sink for the time Δt of the coupling interval and so the next measured value h^* will be lower than h . A lower water-level h^* now leads to a computed discharge q^* which is smaller than q and thus the water-level starts rising again. This oscillation around the correct value can no longer be guaranteed when the time-delay is taken into consideration. This is shown on the right side of Fig.2. The water-level keeps rising during all the time needed for the computation of the value q^* for the discharge which, when available, does no longer corresponds to the actual water-level. The computed discharge is too small now and the next water-level will remain too high. But then a rather strong variation of the discharge may follow which will surely induce a considerable error and may even make the system to run out of control. An analytical analysis of such conditions can hardly be given due to the nonlinearity of the describing differential equations. So

experiments have to be run in order to find out, up to which delay the hybrid model will give satisfactory answers.

Time Elements

Time delays inherent in the coupling procedure are basically caused by three elements (Fig.3).

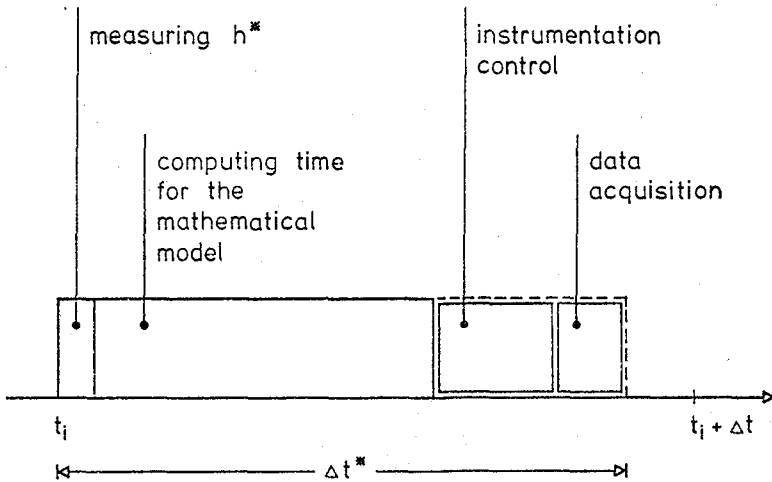

Fig. 3 Time Elements

Within one coupling interval the water-level has to be measured which takes a very short time only. An interrupt is generated by the computer, the sampling performed via the multiplexer and the analog signal from the instrumentation converted into a digital form. A brief subroutine subsequently transforms the measured value into the wanted water-level quantity taking the calibration curve of the instrumentation into account. Performing all these operations takes mostly less than 0.01 sec. So this time element is very small and can be neglected for further considerations. The second step within the coupling routine is the computation of the mathematical model. This may take a considerable amount of time depending on the size of the system and the chosen numerical algorithm for solving the differential equations. These are given by the equation of motion

$$v, _t + v v, _x + g h, _x + R v = J \quad (1)$$

and the equation of mass conservation

$$h, _t + h v, _x + v h, _x = 0 . \quad (2)$$

v is the velocity, h the water-level, J the bottom slope and R stands for a parametric term including turbulence and friction. Numerical solutions mostly start from the linearized version of the equations

$$v, _t + \bar{v} v, _x + g h, _x + R v = J \quad (3)$$

$$h, _t + \bar{h} v, _x + \bar{v} h, _x = 0 \quad (4)$$

The bar-marked quantities are assumed to be known and are chosen identical to the initial conditions for the actual computational time-step.

The numerical solution schemes can be formulated in quite different ways using either a finite difference or a finite element approach. In any case a set of explicit equations is obtained if the problem is formulated explicitly or an equation system will result if an implicit strategy is chosen. With respect to the real-time application in a hybrid model, the computational expense of both formulations has to be analyzed. The solution of the equation system can be performed rather economically by the double-sweep algorithm [4,5], but explicit schemes are still more economical if a comparison is made on a per step basis. However, these schemes are not unconditionally stable and so often several computational steps are necessary to arrive at a time-level the solution for which is obtained by implicit schemes within only one step. So implicit schemes may become again faster on the coupling interval basis. Furthermore the time-step may be varied arbitrarily without altering space discretizations due to the stability properties of such schemes. These considerations lead to the use of a double-sweep implicit model for this study.

The third time-element is represented by the control operations on the pump when this is set to the computed new discharge value. This can be performed either under direct computer control or by using additional technical equipment. In any case the computed discharge must first of all be converted into an electrical or mechanical quantity. This is achieved by a simple subroutine referring to the calibration curve of the pump. Then this digital value is given via an output relay to the instrumentation. If this is set to the

new position in only one step this would surely be the most time saving way in a real-time application, however, a sudden change in discharge will cause big disturbances near the coupling point and thus falsify the next measurement of the water-level h^* . So it is preferable to vary the flow conditions slowly bringing the instrumentation up to the new position by an independent unit being supplied with a clock and a counter or in a more flexible and cheaper way by the computer itself using the interrupt facilities. The gradient, by which the new position is approached, can then be determined by a software solution but then the computer is kept busy and cannot yet start the next coupling interval. So this time must be considered to be the third time-element. However, as the computer calculations are performed much faster than output signals can be given to the instrumentation, this time-element may include additional functions. During intermediate intervals data acquisition routines for the hydraulic model can be run and thus a task be taken into account, for which in many laboratories computers originally have been made available. From this then follows that for hybrid models mostly no additional installations are needed.

Besides this way of performing the control operations, which can be programmed very easily, there is still a more complex alternative. In this again the interrupt facilities of the computer are used, now interrupting the computing process of the numerical model for control and data acquisition. This leads to a more complicated software solution, but allows for neglecting the third time-element in all considerations. So the only element, causing any delay, is the computing time of the numerical model.

Experimental Tests

The test series on the time conditions are run for the system shown by Fig.4.

Fig. 4 Hybrid Model

At the left hand side a sinus-shaped variation of the water-level with an amplitude of 2.5 cm and a period of 300 sec is generated. The mean water depth is 12.5 cm. These values correspond to conditions which are often found in estuary studies of shallow water areas. The numerical part of the model is discretized by 5 elements thus giving a computation time of about 0.1 sec per time-step. For comparisons between the original hydraulic and the later hybrid model the time-history of water-levels and velocities is gauged at always the same station (Fig.4) in the hydraulic model part. Any discrepancy in the results can than be interpreted as an error induced by the hybrid realization and by increased or decreased time-elements.

The first test concerns a minimum of delay. The computed new discharge q^* is then available after 0.1 sec already, but the control operations on the instrumentation need much more time. So a coupling interval of $\Delta t = 1$ sec is chosen within which the numerical model takes 0.1 sec, the control operations take 0.7 sec and 0.2 sec are left for data acquisition. The results from this test for the hydraulic and hybrid formulation are given by Fig.5. In the upper part a comparison for the water-levels over 5 tidal cycles is made. It shows very good agreement. The same can be stated for the velocities as shown in the lower part of Fig.5. The rather nervous behaviour of these curves must be explained from the instrumentation. A thermo-element based instrument had been used, giving the resultant velocity component at one fixed point only. As no artificial damping on the analog output was made and no averaging performed, turbulent variations are still inherent in the data. The decreasing magnitude of the velocities for the first three periods has to be explained by the fact that the system starts from rest. Quasi stationary conditions are not obtained up to the fourth period.

The object of the experiments is to find out up to which size the computing time of the numerical model can be extended. So a further test is run with a delay of 2.1 sec. As the coupling interval is made $\Delta t = 2.0$ sec, all control operations have to interrupt the computation of the numerical model. Due to programming simplification no interrupt is allowed within the first 0.1 sec of a coupling interval, in which all measuring procedures are run. So finally a delay of 2.1 sec results. Figure 6 shows the comparison for the water-levels. In the lower part of the figure a detailed analysis for two periods is made. Referring to the water-levels measured in the original hydraulic model the error for the hybrid formulation can be calculated on a per centage basis. The errors found do not exceed the range of 1%. So the difference between measured water-levels in the hydraulic and hybrid model is of about 1.5 mm at maximum, or when referring to the tidal range of 50 mm, of about 3%. An error of this magnitude, however, seems still to be acceptable as this is within the same range of accuracy in which in many cases also field-data are.

A further extension of the time-delay up to 3.1 sec leads to

only slightly increased errors. More interesting to note, however, is the fact, that small local disturbances on the

Fig. 5 Comparison of Hybrid and Hydraulic Test, Delay 0.1 sec

measured water-levels at the coupling point, as for instance caused by air bubbles in the water, induce very heavy oscillations of the water-level. Though these mostly disappear after slack water, in general test run at this and further extended time-delays gave no satisfactory agreement with hydraulic model tests.

Fig. 6 Comparison of Water-Level, Delay 2.1 sec

Conclusions

A feasibility study was run on the realization of a hybrid model technique for open channel flow situations. An analysis on the time-delay, caused by the computation of the numerical model part, showed that for the system under investigation a delay of about 2 sec lead to an error of about 1.0% for the water-levels. This magnitude seems to be acceptable in practical applications, as it is of the same order, of which in many cases field data are. On the other hand a time of 2 sec allows for the computation of about 100 elements in the used numerical model. In many investigations this number is fully sufficient for a good representation of the far-field area of a system. So these results lead to the conclusion, that the hybrid model technique can readily be applied in practical investigations.

CHAPTER 200

PLANFORM INFLUENCE ON FLUSHING AND CIRCULATION IN SMALL HARBORS

by

Ronald E. Nece¹, Roger A. Falconer², and Toshiro Tsutsumi³

ABSTRACT

Laboratory data showing the influence of planform geometry on the tidal flushing characteristics of small harbors of simple surface shape. The tide ranges, water depths, and planform areas are typical of those encountered in small-boat marinas in Puget Sound, Washington. Each harbor investigated had a single, asymmetric entrance.

Flushing and circulation patterns within such harbors depend strongly upon the characteristics of the angular momentum established within the basin and upon the effective penetration distance into the basin of the stream of ambient water entering the harbor on the flood tide.

Experimental results confirm that best gross tidal flushing occurs when rectangular harbors have an aspect ratio L/B near unity, and that rounded interior corners of the basin has little effect on the gross tidal flushing but does improve local exchange. Aspect ratios L/B less than 3 lead to the creation of more than one circulation cell (gyre) within the basin.

INTRODUCTION

This paper reports on a laboratory study of tide-induced circulation in small, constructed harbors. Effects of wind and waves upon water motions within the harbors are not considered.

The study was keyed to the continuing demand for more small-boat marinas in Puget Sound, Washington. A common construction approach is to dredge the marina basin from a tideflat area, with the dredged material providing fill for parking lots, dry land work and storage areas, etc. A breakwater is provided on the seaward side, usually with a single asymmetric entrance located to provide best wave protection. Surface areas typically range from 10 to 30 acres, with provisions for from 200 to 800 boat moorages. Such marinas can truly be classified as "small" harbors.

Questions related to water quality are of considerable importance in

the planning and design of such harbors. Of particular concern in the Puget Sound area is the potential impact of water quality in marinas on fish, particularly migrating juvenile salmon. Poor tidal flushing can lead to detrimental algal growths and low dissolved oxygen contents, dangerous to the migrating fish. It becomes imperative in the design of new marinas, and in the design evaluation leading to the legal permission to proceed with construction, that both the gross tidal flushing and the local circulation patterns within the proposed basins be considered. The particular concern of the present study is the question of how much the basin planform geometry affects the overall exchange and the internal circulation patterns.

The approach followed has been to utilize physical models. Numerical modeling procedures have been employed to study flow fields in existing small harbors (e.g., Grubert (1)), but in order to predict actual water exchanges a convective-diffusion solution would have to be superimposed on the hydrodynamic solution. Efficacy of the numerical techniques depends upon a valid determination of the separation streamline of the flood currents around the edges of the harbor entrance and on the time-and-space unsteady circulation cell which is initially engendered by this separation phenomenon, as well as upon the correct representation of diffusion coefficients. For designed but not built basins, the physical model approach has been considered the more economical and graphical approach to a combination of design tool and screen (2).

The laboratory tests described here utilized single-fluid vertically distorted models with a 10:1 distortion ratio. Such models do not properly scale diffusion-dispersion processes (3); therefore, the assumption must be made the convective transport is the dominant mode of water exchange and that diffusion per se is of less significance, allowing the use of tracer dyes in the model. This assumption has been used in a number of specific model studies of tidal exchange in small harbors subject to fairly large tides, where tidal currents are the dominant circulation feature (2). Field verification studies of water exchange are still needed; the models do reproduce depth-averaged velocities in the small harbors (4).

Because the tidal currents are indeed quite strong in the basins modeled it is safe to ignore Coriolis as well as wind and wave effects, and because the basins are relatively short and deep the absence of a friction calibration is not viewed as a major concern. Results are restricted to non-stratified harbors having no fresh water inflow; this is indeed the situation for the well-mixed water bodies which have been investigated so far in the Puget Sound marina studies. These limitations are listed here because they do restrict the generality of the results.

RANGE OF TESTS

The laboratory studies were treated as model studies of idealized basin shapes. The scale ratios were 1:500 horizontal, 1:50 vertical. Tides were restricted to repetitive, sinusoidal tides of constant period of 10.52 minutes in the model corresponding, via Froude law scaling relations, to a 12.4-hour semi-diurnal tide.

Gross water exchange (flushing) was determined by measuring changes in the concentration of fluorescent dye Rhodamine-WT in the basin over a number of cycles. Ink dye was used for visual observation of internal circulation patterns. Laboratory techniques and details of the tidal model basin used have been described previously (2,4).

Flushing data are presented in terms of E, the average per-cycle exchange coefficient, defined as that fraction of the water in the basin at high water slack which is removed from the basin and replaced by ambient water during the cycle ending at the next high water slack. The choice of selecting the period from high-water to high-water is arbitrary, but leads to a simple comparison with the tidal prism ratio, defined conventionally as

$$\text{Tidal Prism Ratio (TPR)} = \frac{(\text{Basin Vol. at High Tide}) - (\text{Basin Vol. at Low Tide})}{\text{Basin Volume at High Tide}}$$

where the numerator is known as the "tidal prism." A "flushing efficiency" is defined as

$$\eta = \frac{E}{\text{TRR}} \times 100, \text{ percent}$$

and compares measured water exchanges with those predicted by the simple tidal prism theory.

Three planforms--rectangular, rectangular with rounded corners, and circular--were investigated. For simplicity, vertical walls and horizontal basin bottoms were used in all cases. The basin planforms and notation used are shown in Figure 1. Semi-circular "jetties" were used at the entrance in each case.

The basin area was maintained at 1.25×10^6 square feet (28.7 acres). The equivalent $L/B = 1.00$ basin (which was not tested) has a side length of 1180 feet, or approximately 0.2 mi. The mean depth d within the harbor was 16 feet, taken at mean water level. The three tide ranges used in the tests were: neap, 4 feet; mean, 8 feet; spring, 12 feet. These values are representative of small boat basins in Puget Sound. The range of L/B in the rectangular basin tests varied from 0.20 to 5.00, more than spanning the usual range of aspect ratios found in such small harbors with single entrances aligned with one side wall. Entrance widths w were 125, 250, and 500 feet; the first is the most representative of field dimensions, and is emphasized most in following results. Data are presented in terms of equivalent prototype dimensions.

TIDAL FLUSHING

Essentials of the flushing (water exchange) test results are summarized in Figure 2 on which are shown data for three entrance widths w , three tides H , for rectangular basins over the aspect ratio L/B range 0.2 to 5.0. No data points are shown on Figure 2; a representative set is shown on Figure 3, illustrating the degree of experimental scatter which can be obtained in the rather sensitive exchange tests.

A few conclusions are apparent. Over the range of L/B from $2/3$ to 3.2 there is relatively little variation in exchange coefficient E for a given tide range H . The overall flushing falls off markedly for L/B less than $1/3$ and greater than 3 . This trend holds for the narrow entrance widths w . The dip in the E -curve near $L/B = 1.0$ is confirmed by the test points in Figure 3. At the larger tides H , the narrower entrance generally produces better overall flushing. As H decreases, the flushing efficiency η increases; this behavior has been noted on model studies of specific marinas having the very short entrance channel lengths used in the present tests.

Effects of L/B and w noted above are linked to the angular momentum of the complex flow within the harbor. The preservation of this angular momentum, associated with the deflection of flood tide flows through the entrance, is especially important to the internal circulation and, hence, harbor flushing. Circulation cells, or gyres, are created on the flood tide flow by moments of effective stresses associated with flow separation past the breakwater. These cells grow in both circulation strength and in size until they occupy a significant part of the basin, and may persist well into the ebb phase of the tidal cycle. As a consequence of the angular momentum established within the basin, even in the absence of longshore currents ebb flows are often skewed instead of leaving the basin in a direction parallel to the entrance axis. Higher velocities occur near the basin perimeter, and lower velocities near its center. These conditions in some respects are comparable to those occurring when tangential entrance jets of small size are used to produce a slow-moving large-scale circulation in water supply reservoirs (5). This angular momentum allows the inflowing ambient water to sweep past a major portion of the interior boundaries of the basin without losing its identity through diffusion. Thus, factors which contribute to increased angular momentum would be expected to improve overall flushing.

A preliminary simple angular momentum control volume analysis was made which considered shear forces on the walls and bottom of the basin and pressure forces on the walls; these would enter calculations of angular momentum about a vertical axis at the basin center. While details of these forces were not considered because interior velocities were not known, it was demonstrated that the optimum rectangular planform for maximizing the interior velocities at any instant of time is a square, $L/B = 1.0$ (6). For a constant surface area A the square planform has the minimum boundary perimeter, so that for a given H , w combination there is the greatest possibility in such small harbors that the ambient water entering as a two-dimensional jet will be able to circumnavigate the basin. Water which so completes the circuit around the boundary has a velocity component along the breakwater side of the basin as it approaches the entrance from within (clockwise, in Figure 1); if this not fully mixed ambient stream reaches the entrance at about high water slack some of it will be deflected back into the basin but some will exit the basin and not accomplish any effective exchange. The dips on the E -curves near $L/B = 1.0$ on Figures 2 and 3 reflect this phenomenon.

The 125-foot entrance width w is narrow enough to lend itself to the above reasoning over the full L/B range tested, and the 250-foot width nearly so. For the 500-foot width, tested for the 8-foot tide only, at small L/B the entrance width approached L and for large L/B for the constant surface area the width w approached B , and in neither case do the foregoing angular momentum considerations apply. Actual entrance widths are seldom much less than

the smallest (125 feet) valve tested, due to navigation considerations.

The reason for the fall-off in E for L/B less than 1/3 and greater than 3 will be discussed in the next section.

Figure 4 shows there is little difference in gross flushing performance between the rectangular and rounded-corner basins of equal aspect ratio. The benefit of the rounded interior corners is that local separation zones, hence areas of relatively stagnant water, are eliminated; this is a point of concern to fisheries resource managers.

Figure 5 reflects the data of Figure 2, and indicates more clearly that the flushing efficiency for these short-entrance basins increases as the tide range H decreases. This is contrary to what can happen if entrance channels are longer or if exterior constraints such as a detached breakwater located athwart the channel axis impede the free exchange of basin and ambient waters, so that at the smaller tide ranges some of water exhausted from the basin on the ebb is returned to the basin on the flood.

Figures 6 and 7 indicate very little difference in the flushing performance of rectangular and rounded-corner basins with L/B = 1.0 and of a circular basin of the same surface area. At the "mean" tide of 8.0 feet flushing coefficients are nearly identical, and all exchange coefficients are above 80 percent. Extrapolation of these results to tide ranges of less than 4 feet may not be safe. It also is pointed out again that the combination of A, H, and d tested apply to limited geographical areas.

CIRCULATION PATTERNS IN HARBOR

Insight into the mechanisms of the tidal flushing process can be gained by considering the path and distance penetrated into the harbor on the flood tide by the inflow stream of ambient water and by relating this distance to the planform geometry of the basin. This section deals with a simple correlation of these quantities.

Experimental results are shown in Figure 8 for two tidal ranges for each of four harbor geometries. Small tubular drogues, weighted to provide adequate vertical penetration so that the drogues move with the local depth-averaged velocity, were released at the center of the entrance at the time of mean water level crossing and were tracked through the basin for the subsequent one-quarter cycle to high water slack. The locations of the drogues at one-eighth and one-fourth of the tidal period T after release are indicated, as well as the paths followed. The effect of doubling the range H from 4 feet to 8 feet is apparent.

For the elongated basins of L/B = 3.20 and L/B = 0.31, the drogue paths indicate how two circulation cells are developed in the harbors. For the inlet orientation shown the cell near the harbor entrance is clockwise in each case, while that in the rear portion of the harbor is counterclockwise. The drogue pathlines for these two configurations do not show that part of the ambient water stream does not follow the plotted pathline into the rear section of the harbor but rather moves into the gyre in the front section of the harbor. Figure 8 indicates pathlines for water entering at the time of mean

water level crossing. Ambient water entering the basin prior to this time on the flood tide has followed much the same path after initial development of the cell inside the harbor entrance; as a consequence, at the time of high water slack there are currents moving along the walls of the harbor and toward the mouth.

For purposes of comparison, a penetration distance p has been defined as the distance traveled along its pathline by a particle of water which enters the basin at the time of the mean sea level crossing, which for practical purposes in an entrance of the type used in the present study is the time of maximum velocity of the flood tide current. The flood current has maximum or near-maximum momentum at this arbitrarily selected but convenient time, and from consideration of conservation of momentum of the inflow "jet" it possesses the capability of penetrating a maximum distance into the basin in a finite time. The following simple analysis considers the penetration distance p at high water slack, a time $T/4$ after water entrance into the basin. Notation is shown in the definition sketch, Figure 9. The rounded jetties used in the tests minimized contraction of the inflow as it passed through the inlet, so that a one-dimensional condition of uniform velocity V_0 over the entrance area $w d$ could be a reasonable assumption.

The inflow stream initially flows parallel to one wall in the harbor planforms studied, but in all cases ultimately deflects from its initial direction. The choice remains, in a simple momentum correlation, whether to employ a wall-jet analysis or a slot-jet analysis. In either case, neither of which matches the physics of the tidal currents in the small harbors, the expression for the velocity v along the streamline of maximum velocity is

$$\frac{v}{V_0} = C \left(\frac{x}{w} \right)^{-1/2}$$

Values of the constant C are 3.45 for the wall-jet (7) and 2.28 for the slot-jet (8), respectively. Assuming that the steady flow relations can be applied to a water particle moving along this streamline, integration of the expression $v = dx/dt$ along the initial direction of motion, x , gives

$$x = \left(\frac{3}{2} C \right)^{2/3} V_0^{2/3} w^{1/3} t^{2/3}$$

It remains to relate V_0 to the tidal range and to the basin geometry. Applying the simple one-dimensional continuity equation for a sinusoidal tide of range H and period T to the basin of planform area A and inlet cross-sectional area $w d$ at the mean water level, V_0 at this time is given by

$$V_0 = \frac{\pi H}{T} \frac{A}{w d}$$

Interchanging the penetration distance p for the distance along the x -direction gives

$$p = \left(\frac{3}{2} \pi C \right)^{2/3} \frac{H^{2/3}}{w^{1/3}} \left(\frac{A}{d} \right)^{2/3} \left(\frac{\pi T}{T} \right)^{2/3}$$

where n = the fractional part of the tidal cycle after $t = 0$ at which p is evaluated.

The results of Figure 8 have been replotted in Figure 10, in which the maximum value $n = 1/4$ represents conditions at high water slack. The slot-jet value of $C = 2.28$ was used because it correlates more closely with the experimental observations; the wall-jet empirical constant C over-predicts the penetration. Numerical agreement with the jet models considered could not be expected, but the test results do show agreement in the form of the penetration distance vs. time relationships. Therefore, the form of the last equation given above can be used to predict changes in the ambient-water penetration into a harbor with variations in tidal range H or in harbor geometry parameters A , d , and w .

CONCLUSIONS

The effect of planform geometry upon the tidal flushing characteristics of small harbors with single asymmetric entrances has been studied for simple, rectangular basins in which wind and stratification effects are negligible and tidal action is the dominant flow-producing mechanism. When harbor aspect ratios exceed 3 or are less than $1/3$, multiple circulation cells exist within the harbor and the basin-average tidal flushing is reduced. So long as the aspect ratio is kept within these limits there is relatively little variation in the tidal exchange coefficient, E , with L/B for a given tidal range H , although best flushing occurs when the aspect ratio is close but not necessarily equal to unity, the value predicted by simple considerations of angular momentum of the internal tidal currents.

The experimental data indicate that rounding interior corners of the harbor does not improve the gross flushing. The elimination of sharp interior corners does, however, eliminate local stagnation zones and thus improves local water exchange and local water quality. This latter consideration is important to the safety of fish which pass through or temporarily reside in small-boat basins of the size range tested. In the Puget Sound area of Washington, this point is of particular concern in the safe migration of juvenile salmon. Figure 11 illustrates changes in typical marina planform shapes for small-boat basins in the Puget Sound region which have in some part been brought about by considerations of tidal flushing and internal circulation patterns, particularly the latter.

Results of this study may be used to answer some of the hydraulic questions considered in the design of such harbors and may reduce the need for individual model studies on a case-by-case basis.

ACKNOWLEDGMENT

The experiments reported were conducted in the C. W. Harris Hydraulics Laboratory, University of Washington, Seattle, U.S.A.

COASTAL PROBLEMS IN SRI LANKA

Frans Gerritsen¹ and Summa R. Amarasinghe²

ABSTRACT

As an island state with about 900 miles of coastline, Sri Lanka is endowed with a large natural resource: its 720 miles of sandy beaches. The coastal zone is under stress by a burgeoning population, living in the coastal belt, and a variety of other demands with conflicting interests. Due to natural causes and interference of men, erosion is a serious problem in the densely populated southwest part of the island.

This paper describes the principal characteristics of the coastal environment and discusses the nature of some of the basic problems. In the recommendations, emphasis is placed on the setting up of an organizational structure to study the problems, both in the field and in the laboratory, with respect to the management aspects in the coastal zone.

INTRODUCTION

The island of Sri Lanka, 25,000 square miles in area with a coastal perimeter of about 900 miles (at least 80% of which are sandy beaches) is located at the southern tip of India; it lies between 6° and 10° north latitudes and between 79° and 82° east longitude. It has a population of 13 million and of this as many as two million are concentrated in the southwestern coastal belt up to a distance of 100 miles south of the capital city of Colombo (see map, Fig. 1).

A coastal retreat, due to erosion by the sea (at one point up to 1,000 ft in the last 50 years), has resulted in the loss of several square miles of the coast especially in the densely populated southwestern region. Of the several protective structures, viz. boulder revetments, sea walls and later on groins, erected in the last few decades only some were successful in combatting the erosion problem. In more recent times the problem has been aggravated by both the direct and indirect consequences of sand and coral mining and other engineering and industrial activity in the coastal zone by numerous individuals and organizations. The rapid development of the country's tourist industry in the last decade has had its impact on the coastal zone. The preservation, restoration, and environmental control of the beaches and above all the effective management of the coastal zone has high priority in the country's development plans.

It was obviously futile to permit illegal and uncontrolled operations to continue on the coast and then spend large sums of money to protect the coast. In addition, existing legislation for seashore protection was weak, while a solution was also necessary for the socio-economic problem of those engaged in the illegal mining of sand and coral for a livelihood. In this connection,

¹Professor, Dept. of Ocean Engineering, University of Hawaii.

²Head, Coast Conservation Division, Colombo Port Commission, Colombo, Sri Lanka (formerly Ceylon).

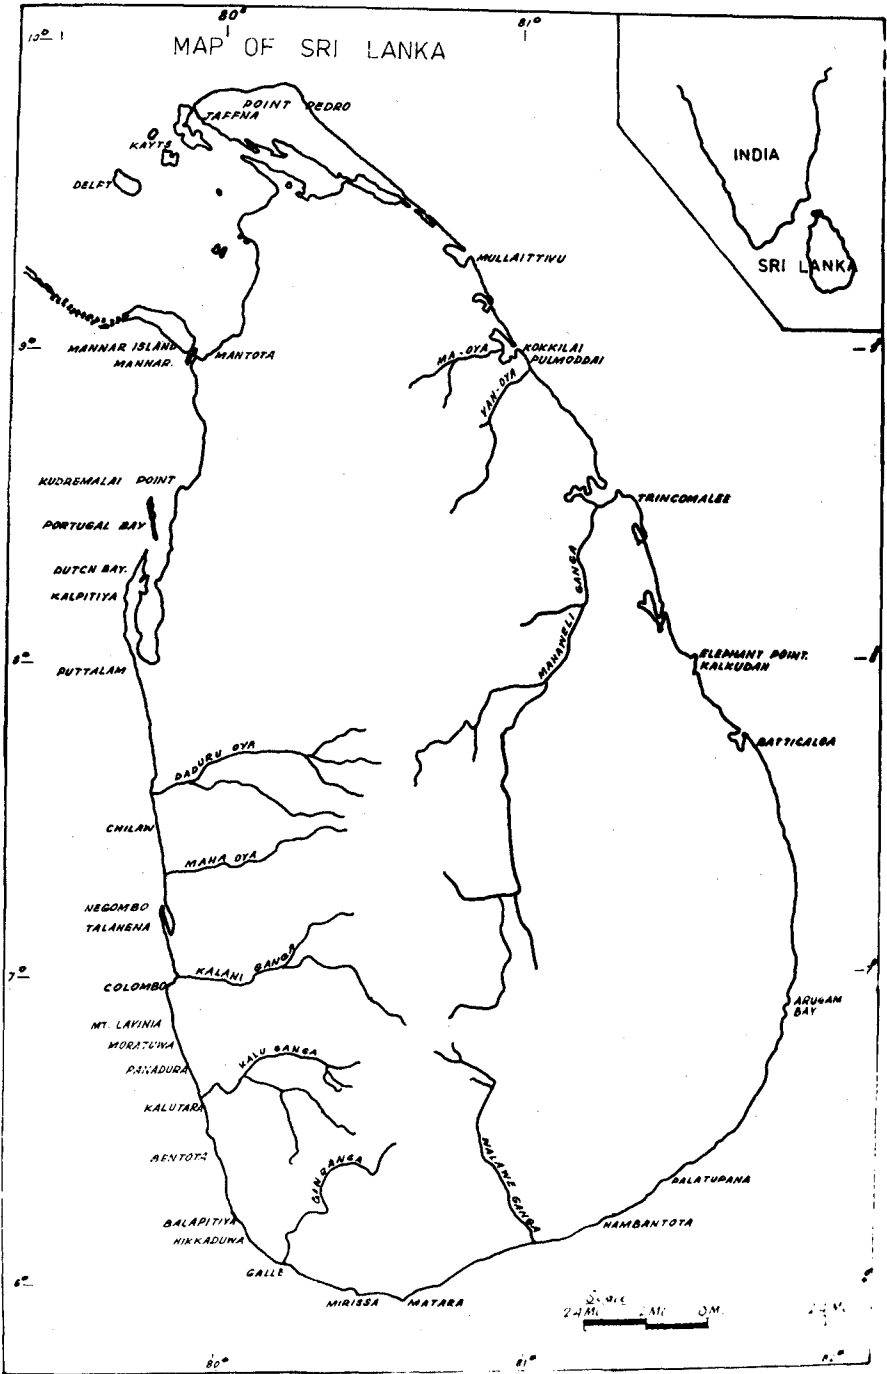

FIG. 1 MAP OF SRI LANKA

proposals made by the Ministry of Shipping and Tourism three years ago and accepted by the government consisted broadly of: (a) the creation of a single authority to control, regulate and coordinate all activity within the coastal zone which may have adverse effects on coast conservation in Sri Lanka; and (b) the framing of separate legislation for the conservation of the country's coast.

Action as proposed above was pursued by seeking assistance from the United Nations for the services of an expert in coastal engineering. In this capacity the senior author spent three months in Sri Lanka (July - September, 1974) to study the coastal problems, to recommend solutions and to make appropriate recommendations for a Coastal Zone Management Program in Sri Lanka. Furthermore, the Colombo Port Commission and the Ministry of Shipping and Tourism, in collaboration with the country's Legal Draughtsman's Department drafted new legislation for coast conservation in Sri Lanka. This draft legislation is now awaiting debate in the country's National State Assembly.

DISCUSSION OF ENVIRONMENTAL FACTORS

Prior to discussing the particular coastal problems in the State, this section provides information on the environment and the general characteristics of the littoral drift.

Geology

The major portion of the island (about nine-tenth) consists of crystalline rocks of Archaean age, with narrow belts of sediments in the coastal zone [1]. Extensive development of sedimentary rock is found along the northwest coast of the island, where limestones of Miocene age are found. Beaches are found all around the island. Along considerable portions of the west coast a shallow coastal reef of sedimentary sandstone of recent age is found. This reef has been a stabilizing factor against beach erosion. The reef runs parallel to the shoreline between Colombo and Mt. Lavinia; at other locations (Negombo, North of Colombo) it makes a small angle with the present shoreline.

Along the greater part of the southwestern and eastern shoreline, beaches are situated between rocky headlands of gneis or granite. In many locations, beaches are backed by lagoons, estuarine deltas and marshes indicative of progradation and coastal rectification that followed a phase of submergence [1]. Cliff coasts occur in the south of the island between Dondera and Tangalle and in the Trincomalee area on the northeast coast.

As to the possibility of tilting of the island around an east-west axis (between Colombo and Pottuvil) with the southern portion of the island going down, this theory has been dismissed by Swan [1]. Instead there seems more evidence for a steady rise in sea level in post Würm times, with minor oscillations superimposed thereon.

The present phase of increased erosion seems due to a slight rise in sea level since the mid-19th century.

Coral reefs are found along parts of the west and east coast. Most coral beds are dead but live coral is still found near Hikkaduwa on the southwest coast and near Trincomalee on the east coast.

Winds and Waves

There are two distinct climatological periods--the southwest monsoon from May to September and the northeast monsoon from November to January. Waves from the southwest are predominant during the southwest monsoon, although waves from the northwest occur occasionally. Winds from the southwest are considerably stronger than from the northeast and the wave conditions on the west coast during the southwest monsoon are more severe than on the east coast during the northeast monsoon. In both cases, the height and period of the significant waves are somewhat reduced during periods of high wind speed due to a limited fetch length, so that the condition of a fully-developed sea will not be reached (Fig. 2).

Waves from the southwest have a median significant height of about 5 ft with a significant period of 5 1/2-6 sec; whereas, waves from the northeast have a median significant wave height of about 3 ft with a significant period of approximately 4 1/2 sec.

In addition to the waves generated by the wind there is the southern swell (from directions between south and southeast), originated by winds and storms on the southern hemisphere. It has a significant effect on the direction and magnitude of the littoral drift.

Tides and Currents

Tides are predominantly semi-diurnal; the tidal range varies approximately between 1.5 and 2.0 ft during spring tides and between 0.3 and 0.8 ft during neap tides [2]. In addition, there is a small seasonal variation.

General ocean circulation around Sri Lanka depends on the monsoon season, as shown in Fig. 3. In a study on oceanographic conditions [3] currents along the west coast were found to run in northerly direction during the southwest monsoon and in southerly direction during the northeast monsoon. The strength of these currents was usually less than 0.5 ft/sec in the Colombo area, but got as high as 1.7 ft/sec in the Galle area. Occasionally considerably higher values (up to 2.9 ft/sec) were observed for no obvious reasons.

Tidal currents become important in the vicinity of tidal inlets and at the mouths of bays and lagoons. Near the breaker zone, wave induced currents become significant and are a primary cause for the movement of sand along the shoreline.

Rainfall and Hydrology

Rainfall is heavy in the mountain areas of the central part of the country, about 100 inches per year, and very heavy on the southwestern slopes of the central hills (up to 200 inches per year). In the coastal belt it averages 50 inches per year. The extreme southeast and northeast coastal zones are dry; the annual rainfall there is below 50 inches.

FIG. 2 WIND CIRCULATION PATTERNS IN INDIAN OCEAN

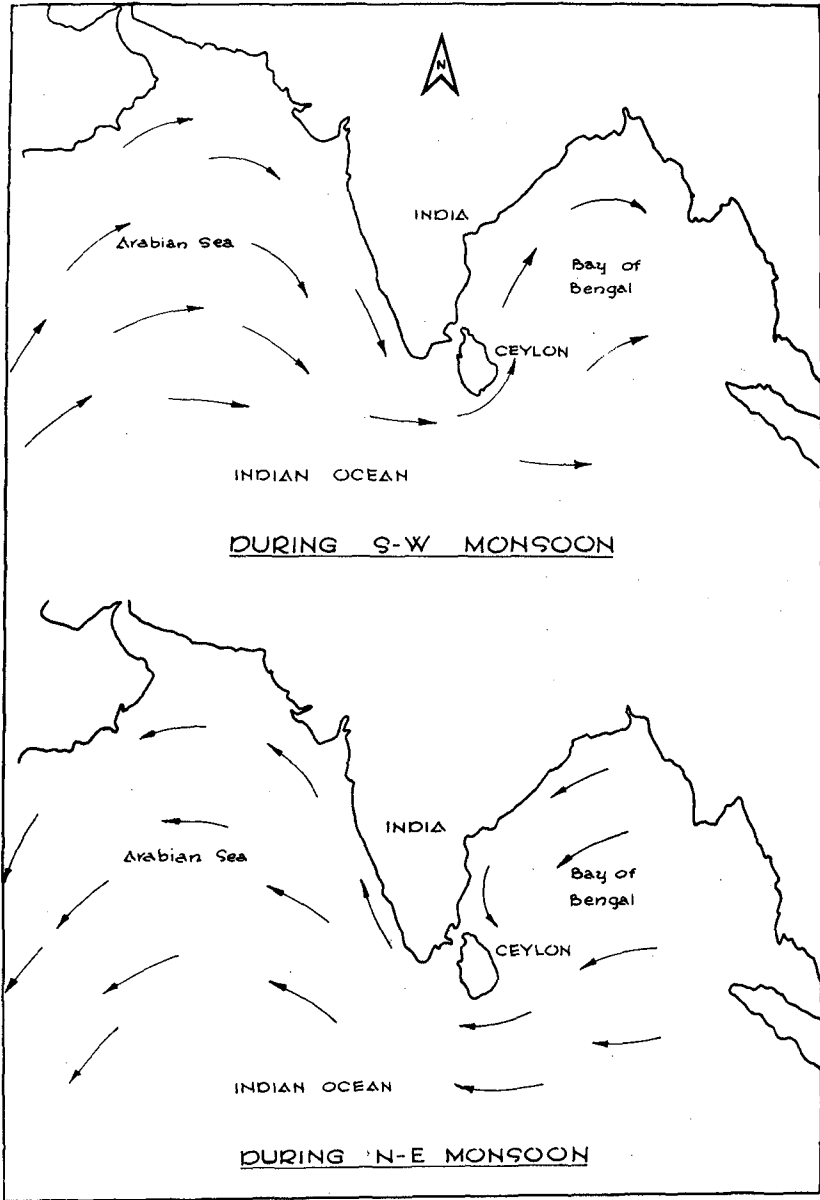

FIG. 3 OCEAN CURRENTS OFF SRI LANKA

The greater part of the precipitation in Sri Lanka returns to the atmosphere through evapotranspiration [2]. The remaining part is discharged to the ocean by a number of rivers of different sizes, which originate in the central highlands and flow toward the coastline. The largest rivers are the Dadura Oye*, north of Chilaw; the Kalani Ganga*, north of Colombo; and the Kalatura Ganga, all on the west coast and the Mahawela Ganga, flowing into Trincomalee Bay on the east coast. These rivers carry large amounts of sediment (sand) to the various coastal sections.

In a number of locations the rivers discharge their sediments into a coastal lagoon where part of the sediment load is temporarily deposited. The steeper the river, the greater the current velocities and the larger the size of the sediment particles that can be transported.

Littoral Drift

The wave climate responsible for the littoral drift along Sri Lanka's shoreline is strongly related to the monsoon periods. Along the west coast the southwesterly waves induce a littoral transport in a northerly direction. Occasionally the drift is reversed during periods of northwesterly storms. The northerly drift is reinforced by the effect of the southern swell for most of the west and southwest coasts. Locally the littoral drift is reversed due to wave refraction and/or diffraction.

During the southwest monsoon, the southwest coast of the island has a nodal point of the littoral drift in the vicinity of Hikkaduwa (see Fig. 1). North of this point the waves are moving sediments in northwesterly direction, south of there in southeasterly direction. In the vicinity of a nodal point the sediments transported by the waves must be supplied from upland or from local sources and often this supply is not adequate to meet the demand. The rate of erosion in this area is the largest in the State (see Fig. 4); in addition, natural erosion here is reinforced by offshore mining of coral. Along the east coast the drift is predominantly to the north during the southwest monsoon under the effect of the southern swell. During the northeast monsoon the transport is basically southward under the predominant effect of the wind-generated waves from the northeast. The southeast coastal area of the state is an area of deposition, as is the northeast coast of the Jaffna Peninsula.

PROBLEMS IN THE COASTAL ZONE

Erosion

The causes of erosion in Sri Lanka can be broadly classified as due to: (a) natural erosion, (b) erosion and sedimentation due to man-made activity, and (c) erosion due to biological activity.

Natural erosion has manifested itself in the formation of a series of bays on the southwest coast suspended by rocky headlands most of which form reasonable stable shorelines. The eroding tendencies of convex shorelines have also resulted in the long term in the creation of several exposed reefs especially on the southwest coast where beach material has been removed by currents over the years. These shorelines have had to be protected by the construction of revetments and in some places by groins.

* Local words for "river".

FIG. 4 TYPICAL SHORELINE CHANGES (rates of erosion or accretion) SINCE 1910

Another aspect of natural erosion is the cyclic changes of shorelines adjacent to tidal inlets. An example of the latter is the erosion pattern at the Kalutara inlet where the Kalu Ganga, which discharges the largest volume of water in Sri Lanka, has a fluctuating river mouth. Coast erosion of the adjacent shoreline occurs either on the north or south shores depending on the position of the inlets and the mechanism of the littoral drift in its vicinity. The inlet or river mouth is also called outfall because it allows the discharge of flood water into the ocean. Reference is made to the following section for further discussion.

The existence of a deep canyon or a deep harbor entrance traversing the coastline may act as a barrier to the littoral drift resulting in erosion of the downdrift shoreline. Such a barrier most likely exists in the entrance to Trincomalee Harbor on the east coast, where the predominantly northerly drift caused by the southern swell is interrupted by the over 100-fathom deep entrance to Trincomalee Harbor. Erosion of the shoreline to the north of Trincomalee as seen in Fig. 4 seems to be the result of this condition.

By far the largest contribution to problems of erosion and sedimentation of the island's shoreline has been made by the interference by man with the natural processes that occur in the coastal zone. Such activity in Sri Lanka has consisted of: (a) the legal and illegal mining of sand and coral from the coastal zone, the latter usually by the destruction of reefs; (b) construction of training works at outlets of rivers and streams for drainage purposes without adequate consideration of the consequences to the adjacent shoreline; (c) construction of fishery harbors to meet demands of national priorities without adequate investigation and study; and, (d) the construction of emergency protective works against sea erosion, such as groins and seawalls, to satisfy pressures resulting from the density of human habitation in the coastal zone and which in the long term have adverse consequences on adjacent coastal areas. The problem has been aggravated in recent years especially with the development of the tourist industry and the consequent demand for beach-oriented recreation areas. These and the siting of several activities conflicting with one another in coastal areas, with little concern for coast conservation, have led to the urgent need for coastal area planning. Examples of some of these problems are described later in this section.

The biological reason for erosion mentioned earlier is the destruction of some of the reefs in the Trincomalee area of the east coast by the coral eating starfish (*Acanthaster Planci*). The starfish found abundantly in this region are since 1974 being collected and destroyed under a program executed by the Fisheries Department. In 1974 a team of six divers collected and buried about 24,000 starfish in a period of about three months. It has been suggested that a likely cause for the outburst of starfish attack since about 1972 is a direct consequence of the collection of tropical fish for export (an expanding activity in recent years), some of which are the natural predators of the starfish larvae. Investigations made by the Fisheries Department over the last two years have revealed that the presence of starfish is fortunately confined only to the Trincomalee region of the island's coastal waters giving rise to the hope that the present program of eliminating this menace would have successful results.

Coastal Inlet ProblemsKalutara Inlet

An excellent example of unplanned activity in a coastal area resulting in multiple-use conflicts is found at the outfall of the Kalu Ganga, one of the island's major rivers. Figure 5 shows five significant positions of the outfall between 1921 and 1976. In 1921 the outfall was at the northern extremity of the barrier beach and the lagoon had been enclosed by the sandbar to form a lake. Changes between 1921 and 1931 resulted in the re-opening of the lagoon and the migration of the outfall to the south combined with a seaward shift of the southern sandbar. The migration to the south continued until 1940 when the outfall was close to the southern extremity, at which stage the outfall was diverted back to the north by artificially opening up a channel close to the northern end. The migration to the south increased rapidly thereafter and the outfall shifted back to the southern end by 1943 where it remained until after 1954, when once more a northerly shift was affected by artificial means. From 1926 to 1940 the position of the outfall oscillated between north of mid-way to the northern end. It was during this period that severe erosion was experienced on the shoreline to the north of this area, necessitating the construction of a field of groins which was successful to arrest the local erosion. After 1940 the southerly migration commenced once more up to the present position of the outfall at a point south of the mid-way mark. This time, however, the effects were going to be disastrous as an entrepreneur had obtained a lease of the land on the southern sandbar from the Government Agent of Kalutara (the Chief Executive of the Government's district administration) in 1973, and with foreign collaboration had commenced the building of a 72-room hotel (to service the growing tourist industry), at an estimated cost of one million US dollars. He then found to his alarm that the outfall was migrating towards his hotel site and his land area was dwindling daily until in 1976 the distance of the outfall from the hotel had reduced to 410 feet. Based on a plan prepared by the Coast Conservation Division of the Colombo Port Commission, the entrepreneur undertook the construction of a combination of boulder groins and rubble revetments to hold the head of the southern spit from further recession and to train the outfall of the river at this point. The first phase of the project has been successfully completed and the immediate danger seems to have receded. These protective works are estimated to cost 50,000 US dollars, which is 5% of the main investment on the hotel. An interesting aspect of this problem was that in view of the heavy river discharge and the periodic flooding of low-lying land in the coastal zone upstream, the need to train the outfall was always under consideration by the Department of Irrigation (vested with the responsibility for inland waterways). The need for costly and time-consuming hydraulic studies and the absence of habitation and activity on the migrating sandbars presumably lent low priority to the study of this project. The lack of coastal area planning becomes apparent when considering the fact that neither the Department of Irrigation nor the Coast Conservation Division were consulted prior to the commencement of the hotel project either by the entrepreneur or the local approving the project. To complicate matters further, a fishery harbor consisting of a channel from the sea to the lagoon, its entrance protected by two breakwaters projecting to the sea complemented by an offshore breakwater parallel to the shoreline was proposed for construction at a point south of the hotel, with a view to using the lagoon for the mooring of craft. The obvious consequence of this proposal would have been downdrift beach erosion north of the breakwaters to additionally affect the

hotel from the seaside. Even if the hotel project was not undertaken, it was clear that the fishery harbor proposal had to be studied together with the project of training the outfall and an investigation of the effect on the adjacent shoreline, in order to obtain a meaningful solution. Fortunately, action on the harbor proposal has been deferred pending further study. The total problem of the Kalutara inlet demonstrates so very well the need for and importance of integrated field and laboratory studies, as well as coastal zone management.

Panadura Inlet

The Panadura outfall (Fig. 6) drains the waters of a large inland lake bordered by several acres of cultivated paddy land. The runoff being low during the non-monsoonal period on the west coast (i.e. from October to April), the outfall tended to close up with the formation of a sandbar as the tidal prism is insufficient to keep it open by means of tidal flushing. The consequence of this situation was the destruction of vast tracts of paddy land by flooding, usually at the commencement of the monsoonal rains. It was usual to open the sandbar by mechanical means to drain the flood waters, but this was too late to prevent the damage. The Department of Irrigation therefore constructed a groin or jetty on the south bank of the outfall to train the waters to keep the outlet always open by means of tidal flushing. This project was completed a few years ago and has successfully achieved the objective of a permanently open outfall. In addition, this has facilitated the navigation of fishing boats to mooring areas within the river throughout the year; a boon to dwellers of this area engaged in the fishing industry. An adverse consequence of this project, however, has been the severe erosion of the shoreline to the north caused by a partial interruption of the littoral drift (despite the beneficial effect on a "clair voie", an opening in the updrift jetty, that promotes sand bypassing to the downdrift coast) and a change in the littoral drift gradient along the downdrift coast. The Coast Conservation Division has since been engaged in the construction of protective works in the affected area utilizing its own funds. Artificial nourishment would provide an attractive solution in this case, dredging sand deposits from the inlet and from the lagoon and pumping these to the downdrift shore. A small dredge suitable for this work is presently available in Sri Lanka. The outfall scheme had obviously not taken into account the problem of this consequence when studies for the outfall design were carried out--another example of poor coastal area planning. The economic evaluation of the original project needs then to be reviewed to accommodate the additional cost of the coast protective works. Several problems of a similar nature exist, while the construction of several outfall works schemes around the island are envisaged. It is hoped that this short fall in planning would be recognized and corrected in the design of future works.

Fishery Harbors

As an example of a coastal fishery harbor, the harbor at Tangalle will be discussed (Photo. 4). Tangalle is a seaside town, 22 miles east of the southern tip of the island; it has an expanding fishing industry, therefore, the site was chosen for the construction of a fishery harbor in 1964, as one of the first of a network of such harbors planned for the development of the island's fishing industry. Local pressures compelled the government to direct

the immediate construction of this harbor precluding the apparent luxury of time-consuming pre-design studies. Based on a hydrographic survey chart, the layout was planned to consist of a main breakwater parallel to the shoreline partially enclosing the bay and a second minor breakwater at right angles to the shoreline and within the shadow of the main breakwater. Adequate depths existed in the bay to accommodate the class of craft catered for and the need for dredging was minimal. The usually closed outfall of an apparently small stream (but with an appreciable sediment carrying capacity during heavy rainfall), was presumably ignored as inconsequential during the short time available for planning and design, and the design seemed to lay stress on protection of the harbor from wave attack only. There was, in addition, a littoral drift from east to west during the northeast monsoon to be reckoned with. The result of the construction (the main breakwater first) was the rapid silting-up of the harbor even while construction was progressing. A quick solution was necessary and it was decided to block the littoral drift and divert the river discharge by the construction of another breakwater normal to the shoreline on the west bank of the outfall. Providentially, success was immediate, when in addition to overcoming the sediment problem, a beach built itself up between the breakwaters normal to the shoreline, and this proved to be an excellent spending beach for the dissipation of wave energy. Dredging of the harbor has since been undertaken in a reduced water area as shore structures have been built in areas reclaimed by the unexpected siltation. The almost ideal layout of the harbor as it now stands, achieved by accident, has entailed considerable additional expenditure. The importance of pre-design study has now been realized by those concerned as an essential ingredient in the economy of coastal engineering structures.

Coral and Sand Mining in the Coastal Zone

This activity although illegal for most areas has been carried out in particular areas for several decades and the consequences of which are now proving to be serious especially in areas with strong tendencies for natural erosion, e.g. the southwest coast of Sri Lanka.

Coral mining (providing lime for the building industry) has been concentrated within a coastal area about 22 miles north of Galle on the west coast. Coral is obtained by breaking the reef with sharp instruments and by digging in the nearshore and low-lying coastal areas. The excavated material is then burnt in neighborhood kilns and the extracted lime (calcium oxide) is supplied by the producer to the building industry usually through middlemen. It has been estimated that the quantity of coral removed from this area exceeds 75,000 tons per year. This in turn represents a retreat inland of the affected 6-mile stretch of shoreline of about 6 ft per year, only taking into account the sand required to fill in the gaps, while the effect of weakening the protective function of the coral reef and the removal of coral from the littoral drift will be additional in the occurrence of erosion. It has been further estimated that about 20,000 people in this area are dependent on this illegal activity for their livelihood. While existing legislation is weak and new legislation has been prepared, solution of the socio-economic problem is primary in eliminating this destructive activity. As a large percentage of lime for the building industry is supplied from this area, alternative sources of this material have been proposed to meet the demand when coral mining activity in the coastal zone is terminated.

Sand mining, mostly illegal, is also carried out extensively in the coastal zone, especially at the Kelani river outfall, the Kalutara inlet, and south of the Panadura outfall on the west coast. The total quantity mined from these areas would exceed 325,000 cubic yards per year, while legal mining at Pulmoddai on the northeast coast by the State Mineral Sands Corporation for extraction of ilmenite, rutile and zircon, accounts for about 200,000 cubic yards per year in a three mile stretch of foreshore and backshore areas. The consequences of the latter operation will need to be considered in the economic evaluation of the mineral extraction project. The new legislation provides for the control of sand mining in the coastal zone and as before alternative sources have been proposed to meet the commercial demand for sand.

POTENTIAL OF SRI LANKA BEACHES FOR RECREATION

Sri Lanka possesses a number of beautiful beaches and an attractive climate for vacationing. The temperature of the water of the ocean varies between narrow boundaries and is therefore attractive for swimming. Calm sea conditions and gently sloping beaches are present on the west coast during the northeast monsoon and similarly on the east coast during the southwest monsoon. Beach-oriented resort development has taken place in Bentota and Negombo on the west coast, and Kalkudah and just north of Trincomalee on the east coast. The better beaches are found on the east coast where many of them are yet unspoiled by man in the sparsely populated areas where access is hindered by low-key communication development. Arugam Bay on the east coast and the region between Galle and Matara on the southwest coast are other beach recreational areas gaining in popularity in recent years.

Resort developers have sought the assistance of the Coast Conservation Division for the provision of safe bathing areas during the monsoonal period of such areas and for neighborhood beach development. In many such cases, studies are to be undertaken for optimum solutions to be determined, while the topography of some areas have lent themselves to evolving solutions both economical and unusual. An example of the latter is the building of a "sea-pool", where only a narrow beach exists at present on a sandstone reef which drops sharply into the sea making any attempt at swimming a hazardous exercise. A bathing enclosure was therefore excavated by blasting an area 150 x 50 ft out of the sandstone ledge (leaving adequate seaside cover for coast protection) and removing a 6-8 ft layer of sandstone down to the sand base below, which provides bathing depths up to about 8 ft. Sea water enters the pool through a natural inlet at one end and wave attack (when present), is controlled by artificially placed boulder protection on the seaside edge of the sandstone ledge.

PLANNING GUIDELINES PROPOSED

Interest shown by those concerned in the conservation of the country's coast led to the development of a United Nations project in 1974 for the solution of Sri Lanka's coastal problems. The expert's recommendations include the establishment of a Coastal Engineering Research Center to be

located within a separate administrative organization for Coast Conservation, along with training of local personnel and curricula development in Coastal Engineering at the University of Ceylong, as the main features of the Program. Complementarily, new legislation titled "Coast Conservation" was prepared and is now awaiting debate in the country's legislature.

The main provisions of this law are:

1. The appointment of a Director of Coast Conservation to be statutorily responsible for the control and management of the coastal zone and the permitting of all schemes of work therein.
2. The creation of a Coastal Advisory Council to advise the Minister in charge of the subject on matters concerning coast conservation.
3. The control of excavation of material within the coastal zone.

Major uses in the Coastal Zone of Sri Lanka that would need to be considered to define shore objectives are: recreation and aesthetic aspects; resource extraction; waste disposal; transportation; residential, commercial, and industrial development; and ecological aspects. After examining techniques for achieving the objectives, a coastal area management plan would be formulated for the purpose of implementation. Some of the studies considered immediately necessary for this Plan are:

1. Physical information of the coast to include an inventory of all maritime structures in Sri Lanka.
2. An estimate of annual mining of coral and sand and the corresponding demand of the building industry.
3. Alternative sources of sand and lime for the building industry.
4. A census of those engaged in illegal mining of coral and sand and the provision of alternative sources of employment.
5. A benefit/cost evaluation of maritime structures built for coast protection in Sri Lanka.

CONCLUSIONS AND RECOMMENDATIONS

1. The coastal zone is of increasing importance for Sri Lanka as a natural resource and deserves careful management and protection.
2. Coastal erosion is a serious threat to the beaches of the State, and particularly to the southwest coast, which is the area of highest population density. Three causes of erosion may be distinguished: natural erosion; man-made erosion; and erosion due to biological activity.
3. Among the adverse effects of the actions by men, most significant are the construction of ill-designed harbors and coastal protection works (seawalls and groins) and the mining of sand and coral from various coastal areas.
4. Solution of the various problems can only be found after a thorough understanding of the coastal processes is obtained. Such understanding may vary between the realization of possible adverse effects of a groin or groin system on the adjacent beaches and the complexities of the sediment transport mechanism in natural inlets or constructed outfalls.

5. The construction of seawalls too close to the waterline as a measure of coastal protection is usually ineffective; it possibly induces increased erosion. Measures to cope with bluff erosion should be tied in with a scheme to stabilize the beach.

6. The mining of sand or coral from eroding areas should be prohibited.

7. Schemes of new fishery harbors on the southwest coast should be based on the results of careful analysis of the sediment transport of the coastal regime. This will usually require both field and model studies prior to the design and construction.

8. For the study and planning of coastal measures the organization of a Coastal Engineering Research Center is recommended. Such a center will be charged with the field and model studies and will give guidance to the branches engaged in engineering design.

9. To solve the problems associated with the conflicting demands on the coastal zone the establishment of a Department of Coast Conservation is recommended under the Ministry of Shipping and Tourism with the power to define priorities and prepare new legislation.

10. For the staffing on the new research center it will be necessary to establish educational programs in coastal engineering at the various campuses of the University of Sri Lanka. The educational aspects will also include training of coastal engineers abroad.

ACKNOWLEDGEMENTS

The authors wish to thank the UNOP for supporting the Sri Lanka Coastal Engineering Project and the Government of Sri Lanka for initiating action on this study. Special thanks are due to Mr. P.B. Karandawala, Secretary of the Ministry of Shipping and Tourism, whose active interest since 1970 and the assignment of high priority to the country's coastal problems contributed greatly to the positive action in the field of coastal area planning.

The authors record their deep appreciation of all the assistance given and contribution made by Mr. H.V. Dayananda, Engineer Coastal Research and Investigations of the Colombo Port Commission, and his team of Port Commission Hydrographers, in the collection of data, and the preparation of maps, photographs and diagrams. Thanks are also due to the Colombo Port Commission without whose facilities this work would not have been possible.

The authors thank Mildred Frank of the Department of Ocean Engineering for the typing of the manuscript.

CHAPTER 202

ENVIRONMENTAL IMPACTS ON AN ISLAND COMMUNITY

Gordon A. Chapman¹

INTRODUCTION

The environmental impacts of coastal engineering projects generally affect island communities to a greater degree than they would affect continental land mass communities. This occurs because of the smaller land area; close interdependence and interaction of land and sea communities, both natural and human; and relatively small projects having relatively large overall impacts on island ecosystems.

The natural flora and fauna of Pacific Islands have developed rather precariously unbalanced communities that are extremely fragile and susceptible to change, both natural and man induced. This susceptibility dictates that, where possible, man induced or proposed changes, such as coastal engineering projects, should be designed such that as little change as possible occurs to the natural environment. Additionally, the natural resources of island communities are generally limited and this too dictates that conservation practices be employed that assure the highest and best use of those limited resources.

The purpose of this paper is to indicate the environmental effects of a major coastal engineering project on an island community. This will be accomplished by describing the environmental quality control monitoring program that has been performed as an integral part of the Honolulu International Airport (HIA) Reef Runway construction project on Oahu, Hawaii, and presenting the initial findings of that environmental monitoring program.

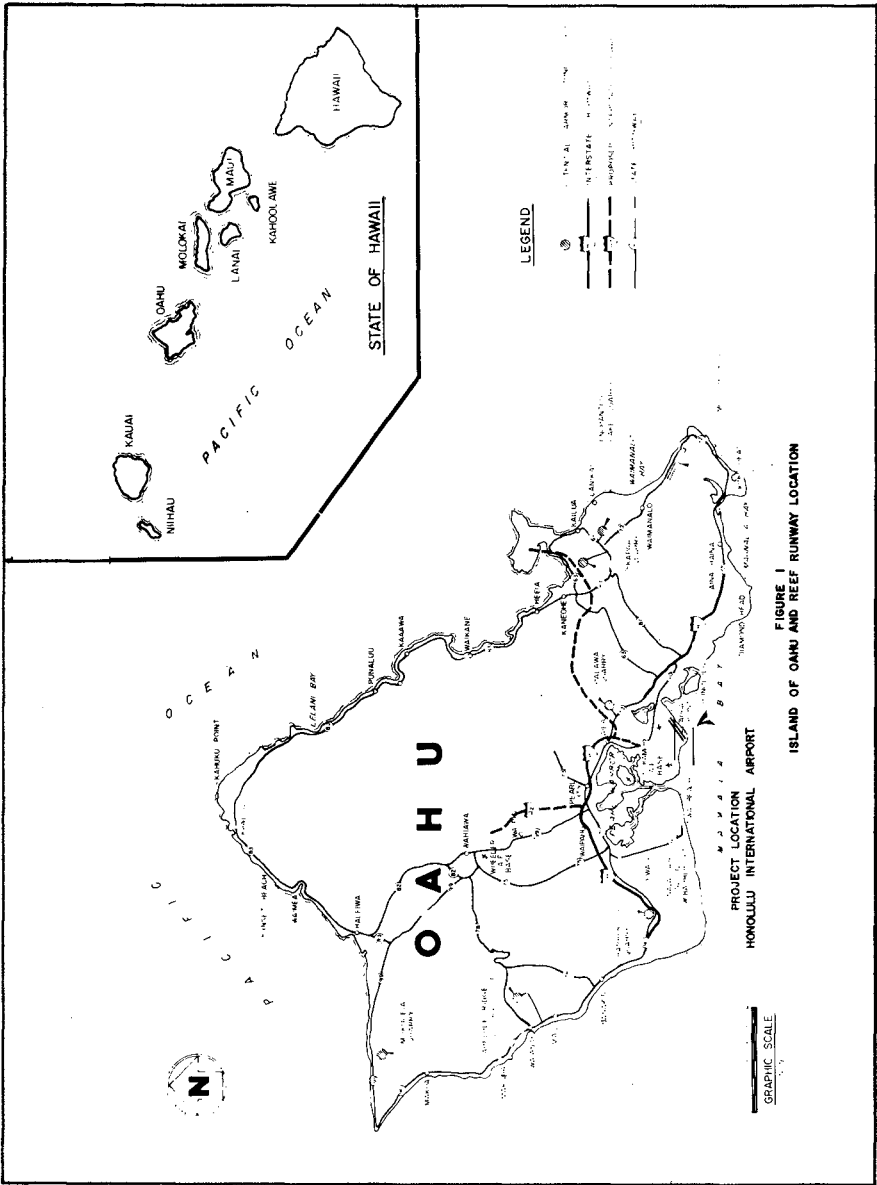

The Honolulu International Airport reef runway planning and design began in earnest in 1968 and 1969 with hydrographic and topographic surveys, foundation investigations, two- and three-dimensional hydraulic model studies, and environmental studies that were conducted (J. K. K. Look, 1970; Berger, 1971; Sunn, et al, 1969). These studies, and others, were utilized to determine the technical feasibility, and to gather the engineering and environmental data for final design and construction.

The Reef Runway, located south of the HIA runway system on the fringing coral reef, seaward of Keehi Lagoon, in Mamala Bay, is 12,000 feet long and 200 feet wide. The runway and taxiway complex is protected from the sea by a 16,000-foot long protective structure constructed of rock and dollose (Figure 1).

MATERIALS AND METHODS

The Reef Runway environmental monitoring program began during the 1970-1972 period when various oceanographic, marine biology and ecology, water quality, and avifauna baseline studies were conducted (J. K. K. Look, 1971; Berger, 1971; Harvey, et al, 1971; Sunn, et al, 1972a; Bathen, 1970). During the initial planning and design

¹Senior Environmental Analyst, The Ralph M. Parsons Company, Honolulu, Hawaii.

phases of the Reef Runway project, and during the preparation of the Environmental Impact Statement (Federal Aviation Administration, 1972), it was determined that extensive baseline studies as well as a construction period monitoring program were required. The baseline studies were needed to adequately describe existing conditions and to predict probable environmental impacts of the project, and the monitoring program to ensure compliance with all applicable State and Federal environmental protection regulations during construction activities.

The "during construction" water quality monitoring program was initiated in June, 1973, approximately one month prior to the start of construction and continued until August 30, 1976, approximately one month following major offshore and onshore construction activities. The program consisted of bimonthly water quality sampling, initially at 19 preselected stations, and finally at 13 of the original stations and one added station (Figure 2). Dissolved oxygen (D.O.) was measured using a Yellow Springs D.O. probe and turbidity measured with a standard 30 c.m. diameter Secchi disk. In-situ measurements of temperature and salinity were made utilizing a Beckman in-situ thermister probe and induction salinometer. Laboratory measurements of pH, total phosphorus, and total Kjeldahl nitrogen were made. Station depths varied from 6 feet to 45 feet, with most being 15 to 20 feet. All in-situ measurements and water samples were taken at mid-depths. Sampling was accomplished at different times of the day and at varying tidal, wind, and weather conditions.

Water quality sampling was conducted on 88 separate days during the 38-month period the reef runway environmental monitoring program existed. Over 1,300 samples were collected and 9,000 separate data entries have been recorded.

RESULTS

In order to assess the effects of the reef runway construction on Keehi Lagoon water quality, six water quality parameters have been analyzed in general and four in detail for five lagoon and two open ocean monitoring stations. Of the six parameters (temperature, salinity, turbidity, dissolved oxygen, total Kjeldahl nitrogen, and total phosphorus), the latter four have been analyzed in detail. Arithmetic means, standard deviations and geometric means of field and laboratory measurements have been calculated for annual, bi-annual, quarterly and seasonal periods. Quarterly arithmetic mean, standard deviation and geometric mean data for the stations analyzed are presented in Table 1.

Prior to regular monitoring activities, baseline data for most of the sampling stations shown on Figure 2 was assembled from various preconstruction studies. This baseline data and applicable State of Hawaii Water Quality Standards (State of Hawaii, 1974) formed the standards against which water quality readings during construction were measured. Keehi Lagoon, with the exception of the small boat marina areas along the eastern shoreline (Figure 2), is classified by the State Water Quality Standards as Class A waters. The small boat marina areas are Class B waters. Baseline data available for Stations 2, 2b, 3, 4, 6, 22 and 24 is presented in Table 2.

TEMPERATURE AND SALINITY

Temperature and salinity are two of the most potent physical factors in the life of marine organisms. They largely characterize the physicochemical properties of a given body of water (Kinne, 1963). There exists a complex correlation between the biological effects of temperature and salinity. Temperature can modify the effects

24	NA	NA	NA	NA	NA	NA

NA - Not Available

*Turbidity lower limits were established by subtracting twice the standard deviation from mean Secchi disk readings taken during pre-construction studies (Sunn, et al, 1972).

Mid-depth temperature readings taken at Stations 2, 2b, 3, 4, 6, 22 and 24 demonstrate characteristics similar to those for open ocean conditions in the tropics. That is, fairly narrow variations ($+5^{\circ}\text{C}$) between high and low readings, and normal variations between summer and winter months. Table 3 indicates high and low quarterly arithmetic means, standard deviation, and geometric means for temperature data collected.

All high temperature readings were taken during the fifth quarter (July-September, 1974) and low readings were taken during the seventh quarter (January-March, 1975) and the eleventh quarter (January-March, 1976). The lowest average temperature was recorded at Station 6 and the highest average at Station 3. The temperature ranges and patterns indicated in Table 3 are comparable to those described in the literature for similar estuarine water bodies (Ekman, 1953, Sverdrup, et al, 1942).

Salinity, like water temperature, is influenced by outside forces, primarily water temperature and wind. Salinity ranges for individual and/or all stations collectively varies only slightly, less than two parts per thousand (0/00 - Table 4). As with temperature, the highest salinity values are found in the spring and summer months (April-August, 1976) and generally, the lowest in the winter months (January-March, 1974).

The one exception occurred at Station 22 where the lowest average was recorded during the June-September, 1973 period. Higher ambient air temperatures and generally stronger tradewind conditions cause greater evaporation rates to occur in the summer months, resulting in higher salinity values. Conversely, lower ambient air temperatures, less tradewind activity, and greater inflows of fresh water, tend to cause lower salinities in the winter months.

TURBIDITY

The possibility of significantly decreasing water clarity as a result of dredging activities was believed to be potentially one of the most detrimental construction effects on the marine environment of Keehi Lagoon. High turbidity and associated suspended solids would reduce the amount of light available for photosynthesis, would smother bottom dwelling organisms, and if ingested, affect the vital life processes of marine organisms (Johannes, 1972). Although occasional violations of Secchi disk lower limits occurred, generally water clarity at all stations was not significantly different from baseline conditions.

High and low quarterly arithmetic mean, standard deviation, and geometric mean Secchi disk data are shown in Table 5. All low Secchi disk readings occurred during the April-September period and high readings occurred throughout the three-year program. Low readings can be expected during the summer months since the south coast of Oahu is subjected to fairly heavy southerly swell and wave action during those months.

DISSOLVED OXYGEN

Dissolved oxygen (D.O.) is an important environmental parameter since low levels, i.e., less than 5.0 milligrams per liter (mg/l) may significantly affect marine life. A complex set of factors, including organic decay, photosynthesis, and respiration affect D.O. values to range from less than 5.0 mg/l to over 8.5 mg/l or supersaturation on any given day. Oxygen saturation is dependent upon temperature and salinity, but roughly ranges from 6.8 to 7.1 mg/l for the temperature ranges generally recorded in the Keehi Lagoon area.

State of Hawaii Class A Water Quality Standard for D.O. is values greater than 5.0 mg/l except from natural causes, e.g., heavy phytoplankton bloom and ensuing temporary depletion of dissolved oxygen. Table 6 indicates that all quarterly means for all stations fall within the generally accepted range of values, i.e., between 5.0 and 7.0 mg/l.

TABLE 6

24	7.07	0.58	7.04	12	5.86	0.28	5.85	2

Table 6 also indicates that all high D.O. readings were recorded during the January-June, 1976 period and that all low readings, with the exception of Station 22, occurred during the October-December period. The low readings for Station 22 occurred during June-September, 1973 period.

All D.O. values are at acceptable levels, indicating adequate O₂ levels for marine biological processes. However, unrecorded bottom level readings, particularly at Stations 3 and 4, have, on occasion, indicated greatly depleted O₂ levels (less than 2.0 mg/l), indicating a lack of water mixing, overpopulation by planktonic organisms, or extreme putrefaction or eutrophication conditions.

NUTRIENTS

The significance of total Kjeldahl nitrogen and total phosphorus levels is difficult to assess due to the wide variation in natural conditions. For example, State of

Hawaii Standards for Class A waters are often exceeded in pristine open ocean waters surrounding Hawaii (Tetra Tech, 1976). The measured levels of nitrogen and phosphorus in Keehi Lagoon vary widely. In some cases, it has been possible to determine exact or definite probable causes of high nutrient readings. In other cases, the causes of extremely high or low readings was not apparent even after investigating several probable causes.

As an example of the wide range of nutrient levels recorded, nitrogen levels at Station 4 have varied from less than 0.010 mg/l (August 20, 1973) to 1.080 mg/l (December 4, 1975) and phosphorus readings have varied from less than 0.001 mg/l (August 30, 1974) to 0.075 mg/l (September 11, 1975). Similar extreme high and low readings have been recorded for all stations, inside and outside Keehi Lagoon. Tables 7 and 8 indicate nutrient data collected.

Low nitrogen readings occur generally during the fall (October-December) and winter (January-March) months while high readings occur during the winter, spring (April-June) and summer (July-September) months. All stations exceed Class A Standards (0.15 mg/l). Generally, it can be expected that nitrogen readings will be highest after the period of most rapid utilization of nitrate by plants in the spring and summer, and then generally decrease. Also, it has been found that higher quantities of nitrite are generally found in surface waters during the summer and autumn and

therefore definitely associated with the distribution of density and of water temperature (Sverdrup, 1942). These findings indicate that the low fall and winter month readings and high spring and summer month readings are fairly typical of naturally occurring situations. However, high winter readings for total nitrogen are atypical and may, in Keehi Lagoon, be caused by storm water runoff inflows.

Low phosphorus readings were found during the spring and summer months, except for Stations 3 and 22, and exceed Class A water standards. Generally, the values recorded are fairly atypical of natural conditions. Highest phosphorus values generally occur during the winter, and lowest values during the summer, when phytoplankton growth has been great.

It is known that in shallow water communities, e.g., Keehi Lagoon, bottom sediments may be a large reservoir of phosphorus. Even the release of a small part of this phosphorus could significantly increase the concentration in the water. When O_2 levels in bottom waters are reduced (e.g., from organic pollution) phosphate is released from the sediments. Dredging, with the consequent suspension of oxygen-consuming sediment particles, may increase total phosphorus concentrations (Ferguson Wood and Johannes, 1975).

As noted previously, bottom D.O. readings have indicated extremely low levels (less than 2.0 mg/l). This fact, acting in concert with the large amount of suspended sediment particles and disturbance of bottom conditions, may be the cause of high summer total phosphorus values recorded. However, also to be considered are the outside influences of drainage canals, streams, and sewer outfalls.

MARINE ECOLOGY SURVEYS

During the conduct of the water quality monitoring program, quarterly marine ecology surveys were being performed at four of the water quality stations (4, 13, 21 and 24 - Figure 2). Three of the stations (13, 21 and 24) are located seaward of the construction project on reef tops (15 to 40 feet below the surface). These reef tops have been exposed to little, if any, environmental stress (Bowers, 1976). Station 4 is located within Keehi Lagoon in an area that has been exposed to stress, including siltation, industrial pollution, and domestic sewage pollution (Bowers, 1976).

Live coral coverage of the substratum, numbers of sea urchins and fish, and zooplankton samples were recorded and collected. Coral coverage varied considerably from one quarterly monitoring period to the next. However, it appears that this variation represents an estimate of the natural variation inherent in the distribution of coral colonies throughout the station area.

The variations in numbers of sea urchins and fish that were observed were due, in part, to natural movements in and out of the station areas, requirements for irregular habitats, and mobility of the organisms.

Table 9 indicates yearly variations of coral coverage, numbers of urchins and fish, and total zooplankton types found at the four stations.

TABLE 9
YEARLY VARIATIONS OF MARINE ORGANISMS

Year	Percent Coral Coverage			Number Of Urchins Observed			Number Of Fish Observed			Number Of Zooplankton Types Observed		
	1	2	3	1	2	3	1	2	3	1	2	3
Station

24	26.3	25.5	25.8	7.2	7.5	14.0	557	418	416	18.0	14.7	16.7

CIRCULATION

Hawaii is located in an eastern central Pacific anti-cyclonic gyre. It is thought that water approaches the island of Oahu from the northeast in the winter and from the south to southeast in the spring and summer, depending on the position of the gyre (Sverdrup, 1942; R. M. Towill Corp., 1975). The winds, waves, tides, configuration of the coastline, and the bathymetry strongly influence the flow of water around the island at any given location. Flows in and out of major estuaries, e.g., Keehi Lagoon or Pearl Harbor, with each tide result in important local effects. The circulation in the entire Mamala Bay area (Figure 1) is strongly influenced by winds and tides, and therefore, varies seasonally (R. M. Towill Corp., 1975).

Circulation studies conducted prior to the construction of the reef runway (Bathen, 1970; Summ, et al, 1969) indicated that there were weak but definite flows of water inward over the barrier reef and westward around Ahua Point to the Hickam Harbor area and on out to the open ocean (Figures 3 and 4). Since the reef runway has blocked this flow, water entering Keehi Lagoon via Honolulu Harbor, Kalihi and Moanalua Streams, Kalihi Channel, and over the reef, must now pass over the reef, back through Kalihi Channel or out Circulation Channel "B" (Figure 2).

Prior to the dredging of Circulation Channel "B", a circulation study was performed (R. M. Towill Corp., 1976a) that indicated most outward flow as occurring in Kalihi Channel (Figure 5).

Recent post-construction aerial observations of Keehi Lagoon and the reef runway project area indicate that there is now a definite outflow of water in Circulation Channel "B". A portion of this outward flow can be seen on Figure 6. Circulation Channel "B" is approximately 500 feet wide at the surface, with a bottom width of 300 feet. The channel is dredged to minus 45-50 feet.

DISCUSSION

The obvious environmental impact of the reef runway project has been the covering of over 850 acres of coral reef flat with over 19 million cubic yards of dredged coral materials. This has resulted in some changes to the water quality and circulation patterns of Keehi Lagoon.

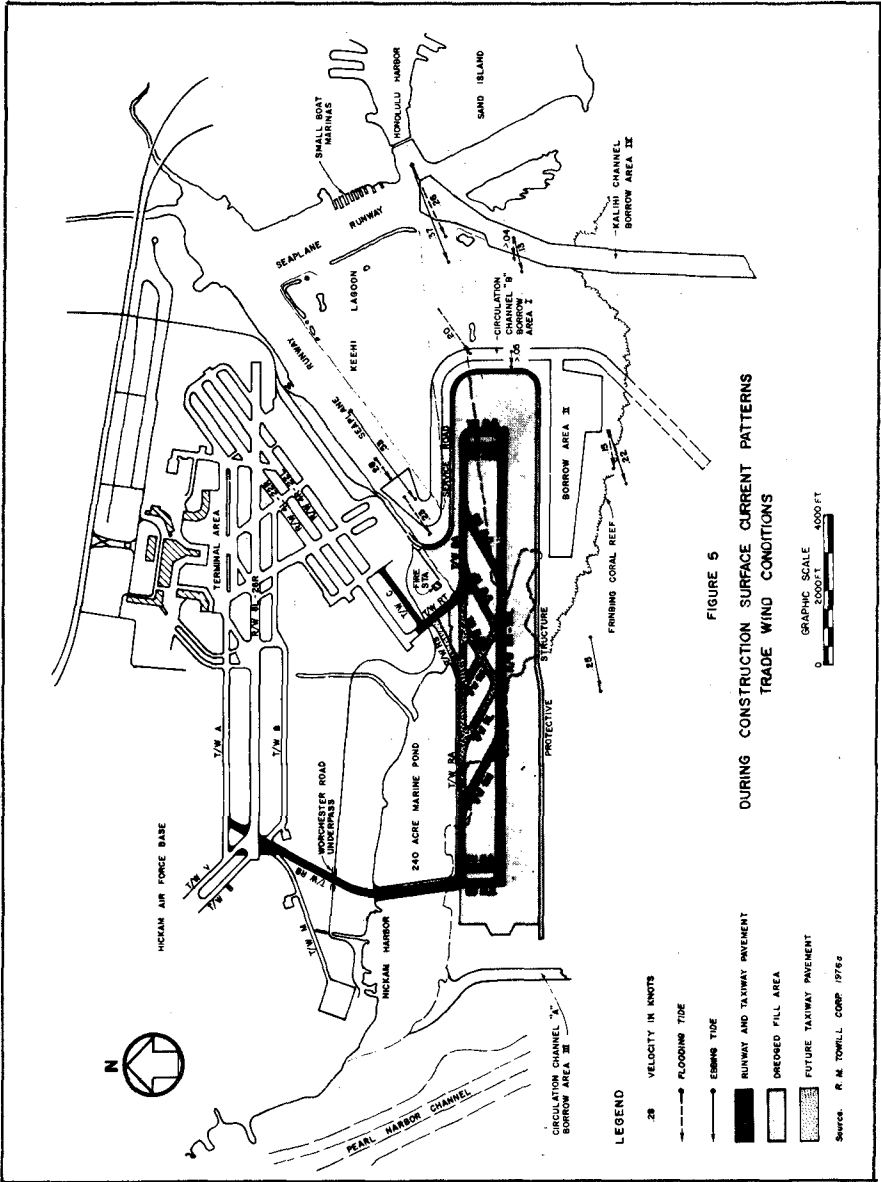

Figure 6 Aerial View of Reef Runway, September, 1976.

Temperature and salinity levels at the seven stations analyzed (2, 2b, 3, 4, 6, 22 and 24) do not appear to indicate variations other than normal seasonal differences. That is, highest temperatures were found during the summer months and lowest during winter months. Highest salinity values were recorded during the spring and summer months and lowest values were recorded during the winter months, except at Station 22 where the lowest average was recorded during the summer. The reason for this anomaly is unclear, but it appears to be a local condition and not indicative of a long term situation.

Water clarity at all stations except two (3 and 24) is greater now than before the reef runway construction. It was apparent during the construction and dredging activities, that as dredging and filling approached any particular station, that water clarity decreased. However, as these activities proceeded by a given station and the area allowed to restabalize, water clarity increased. The exceptions to this are Stations 3 and 24. Station 3 is influenced by fresh water inflow from Kalihi and Moanalua streams. This inflow is generally silt laden and causes minor daily variations in water clarity. The effects of construction appear to have affected the water quality at Station 3 only to the degree that circulation patterns have been altered. Possibly resulting in decreased flow rates out of the area. However, until a detailed circulation study has been performed, definitive conclusions cannot be reached.

Station 24 is influenced by swell, wave, and offshore current action. It appears that dredging in Borrow Area II and Circulation Channel "B", plus the present outflow of water through Channel "B" may be causing some silt build-up along the 40- to 60-foot bottom contours. During the ecological surveys, a fine layer of silt was occasionally observed on corals at Station 24. However, it appears that this silt is naturally carried away by subsurface currents and is dispersed over a wide area. During spring and summer southerly swell conditions, this silt is placed into suspension and decreases water clarity. This condition is expected to continue for several years until the borrow areas and circulation channel have been cleansed of fine silts.

Dissolved oxygen levels at all stations indicate that construction activities have had little, if any, effect. As indicated previously, all sampling was performed at mid-depths and as such stratification of the various water quality parameters was not measured. However, unrecorded bottom D.O. measurements did indicate O_2 depleted conditions. These readings were made prior to completion of Circulation Channel "B" and it is, therefore, not possible at this time to indicate whether flushing or mixing within the lagoonal water column is occurring.

The general increases in nutrient levels (total Kjeldahl nitrogen and total phosphorus) that appear to be occurring are difficult to assess due to numerous other influences. As noted above, Kalihi and Moanalua Streams and Honolulu Harbor enter Keehi Lagoon. The Sand Island Sewer Outfall, which presently disposes of over 55 million gallons of raw sewage daily, is less than two miles upwind the reef runway project area. Predominant currents flow towards the reef runway area. It is known (Ferguson Wood and Johannes, 1975) that dredging operations cause the release of nutrients stored in bottom sediments. It is also possible that if subsurface current flows through Keehi Lagoon have increased as a result of Circulation Channel "B", nutrients could be released from bottom sediments through increased scouring and the resultant suspension of silt particles in the water column.

An indication of the effects of changes in water quality that have occurred is provided by the marine ecology surveys. As noted previously, percent coral coverage variations that have occurred tend to indicate natural variation rather than one produced by construction activities or abrupt changes in water quality. Sea urchin and fish counts also tend to indicate variations due to natural causes rather than construction induced changes. Bowers (1976) reports that variations in numbers of sea urchins similar to those found at the reef runway have also been observed at other areas on Oahu, and that these variations may be natural cyclic occurrences.

The variations in the numbers of fish and fish species observed during the 3-year monitoring period can be generally explained by changes in the underwater visibility and natural fish movements.

The variations in the numbers and types of zooplankton observed does not indicate any general trend. The relatively small changes that have occurred, tend to imply that natural variation as opposed to environmental stress conditions, such as construction, are responsible for the variations in total plankton types noted.

CONCLUSIONS

As noted previously, a major purpose of the reef runway environmental monitoring program was the detection of non-compliance with State of Hawaii and construction project specification water quality standards.

Of major importance was the early detection of turbidity violations. Turbidity was controlled through the use of sea curtains and the requirement that all dredged spoil material be pumped into confined areas. Only in a few instances did turbidity levels go below allowable standards, and these situations were quickly and easily corrected. Violations of other water quality standards, e.g. nutrient levels, have also occurred. However, it appears that these violations have not been entirely due to construction efforts, but more likely, due to outside influences. As noted, when water quality, circulation, and marine biological factors are considered, it appears, at this time, that the reef runway construction project has not had any negative impacts. Definitive conclusions regarding the long-term effects of the reef runway project will not be possible until future water quality, circulation, and marine ecology studies have been conducted.

The analysis of water quality data collected during the reef runway project, and examinations of water quality data collected during other coastal engineering projects in Hawaii, suggests that present State Water Quality Standards require review and adjustment to reflect naturally occurring conditions. As noted previously, studies (Tetra Tech, 1976) have shown that pristine open ocean water, on the windward and leeward sides of Oahu and other islands, does not meet State Water Quality Standards. Studies performed at other construction sites on other Hawaiian islands also tend to indicate these findings (Sunn, et al, 1972b and 1975; Oceanic Foundation, 1975; J. K. K. Look, 1972; U.S. Army Engineers, 1976).

The long-term environmental effects of the reef runway construction can only be determined following additional data reduction analyses, and future water quality, circulation, and marine ecological studies. These studies, which should be conducted over at least a one-year period following major offshore construction efforts, will provide the data base upon which fairly definitive conclusions can be reached.

ACKNOWLEDGEMENTS

The preparation of this paper would not have been possible without the valuable assistance and guidance of Mr. Owen Miyamoto, Chief, Airports Division, Mr. Robert S. Chun, Airports Engineer, and Mr. Frank Okimoto, Engineer, Airports Division, State of Hawaii Department of Transportation. The field work, compilation and reporting of data collected was performed by Messrs. Frank Doyle, F. L. Vuillemont, and Roy Tsutsui of the R. M. Towill Corporation. Their assistance, perseverance, and patience are gratefully acknowledged. I would especially like to extend my sincere thanks to Messrs. Lowell Anderson and Francois Iragui, Reef Runway Project Managers, The Ralph M. Parsons Company, for their financial and moral assistance and their perseverance and dedication to complete a program that, at times, contributed additional problems to an already complex construction sequence and methods situation. Finally, I would like to thank Ms. Francee Matlock for her patience and help in preparing the tables and typing the manuscript.

Without all of this help, the monitoring program would not have been possible. One of the pleasures inherent in the completion of a research project is the opportunity to express gratitude to all those who made it possible.

STUDY OF AN ARTIFICIAL ISLAND

by

J.P. LEPETIT and S. MOREAU *

1 - INTRODUCTION

The location of large surface industrial zones along sea shores often competes with other coastal activities, such as recreational pursuits, fishing, nature reserves, etc. The construction of an artificial island in the sea, near the shore, is a solution to which it will perhaps be necessary to have recourse in the fairly near future. The design of such a project poses many problems particularly in respect of its impact on the environment. We present here the results of a study which examines this aspect.

The problems are as follows :

- influence of the island on the local wave climate, or swell, and consequent shoreline changes,
- influence of the island on tidal currents and resulting evolution of the sandy sea bed,
- dispersion of industrial effluents.

The effect of the island on swell and on shore stability and the calculation of pollutant dispersion are approached by the use of mathematical models ; the effect of the island on tidal currents is analysed on a reduced scale physical model.

* Division Hydraulique Maritime - Laboratoire National d'Hydraulique Electricite de France - Chatou - France.

2 - IMPACT ON THE SHORE

The impact on the shore is determined by computer calculations [1] of the wave pattern and of its resulting effect on littoral drift (fig. 1). The computation of the wave pattern takes account of refraction, due to variations in water depth, and diffraction, due to the presence of the island : both mechanisms are computed independently and then combined by multiplying the coefficients of wave height variation so obtained.

The variations in wave height and incidence along the shore are determined for each wave period and direction considered ; then, using a classical littoral drift formula, the variation in the discharge of sand is estimated. By summing the volumes of sand transported by waves in each category considered, weighted according to their frequency of occurrence, the net sand transport along the shore can be obtained. The stage-by-stage evolution of the shoreline is derived by calculation of the continuity.

During the computation the discharge of sand is modified daily according to changes in the orientation of the shoreline, and the computation of the wave pattern is repeated every three years. This computation is carried out for the existing situation in the absence of the island, and then repeated with the island present.

Without the island, waves (6s period, 4 m annual significant height) originating from directions between west and north-east produce a net littoral drift eastwards of 10 to 20 m³/day on a straight east-west shore consisting of fine sand (0,25 mm).

The location of an island, 3500 m offshore, induces the formation of a tombolo with erosion of the beach on either side. Due to the predominant direction of littoral drift, the north-south axis of the tombolo is slightly west of the intersection of the north-south axis of the island with the shore (fig. 2). However, the drift being low, the shoreline changes are rather slow. The average shoreline advance is 0,30 m/year with a 2200 m long island & 0,45 m/year with a 3500 m long island. The average rates of shoreline recession are 0,10 m/year and 0,25 m/year respectively.

Shoreline changes may be prevented by periodical dredging. The construction of groynes on the shore on either side of the island would also reduce the volume of sand trapped in the sheltered zone between island and shore.

[1] LEPETIT J.P. Transport littoral : essais et calculs. Proc. 13th Conf. Coastal Engineering. Vancouver 1972.

3 - IMPACT ON CURRENTS AND BATHYMETRY

This is analysed on a reduced scale model with a fixed bed (horizontal scale 1/1000, vertical scale 1/100) equipped with tide and current generators. The surface current paths are measured by taking time exposures of floats before and after the construction of the island on the model. The effect of the island can be assessed from charts indicating zones of increase and decrease in current velocity (fig.3).

A 700 m wide island oriented in the direction of maximum long shore currents has little significant effect on discharge. However, appreciable changes occur near the island. Decreases in velocity are noted around the island, both upstream and downstream. On both sides of the island, particularly between the island and the shore, increase occur. In both cases the maximum change in velocity is 25 %.

The result is very sensitive to several parameters which are :

- the length of the island
- the width of the island
- the distance from the shore
- and the shape of the island itself.

More tests are necessary to understand the effect of each parameter but as regards the increase of velocity between the shore and the island it seems that this variation is more important when the island is wider, is nearer from the shore and is shorter.

A particular shape of the upstream extremity of the island with deflects the current seawards reduces the increase of velocity between the island and the shore (fig. 4).

When the sea bed is sandy, these results may be used to give an indication of the likely zones of deposition and erosion. Thus, it is possible to extrapolate the formation of a sand bank behind the island, and an area of scour between the island and the shore ; furthermore, such an eroded area may limit the accretion of the shore due to wave refraction.

4 - EFFLUENT DISPERSION

The dispersion of industrial effluents is assessed by a stage-by-stage computer calculation, 2 dimensional in plan, which takes into account convection and dispersion due to tidal currents. The dispersion coefficient used is about $5 \text{ m}^2/\text{s}$ in each horizontal direction. Concentrations are assumed to be uniform throughout the depth - an assumption which is satisfied during strong tidal currents. The current values used in the computation are those measured with the island represented on the physical model.

With a slightly rotating, reversing tidal current parallel to the shore, having a maximum velocity of 1 m/s and an effluent discharge of 200 m³/s seawards from the centre of the island, the surface areas affected by concentrations of 10 % and 20 % of the discharged concentration are approximately and respectively 2 km² and 0,5 km² (fig. 5).

Computations carried out for a nearby coastal site with reversing but non-rotating currents give 10 % concentrations over areas 2 to 3 times greater. For a site inside of an estuary the areas concerned are even more higher (fig. 6).

The comparison therefore favours discharging effluents into the open sea, but the difference is due to several factors whose effects are difficult to assess - distance from the shore, stronger residual current, rotating currents and also greater depth.

A more succinct assessment is carried out by simulating the effluent discharge by coloured water on a reduced scale model. The results obtained are in relatively good agreement with the computed results, perhaps because the convection by tidal currents is the major effect and precisely the currents introduced in the calculation are those recorded on the model where dye tests are made.

CHAPTER 204

WAVE INDUCED OSCILLATIONS OF HARBORS WITH VARIABLE DEPTH

by

F. Raichlen¹ and E. Naheer²

ABSTRACT

A numerical method is presented to treat the wave-induced oscillations of a harbor with a variable depth and width. A two-dimensional finite difference approach is used inside the harbor matched at the entrance to a solution for the open-sea based on the Helmholtz Equation which includes incident, reflected, and radiated wave energy. Examples of the response and the modal shapes of the water surface are presented for harbors with simple and complex shapes.

INTRODUCTION

In recent years significant progress has been made in developing analytical models to determine the response of harbors to incident waves. The ultimate objective in such research is to be able to treat a harbor with variable depth, planform, and coastline configuration, and with a variable interior reflectivity. Such a model would be extremely useful in preliminary design work and guiding laboratory studies of the phenomenon.

Early theoretical investigations of harbor resonance concentrated on harbors with constant depth and simple geometric shapes. Examples of these studies are: Miles and Munk (1961) and Ippen and Goda (1962). One of the major results of these investigations was the realization that the open-sea was important in allowing for the loss of energy radiated from a harbor. For the steady-state excitation of a harbor the radiated energy from the harbor to the open-sea is an important aspect of the response problem, and provides a form of "dissipation" in an otherwise inviscid theoretical approach. Methods were presented which demonstrated, quite well, (particularly the study of Ippen and Goda (1962)) the effect on the harbor response of geometric characteristics of the harbor, such as the ratios of: width to length and entrance width to harbor width.

Lee (1969), Hwang and Tuck (1970), and Lee and Raichlen (1971) investigated the problem of the wave-induced oscillations of constant depth harbors of arbitrary shape. Numerical methods were developed to treat the problem of a complex harbor with perfectly reflecting interior boundaries. In the study of Hwang and Tuck (1970) the open-sea and the harbor were treated as one region; Lee (1969) and Lee and Raichlen (1971) treated the harbor and the open-sea separately, then matched the solutions at the harbor entrance. (This difference leads to the study reported herein.)

Several approaches have been proposed to determine the response of harbors with variable shape and depth to incident waves, e.g., Raichlen (1965), Wilson et al. (1965), Olsen and Hwang (1971), and Chen and Mei (1974). Comments are made by Miles (1974) relative to the applicability of certain of these methods, and the interested reader is directed to that publication.

A two-dimensional approach was presented by Raichlen (1965) to treat the oscillations of long waves in closed basins of arbitrary planform and variable depth. This was extended, in an approximate fashion, to the case of a harbor

¹Professor of Civil Engineering, W. M. Keck Lab. of Hydr. and Water Res., Calif. Inst. of Tech., Pasadena, CA, USA.

²Graduate Research Assistant, W. M. Keck Lab. of Hydr. and Water Res., Calif. Inst. of Tech., Pasadena, CA, USA.

connected to the open-sea. The major assumption in the case of the harbor was that a node existed at the harbor entrance. It was realized at the time that this was a serious limitation to the analysis, especially in view of the work of Ippen and Goda (1962) where it was shown, for rectangular harbors, that only for small ratios of width to length and large ratios of entrance width to harbor width is this assumption reasonable. Suggestions were made for improving this, but these were not attempted at the time.

The objective of the study reported herein is to eliminate this imposed entrance condition and develop a simple method which allows the wave amplitude at the entrance to adjust naturally to the external and internal waves similar to the analyses presented by Ippen and Goda (1962) and Lee (1969) for simple and complex shapes, respectively. The harbor and the ocean are considered as two separate regions with the wave amplitude and the water surface slope obtained in each region matched at the harbor entrance. In this manner, it is possible to use analytical approaches which are different in each of the two regions.

ANALYTICAL CONSIDERATIONS

In this section the analytical method used will be discussed considering in order: the solution inside the harbor, the solution in the open-sea, and the solution for the combined region. There are certain limitations which are placed on the solution which may or may not restrict its application. These are:

- (1) Only shallow water waves are considered.
- (2) The problem is reduced to a two-dimensional problem; no surface variations are allowed in the harbor in a direction perpendicular to the *talweg* of the harbor.
- (3) The open-sea has a constant depth equal to the average depth at the entrance.
- (4) The coastline is assumed to be straight.

Harbor Region

The solution for the interior of the harbor follows the method proposed by Raichlen (1965), and it will be summarized here. A body of water is considered with a length l measured along the natural coordinate direction s , see Fig. 1. The natural coordinate is directed along the *talweg* which is the line which smoothly connects the deepest parts of the body of water. The variation of surface width and cross-section area perpendicular to the s -direction are denoted as $b(s)$ and $A(s)$, respectively.

Fig. 1. Definition Sketch of Harbor and Open-Sea Regions.

For long waves with small amplitude the equation of continuity for the fluid body may be written as:

$$\frac{\partial}{\partial s} (Au) + b \frac{\partial \eta}{\partial t} = 0 \quad (1)$$

where u is the water partical velocity in the s -direction averaged over the cross-section and η is the amplitude of the water surface relative to the mean water level.

Neglecting friction, the equation of motion in the s -direction for two-dimensional flow (without body forces) is:

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial s} = - \frac{1}{\rho} \frac{\partial p}{\partial s} \quad (2)$$

where ρ is the density of the fluid and p is the local pressure. For small amplitude shallow water waves, the pressure can be assumed hydrostatic:

$$p = \gamma(\eta - z) \quad (3)$$

where γ is the specific weight of the fluid and the coordinate direction z is positive upwards. Neglecting the convective acceleration in Eq. 2 (which is reasonable for this small amplitude approach), Eqs. 2 and 3 can be combined to give:

$$\frac{\partial \eta}{\partial s} = - \frac{\partial u / \partial t}{g} \quad (4)$$

Eq. 4 states that the local water surface slope in the s -direction is given by the ratio of the local acceleration to the acceleration of gravity. It is assumed that the amplitude variation of the free surface can be expressed as a separable function of space and time as:

$$\eta = \eta(s) \cos \sigma t \quad (5)$$

where σ is the circular wave frequency, 2π /wave period. Differentiating the continuity equation (Eq. 1) with respect to time, substituting for the local acceleration from Eq. 4 and using Eq. 5 in the resulting expression, the following is obtained:

$$\frac{\partial}{\partial s} \left[A \frac{\partial \eta}{\partial s} \right] + \frac{b\sigma^2}{g} \eta = 0 \quad (6)$$

Eq. 6 can be expanded into an equation of the Sturm-Lionville form:

$$A \frac{d^2 \eta}{ds^2} + \frac{dA}{ds} \frac{d\eta}{ds} + \lambda_m b \eta = 0 \quad (7)$$

where $\lambda_m = \frac{\sigma^2}{g}$ $m = 1, 2, \dots, M$

and λ_m is a characteristic or an eigenvalue of the problem, and A and b are functions of s alone. Wilson et al. (1965) describe two boundary conditions that may exist at the end of the basin opposite to the entrance:

- (1) The cross-section area tends to zero or,
- (2) there is perfect reflection from the end.

From Eq. 7, these conditions can be expressed respectively as:

$$(1) \quad A = 0 \quad \frac{dA}{ds} \frac{d\eta}{ds} + \lambda_m b \eta = 0 \quad (8a)$$

$$(2) \quad \frac{d\eta}{ds} = 0 \quad \Lambda \frac{d^2\eta}{ds^2} + \lambda_m b \eta = 0 \quad (8b)$$

If both conditions exist simultaneously, the trivial case of $\eta = 0$ is obtained from Eq. 7. In addition, inherent in the assumption of $\Lambda = 0$ at the end is the fact that $b \neq 0$ at that point; if not, Eq. 7 reduces to $\frac{dA}{ds} \frac{d\eta}{ds} = 0$. Thus, the two boundary conditions at the closed end of the harbor are somewhat restrictive, although they do cover most of the interesting problems.

To obtain a numerical solution to Eq. 7, the basin is divided into N cross-sections spaced a distance Δs apart, where $\Delta s = \ell / (N-1)$; the cross-sections are perpendicular to the *talweg*. The section $n=1$ is the closed end of the basin and $n=N$ is at the entrance which communicates with the open-sea. The first and second derivatives are expressed in finite difference form using central differences, and Eq. 7 becomes:

$$a_{n,n-1} \eta_{n-1} + a_{n,n} \eta_n + a_{n,n+1} \eta_{n+1} = \Lambda_m \eta_n \quad (9)$$

where:

$$a_{n,n-1} = -\frac{1}{b_n} \left[A_n - \frac{1}{4}(A_{n+1} - A_{n-1}) \right] \quad a_{n,n} = 2A_n/b_n$$

$$a_{n,n+1} = -\frac{1}{b_n} \left[A_n + \frac{1}{4}(A_{n+1} - A_{n-1}) \right] \quad \Lambda_m = \lambda_m \Delta s^2$$

For the boundary condition where the area at the end section ($n=1$) goes to zero, Eq. 8a, forward differences are used to define the derivatives and Eq. 8a becomes:

$$a_{1,1} \eta_1 + a_{1,2} \eta_2 = \Lambda_m \eta_1 \quad (10a)$$

where:

$$a_{1,1} = (A_2/b_2) = -a_{1,2}$$

Therefore, the wave amplitude at the next section ($n=2$) can be expressed in terms of the amplitude at section $n=1$ from Eq. 10a as:

$$\eta_2 = \left(1 - \frac{b_2 \sigma^2 \Delta s^2}{g \Lambda_2} \right) \eta_1 = E_2 \eta_1 \quad (10b)$$

In the case of perfect reflection from the end boundary ($n=1$) when the depth does not go to zero, the water surface slope becomes zero in accordance with Eq. 8b. This equation could be written in difference form similar to that shown in Eqs. 10a and 10b. However, to obtain a solution a zero water surface slope can be forced to occur at the end by using the "mirror-image" method proposed by Raichlen (1965). In that method the basin is extended one cross-section beyond the end wall to construct a mirror image; for example, for reflections at $n=1$ a cross-section at $n=0$ is defined with $A_0 = A_2$, $b_0 = b_2$ and $\eta_0 = \eta_2$. In this manner, by symmetry about $n=1$, a zero water surface slope is forced at $n=1$. The difference equations written for this are:

$$a_{1,2} \eta_2 + a_{1,1} \eta_1 = \Lambda_m \eta_1 \quad (11a)$$

where

$$a_{1,1} = (2A_1/b_1) = -a_{1,2}$$

Hence, the wave amplitude at $n=2$ can be expressed in terms of the amplitude at the end of the basin as:

$$\eta_2 = \left(1 - \frac{b_1 \sigma^2 \Delta s^2}{2gA_1} \right) \eta_1 = E_2' \eta_1 \quad (11b)$$

It should be recalled, the analytical method used is to obtain a solution inside the harbor that can be matched at the entrance to a solution obtained by a different method for the outside region (the open-sea). To accomplish this, an inside solution must be evaluated at the entrance, $n=N$. Eq. 9 and the appropriate boundary condition (Eq. 10b or 11b) is used for this. In this regard, it is instructive to look first at the wave amplitude at the cross-section $n=3$.

$$\eta_3 = \frac{1}{A_2 + \frac{1}{4}(A_3 - A_1)} \left\{ \left[\frac{1}{4}(A_3 - A_1) - A_2 \right] + \left[2A_2 - \frac{b_2 \sigma^2 \Delta s^2}{g} \right] \left[E_2 \text{ or } E_2' \right] \right\} \eta_1 = E_3 \eta_1 \quad (12)$$

Therefore, knowing the wave amplitude at the end of the basin, $n=1$, and the cross-section geometry and wave period, the wave amplitude at $n=3$ can be evaluated. Proceeding iteratively, the amplitudes at arbitrary cross-sections are expressed as:

$$\eta_{n-1} = E_{n-1} \eta_1 \quad (13a)$$

and

$$\eta_n = E_n \eta_1 \quad (13b)$$

where E_n is a coefficient which can be evaluated easily.

Using backward differences, the water surface slope at the entrance ($n=N$) is approximated as:

$$\frac{d\eta_N}{ds} = \frac{\eta_N - \eta_{N-1}}{\Delta s} = F_N \eta_1 \quad (14)$$

where

$$F_N = \frac{E_N - E_{N-1}}{\Delta s} .$$

For any cross-section, E_n (and ultimately F_N) is determined by arbitrarily setting $\eta_1 = 1$ and the calculating $\eta_2, \eta_3, \dots, \eta_N$ iteratively. Dividing η_N and η_{N-1} by η_1 , the desired values of E_N and E_{N-1} are obtained, and the slope of the water surface (or the velocity) at the entrance is defined.

The wave amplitude η is a complex quantity which, at the entrance ($n=N$), can be written as:

$$\eta_N = \eta_N^{(R)} + i \eta_N^{(I)} \quad (15)$$

where $\eta_N^{(R)}$ and $\eta_N^{(I)}$ are the real and imaginary parts of the entrance wave amplitude, respectively, and thus provide both amplitude and phase information.

Open-Sea Region

The solution for the open-sea region is taken from Lee (1969) and will be summarized here; the interested reader is directed to the publication cited for

a more comprehensive description. As mentioned previously, for this development the open-sea is assumed to be a constant depth equal to the average depth at the harbor entrance. If a separable solution of the velocity potential ϕ is sought, within the limitations of small amplitude wave theory, the following expression can be used for the velocity potential:

$$\phi(x, y, z; t) = -\frac{1}{i\sigma} \frac{a_1 g \cosh k(h+z)}{\cosh kh} f(x, y) e^{-i\sigma t} \quad (16a)$$

and hence:

$$\eta(x, y; t) = a_1 f(x, y) e^{-i\sigma t} \quad (16b)$$

wherein a_1 is the wave amplitude, k is the wave number, and h is the depth. From Laplace's Equation ($\nabla^2 \phi = 0$) it is found that the spacial wave function, f , must satisfy the Helmholtz Equation:

$$\frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} + k^2 f = 0 \quad (17)$$

In the outside region the wave function is defined as:

$$f_{out} = f_{inc} + f_{ref} + f_{rad} \quad (18a)$$

where f_{inc} is the incident wave function, f_{ref} is the wave function for the reflected wave, and f_{rad} is the wave function for the wave which is radiated outward from the harbor entrance. From Eq. 16b the wave amplitude can be expressed as:

$$\eta = a_1 (f_{inc} + f_{ref} + f_{rad}) e^{-i\sigma t} \quad (18b)$$

Referring to Fig. 1, the following boundary conditions are imposed on f_{out} .

$$(1) \quad \frac{\partial f_{out}}{\partial n} = 0 \text{ on } \overline{AC'} \text{ and } \overline{BC} \text{ at } y=0 \quad (19a)$$

$$(2) \quad \frac{\partial f_{out}}{\partial n} = -c \text{ on } \overline{AB} \text{ at } y=0 \quad (19b)$$

$$(3) \quad f_{out} \rightarrow (f_{inc} + f_{ref}) \text{ as } (x^2 + y^2) \rightarrow \infty \quad (19c)$$

The first boundary condition implies a zero velocity along the impermeable coastline where n is the normal to the boundary. The second boundary condition expresses the average velocity across the entrance in terms of the solution of the velocity obtained from inside the harbor. (This does not pertain to the immediate solution sought, but it is presented here for its usefulness later.) The third boundary condition ensures the radiated wave system, f_{rad} , disappears with increasing distance from the harbor entrance and the wave becomes simply a standing wave at infinity.

Lee (1969) obtains the radiated wave function using Weber's solution for the Helmholtz Equation (Eq. 17) letting the standing wave amplitude at infinity be a_1 , i.e., $(f_{inc} + f_{ref}) = 1$. Thus the wave function along the entrance is written as:

$$f_{out}(x, 0) = 1 - \frac{i}{2} \int_{\overline{AB}} C(x, 0) H_0^{(1)}(kr) dx \quad (20)$$

where $H_0^{(1)}(kr)$ is the Hankel function of the first kind and zero order chosen as a fundamental solution of the Helmholtz Equation. If variations in amplitude and velocity across the entrance in the x direction are considered small, f_{out} and $C(x,0)$ in Eq. 20 can be replaced by their values averaged over the width of the entrance: \bar{f}_{out} and \bar{C} . Hence, from Eq. 20 one obtains

$$\bar{f}_{out} = 1 - \frac{i}{2} \left[J_c + i \frac{2}{\pi} Y_c \right] b_N \bar{C} \quad (21)$$

where:

$$J_c = 1 - \frac{1}{6} \left(\frac{kb_N}{2} \right)^2 + \frac{1}{60} \left(\frac{kb_N}{2} \right)^4 - \frac{1}{1008} \left(\frac{kb_N}{2} \right)^6 + \frac{1}{25920} \left(\frac{kb_N}{2} \right)^8 + \dots$$

$$Y_c = \left[\ln \left(\frac{kb_N}{2} \right) + \gamma - \frac{3}{2} \right] - \frac{1}{6} \left(\frac{kb_N}{2} \right)^2 \left[\ln \left(\frac{kb_N}{2} \right) + \gamma - \frac{19}{12} \right] + \frac{1}{60} \left(\frac{kb_N}{2} \right)^4 \left[\ln \left(\frac{kb_N}{2} \right) + \gamma - \frac{55}{30} \right] - \frac{1}{1008} \left(\frac{kb_N}{2} \right)^6 \left[\ln \left(\frac{kb_N}{2} \right) + \gamma - \frac{353}{168} \right] + \frac{1}{25920} \left(\frac{kb_N}{2} \right)^8 \left[\ln \left(\frac{kb_N}{2} \right) + \gamma - \frac{826}{360} \right] + \dots$$

and: $\gamma = 0.5772157$ (Euler's constant). (To handle relatively large ratios of entrance width to wave length, the numerical computations for J_c and Y_c are carried to terms of order $(kb_N/2)^8$.)

Solution for the Combined Regions

Eq. 21 provides a first approximation to the outside wave function, f_{out} , and hence the wave amplitude in terms of an unknown average water surface slope, \bar{C} , at the harbor entrance. Since the \bar{C} can be complex, it is described by the derivative of Eq. 15 with respect to the s-direction, i.e., $\bar{C} = (1/a_1)(d\eta_N/ds)$. This substituted into Eq. 21 provides a general expression for the wave function at the entrance averaged over the entrance width. Separating the resulting expression into the real and imaginary parts the following are obtained:

$$\eta_N^{(R)} = a_1 + \frac{1}{2} \left[J_c \frac{d\eta_N^{(I)}}{ds} + \frac{2}{\pi} Y_c \frac{d\eta_N^{(R)}}{ds} \right] b_N \quad (22a)$$

$$\eta_N^{(I)} = -\frac{1}{2} \left[J_c \frac{d\eta_N^{(R)}}{ds} - \frac{2}{\pi} Y_c \frac{d\eta_N^{(I)}}{ds} \right] b_N \quad (22b)$$

Substituting Eqs. 13 and 14 obtained from the interior solution into Eqs. 22, the latter can be rewritten as:

$$\eta_1^{(R)} = \frac{a_1}{E_N} + \frac{1}{2} \left[J_c F_N \eta_1^{(I)} + \frac{2}{\pi} Y_c F_N \eta_1^{(R)} \right] \frac{b_N}{E_N} \quad (23a)$$

$$\eta_1^{(I)} = -\frac{1}{2} \left[J_c F_N \eta_1^{(R)} - \frac{2}{\pi} Y_c F_N \eta_1^{(I)} \right] \frac{b_N}{E_N} \quad (23b)$$

Eqs. 23a and 23b can be solved simultaneously for the real and the imaginary parts of η_1 , the amplitude at the end of the harbor ($n=1$):

$$\eta_1^{(R)} = a_i (E_N - \frac{1}{\pi} Y_c F_N b_N) / \alpha_N \quad (24a)$$

$$\eta_1^{(I)} = a_i (-\frac{1}{2} J_c F_N b_N) / \alpha_N \quad (24b)$$

where:

$$\alpha_N = \left(E_N - \frac{1}{\pi} Y_c F_N b_N \right)^2 + \left(\frac{1}{2} J_c F_N b_N \right)^2.$$

If the response function for the harbor is defined as the ratio of the wave amplitude at a position in the harbor (e.g., at the backwall, $n=1$) divided by the amplitude at the entrance if the entrance were closed, then from Eqs. 24 this becomes (for the backwall):

$$R_1 = \frac{1}{a_i} \left[\left(\eta_1^{(R)} \right)^2 + \left(\eta_1^{(I)} \right)^2 \right]^{1/2} \quad (25)$$

The amplification factor, R_1 , can be evaluated by setting the standing wave amplitude to unity ($a_i=1$) and substituting Eqs. 24a and b into Eq. 25. With reference to Eq. 13, the response at any other location becomes:

$$R_n = E_n R_1 \quad (26)$$

where E_n is defined, as before, from an expression similar to Eq. 12. Therefore, from Eqs. 24, 25, and 26 the response of a variable depth harbor to incident waves can be investigated keeping in mind the restrictions imposed on the solution by the assumptions stated previously.

DISCUSSION OF RESULTS

In evaluating this method of analysis, a harbor of simple geometry was considered first. This was a rectangular harbor with a width w , a linearly varying depth, and a fully open entrance connected directly to the open-sea. The depth of the open-sea region was set equal to the depth at the harbor entrance. The ratio of the depth at the backwall of the harbor to that at the entrance varied from zero to unity. The ratio of the harbor width to the length for the case considered was: $w/l = 0.194$; the same ratio as the constant depth case considered by Ippen and Goda (1962) and Lee (1969).

The response curves obtained are presented in Fig. 2 for four ratios of depths at the backwall to the entrance: $h_1/h_2 = 0, 0.67, 0.33, 1.0$. The ordinate is the response function as defined by Eq. 25 and the abscissa is the product of the harbor length and the wave number based on the wave period and the depth of water at the harbor entrance. The response for $h_1/h_2 = 1$ is the same as obtained by Ippen and Goda (1962) and Lee (1969). As the slope of the bottom increases the amplification at resonance increases significantly and the maximum response shifts to smaller values of $k_2 l$. Note that as $k_2 l$ tends to zero (the wave length tends to infinity) the response tends to unity, i.e., the wave length is so large that the wave essentially does not "see" the harbor and the amplitude is the same as the standing wave with the harbor entrance

Fig. 2. Response at the Backwall of a Rectangular Harbor with a Linearly Varying Depth; the Fundamental Mode (length = 31.15 cm, width = 6.03 cm, $h_2 = 7.62$ cm).

closed. The variation of the amplification and the product $k_2 l$ at resonance with the depth ratio are presented in the inset to Fig. 2; it is apparent that the effect of the change in depth on the amplification at resonance is much more significant than the effect on the resonant wave number, k_2 . The former can be considered an effect of shoaling; the latter also is an effect of shoaling and represents a change in the resonant wave length caused by the change in mean depth.

In Fig. 3 the response of a fully open rectangular harbor with a linearly varying depth is presented for two cases: a width to length of 0.1 and 1.0; the fundamental mode is shown for each case. (It should be noted, the response function is presented logarithmically along the ordinate.) The amplification at resonance is reduced by nearly an order of magnitude by increasing the ratio of width to length in the same amount. In addition, the resonant wavelength increases as the width of the harbor increases (the resonant wave number decreases). In fact, it appears that if the width were great enough compared to the length, the response at the backwall would be equal to unity independent of wave number. This is the case where the harbor is so wide compared to the length that it simply becomes like the coastline.

In Fig. 4 the variation of the relative amplitude with relative length is shown for the fundamental mode of three harbors with a varying ratio of width to length. For the three cases the ratio of the depth at the backwall to the depth at the entrance is zero. The results of the numerical analysis are shown along with the exact solution of Lamb (1945) for a long wave in a canal with a linearly varying depth, and the agreement is good. At $x/l=1$ the entrance effect can be seen, and as the ratio of width to length, w/l , decreases, the relative amplitude at the entrance also decreases. In fact, it appears that if $w/l \gg 1$ the amplitude in the harbor would be approximately uniform in the x -direction; this is the same trend observed in Fig. 3 as w/l increases.

An example of the response of a harbor with a more general shape is the case of Apra Harbor, Guam, M. I. This harbor was chosen because of the availability of the results of hydraulic model tests which were conducted in the late 1940's to evaluate certain inner harbor modifications and the design of a proposed breakwater (see Knapp and Vanoni (1949)).

A schematic drawing of the harbor is presented in Fig. 5. In the analysis, the outer harbor was limited near the East end by a series of shoals; in the hydraulic model one proposed method to protect the inner harbors was to build a series of breakwaters connecting certain of the shoals. In the analytical model the shoal-breakwater location and the LST berth were considered to be closed ends and the results were compared to the experimental results with the breakwaters in place. The general direction of the *talweg* is shown in Fig. 5 and the areas and surface widths of sections perpendicular to the *talweg* are shown in Fig. 6. The depth averaged over the cross-section varies from approximately 60 ft at the entrance to a maximum of 113 ft about one-third of the harbor length from the entrance and 18 ft near the LST berth.

A response curve obtained for this harbor is presented in Fig. 7; the ordinate is the ratio of wave amplitude at the LST berth (see Fig. 5) to that at the harbor entrance with the entrance closed. The abscissa is the product of the wave number and the harbor length along the *talweg*; the length used is 16,000 ft with the harbor divided into 33 sections. The theoretical response curve exhibits six modes of oscillation for the range of kl shown. This response curve must be somewhat in error, since the oscillations corresponding to the response shown in Fig. 7 are two-dimensional and three-dimensionality would probably become important in such a harbor for the higher modes of oscillation. Nevertheless, this does show certain aspects of the response in a variable depth, arbitrary shaped harbor.

Fig. 3. Response at the Backwall of a Rectangular Harbor with a Linearly Varying Depth ($h_1/h_2 = 0$); the Fundamental Mode.

Fig. 4. Relative Wave Amplitude vs. Relative Length for the Fundamental Mode.

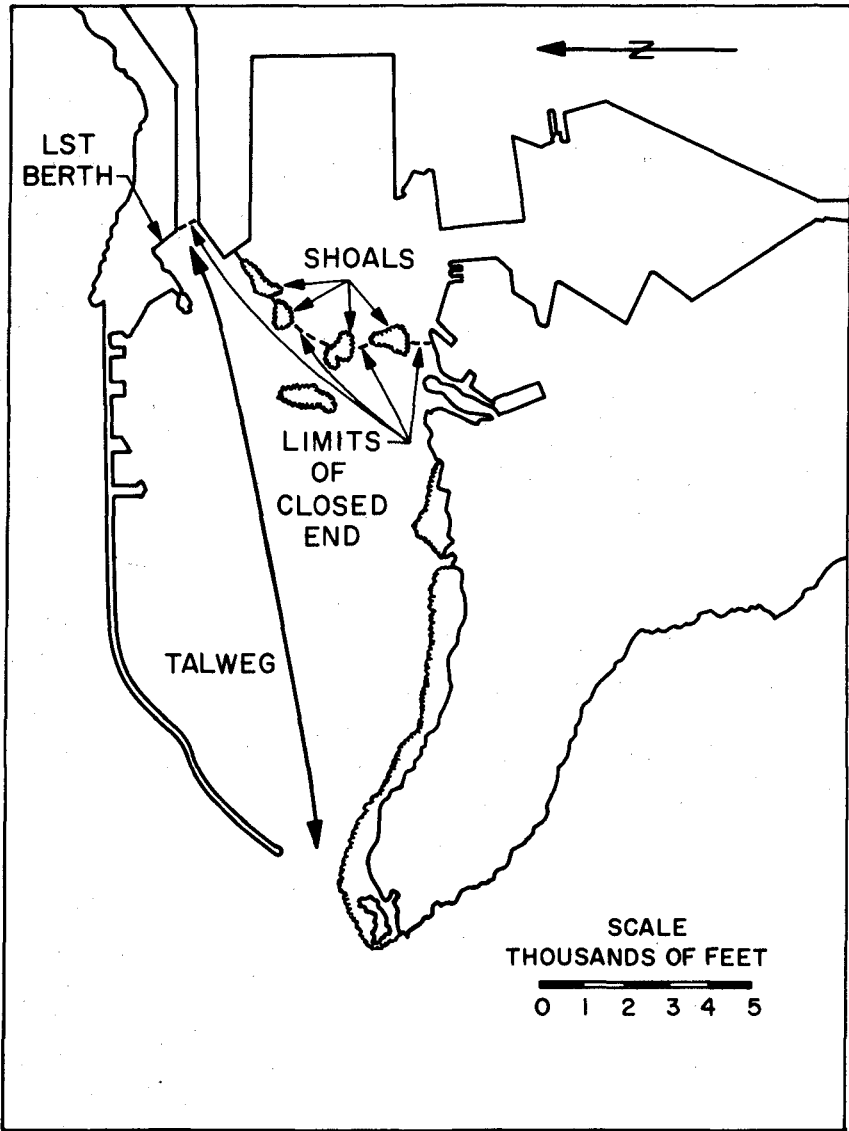

Fig. 5. Schematic Drawing of Apra Harbor, Guam, M.I.

Fig. 6. Variation of Surface Width and Cross-Section Area, Apra Harbor, Guam, M.I.

Fig. 7. Response Curve at the LST Berth, Apra Harbor, Guam, M.I.

The experimental data presented in Fig. 7 were obtained by Knapp and Vanoni (1949); the definition of the response function used in that study was not precisely the same as that used in the theory. In their experiments the amplification factor was defined as the ratio of the maximum amplitude at the location of interest to the maximum amplitude outside the harbor with the entrance open. Since there must be an effect on the outside wave due to the harbor, in comparing the experiments to the theory one would expect differences. In Fig. 7 the agreement in the shape of the response curve perhaps is reasonable for the second and third modes but considerably poorer thereafter. This may be due to the failure of a two-dimensional theory in describing the higher modes of oscillation where three-dimensionality must be important as well as the differences mentioned between the theory and the experiments.

The periods of the various modes are shown in Fig. 7 next to the peaks. It is noted that the lowest mode, the fundamental, has a period of 27.9 min; the maximum amplification for $0 < k\ell < 19$ is exhibited by the third mode with a period of 3.7 min. (These periods are based on an average depth of 84.7 ft inside the harbor.) The shape of the water surface for the first three modes are shown in Fig. 8 where the local amplification factor (R_n in Eq. 26) is plotted as a function of distance from the LST berth along the *talweg*. By plotting in this manner, the relative importance of mode shape at a given location can be observed. An interesting feature of Fig. 8 is the water surface amplitude at the entrance ($n=N$). For these three modes the classical condition of a node at the entrance certainly is not met. Thus, the approach proposed by Raichlen (1965) and Wilson et al. (1965) would be in error in predicting both the resonant periods and the mode shapes.

For a rectangular harbor with a similar geometry ($2b/\ell \cong 0.33$ and $d/b = 0.5$) the value of $k\ell$ at resonance for the first mode would be 1.15. (It should be noted, the width of both the harbor and the entrance used for this computation are approximate.) Referring to Fig. 7, the value of $k\ell$ at resonance for the first mode, the pumping mode, is about the same as that predicted for the corresponding mode for the rectangular harbor. Hence, the fact that a node does not exist at the entrance is partly due to the aspect ratio of the harbor and partly due to the partially closed condition.

The second basin investigated was Monterey Bay, California. This bay has experienced problems due to long period oscillations in the past, and in connection with an approximate numerical model presented by Raichlen (1965) and Wilson et al. (1965) it is of some interest. This is a large bay with a length along the *talweg* of approximately 56,000 ft from the shore to the entrance, a maximum width near the entrance of 138,000 ft and an average depth which decreases from 581 ft at the entrance to nearly zero at the shore. The longitudinal variation of the surface width and cross-section area are presented in Fig. 9. For the numerical calculations the harbor was divided into 20 sections.

The response curve for a location at the shoreline ($n=1$) is presented in Fig. 10. It is interesting that due to the shape of the basin, the modes of oscillation are not defined as distinctly as those for Apra Harbor shown in Fig. 7. Nevertheless, the first three modes of oscillation are evident in Fig. 10 and are defined therein. For this harbor the ratio of width to length is nearly 2.5, thus three-dimensional effects would be expected for higher modes of oscillation. The results of the two-dimensional analysis of Raichlen (1965) and Wilson et al. (1965) for this case are indicated along the abscissa; in those analyses a node was assumed at the entrance. That this is not so is evident from Fig. 10 and is emphasized even more in Fig. 11 where the shape of the water surface is shown for the first three modes of oscillation. It is seen that nodal conditions

Fig. 8. The Shape of Three Modes of Oscillation for Apra Harbor, Guam, M.I.

Fig. 9. Variation of Surface Width and Cross-Section Area, Monterey Bay, California.

Fig. 10. Response Curve at the Backwall of Monterey Bay, California.

Fig. 11. The Shape of Three Modes of Oscillation for Monterey Bay, California.

are not met for any of these modes of oscillation. This emphasizes the importance of not imposing entrance boundary conditions for a harbor. The conditions at the entrance must respond naturally, depending upon the shape of the basin and the period of the incident waves.

CONCLUSIONS

The following major conclusions may be drawn from this study:

1. Using matching conditions at the entrance to a harbor it is possible to use two completely different methods of analyses in the two domains: the harbor region and the open-sea region.
2. Reasonably good agreement is found for the period of the lower modes of oscillation measured experimentally compared to the results of the numerical analysis for a harbor with a relatively complex shape.
3. The boundary condition at the entrance of a harbor must be allowed to develop naturally and a particular amplitude such as a node cannot be forced to occur. In the event this is done, the response of a harbor determined numerically may be considerably in error.

CHAPTER 205

PROBABLE UTILIZATION LEVEL FOR A BARGE HARBOR

Martin T. Czerniak¹
Choule J. Sonu²

INTRODUCTION

The main consideration in harbor master planning is to maximize the amount of time that the harbor can be used. The potential level of harbor utilization can be evaluated by analyzing vessel performance during harbor operations in terms of the range of imposed environmental conditions. The harbor utilization level is expressed statistically as the probable amount of time that the harbor can be used as planned.

In this paper, a siting study for a towboat-barge harbor will be described. This example will demonstrate the use of harbor utilization statistics for a simplified case of a single-purpose harbor and a single design vessel. This scheme can be applied to more complex cases of multi-purpose harbors used by a variety of vessels. The purpose of this paper is twofold. First, it outlines the basic concept of harbor utilization statistics and their value to harbor master planning. While it seems that studies of this type would have been undertaken in the past, at present no examples have been found by the authors among published literature. Secondly, considering the lack of published information, it is beneficial to record some practical experience regarding towboat and barge systems as design vessels.

APPLICATION

Many harbor operations can be analyzed using harbor utilization statistics. For example, an evaluation of entrance/exit conditions will lead to utilization statistics that define the percentage of time that vessels can safely negotiate the harbor entrance. The loading/unloading/berthing utilization can also be considered. This calculation would involve the wave height in the berth area of the harbor and may influence harbor configuration by revealing the need for additional breakwater sections (LeMehaute, 1976). A "harbor-of-refuge" can be better planned to provide safe entrance and safe mooring during storms if utilization statistics are compiled for the types of small craft generally found in nearby waters.

Harbor utilization statistics can be interpreted in terms of the economic and functional feasibility of a specific harbor configuration, location, and operational plan. The computations will reveal how harbor utilization can be improved by plan modifications. Economic analyses are improved because the benefits attributable to the harbor's presence can be more accurately established.

¹Senior Engineer and ²Principal Engineer,
Tetra Tech, Inc., Pasadena, California, U.S.A.

PROCEDURE

Once the design vessels and the intended purpose of the harbor have been decided, three steps are necessary to determine the utilization level of a particular harbor operation:

- (1) Identify the environmental parameters which influence vessel behavior during the harbor operation of interest;
- (2) Determine the "critical level" of each parameter beyond which safe operations are jeopardized;
- (3) Determine the probable amount of time that the harbor will be closed due to the exceedance or joint exceedance of the "critical levels."

Often the occurrence statistics for the important parameters that are identified in step 1 will not be directly available from environmental data summaries. In such cases, appropriate engineering analyses must be employed to develop the needed data from the available statistics. For example, if it has been determined (step 2) that the maximum allowable wave height in the berth area of a proposed harbor is 40 cm, then refraction and diffraction techniques must be used to establish all the incident wave conditions that will result in this wave height there. Once these conditions are known, data summaries of incident wave height, period and direction can be used to establish the probability of exceeding the allowable wave agitation in the berth area (step 3).

EXAMPLE: TOWBOAT - BARGE HARBOR

Harbor utilization statistics were used to select the best site during the master planning of a proposed harbor for the central California coast. The proposed harbor must provide year round safe entrance and unloading conditions for barges in order to maintain the delivery schedule of construction materials for the development of the Vandenburg Air Force Base. Due to the nature of the coastline, a "shoreline harbor" is required. That is, primary harbor protection is provided by breakwaters, and the harbor basin is located seaward of the existing shoreline. The vessels that will be used for the delivery operation are ocean-going towboats, which commonly draw about 4.5 meters, connected by a towing cable to a medium-sized commercial barge. These barges are about 115 meters long, 25 meters wide, and have a loaded draft of about 4 meters when not ballasted with sea water.

Step 1: Identify Parameters: Three parameters are judged most important in defining the amount of time that the towboat-barge system can safely enter the harbor: (1) the wave height one to four kilometers offshore of the harbor entrance, (2) the wind speed, and (3) the visibility level.

The procedure used by the vessel in approaching and entering the harbor must be known in order to judge which oceanographic and meteorological factors are most important to safety. While underway on the open ocean, about 500 meters of towing cable connect the towboat and the barge (Brady, 1967). As shown in Figure 1a, the tow cable takes a catenary shape and functions as a "spring" to absorb the ship motions of both vessels. Generally, the barge will be ballasted during ocean towing, which helps to reduce its amplitude of response to the waves. Prior to entering the harbor, perhaps one to four kilometers offshore of the harbor entrance, the cable must be shortened for better towing control and the barge must be deballasted of sea water to reduce its draft. In this condition (Figure 1b), the spring action provided by the cable is considerably reduced and the cable could be in danger of parting if the towboat and barge do not ride the wave synchronously. Now deballasted, the barge will respond more to the wave action than it will under ocean-going conditions thus increasing tension in the cable.

The likelihood of a navigational mishap is highest during this period of approach to the harbor. High wave heights during the time when the tow cable is shortened and the barge deballasted may cause the cable to part or the barge to capsize. High winds may make the barge difficult to control while towing, especially if the cargo is bulky and presents a large "sail" area. For the proposed harbor, the vessels must come broadside to the predominant wind direction in order to enter the harbor. Thus, with the slower vessel speed necessary near the harbor, high wind speeds may cause the barge to drift from the course set by the towboat and strike the breakwater or other vessels. Poor visibility is especially hazardous in this case because dense fog is common along the central California coast. No electronic vessel traffic guidance system will be available at the harbor, a condition which when coupled with the rugged wave climate and brisk winds, makes the safe transit of a towed barge into an open-coast harbor quite dependent upon good visibility.

Breaker conditions are not included among the factors influencing the harbor entrance utilization level. By proper planning it is possible to locate the harbor entrance at a depth such that the occurrence of breaker conditions alone would not close the harbor. Two cases must be considered in this planning. First, when the sea state is too high to permit the vessels to safely execute their harbor approach procedures, they must lay off the coast until conditions are more favorable. In this case, the occurrence of high offshore waves effectively closes the harbor to the towboat and barge traffic and it does not matter if the waves are breaking across the harbor entrance. In the second case, the sea state is low enough to permit a normal approach to the harbor and the location of the breaker zone with respect to the harbor entrance is important. For maximum utilization, the harbor entrance should be negotiable by vessels under any wave conditions that the harbor can be safely approached. In this study the minimum depth for the outer breakwaters defining the harbor entrance was taken to be the breaker depth for the highest 2% of the waves in the Rayleigh distribution for the maximum sea state defining the limit of safe vessel approach procedures.

(a) Ocean towing

(b) Entering Harbor

Figure 1: Towing Conditions a) under open ocean towing, and b) while entering the harbor

Step 2: Critical Levels: The critical values of offshore wave height, wind speed, and visibility beyond which safe navigation is jeopardized depends upon the vessel size and type, the operational procedures, and the acceptable risk. Due to the lack of published data on critical levels vis-a-vis design vessels, the harbor engineer must analytically determine them or rely on experienced advice and judgment in selecting them.

An analytical determination of the actual critical wave height for safe operation of the towboat-barge system would require knowledge of the cable-breaking conditions and the risk probability of collision and grounding as a function of wave agitation and vessel response. Such an analysis is costly and time-consuming, and for this reason towboat operators familiar with the central California coast were consulted. While commercial barges commonly operate successfully during offshore wave heights of about three meters (John Turner, personal communication), harbor entrance procedures involving barge deballasting and the shortening of the tow wire require a calmer sea state. Thus, the critical values defining safe navigation were judged to be:

- Critical wave height, $H_c = 2$ meters
- Critical wind speed, $U_c = 20$ knots
- Critical visibility level, $V_c = 1/4$ mile

Although some level of operational risk is implicit in selecting "critical levels," the actual risk will, in fact, vary on a case-by-case basis for each vessel transit into the harbor. This is caused by variables which cannot be realistically considered such as the experience and judgment of the towboat captain and the condition of the equipment.

Step 3: Exceedance Statistics: The harbor cannot be entered safely by the towboat and barge when one or more of the three governing environmental parameters exceed the critical level. The equation which expresses the expected amount of time that the harbor will be closed, $P(\text{closure})$, is:

$$P(\text{closure}) = P(H_c) + P(U_c) + P(V_c) - P(H_c, U_c) - P(H_c, V_c) - P(U_c, V_c) + P(H_c, U_c, V_c)$$

(1) (2) (3) (4) (5) (6) (7)

In this equation, all the terms on the right side express the probability of occurrence or joint occurrence of environmental conditions more severe than those which are safe for navigation. As such, $P(H_c)$ indicates the probability that the wave height exceeds the critical wave height, $P(V_c)$ indicates the probability that the visibility is worse than the critical visibility, and $P(H_c, U_c)$ indicates the probability that both the critical wave height and critical wind speed are exceeded.

The first three terms of the P(closure) equation are determined from cumulative probability distribution plots of the data. Since the probability of the joint occurrence of high waves and high winds is significant, term (4) of the P(closure) equation must be evaluated. This value can be evaluated using a joint exceedance probability plot, as shown in Figure 2 for the January statistics in the study area. Using this figure, the probability that winds greater than 20 knots and offshore waves higher than 2 meters occur simultaneously is 5.5%.

In the study area, most events of poor visibility are caused by fog or haze. Intuitively then, it would seem that poor visibility would be largely a calm weather phenomenon, not occurring when wind speed and wave heights are high. An evaluation of the available data showed this to be true more than 99.9% of the time. In practical usage, therefore, events of high wind or high waves are mutually exclusive of events of poor visibility in this area, causing terms (5), (6), and (7) to drop out of the P(closure) equation.

Results: With P(closure) determined by an evaluation of terms (1), (2), (3) and (4), the harbor utilization is solved by $1-P(\text{closure})$. For the example problem, harbor utilization statistics were compiled for two potential harbor sites using data supplied by the U. S. Air Force and by the Summary of Synoptic Meteorological Observations (SSMO). The results are given in Table 1 and plotted by month in Figure 3. Note that site A would provide a higher overall harbor utilization level, but that the two sites differ markedly in the probability of supercritical conditions for each of the three important parameters. These differences are consistent with the varying site conditions, including coastal exposure, air flow patterns and local shoreline topography. This example illustrates how harbor utilization statistics help provide a rational comparison among potential harbor sites which possess counterbalancing siting characteristics. Harbor utilization can be improved over the level shown in Figure 3 by the selection of larger design vessels which can safely operate under more severe environmental conditions.

ECONOMIC IMPLICATIONS

When monetary values are assigned to harbor operational time and harbor down time, the harbor utilization concept provides a basis for a rational comparison of harbor costs and benefits. As an evaluation of berthing and unloading conditions may indicate that one potential harbor site requires more breakwater sections than another in order to achieve the same utilization level, the relative construction costs are also indicated.

The economic feasibility of harbor protection by breakwaters can also be addressed. For example, consider Figure 4 which shows the annual cumulative probability distribution of wave heights at a potential harbor site. Table 2 summarizes the various navigation conditions which ships using the harbor would encounter and the probability of occurrence of each condition based on the wave statistics given in Figure 4. The

Figure 4: Annual Probability Distribution of Waves at a Potential Harbor Site Showing Range of Navigational Conditions Experienced by Approaching Ships

Table 2

DESCRIPTION AND PROBABILITY OF OCCURRENCE OF
NAVIGATIONAL CONDITIONS

Condition	Description	Incident Wave Height Outside Harbor (meters)	Annual Probability of Occurrence (percent)
1	Sea traffic not possible	$H > 3$	1.6
2	Sea traffic possible, but cannot safely enter harbor	$3 > H > 2$	6.4
3a	Ships can enter harbor but cannot safely unload cargo	$2 > H > H_i$	67.0
3b	Ships can unload cargo in sheltered harbor area, but could not unload without protection of breakwater	$H_i > H > 0.4$	
4	Ships can unload cargo even without shelter of breakwater	$0.4 > H > 0$	25.0

allowable wave height for unloading depends upon the particular cargo, the method of unloading, the type of ship being unloaded, and the location of stowage aboard ship. If the allowable wave height in the berth area is 40 cm for a particular set of unloading conditions, then there exists an incident wave height outside the harbor, H_i , which after transformation will result in the 40 cm wave in the harbor. For incident wave heights between 0.4 and H_i meters, breakwater protection is required to unload the cargo (condition 3b in Table 2). For incident wave heights between H_i and 2 meters, the ships can safely enter the harbor, but cannot unload because wave heights at the berth will be greater than 40 cm (condition 3a). For maximum harbor utilization, therefore, it is clear that the harbor should be designed so that ships can unload any time that they can safely enter the harbor.

During condition 4, the breakwater is not needed at all, and the ships can unload while moored at a pier or quay. Under conditions 1 and 2, the harbor cannot be utilized, no matter how well designed and situated. Only during condition 3 is the cost of the breakwater being converted usefully into increased harbor operating time.

SUMMARY

A method of determining the probable amount of time that a harbor will be operational has been outlined. This method requires the harbor engineer to evaluate vessel performance capabilities in terms of environmental parameters. These "harbor utilization statistics" are a valuable tool for harbor master planning because they provide a rational means of comparing alternate harbor sites in terms of their functional and economic feasibility.

The use of harbor utilization statistics has been illustrated herein by a study to site a barge harbor along the central California coast. Although this example provides a simplified case of a single-purpose harbor and a single design vessel, the scheme should provide valuable results for a number of other harbor studies:

- Safety analysis of harbors for the shipment or receiving of hazardous cargoes.
- Improved planning and design of small "harbors-of-refuge" in terms of safe entrance, anchorage, and berthing during storms of various intensities and for the various types of small craft generally found in nearby waters.
- Rational harbor site selection among alternative locations having counterbalancing beneficial and detrimental characteristics.
- More realistic economic analyses of costs and benefits of harbor construction.

ACKNOWLEDGMENTS

The study reported on in this paper was performed for the U. S. Department of the Air Force, Space and Missile Systems Organization, Los Angeles. The authors appreciate their cooperation and the meteorological data provided by them. The authors also appreciate the valuable suggestions made by Bernard LeMehaute and Raymond Rodrigue of Tetra Tech during the course of this study and the editorial suggestions of Allene S. Czerniak.

CHAPTER 206

APPLICATION OF CERC SPECIAL REPORT NO. 2

by James W. Dunham, F. ASCE

Coastal Engineer, Moffatt & Nichol, Engineers, Long Beach, Calif.

PURPOSE AND SCOPE

The purpose of this paper is to discuss the new manual titled Small Craft Harbors: Design, Construction and Operation, published by the U. S. Army Corps of Engineers Coastal Engineering Research Center (CERC) as Special Report No. 2 dated December 1974. The objective of the manual is to enable anyone with a basic engineering background to plan and design small craft harbors or do so with the help of one or more specialists. The manual outlines methods of investigating the problems involved and the various engineering, economic and environmental criteria to be applied. It covers much of the planning and design considerations discussed by the A.S.C.E. Committee on Small Craft Harbors in manuals and reports on engineering practice, #50, "Report on Small Craft Harbors 1969". However, it also incorporates a considerable amount of additional information in the form of special design and construction techniques, certain rules of thumb commonly accepted in marina design practice, and observations as to elements of good practice in this field. It provides a compendium of planning data gleaned through a nationwide canvassing of marina operators, marina design engineers, and trades people who provide commonly used marina construction products. Also included in the manual are some of the design and construction requirements of various Federal, state and local government agencies having jurisdiction over, or assisting with the development of small craft harbors.

CONTENT

SR-2 takes the reader step by step through the process of planning and designing a marina, beginning with site analysis and ending with the functional design of structures. It covers the special problems of harbor sites on rivers, in interior lakes and bays, in roadsteads and along open continental shorelines. Environmental considerations such as snow, wind, ice, fog, waves, surge, tides, littoral drift, river deposits, material sources, soils and seismic activity are discussed. Ecological and sociological factors are evaluated as they relate to harbor construction and operation. The special problems of entrance design under various conditions are discussed at length, including methods of construction and the capabilities and limitations of presently available construction equipment. The proper layout of the various components of a marina for functional efficiency is demonstrated, and rules of thumb are given for allocating space. Detail design criteria are then presented for such items as basin geometry, perimeter stabilization, fixed and floating docks, geometric requirements for various types and sizes of craft, launching equipment, etc., along with charts and graphs for layout and design. Numerous line drawings and photographs are presented to illustrate both good and inferior design.

Following the planning and design chapters of SR-2 is a description of the roles played by various Federal, state, and local governments in marina financing, construction, and operation. Because a successful marina requires a sound economic foundation, one chapter deals with feasibility studies, pre-design planning, and methods of financing. Construction contracting and timing are discussed, operating principles are outlined, and some of the more important features of marina maintenance are described. Statistical data on U.S. marina practice derived from replies to questionnaires are tabulated, and 12 case studies are presented to illustrate different planning, management, and design techniques.

It is the intention of CERC to eventually incorporate a manual such as this as an appendix to its Coastal Engineering Manual which will extend the present Shore Protection Manual coverage to all facets of the coastal engineering discipline. This initial effort by CERC in the small craft harbors field was pursued through a contract with Moffatt & Nichol, Engineers, of Long Beach, California, to prepare such a manual under a set of general guidelines as to content. Although this placed the responsibility for the publication primarily with that firm, every effort was made to reflect the soundest thinking in marina design construction and operation that evolved through the many contacts made with personnel living daily with marina design and operation problems. Because it was impossible to contact personnel in many areas, some features may have been overlooked or additional criteria should have been included to cover special cases or conditions of environment.

COMMENTS INVITED

In the preface of SR-2 is the statement "Comments on this Publication are invited". Because the intent of CERC is to upgrade SR-2 to the status of a manual of proven worth and highest possible quality for inclusion as an appendix to the Coastal Engineering Manual, it is imperative that all personnel actively engaged in the small craft harbors field review the publications and submit comments to CERC. Thus, the purpose of presenting this paper at a coastal engineering conference is to call the attention of the coastal engineering profession to the existence of this publication and to solicit comments on it. Most desirable would be comments concerning ideas that were not included or that were covered insufficiently and could be improved upon by inclusion of additional information. Comments of a general nature, such as which parts of the manual are considered too detailed and which too general would also be welcome. Comments should be addressed to the Director, Coastal Engineering Research Center, Kingman Building, Fort Belvoir, Virginia 22060.

SR-2 is available from the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402, under Stock No. 0822-00091. Checks should be made payable to the Superintendent of Documents. The price, postpaid, is \$4.50 in the United States, Canada, and some Latin American countries. The price to other foreign countries is \$5.63, postpaid.

Subject Index

Design, Analysis and Field Test of a Dynamic Floating Breakwater, D. J. Agerton, G. H. Savage and K. C. Stotz, 2792

- Bypasses; Erosion; Great Lakes; Michigan; Sand; Shore protection; Water levels; Beach erosion; Beach nourishment**
Sand-Bypass and Shore Erosion, Bridgman, Michigan, C. N. Johnson and L. W. Hiipakka, 1361
- Bypasses; Jet pumps; Littoral current; Sand; Shore protection; Surf**
A Sand Bypassing System Using a Jet Pump, E. C. McNair, Jr., 1342
- Caissons; Concrete (reinforced); Cylindrical bodies; Tidal tests; Pressure cells; Shock tests; Strain; Strain gages; Breakwaters**
Cylindrical Caisson Breakwater: Strain Model Tests, Helge Gravsen, Finn P. Brodersen, Jorn S. Larsen and H. Lundgren, 2357
- Caissons; Model tests; Overturning tests; Wave action; Wave energy; Wave height; Wave period**
Wave Forces on Aquare Caissons, G. R. Mogridge and W. W. Jamieson, 2271
- Calibration; Discharge (water); Estuaries; Open channel flow; Water meters; Water quality**
Calibration of Branched Estuary Models, James P. Bennett, 3416
- California; Coastal engineering; Coastal structures; Numerical analysis; Wave energy; Wave recorders (water waves)**
Regional Network for Coastal Engineering Data, Richard J. Seymour and Meredith H. Sessions, 60
- California; Discharge (water); Numerical analysis; Tidal currents; Tidal effects; Algorithms**
Tidal Stream Flow Solved by Galerkin Technique, L. H. Smith and Ralph T-S Cheng, 3358
- California; Equilibrium; Tidal effects; Wave energy; Wave spectrum; Beach erosion; Beaches**
Beach Profiles at Torrey Pines, California, David G. Aubrey, Douglas L. Inman and Charles E. Nordstrom, 1297
- California; Jetties; Littoral current; Littoral drift; Sediment transport; Surf; Wave energy; Barriers; Breakwaters**
Longshore Transport at a Total Littoral Barrier, Richard O. Bruno and Christopher G. Gable, 1203
- Canada; Density currents; Hydraulic models; Saline water-freshwater interfaces; Salinity; Salt water intrusion; Tidal effects**
Churchill River Salt-Water Tidal Model, Bruce D. Pratte, 3445
- Canada; Littoral current; Littoral drift; Morphology; Sandbars; Sediment deposits; Wave energy; Barriers; Beaches**
Process and Morphology Characteristics of Two Barrier Beaches in the Magdalen Islands, Gulf of St. Lawrence, Canada, E. H. Owens, 1975
- Cavities; Deep water; Explosions; Predictions; Wave generation; Wave height; Wave propagation; Waves**
Calculations of Waves Formed From Surface Cavities, Charles L. Mader, 1079
- Channels (waterways); Dunes; Dune sands; Sand waves; Sediment transport; Tidal effects; West Germany**
Transport Mechanism in Tidal Dunes, Horst Nasner, 2136
- Channels (waterways); River regulation; Sandbars; Sediment transport; Stability; Tidal effects; Tidal hydraulics; Tidal waters**
Stability of Tidal Channels Dependent on River Improvement, Volker Barthel, 1775
- Circulation; Inlets (waterways); Littoral current; Littoral drift; Sand; Scouring; Sediment transport; South Carolina; Tidal currents; Bed forms**
Sand Circulation Pattern at Price Inlet, South Carolina, Duncan M. FitzGerald, Dag Nummedal and Timothy W. Kana, 1868
- Climatic data; Estuaries; Estuarine environment; Sediment deposits; Sediment distribution; Sediments; Tidal effects; Wave action; Beach erosion**
Factors Influencing Estuary Sediment Distribution, Mary P. Kendrick and B. V. Derbyshire, 2072
- Climatic data; Ocean waves; Wave energy; Wave height; Wavemeters; Wave recorders (water waves); Waves**
Wave Climate Analysis for Engineering Purpose, Hans H. Dette and Alfred Fuhrboter, 10
- Climatology; Coastal engineering; Ocean waves; Spectral analysis; Statistical analysis; Wave forecasting; Wave period; Waves; Wave spectrum**
Ocean Wave Statistics from FNWC Spectral Analysis, Warren C. Thompson and F. Michael Reynolds, 238
- Coastal engineering; Coastal plains; Japan; Power spectra; Refraction; Shoaling; Tsunamis; Warning systems**
Transformation of Tsunamis in a Coastal Zone, Shigehisa Nakamura, Haruo Higuchi and Yoshito Tsuchiya, 988
- Coastal engineering; Coastal structures; Data collection; Data collection systems; Hydrographic surveys; Waves; Wind (meteorology)**
Data Collection and Analysis for Coastal Projects, E. Loewy, K. G. Witthaus, L. Summers and R. J. Maddrell, 43
- Coastal engineering; Coastal structures; Directional measurement; Sediment transport; Wave energy; Wavemeters**
Wave Direction Computations with Three Gage Arrays, D. Esteve, 349
- Coastal engineering; Coastal structures; Numerical analysis; Wave energy; Wave recorders (water waves); California**
Regional Network for Coastal Engineering Data, Richard J. Seymour and Meredith H. Sessions, 60
- Coastal engineering; Coastal structures; Stability; Wave energy; Wave height; Wave period; Waves**
Consecutive High Waves in Coastal Waters, Winfried Siefert, 171
- Coastal engineering; Computation; Periodic variations; Refraction; Wave energy; Wave propagation; Waves; Boundary value problems**
Physics and Mathematics of Waves in Coastal Zones, H. Lundgren, 880
- Coastal engineering; Costs; Erosion; Groins (structures); Revetments; Sea walls; Shore protection; Breakwaters**
Low-Cost Shoreline Protection, Billy L. Edge, John G. Housley and George M. Watts, 2888

- Coastal engineering; Currents; Littoral drift; Ocean currents; Sediment transport; Storm surges; Tidal marshes**
Currents in Tidal Flats During Storm Surges, Harald Gohren, 959
- Coastal engineering; Environmental factors; Monitoring; Nuclear power plants; Social impact**
Coastal Environment and a Nuclear Power Plant, Ralph A. de la Parra, 3014
- Coastal engineering; Field tests; Littoral drift; Ocean currents; Photogrammetry; Stereophotography; Water levels; Waves; Breaking**
Terrestrial Photogrammetric Measurements of Breaking Waves and Longshore Currents in the Nearshore Zone, Joseph W. Maresca, Jr. and Erwin Seibel, 681
- Coastal engineering; India; Statistical analysis; Wave height; Wavemeters; Wave recorders (water waves); Wave spectrum**
Ocean Wave Record Analysis by Tucker's Method — An Evaluation, Jade Dattatri and Irvathur Vasudeva Nayak, 289
- Coastal engineering; Ocean waves; Spectral analysis; Statistical analysis; Wave forecasting; Wave period; Waves; Wave spectrum; Climatology**
Ocean Wave Statistics from FNWC Spectral Analysis, Warren C. Thompson and F. Michael Reynolds, 238
- Coastal engineering; Ocean waves; Taiwan; Wave height; Wave period; Waves; Wind speed**
Waves Off Taichung Coast of Taiwan, Charles C.C. Chang, M. H. Wang and J. T. Juang, 129
- Coastal engineering; Recreational facilities; Shore protection; Sri Lanka; Beach nourishment**
Coastal Problems in Sri Lanka, Francisus Gerritsen and Summa R. Amarasinghe, 3487
- Coastal plains; Japan; Power spectra; Refraction; Shoaling; Tsunamis; Warning systems; Coastal engineering**
Transformation of Tsunamis in a Coastal Zone, Shigehisa Nakamura, Haruo Higuchi and Yoshito Tsuchiya, 988
- Coastal structures; Cooling water; Intake systems; Mathematical models; Nuclear power plants; Numerical analysis; Refraction; Sediment transport; Wave dispersion; Waves**
Application of a Sediment Transport Model, C. A. Fleming and J. N. Hunt, 1184
- Coastal structures; Damping; Numerical analysis; Wave action; Wave energy; Wave runoff; Wave velocity**
Numerical Calculation of Wave Forces on Structures, B. D. Nichols and C. W. Hirt, 2254
- Coastal structures; Data collection; Data collection systems; Hydrographic surveys; Waves; Wind (meteorology); Coastal engineering**
Data Collection and Analysis for Coastal Projects, E. Loewy, K. G. Withaus, L. Summers and R. J. Maddrell, 43
- Coastal structures; Directional measurement; Sediment transport; Wave energy; Wavemeters; Coastal engineering**
Wave Direction Computations with Three Gage Arrays, D. Esteva, 349
- Coastal structures; Experimentation; Field tests; Scour; Scouring; Water levels; Wave action; Wave height; Breakwaters**
Local Scour and Current Around a Porous Breakwater, Shintaro Hotta and Nobuo Marui, 1590
- Coastal structures; Hazards; Tsunamis; Wave action; Wave energy; Wave generation; Wave height**
Tsunami Hazard and Design of Coastal Structures, George Pararas-Carayannis, 2248
- Coastal structures; Israel; Littoral drift; Sedimentation; Sediment deposits; Sediment transport; Shore protection; Breakwaters**
Protection by Means of Offshore Breakwaters, I. Fried, 1407
- Coastal structures; Lateral forces; Pile foundations; Steel piles; Structural design**
Concepts in Design of Coastal Structures, Casimir J. Kray, 2209
- Coastal structures; Numerical analysis; Wave energy; Wave recorders (water waves); California; Coastal engineering**
Regional Network for Coastal Engineering Data, Richard J. Seymour and Meredith H. Sessions, 60
- Coastal structures; Random processes; Reflection; Water waves; Wave dispersion; Wave energy; Wave spectrum**
Decomposition of Co-Existing Random Wave Energy, Dennis B. Morden, Eugene P. Richey and Derald R. Christensen, 846
- Coastal structures; Stability; Wave energy; Wave height; Wave period; Waves; Coastal engineering**
Consecutive High Waves in Coastal Waters, Winfried Siefert, 171
- Coastal topographic features; Eigenvalues; Responses; Rip currents; Velocity distribution; Water waves; Wave equations**
Rip-Current and Coastal Topography, Mikio Hino, 1326
- Coliform bacteria; Drainage; Estuaries; Runoff; Sampling; Simulation; Water circulation; Water quality**
State Estimation of Estuarine Circulation and Water Quality by Numerical Simulation and Observation, Jan J. Leendertse and S. K. Liu, 3223
- Collisions; Harbor structures; Mooring; Moorings; Offshore drilling; Ships; Wave tanks; Accidents**
Protection of Maritime Structures Against Ship Collisions, Kazuki Oda and Shositiro Nagai, 2810
- Computation; Periodic variations; Refraction; Wave energy; Wave propagation; Waves; Boundary value problems; Coastal engineering**
Physics and Mathematics of Waves in Coastal Zones, H. Lundgren, 880
- Computerized simulation; Concrete (blocks); Harbor structures; Quays; Reflection; Revetments; Shore protection; Wave dispersion**
Quay Wall with Wave Absorber "Igloo", Naofumi Shiraishi, Robert Q. Palmer and Hiroshi Okamoto, 2677

- Computer models; Forecasting; Hurricanes; Numerical analysis; Storm surges; Tropical cyclones**
SPLASH — A Model for Forecasting Tropical Storm Surges, Celso S. Barrientos and Chester P. Jelecnianski, 941
- Computer models; Slopes; Wave spectrum; Beach erosion; Beaches**
 Study of Equilibrium Beach Profiles, Robert A. Dalrymple and William W. Thompson, 1277
- Concrete (blocks); Harbor structures; Quays; Reflection; Revetments; Shore protection; Wave dispersion; Computerized simulation**
 Quay Wall with Wave Absorber "Igloo", Naofumi Shiraishi, Robert Q. Palmer and Hiroshi Okamoto, 2677
- Concrete (blocks); Permeability; Reservoirs; Sea walls; Wave energy; Wave period**
 Permeable Seawall with Reservoir and the Use of "Warock", Takeshi Iijima, Enzoh Tanaka and Hideaki Okuzono, 2623
- Concrete (reinforced); Cylindrical bodies; Model tests; Pressure cells; Shock tests; Strain; Strain gages; Breakwaters; Caissons**
 Cylindrical Caisson Breakwater: Strain Model Tests, Helge Gravesen, Finn P. Brodersen, Jorn S. Larsen and H. Lundgren, 2357
- Construction; Harbor structures; Japan; Ocean bottom; Shoaling; Topographical factors; Beach erosion; Beaches; Breakwaters**
 Topographic Change Resulting from the Construction of a Harbor on a Sandy Beach, Kashima Port, Norio Tanaka and Shoji Sato, 1824
- Continental shelf; Cyclic loads; Foundations; Ocean bottom; Offshore structures; Predictions; Stability; Wave action; Wave energy; Bottom water**
 Prediction of Wave-Induced Seafloor Movements, Leland Milo Kraft, Jr. and David James Watkins, 1605
- Continental shelf; Storms; Storm surges; Storm water; Wave energy; Wave height; Wave period; Wave recorders (water waves); Waves; Wave spectrum**
 Extreme Wave Parameters Based on Continental Shelf Storm Wave Records, R. E. Haring, A. R. Osborne and L. P. Spencer, 151
- Convection; Diffusion; Dispersion; Finite element method; Numerical analysis; Stratification; Two phase flow**
 Numerical Modeling of Dispersion in Stratified Waters, George C. Christodoulou and Jerome J. Connor, 3138
- Cooling water; Cylindrical bodies; Field tests; Intake structures; Nuclear power plants; Wave dispersion; Wave energy**
 Wave Pressures on Large Circular Cylindrical Structure, Hiroshi Nakamura, 2290
- Cooling water; Intake systems; Mathematical models; Nuclear power plants; Numerical analysis; Refraction; Sediment transport; Wave dispersion; Waves; Coastal structures**
 Application of a Sediment Transport Model, C. A. Fleming and J. N. Hunt, 1184
- Costs; Erosion; Great Lakes; Groins (structures); Shore protection; Storms; Breakwaters**
 Low-Cost Shore Protection on the Great Lakes: A Demonstration/Research Program, John M. Armstrong, 2858
- Costs; Erosion; Groins (structures); Revetments; Sea walls; Shore protection; Breakwaters; Coastal engineering**
 Low-Cost Shoreline Protection, Billy L. Edge, John G. Housley and George M. Watts, 2888
- Current meters; Friction coefficient (hydraulic); Inlets (waterways); Tidal effects; Bed load**
 Measurement of Bed Friction in Tidal Inlets, Ashish J. Mehta, R. J. Byrne and Joseph T. DeAlteris, 1701
- Current meters; Water circulation; Wave recorders (water waves); Wind pressure; Wind tides**
 Wind-Driven Circulation of Saginaw Bay, James H. Saylor and Larry J. Danek, 3262
- Currents; Dredging; Estuaries; Harbors; Littoral drift; Sand traps; Storms; Wave action**
 Design and Behaviour of Sandtraps in Regions of High Littoral Drift, P. C. Saxena, Pashhayannur P. Vaidyaraman and R. Srinivasan, 1377
- Currents; Finite elements; Gravity waves; Predictions; Refraction; Surf; Water depth; Waves**
 Current Depth Defraction Using Finite Elements, Ove Skovgaard and Ivar G. Jonsson, 721
- Currents; Great Lakes; Harbors; Seiches; Tidal effects; Water levels; Wave generation**
 Hydraulics of Great Lakes Inlet — Harbors Systems, Robert M. Sorensen and William N. Seelig, 1646
- Currents; Littoral drift; Ocean currents; Sediment transport; Storm surges; Tidal marshes; Coastal engineering**
 Currents in Tidal Flats During Storm Surges, Harald Gohren, 959
- Currents (water); Interactions; Turbulence; Wave action; Wave damping; Wave dispersion; Wave energy; Wave velocity**
 Interaction of Waves and a Turbulent Current, J. D.A. van Hoften and Susumu Karaki, 404
- Cyclic loads; Foundations; Ocean bottom; Offshore structures; Predictions; Stability; Wave action; Wave energy; Bottom water; Continental shelf**
 Prediction of Wave-Induced Seafloor Movements, Leland Milo Kraft, Jr. and David James Watkins, 1605
- Cylinders; Drag; Hydraulic models; Lift; Oscillations; Reynolds number; Stream flow; Water flow; Wave action; Wave energy**
 High Reynolds Number Oscillating Flow by Cylinders, Tokuo Yamamoto and John H. Nath, 2321
- Cylindrical bodies; Drag; Force; Oscillation; Roughness (hydraulic); Vortices; Water flow**
 Forces on Rough-Walled Circular Cylinders in Harmonic Flow, Turgut Sarpkaya, 2301
- Cylindrical bodies; Field tests; Intake structures; Nuclear power plants; Wave dispersion; Wave energy; Cooling water**
 Wave Pressures on Large Circular Cylindrical Structure, Hiroshi Nakamura, 2290

- Cylindrical bodies; Flow separation; Oscillations; Pressure distribution; Vortices; Wakes; Water waves**
Flow Separation, Wake Vortices and Pressure Distribution Around a Circular Cylinder under Oscillatory Waves, Yuichi Iwagaki and Hajime Ishida, 2341
- Cylindrical bodies; Model tests; Pressure cells; Shock tests; Strain; Strain gages; Breakwaters; Caissons; Concrete (reinforced)**
Cylindrical Caisson Breakwater: Strain Model Tests, Helge Gravesen, Finn P. Brodersen, Jorn S. Larsen and H. Lundgren, 2357
- Damage; Dikes; Impact; Revetments; Wave action; Wave energy; Air entrainment**
Response of Seadykes due to Wave Impacts, Alfred Fuhrboter, Hans H. Dette and J. Grune, 2604
- Damage; Hydraulic models; Rubble; Rubble mounds; Stability; Wave action; Wave energy; Breakwaters**
Effect of Broken Dolosse on Breakwater Stability, D. Donald Davidson and Dennis G. Markle, 2544
- Damping; Energy dissipation; Estuaries; Stratification; Tidal effects; Wave energy; West Germany**
Energy Dissipation in Tidal Estuaries, Hans-Werner Partensky and Gunther Barg, 3312
- Damping; Numerical analysis; Wave action; Wave energy; Wave runoff; Wave velocity; Coastal structures**
Numerical Calculation of Wave Forces on Structures, B. D. Nichols and C. W. Hirt, 2254
- Data collection; Data collection systems; Hydrographic surveys; Waves; Wind (meteorology); Coastal engineering; Coastal structures**
Data Collection and Analysis for Coastal Projects, E. Loewy, K. G. Witthaus, L. Summers and R. J. Maddrell, 43
- Data collection systems; Hydrographic surveys; Waves; Wind (meteorology); Coastal engineering; Coastal structures; Data collection**
Data Collection and Analysis for Coastal Projects, E. Loewy, K. G. Witthaus, L. Summers and R. J. Maddrell, 43
- Deep water; Explosions; Predictions; Wave generation; Wave height; Wave propagation; Waves; Cavities**
Calculations of Waves Formed From Surface Cavities, Charles L. Mader, 1079
- Deformation; Periodic functions; Phase velocity; Water depth; Wave energy; Wave height; Waves; Beaches**
Deformation up to Breaking of Periodic Waves on a Beach, Ib A. Svendsen and J. Buhr Hansen, 477
- Delaware; New Jersey; Probability; Simulation; Simulation models; Storm surges**
Simulation Model for Storm Surge Probabilities, Mohammad H. Fallah, J. N. Sharma and Cheng Y. Yang, 934
- Deltas; Hydraulic models; Nigeria; Sedimentation; Sediment concentration; Sediment distribution; Sediment transport; Breakwaters**
Sedimentation Studies on the Niger River Delta, Ramiro Mayor-Mora, Preben Mortensen and Jorgen Fredsoe, 2151
- Density currents; Estuaries; Friction coefficient (hydraulic); Mathematical models; Numerical analysis; Saline water intrusion; Stratification; Transport phenomena**
Numerical Model for Density Currents in Estuaries, Karsten Fischer, 3295
- Density currents; Flow patterns; Mathematical models; Scour; Scouring; Stratified flow; Troughs**
Generation of Troughs by Density Currents, Hans Speekenbrink, 2170
- Density currents; Hydraulic models; Saline water-freshwater interfaces; Salinity; Salt water intrusion; Tidal effects; Canada**
Churchill River Salt-Water Tidal Model, Bruce D. Pratte, 3445
- Diffraction; Mach number; Reflection; Walls; Water waves; Wave height**
Mach-Reflection as a Diffraction Problem, Udo Berger and Soren Kohlhasse, 796
- Diffusers; Dilution; Discharge (water); Eddies; Experimentation; Jets; Slots; Buoyancy**
Negatively Buoyant Slot Jets, D. M. Shahrabani and J. D. Ditmars, 2976
- Diffusers; Dilution; Mixing; Outfall sewers; Site selection; Water quality**
Design Procedures for Ocean Outfalls, Jeffrey A. Layton, 2919
- Diffusers; Discharge (water); Hydraulic models; Nuclear power plants; Plume detection; Plumes; Thermal pollution; Two phase flow**
Field Studies of Submerged-Diffuser Thermal Plumes with Comparisons to Predictive Model Results, A. A. Frigo, Richard A. Paddock and J. D. Ditmars, 3028
- Diffusers; Environmental effects; Hydrodynamics; Ocean engineering; Outfall sewers; Underwater pipelines**
Design Considerations for the Sand Island and Barbers Point Outfalls, Robert C.Y. Koh, Norman H. Brooks and Floyd Louis Vuillemot, 2941
- Diffusion; Dispersion; Finite element method; Numerical analysis; Stratification; Two phase flow; Convection**
Numerical Modeling of Dispersion in Stratified Waters, George C. Christodoulou and Jerome J. Connor, 3138
- Diffusion; Eddies; Estuaries; Interfaces; Saline water-freshwater interfaces; Salinity; Salt water intrusion; Stratification**
Determination of the Interfacial Eddy Diffusion Coefficient of a Highly Stratified Estuary, Yu-Hwa Wang, 3158
- Diffusion; Eddies; Hydraulic models; Scale effect; Statistical analysis; Tidal effects; Turbulence**
Horizontal Diffusion in Tidal Models and Scaling Criteria for Thermal-Hydraulic Model Tests, Gerd Flugge, 3097

- Diffusion; Estuaries; Frequency analysis; Hydraulic models; Mathematical models; Mixing; Algorithms**
Algorithm for Vertical Diffusion, Soren Peter Kjeldsen, 3321
- Dikes; Discharge (water); Overtopping; Periodic variations; Wave height; Wave runup; Waves**
Characteristics of Flow in Run-Up of Periodic Waves, Ary Roos and Jurjen A. Battjes, 781
- Dikes; Echo sounding; Field investigations; Instrumentation; Ocean waves; Scale effect; Storm surges; Wave equations; Wave height; Wave period; Wave runup**
Wave Run-Up in Field Measurements with Newly Developed Instrument, Heie F. Erchinger, 767
- Dikes; Impact; Revetments; Wave action; Wave energy; Air entrainment; Damage**
Response of Seadykes due to Wave Impacts, Alfred Fuhrboter, Hans H. Dette and J. Grune, 2604
- Dilution; Discharge (water); Eddies; Experimentation; Jets; Slots; Buoyancy; Diffusers**
Negatively Buoyant Slot Jets, D. M. Shahrabani and J. D. Ditmars, 2976
- Dilution; Mixing; Outfall sewers; Site selection; Water quality; Diffusers**
Design Procedures for Ocean Outfalls, Jeffrey A. Layton, 2919
- Dimensional analysis; Experimentation; Surf; Wave height; Wave period; Waves; Wave spectrum; Breaking**
Wave Spectrum of Breaking Wave, Toru Sawaragi and Koichiro Iwata, 580
- Directional measurement; Sediment transport; Wave energy; Wavemeters; Coastal engineering; Coastal structures**
Wave Direction Computations with Three Gage Arrays, D. Esteve, 349
- Discharge (water); Eddies; Experimentation; Jets; Slots; Buoyancy; Diffusers; Dilution**
Negatively Buoyant Slot Jets, D. M. Shahrabani and J. D. Ditmars, 2976
- Discharge (water); Effluents; Field tests; Mathematical models; Numerical analysis; Water flow; Wave energy; Wind pressure**
Numerical Modelling -- An Aid to Assessing Field Data, H. P. Riedel and F. L. Wilkinson, 3243
- Discharge (water); Estuaries; Open channel flow; Water meters; Water quality; Calibration**
Calibration of Branched Estuary Models, James P. Bennett, 3416
- Discharge (water); Hydraulic models; Nuclear power plants; Plume detection; Plumes; Thermal pollution; Two phase flow; Diffusers**
Field Studies of Submerged-Diffuser Thermal Plumes with Comparisons to Predictive Model Results, A. A. Frigo, Richard A. Paddock and J. D. Ditmars, 3028
- Discharge (water); Hydraulic models; Nuclear power plants; Prototype tests; Temperature distribution; Thermal diffusion; Thermal pollution; Water temperature**
Thermal Discharges: Prototype vs. Hydraulic Model, Gary C. Parker, Ching S. Fang and Albert Y. Kuo, 3049
- Discharge (water); Interfacial tension; Stability; Stratified flow; Thermal pollution; Turbulence**
Interfacial Instability in Stratified Flow, Richard H. French, 3124
- Discharge (water); Numerical analysis; Tidal currents; Tidal effects; Algorithms; California**
Tidal Stream Flow Solved by Galerkin Technique, L. H. Smith and Ralph T-S Cheng, 3358
- Discharge (water); Overtopping; Periodic variations; Wave height; Wave runup; Waves; Dikes**
Characteristics of Flow in Run-Up of Periodic Waves, Ary Roos and Jurjen A. Battjes, 781
- Dispersion; Distribution; Dyes; Estuaries; Predictions; Sewage disposal; Sewage effluents; Tracers; Water pollution**
Prediction of Pollutant Distribution in Estuaries, Albert Y. Kuo and John P. Jacobson, 3276
- Dispersion; Effluent reuse; Effluents; Islands (landforms); Scale effect; Shore protection; Tidal currents**
Study of an Artificial Island, J. P. Lepetit and S. Moreau, 3526
- Dispersion; Finite element method; Numerical analysis; Stratification; Two phase flow; Convection; Diffusion**
Numerical Modeling of Dispersion in Stratified Waters, George C. Christodoulou and Jerome J. Connor, 3138
- Dispersion; Mass transfer; Open channel flow; River flow; Sediment transport; Tidal currents**
Dispersive Transport in River and Tidal Flows, R. B. Taylor, 3336
- Distribution; Dyes; Estuaries; Predictions; Sewage disposal; Sewage effluents; Tracers; Water pollution; Dispersion**
Prediction of Pollutant Distribution in Estuaries, Albert Y. Kuo and John P. Jacobson, 3276
- Distribution functions; Distribution patterns; Frequency; Ocean waves; Surface waves; Wave energy; Wave spectrum**
Directional Spectral of Ocean Surface Waves, Hisashi Mitsuyasu and S. Mizuno, 329
- Distribution patterns; Frequency; Ocean waves; Surface waves; Wave energy; Wave spectrum; Distribution functions**
Directional Spectral of Ocean Surface Waves, Hisashi Mitsuyasu and S. Mizuno, 329
- Distribution patterns; Wave height; Wavelengths; Waves; Wave spectrum; Wave tanks; Wind (meteorology)**
Wave Height Distribution of Wind Waves Over Long Waves, Shan-Hwei Ou and Frederick L.W. Tang, 388
- Dolphins (structures); Head losses; Mass; Shell water; Tanker ships; Water depth; Berths**
Added Masses of Large Tankers Berthing to Dolphins, Taizo Hayashi and Masujiro Shirai, 2830
- Drag; Force; Oscillation; Roughness (hydraulic); Vortices; Water flow; Cylindrical bodies**
Forces on Rough-Walled Circular Cylinders in Harmonic Flow, Turgut Sarpkaya, 2301

- Drag; Force; Separation; Spheres; Water circulation; Wave action; Wave energy**
Forces on a Sphere Under Linear Progressive Waves, Scott A. Jenkins and Douglas L. Inman, 2413
- Drag; Hydraulic models; Lift; Oscillations; Reynolds number; Stream flow; Water flow; Wave action; Wave energy; Cylinders**
High Reynolds Number Oscillating Flow by Cylinders, Tokuo Yamamoto and John H. Nath, 2321
- Drag; Inertial forces; Submerged flow; Underwater structures; Wave action; Wave energy**
Wave Forces on Submerged Objects, Suphat Vongvisessomjai and Richard Silvester, 2387
- Drainage; Estuaries; Runoff; Sampling; Simulation; Water circulation; Water quality; Coliform bacteria**
State Estimation of Estuarine Circulation and Water Quality by Numerical Simulation and Observation, Jan J. Leendertse and S. K. Liu, 3223
- Dredges; Dredging; Sedimentation; Sediment deposits; Sediment transport; Breakwaters**
Sedimentation Problems at Offshore Dredged Channels, A. A. Kadib, 1756
- Dredging; Estuaries; Estuarine environment; San Francisco; Sediments; Spoil; Tracers (radioactive)**
Tracing Estuarine Sediments by Neutron Activation, Richard M. Ecker, John F. Sustar and William T. Harvey, 2009
- Dredging; Estuaries; Harbors; Littoral drift; Sand traps; Storms; Wave action; Currents**
Design and Behaviour of Sandtraps in Regions of High Littoral Drift, P. C. Saxena, Pazhayanur P. Vaidyaraman and R. Srinivasan, 1377
- Dredging; Sedimentation; Sediment deposits; Sediment transport; Breakwaters; Dredges**
Sedimentation Problems at Offshore Dredged Channels, A. A. Kadib, 1756
- Dunes; Dune sands; Movable bed models; Sediment transport; Tidal currents; Tidal effects**
Origin of Submarine Dunes, Mehmet S. Yalin, 2127
- Dunes; Dune sands; Sand waves; Sediment transport; Tidal effects; West Germany; Channels (waterways)**
Transport Mechanism in Tidal Dunes, Horst Nasner, 2136
- Dune sands; Movable bed models; Sediment transport; Tidal currents; Tidal effects; Dunes**
Origin of Submarine Dunes, Mehmet S. Yalin, 2127
- Dune sands; Sand waves; Sediment transport; Tidal effects; West Germany; Channels (waterways); Dunes**
Transport Mechanism in Tidal Dunes, Horst Nasner, 2136
- Dyes; Estuaries; Predictions; Sewage disposal; Sewage effluents; Tracers; Water pollution; Dispersion; Distribution**
Prediction of Pollutant Distribution in Estuaries, Albert Y. Kuo and John P. Jacobson, 3276
- Dynamics; Equilibrium; Erosion; Reflection; Sandbars; Sand traps; Three-dimensional; Wave action; Beach erosion; Beach nourishment**
Three Dimensional Tests on Dynamic Equilibrium and Artificial Nourishment, J. William Kamphuis and R. M. Myers, 1532
- Echo sounding; Field investigations; Instrumentation; Ocean waves; Scale effect; Storm surges; Wave equations; Wave height; Wave period; Wave runup; Dikes**
Wave Run-Up in Field Measurements with Newly Developed Instrument, Heie F. Erchingler, 767
- Ecology; Environmental effects; Littoral drift; Marinas; Seismic studies; Site selection**
Application of CERC Special Report No.2, James W. Dunham, 3570
- Economic analysis; Environmental effects; Harbors; Performance; Safety; Site selection; Utilization; Barges**
Probable Utilization Level for a Barge Harbor, Martin T. Czerniak and Choule J. Sonu, 3557
- Eddies; Estuaries; Interfaces; Saline water-freshwater interfaces; Salinity; Salt water intrusion; Stratification; Diffusion**
Determination of the Interfacial Eddy Diffusion Coefficient of a Highly Stratified Estuary, Yu-Hwa Wang, 3158
- Eddies; Experimentation; Jets; Slots; Buoyancy; Diffusers; Dilution; Discharge (water)**
Negatively Buoyant Slot Jets, D. M. Shahrabani and J. D. Ditmars, 2976
- Eddies; Hydraulic models; Scale effect; Statistical analysis; Tidal effects; Turbulence; Diffusion**
Horizontal Diffusion in Tidal Models and Scaling Criteria for Thermal-Hydraulic Model Tests, Gerd Flugge, 3097
- Effluent reuse; Effluents; Islands (landforms); Scale effect; Shore protection; Tidal currents; Dispersion**
Study of an Artificial Island, J. P. Lepetit and S. Moreau, 3526
- Effluents; Field tests; Mathematical models; Numerical analysis; Water flow; Wave energy; Wind pressure; Discharge (water)**
Numerical Modelling — An Aid to Assessing Field Data, H. P. Riedel and F. L. Wilkinson, 3243
- Effluents; Islands (landforms); Scale effect; Shore protection; Tidal currents; Dispersion; Effluent reuse**
Study of an Artificial Island, J. P. Lepetit and S. Moreau, 3526
- Eigenvalues; Impulses; Responses; Stability; Statistical analysis; Storms; Variability; Beach erosion**
Stability and Impulse Response of Empirical Eigenfunctions, Clinton D. Winant and David G. Aubrey, 1312
- Eigenvalues; Responses; Rip currents; Velocity distribution; Water waves; Wave equations; Coastal topographic features**
Rip-Current and Coastal Topography, Mikio Hino, 1326
- Enclosures; Groins (structures); Israel; Recreational facilities; Social needs; Beaches; Breakwaters**
Enclosing Scheme for Bathing-Beach Development, Joseph Tauman, 1425

- Energy conversion; Surface waves; Thermal energy; Thermal gradient; Two phase flow; Water flow**
Flow Field Near an Ocean Thermal Energy Conversion Plant, D. M. Sheppard, G. M. Powell and I. B. Chou, 3068
- Energy dissipation; Estuaries; Stratification; Tidal effects; Wave energy; West Germany; Damping**
Energy Dissipation in Tidal Estuaries, Hans-Werner Partenscky and Gunther Barg, 3312
- Energy dissipation; Field tests; Floating bodies; Scale effect; Tethered tests; Wave action; Wave energy; Wave spectrum; Wave tanks; Breakwaters; Buoys**
Design, Analysis and Field Test of a Dynamic Floating Breakwater, D. J. Agerton, G. H. Savage and K. C. Stotz, 2792
- Energy equation; Littoral current; Littoral drift; Rip currents; Sediment transport; Shore protection**
Longshore Transport Prediction — SPM 1973 Equation, Cyril J. Galvin and Philip Vitale, 1133
- Environmental effects; Harbors; Performance; Safety; Site selection; Utilization; Barges; Economic analysis**
Probable Utilization Level for a Barge Harbor, Martin T. Czerniak and Choule J. Sonu, 3557
- Environmental effects; Hawaii; Islands (landforms); Monitoring; Reefs; Runways; Water quality**
Environmental Impacts on an Island Community, Gordon A. Chapman, 3506
- Environmental effects; Hydrodynamics; Ocean engineering; Outfall sewers; Underwater pipelines; Diffusers**
Design Considerations for the Sand Island and Barbers Point Outfalls, Robert C.Y. Koh, Norman H. Brooks and Floyd Louis Vuillemot, 2941
- Environmental effects; Inlets (waterways); Littoral drift; New Jersey; Scouring; Sea level; Tidal effects; Tidal waters**
Beach Haven and Little Egg Inlets, A Case Study, Joseph T. DeAlteris, Thomas McKinney and James Roney, 1881
- Environmental effects; Littoral drift; Marinas; Seismic studies; Site selection; Ecology**
Application of CERC Special Report No.2, James W. Dunham, 3570
- Environmental factors; Monitoring; Nuclear power plants; Social impact; Coastal engineering**
Coastal Environment and a Nuclear Power Plant, Ralph A. de la Parra, 3014
- Equilibrium; Erosion; Reflection; Sandbars; Sand traps; Three-dimensional; Wave action; Beach erosion; Beach nourishment; Dynamics**
Three Dimensional Tests on Dynamic Equilibrium and Artificial Nourishment, J. William Kamphuis and R. M. Myers, 1532
- Equilibrium; Forecasting; France; Marinas; Ports; Beach erosion; Beach nourishment**
Impact of Yachting Marinas on Beaches, J. P. Lepetit, 1844
- Equilibrium; Gravel; Laboratory tests; Littoral current; Sediment transport; Shore protection; Wave energy; Beach erosion; Beaches**
Equilibrium Profiles and Longshore Transport of Coarse Material Under Oblique Wave Attack, E. van Hijum, 1258
- Equilibrium; Tidal effects; Wave energy; Wave spectrum; Beach erosion; Beaches; California**
Beach Profiles at Torrey Pines, California, David G. Aubrey, Douglas L. Inman and Charles E. Nordstrom, 1297
- Erosion; Erosion control; Gullies; Netherlands; Shore protection; Weed control; Weeds**
Recent Applications of Artificial Seaweed in the Netherlands, Henk G.H. ten Hoopen, 2905
- Erosion; Field tests; Groins (structures); Laboratory tests; Littoral drift; Shore protection; Storms; Water temperature; Wave height; Beach erosion**
Laboratory Investigation of Shore Erosion Processes, Ernest F. Brater and David Ponce-Campos, 1493
- Erosion; Great Lakes; Groins (structures); Shore protection; Storms; Breakwaters; Costs**
Low-Cost Shore Protection on the Great Lakes: A Demonstration/Research Program, John M. Armstrong, 2858
- Erosion; Great Lakes; Michigan; Sand; Shore protection; Water levels; Beach erosion; Beach nourishment; Bypasses**
Sand-Bypass and Shore Erosion, Bridgman, Michigan, C. N. Johnson and L. W. Hiipakka, 1361
- Erosion; Groins (structures); Revetments; Sea walls; Shore protection; Breakwaters; Coastal engineering; Costs**
Low-Cost Shoreline Protection, Billy L. Edge, John G. Housley and George M. Watts, 2888
- Erosion; Groins (structures); Rip currents; Waves; Wave tanks; Beach erosion**
Groin Length and the Generation of Edge Waves, Michael K. Gaughan and Paul D. Komar, 1459
- Erosion; Islands (landforms); Sediment deposits; Surges; Aeolian soils; Barriers; Beach erosion**
Barrier Island Dynamics: Overwash Processes and Eolian Transport, Stephen P. Leatherman, 1958
- Erosion; Jetties; Oregon; Sedimentation; Sediment deposits; Shoaling; Bays (topographic features); Beach erosion**
Changes due to Jetties at Tillamook Bay, Oregon, Paul D. Komar and Thomas A. Terich, 1791
- Erosion; Littoral current; Recreational facilities; Storms; Storm surges; Wave action; Wave energy; Beach erosion; Beach nourishment**
Cape Hatteras Beach Nourishment, John S. Fisher and Wilson N. Felder, 1512
- Erosion; Movable bed models; Prototype tests; Scale effect; Scour; Scouring; Tidal waters; Tides**
Movable Bed Tidal Inlet Models, Subhash C. Jain and John F. Kennedy, 3435
- Erosion; Reflection; Sandbars; Sand traps; Three-dimensional; Wave action; Beach erosion; Beach nourishment; Dynamics; Equilibrium**
Three Dimensional Tests on Dynamic Equilibrium and Artificial Nourishment, J. William Kamphuis and R. M. Myers, 1532

- Erosion control; Gullies; Netherlands; Shore protection; Weed control; Weeds; Erosion**
Recent Applications of Artificial Seaweed in the Netherlands, Henk G.H. ten Hoopen, 2905
- Estuaries; Estuarine environment; San Francisco; Sediments; Spoil; Tracers (radioactive); Dredging**
Tracing Estuarine Sediments by Neutron Activation, Richard M. Ecker, John F. Sustar and William T. Harvey, 2009
- Estuaries; Estuarine environment; Sediment deposits; Sediment distribution; Sediments; Tidal effects; Wave action; Beach erosion; Climatic data**
Factors Influencing Estuary Sediment Distribution, Mary P. Kendrick and B. V. Derbyshire, 2072
- Estuaries; Feasibility; Hydraulic models; Mathematical models; Rivers; Tidal effects; Time**
Analysis of Time Conditions for Hybrid Tidal Models, Klaus-Peter Holz, 3460
- Estuaries; Finite element method; Numerical analysis; Shallow water; Tidal effects; Tidal marshes; Water waves**
Finite Element Model for Estuaries with Inter-Tidal Flats, Bruno Herrling, 3396
- Estuaries; Flooding; Hydrographic surveys; Jetties; River flow; Sandbars; Training walls; Australia**
Results of River Mouth Training on the Clarence Bar, New South Wales, Australia, Cyril D. Floyd and Bruce M. Druey, 1738
- Estuaries; Flooding; Inlets (waterways); Tidal currents; Tidal effects; Tidal energy; Tidal hydraulics; Vortices**
Harbour Inlets on Tidal Estuaries, Hans Vollmers, 1854
- Estuaries; Flooding; River flow; Sandbars; Sedimentation; Sediment deposits; Wave action; Wave energy**
Morphodynamics of a Wave-Dominated River Mouth, L. D. Wright, 1721
- Estuaries; Frequency analysis; Hydraulic models; Mathematical models; Mixing; Algorithms; Diffusion**
Algorithm for Vertical Diffusion, Soren Peter Kjeldsen, 3321
- Estuaries; Friction coefficient (hydraulic); Mathematical models; Numerical analysis; Saline water intrusion; Stratification; Transport phenomena; Density currents**
Numerical Model for Density Currents in Estuaries, Karsten Fischer, 3295
- Estuaries; Harbors; Littoral drift; Sand traps; Storms; Wave action; Currents; Dredging**
Design and Behaviour of Sandtraps in Regions of High Littoral Drift, P. C. Saxena, Pazhayanur P. Vaidyaraman and R. Srinivasan, 1377
- Estuaries; Interfaces; Saline water-freshwater interfaces; Salinity; Salt water intrusion; Stratification; Diffusion; Eddies**
Determination of the Interfacial Eddy Diffusion Coefficient of a Highly Stratified Estuary, Yu-Hwa Wang, 3158
- Estuaries; Landforms; Nonuniform flow; Open channel flow; Specific energy**
Concept of Minimum Specific Energy and Its Relation to Natural Forms, Gordon R. McKay and Ahad K. Kazempour, 2186
- Estuaries; Open channel flow; Water meters; Water quality; Calibration; Discharge (water)**
Calibration of Branched Estuary Models, James P. Bennett, 3416
- Estuaries; Predictions; Sewage disposal; Sewage effluents; Tracers; Water pollution; Dispersion; Distribution; Dyes**
Prediction of Pollutant Distribution in Estuaries, Albert Y. Kuo and John P. Jacobson, 3276
- Estuaries; Reservoirs; Tidal currents; Tidal effects; Tidal hydraulics; Tidal marshes; Wave height; Waves**
Waves Used for Inter-Tidal Design and Construction, D. C. Keiller and T. D. Ruxton, 23
- Estuaries; Runoff; Sampling; Simulation; Water circulation; Water quality; Coliform bacteria; Drainage**
State Estimation of Estuarine Circulation and Water Quality by Numerical Simulation and Observation, Jan J. Leendertse and S. K. Liu, 3223
- Estuaries; Saline water-freshwater interfaces; Saline water intrusion; Salinity; Stratified flow; Tracers**
Dynamics of a Longitudinally Stratified Estuary, Jorg Imberger, 3108
- Estuaries; Saline water-freshwater interfaces; Salinity; Salt water intrusion; Tidal currents; Tidal effects; Two phase flow**
Tidal Response of Two-Layer Flow at a River Mouth, Shizuo Yoshida and Masakazu Kashiwamura, 3189
- Estuaries; Stratification; Tidal effects; Wave energy; West Germany; Damping; Energy dissipation**
Energy Dissipation in Tidal Estuaries, Hans-Werner Partenscky and Gunther Barg, 3312
- Estuarine environment; San Francisco; Sediments; Spoil; Tracers (radioactive); Dredging; Estuaries**
Tracing Estuarine Sediments by Neutron Activation, Richard M. Ecker, John F. Sustar and William T. Harvey, 2009
- Estuarine environment; Sediment deposits; Sediment distribution; Sediments; Tidal effects; Wave action; Beach erosion; Climatic data; Estuaries**
Factors Influencing Estuary Sediment Distribution, Mary P. Kendrick and B. V. Derbyshire, 2072
- Experimentation; Field tests; Scour; Scouring; Water levels; Wave action; Wave height; Breakwaters; Coastal structures**
Local Scour and Current Around a Porous Breakwater, Shintaro Hotta and Nobuo Marui, 1590
- Experimentation; Jets; Slots; Buoyancy; Diffusers; Dilution; Discharge (water); Eddies**
Negatively Buoyant Slot Jets, D. M. Shahrabani and J. D. Ditmars, 2976
- Experimentation; Random processes; Wave energy; Wave period; Wave recorders (water waves); Waves; Wave spectrum**
Estimation of Incident and Reflected Waves in Random Wave Experiments, Yoshimi Goda and Yasumasa Suzuki, 828

- Experimentation; Stresses; Testing; Armoring (streambed); Breakwaters**
Experimental Studies of Stresses Within the Breakwater Armor Piece "Dolos", Omar J. Lillevang and Wayne E. Nickola, 2519
- Experimentation; Surf; Wave height; Wave period; Waves; Wave spectrum; Breaking; Dimensional analysis**
Wave Spectrum of Breaking Wave, Toru Sawaragi and Koichiro Iwata, 580
- Explosions; Predictions; Wave generation; Wave height; Wave propagation; Waves; Cavities; Deep water**
Calculations of Waves Formed From Surface Cavities, Charles L. Mader, 1079
- Failure; Harbors; Harbor structures; Hydraulic models; Model tests; Portugal; Breakwaters**
Design of Main Breakwater at Sines Harbour, John Dorrington Mettam, 2499
- Failure; Slope protection; Slope stability; Wave action; Wave energy; Wave period; Armoring (streambed); Breakwaters**
Armour Blocks as Slope Protection, A. F. Whillock and W. A. Price, 2564
- Failures; Laboratory tests; Sandbars; Scale effect; Scour; Scouring; Underwater pipelines; Wave action**
Scour Around Model Pipelines Due to Wave Action, John B. Herbich, 1624
- Feasibility; Hydraulic models; Mathematical models; Rivers; Tidal effects; Time; Estuaries**
Analysis of Time Conditions for Hybrid Tidal Models, Klaus-Peter Holz, 3460
- Fenders; Force; Harmonic functions; Mooring; Moorings; Oscillations; Wave action; Wave energy; Wave period**
Subharmonic Components in Hawser and Fender Forces, J. H. van Oorschot, 2840
- Fetch; Great Lakes; Wave energy; Wave equations; Wave height; Wave period; Waves; Wave spectrum**
Applications of Empirical Fetch-Limited Spectral Formulas to Great Lakes Waves, Paul C. Liu, 113
- Fetch; Ocean waves; Wave energy; Wave forecasting; Waves; Wave spectrum; Wind forces; Wind speed**
Application of Fetch Area Method in Monsoon Wave Hindcasting, Nai-Kuang Liang, Shih-Tsan Tang and Ben-Juen Lee, 258
- Field investigations; Instrumentation; Ocean waves; Scale effect; Storm surges; Wave equations; Wave height; Wave period; Wave runup; Dikes; Echo sounding**
Wave Run-Up in Field Measurements with Newly Developed Instrument, Heie F. Erchinger, 767
- Field investigations; Littoral current; Sediment deposits; Sediment transport; Suspended sediments; Aerial photography; Bathymetry; Beach erosion; Beaches**
Field Investigation of Sediment Transport Pattern in a Closed System, Tsuguo Sunamura and Kiyoshi Horikawa, 1240
- Field tests; Floating bodies; Scale effect; Tethered tests; Wave action; Wave energy; Wave spectrum; Wave tanks; Breakwaters; Buoys; Energy dissipation**
Design, Analysis and Field Test of a Dynamic Floating Breakwater, D. J. Agerton, G. H. Savage and K. C. Stotz, 2792
- Field tests; Groins (structures); Laboratory tests; Littoral drift; Shore protection; Storms; Water temperature; Wave height; Beach erosion; Erosion**
Laboratory Investigation of Shore Erosion Processes, Ernest F. Brater and David Ponce-Campos, 1493
- Field tests; Intake structures; Nuclear power plants; Wave dispersion; Wave energy; Cooling water; Cylindrical bodies**
Wave Pressures on Large Circular Cylindrical Structure, Hiroshi Nakamura, 2290
- Field tests; Littoral drift; Ocean currents; Photogrammetry; Stereophotography; Water levels; Waves; Breaking; Coastal engineering**
Terrestrial Photogrammetric Measurements of Breaking Waves and Longshore Currents in the Nearshore Zone, Joseph W. Maresca, Jr. and Erwin Seibel, 681
- Field tests; Mathematical models; Numerical analysis; Water flow; Wave energy; Wind pressure; Discharge (water); Effluents**
Numerical Modelling — An Aid to Assessing Field Data, H. P. Riedel and F. L. Wilkinson, 3243
- Field tests; Ocean bottom; Ocean waves; Wave action; Wave dispersion; Wave energy; Wave velocity**
Near-Bottom Water Motion Under Ocean Waves, Robert A. Grace, 2371
- Field tests; Scour; Scouring; Water levels; Wave action; Wave height; Breakwaters; Coastal structures; Experimentation**
Local Scour and Current Around a Porous Breakwater, Shintaro Hotta and Nobuo Marui, 1590
- Finite differences; Shallow water; Simulation; Walls; Water waves; Wave action; Waves; Barriers**
Action of Non-Linear Waves at a Solid Wall, Mohamed S. Nasser and John A. McCorquodale, 815
- Finite element method; Numerical analysis; Shallow water; Tidal effects; Tidal marshes; Water waves; Estuaries**
Finite Element Model for Estuaries with Inter-Tidal Flats, Bruno Herrling, 3396
- Finite element method; Numerical analysis; Stratification; Two phase flow; Convection; Diffusion; Dispersion**
Numerical Modeling of Dispersion in Stratified Waters, George C. Christodoulou and Jerome J. Connor, 3138
- Finite elements; Gravity waves; Predictions; Refraction; Surf; Water depth; Waves; Currents**
Current Depth Defraction Using Finite Elements, Ove Skovgaard and Ivar G. Jonsson, 721
- Floating bodies; Forecasting; Harbors; Marinas; Model studies; Mooring; Moorings; Breakwaters**
Floating Breakwater Performance, Bruce H. Adee, 2777

- Floating bodies; Scale effect; Tethered tests; Wave action; Wave energy; Wave spectrum; Wave tanks; Breakwaters; Buoys; Energy dissipation; Field tests**
Design, Analysis and Field Test of a Dynamic Floating Breakwater, D. J. Agerton, G. H. Savage and K. C. Stotz, 2792
- Flooding; Hydrographic surveys; Jetties; River flow; Sandbars; Training walls; Australia; Estuaries**
Results of River Mouth Training on the Clarence Bar, New South Wales, Australia, Cyril D. Floyd and Bruce M. Druery, 1738
- Flooding; Inlets (waterways); Tidal currents; Tidal effects; Tidal energy; Tidal hydraulics; Vortices; Estuaries**
Harbour Inlets on Tidal Estuaries, Hans Vollmers, 1854
- Flooding; Predictions; Storm surges; Tsunamis; Wave runup**
Tsunami Inundation Prediction, Charles L. Bretschneider and Pieter G. Wybro, 1006

Numerical Calculation of Wave Forces on Structures, B. D. Nichols and C. W. Hirt, 2254
- Numerical analysis; Wave energy; Wave recorders (water waves); California; Coastal engineering; Coastal structures**
Regional Network for Coastal Engineering Data, Richard J. Seymour and Meredith H. Sessions, 60
- Ocean bottom; Oceanography; Refraction; Resonance; Islands (landforms)**
Resonant Refraction by Round Islands, Richard E. Meyer, 866
- Ocean bottom; Ocean waves; Wave action; Wave dispersion; Wave energy; Wave velocity; Field tests**
Near-Bottom Water Motion Under Ocean Waves, Robert A. Grace, 2371
- Ocean bottom; Offshore structures; Predictions; Stability; Wave action; Wave energy; Bottom water; Continental shelf; Cyclic loads; Foundations**
Prediction of Wave-Induced Seafloor Movements, Leland Milo Kraft, Jr. and David James Watkins, 1605
- Ocean bottom; Ripple marks; Shallow water; Turbulent diffusion; Friction coefficient (hydraulic)**
Consideration on Friction Coefficient for Sea Bottom, Toru Sawaragi, Koichiro Iwata and Masayoshi Kubo, 595
- Ocean bottom; Scale effect; Sediment transport; Simulation models; Tidal effects; Wave energy; Bed forms; Inlets (waterways)**
Tidal Inlet Flow Dynamics and Sediment Movement, Jerry L. Machemehl, N. E. Bird and A. N. Chambers, 1681
- Ocean bottom; Shoaling; Topographical factors; Beach erosion; Beaches; Breakwaters; Construction; Harbor structures; Japan**
Topographic Change Resulting from the Construction of a Harbor on a Sandy Beach, Kashima Port, Norio Tanaka and Shoji Sato, 1824
- Ocean bottom; Shore protection; Subsidence; Beach erosion; Breakwaters; Japan**
Changes of Sea Bed Due to Detached Breakwaters, Osamu Toyoshima, 1572
- Ocean currents; Photogrammetry; Stereophotography; Water levels; Waves; Breaking; Coastal engineering; Field tests; Littoral drift**
Terrestrial Photogrammetric Measurements of Breaking Waves and Longshore Currents in the Nearshore Zone, Joseph W. Maresca, Jr. and Erwin Seibel, 681
- Ocean currents; Rip currents; Sediment transport; Wave height; Wave phases; Littoral drift**
Physical Aspects of Wave-Induced Nearshore Current System, Masaru Mizuguchi and Kiyoshi Horikawa, 607
- Ocean currents; Rip currents; Time dependence; Wave height; Wave period; Wave spectrum; Wave velocity; Flowmeters**
Time Dependent Fluctuations in Longshore Currents, Guy A. Meadows, 660
- Ocean currents; Rip currents; Wave recorders (water waves); Beaches; Japan; Littoral drift**
Nearshore Current on a Gently Sloping Beach, Tamio Sasaki, Kiyoshi Horikawa and Shintaro Hotta, 626

- Ocean currents; Sediment transport; Storm surges; Tidal marshes; Coastal engineering; Currents; Littoral drift**
Currents in Tidal Flats During Storm Surges, Harald Gohren, 959
- Ocean currents; Spreading; Time dependence; Wastewater; Buoyancy; Fluid mechanics; Gravitation**
Buoyancy-Driven Gravitational Spreading, Robert C.Y. Koh, 2956
- Ocean currents; Three-dimensional; Wave dispersion; Wave height; Waves; Breaking; Breakwaters; Friction coefficient (hydraulic); Littoral drift**
Non-Uniform Alongshore Currents, Michael R. Gourlay, 701
- Ocean engineering; Outfall sewers; Underwater pipelines; Diffusers; Environmental effects; Hydrodynamics**
Design Considerations for the Sand Island and Barbers Point Outfalls, Robert C.Y. Koh, Norman H. Brooks and Floyd Louis Vuillemot, 2941
- Oceanography; Refraction; Resonance; Islands (landforms); Ocean bottom**
Resonant Refraction by Round Islands, Richard E. Meyer, 866
- Ocean waves; Radar equipment; Wave height; Wavemeters; Wave recorders (water waves); Wave spectrum**
Wave Measurements in Open Ocean, Davidson T. Chen, Benjamin S. Yaplee, Donald L. Hammond and Paul Bey, 72
- Ocean waves; Random variables; Simulation; Waves; Wave tanks; Laboratory tests**
Random Wave Simulation in a Laboratory Wave Tank, Akira Kimura and Yuichi Iwagaki, 368
- Ocean waves; Resonance; Simulation; Water levels; Wave height; Wave runoff; Beaches**
Wave Run-Up on a Simulated Beach, A. J. Sutherland, J. N. Sharma and Omar H. Shemdin, 752
- Ocean waves; Scale effect; Storm surges; Wave equations; Wave height; Wave period; Wave runoff; Dikes; Echo sounding; Field investigations; Instrumentation**
Wave Run-Up in Field Measurements with Newly Developed Instrument, Heie F. Erchinger, 767
- Ocean waves; Spectral analysis; Statistical analysis; Storms; Wave height; Wave spectrum**
Six-Parameter Wave Spectra, Michel K. Ochi and E. Nadine Hubble, 301
- Ocean waves; Spectral analysis; Statistical analysis; Wave forecasting; Wave period; Waves; Wave spectrum; Climatology; Coastal engineering**
Ocean Wave Statistics from FNWC Spectral Analysis, Warren C. Thompson and F. Michael Reynolds, 238
- Ocean waves; Surface waves; Wave energy; Wave spectrum; Distribution functions; Distribution patterns; Frequency**
Directional Spectral of Ocean Surface Waves, Hisashi Mitsuyasu and S. Mizuno, 329
- Ocean waves; Taiwan; Wave height; Wave period; Waves; Wind speed; Coastal engineering**
Waves Off Taichung Coast of Taiwan, Charles C.C. Chang, M. H. Wang and J. T. Juang, 129
- Ocean waves; Wave action; Wave dispersion; Wave energy; Wave velocity; Field tests; Ocean bottom**
Near-Bottom Water Motion Under Ocean Waves, Robert A. Grace, 2371
- Ocean waves; Wave action; Wave height; Wave propagation; Wave spectrum**
Revisions in Wave Data Presentation, Laurence Draper, 3
- Ocean waves; Wave energy; Wave forecasting; Waves; Wave spectrum; Wind forces; Wind speed; Fetch**
Application of Fetch Area Method in Monsoon Wave Hindcasting, Nai-Kuang Liang, Shih-Tsan Tang and Ben-Juen Lee, 258
- Ocean waves; Wave energy; Wave height; Wavemeters; Wave recorders (water waves); Waves; Climatic data**
Wave Climate Analysis for Engineering Purpose, Hans H. Dette and Alfred Fuhrboter, 10
- Offshore drilling; Ships; Wave tanks; Accidents; Collisions; Harbor structures; Mooring; Moorings**
Protection of Maritime Structures Against Ship Collisions, Kazuki Oda and Shositiro Nagai, 2810
- Offshore structures; Predictions; Stability; Wave action; Wave energy; Bottom water; Continental shelf; Cyclic loads; Foundations; Ocean bottom**
Prediction of Wave-Induced Seafloor Movements, Leland Milo Kraft, Jr. and David James Watkins, 1605
- Offshore structures; Prototype tests; Scour; Scouring; Wave action; Wave energy; Wharves**
Wave Action on Large Off-Shore Structures, C. J. Apelt and A. Macknight, 2228
- Open channel flow; River flow; Sediment transport; Tidal currents; Dispersion; Mass transfer**
Dispersive Transport in River and Tidal Flows, R. B. Taylor, 3336
- Open channel flow; Specific energy; Estuaries; Landforms; Nonuniform flow**
Concept of Minimum Specific Energy and Its Relation to Natural Forms, Gordon R. McKay and Ahad K. Kazemipour, 2186
- Open channel flow; Water meters; Water quality; Calibration; Discharge (water); Estuaries**
Calibration of Branched Estuary Models, James P. Bennett, 3416
- Oregon; Sedimentation; Sediment deposits; Shoaling; Bays (topographic features); Beach erosion; Erosion; Jetties**
Changes due to Jetties at Tillamook Bay, Oregon, Paul D. Komar and Thomas A. Terich, 1791
- Orifices; Pipes; Porous materials; Air bubbles; Air flow rates; Manifold air injection systems; Model tests**
Guidelines for the Design of Air Bubble Systems, Nabil Ismail, 2994
- Oscillation; Roughness (hydraulic); Vortices; Water flow; Cylindrical bodies; Drag; Force**
Forces on Rough-Walled Circular Cylinders in Harmonic Flow, Turgut Sarpkaya, 2301
- Oscillation; Sediment transport; Unsteady flow; Wave equations; Waves; Breakwaters**
Quantitative Description of Sediment Transport, Ole Secher Madsen and William D. Grant, 1093

- Oscillations; Pressure distribution; Vortices; Wakes; Water waves; Cylindrical bodies; Flow separation**
Flow Separation, Wake Vortices and Pressure Distribution Around a Circular Cylinder under Oscillatory Waves, Yuichi Iwagaki and Hajime Ishida, 2341
- Oscillations; Responses; Water depth; Water surface profiles; Wave action; Wave energy; Numerical analysis**
Wave Induced Oscillations of Harbors with Variable Depth, Fredric Raichlen and Ehud Naheer, 2536
- Oscillations; Reynolds number; Stream flow; Water flow; Wave action; Wave energy; Cylinders; Drag; Hydraulic models; Lift**
High Reynolds Number Oscillating Flow by Cylinders, Tokuo Yamamoto and John H. Nath, 2321
- Oscillations; Wave action; Wave energy; Wave period; Fenders; Force; Harmonic functions; Mooring; Moorings**
Subharmonic Components in Hawser and Fender Forces, J. H. van Oorschot, 2840
- Outfall sewers; Site selection; Water quality; Diffusers; Dilution; Mixing**
Design Procedures for Ocean Outfalls, Jeffrey A. Layton, 2919
- Outfall sewers; Underwater pipelines; Diffusers; Environmental effects; Hydrodynamics; Ocean engineering**
Design Considerations for the Sand Island and Barbers Point Outfalls, Robert C.Y. Koh, Norman H. Brooks and Floyd Louis Vuillemot, 2941
- Overtopping; Periodic variations; Wave height; Wave runup; Waves; Dikes; Discharge (water)**
Characteristics of Flow in Run-Up of Periodic Waves, Ary Roos and Jurjen A. Batjjes, 781
- Overtopping; Rubble mounds; Wave action; Wave energy; Waves; Wave spectrum; Breakwaters**
Overtopping of Rubble-Mound Breakwaters by Irregular Waves, Yvon Ouellet and Pierre Eubanks, 2756
- Overtopping; Scale effect; Shore protection; Slopes; Wave equations; Wave runup**
Wave Overtopping Equation, J. Richard Weggel, 2737
- Overturning tests; Wave action; Wave energy; Wave height; Wave period; Caissons; Model tests**
Wave Forces on Aquare Caissons, G. R. Mogridge and W. W. Jamieson, 2271
- Performance; Safety; Site selection; Utilization; Barges; Economic analysis; Environmental effects; Harbors**
Probable Utilization Level for a Barge Harbor, Martin T. Czerniak and Choule J. Sonu, 3557
- Periodic functions; Phase velocity; Water depth; Wave energy; Wave height; Waves; Beaches; Deformation**
Deformation up to Breaking of Periodic Waves on a Beach, Ib A. Svendsen and J. Buhr Hansen, 477
- Periodic variations; Refraction; Wave energy; Wave propagation; Waves; Boundary value problems; Coastal engineering; Computation**
Physics and Mathematics of Waves in Coastal Zones, H. Lundgren, 880
- Periodic variations; Shoaling; Slopes; Wave period; Wave runup; Waves; Breaking**
Set-Up and Run-Up in Shoaling Breakers, William G. Van Dorn, 738
- Periodic variations; Wave height; Wave runup; Waves; Dikes; Discharge (water); Overtopping**
Characteristics of Flow in Run-Up of Periodic Waves, Ary Roos and Jurjen A. Batjjes, 781
- Permeability; Reflection; Wave height; Breakwaters; Laboratory tests**
Laboratory Study of Pervious Core Breakwaters, Hideo Kondo, Satoshi Toma and Kenji Yano, 2643
- Permeability; Reservoirs; Sea walls; Wave energy; Wave period; Concrete (blocks)**
Permeable Seawall with Reservoir and the Use of "Warock", Takeshi Ijima, Enzoh Tanaka and Hideaki Okuzono, 2623
- Permeability; Sea walls; Two-dimensional; Water depth; Water waves; Wave height; Boundary value problems; Breakwaters**
Method of Analyses for Two-Dimensional Water Wave Problems, Takeshi Ijima, Chung Ren Chou and Akinori Yoshida, 2717
- Phase velocity; Water depth; Wave energy; Wave height; Waves; Beaches; Deformation; Periodic functions**
Deformation up to Breaking of Periodic Waves on a Beach, Ib A. Svendsen and J. Buhr Hansen, 477
- Photogrammetry; Stereophotography; Water levels; Waves; Breaking; Coastal engineering; Field tests; Littoral drift; Ocean currents**
Terrestrial Photogrammetric Measurements of Breaking Waves and Longshore Currents in the Nearshore Zone, Joseph W. Maresca, Jr. and Erwin Seibel, 681
- Pile foundations; Steel piles; Structural design; Coastal structures; Lateral forces**
Concepts in Design of Coastal Structures, Casimir J. Kray, 2209
- Pipes; Porous materials; Air bubbles; Air flow rates; Manifold air injection systems; Model tests; Orifices**
Guidelines for the Design of Air Bubble Systems, Nabil Ismail, 2994
- Plume detection; Plumes; Thermal pollution; Two phase flow; Diffusers; Discharge (water); Hydraulic models; Nuclear power plants**
Field Studies of Submerged-Diffuser Thermal Plumes with Comparisons to Predictive Model Results, A. A. Frigo, Richard A. Paddock and J. D. Ditmars, 3028
- Plumes; Thermal pollution; Two phase flow; Diffusers; Discharge (water); Hydraulic models; Nuclear power plants; Plume detection**
Field Studies of Submerged-Diffuser Thermal Plumes with Comparisons to Predictive Model Results, A. A. Frigo, Richard A. Paddock and J. D. Ditmars, 3028

- Porous materials; Air bubbles; Air flow rates; Manifold air injection systems; Model tests; Orifices; Pipes**
Guidelines for the Design of Air Bubble Systems, Nabil Ismail, 2994
- Ports; Beach erosion; Beach nourishment; Equilibrium; Forecasting; France; Marinas**
Impact of Yachting Marinas on Beaches, J. P. Lepetit, 1844
- Portugal; Breakwaters; Failure; Harbors; Harbor structures; Hydraulic models; Model tests**
Design of Main Breakwater at Sines Harbour, John Dorrington Mettam, 2499
- Power spectra; Refraction; Shoaling; Tsunamis; Warning systems; Coastal engineering; Coastal plains; Japan**
Transformation of Tsunamis in a Coastal Zone, Shigehisa Nakamura, Haruo Higuchi and Yoshito Tsuchiya, 988
- Predictions; Prototype tests; Scale effect; Surface tension; Thermal diffusion; Viscosity; Water temperature; Hydraulic models**
Adaptability of Prediction Method of Hydraulic Model Experiment for Thermal Diffusion, Masanobu Kato and Akira Wada, 3082
- Predictions; Refraction; Surf; Water depth; Waves; Currents; Finite elements; Gravity waves**
Current Depth Defraction Using Finite Elements, Ove Skovgaard and Ivar G. Jonsson, 721
- Predictions; Sediment deposits; Sediment transport; Beach nourishment; Beach sands; Littoral current**
Predictive Equations Regarding Coastal Transport, D. H. Swart, 1113
- Predictions; Sewage disposal; Sewage effluents; Tracers; Water pollution; Dispersion; Distribution; Dyes; Estuaries**
Prediction of Pollutant Distribution in Estuaries, Albert Y. Kuo and John P. Jacobson, 3276
- Predictions; Stability; Wave action; Wave energy; Bottom water; Continental shelf; Cyclic loads; Foundations; Ocean bottom; Offshore structures**
Prediction of Wave-Induced Seafloor Movements, Leland Milo Kraft, Jr. and David James Watkins, 1605
- Predictions; Storm surges; Tsunamis; Wave runoff; Flooding**
Tsunami Inundation Prediction, Charles L. Bretschneider and Pieter G. Wybro, 1006
- Predictions; Wave generation; Wave height; Wave propagation; Waves; Cavities; Deep water; Explosions**
Calculations of Waves Formed From Surface Cavities, Charles L. Mader, 1079
- Pressure cells; Shock tests; Strain; Strain gages; Breakwaters; Caissons; Concrete (reinforced); Cylindrical bodies; Model tests**
Cylindrical Caisson Breakwater: Strain Model Tests, Helge Gravesen, Finn P. Brodersen, Jorn S. Larsen and H. Lundgren, 2357
- Pressure distribution; Vortices; Wakes; Water waves; Cylindrical bodies; Flow separation; Oscillations**
Flow Separation, Wake Vortices and Pressure Distribution Around a Circular Cylinder under Oscillatory Waves, Yuichi Iwagaki and Hajime Ishida, 2341
- Probability; Simulation; Simulation models; Storm surges; Delaware; New Jersey**
Simulation Model for Storm Surge Probabilities, Mohammad H. Fallah, J. N. Sharma and Cheng Y. Yang, 934
- Propagation; Shallow water; Tsunamis; Wave height; Friction coefficient (hydraulic); Numerical analysis**
Tsunami Propagation in the Pacific Ocean, Manfred Engel and Wilfried Zahel, 971
- Propagation; Shore protection; Simulation; Tsunamis; Numerical analysis**
Numerical Simulation of Tsunamis Originating in the Peru-Chile Trench, A. W. Garcia and H. L. Butler, 1025
- Prototype tests; Roughness (hydraulic); Tidal currents; Tidal effects; Tidal energy; Hydraulic models**
Model Verification for Tidal Constituents, R. W. Whalin, F. C. Perry and D. L. Durham, 3377
- Prototype tests; Scale effect; Scour; Scouring; Tidal waters; Tides; Erosion; Movable bed models**
Movable Bed Tidal Inlet Models, Subhash C. Jain and John F. Kennedy, 3435
- Prototype tests; Scale effect; Surface tension; Thermal diffusion; Viscosity; Water temperature; Hydraulic models; Predictions**
Adaptability of Prediction Method of Hydraulic Model Experiment for Thermal Diffusion, Masanobu Kato and Akira Wada, 3082
- Prototype tests; Scour; Scouring; Wave action; Wave energy; Wharves; Offshore structures**
Wave Action on Large Off-Shore Structures, C. J. Apelt and A. Macknight, 2228
- Prototype tests; Temperature distribution; Thermal diffusion; Thermal pollution; Water temperature; Discharge (water); Hydraulic models; Nuclear power plants**
Thermal Discharges: Prototype vs. Hydraulic Model, Gary C. Parker, Ching S. Fang and Albert Y. Kuo, 3049
- Quays; Reflection; Revetments; Shore protection; Wave dispersion; Computerized simulation; Concrete (blocks); Harbor structures**
Quay Wall with Wave Absorber "Igloo", Naofumi Shiraishi, Robert Q. Palmer and Hiroshi Okamoto, 2677
- Radar equipment; Wave height; Wavemeters; Wave recorders (water waves); Wave spectrum; Ocean waves**
Wave Measurements in Open Ocean, Davidson T. Chen, Benjamin S. Yaplee, Donald L. Hammond and Paul Bey, 72
- Random processes; Reflection; Water waves; Wave dispersion; Wave energy; Wave spectrum; Coastal structures**
Decomposition of Co-Existing Random Wave Energy, Dennis B. Morden, Eugene P. Richey and Derald R. Christensen, 846
- Random processes; Wave energy; Wave period; Wave recorders (water waves); Waves; Wave spectrum; Experimentation**
Estimation of Incident and Reflected Waves in Random Wave Experiments, Yoshimi Goda and Yasumasa Suzuki, 828

- Random variables; Simulation; Waves; Wave tanks; Laboratory tests; Ocean waves**
Random Wave Simulation in a Laboratory Wave Tank, Akira Kimura and Yuichi Iwagaki, 368
- Recreational facilities; Shore protection; Sri Lanka; Beach nourishment; Coastal engineering**
Coastal Problems in Sri Lanka, Franciscus Gerritsen and Summa R. Amarasinghe, 3487
- Recreational facilities; Shore protection; Swimming; Beaches; Beach nourishment; Breakwaters; Hawaii**
Proposed "Improvement" of Kaimu Beach, Hawaii, Doak C. Cox, Franciscus Gerritsen and Theodore T. Lee, 1552
- Recreational facilities; Social needs; Beaches; Breakwaters; Enclosures; Groins (structures); Israel**
Enclosing Scheme for Bathing-Beach Development, Joseph Tauman, 1425
- Recreational facilities; Storms; Storm surges; Wave action; Wave energy; Beach erosion; Beach nourishment; Erosion; Littoral current**
Cape Hatteras Beach Nourishment, John S. Fisher and Wilson N. Felder, 1512
- Reefs; Runways; Water quality; Environmental effects; Hawaii; Islands (landforms); Monitoring**
Environmental Impacts on an Island Community, Gordon A. Chapman, 3506
- Reefs; Slope protection; Slope stability; Airports; Breakwaters; Hawaii**
Design and Construction of Protective Structure for New Reef Runway at Honolulu International Airport, Wilfred D. Darling, 2589
- Reflection; Revetments; Shore protection; Wave dispersion; Computerized simulation; Concrete (blocks); Harbor structures; Quays**
Quay Wall with Wave Absorber "Igloo", Naofumi Shiraiishi, Robert Q. Palmer and Hiroshi Okamoto, 2677
- Reflection; Sandbars; Sand traps; Three-dimensional; Wave action; Beach erosion; Beach nourishment; Dynamics; Equilibrium; Erosion**
Three Dimensional Tests on Dynamic Equilibrium and Artificial Nourishment, J. William Kamphuis and R. M. Myers, 1532
- Reflection; Slitting; Wave action; Wave damping; Wave energy; Breakwaters**
Slit-Type Breakwater: Box-Type Wave Absorber, Shositiro Nagai and Shohachi Kakuno, 2697
- Reflection; Walls; Water waves; Wave height; Diffraction; Mach number**
Mach-Reflection as a Diffraction Problem, Udo Berger and Soren Kohlhasse, 796
- Reflection; Water waves; Wave dispersion; Wave energy; Wave spectrum; Coastal structures; Random processes**
Decomposition of Co-Existing Random Wave Energy, Dennis B. Morden, Eugene P. Richey and Derald R. Christensen, 846
- Reflection; Wave height; Breakwaters; Laboratory tests; Permeability**
Laboratory Study of Pervious Core Breakwaters, Hideo Kondo, Satoshi Toma and Kenji Yano, 2643
- Refraction; Resonance; Islands (landforms); Ocean bottom; Oceanography**
Resonant Refraction by Round Islands, Richard E. Meyer, 866
- Refraction; Sediment transport; Wave dispersion; Waves; Coastal structures; Cooling water; Intake systems; Mathematical models; Nuclear power plants; Numerical analysis**
Application of a Sediment Transport Model, C. A. Fleming and J. N. Hunt, 1184
- Refraction; Shoaling; Tsunamis; Warning systems; Coastal engineering; Coastal plains; Japan; Power spectra**
Transformation of Tsunamis in a Coastal Zone, Shigehisa Nakamura, Haruo Higuchi and Yoshito Tsuchiya, 988
- Refraction; Shoaling; Wave action; Wave dispersion; Wave height; Waves; Wave velocity; Breaking**
Refraction of Finite-Height and Breaking Waves, James R. Walker, 507
- Refraction; Surf; Water depth; Waves; Currents; Finite elements; Gravity waves; Predictions**
Current Depth Defraction Using Finite Elements, Ove Skovgaard and Ivar G. Jonsson, 721
- Refraction; Wave energy; Wave propagation; Waves; Boundary value problems; Coastal engineering; Computation; Periodic variations**
Physics and Mathematics of Waves in Coastal Zones, H. Lundgren, 880
- Remote sensing; Water temperature; Air-water interfaces; Heat flux; Heat transfer; Infrared scanners; Infrared scanning**
Evaluation of Air-Sea Interface Heat Flux, Robert L. Street and A. Woodruff Miller, Jr., 3208
- Reservoirs; Sea walls; Wave energy; Wave period; Concrete (blocks); Permeability**
Permeable Seawall with Reservoir and the Use of "Warock", Takeshi Ijima, Enzoh Tanaka and Hideaki Okuzono, 2623
- Reservoirs; Tidal currents; Tidal effects; Tidal hydraulics; Tidal marshes; Wave height; Waves; Estuaries**
Waves Used for Inter-Tidal Design and Construction, D. C. Keiller and T. D. Ruxton, 23
- Resonance; Islands (landforms); Ocean bottom; Oceanography; Refraction**
Resonant Refraction by Round Islands, Richard E. Meyer, 866
- Resonance; Rubble; Rubble mounds; Slope stability; Stability; Surf; Wave period; Wave runup; Breakwaters**
New Design Principles for Rubble Mound Structures, Per Moller Bruun and Ali Riza Gunbak, 2429
- Resonance; Simulation; Water levels; Wave height; Wave runup; Beaches; Ocean waves**
Wave Run-Up on a Simulated Beach, A. J. Sutherland, J. N. Sharma and Omar H. Shemdin, 752
- Resonance; Surges; Turbulence; Wave height; Wave runup; Waves; Beaches; Breaking**
Resonant Interactions for Waves Breaking on a Beach, Robert T. Guza and Anthony J. Bowen, 560

- Responses; Rip currents; Velocity distribution; Water waves; Wave equations; Coastal topographic features; Eigenvalues**
Rip-Current and Coastal Topography, Mikio Hino, 1326
- Responses; Stability; Statistical analysis; Storms; Variability; Beach erosion; Eigenvalues; Impulses**
Stability and Impulse Response of Empirical Eigenfunctions, Clinton D. Winant and David G. Aubrey, 1312
- Responses; Water depth; Water surface profiles; Wave action; Wave energy; Numerical analysis; Oscillations**
Wave Induced Oscillations of Harbors with Variable Depth, Fredric Raichlen and Ehud Naheer, 3536
- Revetments; Sea walls; Shore protection; Breakwaters; Coastal engineering; Costs; Erosion; Groins (structures)**
Low-Cost Shoreline Protection, Billy L. Edge, John G. Housley and George M. Watts, 2888
- Revetments; Shore protection; Wave dispersion; Computerized simulation; Concrete (blocks); Harbor structures; Quays; Reflection**
Quay Wall with Wave Absorber "Igloo", Naofumi Shiraishi, Robert Q. Palmer and Hiroshi Okamoto, 2677
- Revetments; Wave action; Wave energy; Air entrainment; Damage; Dikes; Impact**
Response of Seadykes due to Wave Impacts, Alfred Fuhrboter, Hans H. Dette and J. Grune, 2604
- Reynolds number; Stream flow; Water flow; Wave action; Wave energy; Cylinders; Drag; Hydraulic models; Lift; Oscillations**
High Reynolds Number Oscillating Flow by Cylinders, Tokuo Yamamoto and John H. Nath, 2321
- Rip currents; Sediment transport; Shore protection; Energy equation; Littoral current; Littoral drift**
Longshore Transport Prediction — SPM 1973 Equation, Cyril J. Galvin and Philip Vitale, 1133
- Rip currents; Sediment transport; Wave height; Wave phases; Littoral drift; Ocean currents**
Physical Aspects of Wave-Induced Nearshore Current System, Masaru Mizuguchi and Kiyoshi Horikawa, 607
- Rip currents; Surf; Turbulence; Beaches; Flowmeters; Friction coefficient (hydraulic)**
Lateral and Bottom Forces on Longshore Currents, David A. Huntley, 645
- Rip currents; Time dependence; Wave height; Wave period; Wave spectrum; Wave velocity; Flowmeters; Ocean currents**
Time Dependent Fluctuations in Longshore Currents, Guy A. Meadows, 660
- Rip currents; Velocity distribution; Water waves; Wave equations; Coastal topographic features; Eigenvalues; Responses**
Rip-Current and Coastal Topography, Mikio Hino, 1326
- Rip currents; Wave recorders (water waves); Beaches; Japan; Littoral drift; Ocean currents**
Nearshore Current on a Gently Sloping Beach, Tamio Sasaki, Kiyoshi Horikawa and Shintaro Hotta, 626
- Rip currents; Waves; Wave tanks; Beach erosion; Erosion; Groins (structures)**
Groin Length and the Generation of Edge Waves, Michael K. Gaughan and Paul D. Komar, 1459
- Ripple marks; Sand; Sonar detection; Wave action; Wave generation; Bedding materials; Bed ripples**
Wave-Formed Ripples in Nearshore Sands, John R. Dinger and Douglas L. Inman, 2109
- Ripple marks; Shallow water; Turbulent diffusion; Friction coefficient (hydraulic); Ocean bottom**
Consideration on Friction Coefficient for Sea Bottom, Toru Sawaragi, Koichiro Iwata and Masayoshi Kubo, 595
- River flow; Sandbars; Sedimentation; Sediment deposits; Wave action; Wave energy; Estuaries; Flooding**
Morphodynamics of a Wave-Dominated River Mouth, L. D. Wright, 1721
- River flow; Sandbars; Training walls; Australia; Estuaries; Flooding; Hydrographic surveys; Jetties**
Results of River Mouth Training on the Clarence Bar, New South Wales, Australia, Cyril D. Floyd and Bruce M. Druery, 1738
- River flow; Sediment transport; Tidal currents; Dispersion; Mass transfer; Open channel flow**
Dispersive Transport in River and Tidal Flows, R. B. Taylor, 3336
- River regulation; Sandbars; Sediment transport; Stability; Tidal effects; Tidal hydraulics; Tidal waters; Channels (waterways)**
Stability of Tidal Channels Dependent on River Improvement, Volker Barthel, 1775
- Rivers; Tidal effects; Time; Estuaries; Feasibility; Hydraulic models; Mathematical models**
Analysis of Time Conditions for Hybrid Tidal Models, Klaus-Peter Holz, 3460
- Roughness (hydraulic); Tidal currents; Tidal effects; Tidal energy; Hydraulic models; Prototype tests**
Model Verification for Tidal Constituents, R. W. Whalin, F. C. Perry and D. L. Durham, 3377
- Roughness (hydraulic); Vortices; Water flow; Cylindrical bodies; Drag; Force; Oscillation**
Forces on Rough-Walled Circular Cylinders in Harmonic Flow, Turgut Sarpkaya, 2301
- Rubble; Rubble mounds; Slope stability; Stability; Surf; Wave period; Wave runoff; Breakwaters; Resonance**
New Design Principles for Rubble Mound Structures, Per Moller Bruun and Ali Riza Gunbak, 2429
- Rubble; Rubble mounds; Stability; Wave action; Wave energy; Breakwaters; Damage; Hydraulic models**
Effect of Broken Dolosse on Breakwater Stability, D. Donald Davidson and Dennis G. Markle, 2544

- Rubble mounds; Slope stability; Stability; Surf; Wave period; Wave runoff; Breakwaters; Resonance; Rubble**
New Design Principles for Rubble Mound Structures, Per Moller Bruun and Ali Riza Gunbak, 2429
- Rubble mounds; Stability; Wave action; Wave energy; Breakwaters; Damage; Hydraulic models; Rubble**
Effect of Broken Dolosse on Breakwater Stability, D. Donald Davidson and Dennis G. Markle, 2544
- Rubble mounds; Wave action; Wave dispersion; Wave energy; Waves; Breakwaters; Laboratory tests**
Wave Transmission Through Trapezoidal Breakwaters, Ole Secher Madsen and Stanley M. White, 2662
- Rubble mounds; Wave action; Wave energy; Harbors; Harbor structures; History; Jetties**
Design and Construction of Humboldt Jetties, 1880 to 1975, Orville T. Magoon, Robert L. Sloan and Nobuyuki Shimizu, 2474
- Rubble mounds; Wave action; Wave energy; Waves; Wave spectrum; Breakwaters; Overtopping**
Overtopping of Rubble-Mound Breakwaters by Irregular Waves, Yvon Ouellet and Pierre Eubanks, 2756
- Runoff; Sampling; Simulation; Water circulation; Water quality; Coliform bacteria; Drainage; Estuaries**
State Estimation of Estuarine Circulation and Water Quality by Numerical Simulation and Observation, Jan J. Leendertse and S. K. Liu, 3223
- Runways; Water quality; Environmental effects; Hawaii; Islands (landforms); Monitoring; Reefs**
Environmental Impacts on an Island Community, Gordon A. Chapman, 3506
- Safety; Site selection; Utilization; Barges; Economic analysis; Environmental effects; Harbors; Performance**
Probable Utilization Level for a Barge Harbor, Martin T. Czerniak and Choule J. Sonu, 3557
- Saline water-freshwater interfaces; Saline water intrusion; Salinity; Stratified flow; Tracers; Estuaries**
Dynamics of a Longitudinally Stratified Estuary, Jorg Imberger, 3108
- Saline water-freshwater interfaces; Salinity; Salt water intrusion; Stratification; Diffusion; Eddies; Estuaries; Interfaces**
Determination of the Interfacial Eddy Diffusion Coefficient of a Highly Stratified Estuary, Yu-Hwa Wang, 3158
- Saline water-freshwater interfaces; Salinity; Salt water intrusion; Tidal currents; Tidal effects; Two phase flow; Estuaries**
Tidal Response of Two-Layer Flow at a River Mouth, Shizuo Yoshida and Masakazu Kashiwamura, 3189
- Saline water-freshwater interfaces; Salinity; Salt water intrusion; Tidal effects; Canada; Density currents; Hydraulic models**
Churchill River Salt-Water Tidal Model, Bruce D. Pratte, 3445
- Samplers; Sampling; Sediment concentration; Sediment samplers; Sediment sampling; Surf; Suspended sediments; Wave action**
Measurement of Suspended Sediment in the Surf Zone, F. A. Kilner, 2045
- Sampling; Sediment concentration; Sediment samplers; Sediment sampling; Surf; Suspended sediments; Wave action; Samplers**
Measurement of Suspended Sediment in the Surf Zone, F. A. Kilner, 2045
- Sampling; Simulation; Water circulation; Water quality; Coliform bacteria; Drainage; Estuaries; Runoff**
State Estimation of Estuarine Circulation and Water Quality by Numerical Simulation and Observation, Jan J. Leendertse and S. K. Liu, 3223
- Saline water intrusion; Salinity; Stratified flow; Tracers; Estuaries; Saline water-freshwater interfaces**
Dynamics of a Longitudinally Stratified Estuary, Jorg Imberger, 3108
- Saline water intrusion; Stratification; Transport phenomena; Density currents; Estuaries; Friction coefficient (hydraulic); Mathematical models; Numerical analysis**
Numerical Model for Density Currents in Estuaries, Karsten Fischer, 3295
- Salinity; Salt water intrusion; Stratification; Diffusion; Eddies; Estuaries; Interfaces; Saline water-freshwater interfaces**
Determination of the Interfacial Eddy Diffusion Coefficient of a Highly Stratified Estuary, Yu-Hwa Wang, 3158

Model Verification for Tidal Constituents, R. W. Whalin, F. C. Perry and D. L. Durham, 3377
- Tidal energy; Tidal hydraulics; Tidal waters; Wave energy; Inlets (waterways); Japan; Tidal effects**
Characteristics of Tidal Inlets on the Pacific Coast of Japan, Toshiyuki Shigemura, 1666
- Tidal energy; Tidal hydraulics; Vortices; Estuaries; Flooding; Inlets (waterways); Tidal currents; Tidal effects**
Harbour Inlets on Tidal Estuaries, Hans Vollmers, 1854
- Tidal energy; Warning systems; Flood plain insurance; Hurricanes; Storms; Tidal effects**
Hurricane Tide Frequencies on the Atlantic Coast, Francis P. Ho, 886
- Tidal hydraulics; Tidal marshes; Wave height; Waves; Estuaries; Reservoirs; Tidal currents; Tidal effects**
Waves Used for Inter-Tidal Design and Construction, D. C. Keiller and T. D. Ruxton, 23
- Tidal hydraulics; Tidal waters; Channels (waterways); River regulation; Sandbars; Sediment transport; Stability; Tidal effects**
Stability of Tidal Channels Dependent on River Improvement, Volker Barthel, 1775
- Tidal hydraulics; Tidal waters; Wave energy; Inlets (waterways); Japan; Tidal effects**
Characteristics of Tidal Inlets on the Pacific Coast of Japan, Toshiyuki Shigemura, 1666
- Tidal hydraulics; Tides; Washington; Water circulation; Water depth; Flushing; Harbors; Tidal currents; Tidal effects**
Planform Influence on Flushing and Circulation in Small Harbors, Ronald C. Nece, Roger A. Falconer and Toshiro Tsutsumi, 3471
- Tidal hydraulics; Vortices; Estuaries; Flooding; Inlets (waterways); Tidal currents; Tidal effects; Tidal energy**
Harbour Inlets on Tidal Estuaries, Hans Vollmers, 1854
- Tidal marshes; Coastal engineering; Currents; Littoral drift; Ocean currents; Sediment transport; Storm surges**
Currents in Tidal Flats During Storm Surges, Harald Gohren, 959
- Tidal marshes; Water waves; Estuaries; Finite element method; Numerical analysis; Shallow water; Tidal effects**
Finite Element Model for Estuaries with Inter-Tidal Flats, Bruno Herrling, 3396
- Tidal marshes; Wave height; Waves; Estuaries; Reservoirs; Tidal currents; Tidal effects; Tidal hydraulics**
Waves Used for Inter-Tidal Design and Construction, D. C. Keiller and T. D. Ruxton, 23
- Tidal waters; Channels (waterways); River regulation; Sandbars; Sediment transport; Stability; Tidal effects; Tidal hydraulics**
Stability of Tidal Channels Dependent on River Improvement, Volker Barthel, 1775
- Tidal waters; Environmental effects; Inlets (waterways); Littoral drift; New Jersey; Scouring; Sea level; Tidal effects**
Beach Haven and Little Egg Inlets, A Case Study, Joseph T. DeAlteris, Thomas McKinney and James Roney, 1881
- Tidal waters; Tides; Erosion; Movable bed models; Prototype tests; Scale effect; Scour; Scouring**
Movable Bed Tidal Inlet Models, Subhash C. Jain and John F. Kennedy, 3435
- Tidal waters; Wave energy; Inlets (waterways); Japan; Tidal effects; Tidal hydraulics**
Characteristics of Tidal Inlets on the Pacific Coast of Japan, Toshiyuki Shigemura, 1666
- Tides; Erosion; Movable bed models; Prototype tests; Scale effect; Scour; Scouring**
Movable Bed Tidal Inlet Models, Subhash C. Jain and John F. Kennedy, 3435
- Tides; Washington; Water circulation; Water depth; Flushing; Harbors; Tidal currents; Tidal hydraulics**
Planform Influence on Flushing and Circulation in Small Harbors, Ronald C. Nece, Roger A. Falconer and Toshiro Tsutsumi, 3471
- Time; Estuaries; Feasibility; Hydraulic models; Mathematical models; Rivers; Tidal effects**
Analysis of Time Conditions for Hybrid Tidal Models, Klaus-Peter Holz, 3460
- Time dependence; Wastewater; Buoyancy; Fluid mechanics; Gravitation; Ocean currents; Spreading**
Buoyancy-Driven Gravitational Spreading, Robert C.Y. Koh, 2956
- Time dependence; Wave height; Wave period; Wave spectrum; Wave velocity; Flowmeters; Ocean currents; Rip currents**
Time Dependent Fluctuations in Longshore Currents, Guy A. Meadows, 660
- Time dependence; Wave height; Waves; Wave velocity; Breaking; Gravity waves; Solitary waves**
Recent Developments in the Study of Breaking Waves, Michael S. Longuet-Higgins, 441
- Topographical factors; Beach erosion; Beaches; Breakwaters; Construction; Harbor structures; Japan; Ocean bottom; Shoaling**
Topographic Change Resulting from the Construction of a Harbor on a Sandy Beach, Kashima Port, Norio Tanaka and Shoji Sato, 1824
- Tracers; Estuaries; Saline water-freshwater interfaces; Saline water intrusion; Salinity; Stratified flow**
Dynamics of a Longitudinally Stratified Estuary, Jorg Imberger, 3108

- Tracers; Water pollution; Dispersion; Distribution; Dyes; Estuaries; Predictions; Sewage disposal; Sewage effluents**
Prediction of Pollutant Distribution in Estuaries, Albert Y. Kuo and John P. Jacobson, 3276
- Tracers (radioactive); Dredging; Estuaries; Estuarine environment; San Francisco; Sediments; Spoil**
Tracing Estuarine Sediments by Neutron Activation, Richard M. Ecker, John F. Sustar and William T. Harvey, 2009
- Tracers (radioactive); West Germany; Hydraulic models; Movable bed models; Scale effect; Sediment transport**
Sand Movement Investigations by Means of Radioactive Tracers in a Hydraulic Model and in the Field, Hans Rohde, 2027
- Training walls; Australia; Estuaries; Flooding; Hydrographic surveys; Jetties; River flow; Sandbars**
Results of River Mouth Training on the Clarence Bar, New South Wales, Australia, Cyril D. Floyd and Bruce M. Druery, 1738
- Transport phenomena; Density currents; Estuaries; Friction coefficient (hydraulic); Mathematical models; Numerical analysis; Saline water intrusion; Stratification**
Numerical Model for Density Currents in Estuaries, Karsten Fischer, 3295.
- Tropical cyclones; Computer models; Forecasting; Hurricanes; Numerical analysis; Storm surges**
SPLASH — A Model for Forecasting Tropical Storm Surges, Celso S. Barrientos and Chester P. Jelesnianski, 941
- Troughs; Density currents; Flow patterns; Mathematical models; Scour; Scouring; Stratified flow**
Generation of Troughs by Density Currents, Hans Speekenbrink, 2170
- Tsunamis; Numerical analysis; Propagation; Shore protection; Simulation**
Numerical Simulation of Tsunamis Originating in the Peru-Chile Trench, A. W. Garcia and H. L. Butler, 1025
- Tsunamis; Warning systems; Coastal engineering; Coastal plains; Japan; Power spectra; Refraction; Shoaling**
Transformation of Tsunamis in a Coastal Zone, Shigehisa Nakamura, Haruo Higuchi and Yoshito Tsuchiya, 988
- Tsunamis; Wave action; Wave energy; Wave generation; Wave height; Coastal structures; Hazards**
Tsunami Hazard and Design of Coastal Structures, George Pararas-Carayannis, 2248
- Tsunamis; Wave dispersion; Wave height; Japan; Models; Numerical analysis; Statistical models**
Numerical Models of Huge Tsunamis Off the Sanriku Coast, Toshio Iwasaki, 1044
- Tsunamis; Wave height; Friction coefficient (hydraulic); Numerical analysis; Propagation; Shallow water**
Tsunami Propagation in the Pacific Ocean, Manfred Engel and Wilfried Zahel, 971
- Tsunamis; Wave runup; Flooding; Predictions; Storm surges**
Tsunami Inundation Prediction, Charles L. Bretschneider and Pieter G. Wybro, 1006
- Turbulence; Beaches; Flowmeters; Friction coefficient (hydraulic); Rip currents; Surf**
Lateral and Bottom Forces on Longshore Currents, David A. Huntley, 645
- Turbulence; Diffusion; Eddies; Hydraulic models; Scale effect; Statistical analysis; Tidal effects**
Horizontal Diffusion in Tidal Models and Scaling Criteria for Thermal-Hydraulic Model Tests, Gerd Flugge, 3097
- Turbulence; Discharge (water); Interfacial tension; Stability; Stratified flow; Thermal pollution**
Interfacial Instability in Stratified Flow, Richard H. French, 3124
- Turbulence; Wave action; Wave damping; Wave dispersion; Wave energy; Wave velocity; Currents (water); Interactions**
Interaction of Waves and a Turbulent Current, J. D.A. van Hoften and Susumu Karaki, 404
- Turbulence; Wave height; Wave runup; Waves; Beaches; Breaking; Resonance; Surges**
Resonant Interactions for Waves Breaking on a Beach, Robert T. Guza and Anthony J. Bowen, 560
- Turbulent diffusion; Friction coefficient (hydraulic); Ocean bottom; Ripple marks; Shallow water**
Consideration on Friction Coefficient for Sea Bottom, Toru Sawaragi, Koichiro Iwata and Masayoshi Kubo, 595
- Two-dimensional; Water depth; Water waves; Wave height; Boundary value problems; Breakwaters; Permeability; Sea walls**
Method of Analyses for Two-Dimensional Water Wave Problems, Takeshi Ijima, Chung Ren Chou and Akinori Yoshida, 2717
- Two-dimensional; Wave equations; Wave height; Breaking; Surf; Three-dimensional**
Three-Dimensional Conditions of Surf, William L. Wood, 525
- Two phase flow; Convection; Diffusion; Dispersion; Finite element method; Numerical analysis; Stratification**
Numerical Modeling of Dispersion in Stratified Waters, George C. Christodoulou and Jerome J. Connor, 3138
- Two phase flow; Diffusers; Discharge (water); Hydraulic models; Nuclear power plants; Plume detection; Plumes; Thermal pollution**
Field Studies of Submerged-Diffuser Thermal Plumes with Comparisons to Predictive Model Results, A. A. Frigo, Richard A. Paddock and J. D. Dittmars, 3028
- Two phase flow; Estuaries; Saline water-freshwater interfaces; Salinity; Salt water intrusion; Tidal currents; Tidal effects**
Tidal Response of Two-Layer Flow at a River Mouth, Shizuo Yoshida and Masakazu Kashiwamura, 3189
- Two phase flow; Water flow; Energy conversion; Surface waves; Thermal energy; Thermal gradient**
Flow Field Near an Ocean Thermal Energy Conversion Plant, D. M. Sheppard, G. M. Powell and I. B. Chou, 3068

- Two phase flow; Wave equations; Wave height; Wave velocity; Friction coefficient (hydraulic); Interfaces**
Friction at the Interface of Two-Layered Flows, Nobuyuki Tamai, 3169
- Underwater pipelines; Diffusers; Environmental effects; Hydrodynamics; Ocean engineering; Outfall sewers**
Design Considerations for the Sand Island and Barbers Point Outfalls, Robert C.Y. Koh, Norman H. Brooks and Floyd Louis Vuillemot, 2941
- Underwater pipelines; Wave action; Failures; Laboratory tests; Sandbars; Scale effect; Scour; Scouring**
Scour Around Model Pipelines Due to Wave Action, John B. Herbich, 1624
- Underwater structures; Wave action; Wave energy; Drag; Inertial forces; Submerged flow**
Wave Forces on Submerged Objects, Suphat Vongvisessomjai and Richard Silvester, 2387
- Unsteady flow; Wave equations; Waves; Breakwaters; Oscillation; Sediment transport**
Quantitative Description of Sediment Transport, Ole Secher Madsen and William D. Grant, 1093
- Utilization; Barges; Economic analysis; Environmental effects; Harbors; Performance; Safety; Site selection**
Probable Utilization Level for a Barge Harbor, Martin T. Czerniak and Choule J. Sonu, 3557
- Variability; Beach erosion; Eigenvalues; Impulses; Responses; Stability; Statistical analysis; Storms**
Stability and Impulse Response of Empirical Eigenfunctions, Clinton D. Winant and David G. Aubrey, 1312
- Velocity distribution; Water waves; Wave equations; Coastal topographic features; Eigenvalues; Responses; Rip currents**
Rip-Current and Coastal Topography, Mikio Hino, 1326
- Verification inspection; Wave height; Wave spectrum; Bathymetry; Groins (structures); Littoral drift; Sandbars; Sediment transport**
Experimental Verification of Groyne Theory, C. H. Hulsbergen, W. T. Bakker and G. van Bochove, 1439
- Viscosity; Water temperature; Hydraulic models; Predictions; Prototype tests; Scale effect; Surface tension; Thermal diffusion**
Adaptability of Prediction Method of Hydraulic Model Experiment for Thermal Diffusion, Masanobu Kato and Akira Wada, 3082
- Viscosity; Wave action; Wave dispersion; Wave energy; Wave functions; Wave height; Mud flats**
Wave Action and Bottom Movements in Fine Sediments, Michael W. Tubman and Joseph N. Suhayda, 1168
- Vortices; Estuaries; Flooding; Inlets (waterways); Tidal currents; Tidal effects; Tidal energy; Tidal hydraulics**
Harbour Inlets on Tidal Estuaries, Hans Vollmers, 1854
- Vortices; Wakes; Water waves; Cylindrical bodies; Flow separation; Oscillations; Pressure distribution**
Flow Separation, Wake Vortices and Pressure Distribution Around a Circular Cylinder under Oscillatory Waves, Yuichi Iwagaki and Hajime Ishida, 2341
- Vortices; Water flow; Cylindrical bodies; Drag; Force; Oscillation; Roughness (hydraulic)**
Forces on Rough-Walled Circular Cylinders in Harmonic Flow, Turgut Sarpkaya, 2301
- Wakes; Water waves; Cylindrical bodies; Flow separation; Oscillations; Pressure distribution; Vortices**
Flow Separation, Wake Vortices and Pressure Distribution Around a Circular Cylinder under Oscillatory Waves, Yuichi Iwagaki and Hajime Ishida, 2341
- Walls; Water waves; Wave action; Waves; Barriers; Finite differences; Shallow water; Simulation**
Action of Non-Linear Waves at a Solid Wall, Mohamed S. Nasser and John A. McCorquodale, 815
- Walls; Water waves; Wave height; Diffraction; Mach number; Reflection**
Mach-Reflection as a Diffraction Problem, Udo Berger and Soren Kohlhasse, 796
- Warning systems; Coastal engineering; Coastal plains; Japan; Power spectra; Refraction; Shoaling; Tsunamis**
Transformation of Tsunamis in a Coastal Zone, Shigehisa Nakamura, Haruo Higuchi and Yoshito Tsuchiya, 988
- Warning systems; Flood plain insurance; Hurricanes; Storms; Tidal effects; Tidal energy**
Hurricane Tide Frequencies on the Atlantic Coast, Francis P. Ho, 886
- Washington; Water circulation; Water depth; Flushing; Harbors; Tidal currents; Tidal hydraulics; Tides**
Planform Influence on Flushing and Circulation in Small Harbors, Ronald C. Nece, Roger A. Falconer and Toshiro Tsutsumi, 3471
- Wastewater; Buoyancy; Fluid mechanics; Gravitation; Ocean currents; Spreading; Time dependence**
Buoyancy-Driven Gravitational Spreading, Robert C.Y. Koh, 2956
- Water circulation; Water depth; Flushing; Harbors; Tidal currents; Tidal hydraulics; Tides; Washington**
Planform Influence on Flushing and Circulation in Small Harbors, Ronald C. Nece, Roger A. Falconer and Toshiro Tsutsumi, 3471
- Water circulation; Water quality; Coliform bacteria; Drainage; Estuaries; Runoff; Sampling; Simulation**
State Estimation of Estuarine Circulation and Water Quality by Numerical Simulation and Observation, Jan J. Leendertse and S. K. Liu, 3223
- Water circulation; Wave action; Wave-energy; Drag; Force; Separation; Spheres**
Forces on a Sphere Under Linear Progressive Waves, Scott A. Jenkins and Douglas L. Inman, 2413

- Water circulation; Wave recorders (water waves); Wind pressure; Wind tides; Current meters**
Wind-Driven Circulation of Saginaw Bay, James H. Saylor and Larry J. Danek, 3262
- Water depth; Berths; Dolphins (structures); Head losses; Mass; Shallow water; Tanker ships**
Added Masses of Large Tankers Berthing to Dolphins, Taizo Hayashi and Masujiro Shirai, 2830
- Water depth; Flushing; Harbors; Tidal currents; Tidal hydraulics; Tides; Washington; Water circulation**
Planform Influence on Flushing and Circulation in Small Harbors, Ronald C. Nece, Roger A. Falconer and Toshiro Tsutsumi, 3471
- Water depth; Water surface profiles; Wave action; Wave energy; Numerical analysis; Oscillations; Responses**
Wave Induced Oscillations of Harbors with Variable Depth, Fredric Raichlen and Ehud Naheer, 3536
- Water depth; Water waves; Wave height; Boundary value problems; Breakwaters; Permeability; Sea walls; Two-dimensional**
Method of Analyses for Two-Dimensional Water Wave Problems, Takeshi Iijima, Chung Ren Chou and Akinori Yoshida, 2717
- Water depth; Wave energy; Wave height; Waves; Beaches; Deformation; Periodic functions; Phase velocity**
Deformation up to Breaking of Periodic Waves on a Beach, Ib A. Svendsen and J. Buhr Hansen, 477
- Water depth; Waves; Currents; Finite elements; Gravity waves; Predictions; Refraction; Surf**
Current Depth Defraction Using Finite Elements, Ove Skovgaard and Ivar G. Jonsson, 721
- Water flow; Cylindrical bodies; Drag; Force; Oscillation; Roughness (hydraulic); Vortices**
Forces on Rough-Walled Circular Cylinders in Harmonic Flow, Turgut Sarpkaya, 2301
- Water flow; Energy conversion; Surface waves; Thermal energy; Thermal gradient; Two phase flow**
Flow Field Near an Ocean Thermal Energy Conversion Plant, D. M. Sheppard, G. M. Powell and I. B. Chou, 3068
- Water flow; Laboratory tests; Sediment concentration; Sediments; Sediment samplers**
Iowa Sediment Concentration Measuring System, Tatsuaki Nakato, Frederick A. Locher, John R. Glover and John F. Kennedy, 2060
- Water flow; Wave action; Wave energy; Cylinders; Drag; Hydraulic models; Lift; Oscillations; Reynolds number; Stream flow**
High Reynolds Number Oscillating Flow by Cylinders, Tokuo Yamamoto and John H. Nath, 2321
- Water flow; Wave energy; Wind pressure; Discharge (water); Effluents; Field tests; Mathematical models; Numerical analysis**
Numerical Modelling — An Aid to Assessing Field Data, H. P. Riedel and F. L. Wilkinson, 3243
- Water level fluctuations; Water levels; Wave action; Wave energy; Waves; Wave spectrum; Storm surges; Surf**
Energy Spectra of Irregular Surf Waves, Fritz Busching, 539
- Water levels; Beach erosion; Beach nourishment; Bypasses; Erosion; Great Lakes; Michigan; Sand; Shore protection**
Sand-Bypass and Shore Erosion, Bridgman, Michigan, C. N. Johnson and L. W. Hiipakka, 1361
- Water levels; Wave action; Wave energy; Waves; Wave spectrum; Storm surges; Surf; Water level fluctuations**
Energy Spectra of Irregular Surf Waves, Fritz Busching, 539
- Water levels; Wave action; Wave height; Breakwaters; Coastal structures; Experimentation; Field tests; Scour; Scouring**
Local Scour and Current Around a Porous Breakwater, Shintaro Hotta and Nobuo Marui, 1590
- Water levels; Wave generation; Currents; Great Lakes; Harbors; Seiches; Tidal effects**
Hydraulics of Great Lakes Inlet — Harbors Systems, Robert M. Sorensen and William N. Seelig, 1646
- Water levels; Wave height; Wave runup; Beaches; Ocean waves; Resonance; Simulation**
Wave Run-Up on a Simulated Beach, A. J. Sutherland, J. N. Sharma and Omar H. Shemdin, 752
- Water levels; Waves; Breaking; Coastal engineering; Field tests; Littoral drift; Ocean currents; Photogrammetry; Stereophotography**
Terrestrial Photogrammetric Measurements of Breaking Waves and Longshore Currents in the Nearshore Zone, Joseph W. Maresca, Jr. and Erwin Seibel, 681
- Water meters; Water quality; Calibration; Discharge (water); Estuaries; Open channel flow**
Calibration of Branched Estuary Models, James P. Bennett, 3416
- Water pollution; Dispersion; Distribution; Dyes; Estuaries; Predictions; Sewage disposal; Sewage effluents; Tracers**
Prediction of Pollutant Distribution in Estuaries, Albert Y. Kuo and John P. Jacobson, 3276
- Water quality; Calibration; Discharge (water); Estuaries; Open channel flow; Water meters**
Calibration of Branched Estuary Models, James P. Bennett, 3416
- Water quality; Coliform bacteria; Drainage; Estuaries; Runoff; Sampling; Simulation; Water circulation**
State Estimation of Estuarine Circulation and Water Quality by Numerical Simulation and Observation, Jan J. Leendertse and S. K. Liu, 3223
- Water quality; Diffusers; Dilution; Mixing; Outfall sewers; Site selection**
Design Procedures for Ocean Outfalls, Jeffrey A. Layton, 2919

- Water quality; Environmental effects; Hawaii;**
Islands (landforms); Monitoring; Reefs; Runways
 Environmental Impacts on an Island Community,
 Gordon A. Chapman, 3506
- Water surface profiles; Wave action; Wave energy;**
Numerical analysis; Oscillations; Responses; Water depth
 Wave Induced Oscillations of Harbors with
 Variable Depth, Fredric Raichlen and Ehud
 Naheer, 3536
- Water temperature; Air-water interfaces; Heat flux;**
Heat transfer; Infrared scanners; Infrared scanning; Remote sensing
 Evaluation of Air-Sea Interface Heat Flux, Robert
 L. Street and A. Woodruff Miller, Jr., 3208
- Water temperature; Discharge (water); Hydraulic models; Nuclear power plants; Prototype tests; Temperature distribution; Thermal diffusion; Thermal pollution**
 Thermal Discharges: Prototype vs. Hydraulic Model, Gary C. Parker, Ching S. Fang and Albert Y. Kuo, 3049
- Water temperature; Hydraulic models; Predictions; Prototype tests; Scale effect; Surface tension; Thermal diffusion; Viscosity**
 Adaptability of Prediction Method of Hydraulic Model Experiment for Thermal Diffusion, Masanobu Kato and Akira Wada, 3082
- Water temperature; Wave height; Beach erosion; Erosion; Field tests; Groins (structures); Laboratory tests; Littoral drift; Shore protection; Storms**
 Laboratory Investigation of Shore Erosion Processes, Ernest F. Brater and David Ponce-Campos, 1493
- Water waves; Cylindrical bodies; Flow separation; Oscillations; Pressure distribution; Vortices; Wakes**
 Flow Separation, Wake Vortices and Pressure Distribution Around a Circular Cylinder under Oscillatory Waves, Yuichi Iwagaki and Hajime Ishida, 2341
- Water waves; Estuaries; Finite element method; Numerical analysis; Shallow water; Tidal effects; Tidal marshes**
 Finite Element Model for Estuaries with Inter-Tidal Flats, Bruno Herrling, 3396
- Water waves; Wave action; Waves; Barriers; Finite differences; Shallow water; Simulation; Walls**
 Action of Non-Linear Waves at a Solid Wall, Mohamed S. Nasser and John A. McCorquodale, 815
- Water waves; Wave dispersion; Wave energy; Wave spectrum; Coastal structures; Random processes; Reflection**
 Decomposition of Co-Existing Random Wave Energy, Dennis B. Morden, Eugene P. Richey and Derald R. Christensen, 846
- Water waves; Wave equations; Coastal topographic features; Eigenvalues; Responses; Rip currents; Velocity distribution**
 Rip-Current and Coastal Topography, Mikio Hino, 1326
- Water waves; Wave generation; Waves; Hydraulic models; Three-dimensional**
 3-D Hydraulic Model of Wave Generated by Displacements, Shin-Lin Liu and Robert L. Wiegell, 1060
- Water waves; Wave height; Boundary value problems; Breakwaters; Permeability; Sea walls; Two-dimensional; Water depth**
 Method of Analyses for Two-Dimensional Water Wave Problems, Takeshi Ijima, Chung Ren Chou and Akinori Yoshida, 2717
- Water waves; Wave height; Diffraction; Mach number; Reflection; Walls**
 Mach-Reflection as a Diffraction Problem, Udo Berger and Soren Kohlbase, 796
- Wave action; Beach erosion; Beach nourishment; Dynamics; Equilibrium; Erosion; Reflection; Sandbars; Sand traps; Three-dimensional**
 Three Dimensional Tests on Dynamic Equilibrium and Artificial Nourishment, J. William Kamphuis and R. M. Myers, 1532
- Wave action; Beach erosion; Climatic data; Estuaries; Estuarine environment; Sediment deposits; Sediment distribution; Sediments; Tidal effects**
 Factors Influencing Estuary Sediment Distribution, Mary P. Kendrick and B. V. Derbyshire, 2072
- Wave action; Currents; Dredging; Estuaries; Harbors; Littoral drift; Sand traps; Storms**
 Design and Behaviour of Sandtraps in Regions of High Littoral Drift, P. C. Saxena, Pazhayannur P. Vaidyaraman and R. Srinivasan, 1377
- Wave action; Failures; Laboratory tests; Sandbars; Scale effect; Scour; Scouring; Underwater pipelines**
 Scour Around Model Pipelines Due to Wave Action, John B. Herbich, 1624
- Wave action; Samplers; Sampling; Sediment concentration; Sediment samplers; Sediment sampling; Surf; Suspended sediments**
 Measurement of Suspended Sediment in the Surf Zone, F. A. Kilner, 2045
- Wave action; Wave damping; Wave dispersion; Wave energy; Wave velocity; Currents (water); Interactions; Turbulence**
 Interaction of Waves and a Turbulent Current, J. D.A. van Hoften and Susumu Karaki, 404
- Wave action; Wave damping; Wave energy; Breakwaters; Reflection; Slitting**
 Slit-Type Breakwater: Box-Type Wave Absorber, Shositiro Nagai and Shohachi Kakuno, 2697
- Wave action; Wave dispersion; Wave energy; Wave functions; Wave height; Mud flats; Viscosity**
 Wave Action and Bottom Movements in Fine Sediments, Michael W. Tubman and Joseph N. Suhayda, 1168
- Wave action; Wave dispersion; Wave energy; Waves; Breakwaters; Laboratory tests; Rubble mounds**
 Wave Transmission Through Trapezoidal Breakwaters, Ole Secher Madsen and Stanley M. White, 2662
- Wave action; Wave dispersion; Wave energy; Wave velocity; Field tests; Ocean bottom; Ocean waves**
 Near-Bottom Water Motion Under Ocean Waves, Robert A. Grace, 2371

- Wave action; Wave dispersion; Wave height; Waves; Wave velocity; Breaking; Refraction; Shoaling**
Refraction of Finite-Height and Breaking Waves, James R. Walker, 507
- Wave action; Wave energy; Air entrainment; Damage; Dikes; Impact; Revetments**
Response of Seadykes due to Wave Impacts, Alfred Fuhrboter, Hans H. Dette and J. Grune, 2604
- Wave action; Wave energy; Bays (topographic features); Beach erosion; Breakwaters; Shore protection**
Headland Defense of Coasts, Richard Silvester, 1394

- Wave dispersion; Wave energy; Wave spectrum; Coastal structures; Random processes; Reflection; Water waves**
Decomposition of Co-Existing Random Wave Energy, Dennis B. Morden, Eugene P. Richey and Derald R. Christensen, 846
- Wave dispersion; Wave energy; Wave velocity; Currents (water); Interactions; Turbulence; Wave action; Wave damping**
Interaction of Waves and a Turbulent Current, J. D.A. van Hoften and Susumu Karaki, 404
- Wave dispersion; Wave energy; Wave velocity; Field tests; Ocean bottom; Ocean waves; Wave action**
Near-Bottom Water Motion Under Ocean Waves, Robert A. Grace, 2371
- Wave dispersion; Wave height; Japan; Models; Numerical analysis; Statistical models; Tsunamis**
Numerical Models of Huge Tsunamis Off the Sanriku Coast, Toshio Iwasaki, 1044
- Wave dispersion; Wave height; Wavelengths; Wave propagation; Waves; Friction coefficient (hydraulic)**
Transformation of Nonlinear Long Waves, Nobuo Shuto, 423
- Wave dispersion; Wave height; Waves; Breaking; Breakwaters; Friction coefficient (hydraulic); Littoral drift; Ocean currents; Three-dimensional Non-Uniform Alongshore Currents, Michael R. Gourlay, 701**
- Wave dispersion; Wave height; Waves; Wave velocity; Breaking; Refraction; Shoaling; Wave action**
Refraction of Finite-Height and Breaking Waves, James R. Walker, 507
- Wave dispersion; Waves; Coastal structures; Cooling water; Intake systems; Mathematical models; Nuclear power plants; Numerical analysis; Refraction; Sediment transport**
Application of a Sediment Transport Model, C. A. Fleming and J. N. Hunt, 1184
- Wave energy; Air entrainment; Damage; Dikes; Impact; Revetments; Wave action**
Response of Seadykes due to Wave Impacts, Alfred Fuhrboter, Hans H. Dette and J. Grune, 2604
- Wave energy; Barriers; Beaches; Canada; Littoral current; Littoral drift; Morphology; Sandbars; Sediment deposits**
Process and Morphology Characteristics of Two Barrier Beaches in the Magdalen Islands, Gulf of St. Lawrence, Canada, E. H. Owens, 1975
- Wave energy; Barriers; Breakwaters; California; Jetties; Littoral current; Littoral drift; Sediment transport; Surf**
Longshore Transport at a Total Littoral Barrier, Richard O. Bruno and Christopher G. Gable, 1203
- Wave energy; Bays (topographic features); Beach erosion; Breakwaters; Shore protection; Wave action**
Headland Defense of Coasts, Richard Silvester, 1394
- Wave energy; Beach erosion; Beaches; Equilibrium; Gravel; Laboratory tests; Littoral current; Sediment transport; Shore protection**
Equilibrium Profiles and Longshore Transport of Coarse Material Under Oblique Wave Attack, E. van Hījum, 1258
- Wave energy; Beach erosion; Beach nourishment; Erosion; Littoral current; Recreational facilities; Storms; Storm surges; Wave action**
Cape Hatteras Beach Nourishment, John S. Fisher and Wilson N. Felder, 1512
- Wave energy; Bed forms; Inlets (waterways); Ocean bottom; Scale effect; Sediment transport; Simulation models; Tidal effects**
Tidal Inlet Flow Dynamics and Sediment Movement, Jerry L. Machemehl, N. E. Bird and A. N. Chambers, 1681
- Wave energy; Bottom water; Continental shelf; Cyclic loads; Foundations; Ocean bottom; Offshore structures; Predictions; Stability; Wave action**
Prediction of Wave-Induced Seafloor Movements, Leland Milo Kraft, Jr. and David James Watkins, 1605
- Wave energy; Breakwaters; Damage; Hydraulic models; Rubble; Rubble mounds; Stability; Wave action**
Effect of Broken Dolosse on Breakwater Stability, D. Donald Davidson and Dennis G. Markle, 2544

- Wave energy; Breakwaters; Reflection; Slitting; Wave action; Wave damping**
Slit-Type Breakwater: Box-Type Wave Absorber, Shositiro Nagai and Shohachi Kakuno, 2697
- Wave energy; Cooling water; Cylindrical bodies; Field tests; Intake structures; Nuclear power plants; Wave dispersion**
Wave Pressures on Large Circular Cylindrical Structure, Hiroshi Nakamura, 2290
- Wave energy; Cylinders; Drag; Hydraulic models; Lift; Oscillations; Reynolds number; Stream flow; Wave flow; Wave action**
High Reynolds Number Oscillating Flow by Cylinders, Tokuo Yamamoto and John H. Nath, 2321
- Wave energy; Drag; Force; Separation; Spheres; Wave circulation; Wave action**
Forces on a Sphere Under Linear Progressive Waves, Scott A. Jenkins and Douglas L. Inman, 2413
- Wave energy; Drag; Inertial forces; Submerged flow; Underwater structures; Wave action**
Wave Forces on Submerged Objects, Suphat Vongvissomsomjai and Richard Silvester, 2387
- Wave energy; Estuaries; Flooding; River flow; Sandbars; Sedimentation; Sediment deposits; Wave action**
Morphodynamics of a Wave-Dominated River Mouth, L. D. Wright, 1721
- Wave energy; Harbors; Harbor structures; History; Jetties; Rubble mounds; Wave action**
Design and Construction of Humboldt Jetties, 1880 to 1975, Orville T. Magoon, Robert L. Sloan and Nobuyuki Shimizu, 2474
- Wave energy; Inlets (waterways); Japan; Tidal effects; Tidal energy; Tidal hydraulics; Tidal waters**
Characteristics of Tidal Inlets on the Pacific Coast of Japan, Toshiyuki Shigemura, 1666
- Wave energy; Numerical analysis; Oscillations; Responses; Water depth; Water surface profiles; Wave action**
Wave Induced Oscillations of Harbors with Variable Depth, Fredric Raichlen and Ehud Nahcer, 3536
- Wave energy; Wave equations; Wave height; Wave period; Waves; Wave spectrum; Fetch; Great Lakes**
Applications of Empirical Fetch-Limited Spectral Formulas to Great Lakes Waves, Paul C. Liu, 113
- Wave energy; Wave forecasting; Waves; Wave spectrum; Wind forces; Wind speed; Fetch; Ocean waves**
Application of Fetch Area Method in Monsoon Wave Hindcasting, Nai-Kuang Liang, Shih-Tsan Tang and Ben-Juen Lee, 258
- Wave energy; Wave functions; Wave height; Mud flats; Viscosity; Wave action; Wave dispersion**
Wave Action and Bottom Movements in Fine Sediments, Michael W. Tubman and Joseph N. Suhayda, 1168
- Wave energy; Wave generation; Wave height; Coastal structures; Hazards; Tsunamis; Wave action**
Tsunami Hazard and Design of Coastal Structures, George Pararas-Carayannis, 2248
- Wave energy; Wave height; Wavemeters; Wave recorders (water waves); Waves; Climatic data; Ocean waves**
Wave Climate Analysis for Engineering Purpose, Hans H. Dette and Alfred Fuhrboter, 10
- Wave energy; Wave height; Wave period; Caissons; Model tests; Overturning tests; Wave action**
Wave Forces on Aquare Caissons, G. R. Mogridge and W. W. Jamieson, 2271
- Wave energy; Wave height; Wave period; Statistical analysis; Statistical distributions**
Characteristic Wave Period, Madhav Manohar, Ismail E. Mobarak and N. A. El Sharaky, 273
- Wave energy; Wave height; Wave period; Wave recorders (water waves); Waves; Wave spectrum; Continental shelf; Storms; Storm surges; Storm water**
Extreme Wave Parameters Based on Continental Shelf Storm Wave Records, R. E. Haring, A. R. Osborne and L. P. Spencer, 151
- Wave energy; Wave height; Wave period; Waves; Coastal engineering; Coastal structures; Stability**
Consecutive High Waves in Coastal Waters, Winfried Siefert, 171
- Wave energy; Wave height; Waves; Beaches; Deformation; Periodic functions; Phase velocity; Water depth**
Deformation up to Breaking of Periodic Waves on a Beach, Ib A. Svendsen and J. Buhr Hansen, 477
- Wave energy; Wavemeters; Coastal engineering; Coastal structures; Directional measurement; Sediment transport**
Wave Direction-Computations with Three Gage Arrays, D. Esteve, 349
- Wave energy; Wave period; Armoring (streambed); Breakwaters; Failure; Slope protection; Slope stability; Wave action**
Armour Blocks as Slope Protection, A. F. Whillock and W. A. Price, 2564
- Wave energy; Wave period; Concrete (blocks); Permeability; Reservoirs; Sea walls**
Permeable Seawall with Reservoir and the Use of "Warock", Takeshi Ijima, Enzoh Tanaka and Hideaki Okuzono, 2623
- Wave energy; Wave period; Fenders; Force; Harmonic functions; Mooring; Moorings; Oscillations; Wave action**
Subharmonic Components in Hawser and Fender Forces, J. H. van Oorschot, 2840
- Wave energy; Wave period; Wave recorders (water waves); Waves; Wave spectrum; Experimentation; Random processes**
Estimation of Incident and Reflected Waves in Random Wave Experiments, Yoshimi Goda and Yasumasa Suzuki, 828
- Wave energy; Wave propagation; Waves; Boundary value problems; Coastal engineering; Computation; Periodic variations; Refraction**
Physics and Mathematics of Waves in Coastal Zones, H. Lundgren, 880

- Wave energy; Wave recorders (water waves); California; Coastal engineering; Coastal structures; Numerical analysis**
Regional Network for Coastal Engineering Data, Richard J. Seymour and Meredith H. Sessions, 60
- Wave energy; Wave runup; Wave velocity; Coastal structures; Damping; Numerical analysis; Wave action**
Numerical Calculation of Wave Forces on Structures, B. D. Nichols and C. W. Hirt, 2254
- Wave energy; Waves; Breakwaters; Laboratory tests; Rubble mounds; Wave action; Wave dispersion**
Wave Transmission Through Trapezoidal Breakwaters, Ole Secher Madsen and Stanley M. White, 2662
- Wave energy; Waves; Wave spectrum; Breakwaters; Overtopping; Rubble mounds; Wave action**
Overtopping of Rubble-Mound Breakwaters by Irregular Waves, Yvon Ouellet and Pierre Eubanks, 2756
- Wave energy; Waves; Wave spectrum; Storm surges; Surf; Water level fluctuations; Water levels; Wave action**
Energy Spectra of Irregular Surf Waves, Fritz Busching, 539
- Wave energy; Wave spectrum; Beach erosion; Beaches; California; Equilibrium; Tidal effects**
Beach Profiles at Torrey Pines, California, David G. Aubrey, Douglas L. Inman and Charles E. Nordstrom, 1297
- Wave energy; Wave spectrum; Coastal structures; Random processes; Reflection; Water waves; Wave dispersion**
Decomposition of Co-Existing Random Wave Energy, Dennis B. Morden, Eugene P. Richey and Derald R. Christensen, 846
- Wave energy; Wave spectrum; Distribution functions; Distribution patterns; Frequency; Ocean waves; Surface waves**
Directional Spectral of Ocean Surface Waves, Hisashi Mitsuyasu and S. Mizuno, 329
- Wave energy; Wave spectrum; Wave tanks; Breakwaters; Buoys; Energy dissipation; Field tests; Floating bodies; Scale effect; Tethered tests; Wave action**
Design, Analysis and Field Test of a Dynamic Floating Breakwater, D. J. Agerton, G. H. Savage and K. C. Stotz, 2792
- Wave energy; Wave velocity; Currents (water); Interactions; Turbulence; Wave action; Wave damping; Wave dispersion**
Interaction of Waves and a Turbulent Current, J. D.A. van Hoften and Susumu Karaki, 404
- Wave energy; Wave velocity; Field tests; Ocean bottom; Ocean waves; Wave action; Wave dispersion**
Near-Bottom Water Motion Under Ocean Waves, Robert A. Grace, 2371
- Wave energy; West Germany; Damping; Energy dissipation; Estuaries; Stratification; Tidal effects**
Energy Dissipation in Tidal Estuaries, Hans-Werner Partenscky and Gunther Barg, 3312
- Wave energy; Wharves; Offshore structures; Prototype tests; Scour; Scouring; Wave action**
Wave Action on Large Off-Shore Structures, C. J. Apelt and A. Macknight, 2228
- Wave energy; Wind pressure; Discharge (water); Effluents; Field tests; Mathematical models; Numerical analysis; Water flow**
Numerical Modelling — An Aid to Assessing Field Data, H. P. Riedel and F. L. Wilkinson, 3243
- Wave equations; Coastal topographic features; Eigenvalues; Responses; Rip currents; Velocity distribution; Water waves**
Rip-Current and Coastal Topography, Mikio Hino, 1326
- Wave equations; Wave functions; Waves; Wave velocity; Shoaling**
Wave Shoaling of Finite Amplitude Waves, Masataka Yamaguchi and Yoshito Tsuchiya, 497
- Wave equations; Wave height; Breaking; Surf; Three-dimensional; Two-dimensional**
Three-Dimensional Conditions of Surf, William L. Wood, 525
- Wave equations; Wave height; Wave period; Wave runup; Dikes; Echo sounding; Field investigations; Instrumentation; Ocean waves; Scale effect; Storm surges**
Wave Run-Up in Field Measurements with Newly Developed Instrument, Heie F. Erchinger, 767
- Wave equations; Wave height; Wave period; Waves; Wave spectrum; Fetch; Great Lakes; Wave energy**
Applications of Empirical Fetch-Limited Spectral Formulas to Great Lakes Waves, Paul C. Liu, 113
- Wave equations; Wave height; Wave velocity; Friction coefficient (hydraulic); Interfaces; Two phase flow**
Friction at the Interface of Two-Layered Flows, Nobuyuki Tamai, 3169
- Wave equations; Wave runup; Overtopping; Scale effect; Shore protection; Slopes**
Wave Overtopping Equation, J. Richard Weggel, 2737
- Wave equations; Waves; Breakwaters; Oscillation; Sediment transport; Unsteady flow**
Quantitative Description of Sediment Transport, Ole Secher Madsen and William D. Grant, 1093
- Wave forecasting; Wave period; Waves; Wave spectrum; Climatology; Coastal engineering; Ocean waves; Spectral analysis; Statistical analysis**
Ocean Wave Statistics from FNWC Spectral Analysis, Warren C. Thompson and F. Michael Reynolds, 238
- Wave forecasting; Waves; Wave spectrum; Wind forces; Wind speed; Fetch; Ocean waves; Wave energy**
Application of Fetch Area Method in Monsoon Wave Hindcasting, Nai-Kuang Liang, Shih-Tsan Tang and Ben-Juen Lee, 258
- Wave forecasting; Wind forces; Wind speed; Forecasting; Hurricanes; Wave action**
Hurricane Wind and Wave Forecasting Techniques, Charles L. Bretschneider and Elaine E. Tamaye, 202

- Wave functions; Wave height; Mud flats; Viscosity; Wave action; Wave dispersion; Wave energy**
Wave Action and Bottom Movements in Fine Sediments, Michael W. Tubman and Joseph N. Suhayda, 1168
- Wave functions; Waves; Wave velocity; Shoaling; Wave equations**
Wave Shoaling of Finite Amplitude Waves, Masataka Yamaguchi and Yoshito Tsuchiya, 497
- Wave generation; Bedding materials; Bed ripples; Ripple marks; Sand; Sonar detection; Wave action**
Wave-Formed Ripples in Nearshore Sands, John R. Dingler and Douglas L. Inman, 2109
- Wave generation; Currents; Great Lakes; Harbors; Seiches; Tidal effects; Water levels**
Hydraulics of Great Lakes Inlet — Harbors Systems, Robert M. Sorensen and William N. Seelig, 1646
- Wave generation; Wave height; Coastal structures; Hazards; Tsunamis; Wave action; Wave energy**
Tsunami Hazard and Design of Coastal Structures, George Pararas-Carayannis, 2248
- Wave generation; Wave height; Wave propagation; Waves; Cavities; Deep water; Explosions; Predictions**
Calculations of Waves Formed From Surface Cavities, Charles L. Mader, 1079
- Wave generation; Waves; Hydraulic models; Three-dimensional; Water waves**
3-D Hydraulic Model of Wave Generated by Displacements, Shin-Lin Liu and Robert L. Wiegel, 1060
- Wave height; Beach erosion; Erosion; Field tests; Groins (structures); Laboratory tests; Littoral drift; Shore protection; Storms; Water temperature**
Laboratory Investigation of Shore Erosion Processes, Ernest F. Brater and David Ponce-Campos, 1493
- Wave height; Boundary value problems; Breakwaters; Permeability; Sea walls; Two-dimensional; Water depth; Water waves**
Method of Analyses for Two-Dimensional Water Wave Problems, Takeshi Ijima, Chung Ren Chou and Akinori Yoshida, 2717
- Wave height; Breaking; Surf; Three-dimensional; Two-dimensional; Wave equations**
Three-Dimensional Conditions of Surf, William L. Wood, 525
- Wave height; Breakwaters; Coastal structures; Experimentation; Field tests; Scour; Scouring; Water levels; Wave action**
Local Scour and Current Around a Porous Breakwater, Shintaro Hotta and Nobuo Marui, 1590
- Wave height; Breakwaters; Laboratory tests; Permeability; Reflection**
Laboratory Study of Pervious Core Breakwaters, Hideo Kondo, Satoshi Toma and Kenji Yano, 2643
- Wave height; Coastal structures; Hazards; Tsunamis; Wave action; Wave energy; Wave generation**
Tsunami Hazard and Design of Coastal Structures, George Pararas-Carayannis, 2248
- Wave height; Diffraction; Mach number; Reflection; Walls; Water waves**
Mach-Reflection as a Diffraction Problem, Udo Berger and Soren Kohlhasse, 796
- Wave height; Friction coefficient (hydraulic); Numerical analysis; Propagation; Shallow water; Tsunamis**
Tsunami Propagation in the Pacific Ocean, Manfred Engel and Wilfried Zahel, 971
- Wave height; Japan; Models; Numerical analysis; Statistical models; Tsunamis; Wave dispersion**
Numerical Models of Huge Tsunamis Off the Sanriku Coast, Toshio Iwasaki, 1044
- Wave height; Mud flats; Viscosity; Wave action; Wave dispersion; Wave energy; Wave functions**
Wave Action and Bottom Movements in Fine Sediments, Michael W. Tubman and Joseph N. Suhayda, 1168
- Wave height; Wavelengths; Wave propagation; Waves; Friction coefficient (hydraulic); Wave dispersion**
Transformation of Nonlinear Long Waves, Nobuo Shuto, 423
- Wave height; Wavelengths; Waves; Wave spectrum; Wave tanks; Wind (meteorology); Distribution patterns**
Wave Height Distribution of Wind Waves Over Long Waves, Shan-Hwei Ou and Frederick L.W. Tang, 388
- Wave height; Wavemeters; Wave recorders (water waves); Waves; Climatic data; Ocean waves; Wave energy**
Wave Climate Analysis for Engineering Purpose, Hans H. Dette and Alfred Fuhrboter, 10

Wave Run-Up on a Simulated Beach, A. J. Sutherland, J. N. Sharma and Omar H. Shemdin, 752
- Wave runup; Breakwaters; Resonance; Rubble; Rubble mounds; Slope stability; Stability; Surf; Wave period**
New Design Principles for Rubble Mound Structures, Per Moller Bruun and Ali Riza Gunbak, 2429
- Wave runup; Dikes; Echo sounding; Field investigations; Instrumentation; Ocean waves; Scale effect; Storm surges; Wave equations; Wave height; Wave period**
Wave Run-Up in Field Measurements with Newly Developed Instrument, Heie F. Erchinger, 767
- Wave runup; Flooding; Predictions; Storm surges; Tsunamis**
Tsunami Inundation Prediction, Charles L. Bretschneider and Pieter G. Wybro, 1006
- Wave runup; Overtopping; Scale effect; Shore protection; Slopes; Wave equations**
Wave Overtopping Equation, J. Richard Weggel, 2737
- Wave runup; Waves; Beaches; Breaking; Resonance; Surges; Turbulence; Wave height**
Resonant Interactions for Waves Breaking on a Beach, Robert T. Guza and Anthony J. Bowen, 560
- Wave runup; Waves; Breaking; Periodic variations; Shoaling; Slopes; Wave period**
Set-Up and Run-Up in Shoaling Breakers, William G. Van Dorn, 738
- Wave runup; Waves; Dikes; Discharge (water); Overtopping; Periodic variations; Wave height**
Characteristics of Flow in Run-Up of Periodic Waves, Ary Roos and Jurjen A. Battjes, 781
- Wave runup; Wave velocity; Coastal structures; Damping; Numerical analysis; Wave action; Wave energy**
Numerical Calculation of Wave Forces on Structures, B. D. Nichols and C. W. Hirt, 2254
- Waves; Barriers; Finite differences; Shallow water; Simulation; Walls; Water waves; Wave action**
Action of Non-Linear Waves at a Solid Wall, Mohamed S. Nasser and John A. McCorquodale, 815
- Waves; Beaches; Breaking; Resonance; Surges; Turbulence; Wave height; Wave runup**
Resonant Interactions for Waves Breaking on a Beach, Robert T. Guza and Anthony J. Bowen, 560

- Waves; Beaches; Deformation; Periodic functions; Phase velocity; Water depth; Wave energy; Wave height**
Deformation up to Breaking of Periodic Waves on a Beach, Ib A. Svendsen and J. Buhr Hansen, 477
- Waves; Boundary value problems; Coastal engineering; Computation; Periodic variations; Refraction; Wave energy; Wave propagation**
Physics and Mathematics of Waves in Coastal Zones, H. Lundgren, 880
- Waves; Breaking; Breakwaters; Friction coefficient (hydraulic); Littoral drift; Ocean currents; Three-dimensional; Wave dispersion; Wave height**
Non-Uniform Alongshore Currents, Michael R. Gourlay, 701
- Waves; Breaking; Coastal engineering; Field tests; Littoral drift; Ocean currents; Photogrammetry; Stereophotography; Water levels**
Terrestrial Photogrammetric Measurements of Breaking Waves and Longshore Currents in the Nearshore Zone, Joseph W. Maresca, Jr. and Erwin Seibel, 681
- Waves; Breaking; Periodic variations; Shoaling; Slopes; Wave period; Wave runup**
Set-Up and Run-Up in Shoaling Breakers, William G. Van Dorn, 738
- Waves; Breakwaters; Laboratory tests; Rubble mounds; Wave action; Wave dispersion; Wave energy**
Wave Transmission Through Trapezoidal Breakwaters, Ole Secher Madsen and Stanley M. White, 2662
- Waves; Breakwaters; Oscillation; Sediment transport; Unsteady flow; Wave equations**
Quantitative Description of Sediment Transport, Ole Secher Madsen and William D. Grant, 1093
- Waves; Cavities; Deep water; Explosions; Predictions; Wave generation; Wave height; Wave propagation**
Calculations of Waves Formed From Surface Cavities, Charles L. Mader, 1079
- Waves; Climatic data; Ocean waves; Wave energy; Wave height; Wavemeters; Wave recorders (water waves)**
Wave Climate Analysis for Engineering Purpose, Hans H. Dette and Alfred Fuhrboter, 10
- Waves; Coastal engineering; Coastal structures; Stability; Wave energy; Wave height; Wave period**
Consecutive High Waves in Coastal Waters, Winfried Siefert, 171
- Waves; Coastal structures; Cooling water; Intake systems; Mathematical models; Nuclear power plants; Numerical analysis; Refraction; Sediment transport; Wave dispersion**
Application of a Sediment Transport Model, C. A. Fleming and J. N. Hunt, 1184
- Waves; Currents; Finite elements; Gravity waves; Predictions; Refraction; Surf; Water depth**
Current Depth Defraction Using Finite Elements, Ove Skovgaard and Ivar G. Jonsson, 721
- Waves; Dikes; Discharge (water); Overtopping; Periodic variations; Wave height; Wave runup**
Characteristics of Flow in Run-Up of Periodic Waves, Ary Roos and Jurjen A. Battjes, 781
- Waves; Estuaries; Reservoirs; Tidal currents; Tidal effects; Tidal hydraulics; Tidal marshes; Wave height**
Waves Used for Inter-Tidal Design and Construction, D. C. Keiller and T. D. Ruxton, 23
- Waves; Friction coefficient (hydraulic); Wave dispersion; Wave height; Wavelengths; Wave propagation**
Transformation of Nonlinear Long Waves, Nobuo Shuto, 423
- Waves; Hydraulic models; Three-dimensional; Water waves; Wave generation**
3-D Hydraulic Model of Wave Generated by Displacements, Shin-Lin Liu and Robert L. Wiegel, 1060
- Waves; Littoral drift; Sandbars; Sands; Secondary waves; Sediment transport; Wave propagation**
Sand Transport by Waves, E. W. Bijker, E. van Hijum and P. Vellinga, 1149
- Waves; Wave spectrum; Breaking; Dimensional analysis; Experimentation; Surf; Wave height; Wave period**
Wave Spectrum of Breaking Wave, Toru Sawaragi and Koichiro Iwata, 580
- Waves; Wave spectrum; Breakwaters; Overtopping; Rubble mounds; Wave action; Wave energy**
Overtopping of Rubble-Mound Breakwaters by Irregular Waves, Yvon Ouellet and Pierre Eubanks, 2756
- Waves; Wave spectrum; Climatology; Coastal engineering; Ocean waves; Spectral analysis; Statistical analysis; Wave forecasting; Wave period**
Ocean Wave Statistics from FNWC Spectral Analysis, Warren C. Thompson and F. Michael Reynolds, 238
- Waves; Wave spectrum; Continental shelf; Storms; Storm surges; Storm water; Wave energy; Wave height; Wave period; Wave recorders (water waves)**
Extreme Wave Parameters Based on Continental Shelf Storm Wave Records, R. E. Haring, A. R. Osborne and L. P. Spencer, 151
- Waves; Wave spectrum; Experimentation; Random processes; Wave energy; Wave period; Wave recorders (water waves)**
Estimation of Incident and Reflected Waves in Random Wave Experiments, Yoshimi Goda and Yasumasa Suzuki, 828
- Waves; Wave spectrum; Fetch; Great Lakes; Wave energy; Wave equations; Wave height; Wave period**
Applications of Empirical Fetch-Limited Spectral Formulas to Great Lakes Waves, Paul C. Liu, 113
- Waves; Wave spectrum; Storm surges; Surf; Water level fluctuations; Water levels; Wave action; Wave energy**
Energy Spectra of Irregular Surf Waves, Fritz Busching, 539
- Waves; Wave spectrum; Wave tanks; Wind (meteorology); Distribution patterns; Wave height; Wavelengths**
Wave Height Distribution of Wind Waves Over Long Waves, Shan-Hwei Ou and Frederick L.W. Tang, 388

- Waves; Wave spectrum; Wind forces; Wind speed; Fetch; Ocean waves; Wave energy; Wave forecasting**
Application of Fetch Area Method in Monsoon Wave Hindcasting, Nai-Kuang Liang, Shih-Tsan Tang and Ben-Juen Lee, 258
- Waves; Wave spectrum; Wind forces; Wind speed; Wave height**
Parametric Representation of a Wind-Wave Field, Henrik Rye and Roald Svee, 183
- Waves; Wave spectrum; Wind speed; Great Lakes; Wave action; Wave height; Wave period**
Great Lakes Wave Information, D. T. Resio and L. W. Hiipakka, 92
- Waves; Wave tanks; Beach erosion; Erosion; Groins (structures); Rip currents**
Groin Length and the Generation of Edge Waves, Michael K. Gaughan and Paul D. Komar, 1459
- Waves; Wave tanks; Laboratory tests; Ocean waves; Random variables; Simulation**
Random Wave Simulation in a Laboratory Wave Tank, Akira Kimura and Yuichi Iwagaki, 368
- Waves; Wave velocity; Breaking; Gravity waves; Solitary waves; Time dependence; Wave height**
Recent Developments in the Study of Breaking Waves, Michael S. Longuet-Higgins, 441
- Waves; Wave velocity; Breaking; Refraction; Shoaling; Wave action; Wave dispersion; Wave height**
Refraction of Finite-Height and Breaking Waves, James R. Walker, 507
- Waves; Wave velocity; Shoaling; Wave equations; Wave functions**
Wave Shoaling of Finite Amplitude Waves, Masataka Yamaguchi and Yoshito Tsuchiya, 497
- Waves; Wind (meteorology); Coastal engineering; Coastal structures; Data collection; Data collection systems; Hydrographic surveys**
Data Collection and Analysis for Coastal Projects, E. Loewy, K. G. Withaus, L. Summers and R. J. Maddrell, 43
- Waves; Wind speed; Coastal engineering; Ocean waves; Taiwan; Wave height; Wave period**
Waves Off Taichung Coast of Taiwan, Charles C.C. Chang, M. H. Wang and J. T. Juang, 129
- Wave spectrum; Bathymetry; Groins (structures); Littoral drift; Sandbars; Sediment transport; Verification inspection; Wave height**
Experimental Verification of Groyne Theory, C. H. Hulsbergen, W. T. Bakker and G. van Bochove, 1439
- Wave spectrum; Beach erosion; Beaches; California; Equilibrium; Tidal effects; Wave energy**
Beach Profiles at Torrey Pines, California, David G. Aubrey, Douglas L. Inman and Charles E. Nordstrom, 1297
- Wave spectrum; Beach erosion; Beaches; Computer models; Slopes**
Study of Equilibrium Beach Profiles, Robert A. Dalrymple and William W. Thompson, 1277
- Wave spectrum; Breaking; Dimensional analysis; Experimentation; Surf; Wave height; Wave period; Waves**
Wave Spectrum of Breaking Wave, Toru Sawaragi and Koichiro Iwata, 580
- Wave spectrum; Breakwaters; Overtopping; Rubble mounds; Wave action; Wave energy; Waves**
Overtopping of Rubble-Mound Breakwaters by Irregular Waves, Yvon Ouellet and Pierre Eubanks, 2756
- Wave spectrum; Climatology; Coastal engineering; Ocean waves; Spectral analysis; Statistical analysis; Wave forecasting; Wave period; Waves**
Ocean Wave Statistics from FNWC Spectral Analysis, Warren C. Thompson and F. Michael Reynolds, 238
- Wave spectrum; Coastal engineering; India; Statistical analysis; Wave height; Wavemeters; Wave recorders (water waves)**
Ocean Wave Record Analysis by Tucker's Method — An Evaluation, Jade Dattatri and Irvathur Vasudeva Nayak, 289
- Wave spectrum; Coastal structures; Random processes; Reflection; Water waves; Wave dispersion; Wave energy**
Decomposition of Co-Existing Random Wave Energy, Dennis B. Morden, Eugene P. Richey and Derald R. Christensen, 846
- Wave spectrum; Continental shelf; Storms; Storm surges; Storm water; Wave energy; Wave height; Wave period; Wave recorders (water waves); Waves**
Extreme Wave Parameters Based on Continental Shelf Storm Wave Records, R. E. Haring, A. R. Osborne and L. P. Spencer, 151
- Wave spectrum; Distribution functions; Distribution patterns; Frequency; Ocean waves; Surface waves; Wave energy**
Directional Spectral of Ocean Surface Waves, Hisashi Mitsuyasu and S. Mizuno, 329
- Wave spectrum; Experimentation; Random processes; Wave energy; Wave period; Wave recorders (water waves); Waves**
Estimation of Incident and Reflected Waves in Random Wave Experiments, Yoshimi Goda and Yasumasa Suzuki, 828
- Wave spectrum; Fetch; Great Lakes; Wave energy; Wave equations; Wave height; Wave period; Waves**
Applications of Empirical Fetch-Limited Spectral Formulas to Great Lakes Waves, Paul C. Liu, 113
- Wave spectrum; Ocean waves; Radar equipment; Wave height; Wavemeters; Wave recorders (water waves)**
Wave Measurements in Open Ocean, Davidson T. Chen, Benjamin S. Yaple, Donald L. Hammond and Paul Bey, 72
- Wave spectrum; Ocean waves; Spectral analysis; Statistical analysis; Storms; Wave height**
Six-Parameter Wave Spectra, Michel K. Ochi and E. Nadine Hubble, 301
- Wave spectrum; Ocean waves; Wave action; Wave height; Wave propagation**
Revisions in Wave Data Presentation, Laurence Draper, 3

- Wave spectrum; Storm surges; Surf; Water level fluctuations; Water levels; Wave action; Wave energy; Waves**
Energy Spectra of Irregular Surf Waves, Fritz Busching, 539
- Wave spectrum; Wave tanks; Breakwaters; Buoys; Energy dissipation; Field tests; Floating bodies; Scale effect; Tethered tests; Wave action; Wave energy**
Design, Analysis and Field Test of a Dynamic Floating Breakwater, D. J. Agerton, G. H. Savage and K. C. Stotz, 2792
- Wave spectrum; Wave tanks; Wind (meteorology); Distribution patterns; Wave height; Wavelengths; Waves**
Wave Height Distribution of Wind Waves Over Long Waves, Shan-Hwei Ou and Frederick L.W. Tang, 388
- Wave spectrum; Wave velocity; Breaking energy; Secondary waves; Wave height; Wave period; Wave recorders (water waves)**
Kinematics of Breaking Waves, Edward B. Thornton, James J. Galvin, Frank L. Bub and David P. Richardson, 461
- Wave spectrum; Wave velocity; Flowmeters; Ocean currents; Rip currents; Time dependence; Wave height; Wave period**
Time Dependent Fluctuations in Longshore Currents, Guy A. Meadows, 660
- Wave spectrum; Wind forces; Wind speed; Fetch; Ocean waves; Wave energy; Wave forecasting; Waves**
Application of Fetch Area Method in Monsoon Wave Hindcasting, Nai-Kuang Liang, Shih-Tsan Tang and Ben-Juen Lee, 258
- Wave spectrum; Wind forces; Wind speed; Wave height; Waves**
Parametric Representation of a Wind-Wave Field, Henrik Rye and Roald Svee, 183
- Wave spectrum; Wind speed; Great Lakes; Wave action; Wave height; Wave period; Waves**
Great Lakes Wave Information, D. T. Resio and L. W. Hiipakka, 92
- Wave tanks; Accidents; Collisions; Harbor structures; Mooring; Moorings; Offshore drilling; Ships**
Protection of Maritime Structures Against Ship Collisions, Kazuki Oda and Shositiro Nagai, 2810
- Wave tanks; Beach erosion; Erosion; Groins (structures); Rip currents; Waves**
Groin Length and the Generation of Edge Waves, Michael K. Gaughan and Paul D. Komar, 1459
- Wave tanks; Breakwaters; Buoys; Energy dissipation; Field tests; Floating bodies; Scale effect; Tethered tests; Wave action; Wave energy; Wave spectrum**
Design, Analysis and Field Test of a Dynamic Floating Breakwater, D. J. Agerton, G. H. Savage and K. C. Stotz, 2792
- Wave tanks; Laboratory tests; Ocean waves; Random variables; Simulation; Waves**
