

An aerial, black and white photograph of a coastal city and harbor. The image shows a dense urban area with numerous buildings, a complex highway interchange, and a large harbor area with several piers and ships. The water is dark, and the sky is light. The overall scene is a detailed view of a major coastal city.

VOLUME I

Coastal Engineering

1980 PROCEEDINGS

PROCEEDINGS
OF THE

Seventeenth Coastal Engineering Conference

March 23 to 28, 1980
Sydney, Australia

Volume I

Sponsored by
ASCE Coastal Engineering Research Council
ASCE Waterway, Port, Coastal and Ocean Division
and
The Institution of Engineers, Australia

FOREWORD

The Seventeenth International Conference on Coastal Engineering was extremely important in many ways to those who attended the conference and to those who will benefit from use of these *Proceedings*. The Seventeenth Conference marked the 30 year point in the history of the coastal engineering conference series and a change in leadership. Since the first conference was held in Long Beach, California in October 1950, Dean Morrough P. O'Brien and Professor Joe W. Johnson have provided the continuity, direction, and motivation that have made the International Coastal Engineering Conferences so successful. For thirty years Dean O'Brien has served as Chairman and Professor Johnson as Secretary of first the Council on Wave Research and now the Coastal Engineering Research Council. Because of the importance of their contributions to the coastal engineering conferences the Council decided that these *Proceedings* will be dedicated to these two leaders. A summary of the accomplishments of each in coastal engineering is presented here.

MORROUGH P. O'BRIEN

His distinguished career in coastal engineering has been much too full to cover adequately in this space; only a sketch of his accomplishments are included here. M. P. O'Brien retired as Dean of the College of Engineering at the University of California, Berkeley, in 1959. His tenure at Berkeley included an impressive record of teaching, research and university administration. During this interval, through his students and research, he established the reputation of "The Father of Coastal Engineering." After leaving his post at Berkeley he has been very active in industrial and governmental research and development projects. At his present age, 78, Dean O'Brien is still an extremely active professional in coastal engineering.

Dean O'Brien graduated from Massachusetts Institute of Technology in 1925 and pursued graduate work at Purdue University. In 1927 he was awarded the ASCE John R. Freeman Scholarship which allowed him to attend the Technische Hochschule, Danzig, and the Royal College of Engineering, Stockholm, to study hydraulic structures and machinery. He has received honorary degrees from Northwestern University, D.Sc.; Purdue University, D.Eng.; and University of California, Berkeley, LL.D.

He joined the Mechanical Engineering Department at the University of California becoming Department Chairman in 1936 and Dean of the College in 1943. During his tenure as Dean he was instrumental in the development of graduate education and research and in the modernization of the undergraduate program.

In 1929, Dean O'Brien organized and initiated a program of research on shoreline processes and coastal engineering for a board appointed by the Chief of Engineers of the Army; subsequently, Congress established this work on a permanent basis under the U.S. Beach Erosion Board. Dean O'Brien has served as a member of this board and its successor, the Coastal Engineering Research Board from 1938 to 1980. He has maintained an active interest in ocean waves and shoreline phenomena. During the war years, this interest led to work on the design of landing craft, on forecasting surf conditions,

and on intelligence studies of landing beaches. Following the war he served as Chairman of the ad hoc committee on Amphibious Operations of the National Research Council which reviewed the plans for modernization of the Marine Corps. Consulting engagements in the field of coastal engineering included restoration of the beach at Santa Barbara, regulation of the estuary of the Columbia River, Dos Bocas Harbor in the Gulf of Campache and other similar coastal projects.

Dean O'Brien's research on hydraulic machinery led to many practical applications by industry. Most of the jet pumps sold in the United States follow the designs of O'Brien and Gosline. Application of the theory of airfoils to the design of propeller pumps and fans by O'Brien and Folsom provided the basis for extensive production of low-head, high-capacity pumps for irrigation and drainage. Consulting engagements on hydraulic machinery during this period included Byron Jackson, Food Machinery, Fairbanks-Morse, Becker Pump, Navy Department, Corps of Engineers, and many other governmental agencies. His experience with turbo-machinery led to his appointment in 1949 as a consulting engineer by the Aircraft Gas Turbine Division of the General Electric Company, an association which has continued to the present. He is now a consultant to the Technical Systems and Materials Sector of General Electric, dealing with both technical and management problems of jet engines, missiles and space vehicles, ordnance, and electronic systems.

During the war years, Dean O'Brien directed the University of California's program of engineers' science and management war training for technical and professional personnel in the aircraft and shipbuilding industries. During the four years of its existence, this program included 1800 instructors and 46,000 students. Concurrently, he served as dean of the college and as consultant in the research section of the Bureau of Ships on problems of submarine propeller noise, and on amphibious operations. In 1946, he participated in Operation Crossroads at Bikini as a consultant on the measurement of waves generated by the bomb tests; most of the photographs of the Baker tests, which appeared in the press, were taken by the tower and aerial cameras which Dean O'Brien and his associates operated for wave measurements.

Twice, he has taken full-time leave from academic duties to engage in engineering practice; once, 1947 to 1949, to serve as director of research and engineering with the Air Reduction Company and, again in 1953, to join General Electric Company's Aircraft Nuclear Propulsion Project. He has held membership on many influential boards and commissions, among them the Coastal Engineering Research Board, formerly the Beach Erosion Board; the National Science Foundation's panel of engineering consultants; the Army Scientific Advisory Panel; the Atomic Energy Commission's personnel security board; the Maritime Research Advisory Committee and the Advisory Board on Education of the National Academy of Sciences, National Research Council; and the board of directors, McGraw-Hill Publishing Company. In 1958 President Eisenhower appointed him a member of the Board of the National Science Foundation. During 1958-1959, he was a visiting institute professor at the Massachusetts Institute of Technology, and a visiting research fellow at Harvard University.

Among awards he has received are the Army-Navy Certificate of Appreciation; the Distinguished Civilian Award, Department of the Army (twice); and the Bliss Medal of the Society of American Military Engineers. In 1968 he received the ASEE's Lamme Award, and in 1969 a building at the University of California's Berkeley Campus was named after Dean O'Brien.

He has written more than 100 published articles on technical subjects and engineering education, and is co-author of "Applied Fluid Mechanics," published by McGraw-Hill in 1937. The bibliography is his own selection of the papers which he most enjoyed

writing. He is a registered professional engineer in the states of California and New York, and a chartered Mechanical Engineer in Great Britain. In 1969 he was elected to the National Academy of Engineering. He is an Honorary Member of both the ASCE and ASME.

Selected Bibliography

- Entrance Area Related to Tidal Prism, *Civil Engineering*, 1931.
- Checks on the Model Law for Hydraulic Structures, *Trans. Amer. Geo. Union*, 1932.
- Review of the Theory of Turbulent Flow and its Relation to Sediment Transportation, *Trans. Amer. Geo. Union*, 1933.
- Model Law for Motion of Salt Water through Fresh (with John Chuno), *ASCE Trans.*, vol. 99, 1934.
- The Transportation of Bed-Load by Streams (with B. B. Rindlaub), *Trans. Amer. Geo. Union*, 1934.
- The Water Jet-Pump (with J. E. Gosline), *Univ. Calif. Publ. in Eng.*, vol. 3, no. 3, 1934.
- A Summary of the Theory of Oscillatory Waves, TR No. 2, Beach Erosion Board, 1941.
- The U.S. Tidal Model Laboratory, *Shore & Beach*, vol. 3, no. 2, 1935.

- Model Experiments on Impulsive Waves in Shallow Water, *Trans. Amer. Geo. Union*, April 1947.
- Lag and Reduction of Range in Tide-gage Wells, Beach Erosion Board Bulletin, vol. 4, no. 3, 1950.
- The Nature of Engineering, *Jour. Eng. Educ.*, November 1950.
- The Force Exerted by Waves on Objects (with J. R. Morison), *Trans. Amer. Geo. Union*, February 1952.
- The Engineering of Large Systems, *The World of Engineering*, Chapter 9, McGraw-Hill, 1964.
- The Equilibrium Flow Areas of Tidal Inlets on Sandy Coasts, Tenth Int. Conf. on Coastal Eng., ASCE, 1966.
- Hydraulic Coefficients of Tidal Inlets (with R. Clark), Coastal & Oceanographic Engineering Laboratory, Univ. of Florida, 1974.
- Hydraulic and Sedimentary Stability of Tidal Inlets (with R. G. Dean), ASCE, Thirteenth Int. Conf. on Coastal Engineering, 1972.

JOE W. JOHNSON

Professor Johnson has had a long and very distinguished career in coastal engineering. His reputation extends around the world, reaching forth from his consulting, his research and especially his students. In 1975 he retired as Professor of Civil Engineering from the University of California, Berkeley. Professor Johnson is also well known for his excellent handling of the *Proceedings* of all sixteen prior coastal engineering conferences. Since his retirement from the University of California he has been extremely active in his consulting practice and professional duties.

Professor Johnson graduated from the University of California, Berkeley, in 1931 with a B.S. in Civil Engineering and in 1934 with an M.S. degree. Following a brief stay at the Waterways Experiment Station he devoted eight years to studying sediment transport with the Soil Conservation Service. He then returned to the University of California and enjoyed a very fruitful career of teaching, research and public service.

He has been consultant to many international projects involving shoreline development including: an ore port in Vitoria, Brazil; harbor development along the coast of Venezuela; port development in Northwest Australia; port development in Damietta, Egypt; sedimentation at Bahia Blanca, Argentina; Hay Point Coal Port, Australia; and wave action and sedimentation in Brazil. His associations with coastal engineering projects in the United States are equally extensive; a brief list follows of his involvement: Rio Grande Valley, wind tides in Lake Okeechobee, wave analysis of Marina del Rey, San Francisco Bay Area Rapid Transit, Turkey Point Power Plant in Florida and beach erosion at the Zion Atomic Power Plant.

In addition Professor Johnson has been a member, since 1974, of the Shoreline Erosion Advisory Panel created by the U.S. Congress. His expertise in coastal engineering has been quite instrumental in the success of this research and development program. He also has been selected as the chairman of the U.S. Delegation to the U.S.-Japan Cooperative Seminar on Coastal Engineering held in Japan. Professor Johnson has been appointed to numerous other boards and committees. He was the Secretary of the Council on Wave Research during its existence from 1950 to 1964, and then of the subsequent organization, The Coastal Engineering Research Council of the ASCE. He has been very active in the AGU holding key positions and has been a major driving force behind the American Shore and Beach Preservation Association as Vice President and Editor of *Shore and Beach*.

In 1976, Professor Johnson was elected to membership in the National Academy of Engineering and in 1979, he received the distinguished honor of Honorary Member of the ASCE. He is also the recipient of the Guggenheim Fellowship, The Outstanding Civilian Service Medal for his service in the field of coastal engineering and the Berkeley Citation. A selected listing of his over ninety publications are given below. Professor Johnson has been and still is a very active and important part of international coastal engineering.

Selected Bibliography

- The Transportation of Sediment by Streams: Bed Load, *Inter. Union Geod. and Geophys.*, 1939.
- Transportation of Sediment by Flowing Water, *Soil Conserv.*, vol. 6, 1941.

- A Distinction Between Bed Load and Suspended Load in Natural Streams (with Einstein and Anderson), *Trans. Amer. Geo. Union*, 1940.
- "War-time research on waves and surf." *The Military Engineer*, June 1947.
- "Refraction of surface waves by currents." *Trans. Amer. Geo. Union*, 1947.
- "The force exerted by surface waves on piles," (with J. R. Morison, M. P. O'Brien, and S. A. Schaaf), vol. 189, 1950.
- "The Damping Action of Submerged Breakwaters," (with R. A. Fuchs and J. R. Morison), *Trans. Amer. Geo. Union*, vol. 32, 1951.
- "The March 1962 Storm on the Atlantic Coast of the United States," (with M. P. O'Brien), Proc. Eighth Conference on Coastal Engineering, 1963.
- "Ship Waves in Shoaling Water," Proceedings Eleventh Conference on Coastal Engineering, 1968.
- "Lessons in Coastal Engineering," Symposium on Coastal Engineering, Stellenbosch, South Africa, 1970.
- "Closure of Tidal Entrances," Proc. Fourteenth Conference on Coastal Engineering, 1974.
- "Littoral Processes at Some California Shoreline Harbors," *Shore and Beach*, vol. 43, no. 1, April 1975.

The omissions from the accomplishments of Dean O'Brien and Professor Johnson are solely the responsibility of the writer; however, the magnitude of their contributions to coastal engineering has forced the writer to condense their many activities. Indeed a detailed listing of their individual efforts would fill a volume.

While listening to the discussions of the mechanics of sand waves by Professor Arthur Brebner, Professor Longuet-Higgins was able to tie some of Brebner's findings with the theoretical work he (Longuet-Higgins) had done on water waves of maximum steepness. Since Professor Longuet-Higgins' Keynote address begins the *Proceedings*, it was felt proper to end them with a brief summary explaining the application of his limiting wave theory to sand bed-forms. His discussion can be found on page 3107.

INVITED LECTURE

THE UNSOLVED PROBLEM OF BREAKING WAVES

by

M. S. Longuet-Higgins
Institute of Oceanographic Sciences
Wormley, Surrey, England

PART I

THEORETICAL AND OBSERVED WAVE CHARACTERISTICS

Chapter 1	
SOME IMPLICATIONS OF RECENT ADVANCES IN WAVE THEORIES	
J. R. Chaplin and K. Anastasiou	31
Chapter 2	
ACCURATE NUMERICAL SOLUTIONS FOR NONLINEAR WAVES	
J. D. Fenton and M. M. Rienecker	50
Chapter 3	
MASS TRANSPORT IN PROGRESSIVE WAVES OF PERMANENT TYPE	
Yoshito Tsuchiya, Takashi Yasuda and Takao Yamashita	70
Chapter 4	
RAY CURVATURE AND REFRACTION OF WAVE PACKETS	
J. Ernest Breeding, Jr.	82
Chapter 5	
VERIFICATION OF A WAVE REFRACTION MODEL	
G. Henderson and N. B. Weber	101
Chapter 6	
WAVE SHOALING CALCULATED FROM COKELET'S THEORY	
T. Sakai and J. A. Battjes	121
Chapter 7	
A SURVEY OF "RANDOM" WAVE GENERATION TECHNIQUES	
J. Ploeg and E. R. Funke	135
Chapter 8	
THE MEASUREMENT OF INCIDENT AND REFLECTED SPECTRA USING A LEAST SQUARES METHOD	
E. P. D. Mansard and E. R. Funke	154
Chapter 9	
ORBITAL VELOCITIES IN IRREGULAR WAVES	
F. C. Vis	173

Chapter 10		
INVESTIGATIONS ON IRREGULAR WAVES IN HYDRAULIC MODELS		
Karl-Friedrich Daemrich, Wolf-Dietrich Eggert and Soren Kohlase	186	
Chapter 11		
METHOD OF ANALYSIS OF RANDOM WAVE EXPERIMENTS WITH REFLECTING COASTAL STRUCTURES		
Pierre Gaillard, Michel Gauthier and Forrest Holly	204	
Chapter 12		
WAVE HEIGHT DISTRIBUTION AROUND PERMEABLE BREAKWATERS		
Shintaro Hotta	221	
Chapter 13		
NON-RESONANT WAVE AGITATION IN SMALL CRAFT HARBOURS		
J. W. Kamphuis and D. A. Y. Smith	241	
Chapter 14		
EXPERIMENTAL INVESTIGATIONS OF PERIODIC WAVES NEAR BREAKING		
J. Buhr Hansen	260	
Chapter 15		
AN HEURISTIC MODEL OF WAVE HEIGHT DISTRIBUTION IN SURF ZONE		
Masaru Mizuguchi	278	
Chapter 16		
RESONANCES OF COASTAL WATERS BETWEEN PERTH AND GERALDTON (WESTERN AUSTRALIA)		
H. Allison, A. Grassia and R. Litchfield	290	
Chapter 17		
A CLOSELY RESPONDING, VERSATILE WAVE TUNNEL		
C. H. Hulsbergen and J. J. Bosman	310	
Chapter 18		
CONDITIONAL SIMULATIONS OF OCEAN WAVE PROPERTIES		
Leon E. Borgman	318	
Chapter 19		
WIND WAVES TRANSMISSION THROUGH POROUS BREAKWATER		
Stanislaw R. Massel and Piotr Butowski	333	
Chapter 20		
FIELD MEASUREMENTS OF WIND WAVE KINEMATICS		
J. A. Battjes and J. van Heteren	347	
Chapter 21		
HF RADAR MAPPING OF EXTENSIVE OCEAN WINDFIELDS		
P. E. Dexter and R. C. Casey	363	
Chapter 22		
SOURCES OF MEASURED WAVE DATA		
Laurence Draper	372	
Chapter 23		
VISUALLY OBSERVED WAVE DATA AT PT. MUGU, CALIF.		
Christine Schneider and Richard Weggel	381	
Chapter 24		
WAVE HINDCASTS AND MEASUREMENTS - BASS STRAIT		
M. N. Silbert, T. P. Barnett, D. J. H. Peters and R. C. Hamilton	395	

Chapter 25	
REALTIME WAVE ANALYSIS, NEWCASTLE, AUSTRALIA	
N. V. Lawson and P. H. Oull	412
Chapter 26	
FLORIDA COASTAL DATA NETWORK	
Gary Howell	421
Chapter 27	
A MEASUREMENT OF SLOPE, CURVATURE, AND DIRECTIONAL SPECTRA OF WIND WAVES IN LAKE MICHIGAN	
Paul C. Liu	432
Chapter 28	
WAVE ATTENUATION AND WAVE SET-UP ON A COASTAL REEF	
Franciscus Gerritsen	444
Chapter 29	
LONGSHORE CURRENT FLOWS IN A WAVE BASIN	
P. J. Visser	462
Chapter 30	
DYNAMIC CHARACTERISTICS IN THE NEAR SHORE AREA	
Kiyoshi Horikawa and Masahiko Isobe	480
Chapter 31	
VELOCITY FIELD IN A STEADY BREAKER	
J. A. Battjes and T. Sakai	499
Chapter 32	
THE FLUID MECHANICS OF WAVES APPROACHING BREAKING	
D. H. Peregrine, E. D. Cokelet and P. McIver	512
Chapter 33	
A SIMILARITY MODEL IN THE SURF ZONE	
Hsiang Wang and Wei-Chong	529
Chapter 34	
VELOCITY AND PRESSURE FIELD IN SPILLING BREAKERS	
M. J. F. Stive	547
Chapter 35	
DIRECTIONAL WAVE SPECTRA AND WAVE KINEMATICS IN HURRICANES CARMEN AND ELOISE	
G. Z. Forristall, E. G. Ward and V. J. Cardone	567
Chapter 36	
PREDICTION OF THE SEVEREST SIGNIFICANT WAVE HEIGHT	
Michel K. Ochi and Joseph E. Whalen	587
Chapter 37	
PREDICTION OF DOMINANT WAVE PROPERTIES AHEAD OF HURRICANES	
Omar H. Shemdin	600
Chapter 38	
LONG PERIOD DISTURBANCES DUE TO WAVE GROUPS	
E. C. Bowers	610
Chapter 39	
TWO-DIMENSIONAL SURF BEAT	
Reinhard E. Flick, Douglas L. Inman and Robert T. Guza	624

Chapter 40	
LONG WAVES GENERATED BY COMPLEX BOTTOM MOTIONS	
J. L. Hammack and F. Raichlen	639
Chapter 41	
TSUNAMIS ALONG WEST COAST OF LUZON, PHILIPPINES	
R. L. Wiegel	652
Chapter 42	
TSUNAMI PRONE FRICTION FACTORS FROM WIND MEASUREMENTS	
Charles L. Bretschneider	672
Chapter 43	
RUN-UP OF TSUNAMIS BY LINEAR AND NONLINEAR THEORIES	
Chiaki Goto and Nobuo Shuto	695
Chapter 44	
ON THE CORRECTION OF LAND-BASED WIND MEASUREMENTS FOR OCEANOGRAPHIC APPLICATIONS	
S. A. Hsu	708
Chapter 45	
NUMERICAL MODELLING OF TROPICAL CYCLONE STORM SURGE	
Rodney J. Sobey, Bruce A. Harper, and George M. Mitchell	725
Chapter 46	
A NUMERICAL MODEL OF STORM WAVES IN SHALLOW WATER	
A. Hauguel	746
Chapter 47	
THE GENERATION OF LONG WAVES IN THE LABORATORY	
Derek Goring and Fredric Raichlen	763
Chapter 48	
CORRECT REPRODUCTION OF LONG GROUP INDUCED WAVES	
N. -E. O. Hansen, S. E. Sand, H. Lundgren, T. Sorensen and H. Gravesen	784
Chapter 49	
AN ELECTROMAGNETIC ANALOGY FOR LONG WATER WAVES	
G. W. Jackson and D. L. Wilkinson	801
Chapter 50	
INTERACTIONS OF WAVES WITH SUBMARINE TRENCHES	
Jiin J. Lee, Robert M. Ayer and Wen L. Chiang	812
Chapter 51	
TRANSIENT FINITE-DIFFERENCE TSUNAMI CALCULATIONS	
Ove Skovgaard and Ivar G. Jonsson	823
Chapter 52	
AN INVESTIGATION OF WAVE SHELTERING BY ISLANDS	
S. V. Hsiao, J. F. Vesecky and O. H. Shemdin	840
Chapter 53	
THE DISSIPATION OF WAVE ENERGY BY TURBULENCE	
Yu Kuang-ming	850

**PART II
COASTAL SEDIMENT PROBLEMS**

Chapter 54	
BEACH CUSPS AT POINT REYES AND DRAKES BAY BEACHES, CALIFORNIA	
Robert G. Dean and E. M. Maurmeyer	863
Chapter 55	
BARRON RIVER DELTA INVESTIGATION	
D. A. Robinson, D. J. Cook and J. G. Barff	885
Chapter 56	
SOFT DESIGNS FOR COASTAL PROTECTION AT SEABROOK ISLAND, S.C.	
Miles O. Hayes, Timothy W. Kana and John H. Barwis	897
Chapter 57	
GEOLOGICAL CONTROLS ON PROCESS-RESPONSE, S.E. AUSTRALIA	
P. S. Roy and A. W. Stephens	913
Chapter 58	
BEACH EROSION-ACCRETION AT TWO TIME SCALES	
B. G. Thom and G. M. Bowman	934
Chapter 59	
PHYSICAL PROCESSES AND SEDIMENT FLUX THROUGH REEF-LAGOON SYSTEMS	
Harry H. Roberts	946
Chapter 60	
INSHORE-NEARSHORE MORPHODYNAMICS- A PREDICTIVE MODEL	
John Chappel	963
Chapter 61	
BEACH CUT IN RELATION TO SURF ZONE MORPHODYNAMICS	
L. D. Wright	978
Chapter 62	
BREAKER TYPE AND PHASE SHIFTS ON NATURAL BEACHES	
Peter J. Cowell	997
Chapter 63	
BEACH RESPONSE TO VARIATIONS IN BREAKER HEIGHT	
A. D. Short	1016
Chapter 64	
THE DYNAMIC SWEPT PRISM	
David M. Chapman	1036
Chapter 65	
A LABORATORY STUDY OF OFFSHORE TRANSPORT OF SEDIMENT AND A MODEL FOR ERODING BEACHES	
Tsuguo Sunamura	1051
Chapter 66	
NEARSHORE CURRENTS ON A PARTIALLY ROCKY SHORE	
T. O. Sasaki, H. Igarashi and S. Harikai	1071

Chapter 67	
TOPOGRAPHIC CONTROL OF RUN-UP VARIABILITY	
Mark P. Bradshaw	1091
Chapter 68	
BEACH PROFILES AND ON-OFFSHORE SEDIMENT TRANSPORT	
Akira Watanabe, Yoshihiko Riho and Kiyoshi Horikawa	1106
Chapter 69	
SECONDARY SAND TRANSPORT MECHANISMS	
A. W. Smith and A. D. Gordon	1122
Chapter 70	
SAND TRANSPORT BY WAVES	
Jan van de Graaff and Wiel M. K. Tilmans	1140
Chapter 71	
NEARSHORE SUSPENDED SEDIMENT LOAD DURING STORM AND POST-STORM CONDITIONS	
Timothy W. Kana and Larry G. Ward	1158
Chapter 72	
ONSHORE-OFFSHORE TRANSPORT AND BEACH PROFILE CHANGE	
Masataro Hattori and Ryoichi Kawamata	1175
Chapter 73	
ON-OFFSHORE SEDIMENT TRANSPORT RATE IN THE SURF ZONE	
Toru Sawaragi and Ichiro Deguchi	1195
Chapter 74	
FIELD MEASUREMENTS OF SAND MOTION IN THE SURF ZONE	
Douglas L. Inman, James A. Zampol, Thomas E. White, B. Walton Waldorf, Daniel M. Hanes and Kim A. Kastens	1215
Chapter 75	
AN APPROACH TO UNDERSTANDING COASTAL PROCESSES	
A. D. Gordon and D. B. Lord	1235
Chapter 76	
RELATIONSHIP BETWEEN ALONGSHORE WAVE ENERGY AND LITTORAL DRIFT IN THE MID-WEST COAST AT TAIWAN	
Ho-shong Hou, Chung-Pan Lee, and Lung-Hui Lin	1255
Chapter 77	
LONGSHORE WATER AND SEDIMENT MOVEMENT	
D. H. Swart and C. A. Fleming	1275
Chapter 78	
CRITERION FOR STABILITY OF SHORELINE PLANFORM	
John D. Wang and Bernard le Mehaute	1295
Chapter 79	
ZETA BAYS, POCKET BEACHES AND HEADLAND CONTROL	
R. Silvester, Y. Tsuchiya, and Y. Shibano	1306
Chapter 80	
BEACHES: PROFILES, PROCESSES AND PERMEABILITY	
Michael R. Gourlay	1320
Chapter 81	
SAND BED-FORM LENGTHS UNDER OSCILLATORY MOTION	
Arthur Brebner	1340

Chapter 82	
SEDIMENT TRANSPORT PROCESSES AND COASTAL VARIABILITY ON THE ALASKAN NORTH SLOPE	
E. H. Owens, J. R. Harper and D. Nummedal	1344
Chapter 83	
SEDIMENT DISPERSAL ON THE N. S. W. CONTINENTAL SHELF	
Ron Boyd	1364
Chapter 84	
FLUID MUD DYNAMICS AND SHORELINE STABILIZATION: LOUISIANA CHENIER PLAIN	
John T. Wells and Harry H. Roberts	1382
Chapter 85	
NEARSHORE SEDIMENT TRANSPORT STUDY EXPERIMENTS	
R. J. Seymour and C. G. Gable	1402
Chapter 86	
A SEDIMENT TRAPPING EXPERIMENT AT SANTA CRUZ, CA.	
R. J. Seymour, G. W. Domurat and D. M. Pirie	1416
Chapter 87	
WAVE FORCING OF BEACH GROUNDWATER	
Evans Waddell	1436
Chapter 88	
LONGSHORE TRANSPORT EVALUATIONS AT A DETACHED BREAKWATER	
R. O. Bruno, R. G. Dean, and C. G. Gable	1453
Chapter 89	
MIGRATION OF LONGSHORE BARS	
Hans H. Dette	1476
Chapter 90	
A PHASED-DREDGING PROGRAM FOR SANTA CRUZ HARBOR	
James R. Walker and Peter J. Williams	1493
Chapter 91	
DESIGN OF ENCLOSED HARBORS TO REDUCE SEDIMENTATION	
Craig H. Everts	1512
Chapter 92	
OPENING AND MAINTAINING TIDAL LAGOONS & ESTUARIES	
Scott A. Jenkins, Douglas L. Inman and James A. Bailard	1528
Chapter 93	
RESEARCH IN SOUTHERN QUEENSLAND INTO THE MANAGEMENT OF COASTAL SAND DUNES	
James B. McKenzie and David A. Barr	1548
Chapter 94	
WIND AND SEDIMENT MOVEMENT IN COASTAL DUNE AREAS	
John R. Hails and John Bennett	1565
Chapter 95	
SAND TRANSPORT UNDER THE ACTION OF WIND	
Ulrich Zanke	1576
Chapter 96	
A NUMERICAL MODEL FOR DUNE DYNAMICS	
J. Sundermann, H. -J. Vollmers and W. Puls	1584

Chapter 97	
ESTUARINE RESPONSE TO DREDGING IN THE TWEED RIVER, AUSTRALIA	
Bruce M. Druery	1599
Chapter 98	
NOOSA BEACH RESTORATION SCHEME	
R. J. Lloyd	1619
Chapter 99	
BEACH NOURISHMENT AS A MANAGEMENT TECHNIQUE	
David M. Chapman	1636
Chapter 100	
CAPRICORN COAST BEACHES	
D. C. Patterson and L. R. Ford	1649
Chapter 101	
THE BEACH IMPROVEMENT PROGRAMME: NEW SOUTH WALES	
Heale A. Philip and Philip H. Waite	1669
Chapter 102	
EDDY CURRENTS AND SEDIMENT TRANSPORT OFF THE DAMIETTA NILE	
S. P. Murray, J. M. Coleman, H. H. Roberts and M. Salama	1680
Chapter 103	
A COMPARISON BETWEEN DREDGE INDUCED SEDIMENT RESUSPENSION AND THAT PRODUCED BY NATURAL STORM EVENTS	
W. Frank Bohlen and Marine Sciences Department., Univ. of Conn.	1700
Chapter 104	
SEDIMENTATION IN CHANNELS AND TRENCHES	
E. W. Bijker	1708
Chapter 105	
SEDIMENTATION IN DREDGED NAVIGATION CHANNELS	
Lars Mikkelsen, Preben Mortensen, and Torben Sorensen	1719
Chapter 106	
SOME ASPECTS OF COASTAL ENGINEERING RESEARCH WORKS IN CHINA	
Yen Kai	1735

PART III
COASTAL STRUCTURES AND RELATED PROBLEMS

Chapter 107	
SIMULTANEOUS WAVE AND CURRENT FORCES ON A PIPELINE	
David A. Knoll and John B. Herbich	1742
Chapter 108	
WAVE FORCES ON AN INCLINED CIRCULAR CYLINDRICAL PILE	
Toshiyuki Shigemura	1761
Chapter 109	
WAVE-INDUCED SEEPAGE EFFECTS ON A VERTICAL CYLINDER	
Thomas J. P. Durand and Peter L. Monkmeyer	1781

Chapter 110	
STABILITY ANALYSIS OF SEAFLOOR FOUNDATIONS	
Tokuo Yamamoto and Yasumasa Suzuki	1799
Chapter 111	
WAVE FORCES ON OFFSHORE PIPELINES	
N. Jothishankar and V. Sundar	1819
Chapter 112	
WAVE IMPACT PRESSURES ON COMPOSITE BREAKWATERS	
G. R. Mogridge and W. W. Jamieson	1829
Chapter 113

THE UNSOLVED PROBLEM OF BREAKING WAVES[†]

by M.S. Longuet-Higgins^{*}

I. INTRODUCTION

"There is nothing so practical as a good theory"

One of the outstanding features of coastal waters is the breaking of swell and wind waves within the surf zone. A sound knowledge of the velocity and pressure fields in breaking waves is clearly of basic importance for coastal engineering, not only because of the need to calculate forces on jetties, breakwaters and other structures, but also because of the dominant role played by wave breaking in the dissipation of wave energy, in the transfer of momentum to longshore currents, and in the erosion and transport of sand and sediment.

The astonishing fact remains that our quantitative knowledge of the velocity field in breaking waves is very meagre. Despite praiseworthy attempts (some reported at previous Coastal Engineering Conferences) to measure velocities both in the field and in laboratory wave channels, the present state of knowledge compares very unfavourably with, say, our knowledge of the dynamics of swell in deep water.

Why is this? After all, we know the basic physical laws of fluid motion. The equations for an incompressible fluid with a free surface (but without suspended sediment) can be written down at will. Our trouble is that even in the simplest case, that of a homogeneous, inviscid fluid in two-dimensional, irrotational motion, we have been unable to find either suitable exact solutions, or useful approximations with which to compare and correlate our hard-won experimental results. Thus we do not know the answer to the question: What is the flow, or more generally the possible class of flows, in an overturning wave? The main reason for our ignorance is not that the observations are difficult in themselves; both the surf zone and breaking waves in the laboratory do indeed present formidable difficulties. It is not that we do not understand the physics.

[†]Keynote address: 17th International Conference on Coastal Engineering. Sydney, Australia, 23-29 March 1980.

^{*}Royal Society Research Professor at Cambridge - Department of Applied Mathematics and Theoretical Physics, University of Cambridge, England, and Institute of Oceanographic Sciences, Wormley, Godalming, Surrey.

It is, that we do not have to hand any simple but valid mathematical solutions as the basis for a physical model.

In this situation it is the applied mathematician who must take the lead and find suitable answers, working always closely with experimenter.

It has been said that there is nothing so practical as a good theory. But what do we mean by "good"? A theory should have two desirable quantities: it should be accurate and it should be simple. Often we can achieve accuracy at the expense of simplicity. Only on rare occasions do we get both.

More often the historical sequence is as follows: First we find a rough but very inaccurate model (for example, shallow-water waves as sine-waves). Then we improve the model, perhaps by a second or higher-order approximation. Next we may achieve a highly accurate model, but it is forbiddingly complicated and difficult to apply. Finally we find a simple but reasonably accurate approximation which is both usable and essentially correct.

This sequence will be illustrated in the case of breaking waves.

It is convenient to divide our problem into four sub-problems.

A. The limiting form of steep, symmetric waves. This problem is well-studied, and the solutions will be seen to have passed through all the four stages mentioned above.

B. The form of steep, steady, but not limiting, waves. In this, substantial progress has been made only quite recently, with some surprising and unexpected results.

C. Steep, time-dependent waves; overturning. This is more difficult than either A or B, since it involves a new dimension - time. Some new theoretical approaches will be reported.

D. Waves after breaking.

Whereas A, B and C are problems in pure fluid dynamics, involving mainly one physical parameter g , Problem D involves also turbulence and mixing, and hence is inevitably more empirical. Problems A, B and C represent challenges primarily to the mathematician, in increasing order of complexity.

2. PROBLEM A: LIMITING FORMS OF STEEP, STEADY WAVES.

First consider waves in deep water. Accurate computations of the steepest, symmetric wave go back as far as Michell (1893) who incorporated Stokes's 120° corner-flow for the wave crest into a series expansion for the whole wave. More recent calculations by Yamada (1957a) and others, using widely different methods, are essentially in agreement to four significant figures (see Table 1).

Table 1. The height and speed of the steepest gravity waves in deep water.

Author	H/L	c^2/c_0
Michell (1893)	0.142	1.20
Yamada (1957a)	0.1412	1.1932
Schwartz (1974)	0.1412	1.1930
Longuet-Higgins (1975)	0.1411	1.1931
Cokelet (1977)	0.1411	1.1928
L-H and Fox (1978)	0.14107	1.1931

The above calculations all involve infinite series. On the other hand a very simple approximation has recently been proposed (Longuet-Higgins 1978b, 1979a) in which the surface profile is approximated by the arc of a circle (see Figure 1) whose radius is equal to the wavelength L . This makes the crest-to-trough height to be $0.1340L$, which differs from the accurate value by only $0.0072L$. The motion of a particle at the free surface can now be seen as that of the bob of a light pendulum of length L , swinging through a 60° arc, on which is superposed a horizontal speed equal to the phase speed. This gives the orbit shown in Figure 2. The mean speed of advance of the particle is then easily found to be $U = 0.282c$, compared to the accurate value

$$U = 0.274c \quad (2.1)$$

based on Yamada's profile (see Longuet-Higgins 1979c).

To obtain the orbital motion of particles below the surface we may adopt the almost equally simple approximation in which the free surface is transformed from one side of a

Figure 1. Approximating the profile of a deep-water gravity by the arc of a circle.

Figure 2. The trajectory of a particle at the surface of a gravity wave in deep water, as given by the approximation of Figure 1.

hexagon (Longuet-Higgins 1973) giving as equation for the profile

$$y = \ln \sec x \quad (2.2)$$

(in units where the wavelength equals $\frac{1}{3}\pi$). The corresponding wave height is now $0.1374L$, in error of only $0.0037L$. But (2.2) has the advantage that the corresponding velocity potential is now easily determined, and from these we get the orbital motions shown in Figure 3 (taken from Longuet-Higgins 1979c). It is easy to see how rapidly the mean displacement falls off as one goes deeper.

Figure 3. Orbits of subsurface particles in a deep-water wave of maximum steepness, calculated from the "hexagon approximation", equation (2.2).

Figure 4. Time exposure of the track of a luminous float disturbed by an advancing wave train.

For comparison, Figure 4 shows the track of a small, luminous float, placed ahead of an advancing wave train (period 1.0 sec) in the 180-ft channel at Wormley. Viewing is through a window in the side. Before the waves arrive, the float is almost stationary and burns a hole in the negative. On arrival of the wave front, the track unwinds like a watch-spring. The steepest wave, which has an amplitude somewhat greater than the waves behind, is just breaking.

We turn now to the steepest symmetric waves in shallow water, beginning with the extreme case of the solitary wave.

Some recent determinations of the height and speed of limiting solitary waves are shown in Table 2. The values of a/h are necessarily half those of the corresponding c^2/gh . It is perhaps not fortuitous that the two most recent calculations are in agreement to four significant figures. Though the details of Witting's calculations are not available, it is believed that like Fox (1977) his method requires some extrapolation. In fact these figures cannot be considered quite so reliable as those for deep water.

Table 2. Accurate determinations of the height and speed of the steepest solitary wave.

	a/h	c ² /gh
Yamada (1957b)	0.828	1.656
Lenau (1966)	0.827	1.654
L-H and Fenton (1974)	0.827	1.653
Witting (1975)	0.8332	1.6664
Fox (1977)	0.8332	1.6664

On the other hand a remarkably simple approximation to the surface profile has been derived recently (Longuet-Higgins 1974a, 1976a) namely

$$y = A e^{-\lambda|x|} + B e^{-\mu|x|} \quad (2.3)$$

(in units where the undisturbed depth equals 1). The values of the constants are

$$\left. \begin{aligned} A &= 1.5389, & \lambda &= 1.0495 \\ B &= -0.7093, & \mu &= 1.4630 \end{aligned} \right\} \quad (2.4)$$

giving

$$F^2 = 2(A+B) = 1.659 \quad (2.5)$$

(compare Table 2). The profile is graphically indistinguishable from that calculated by Yamada (1957b). From (2.3) we may easily calculate the trajectory of a particle at the free surface by the method given in Longuet-Higgins (1979a). The result is shown in Figure 5, assuming there is no backwards drift between successive "solitary waves".

In Figure 6 we show the height and width of surface particle orbits in solitary waves of various steepnesses, measured in a shallow-water wave tank (Longuet-Higgins 1980d).

Lastly, for limiting waves at intermediate ratios of wavelength to mean depth, some properties are given in Table 3, deduced from the accurate computations of Cokelet (1977). For such waves, however, no approximate expressions comparable in simplicity to equations (2.2) or (2.3) have yet been given.

Figure 5. Trajectory of a particle at the surface of a solitary wave of maximum steepness.

Figure 6. The overall horizontal displacement X and vertical displacement Y of particles at the surface of steep, solitary waves. Δ and o denote observations at distances 3.5m and 6.1m from wavemaker. The depth of water $h = 10\text{cm}$. Plots in upper right-hand quadrant were for spilling breakers. Δ denotes theory for limiting waves, from Figure 5.

3. PROBLEM B. STEEP, STEADY, BUT NOT LIMITING WAVES

This is clearly more general than Problem A, and more difficult. It is also both surprising and interesting.

Let us begin with waves in deep water. Until recently it was customary to use the small-amplitude expansion of Stokes:

$$(x+iy) = (\phi+i\psi)/c + \sum_n a_n e^{n\psi/c} \cos n\phi/c \quad (3.1)$$

carried to second, third or higher orders, in order to calculate the properties of quite steep waves. Following Stokes (1880), the expansion parameter was assumed proportional to a_1 , the coefficient of the first harmonic. It was Schwartz (1974) who showed that the resulting series fails to converge when the wave steepness exceeds a certain value, namely $H/L = 0.131$, short of the highest. The reason is very simple. In steep waves the surface profile becomes markedly non-sinusoidal, being narrow at the crests and broad in the wave troughs. So for the very highest waves the first Fourier coefficient a_1 , which measures the amplitude of the first harmonic, can be less than for waves that are not as steep but are more rounded at the crests. Consequently the coefficient a_1 , considered as a function of a maximum and then turns down again. For some values of a_1 there can be two different waves; convergence to both waves simultaneously is impossible.

However, even before the critical lower value of the wave steepness is reached, convergence of the series becomes exceedingly slow, and so any computations which use it become inefficient and unreliable. Just as it is useless to base mathematical calculations on unsound physics, so it is useless, or worse, to base physical calculations on unsound mathematics.

The remedy, as Schwartz showed, is to choose a different expansion parameter, one which increases steadily throughout the range of waves we are considering. The simplest such parameter is the wave steepness itself. Thus when h , or $2a/L$ is used as expansion parameter, the series all converge up to the steepest wave.

Not long afterwards it was discovered by Longuet-Higgins (1975) that not only a_1 , a_2 ---- but also the phase speed c (whose inverse can be considered as the lowest Fourier coefficient) also has a maximum before the highest wave is reached (see Figure 7). Hence at large wave steepness there may be two different waves with the same speed

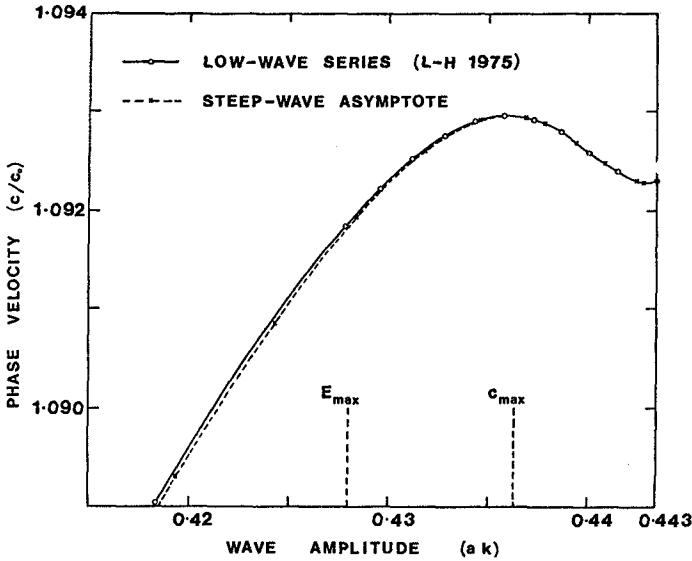

Figure 7. The phase-speed of waves in deep water, at high values of the wave steepnesses ($ak = \pi H/L$). Full curve represents the 80-term series (Padé summed). Broken curve: asymptotic expressions (3.6) and (3.7)

Figure 8. The phase-speed of solitary waves.

and wavelength. This has interesting and unexpected implications for the existence of non-uniform trains of waves (see below).

Meanwhile, similar discoveries had been made for solitary waves. Thus Longuet-Higgins and Fenton (1974) showed by the use of series expansions, that the speed of solitary waves, as a function of their amplitude at fixed depth, increases to a maximum and then decreases again (Figure 8). This was directly related to the profile of the waves. For in a solitary wave, as the wave height increases the crest becomes narrower, and this tendency continues right up to the highest wave (see Byatt-Smith and Longuet-Higgins, 1976). Moreover, the profiles intersect near the crest, so that the highest waves actually lie below the "lower" waves over most of their width. In other words as the highest wave is approached, the "mean elevation"

$$\bar{y} = \int y^2 dx / \int y dx \quad (3.2)$$

tends to diminish. Now (3.2) can be written

$$\bar{y} = 2V/Mg \quad (3.3)$$

where M and V denote the excess mass and potential energy in the wave. But an exact relation for solitary waves due to Starr (1947) is that

$$c^2 = gh + 3V/M \quad (3.4)$$

(A direct proof is given by Longuet-Higgins, 1974). Therefore as \bar{y} diminishes, so must the phase-speed c .

Not only the phase speed but also other quantities such as the mass, momentum and total energy of solitary waves were found to have maxima within the possible range of wave steepness. As pointed out by Longuet-Higgins and Fenton (1974) this implies that steady waves of maximum steepness cannot be attained without some dissipation of energy perhaps by breaking or bottom friction. The maximum may also help to account for the intermittent character of whitecaps in the surf zone as a kind of hysteresis effect.

Waves at intermediate depths between deep and shallow water have been studied by Cokelet (1977) and shown to possess similar characteristics: the speed, energy and other integral properties all take maxima within the possible range of steepness.

These somewhat unexpected results of Longuet-Higgins and Fenton (1974) for solitary waves, of Longuet-Higgins (1975) for deep-water waves and of Cokelet (1977) for waves in water of intermediate depth were all obtained by applying techniques for accelerating the convergence of infinite series, particularly "Padé sums". These are essentially a direct generalisation of the ordinary partial sum. Given a finite number of terms in a power series, the function is approximated not by a polynomial (the partial sum) but by a rational function which has the same power series expansion up to that point. Surprising though they may seem, the results have since been verified in detail by quite different methods of calculation based on integral equations: for solitary waves by Byatt-Smith and Longuet-Higgins (1976), for deep-water waves by Chen and Saffman (1978, Section 5) and Olfe and Rottman (1979) and for waves at intermediate depths by Vanden-Broeck and Schwartz (1979). The stream-function method of Dean, when suitably modified (Chaplin 1979) also gives results consistent with the above.

All such methods, however, are complicated. A radical simplification was introduced by Longuet-Higgins and Fox (1977, 1978) who proposed starting from known solutions for the highest wave and working downwards. First (1977) the rounded form of the wave crest was calculated for a wave approaching (but not quite attaining) the Stokes 120° corner-flow. This is shown in Figure 9. The length-scale ℓ is equal to $q^2/2$, where q is the speed of a particle at the crest, seen in a reference frame moving with the wave. As the highest wave is approached, so q/c and ℓ both tend to zero. Then (1978) this local flow was "matched" asymptotically to the flow in the rest of the wave, assuming that the "matching parameter"

$$\epsilon \propto q/c \quad (3.5)$$

was small. The result is essentially a two-term expression for the total flow. Thus for the height and speed of deep-water waves, for example, Longuet-Higgins and Fox (1978) found that

$$2a/L = 0.14107 - 0.50\pi^{-1}\epsilon^2 + 0.160 \epsilon^3 \cos(2.143 \ln \epsilon - 1.54) \quad (3.6)$$

and

$$c^2/c_0^2 = 1.1931 - 1.18 \epsilon^3 \cos(2.143 \ln \epsilon + 2.22) \quad (3.7)$$

Figure 8 shows a graph of c/c_0 versus $ak = 2 a/L$ for the steepest waves, and it can be seen how closely the two-term asymptotic expansion agrees with the 80-term small-amplitude series.

A further simplification of the theory of the almost-highest wave was introduced by Longuet-Higgins (1979) who showed that the flow near the crest (the "inner solution") is quite accurately described by the simple expression

$$x+iy = \frac{\alpha+\gamma i\chi}{(\beta+i\chi)^{1/3}} \quad (3.8)$$

where $\chi = \phi+i\psi$ and α, β, γ are constants:

$$\begin{aligned} \alpha &= 1.6876 \\ \beta &= 4.8065 \\ \gamma &= 1.3104 \end{aligned} \quad (3.9)$$

A comparison between the profile given by equation (3.8) and the exact inner solution is shown in Figure 9.

Figure 9. Profile of the almost-highest wave near the wave crest. x = exact computation (Longuet-Higgins and Fox 1977). \circ = approximation (3.8).

Before leaving the subject of steady waves, it will be interesting to mention the recent discovery by Chen and Saffman (1978) of steady but non-uniform trains of waves. Although their approach was different, we can show by the following argument that the existence of such wave trains is not unreasonable. We have seen that at very high steepness it is possible for two uniform trains of waves to exist with the same speed and wavelength. Let us then pick one wave alternately from each wave train, and place them side-by-side to form a new train of waves with alternately high and low amplitudes. Is it possible to join the waves up smoothly so that a continuous motion results? For solitary waves in shallow water, where each wave tails off exponentially in the horizontal direction, the answer is convincingly, yes. Does it remain possible, as we increase the ratio of depth to wavelength? The calculations of Chen and Saffman shows in effect that it is indeed possible even when the depth becomes infinite, provided the waves are sufficiently steep.

Similar arguments apply to the case when every third, fourth or in general every n th, wave is higher than the others, and to more complicated cases.

Normally, we expect the envelope of a non-uniform wave train to move with the group-velocity c_g . For low waves in deep water c_g is only about one-half the phase velocity c . But here the c_g waves are so non-linear that the group-velocity has grown to equal the phase-velocity; the envelope moves with speed c .

Table 3. Parameters of waves of limiting steepness, from computations by Cokelet (1977)

e^{-d}	$(d+\bar{y})/L$	H/L	c^2/c_0^2

4. PROBLEM C. TIME-DEPENDENT WAVES: OVERTURNING

We come now to the central part of our main problem. In spite of excellent laboratory investigations, notably by Pazan and van Dorn (1975) and by Killen and Horning (1976) the theoretical analysis has been largely lacking. No doubt this is because of the highly time-dependent and non-linear character of the fluid motion. The accelerations can no longer be assumed small compared to g , and the free surface, on which two nonlinear conditions must be satisfied, is no longer a streamline, as in steady motions.

Some progress with a numerical method of computation was made by Longuet-Higgins and Cokelet (1976; see also Longuet-Higgins 1976a), in which it was shown how the equation for a two-dimensional motion, periodic in space but not time, could be integrated step-by-step by solving at each step an integral equation involving only the values of x, y and ϕ at the free surface. By this method it was shown how a periodic wave, raised to an energy level greater than the maximum for its particular wavelength, could overturn before the formation of a sharp crest.

In the above example, the wave was initially forced, by the application of pressure to the rear face of the wave (though this was withdrawn before the wave overturned). Some examples where breaking occurred after no pressure was applied were given in a second paper (Longuet-Higgins and Cokelet 1978). It had already been shown by Longuet-Higgins (1978a and b) that the normal instabilities of free gravity waves were of two distinct kinds: the subharmonic instabilities of Benjamin and Feir (1967) which tend to produce a "bunching" of the waves into groups of high and low waves, at least initially; and secondly a local type of instability confined mainly to the wave crests and with a relatively high rate of growth. By following perturbations of the second type by their time-stepping technique (see Figures 10 and 11) Longuet-Higgins and Cokelet (1978) were able to show that the second type of instability led rapidly to overturning of the wave crest.

Moreover, by following the more slowly growing instabilities of the first type for a longer period of time, they showed that these led to a modulation of the wave train so severe that ultimately the steeper waves developed local instabilities of the second kind at their crests, and also overturned. All this occurred without the addition of any energy by surface pressures,

The above calculations were for deep-water gravity waves. The stability calculations for deep-water waves by Longuet-Higgins (1978a and b) have recently been extended to water of finite (but uniform) depth by Cleaver (1980). These show that as the ratio of mean depth to wavelength

Figure 10. (from Longuet-Higgins and Cokelet, (1978). Development of the highly unstable mode $n = (\frac{3}{2})^+$ when $ak = 0.41$. The vertical scale on the right is magnified 5 times.

Figure 11. Enlargement of the wave crest in Figure 10 at times near overturning. The time-interval between profiles is $2\pi/50$.

diminishes, so the subharmonic instabilities (those of the first kind) tend to be suppressed. Nevertheless it seems likely the local instabilities (those of the second kind) will be little affected, and may even be enhanced. The corresponding time-stepping test for finite depth has still to be carried out.

One of the most interesting aspects of these results is the close similarity between the overturning of the local instabilities, despite the differences in their initial conditions. This leads us to hope that an overturning progressive wave may assume some typical form asymptotically, largely independent of the initial conditions, save for a local length-scale λ and a time-scale τ related by

$$\lambda/g\tau^2 = O(1) \quad (4.1)$$

Starting from different initial conditions (a progressive sine-wave of large amplitude) Cokelet (1977) has carried the numerical time-stepping well beyond overturning (see Figure 12). The form of the jet is convincing, although the accuracy of the computations near the tip of the jet is questionable.

The same time-stepping technique has also been applied to standing waves in deep water by Saffman and Yuen (1979).

Successful as they may seem, such numerical techniques leave important questions unanswered. For example, what is the appropriate form for the tip of the jet? Is there a sharp cusp? And how are the characteristics of the jet, its total volume, energy and momentum, for example, related to the initial conditions from which the breaking wave begins?

To help answer these questions we need a much simpler, if approximate, analytical model of the overturning wave to complement the numerical results.

Figure 12. (from Cokelet 1977). Later stages of an overturning jet, as given by the numerical time-stepping method.

5. PROBLEM C (continued). ANALYTICAL APPROACHES

An attempt to obtain a simple analytical model for the crest of an overturning wave, was recently begun by the present author (Longuet-Higgins 1980a, b and c). Our problem is to find an expression for the velocity potential χ which shall be an analytic function of the space coordinate $z = x+iy$ and of the time t , and such that on the free surface the two boundary conditions

$$p = 0 \quad \text{and} \quad Dp/Dt = 0 \quad (5.1)$$

are both satisfied simultaneously. Here D/Dt denotes differentiation following a particle. It can be shown (Longuet-Higgins 1980a) that if as coordinates we use not x, y and t , but z, z^* and t , where $z^* = x-iy$, then the boundary conditions (4.1) can be expressed very compactly in terms of the velocity potential χ and its derivatives.

We can distinguish two aspects of the flow: the formation of a sharp corner at the crest of the wave or the tip of the jet, and on the other hand the overturning of the body of the wave as a whole. That the two problems are quite distinct is indicated by the fact that we sometimes observe upwards-pointing crests or jets, and also (as just mentioned) that overturning can occur before the formation of a sharp corner.

A model for the tip of the wave is proposed in Longuet-Higgins (1980b). In this we imagine the pressure field in the fluid to be extended smoothly beyond the free surface, so that the pressure has a saddle-point at some point O , as shown in Figure 13. At O the pressure gradient vanishes, so that the "fluid" has downwards acceleration g . Assuming O moves with the fluid, we can, by taking a frame of reference attached to O , eliminate g from our equations locally. We can then show that in this free-fall frame of reference there are solutions of the simple form

$$\chi = \frac{1}{2}Az^2 \quad (5.2)$$

where A is a function of the time t only. In fact

$$A = \alpha e^{i\sigma} \quad (5.3)$$

where α and σ are real functions of t given by

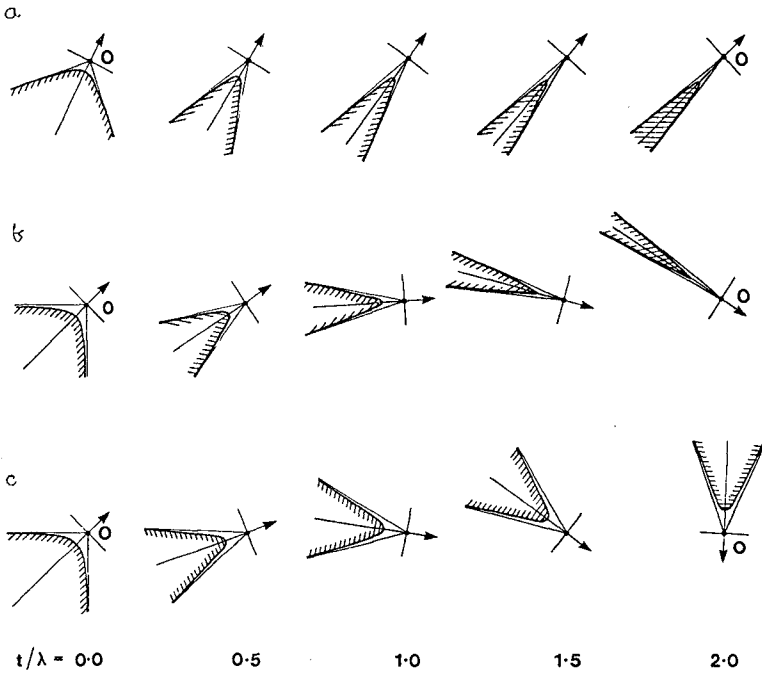

Figure 13. Examples of solutions of type (4.2) for the flow near the tip of the wave (a) when $P/\lambda^4 = 5.0$, (b) when $P/\lambda^4 = 0.30$ (c) when $P/\lambda^4 = 0.25$.

Figure 14. Example of a solution in class (2), when $P/\lambda^4 = 0.20$.

$$\left. \begin{aligned} \sigma &= \int \lambda \alpha^2 dt \\ t &= \int \frac{\lambda d\alpha}{(1-\lambda^2 \alpha^2 + P\alpha^4)^{\frac{1}{2}}} \end{aligned} \right\} \quad (5.4)$$

λ and P being arbitrary constants. The free surface takes the form of a hyperbola, such that the angle γ between the asymptotes varies with time. The principle axes of the hyperbola also rotate, in general, with angular velocity δ , also a function of t .

The solutions to (5.4) fall into two classes:

(1) When $P/\lambda^4 > 1/4$ the angle γ between the asymptotes diminishes monotonically in time, as shown for example in Figure 13. The axes meanwhile rotate through a finite angle, in general. However if $P/\lambda^4 = 1/4$ (Figure 13c) the rate of rotation tends to become a constant.

(2) When $P/\lambda^4 < 1/4$ (Figure 14) the angle γ between the asymptotes can begin at 90° , decrease to a smaller value and then return again to 90° after rotation through a finite angle, as in Figure 14. These solutions resemble the crests of waves partially reflected from a beach or obstacle.

(3) When $P/\lambda^4 < 1/4$ there is a third class of solutions in which the angle γ starts from zero as $t \rightarrow -\infty$, then increases to a maximum less than 45° and falls again to zero as $t \rightarrow +\infty$. These could have applications to falling jets.

These exact solutions are generalisations of the "Dirichlet hyperbolae" studied earlier by Longuet-Higgins (1976b), in which the orientation of the axes was fixed.

Now the origin O is in a free-fall trajectory, that is to say a parabola. When the motion of O is added to the motion just described, we obtain successive configurations such as shown in Figure 15. These are beginning to resemble the flow in the "jet" of a plunging breaker.

The local solution has now to be joined or "matched" mathematically to the flow in the rest of the wave. When we proceed to higher approximations by assuming, in place of (5.2), that

$$\chi = \frac{1}{2}Az^2 + \frac{1}{3}Bz^3 + \dots \quad (5.5)$$

then for certain choices of B the cubic terms are found to dominate and the free surface takes the form of a cusp.

Figure 15. Solutions for the tip of the wave after adding the free-fall motion of the origin 0 .

Figure 16. Successive positions of the free surface corresponding to equation (5.6) when $g = 1$, $U = (-1, 0.5)$ and A is chosen to minimise $\int (Dp/Dt)^2 ds$ along the free surface.

Now to solve the second part of the problem, that is to find an analytic expression for the body of overturning fluid, we may begin by observing that the flow in an overturning wave is essentially multivalued: where the "jet" hits the forward face of the wave, the fluid crosses over onto another sheet of the complex plane. Therefore in the cavity or "tube" of the breaker there must be a singularity of the velocity potential χ . The simplest such singularity is a branch-point of order $\frac{1}{2}$, and it is therefore natural to try an expression of the form

$$\chi = \frac{2}{3}ig^{\frac{1}{2}}z^{3/2} + Uz + 2Az^{\frac{1}{2}} \quad (5.6)$$

U being constant and A some function of the time t . The first term on the right of (5.6) represents the Stokes 120° corner-flow (the real axis of z points downward); the third term represents a parabolic flow which dominates near the origin but is relatively small at large distances $|z|$. The second term represents an arbitrary uniform flow past the branch-point at 0. In Longuet-Higgins (1980c) it is shown that

Figure 17. Successive positions of the free surface corresponding to (5.6) when $g = 1$, $U = (-1, 0)$ and \dot{A} is chosen so as to produce a sharp cusp at which $Dp/Dt = 0$.

we can satisfy both free surface conditions (5.1) asymptotically for large values of z provided that $\dot{A} = dA/dt$ is a constant, with

$$\operatorname{Re}(\dot{A}) = \operatorname{Im}(\frac{1}{2}U) \quad (5.7)$$

This leaves $\operatorname{Im}(\dot{A})$ at our disposal, which may be chosen so as to satisfy the boundary condition $Dp/Dt = 0$ at particular points, or in a least-squares sense, along the "free surface" $p = 0$.

An example of the flow (5.6) when $(Dp/Dt)^2$ is minimised along the free surface at time $t = 0$ (when A is real) is shown in Figure 16. At earlier times $t < 0$ the surface is more rounded; at later times the forward face becomes steeper and eventually overturns.

We can however find parameters in (5.6) such that not only is the boundary condition satisfied for large $|z|$ but also the free surface develops a sharp corner, at which point we can make $Dp/Dt = 0$. An example is shown in Figure 17.

To approximate solutions of the type shown in Figures 17 and 18 we may be able to join the solutions for the wave tip described earlier by asymptotic "matching".

For other forms of breaking waves expressions quite different from (5.6) may be appropriate. For example in a wave breaking against a vertical wall we may expect branch-points at two image-points on opposite sides of the wall.

6. PROBLEM D: WAVES AFTER BREAKING

The quasi-steady flow in a spilling breaker is probably the simplest with which to begin a study of post-breaking waves. It seems likely that at least the initial stages of spilling breakers, overturning near the crest of steep waves, differ only in local scale from those of the more violent and time-dependent plunging type.

After the tip of the jet collides with the forward face of the wave, violent turbulence ensues, often with the entrainment of air. This more complicated situation requires a different type of analysis, akin to the modelling of jets and wakes. A tentative model of a spilling breaker as a turbulent jet riding over a laminar fluid of higher density was proposed by Longuet-Higgins and Turner (1974) and seemed to model the initial stages of whitecaps on solitary waves. However, most reliance must be placed on experimental observations. Longuet-Higgins (1974b) reported laboratory measurements of the turbulence in a breaking bow-wave. Duncan (1979) has made extensive measurements of the spilling breaker induced by a submerged aerofoil towed through the water. One significant observation was the existence of a persistent oscillation of about 4.2 times the period of waves having a phase-speed equal to the towing speed. This is not far from the period of the fastest-growing instability of a uniform train of waves, as reported by Longuet-Higgins (1978a).

In an interesting study of plunging breakers, Miller (1976) has observed the formation of a succession of vortices at the free surface. As many as five may occur in one break. Each vortex tends to produce a pocket of air, forced downwards into the water, which then collapses in a cloud of bubbles.

Although aerial observations have been made of the percentage of the ocean surface covered by white water under various wind conditions (e.g. Monahan 1971), these do not easily give the mean energy or momentum lost to the waves through breaking. A new device which detects and measures the heights of sudden "jumps" or discontinuities in the sea surface has been developed by the present author and N.D. Smith. From observations in the North Sea during the MARSEN

program in September to November 1979 it was found that the number of "jumps" of a given magnitude increases sharply between wind-speeds of 6 to 8 m/s. Further analysis of these observations is in progress.

7. CONCLUSION

Out of the many and varied aspects of coastal engineering, I have chosen to speak about only one topic, but one that is central to an understanding of the surf zone. For want of space several aspects even of this topic, particularly the role played by shoaling depth of water, have had to be omitted.

Nevertheless it will be clear that this is a subject to which mathematical analysis can make a substantial, indeed a leading, contribution. I would emphasize that a satisfactory solution requires and deserves the best efforts of applied mathematicians, working in close collaboration with field observers. Some of our best workers have already taken up the challenge. I look forward to hearing some of their contributions, as well as many others, at this Conference.

1. INTRODUCTION

Calculations using the 'Design Wave' approach in coastal and offshore engineering begin with the specification of wave conditions usually in terms of a wave height, wave period and mean water depth. These three dimensional parameters are sufficient to define all the wave characteristics uniquely if a number of assumptions are adopted, including those of periodicity in space and time, absence of viscosity, and two-dimensional flow. Although these assumptions result in an enormous simplification of waves in the ocean, the ultimate idealised conditions hold some attraction in providing a standard description of wave mechanics for design purposes. Once the design wave approach has been adopted, it follows that the engineer needs to ensure that the theory which he uses to analyse waves generates results equivalent to those of the most accurate theory currently available.

There are in engineering use several wave theories (e.g., Airy, Stokes 5th order, Cnoidal, Stream Function) by means of which required wave properties can be computed from an initial wave specification on the basis of ideal conditions. Unfortunately, none of these theories is exact and in general they disagree, most significantly in conditions of shallow water or high wave steepnesses. The differences between them have stimulated comparative studies based on boundary condition errors (Dean, 1970) and experimental data (Le Méhauté et al, 1968), leading to recommendations on the use of specific theories for given conditions. However, the value of these comparisons has been somewhat limited by the absence of an accurate solution to the problem valid over the whole range of interest.

Such a solution has now been brought nearer by the work of Cokelet (1977), and it is the purpose of this paper to study the implementation of Cokelet's theory and other recent theories in an engineering context. The paper does not make any contribution to the analysis itself but is concerned with applications, and the question whether such developments should influence current engineering practice.

Previously, the wave theory offering greatest analytical accuracy and widest range of application was the Stream Function Theory of Dean (1965).

Tables of functions (Dean, 1974) have facilitated the application of this wave theory, but some results for steep waves given in the tables disagree with Cokelet's results.

The use of Cokelet's theory in an engineering context is discussed in Section 2, and other relevant recent developments introduced in Section 3. In Section 4 numerical results are presented for comparison between different methods.

2. ENGINEERING APPLICATIONS OF THE EXTENDED STOKES THEORY

As Cokelet (1977) presented it, the extended Stokes theory is not in a very convenient form for engineering application. The two dimensionless independent parameters¹ d_* and ϵ_* are not written explicitly in terms of wave height H , period T and mean water depth d . The expansion parameter ϵ_* lies in the range zero (for zero wave height) to unity (for waves of limiting height), and $d_*L/2\pi$ (where L is the wave length) is slightly less than the mean water depth d , and differs from it by 4% at most. In order to relate d_* and ϵ_* to H , T and d , it is necessary to compute some of the series expansions given by Cokelet using Padé approximants. In particular:

$$d/L_0 = \frac{c_*^2}{2\pi} (d_* + \bar{\eta}_*) \quad (1)$$

and

$$H/L_0 = \frac{c_*^2}{\pi} a_* \quad (2)$$

$$\text{where } L_0 = gT^2/2\pi$$

The problem of going in the opposite direction, i.e., finding from given d/L_0 and H/L_0 the corresponding d_* and ϵ_* , and thereby a complete solution for given wave conditions, is a more demanding one. Possibly the extended Stokes solution could be re-formulated with different independent parameters, but in the present work we adopt a more pragmatic approach which provides a satisfactory entry to Cokelet's theory from conditions specified in terms of d/L_0 and H/L_0 . The corresponding values of d_* and ϵ_* are interpolated from Cokelet's (1977) tabulated results as described below.

At points on the d/L_0 , H/L_0 plane corresponding to the intersections of lines at constant d_* and ϵ_* , some of which are shown in Fig. 1, Cokelet provided numerical results of a range of integral wave properties, including c_*^2 , $\bar{\eta}_*$ and a_* . The co-ordinates of the intersections may easily be calculated from Eqs. (1) and (2). In order to interpolate d_* at a specified point in the plane, the procedure adopted in the present work was as follows.

¹ Where Cokelet's parameters are introduced, they appear with a subscripted asterisk.

Conditions of limiting wave height H_B were identified on the axes of Fig. 1 by cubic splines fitted (Ahlberg et al, 1967) through the points at which $\epsilon_* = 1$, to approximate the function H_B/L_0 (d/L_0). The co-ordinates of the intersections at which the data is tabulated could then be transferred to the $d/L_0, H/H_B$ plane, in which lines of constant ϵ_* are predominantly in line with the d/L_0 axis. Cubic splines were then used, along each line of constant ϵ_* in turn, to approximate the functions H/H_B ($d/L_0, \epsilon_*$ =constant) and $d_*(d/L_0, \epsilon_*$ =constant). From each pair of splines H/H_B and d_* were interpolated at the required value of d/L_0 to give a series of (unequally spaced) points on the curve approximating $d_*(H/H_B, d/L_0$ =constant). The final interpolation at the required H/H_B was again performed by means of cubic splines. Linear scales were used throughout, except for d/L_0 and H/L_0 , which were represented in the curve fitting by their logarithms. Various end conditions for the splines were tested and the most accurate results were generally obtained by setting second derivatives equal over the first pair and last pair of data points. Any other of the parameters tabulated in Cokelet's tables (or functions of them) can be interpolated in the same way. Alternative end conditions were used for the limit $H/H_B = 0$ when the behaviour of the required parameter was known from Stokes wave theory.

The accuracy of this method was tested by computing with Padé approximants the parameters $c_*^2, \bar{\eta}_*$ and a_* , for values of d_* and ϵ_* generated by interpolation from Cokelet's data with specified d/L_0 and H/L_0 . The errors in the final d/L_0 and H/L_0 calculated by Eqs. (1) and (2) were always much less than 1%, except in the shallow water conditions $d/L_0 < 0.008$ where some of the integral wave properties converge at best to only one or two significant figures.

Other wave properties which can be computed directly from Cokelet's data by the above method of interpolation (i.e., without the use of Padé approximants) include the wavelength:

$$L/L_0 = c_*^2 \quad (3)$$

the elevation of the crest above mean water level:

$$\frac{\eta_{\text{crest}}}{H} = \frac{K_*}{4a_*} = \frac{2\bar{\eta}_*}{4a_*} \quad (4)$$

the dimensionless particle velocity at the crest $q_{\text{crest}*}$ on a frame of reference moving at the wave celerity:

$$q_{\text{crest}*} = -2a_* + \sqrt{4a_*^2 - c_*^4(\epsilon_*^2 - 1)} \quad (5)$$

and the horizontal particle velocity at the crest on a stationary frame of reference:

$$\frac{u_{\text{crest}}}{H/T} = \frac{\pi(c_* - q_{\text{crest}*})}{c_* a_*} \quad (6)$$

besides the energies and energy flux and other terms presented in the tables.

Unfortunately, no information is available by this means on the profile of the free surface or on particle velocities other than at the crest and the trough. To obtain the free surface profile or general particle velocities and accelerations, it is necessary to solve, (Cokelet, 1977), the series expansions for the coefficients of the Fourier series of the complex potential, from independent parameters d_* and ϵ_* . Since the complex spatial co-ordinate Z_* is expressed in the final solution as a function of the complex potential W_* , rather than vice-versa, it is ultimately necessary to interpolate for Z_* , for instance by complex Newton-Raphson iterations, to obtain conditions at a given location within the wave. A greater handicap, however, is the failure of the series expressions for the high order Fourier coefficients to converge adequately for strongly non-linear cases. Cokelet discussed this problem and showed how the degree of convergence could be determined by comparing values of parameters derived from the surface profile and alternatively directly from a series by Padé approximants.

To define the conditions for which the velocity potential Fourier series would converge we computed a number of cases and compared results for crest elevation and crest particle velocity derived by the two methods. The maximum wave heights for which errors in crest elevation and particle velocity derived from the Fourier series did not exceed 2% are shown as the broken line in Fig. 1. For the most shallow water conditions tested, this occurs at about one half the limiting wave height. In deeper water, with $d/L_0 > 0.1$, satisfactory results were obtained up to within 1% of the limiting height. These computations were carried out in double precision (approximately 28 significant places) on a CDC 7600 to a maximum order of 120. Convergence limits were almost exactly the same for both elevation and particle velocity at the crest. In view of the series formulation of the velocity potential, it might be expected that particle velocity would fail to converge before the profile itself, since the differentiation involved causes the truncated higher spatial frequency components to have a greater relative contribution to the total. This is not the case, however, owing to the inverse formulation of the Stokes series. It is, nevertheless, reasonable to expect that the region of convergence for particle accelerations will be rather more restricted than these, although no numerical comparisons have been carried out.

We conclude that the extended Stokes theory can be used in the same framework as engineering wave theories by means of cubic spline interpolation for the independent parameters d_* and ϵ_* . The velocity potential and its derivatives do not converge in all cases, but much useful information can be computed by interpolation from Cokelet's tables. Comparison of some results with those of other methods follows in Section 4.

3. FURTHER RECENT METHODS

Properties of steep waves can also be computed accurately by the stream function wave theory (Chaplin, 1980). While this method is more cumbersome than Cokelet's, and does not have in-built checks for convergence, it has the advantage of being formulated in conventional terms, and seems to converge better for steep waves in shallow water. The re-formulation necessary to achieve these results was carried out in an attempt to eliminate errors apparent in data for the steepest waves presented in stream function tables by Dean (1974). Some further comparisons using modified stream function results are presented in the next Section.

The analysis of steep waves by either extended Stokes theory or stream function theory demands much costly computer storage and time. Consequently, simple yet accurate approximations for the crest of the almost-highest wave and for the wave of limiting height in deep water by Longuet-Higgins (1979a and 1973) have great appeal. Results of both methods are presented in the next Section.

The almost-highest wave (AHW) approximation (Longuet-Higgins, 1979a) is expressed in terms of a velocity scale which must be derived by other means from given wave conditions. In the present work this has been achieved by means of interpolation by cubic splines, as described above, from Cokelet's (1977) data as follows. The required unit of velocity is $q/\sqrt{2}$, where q is the crest particle velocity in a reference frame moving with the wave. In terms of Cokelet's parameters:

$$\frac{q}{\sqrt{2}} = \frac{q_{\text{crest}*} c_* C_0}{\sqrt{2}} \quad (7)$$

where C_0 is the small amplitude deep water celerity. The associated unit of length is:

$$\frac{q_{\text{crest}*}^2 c_*^2 C_0^2}{2g}$$

and in order to fix the origin it is necessary also to compute in advance the elevation of the crest.

As shown in Eqs. (4) and (5) these parameters can be related to those presented in Cokelet's tables, and thus obtained for any specified wave conditions by interpolation. The computing effort necessary for the interpolation, followed by application of the AHW approximation is a small fraction of 1% of that required for a full solution by series methods. Furthermore, it applies to the crest where conditions for many purposes are likely to be most severe, and where conventional wave theories are at their weakest owing to poor convergence associated with the original Stokes type series formulation. The almost-highest wave approximation is related to more accurate solutions derived by Longuet-Higgins and Fox (1977, 1978). In the second of these papers the solution for the crest is matched to the rest of the wave for deep water

conditions. Particle trajectories near the crest derived from the AHW approximation, the hexagon transformation and other methods are given in Longuet-Higgins (1979b).

4. COMPARISON OF NUMERICAL RESULTS

In comparing results from different wave theories, particular attention is paid to particle velocities in the region close to the crest for the reasons stated above. Also, we concentrate on steep waves since the earlier stream function tables (Dean, 1974) are accurate to within 5% for almost all cases up to 90% of limiting wave height (Chaplin, 1980). While integral parameters can be derived from any of the theories mentioned, they are now more easily and accurately computed from Cokelet's tables.

Fig. 2 shows the percentage errors in crest elevation above mean water level η as a proportion of wave height H for waves of limiting height. The results for cnoidal theory (for which U denotes the Ursell number L^2H/d^3) were computed in accordance with Keulegan and Patterson (1940) and those for Stokes 5th order theory with Skjelbreia and Hendrickson (1960). Clearly the stream function tables (in which nominally breaking waves are denoted as case D) are the most accurate, although they refer to slightly different wave heights.

Similarly, Fig. 3 shows crest particle velocities in a stationary reference frame u_{crest} as a proportion of the celerity for waves of limiting height. Again the stream function tables are the most accurate, giving results closest to unity for most water depths. In both comparisons, cnoidal theory is seriously in error, either at low Ursell numbers for crest elevations, or at high Ursell numbers for crest particle velocities. Since particle velocities vary only gradually through the water depth in shallow water conditions, it is reasonable to expect that the errors in cnoidal theory demonstrated in Fig. 3 are not confined to the region near the surface. Conversely in deep water conditions, the most significant errors in Stokes 5th order theory occur only close to the surface and predominantly at the crest. A comparison of horizontal particle velocities and vertical particle accelerations on a vertical line through the crest of the wave of limiting height in deep water is given in Fig. 4, in which y is measured upwards from mean water level. Since the velocity potential series in the extended Stokes theory does not converge for this case, we adopt the hexagon transformation (Longuet-Higgins, 1973) as an easily computed and accurate alternative. It gives inevitably the crest particle velocity u equal to the celerity and the upward vertical acceleration dv/dt at the crest level equal to $-1/2 g$. Stokes 5th order theory and the stream function tables seriously underestimate both, but their errors diminish rapidly away from the surface.

The surface profile for the wave of limiting height in deep water is plotted without distortion in Fig. 5 for comparison with Stokes 5th order and stream function tables (case 10D) results. Although the latter is only a third order solution, this refers to the number of terms in the stream function series rather than in the Fourier series for the surface profile as in Stokes 5th order theory. The surface

FIG. 5. THE WAVE OF MAXIMUM HEIGHT IN DEEP WATER. COMPARISON OF PROFILES WITH THE HEXAGON TRANSFORMATION (Longuet-Higgins)

profile in the stream function theory is derived from the stream function series, has therefore higher frequency terms and approaches more closely the discontinuity of surface slope at the crest.

The surface particle velocities predicted by the same three methods for the wave of limiting height in deep water are shown in Fig. 6 over the half wave length ahead of the crest. The errors in u at the crest in Stokes 5th order and stream function theories are again not representative of errors elsewhere.

It must be noted that the above comparison of results for limiting deep water waves serves only to demonstrate the performance of Stokes and stream function theories generally in deeper water. For this particular case the hexagon transformation is both more accurate and more convenient to compute than either of them.

If a full solution is needed for very steep waves in transitional water depth, the modified stream function theory (Chaplin, 1980) can provide converged results for cases which are beyond the limits we have found in the extended Stokes theory, and which are shown in Fig. 1. As noted above, the elevation and particle velocity at the crest can be found for all cases from Cokelet's tables by interpolation, and in Fig. 7 are plotted these results for very steep waves for two water depths. The agreement with results taken from full modified stream function solutions is within the accuracy of the interpolation procedure and of Cokelet's tables. Since conditions at the crest are more sensitive than those elsewhere to truncation errors this is taken as some confirmation of the overall accuracy of the full stream function solutions for the profiles and particle velocities of these steep waves.

The flow in a small region near the crest can also be computed, as described in the previous section, by the AHW approximation. For the two water depths referred to in Fig. 7, Figs. 8 and 9, in which x is measured horizontally forwards from the crest, compare elevations and velocity components of surface particles near the crests of steep waves computed by this method and by the modified stream function theory. The extent of agreement between the two methods naturally increases with increasing wave height as the upper part of the surface profile resembles more and more closely the Stokes corner flow which is the asymptote of the AHW approximation away from the crest. Also the two methods agree, not surprisingly, over a greater proportion of the wavelength in the deeper water case because the crest itself is relatively longer. Discrepancies at $x = 0$ are associated with differences between stream function results and those interpolated from Cokelet's tables to provide the scale and the origin of the AHW approximation. Away from the crest the latter tends towards a uniform surface slope and thus increasingly underestimates the actual surface profile elevation. Nevertheless, surface particle horizontal velocity components are accurately predicted by the approximation as far out as $x/L = 0.1$ for the steepest wave with $d/L_0 = 0.2$.

Sub-surface particle velocities are compared in Fig. 10 along a vertical line through the crest. Reasonable agreement is found over a region of similar dimensions as for surface elevations, namely about $L/80$ and $L/20$

for $d/L_0 = 0.01$ and 0.2 , respectively. For deep water conditions the approximation may be extended beyond this region by the method of Longuet-Higgins and Fox (1978).

5. CONCLUSIONS

The extended Stokes theory (Cokelet, 1977) may be used in an engineering context in the same framework as conventional wave theories. From the data which Cokelet tabulated suitable input parameters can be interpolated from known water depth, wave height and period. Integral wave parameters can then be computed for any conditions specified in this way, but the velocity potential series, from which surface profiles and particle velocities and accelerations are derived, does not converge adequately in the region above the broken line in Fig. 1. Full solutions in this region have, however, been obtained for wave heights up to within 1% of limiting wave height by the modified stream function theory (Chaplin, 1980).

Surface elevations and particle velocities near the crest, computed by these methods differ significantly from those calculated by conventional wave theories. However, accurate partial solutions can also be computed much more rapidly by approximations for limiting and near-limiting wave heights (Longuet-Higgins, 1973, 1979a). The almost highest wave approximation (Longuet-Higgins, 1979a) can be applied to specified conditions on the basis of data derived by interpolation from Cokelet's tables. A method for interpolation is described above, and it has been found to yield accurate results with very little computational effort. A subsequent paper will present results for shoaling and refraction computed in this way from Cokelet's tables.

CHAPTER 2

ACCURATE NUMERICAL SOLUTIONS FOR NONLINEAR WAVES

by

J.D. Fenton and M.M. Rienecker
School of Mathematics
University of New South Wales
Kensington, N.S.W., Australia 2033

This paper describes numerical methods for the accurate solution of the nonlinear equations for water waves propagating on irrotational flow over a horizontal bed. Fourier approximation is used throughout. Firstly, the problem of waves propagating without change is considered, giving a set of nonlinear equations which may be conveniently solved by Newton's method. It is emphasized that the usual specification of water depth, wave height and wave period is not enough to solve the problem - an assumption as to wave speed or mean current or mass flux must be included. Comparing results with previous theoretical and experimental results, good agreement was obtained. In the second part unsteady wave motion is examined, and a numerical method proposed for studying the evolution of unsteady disturbances. This is applied to the case of a solitary wave being reflected by a vertical wall. Close agreement with experimental results is obtained. In addition, design criteria for force and moment on the wall are suggested.

1. INTRODUCTION

In water wave problems where viscous forces may be assumed to be negligible and the fluid initially irrotational, fluid motion is governed by Laplace's equation for a velocity potential, and for two-dimensional flow, a stream function as well. This equation is linear, but for water wave problems must be solved subject to nonlinear boundary conditions on the free surface, which is also an unknown of the problem, in addition to the relatively simple linear boundary conditions on solid boundaries. It is the nonlinear dynamic and kinematic conditions which make solution difficult.

Approximate solutions of the equations have generally been found either by assuming that the waves are of small amplitude and nonlinearities ignored, or by assuming that the water depth is small relative to the wavelength, giving the long wave equations, or by a combination of both. These approximations can describe most phenomena associated with the propagation of waves to a first level of approximation. However, in some engineering and experimental applications it is necessary to have more accurate solutions of the complete set of nonlinear equations; for example, the design of maritime structures necessitates an accurate knowledge of the fluid velocity and pressure fields acting on them in the presence of waves.

This paper describes the development of numerical methods for the solution of the exact nonlinear equations for waves on fluid in which the flow is irrotational. In §2 the problem of waves propagating without change over water of constant depth is considered. The two best known analytical approximations to this problem are (i) Stokes' solution, in which series are essentially obtained in terms of powers of wave steepness (height/wavelength) and (ii) the cnoidal solution, using series in terms of shallowness (water depth/wavelength) which may be recast to include wave height. Each of these approaches breaks down for opposite extremes of depth - Stokes wave solutions are not valid for shallow water while cnoidal wave solutions are not valid for deep water. For high waves, neither is particularly accurate without the inclusion of many terms and the use of series enhancement techniques (see Cokelet (1977) for Stokes, and Fenton (1979) for cnoidal wave solutions). A method which has the potential for describing even very high waves in water of almost all depths is that which is known as the "stream function" method (Dean, 1965), but which does not depend on the stream function as such; rather it is a method of Fourier approximation of the stream function, and it is the Fourier approach wherein its power lies. The original technique has been modified by other workers, however, it still seems rather more complicated to use than need be the case. An alternative Fourier approximation method is presented in §2.

The rather more general problem of the complete unsteady equations for arbitrary disturbances is tackled in §3. This problem has received little attention except for the marker and cell method of Chan & Street (1970), the nonlinear integral equation of Byatt-Smith (1971) and the integro-differential equations of Longuet-Higgins and Cokelet (1976) for waves on infinitely deep water. Here, a new method to follow the time evolution of an initial disturbance is proposed wherein all dependent variables are accurately approximated by finite Fourier series. The only approximation is the truncation of the series. This method is applicable to water of any (variable) depth, however all motions and depth variation must be horizontally periodic. The method is applied to the problem of a long, but finite, wave approximating a solitary wave moving over a horizontal bottom and being reflected by a vertical wall. In previous approaches to this problem (for example Chan & Street (1970)) values for the force and moment on the wall due to the wave impact have not been given even though these are two very important engineering quantities. The maximum values for the force and moment are obtained from the impact of a solitary wave, hence any results for these quantities should provide the design criteria for a vertical wall subject to wave impact. In §3 results are given for these and also for the wave run-up which is found to agree closely with experimental results.

2. STEADY WAVES

2.1 Formulation of equations

The problem considered is that of two-dimensional periodic waves propagating without change of form over a layer of fluid on a horizontal

bed. With horizontal co-ordinate x and vertical co-ordinate y , the origin is on the bed, and moves in the x direction with the same speed as the waves so that all motion is steady in this frame of reference. If the fluid is incompressible a stream function $\psi(x,y)$ exists such that the velocity components (u,v) are given by

$$u = \frac{\partial \psi}{\partial y} \text{ and } v = - \frac{\partial \psi}{\partial x},$$

and if the motion is irrotational, ψ satisfies Laplace's equation throughout the fluid:

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} = 0. \quad (2.1)$$

The boundary conditions to be satisfied are

$$\psi(x,0) = 0 \quad (2.2)$$

$$\psi(x,\eta(x)) = -Q \quad (2.3)$$

where $y = \eta(x)$ on the free surface and Q is a positive constant denoting the total volume rate of flow underneath the steady wave per unit length in a direction normal to the (x,y) plane. With this sign convention the apparent flow under the stationary wave is from right to left, in the negative x -direction. On the free surface, the pressure is constant so that Bernoulli's equation gives

$$\frac{1}{2} \left[\left(\frac{\partial \psi}{\partial x} \right)^2 + \left(\frac{\partial \psi}{\partial y} \right)^2 \right] + \eta = R, \quad (2.4)$$

where R is the Bernoulli constant. In these equations all variables have been non-dimensionalised with respect to the average depth $\bar{\eta}$ and gravitational acceleration g : that is, x is used for $x/\bar{\eta}$, y for $y/\bar{\eta}$, η for $\eta/\bar{\eta}$, ψ for $\psi/(g\bar{\eta}^3)^{1/2}$, Q for $Q/(g\bar{\eta}^3)^{1/2}$ and R for $R/g\bar{\eta}$. Other dimensionless variables to be introduced are - wave speed: c for $c/(g\bar{\eta})^{1/2}$, wavenumber: k for $k\bar{\eta} = 2\pi\bar{\eta}/\lambda$ where λ is the wavelength, wave period: τ for $\tau/(g\bar{\eta})^{1/2}$, and an arbitrary reference level: D for $D/\bar{\eta}$.

If the symmetry of the wave about the crest is exploited, a series for $\psi(x,y)$ can be written

$$\psi(x,y) = B_0 y + \sum_{j=1}^N B_j \frac{\sinh jky}{\cosh jkD} \cos jkx, \quad (2.5)$$

satisfying (2.1) and (2.2). The B_0, \dots, B_N are constant for a particular wave. The assumption that N is finite, for computational purposes, is the only approximation made in this method of solution. This assumed form is similar to Dean's (1965) series. The two differences are:

(i) the leading coefficient B_0 is not necessarily the wave speed, which will be discussed below, and (ii) the inclusion of $\cosh jkD$ in the denominator so that waves in deep water can be studied. Without this factor the B_j need to become exponentially small for convergence since the $\sinh jky$ go exponentially large. In subsequent iterative solution methods for the equations this cannot be guaranteed and the method may be rather unstable. However, $\sinh jky / \cosh jkD \sim \exp(|j|k(y-D))$ near the surface, so if D is greater than the crest height this ratio is always less than 1 and no problems of exponential magnification arise.

From here, the present method and the "stream function" method have very few similarities. In the latter, equations are obtained by requiring the mean-square error in one free surface boundary condition to be a minimum. Here (2.5) is used to satisfy both nonlinear boundary conditions (2.3) and (2.4) at a finite number of equally-spaced points, giving a number of nonlinear equations which can be directly solved using standard techniques.

To solve the problem numerically the equations produced by the substitution of (2.5) into (2.3) and (2.4), that is

$$B_0 \eta + \sum_{j=1}^N B_j \frac{\sinh jk\eta}{\cosh jkD} \cos jkx = -Q, \quad (2.6)$$

and

$$\frac{1}{2} \{ B_0 + k \sum_{j=1}^N j B_j \frac{\cosh jk\eta}{\cosh jkD} \cos jkx \}^2 + \frac{1}{2} \{ k \sum_{j=1}^N j B_j \frac{\sinh jk\eta}{\cosh jkD} \sin jkx \}^2 + \eta = R, \quad (2.7)$$

which are valid for all x , are to be satisfied at $2N$ points equally spaced over one wavelength, though by symmetry only $N+1$ points, from the wave crest to the trough, need to be considered. In the development of this method, tests were run where the computational points were clustered near the crest and sparsely spaced in the long flat trough, however it was found that there was very little gain in accuracy, and it is recommended that equi-spaced points be used in applications.

Let $\eta_m = \eta(x_m)$, where $x_m = m\lambda/2N$, $m = 0, 1, \dots, N$, and $kx_m = m\pi/N$, so that (2.6) and (2.7) become

$$B_0 \eta_m + \sum_{j=1}^N B_j \frac{\sinh jk\eta_m}{\cosh jkD} \cos(jm\pi/N) + Q = 0, \quad (2.8)$$

$$\frac{1}{2} u_m^2 + \frac{1}{2} v_m^2 + \eta_m - R = 0, \quad (2.9)$$

also for $m = 0, 1, \dots, N$, where

$$u_m = u(x_m, \eta_m) = B_0 + k \sum_{j=1}^N j B_j \frac{\cosh jk\eta_m}{\cosh jkD} \cos(jm\pi/N)$$

$$\text{and } v_m = v(x_m, \eta_m) = k \sum_{j=1}^N j B_j \frac{\sinh j k \eta_m}{\cosh j k D} \sin(j m \pi / N).$$

These $2N + 2$ nonlinear equations involve the $2N + 5$ unknowns η_m ($m = 0, \dots, N$), B_j ($j = 0, \dots, N$), k , Q and R . To obtain a solution 3 more equations must be specified. Since variables have been non-dimensionalised with respect to $\bar{\eta}$, the mean depth is 1. The simple trapezoidal rule can be used to give one more equation:

$$\frac{1}{2N} [\eta_0 + \eta_N + 2 \sum_{j=1}^{N-1} \eta_j] - 1 = 0, \quad (2.10)$$

where this can be shown to have an error proportional to the $(N+1)$ th term of a Fourier series for η . This is the same level of approximation as the Fourier expansion for ψ which was truncated after the N th term.

Now, numerical values for any two of the variables can be specified and the equations solved. However, for practical problems it is usually values of H (for $H/\bar{\eta}$), the wave height and τ (for $\tau(g/\bar{\eta})^{1/2}$) the wave period which define the problem. Two additional equations which specify these physical parameters are (i) the definition of H as being the elevation difference between crest and trough:

$$\eta_0 - \eta_N - H = 0, \quad (2.11)$$

where η_0 is the surface elevation at the crest and η_N that at the trough, and (ii) the statement that wave period is equal to the wave length divided by the wave speed, or

$$kc\tau - 2\pi = 0, \quad (2.12)$$

where the introduction of the wave speed c has added one more variable. It is possible to solve the problem in a frame relative to which motion is steady, without having to define the wave speed, by specifying the wavelength $\lambda (= 2\pi/k)$ instead of wave period. However, in most situations the waves are viewed from a different frame of reference in which they are not stationary and the wave period in this frame is measured. Hence an assumption as to the speed at which the waves travel must be included. The waves could travel at any speed, in a given frame, without change of form, so that the specification of the usual three quantities, water depth, wave height and period is not sufficient to define the problem. Either the wave speed must be specified or a value given (measured or assumed) for a quantity which determines the wave speed; for example, the mean current C_E (the mean Eulerian velocity through-out the fluid), or the mean Stokes drift C_S (the mass transport velocity) may be specified. In the steady frame, the mean velocity on any level over one wavelength is B_0 , so that in a frame through which the

waves pass at speed c , the time mean velocity at all points always within the fluid $C_E = c + B_O$ and so the appropriate equation to use if C_E is specified is

$$c + B_O - C_E = 0. \quad (2.13a)$$

Some previous works have allowed for the specification of C_E , for example Dean (1965), however many papers concerned with the application of wave theory have implicitly assumed $C_E = 0$, for example Skjelbreia & Hendrickson (1961) and Fenton (1979). In many situations however, the mean current is not as fundamental a quantity in determining the wave speed as is the rate of mass transport: for example, wave tank experiments with a closed end must have no net flux over any section. In the steady wave, a volume rate per unit span of Q is passing under the surface, but from right to left with the convention chosen above, so that the mean velocity of all the fluid particles is $-Q/\bar{\eta} = -Q$, because $\bar{\eta}$ is unity in the present non-dimensionalisation. Thus, if C_S is the mass-transport velocity in the stationary frame $C_S = c - Q$, giving the appropriate equation to use if C_S is specified:

$$c - Q - C_S = 0. \quad (2.13b)$$

2.2. Solution of nonlinear equations by Newton's method

The system of nonlinear equations (2.8 --13) may be written

$$f_i(\eta_j, B_j (j = 0, \dots, N), c, k, Q, R) = 0, \quad (2.14)$$

$i = 1, \dots, 2N + 6$, where for $i = 1$ to $(N+1)$ the f_i represent (2.8), for $i = (N+2)$ to $(2N+2)$ the f_i represent (2.9), f_{2N+3} is (2.10), f_{2N+4} is (2.11), f_{2N+5} is (2.12) and f_{2N+6} is either (2.13a) or (2.13b). This set of equations can be solved by Newton's method which iterates with quadratic convergence to a solution from an initial approximation. If the system of equations (2.14) is represented by

$$f_i(Z_\ell; \ell = 1, \dots, 2N+6) = 0, \quad i = 1, \dots, 2N+6 \quad (2.15)$$

where the Z_ℓ are the arguments of f_i as in (2.14), and if the approximate solution after the n th iteration is Z_ℓ^n , $\ell = 1, \dots, (2N+6)$ the error in each equation is $f_i(Z_\ell^n; \ell = 1, \dots, 2N+6) = f_i^n$. From a multivariable Taylor series expansion the error at the next iteration is

$$f_i^{n+1} = f_i^n + \sum_{\ell=1}^{2N+6} \left(\frac{\partial f_i}{\partial Z_\ell} \right)^n (Z_\ell^{n+1} - Z_\ell^n) + \dots, \quad i = 1, \dots, 2N+6,$$

where
$$\left(\frac{\partial f_i}{\partial Z_\ell}\right)^n = \frac{\partial f_i}{\partial Z_\ell} (Z_j^n, j = 1, \dots, 2N+6).$$

However, the desired result is $f_i^{n+1} = 0$ for each $i = 1, \dots, 2N+6$, and the solution Z_ℓ^{n+1} , $\ell = 1, \dots, 2N+6$ which approximately yields this result is found by truncating the series after the terms shown and solving the resulting system of linear simultaneous equations written as a matrix equation:

$$\left[\left(\frac{\partial f_i}{\partial Z_\ell} \right)^n \right] [Z_\ell^{n+1} - Z_\ell^n] = - [f_i^n].$$

The derivatives $\frac{\partial f_i}{\partial Z_\ell}$ have convenient analytical expressions obtained by differentiation of the equations (2.8 -.13). For example, from (2.8), $\partial f_1 / \partial B_0 = \eta_m$, and so on. Expressions for all these derivatives are simply obtained and are given in Rienecker and Fenton (1980).

The initial approximation to the solution is assumed to be a linear sinusoidal wave, that is, $\eta_m = 1 + \frac{1}{2} H \cos m\pi/N$, $m = 0, \dots, N$; $B_0 = -c$; $B_1 = -\frac{1}{2} H/c/k$; $B_j = 0$, $j = 2, \dots, N$; $R = 1 + \frac{1}{2} c^2$; $Q = c$, where c and k are found recursively from

$$k = 2\pi/\tau c$$

$$c = (\tanh k/k)^{1/2},$$

with an initial guess $c = 1$ corresponding to a long wave approximation.

2.3. Results

The method was run on a CDC Cyber 171 computer; convergence of the iteration was extremely rapid so that 5 iterations were usually sufficient to obtain convergence to 12 decimal places. For very high waves it was found that the linear approximation was not a sufficiently accurate initial estimate of the solution and the method did not converge. In this situation it was necessary to extrapolate the initial estimate from converged solutions for lower waves.

With this solution for the elevation of points on the free surface η_m , for the Fourier coefficients B_j , and for c, k, Q and R , it is possible to obtain results for other quantities which may be of interest, in particular the fluid velocities and pressure at any point. All physical variables considered so far have been in a co-ordinate system which moves with the wave so that all motion is steady in that frame. The steady velocities at any point are from differentiation of (2.5):

$$u(x,y) = B_0 + k \sum_{j=1}^N u_j(x,y), \text{ and}$$

$$v(x,y) = k \sum_{j=1}^N v_j(x,y),$$

$$\text{where } u_j(x,y) = jB_j \frac{\cosh jky}{\cosh jkD} \cos jkx, \text{ and} \quad (2.16a)$$

$$v_j(x,y) = jB_j \frac{\sinh jky}{\cosh jkD} \sin jkx. \quad (2.16b)$$

The pressure at any point, $p(x,y)$, representing $p(x,y)/\rho g\bar{\eta}$ where ρ is fluid density, is given by

$$p(x,y) = R - y - \frac{1}{2}[u^2(x,y) + v^2(x,y)].$$

Now consider a stationary co-ordinate system (X,Y) on the bed in which motion is unsteady as the waves move from left to right with speed c . If the wave crest is at $X = X_0$ when $t = 0$, the unsteady fluid velocities

$U(X,Y,t)$ and $V(X,Y,t)$ become

$$U(X,Y,t) = c + B_0 + k \sum_{j=1}^N u_j(X-X_0-ct,Y)$$

$$V(X,Y,t) = k \sum_{j=1}^N v_j(X-X_0-ct,Y),$$

where the (u_j, v_j) are defined in (2.16a,b). Unsteady pressure is given by

$$p(X,Y,t) = R - Y - \frac{1}{2}[u^2(X-X_0-ct,Y) + v^2(X-X_0-ct,Y)].$$

In addition to the above local quantities, gross integral quantities of the wave train such as potential energy may be calculated from the converged solution. Expressions for these are given in Rienecker and Fenton (1980).

2.4. Accuracy

Cokelet (1977) presented a number of accurate results for integral quantities of the wave train. The wave speed c , for the case $C_E = 0$, was used to test the accuracy of the present method. For each of four different values of kQ/c , which is a measure of the ratio of wavelength to depth of fluid, the variation of c^2 with H is shown on Fig. 1. The results indicate close agreement with Cokelet. Only for the very highest and longest wave with relatively coarse numerical approximation (small N) were significant errors obtained. In these cases it was not the height of the wave which caused the lack of accuracy as the method makes no approximation as to height. Instead, for higher waves the crest becomes increasingly sharp and the Fourier approximation becomes less accurate. Also, for longer waves where the wave is more like an isolated hump on otherwise undisturbed fluid, larger values of N are required to describe the wave accurately.

Figure 1. Comparison between the present method and the results of Cokelet (1977) for wave speed squared, c^2 , as a function of wave height H . Each curve is drawn for a constant value of kQ/c taken from Cokelet's tables A2, A4, A6, A8, giving the almost constant values of wavelength shown.

Figure 2. Horizontal fluid velocity under the wave crest, u_c , plotted against height y above the bottom: comparison between present method (—) and the experimental results of Le Méhauté et al (1968). Dimensionless wave heights and periods are shown.

To compare the predictions of the Fourier method for fluid velocities with experiment, the results of Le Méhauté, Divoky and Lin (1968) were used. As the experiments were performed in a closed wave-tank, the condition (2.13b) was used to determine the wave speed $c = Q$. This condition does not seem to have been used in previous comparisons with these experiments, where the incorrect assumption $C_E = 0$ has been used. Also, it should be pointed out that the experimental velocities measured were particle velocities averaged over a finite time and not the instantaneous velocities given by all wave theories. It can be shown that these experimental velocities should be less than those predicted. In Fig. 2, two sets of experimental results are shown for the two longest waves generated, with a wavelength of about 30 times the depth in each case. These longest waves should provide a severe test for the Fourier approximation method, as described above. It can be seen that agreement between theory and experiment was quite close.

3. UNSTEADY WAVES

3.1. Equations

A solution is sought to the equations governing the evolution of waves travelling over a layer of fluid on a horizontal bed. If the fluid is irrotational a velocity potential $\phi(x,y,t)$ exists such that velocity components $u(x,y,t)$ and $v(x,y,t)$ parallel to the x and y co-ordinates respectively are given by

$$u = \partial\phi/\partial x \text{ and } v = \partial\phi/\partial y.$$

If the motion is incompressible, ϕ satisfies Laplace's equation throughout the fluid:

$$\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} = 0. \quad (3.1)$$

Since the velocity normal to the bed is zero,

$$\frac{\partial\phi}{\partial y}(x,0,t) = 0, \quad (3.2)$$

where the co-ordinate origin has been placed on the horizontal bed. The case where the bed is not horizontal can be treated by the methods of this section, and is described in Fenton & Rienecker (Manuscript in preparation).

On the free surface $y = \eta(x,t)$, the kinematic and dynamic boundary conditions must be satisfied:

$$\frac{\partial\eta}{\partial t} + \frac{\partial\phi}{\partial x} \frac{\partial\eta}{\partial x} - \frac{\partial\phi}{\partial y} = 0 \quad (3.3)$$

$$\frac{\partial\phi}{\partial t} + \frac{1}{2} \left[\left(\frac{\partial\phi}{\partial x} \right)^2 + \left(\frac{\partial\phi}{\partial y} \right)^2 \right] + \eta = C, \quad (3.4)$$

where C is a constant. In these equations all variables have been non-

dimensionalized with respect to the mean depth $\bar{\eta}$, and gravitational acceleration g . If a simple method can be found for solving the linear equations (3.1) and (3.2), and if a convenient and accurate method can be found for approximating all the space derivatives in (3.3) and (3.4), then subject to known initial conditions, (3.3) and (3.4) can be used to advance the solution in time, so that the evolution of disturbances can be followed.

3.2. Numerical approximation and solution of equations

The Fourier methods of §2 are capable of great accuracy, and similar approximations will be used here for $\phi(x,y,t)$ and also for $\eta(x,t)$ so that term by term differentiation can be used for derivatives of each. It is assumed that the dependent variables ϕ and η can be represented by Fourier series in x throughout the region of interest, implying that all motion is periodic in x with some finite period L , referred to as the wavelength.

An expansion for $\phi(x,y,t)$ may be written

$$\phi(x,y,t) = \alpha x + \frac{1}{N} \sum_{j=-\frac{N}{2}+1}^{N/2} A_j(t) \frac{\cosh jky}{\cosh jkD} \exp(-ijkx) \quad (3.5)$$

for some finite value of N , where $k = 2\pi/L$. In general, ϕ is not periodic but will change by a finite amount over the region of interest. The leading term αx has been introduced to allow for the discontinuity in ϕ over one wavelength where $\alpha = (\phi(L,y,t) - \phi(0,y,t))/L$. Now, the finite complex Fourier series shown has to approximate the function $\phi(x,y,t) - \alpha x$ which is continuous. In this case the Fourier series converges absolutely and can be differentiated term by term. The Fourier coefficients $A_j(t)$ are complex, while the $\cosh jkD$ in the denominator (D is an arbitrary depth scale, conveniently chosen to be the mean) has been introduced so that the method may also be used for deep water, as for the steady wave expansion in §2.

A finite complex Fourier series can also be written for $\eta(x,t)$:

$$\eta(x,t) = \frac{1}{N} \sum_{j=-\frac{N}{2}+1}^{N/2} Y_j(t) \exp(-ijkx). \quad (3.6)$$

If η is known at the N discrete points $x_m = mL/N, m = 0 \dots N-1$, such that

$$\eta_m = \eta(x_m, t) = \frac{1}{N} \sum_{j=-\frac{N}{2}+1}^{N/2} Y_j(t) \exp(-i2\pi mj/N), \quad (3.7)$$

then it can be shown that the Y_j can be simply obtained from the η_m :

$$Y_j = \sum_{m=0}^{N-1} \eta_m \exp(i2\pi mj/N), \quad j = -\frac{N}{2} + 1, \dots, \frac{N}{2}.$$

In this form the Y_j are said to be obtained from the η_m by a Discrete Fourier Transform,

$$Y_j = \mathcal{D}[\eta_m],$$

and (3.7) is termed an Inverse Discrete Fourier Transform,

$$\eta_m = \mathcal{D}^{-1}[Y_j].$$

Similarly,
$$\phi(x_m, y, t) = \alpha x_m + \mathcal{D}^{-1}[A_j(t) \frac{\cosh jky}{\cosh jkD}]$$

and
$$A_j(t) \frac{\cosh jky}{\cosh jkD} = \mathcal{D}[\phi(x_m, y, t) - \alpha x_m].$$

Now, the series (3.5) and (3.6) can be differentiated term by term, and substituting $x = x_m$ series (3.8) and (3.9) are obtained, where a subscript x, y or t denotes partial differentiation with respect to that variable. These expressions should be very accurate, provided the coefficients A_j and Y_j decay sufficiently quickly as $|j| \rightarrow N/2$, where the series are truncated.

$$\phi_x(x_m, y, t) = \alpha - ik\mathcal{D}^{-1}[jA_j(t) \frac{\cosh jky}{\cosh jkD}] \tag{3.8}$$

$$\phi_y(x_m, y, t) = k\mathcal{D}^{-1}[jA_j(t) \frac{\sinh jky}{\cosh jkD}]. \tag{3.9}$$

Further differentiation of (3.5) shows that Laplace's equation (3.1) is identically satisfied by (3.5), as is the bottom boundary condition (3.2). Also,

$$\eta_x(x_m, t) = -ik\mathcal{D}^{-1}[jY_j(t)] = -ik\mathcal{D}^{-1}[j\mathcal{D}[\eta_n]].$$

The remaining equations, the nonlinear free surface conditions (3.3-4) become:

$$\begin{aligned} \frac{\partial \phi}{\partial t}(x_m, \eta_m, t) = C - \eta_m - \frac{1}{2}\{\alpha - ik\mathcal{D}^{-1}[jA_j(t) \frac{\cosh jk\eta_m}{\cosh jkD}]\}^2 \\ - \frac{1}{2}k^2\{\mathcal{D}^{-1}[jA_j(t) \frac{\sinh jk\eta_m}{\cosh jkD}]\}^2, \text{ and} \end{aligned} \tag{3.10}$$

$$\begin{aligned} \frac{\partial \eta}{\partial t}(x_m, \eta_m, t) = k\mathcal{D}^{-1}[jA_j(t) \frac{\sinh jk\eta_m}{\cosh jkD}] \\ + ik[\alpha - ik\mathcal{D}^{-1}[jA_j(t) \frac{\cosh jk\eta_m}{\cosh jkD}]]\mathcal{D}^{-1}[j\mathcal{D}[\eta_n]], \end{aligned} \tag{3.11}$$

each for $m = 0, \dots, N-1$. Clearly, if F and G represent the right sides

of these equations, then (3.10) and (3.11) may be written for given k , α , C and D :

$$\frac{\partial \phi}{\partial t}(x_m, \eta_m, t) = F\{A_j(t), j = -\frac{N}{2} + 1, \dots, \frac{N}{2}; \eta(x_n, t), n=0, \dots, N-1\},$$

$$\text{and } \frac{\partial \eta}{\partial t}(x_m, t) = G\{A_j(t), j = -\frac{N}{2} + 1, \dots, \frac{N}{2}; \eta(x_n, t), n = 0, \dots, N-1\},$$

for $m = 0, \dots, N-1$. If all values of $A_j(t)$ and $\eta(x_n, t)$ are known at any time t , then $\partial \phi / \partial t$ and $\partial \eta / \partial t$ may be evaluated, and by discretizing the time domain, the solution may be stepped forward in time. Defining time $t_\ell = \ell \Delta t$, and using centred finite differences to approximate the time derivative, the value of η at the next time step can be written

$$\eta(x_m, t_{\ell+1}) = \eta(x_m, t_{\ell-1}) + 2\Delta t \frac{\partial \eta}{\partial t}(x_m, t_\ell) + O(\Delta t^3),$$

that is,

$$\eta(x_m, t_{\ell+1}) \approx \eta(x_m, t_{\ell-1}) + 2\Delta t G\{A_j(t_\ell), j = -\frac{N}{2} + 1, \dots, \frac{N}{2}; \eta(x_n, t_\ell), n = 0, \dots, N-1\}. \quad (3.12)$$

In the same manner,

$$A_j(t_{\ell+1}) \approx A_j(t_{\ell-1}) + 2\Delta t \frac{\partial A_j}{\partial t}(t_\ell), \quad (3.13)$$

where $\partial A_j / \partial t$ is found from the solution of the N simultaneous linear equations in N unknowns obtained from differentiation of (3.5) with respect to time:

$$\frac{\partial \phi}{\partial t}(x_m, \eta_m, t_\ell) = \frac{1}{N} \sum_{j=-\frac{N}{2}+1}^{\frac{N}{2}} \frac{\partial A_j}{\partial t}(t_\ell) \frac{\cosh jk \eta_m(t_\ell)}{\cosh jk D} \exp(-i2\pi m j / N) \quad (3.14)$$

for $m = 0, \dots, N-1$. Unfortunately these equations cannot be simply inverted by Fourier means to give $\partial A_j / \partial t$ since the $\eta_m(t_\ell) = \eta(x_m, t_\ell)$ vary with m .

To commence solution, initial values of $\eta(x_m, t_\ell)$ at $\ell = 0$ and 1 must be known, as well as values of $A_j(t_\ell)$ $\ell = 0, 1$. The Fourier coefficients are simply found if the values of ϕ are known on some line of constant elevation d :

$$A_j(t_\ell) \frac{\cosh jk d}{\cosh jk D} = \mathcal{D}[\phi(x_m, d, t_\ell) - \alpha x_m], \quad \ell = 0, 1.$$

With these initial values known, $\partial \phi / \partial t$ and $\partial \eta / \partial t$ on the surface can be found from (3.10) and (3.11), $\partial A_j / \partial t$ found from (3.14), and η and A_j found at

the next timestep from (3.12) and (3.13). In this way, the evolution of some known initial disturbance can be followed.

This method of time stepping is susceptible to instability in some finite difference schemes, hence it is necessary to determine if and when the method can be unstable here. To do this, the equations (3.3 & .4) were linearized, and a solution assumed. It was found that for waves of wavelength L/ν , where ν is an integer which can take any value between 1 and $N/2$, on a stream of velocity U , that the stability criterion is

$$\sigma(\nu)\Delta t \leq 1,$$

where $\sigma(\nu)$ is the apparent radian frequency of waves of length L/ν :

$$\sigma(\nu) = \nu k U \pm (\nu k \tanh \nu k)^{1/2}, \quad \nu = 1, \dots, N/2.$$

in which the second part is the frequency of the waves travelling on otherwise undisturbed fluid, while the term $\nu k U$ is the Doppler contribution to the apparent frequency by the waves being carried along on a current U . The criterion $\sigma(\nu)\Delta t \leq 1$ means that time steps must be taken sufficiently small so that a minimum number of time computational points are taken in any one cycle of every frequency component. The most demanding case is the highest frequency component $\nu = N/2$. For $\nu k = Nk/2 = N\pi/L = \pi/\Delta x$ sufficiently large, the criterion is approximately

$$\Delta t \leq (\Delta x/\pi)^{1/2} / (1 + U(\pi/\Delta x)^{1/2}).$$

The most severe case is obtained when U is finite and the waves are convected along with the flow giving a higher apparent frequency at a point. If the fluid is quiescent, $U = 0$, the criterion becomes

$$\Delta t \leq (\Delta x/\pi)^{1/2},$$

which is a relatively weak restriction, when compared with those obtained from diffusion and other equations.

3.3. Reflection of solitary waves by a vertical wall

Here, the method developed in §3.2 is applied to the particular problem of a solitary wave propagating over water of constant depth and being reflected by a vertical wall, a situation studied by Chan and Street (1970) who developed a numerical method for free surface flows based on a marker and cell technique, using finite differences. This problem is of some importance, for the solitary wave is the fastest, highest, largest, and most energetic of all steady waves, comparing the results of Longuet-Higgins & Fenton (1974) and those of Cokelet (1977). In addition, the effects on a wall of an incident solitary wave are greater than those due to a standing wave system even of long wavelength, because the solitary wave can be of full breaking height even before it

strikes the wall, and at the wall will rise to a height about twice that, exerting considerable force. The standing waves, being periodic in time, can never rise greater than their breaking height at the wall, and since this height is lower than the breaking height of the solitary wave, the latter should exert the greatest forces possible and its effects should be used as the design criteria for wall forces and moments. Unfortunately, previous studies have not reported on the forces and moments caused.

Since the horizontal fluid velocity at the wall is zero, it can be seen that the problem of a solitary wave on a wall is precisely one half of the equivalent problem of two equal waves propagating in opposite directions, provided that the effects of viscosity are negligible. Both problems have been studied experimentally by Maxworthy (1976), who reported some unusual aspects of the time lag at the wall of the wave crest.

The method described in §3.2 above was tested on the problem of two equal waves propagating in opposite directions described more fully in Fenton & Rienecker (in preparation). In the following discussion only one half of the problem will be considered and will be referred to as the reflection of a single wave by a vertical wall. As none of the methods developed in this work can handle an infinitely long region, a finite length only was considered for computational purposes. To obtain the initial conditions, where the incoming wave does not yet sense appreciably the presence of the wall, a steady wave solution of specified height and period was calculated, using the method of §2. From trial runs it was found that the resulting body of the wave was independent of wave length, if this exceeded some 20 times the water depth for low waves (height 0.1 of the depth), this limit smoothly decreasing to 10 depths for waves of height 0.4 and above. Each of these waves was considered to be a very close approximation to the solitary wave of the same height, this being verified when quantities such as the propagation speed and potential energy were compared with results for the solitary wave from Longuet-Higgins & Fenton (1974). With the steady wave solution so obtained, two such numerical waves were placed together, so that their velocities of propagation were in opposite directions and of a magnitude such that horizontal fluid velocity under the long flat trough was zero, corresponding to two solitary waves coming together over otherwise undisturbed water. Then each wave was shifted forward slightly by an amount equal to the distance travelled in one computational time step, as if the other wave did not exist (an excellent approximation to motion in this first stage in view of the flatness of the trough, zero velocity under it and the small time step used). With these first two positions of each wave, two complete sets of initial conditions were calculated, so that the leap-frog timestepping procedure described in §3.2 could be initiated.

At first the wave propagated towards the wall, with imperceptible

Figure 3. Surface elevation for a long wave of height 0.3 of the mean depth (approximating a solitary wave of height 0.325 above the trough), being reflected by a vertical wall at the left. Profiles are shown for successive times. Vertical exaggeration $\approx 4:1$.

effect on the main body of the wave, as can be seen in Fig. 3, justifying the finite computational length taken. At the wall, the water level slowly rose until it was almost as high as the crest. After this stage, events happened very quickly, the crest "snapped through" to the wall and quickly reared up to more than twice the height of the incident wave. Far away from the wall, all the fluid was sensibly undisturbed. At its highest elevation, the crest at the wall became rather more curved, and for the highest waves became quite sharp. It is in this limit, at this stage, that the use of the Fourier method becomes questionable. The sharp crest of the breaking wave of limiting height cannot be described by the present method which depends on functions and derivatives having no discontinuities. Whereas a real wave may exhibit breaking at the crest for very high waves the numerical wave showed no such behaviour and can provide no breaking criterion. However, up until this point, the solutions were considered to be very accurate since total mass and energy of the fluid were conserved to at least four significant figures. In addition, when compared with experimental results and previous computational results for the maximum runup at the wall on Fig. 4, it can be seen that the present method gave results which agreed very closely, perhaps surprisingly in view of the fact that runup depends critically on whether the waves break or not.

The maximum force and moment exerted on the wall were calculated by obtaining the pressure on the wall at 21 equally-spaced points between the bottom and the crest and integrating using Simpson's rule. These quantities depend on the whole flow field and should be much less dependent on breaking at the crest than might be expected for the runup. Results from the numerical experiments are shown in Fig. 5, on which least-square parabolas have been fitted to each set of points, but with the condition that each pass through the zero amplitude hydrostatic results in which Force on wall = $\frac{1}{2}\rho gh^2$, where h is the undisturbed depth of water, and Moment about the toe of the wall = $\frac{1}{6}\rho gh^3$.

If H is the height of the incident wave crest above the undisturbed fluid, these results are:

Maximum Force on Wall F:

$$\frac{F}{\rho gh^2} = \frac{1}{2} + 2.25\left(\frac{H}{h}\right) - 0.42\left(\frac{H}{h}\right)^2$$

Maximum Moment on Wall about Toe:

$$\frac{M}{\rho gh^3} = \frac{1}{6} + 1.23\left(\frac{H}{h}\right) + 0.80\left(\frac{H}{h}\right)^2.$$

From the figure it can be seen that these empirical curves agree closely with all numerical results and should provide convenient criteria for design purposes.

Figure 4. Maximum run-up at the wall $R = (\eta_{max}/h) - 1$, where h is undisturbed depth, plotted against incident wave height H/h . Points (\bullet): numerical results from present method. (—): mean of experimental results reported by Chan & Street. (---): mean of experimental results from wave-wall reflection, and (- · -): wave-wave interaction, both from Maxworthy (1976).

Figure 5. Maximum force and moment on the wall, plotted against incident wave height. The points (\bullet) are numerical results from the present method to which curves have been fitted, as described in the text, shown by solid lines.

As the water flowed back down the wall, the process described above was qualitatively reversed, until the wave was totally reflected and was travelling in the opposite direction. Chan and Street (1970) reported that at this stage "the wave had exactly the same surface profile as its corresponding incident wave". However, in the present work, the reflected wave was not the same as the incident wave. This is not clear from the space-time plot on Fig. 3, as differences are relatively small. Fig. 6 shows rather more clearly the differences that were observed - the reflected wave has a depression behind it, it has a slightly steeper front face, it is lower, and in apparent contradiction of this last fact, it is travelling faster! These differences are not numerical errors: the accuracy of the method is shown by the fact that mass and energy of the water were conserved to within 10^{-4} , even for the highest waves reported. Rather, some differences between the waves is to be expected, for all the governing equations are highly nonlinear and it would be remarkable if two solitary waves of height 33% of the depth should collide, the combined crest grow to a height of 73%, and then each wave pass out through the other, without some nonlinear interaction changing the form of each. A number of details such as the time lag experienced in the interaction, the change in wave height and speed and other details of the nonlinear interaction are of little engineering importance and are being written up for publication elsewhere.

INTRODUCTION

Mass transport phenomenon was first recognized by Stokes in 1847 using a Lagrangian description. Later, a basic theory for the mass transport in water waves in viscous fluid and of finite depth was derived by Longuet-Higgins in 1953. Theoretical solutions of mass transport in progressive waves of permanent type are subjected to the definitions of wave celerity in deriving the various finite amplitude wave theories. As it has been generally acknowledged that the Stokes wave theory can not yield a correct prediction of mass transport in the shallow depths, some new theories have been developed. Recently the authors(1974 & 1977) have derived a new finite amplitude wave theory in shallow water for quasi-Stokes and cnoidal waves by the so-called reductive perturbation method, in which the mass transport is formulated both in Lagrangian and Eulerian descriptions.

On the experimental verification, Russell and Osorio(1957) investigated and compared Longuet-Higgins' solution with experimental data of Lagrangian mass transport velocity obtained in a normal closed wave tank of finite length. Since then, many investigations, and nearly all of them, have employed the finite length of wave tank in carrying out their experiments. However, no experiment has yet been attempted at verifying the Stokes drift in progressive waves of permanent type in a wave tank of infinite length. It is not realistic nor economical in constructing such an infinitely long flume to investigate experimentally the mass transport velocity in progressive waves. Instead of using such an ideal wave tank, a new one incorporated with natural water re-circulation was equipped to carry out experiments by the authors(1978). It was confirmed from these experiments that mass transport in progressive waves of permanent type exists in the same direction of wave propagation throughout the depth, and agrees with both the Stokes drift and the authors' new formulations, within the test range of experiments.

THEORETICAL SOLUTIONS OF MASS TRANSPORT

1. Conventional Expressions

The theoretical solutions of mass transport in progressive waves of permanent type can be grouped into two main categories. The first one is derived for the perfect fluid from using a finite amplitude wave theory, whilst the other is resulted from considering viscous effects at the bottom and near the free surface.

In the first category the theoretical expressions of mass transport velocity in Stokes waves have been formulated in Lagrangian description for two different definitions of wave celerity in deriving the wave theory. The first is so-call the Stokes drift in Lagrangian description which is subjected to the definition of wave celerity and then is given for the first and second Stokes definitions respectively as

$$U_M = \frac{H^2 \sigma k \cosh 2kz}{8 \sinh^2 kh} \dots\dots\dots (1)$$

and

$$U_M = \frac{H^2 \sigma k \cosh 2kz}{8 \sinh^2 kh} - \frac{H^2 \sigma \coth kh}{8h} \dots\dots\dots (2)$$

in which U_M is the mass transport velocity formulated in Lagrangian description, H is the wave height of progressive waves of permanent, h the water depth at the still water level, $\sigma = 2\pi/T$ the angular frequency of waves, T the wave period, $k = 2\pi/L$ the wave number and L the wave length as shown in Fig. 1. The mass transport velocity in Eulerian description may be given as

$$\bar{u} = \frac{H^2 \sigma \coth kh}{8h}; \quad -\frac{H}{2h} < \frac{z}{h} + 1 < \frac{H}{2h} \dots\dots\dots (3)$$

in which u is the mass transport velocity in Eulerian description which is defined to be the horizontal water particle velocity averaged for one wave period. In 1968 Le Méhauté derived the mass transport velocity by means of Laitone's second approximation of cnoidal waves. This seems questionable because the limitation of solution corresponding to solitary wave has a finite value of mass flux.

Fig. 1 Co-ordinate system used

On the other hand, Longuet-Higgins' solution represents the second category, and so followed by Huang(1970), Li and Davis(1977) etc. Longuet-Higgins' expression is given as

$$U_M = \frac{H^2 \sigma k}{4 \sinh^2 kh} \left[3 + 2 \cosh 2kz + 3kh \left\{ 3 \left(\frac{z}{h} - 1 \right)^2 + 4 \left(\frac{z}{h} - 1 \right) + 1 \right\} \sinh 2kh + 3 \left\{ \left(\frac{z}{h} - 1 \right)^2 - 1 \right\} \left(\frac{\sinh 2kh}{2kh} + \frac{3}{2} \right) \right] \dots\dots\dots (4)$$

These four kinds of vertical distribution of mass transport velocity are schematically shown in Fig. 2, these are the Stokes drifts of the first and second definitions of wave celerity, and that of Longuet-Higgins. This figure shows the distinctive nature of mass transport when the Eulerian description is considered. In the figure, $U_M/H^2\sigma k$ is the dimensionless mass transport velocity and z/h the dimensionless vertical level from the bottom. It is clear that as well-known relatively strong forward velocity is expected near both boundaries as derived by Longuet-Higgins when viscosity is taken into account.

Fig. 2 Vertical distribution of mass transport velocity by conventional expressions

According to the usual expression of mass transport velocity, there is a quite different vertical distribution in Lagrangian and Eulerian descriptions, as a result from the definition of wave celerity in deriving the finite amplitude wave theory. Bagnold's experimental results in 1947 was used to confirm Longuet-Higgins' solution, in which he noted that the mass transport velocities near both boundaries have stronger forward component in the direction of wave propagation, but with reverse flow in the mid-layer between these two viscous boundaries. Ūniuata and Mei(1970) pointed out that Longuet-Higgins' solution corresponded to that would be derived from assuming a constant pressure gradient along the direction of wave propagation thus that no net transport occurs.

2. New Expressions

The new wave theories of quasi-Stokes(1978) and cnoidal waves(1974 & 1977) have recently been derived by the authors from using the so-called reductive perturbation method by Taniuti(1968). From these, the mass transport velocities are then derived.

a) Mass transport in quasi-Stokes waves The mass transport velocity in Lagrangian description is given as

$$U_M/\sqrt{gh} = (\lambda_0^2/16)\{1 - (1/2)(2\pi h/L)^2\} + (\lambda_0^2/8)(\sqrt{gh}/c) [1 + (2/3)(2\pi h/L)^2\{3(z/h - 1)^2 - 1\}] \dots (5)$$

And the mass transport velocity in Eulerian description is given as

$$\bar{u}/\sqrt{gh} = (\lambda_0^2/16)\{1 - (1/2)(2\pi h/L)^2\} \dots (6)$$

in which λ_0 and the wave celerity c are given respectively as

$$\frac{H}{h} = \lambda_0 + \frac{1}{8\pi^2\epsilon} \left(\frac{27}{512\pi^2\epsilon} + \frac{45}{128} \right) \lambda_0^3, \quad \epsilon = \left(\frac{h}{L} \right)^2 \dots\dots\dots (7)$$

and

$$\frac{c}{\sqrt{gh}} = 1 - \frac{1}{6} \left(\frac{2\pi h}{L} \right)^2 + \frac{19}{360} \left(\frac{2\pi h}{L} \right)^4 - \frac{55}{3024} \left(\frac{2\pi h}{L} \right)^6 + \frac{9\lambda_0}{64} \left(\frac{2\pi h}{L} \right)^{-2} \dots\dots\dots (8)$$

b) Mass transport in cnoidal waves The mass transport velocity in Lagrangian description is given as

$$\begin{aligned} \frac{U_M}{\sqrt{gh}} = & \frac{\lambda^2}{6\kappa^4} \left\{ 1 + 2 \left(\frac{\sqrt{gh}}{c} \right) \right\} \left[- \left(\frac{E}{K} \right) \left\{ 3 \left(\frac{E}{K} \right) + 2\kappa^2 - 4 \right\} + \kappa^2 - 1 \right] + \frac{2\lambda^3}{5\kappa^6} \left(\frac{\sqrt{gh}}{c} \right) \left(\frac{z}{h} - 1 \right)^2 \left\{ 2 \left(\frac{E}{K} \right) (\kappa^4 - \kappa^2 + 1) - \kappa^4 + 3\kappa^2 - 2 \right\} \\ & + \frac{\lambda^3}{10\kappa^6} \left(\frac{\sqrt{gh}}{c} \right) \left[5 \left(\frac{E}{K} \right)^2 \left\{ 9 \left(\frac{E}{K} \right) + 10\kappa^2 - 17 \right\} + \left(\frac{E}{K} \right) (12\kappa^4 - 57\kappa^2 + 47) - 6\kappa^4 + 13\kappa^2 - 7 \right] \\ & + \frac{\lambda^3}{15\kappa^6} \left(\frac{\sqrt{gh}}{c} \right)^3 \left[15 \left(\frac{E}{K} \right)^2 \left\{ \left(\frac{E}{K} \right) + \kappa^2 - 2 \right\} + \left(\frac{E}{K} \right) (4\kappa^4 - 19\kappa^2 + 19) - 2(\kappa^4 - 3\kappa^2 + 2) \right] \dots\dots (9) \end{aligned}$$

and that in Eulerian is also given as

$$\frac{\bar{u}}{\sqrt{gh}} = - \frac{\lambda^2}{6\kappa^4} \left[- \left(\frac{E}{K} \right) \left\{ 3 \left(\frac{E}{K} \right) + 2\kappa^2 - 4 \right\} + \kappa^2 - 1 \right] + \frac{\lambda^3}{20\kappa^6} \left[35 \left(\frac{E}{K} \right)^2 \left(\frac{E}{K} + \kappa^2 - 2 \right) + \left(\frac{E}{K} \right) (6\kappa^4 - 41\kappa^2 + 41) - 3(\kappa^4 - 3\kappa^2 + 2) \right] \dots\dots\dots (10)$$

in which

$$\frac{c}{\sqrt{gh}} = 1 - \frac{\lambda}{2\kappa^2} \left\{ 3 \left(\frac{E}{K} \right) + \kappa^2 - 2 \right\} + \frac{\lambda^2}{40\kappa^4} \left[45 \left(\frac{E}{K} \right) \left\{ 3 \left(\frac{E}{K} \right) + 2\kappa^2 - 4 \right\} + 19\kappa^4 - 64(\kappa^2 - 1) \right] \dots\dots (11)$$

E and K are the complete elliptic integrals of the first and second kinds, κ their modulus, and λ is approximately given as

$$\frac{H}{h} = \lambda + \frac{27}{4096\pi^4\epsilon} \lambda^3 \dots\dots\dots (12)$$

(a)

(b)

(c)

(d)

It is noted in these expressions that the mass transport exists both in Eulerian and Lagrangian descriptions, and the vertical distribution of Eulerian mass transport is uniform at this order of approximation. Vertical distributions of mass transport velocity in Lagrangian description are shown in Fig. 3. In this figure, the symbol S-3-1 stands for the solution of the usual Stokes wave theory to a third-order approximation and by the first Stokes definition of wave celerity, QS-3 and QS-4 indicate that of the quasi-Stokes wave theory to a third- and fourth-order approximation respectively, whilst C-A-E-3 represents the mass transport velocity predicted by the cnoidal wave theory to a third-order derived by the authors (the letter E for exact). The variation in the dimensionless wave period $T\sqrt{g/h}$ for a constant depth h infers the influence of wave period, or implying the shoaling of a wave with constant wave period T . It is seen that these vertical distributions of mass transport velocity are essentially the same within the range of small dimensionless wave period, and are in the same direction as of wave propagation, but the curve of C-A-E-3 is re-

(e)

Fig. 3 Vertical distributions of mass transport velocity in Lagrangian description

markably higher than that of others when a larger dimensionless wave period is considered.

EXPERIMENTAL VERIFICATION

1. A New Wave Flume

In a wave flume test it is highly desired that the uniformity of wave profile, wave celerity and mass transport are achieved to the progressive waves of permanent type produced over a uniform finite depth of water. As the normal wave tank of finite length constrains wave motion by the side walls, sloping end wall, and the wave generator plate, unavoidable forced re-circulation of water mass would eventually be resulted for within the interior of the fluid in the wave tank. This creates the problem of reflecting waves and the secondary flow and so on. This forced recirculation exerts a great influence on the exactness of the wave motion to be measured, especially mass transport and wave celerity.

A new wave flume incorporated with four rectangular orifices at sides as shown in Fig. 4, has been constructed, such that the desired wave conditions in the flume can steadily be maintained. As shown in this figure

Fig. 4 New wave flume used

the water mass accompanied by the waves can flow into the inlet orifices at sides near the bottom, passing the conduit beneath the wave flume, and finally returns to the upstream part of the flume through the outlet orifices. Punched metal plates were randomly arranged at the end of the flume on a very gentle slope, acting as wave absorber. This enabled to keep the wave reflection coefficient within and below 5% during all experimental operations.

2. Experimental Method

Wave profile, wave height, and wave celerity were carefully measured by using two wave gauges of capacitance type, W-1 and W-2 as shown in Fig.

4, which were placed at 2.10 m apart. For measuring the mass transport velocity in Lagrangian description, a visualization method was employed wherein the orbital motions of the neutral buoyant particles, made by mixing xilen and nitrobenzen at a ratio of 0.72 to 1 and with colouring, were recorded by a still camera for over 10 wave cycles continuously. An example of the recorded orbital motions is shown in Photo. 1. From

Photo. 1 An example of recorded orbital motions of neutral buoyant particles in the case of $T/g/h = 12.7$ and $h/H = 3.85$

this picture, the mass transport velocity can be accessed for particles introduced at various levels throughout the depth.

In addition, a series of the experiment of mass transport in progressive waves of permanent type has been carried out by a normal wave tank to confirm the forced re-circulation of water mass in the tank. It was already published by the authors(1978).

3. Comparison of Data with Theoretical Prediction

The uniformity of wave height and wave celerity produced in the wave flume was very carefully checked as function of time, as given in Fig. 5, in which H/h is the ratio of wave height to water depth and c/\sqrt{gh} the dimensionless wave celerity. The repeatability of mass transport velocity in Lagrangian description was also confirmed, besides the measurement of wave celerity. It was thus concluded that the wave height, wave celerity, and mass transport velocity reached the steady and uniform state after approximately 80 to 100 waves, i.e. reached its permanent type. Effect of viscosity may however appear near the bottom and free surface after a longer wave cycles.

Wave profiles in the steady state are shown in Fig. 6, in which comparison is made with the theoretical curves of quasi-Stokes(QS-4) and cnoidal waves(C-A-E-3), proven good agreement between them. Similarly, due comparisons on wave celerity and mass transport velocity can also be deduced for under the stable wave condition.

Fig. 5 An example of changes of wave height and wave celerity with time

Fig. 7 compares the experimental values of wave celerity with the theoretical solutions for the quasi-Stokes (QS-4) and cnoidal waves (C-A-E-3), for the value of dimensionless wave period $T/\sqrt{g/h}$ being 10 and slightly under. Fairly good agreement can again be observed for within the range tested.

Similar comparisons on mass transport velocity in Lagrangian description are presented in Fig. 8, in which the theoretical curves were obtained from using the usual Stokes wave theory, the authors' quasi-Stokes and cnoidal wave theories, and that of Longuet-Higgins'. It can be concluded from the figure that the mass transport velocity in progressive waves of permanent type is in the same direction as of wave propagation, and its vertical distribution follows closely the theoretical curves of Stokes waves, particularly to the first Stokes definition of wave celerity, as well as the quasi-Stokes (QS-4) and cnoidal wave (C-A-E-3) theories, within the ranges of $T/\sqrt{g/h}$ and H/h presented.

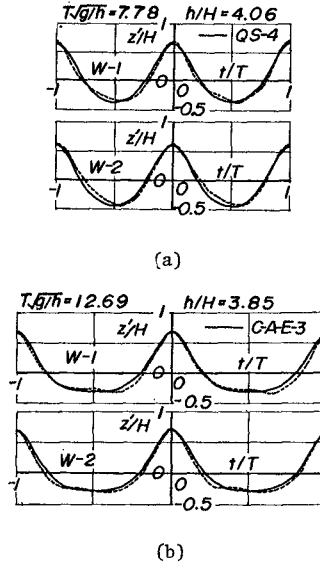

Fig. 6 Comparison of wave profile with theoretical curves

Fig. 7 Comparison of wave celerity with theoretical curves

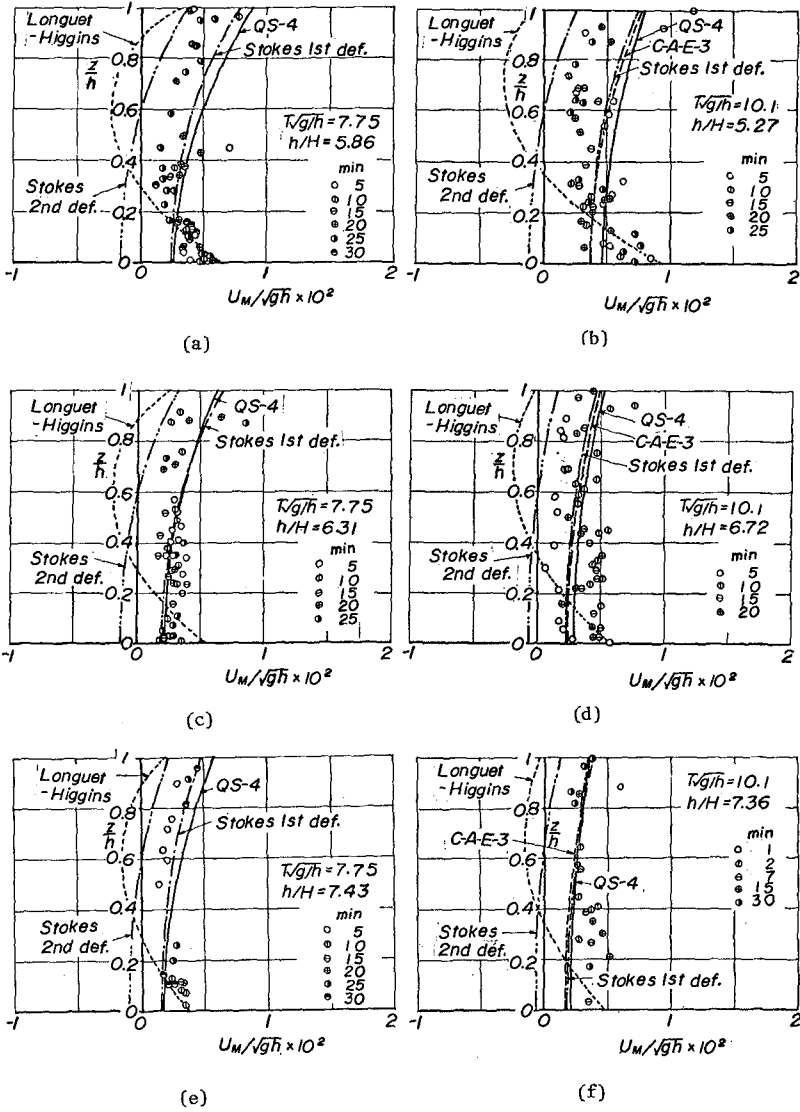

Fig. 8 Comparisons of mass transport velocity with theoretical curves (1)

Fig. 9 Comparisons of mass transport velocity with theoretical curves(2)

Notable scattering occurs as wave height increases, i.e. h/H decreases for a constant depth h . However, slightly smaller in magnitude of the experimental data are generally seen as compared with the theoretical curves. This may well be caused from the back drift appeared in the upper part of the flume. This influence can roughly be estimated from assuming a uniform flow of back drift as follows. As the water depth in the upper part of the flume at the orifices was about 10 cm and that in the conduit below was 30 cm, it was therefore estimated that a 25% reduction will be resulted in the mass transport velocity so measured.

For even higher wave height than that presented in Fig. 8, as seen in Fig. 9, the mass transport velocity is still in the same direction as of wave propagation, but the vertical distribution is likely to differ further from the theoretical curves. This might be attributed to the limitation of the inlet and outlet orifices so equipped and even from the undesired reflection.

Finally, an example of the vertical distributions of mass transport velocity in a normal wave tank is shown in Fig. 10 for comparison with Fig. 8. In the figure, the condition A stands for the state at which the steadiness and uniformity of wave profile and wave celerity were made after about 200 to 250 waves. It can be concluded that the vertical distribution of mass transport velocity in a normal wave tank is quite different from those in Fig. 8, and agrees with the theoretical curve of

Fig. 10 Comparison of mass transport velocity in normal wave tank with theoretical curves

the Stokes waves to the second Stokes definition of wave celerity. It may however be expected that experimental data approach to Longuet-Higgins' curve, as Russell and Osorio(1957) confirmed, when the viscosity effect is considered after very long wave cycles.

CONCLUSIONS

Theoretical formulations of mass transport velocity have been derived for progressive waves of permanent type, both in Lagrangian and Eulerian descriptions, for the quasi-Stokes and cnoidal wave theories by the authors. A new wave flume, equipped with orifices for the natural return of water flow, was constructed for the verification of mass transport velocity, since it is submitted that wave reflection occurs at the end of the normal wave tank which is generally of finite length. It can be concluded that the observed direction of mass transport is the same as that of waves propagating on the water surface, and the vertical distribution agrees with the theoretical curves calculated by the usual Stokes wave theory under the first Stokes definition of wave celerity, and that of quasi-Stokes and cnoidal wave theories derived by the authors.

ACKNOWLEDGEMENTS

The authors wish to express their great appreciation to Dr. J.R.C. Hsu, Visiting Scholar, Disaster Prevention Research Institute, Kyoto University, on leave from the Department of Civil Engineering, University of Western Australia. Part of this investigation was accomplished with the support of the Grant-in-Aid for Scientific Research(No. 155190), Ministry of Education.

RAY CURVATURE AND REFRACTION OF WAVE PACKETS

by

J. Ernest Breeding, Jr.

Department of Oceanography and Ocean Engineering
 Florida Institute of Technology
 Melbourne, Florida 32901

ABSTRACT

Directional wave data obtained simultaneously at two measurement sites is used to confirm the constancy, and therefore the validity, of Snell's laws for wave packets. It is found that the wave packets refract according to Snell's law with the geometric group velocity whereas the wavelets within a packet refract according to Snell's law with phase velocity.

An expression for the ray curvature of a wave packet is derived which is suitable for use in wave prediction programs. The ray curvature of the wave packet is found to vanish if the packet direction becomes either perpendicular or parallel to the wave speed contours, assuming the wavelet direction is not parallel to the contours. This means that as a hydron (wave packet) moves into shoaling water refraction tends eventually to turn the hydron so that it is directed either perpendicular or parallel to the shoreline. The first case is similar to monochromatic waves. For parallel water depth contours, it is the result for hydrons which begin in deep water if the angle of incidence is between 0° and 74.8° with respect to the contour normal. However, for deep water angles of incidence equal to or greater than 74.8° the hydrons are turned and move parallel to shore in water of intermediate depth. The packet ray curvature approaches infinity as the wavelet direction, but not the hydron direction, becomes parallel to the wave speed contours. The result is total reflection of the waves. Total reflection occurs if a hydron is moving into deeper water and its initial direction exceeds a critical angle. At the reflection point the hydron direction becomes perpendicular to the water depth contours. Further, the hydron velocity goes to zero, which is consistent with a particle concept. As in quantum mechanics, the wave-particle duality is encountered.

1 INTRODUCTION

The conventional definition of group speed U has been defined as

$$U = d\omega/dk \quad (1)$$

where ω is the angular frequency and k is the wave number. This equation defines the speed of the group in the direction of the wavelet velocity. The geometric group speed G was defined by Breeding (1978a) as

$$G = U \cos \phi \quad (2)$$

where

$$\phi = \theta - \gamma \quad (3)$$

The direction of movement of the wave packet is represented by θ , and the direction the wavelets move within the packet is specified by γ .

Breeding (1978a) and Black (1979) have found that the trajectories of wave packets are not determined by a monochromatic refraction law, i.e., by simply using Snell's law with phase velocity. Based on a comparison of computed backtracks from the measurement site with the known source of the waves, Breeding (1978a) has shown that wave packets refract according to Snell's law with the geometric group velocity. This refraction law determines the wave path of constructive interference. At each point of the wave packet trajectory the wavelet direction is determined by Snell's law with phase velocity.

One objective of this paper is to investigate more directly the validity of the refraction laws by testing the constancy of Snell's laws for the wave packets and wavelets using directional wave data obtained simultaneously at two measurement sites. A further purpose of the paper is to derive an expression for the ray curvature of a wave packet which is suitable for use in wave prediction programs. Properties of the packet ray curvature are described, and the important features of wave packet refraction are demonstrated using examples of gravity water waves.

2 TEST OF WAVE PACKET REFRACTION LAWS

2.1 Theory

Snell's law for a wave packet can be stated

$$(\sin \theta)/G = C_G \quad (4)$$

where C_G is a constant for a given frequency. The direction of γ is determined by

$$(\sin \gamma)/v = C_v \quad (5)$$

which is Snell's law with phase velocity where $v = \omega/k$ is the phase speed and C_v is a constant for a given frequency. To use (4) and (5) the y-axis is taken parallel with the wave speed contours. By virtue of Snell's law with phase velocity, γ is a function of k . The water depth h is assumed to vary slowly over the distance of a wavelength so that k is given by the classical dispersion relation

$$\omega^2 = gk \tanh kh \quad (6)$$

where g is the acceleration due to gravity. By considering the variation of (5) with respect to frequency it is found that (Breeding, 1978a)

$$\tan \phi = k(d\gamma/dk) \quad (7)$$

which is a useful relation for determining θ from a set of wave measurements.

2.2 Field Observations

2.2.1 Directional wave data

Hurricane Betsy passed over the southern tip of Florida and entered the Gulf of Mexico at about 1500 UT on September 8, 1965. After making a curved path the hurricane entered land at the Mississippi Delta at about 0400 UT on September 10. The storm had winds in excess of 100 knots.

Waves due to Hurricane Betsy were measured (Breeding, 1972) using two independent arrays of six pressure transducers which were placed on the sea floor at the sites of two offshore platforms (stages) near Panama City, Florida. The location and configuration of the arrays are shown in Figure 1. In each array a pressure sensor is located at each corner of a pentagon of side 35.8 m (117.6 ft) and these sensors are located 30.5 m (100.0 ft) from a sensor at the center of the array. Stage 1 is located in 31.7 m (104 ft) of water 17.7 km (11 mi) from shore. Stage 2 is located in 19.2 m (63 ft) of water 2.8 km (1.7 mi) from shore. Directional power spectra with 60 d.f. were computed for time series records about 30 min in length by Bennett (1972) based on the method of Munk et al. (1963).

The results of the wave directional analysis for successive measurement times of 1712 - 1743 and 1744 - 1815 UT on September 9, 1965 at Stage 1 are shown in Figure 2. In the array pressure sensors 1, 2, 4, and 5 were operational. The wavelet directions shown are the bearings from which the waves come relative to true north. It is apparent that the findings for the two measurement periods are consistent. The wave directional results for measurements made independently at Stage 2 for the same times as presented for Stage 1 are shown in Figure 3. For this array all the sensors were working but sensors 2 and 4.

2.2.2 Test of Snell's laws

For the observations presented in Figures 2 and 3 the wavelet direction γ and an estimate of the slope $d\gamma/dk$ were obtained by fitting a quadratic polynomial to the data by the method of least squares. The resulting quadratic curves are shown with the data in the figures. The polynomial obtained for the Stage 1 data is given by

$$\gamma_1 = 3.724 - 17.26 k_1 + 68.32 k_1^2 \quad (8)$$

The similar finding for the Stage 2 data is

$$\gamma_2 = 3.984 - 18.74 k_2 + 92.06 k_2^2 \quad (9)$$

Once γ and $d\gamma/dk$ are determined for a given wavelet period from (8) and (9), the wave packet bearings can be determined for each measurement site, respectively, using (7) and (3). For example, for a wavelet period

Figure 1. Bottom topography and array configuration near Panama City, Florida.

Figure 2. Wavelet directions as a function of wave number at Stage I.

Figure 3. Wavelet directions as a function of wave number at Stage 2.

of 10.9 s, at Stage 1 $v_1 = 14.48$ m/s, $\gamma_1 = 180.19^\circ$, $G_1 = 9.23$ m/s, and $\theta_1 = 154.97^\circ$. The corresponding values at Stage 2 are $v_2 = 12.23$ m/s, $\gamma_2 = 189.37^\circ$, $G_2 = 8.89$ m/s, and $\theta_2 = 164.01^\circ$.

To evaluate the constants in Snell's laws the wave packet and wavelet directions are defined with respect to the normal to the water depth contours. The water depth contours between the stages are approximately parallel with a bearing of 131° with respect to true north. For the data summarized by (8) and (9) the Snell's law constants for both the wave packets and wavelets were evaluated for each wavelet period. The percentage differences of the constants at Stage 2 from the corresponding values at Stage 1 are shown in Figure 4. In the same figure the surface extrapolations of the energy density for the first of the two measurement periods used to determine (8) and (9) are presented for both stages.

2.2.3 Discussion of the results

The difference in the energy density for Stage 1 and Stage 2 shown in Figure 4 is a manifestation of the wave modification occurring between the stages. Over most of the frequency range considered, the Snell's law constants at Stage 2 differ by less than $\pm 10\%$ from the corresponding constants at Stage 1 for both the wave packets and the wavelets. The difference in the constants increases as the waves become less energetic. However, the difference in the constants is less than 5% for both the wave packets and the wavelets at the wave period where the energy density peaks. These findings are significant. Although the validity of Snell's law with phase velocity is well established, the results presented here indicate that Snell's law with the geometric group velocity is equally valid.

There are a number of reasons why different constants are found for Snell's laws for the wave packets and wavelets at the offshore stages. For example, a measurement error of a few degrees for each array is possible from inaccuracies in locating the positions of the pressure sensors. The water depth contours are not exactly parallel as was assumed in the computations. Further, the accuracy in determining the Snell's law constants for the wave packets depends upon the method used in evaluating the slope dy/dk from the data. Higher accuracy could be achieved by the use of higher order polynomials to better fit the data.

3 RAY CURVATURE FOR WAVE PACKETS

It is more convenient to determine ray trajectories using the ray curvature than it is to use Snell's law. The ray curvature κ_v of a ray moving with phase speed v was derived by Munk and Arthur (1952) and Arthur, et al (1952) as

$$\kappa_v = \frac{dy}{ds_v} = \frac{1}{v} \left(\sin \gamma \frac{\partial v}{\partial x} - \cos \gamma \frac{\partial v}{\partial y} \right) \quad (10)$$

Figure 4. Comparison of Snell's law constants for wave packets and wavelets at Stage 1 and Stage 2 for Hurricane Betsy for measurement times of 1712-1743 and 1744-1815 UT on September 9, 1965. The percentage differences of the constants at Stage 2 from the corresponding values at Stage 1 are shown versus wave period. The energy density is presented for both stages for the time period 1712-1743 UT.

where x, y are the Cartesian coordinates, γ is the direction of the ray with respect to the positive x -axis, and s_γ is the arc length along the ray. The ray curvature κ_G for the trajectory of a wave packet is given by

$$\kappa_G = \frac{d\theta}{ds_G} = \frac{1}{G} \left(\sin \theta \frac{\partial G}{\partial x} - \cos \theta \frac{\partial G}{\partial y} \right) \quad (11)$$

where θ is the direction of the packet ray with respect to the positive x -axis and s_G is the arc length along the ray.

3.1 Packet Ray Curvature

The derivation of the packet ray curvature is greatly simplified by using a x', y' -coordinate system which is chosen so that at each ray point the positive x' -axis is in the direction of the gradient of the water depth. As a result, the first partial derivatives of the water depth and the wave speeds with respect to y' vanish. From (2) the spacederivative of G is then

$$\frac{\partial G}{\partial x'} = \frac{\partial U}{\partial x'} \cos \phi - U \sin \phi \left(\frac{\partial \theta'}{\partial x'} - \frac{\partial \gamma'}{\partial x'} \right) \quad (12)$$

Also

$$\partial \theta' / \partial x' = [(\partial G / \partial x') / G] \tan \theta' \quad (13)$$

$$\partial \gamma' / \partial x' = [(\partial v / \partial x') / v] \tan \gamma' \quad (14)$$

After (13), (14), and (12) are substituted into (11) and the result is simplified, the packet ray curvature is found to be

$$\kappa_G = \frac{[(\partial U / \partial x') / U] + [(\partial v / \partial x') / v] \tan \phi \tan \gamma'}{\csc \theta' + \tan \phi \sec \theta'} \quad (15)$$

This expression is used by Breeding (1978b) in a wave prediction program.

3.2 Properties of the Packet Ray Curvature

The ray curvature of a wave packet defined by (15) exhibits some very remarkable properties. To determine the important properties the discussion is simplified by taking the wave speed contours parallel to the y -axis. It is assumed that v, U , and their derivatives are continuous and finite. However, under various conditions the trigonometric terms of the equation can become infinite or have indeterminate forms. The value of κ_G approaches zero as the wave packet direction θ becomes either parallel or perpendicular to the wave speed contours, provided the wavelet direction γ is not parallel to the contours. This means that given a sufficiently long path, refraction tends to turn the wave packet so that it is directed either parallel or perpendicular to the wave speed contours. If θ is neither parallel nor perpendicular to the wave speed contours, then κ_G approaches infinity as γ becomes

parallel to the wave speed contours. In this case, due to the value of γ , the wave packet undergoes total reflection.

To determine the value of κ_G when there are indeterminate forms it is necessary to consider the variations of θ and γ as the indeterminate forms are approached. For example, (15) contains an indeterminate form when θ becomes perpendicular to the wave speed contours while γ becomes parallel to the contours. If γ approaches parallelism to the contours faster than θ approaches the perpendicular to the contours the value of κ_G becomes infinite.

The relationship between θ and γ due to refraction is clearly seen by integrating the ray curvature expressions (10) and (11). The y -derivatives being zero, integration of (11) leads to (4) which can be stated

$$(\sin \theta) / [U \cos (\theta - \gamma)] = C \quad (16)$$

which is Snell's law for a wave packet. Snell's law with phase velocity, which determines γ , is obtained by integrating (10). The cosine term in (16) can be replaced by the identity for the difference of two angles and the terms rearranged to yield

$$\tan \theta = (UC \cos \gamma) / (1 - UC \sin \gamma) \quad (17)$$

where the variation of θ appears only on the left side of the equation.

It is interesting to note that θ becomes zero if $\gamma = (2m+1)(\pi/2)$ where m is an integer. Thus if the wavelet direction becomes parallel to the wave speed contours the wave packet direction becomes perpendicular to the contours. Further, note that $\theta = (2m+1)(\pi/2)$ if $UC \sin \gamma = 1$. For this case the wave packet direction is parallel to the wave speed contours.

Snell's law can be used to derive an expression for $\cos (\theta - \gamma)$. Eq. (17) is substituted into the identity for $\tan (\theta - \gamma)$ and the result is simplified to obtain

$$\tan (\theta - \gamma) = (UC - \sin \gamma) / \cos \gamma \quad (18)$$

In terms of initial values, Snell's law with phase velocity can be written

$$\sin \gamma = v_r \sin \gamma_i \quad (19)$$

where $v_r = (v/v_i)$ and the subscript i denotes an initial value. Before refraction it is assumed that $\theta_i = \gamma_i$. Then

$$C = (\sin \gamma_i) / U_i \quad (20)$$

When (19) and (20) are substituted into (18), it is found that

$$\tan(\theta - \gamma) = \frac{(U_r - v_r) \sin \gamma_i}{(1 - v_r^2 \sin^2 \gamma_i)^{\frac{1}{2}}} \quad (21)$$

where $U_r = (U/U_i)$. This result can be transformed by the use of an identity to

$$\cos(\theta - \gamma) = \left[1 + \frac{(U_r - v_r)^2 \sin^2 \gamma_i}{1 - v_r^2 \sin^2 \gamma_i} \right]^{-\frac{1}{2}} \quad (22)$$

Eqs. (1), (2), and (22) provide a useful means of computing the geometric group speed.

4 HYDRON EXAMPLES OF WAVE PACKET REFRACTION

To demonstrate the properties of wave packet refraction, examples of gravity water waves will be considered. Gravity water waves are particularly suited as examples because of their highly dispersive nature. The term 'hydon,' suggested by Purser and Synge (1962) and Synge (1962), will be used to denote the wave packet of water waves.

4.1 Waves Starting in Deep Water

In Figure 5 hydon trajectories are shown for waves beginning in deep water (water depth greater than one half the wavelength). The water depth contours are parallel. Initially $\theta_i = \gamma_i$ where each initial direction indicated on the figure is the angle between the hydon velocity vector and the normal to the depth contours. Regardless of the wave period, for deep water angles of incidence between 0° and 74.8° the hydrons follow paths such that the angles increase to the depth of the geometric group speed maximum (see Figure 7), then undergo a point of inflection, and then decrease shoreward. As a hydon approaches shore its direction becomes perpendicular to the wave speed contours and the packet ray curvature approaches zero. For deep water angles of incidence equal to or greater than 74.8° the hydon trajectories turn and move parallel to shore in water of intermediate depth. As the hydon direction becomes parallel to shore the packet ray curvature tends to vanish; this is apparent in ray number 5.

For comparison, monochromatic rays are shown in Figure 6 for the same conditions considered in Figure 5. For large incident angles there is a striking difference between hydon and monochromatic trajectories. Whereas all the hydon rays do not reach shore all the monochromatic rays do. Note that the wavelet direction at each point along a hydon path in Figure 5 is the same as the direction of the corresponding monochromatic ray at the corresponding water depth.

Figure 5. Hydron trajectories for a 20 s wave period for waves beginning in deep water. The water depth contours are parallel, the scale of the plot is 1 cm = 4.87 km, and the sounding depths are in meters. The initial hydron direction is shown for each ray and is the angle between the hydron velocity vector and the normal to the depth contours.

Figure 6. Monochromatic rays for comparison with the hydron rays in Figure 5.

It is interesting to compare the values of G and U when they differ due to refraction. As an example, for gravity water waves which begin in deep water it is found that

$$v_r = \tanh kh \quad (23)$$

$$U_r = \left(1 + \frac{2kh}{\sinh 2kh}\right) v_r \quad (24)$$

where h is the water depth. When (23) and (24) are substituted into (22) and the result is substituted into (2) it is found that

$$G = U \left[\frac{1 + \frac{(kh \sin \gamma_i \operatorname{sech}^2 kh)^2}{1 - (\sin \gamma_i \tanh kh)^2}}{1 - (\sin \gamma_i \tanh kh)^2} \right]^{-\frac{1}{2}} \quad (25)$$

The ratio of the geometric group speed to its initial deep water value is presented for several incident angles in Figure 7. The initial hydron directions are defined as in Figure 5. The curve for $\gamma_i = 0^\circ$ is the same as obtained for the ratio of U to the value of U in deep water. The amount by which the other curves differ from it is a measure of the difference between G and U .

Inspection of Figure 7 shows for a given γ_i that the maximum of G/G_i occurs at a greater value of kh than does the minimum of G/U . An increase in γ_i causes a shift in both the minimum of G/U and the maximum of G/G_i to larger values of kh . Further, the maximum peak tends to get flattened out. The curve for $\gamma_i = 74.8^\circ$ is seen to stop abruptly at the maximum value of G/G_i .

When $\gamma_i = 30^\circ$ the maximum percentage difference of G from U is 2.70%. When $\gamma_i = 45^\circ$ the value is 5.91%, for $\gamma_i = 60^\circ$ it is 10.03%, and for $\gamma_i = 74.79^\circ$ the value is 14.27%.

4.2 Reflection Points

To obtain a reflection point it is necessary that the waves propagate into deeper water and that the initial direction of the hydron ($\theta_i = \gamma_i$) exceed a critical angle. The reflection point occurs at an intermediate water depth when, through refraction, the wavelets are turned parallel to the wave speed contours.

In Figure 8 two rays are shown in which the wave period is 20 sec and the initial water depth is 15 m. For this case a reflection point occurs if $\theta_i \geq 22.2^\circ$. Ray number 1 reaches deep water since $\theta_i = 15^\circ$. For ray number 2, $\theta_i = 23^\circ$, and a reflection point occurs at a water depth of 200 m. The variation of the hydron and wavelet directions with water depth for this ray are shown in Figure 9. The wavelet angle increases continuously with water depth and becomes parallel to the water depth contours at the reflection point. The hydron angle first increases, goes through a maximum, and then becomes perpendicular to

Figure 7. The variation of the geometric group speed with kh for hydrons beginning in deep water. The initial value of the geometric group speed is G_i . The hydron directions are defined as in Figure 5.

Figure 8. Hydron trajectories for a 20 s wave period for waves which begin at an intermediate water depth. The scale of the plot is 1 cm = 3.10 km and the sounding depths are in meters. The initial hydron direction is shown for each ray and is defined as in Figure 5.

Figure 9. Variations of the wavelet direction γ , hydron direction θ , the speed $U = d\omega/dk$, and the geometric group speed $G = U \cos(\theta - \gamma)$ up to the reflection point for ray number 2 in Figure 8.

the water depth contours at the reflection point. This is clearly seen in Figure 8.

Plots of how G and U vary with water depth in approaching the reflection point are shown in Figure 9. Both speeds have a maximum value. However, there is a marked contrast between G and U at the reflection point where the geometric group speed is zero.

In Figure 10 the ratio of the packet ray curvature to its initial value is sketched as a function of the wavelet direction for ray number 2 in Figure 8. The most striking feature of this curve is that within about 2° of the reflection point the packet ray curvature suddenly goes to infinity.

It is interesting to observe that the velocity of the wave packet goes to zero at the reflection point. This is exactly what the velocity of a particle should do when there is reflection. Therefore, in water waves, as in quantum mechanics, the wave-particle duality is encountered.

5 CONCLUSIONS

Directional gravity water wave data obtained simultaneously at two field stations were used to test the refraction laws for the wave packets (hydrons) and wavelets. It is found that the constancy of Snell's laws is established with equal precision for both the wave packets and wavelets. From the results it is concluded that the wave packets refract according to Snell's law with the geometric group velocity while the wavelets within a packet refract according to Snell's law with phase velocity.

Refraction causes a hydron trajectory to become directed either parallel or perpendicular to the water depth contours. In either case the packet ray curvature will vanish. For hydrons propagating toward deep water, if the initial direction exceeds a critical angle total reflection occurs. At the reflection point the wavelet direction becomes parallel to the wave speed contours, the hydron direction becomes perpendicular to the contours, the geometric group velocity goes to zero, and the packet ray curvature becomes infinite.

6 ACKNOWLEDGMENTS

The data were collected and the spectral analysis obtained at the Naval Coastal Systems Center, Panama City, Florida, by George B. Austin and Carl M. Bennett, respectively. I thank them for their cooperation and suggestions.

Further, I thank Franklyn C. W. Olson, Kenneth C. Matson, and Kimberly Crane Oppenheimer for their help in preparing this paper. The research was supported by the Geography Programs, Earth Sciences Division, Office of Naval Research (USA) under Contract No. N00014-77-C-0329.

VERIFICATION OF A WAVE REFRACTION MODEL UTILISING
RECORDED AND OBSERVED WAVE DATA

BY G HENDERSON¹ and N B WEBBER²

SUMMARY

There are few references in the published literature to the verification of wave refraction models utilising field data. More often, such models have been compared to the results of analytical solutions or using laboratory models.

This paper reviews the present state of knowledge of such verifications and describes a method which has been successfully employed at a coastal site in the central English Channel. The procedure involves hindcasting recorded Waverider Buoy wave information from a nearshore region to deep water. A comprehensive coverage of wind data has been utilised to provide the offshore wave approach direction.

Wave orthogonals have then been tracked inshore and the breaking wave heights and directions compared with observed data.

The results show reasonable comparison where the waves are free from diffraction. However, for oblique wave attack, diffraction around headlands produces evident anomalies.

1 INTRODUCTION

In many coastal or marine engineering problems wave refraction models are employed to determine the wave pattern throughout the nearshore region for a range of offshore wave conditions. But they are by no means precise tools and if the wave refraction model is to play an important role, then some critical assessment of its validity is needed. In many cases small variations of predicted wave height and direction from those actually occurring can produce quite different results. In the present case, the wave refraction model was to be used to make estimates of longshore drift but similar applications are made for design and site selection of harbours, breakwaters and offshore structures (Skovgaard and Bertelsen, 1974).

There are few references to the verification of a wave refraction model utilising field data. In the majority of cases the computed height and direction of orthogonals are compared with known analytical results or correlated with laboratory data. However, an important question is how well a real sea spectrum of wave frequencies, heights

-
1. Post-doctoral Researcher, Department of Civil Engineering, University of Southampton, UK.
 2. Senior Lecturer, Department of Civil Engineering, University of Southampton, UK.

and directions can be approximated by a single selected frequency and direction in a wave refraction model.

More recently, the direction of wave trains has been observed from radar stations and related to computed wave patterns. Such an instrument was not available in the present instance and, in any case, this would not provide information regarding wave heights. Wave directions may also be examined on aerial photographs, but such flights are seldom made in high wind and hence wave conditions when they would be of most value. Three sets of aerial photographs have been obtained for the region concerned and these were compared with wave patterns from the wave refraction model. However, they do not verify the model and in fact result in more questions than answers.

Having reviewed some of the methods described above, it was decided that a new technique using actual field data was required. This was achieved utilising the wave recordings obtained from a Waverider Buoy stationed near the centre of the modelled area and daily beach observations of breaking wave height and direction. The results of this study also provided useful information regarding the relative accuracy of computed wave directions and heights for waves with varying shoreline approach angles.

2 WAVE REFRACTION DIAGRAMS

The plotting of wave refraction diagrams is fairly commonplace in most countries of the world. Early procedures were to employ graphical techniques (Johnson et al, 1948), although, today, computers are almost invariably employed.

The method of wave refraction has been considered in detail by Henderson and Webber (1979(a)). Briefly wave refraction is analogous to the refraction of other types of wave such as light and sound. In these circumstances for a parallel contoured seabed Snell's Law is applicable where

$$\frac{c_1}{c_2} = \frac{\sin \alpha_1}{\sin \alpha_2} \quad (1)$$

where c_1 , c_2 are wave celerities at locations 1 and 2, and α_1 , α_2 are the corresponding angles made by the wave crest with the bed contour.

With a knowledge of seabed depths the refraction behaviour may be analysed and plotted in the form of a diagram.

Wave heights may be obtained by considering that the rate of transmission of energy remains constant between adjacent orthogonals. Thus, by equating wave power at the two locations, it follows that:

$$\frac{\rho g}{8} H_1^2 b_1 c_{g1} = \frac{\rho g}{8} H_2^2 b_2 c_{g2} \quad (2)$$

$$\text{or} \quad \frac{H_1}{H_2} = \left[\frac{b_1}{b_2} \right]^{\frac{1}{2}} \left[\frac{c_{g1}}{c_{g2}} \right]^{\frac{1}{2}} \quad (3)$$

$$\text{or} \quad \frac{H_1}{H_2} = K_R K_S \quad (4)$$

where K_R , the coefficient of refraction is $(b_1/b_2)^{\frac{1}{2}}$
and K_S , the coefficient of shoaling is $(c_{g1}/c_{g2})^{\frac{1}{2}}$

Thus, it is possible to evaluate all the wave characteristics at any point in the refraction diagram, which may, if desired, be related to the incident wave height H in deep water. But in this procedure certain assumptions are made:

- (i) waves are of constant period, small amplitude and monochromatic, so that linear wave theory is applicable.
- (ii) direction of wave advance is perpendicular to the wave crest.
- (iii) changes in the bed topography are gradual.
- (iv) effects of currents, local wind and reflection from bed or shoreline are negligible.
- (v) wave energy is confined between orthogonals and remains constant; thus there is no viscous dissipation of energy.

Consequently, the refraction analysis is more appropriate to long period swell than it is to short crested storm waves. On the other hand, the refraction diagram occupies a relatively greater area with consequently more scope for minor divergencies.

3 METHODS OF VERIFICATION

3.1 Analytical

The direction and height of wave orthogonals passing over regular known bed forms can be derived from the governing equation. A commonly used cross-section is a uniformly sloping bed with parallel contours as shown in Fig. 1 with the resulting orthogonal propagation. For orthogonals impinging at right angles to the bed contours no refraction takes place, while for the oblique path the orthogonals refract to impinge at right angles to the shoreline.

A more severe test for wave refraction is shown in Fig. 2 for movement towards a circular island. In this case the wave orthogonals are again refracted to impinge at right angles to the island surround. The island can be reduced to the extreme of an isolated point of land shown in Fig. 3.

Fig. 4 shows the orthogonal propagation over a circular shoal and the formation of caustics or crossed wave orthogonals in the lee.

Fig. 1 Wave refraction over a sloping bed with parallel contours

Fig. 2 Wave refraction at a circular island

Fig. 3 Wave refraction at a point island

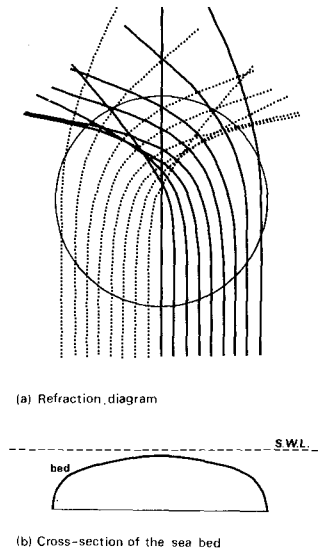

Fig. 4 Wave refraction over a circular shoal

The application of analytical verification was first applied by Arthur (1946) for the direction of wave orthogonals propagating over a number of bed forms. This has since been extended to include wave heights as described by Vastano and Reid (1967), Berkhoff (1972 and 1976), Smith and Sprinks (1975) and Radder (1979).

3.2 Laboratory Models

Laboratory models can be used to simulate wave refraction and enable the recording of directions and heights of wave orthogonals. They have been used to check the analytical solutions described above and computer derived wave refraction diagrams. The most commonly used model is that of a circular shoal first investigated by Pierson (1951). Subsequent studies have included that of Chao and Pierson (1970), Ito and Tanimoto (1972), Whalin (1972) and Berkhoff (1976).

3.3 Radar Observations

Radar observations can be used to identify wave patterns and hence verify the directions of wave orthogonals produced in a refraction diagram. However, radar images cannot be used to estimate wave height.

The use of radar to observe wave trains was described by Oudshoorn (1960), Ijima et al (1964), Loewy et al (1976) and Mattie and Harris (1978).

3.4 Aerial Photography

If the modelled region has been surveyed by aerial photography then it is often possible to determine the direction of incident waves and compare these with a wave refraction diagram. However, as with radar observations the wave height cannot be derived from aerial photographs.

The seaward limit of the photography is limited by the requirement of a recognisable section of land on the photograph. Flying at greater heights will increase the sea coverage but the wave crests become more difficult to distinguish. A major problem when photographing wind waves is that flights are often postponed in high wind which is when waves are most pronounced. This limits the applicability of this method for wind wave verification. Swell waves can more readily be photographed in lower wind speeds, but often the sea surface disturbances are so small that they cannot be easily recognised.

Bryant (1974) has shown reasonable agreement between aerial photographs and wave refraction diagrams for a wind wave and a swell wave case. With this exception no other such comparisons between aerial photography of real sea waves and wave refraction diagrams could be found in the published literature.

3.5 Observed and Measured Wave Data

Although radar observations and aerial photographs can be used

to validate the directions of computed wave orthogonals, the verification of wave heights cannot be made for the case of real sea data. Few references to this topic exist but it appears to be a problem which is undergoing current investigation.

Bryant (1979) has shown a reasonable correlation between breaker wave heights for long period, unidirectional swell waves in Broken Bay, Australia. Offshore wave height was recorded by a Waverider Buoy 30 km from the shoreline, while deep water wave direction was measured at the Buoy. Data for wind waves was not analysed in their study.

King and Hardcastle (1980) refracted a Pierson-Moskowitz wind wave spectrum from deep water and compared this to measured wave heights at three shoreline target areas in Start Bay, UK. Offshore wave height was obtained from a Waverider Buoy located 6 km from the coastline and deep water direction was provided by radar observations. The comparisons between computed and measured nearshore wave heights were reasonable, although the method is undergoing further refinement.

4 WAVE RECORDING IN POOLE BAY

From June 1974 to March 1979 waves were recorded by a Waverider Buoy at a coastal location in Poole Bay, central south coast of England. The Buoy was located (Fig. 5) in a water depth of 14 m below chart datum and was approximately 800 m offshore from Southbourne. Wave information was transmitted from the Buoy to a receiver unit at Boscombe Pier approximately 3 km distant, and waves were recorded for 20 minutes every 3 hours. The wave data was analysed by the Tucker-Draper method (Tucker, 1961 and Draper, 1963) to record parameters such as H_s , H_{max} , T_z etc.

Throughout the operation of the Waverider Buoy two or three observations of the breaking wave height and direction were made at the beach each day. The wave height was estimated to the nearest 10 cm by observing the average peak to trough breaking wave height against a groyne with planks spaced 30 cm apart. Due consideration was given to the tidal height at the time of recording such that the breaking waves were observed. Wave direction was recorded to the nearest 1° using a prismatic compass, the angle between the wave crests and shoreline being recorded. The coastline at this location faces almost due south.

5 THE WAVE REFRACTION METHOD

There are a number of wave refraction methods designed for computer application and many of these have been reviewed by Skovgaard et al (1975). In the present case, the Hydraulics Research Station method was employed which computes the direction of wave orthogonals over a grid of water depths covering the region of interest (Brampton, 1977). This method has been extended to include the calculation of refraction and shoaling coefficients at any position along a wave orthogonal.

Two grids of water depths were used in the present analysis as shown in Fig. 6. The coarser offshore grid extended 50 km south of the Bay shorelines to a depth contour of about 60 m. This was the location

Fig. 7 Schematic representation of sea bed

of deep water for all waves up to 9 seconds period. At approximately the position of the 20 m depth contour, some 10 km from the shoreline, a finer inshore grid was used. Wave orthogonals travelling from deep water over the offshore grid were transferred to the inshore grid over which they moved to the shoreline.

The grids were aligned in the north-south, west-east direction. The bathymetry in the region of interest generally changes more rapidly in a north-south direction and so a rectangular shaped grid element was chosen with greater dimensions in the west-east direction. The offshore grid element size was 1 km west-east by 250 m north-south. For the inshore grid the element size was reduced to 125 m west-east by 31.25 m north-south. The grid of depth values was expressed relative to mean sea level, but a facility was introduced to add or subtract any value to reduce the depths to any tidal condition.

A wave orthogonal originating in deep water with a known period was propagated towards the shoreline. The direction of wave approach was expressed as the anticlockwise angle in degrees made by the wave orthogonal and a positive x-axis as shown in Fig. 6.

Assuming a constant wave period the wave orthogonals having traversed the offshore grid were transferred to the inshore grid before impinging on the shoreline. A new wave orthogonal was then originated in deep water.

The wave orthogonal moved in a series of steps through a set of right-angled triangular elements having vertices at the grid points as shown in Fig. 7. At each step the refraction and shoaling coefficients were computed which permitted the wave height to be calculated using Equation (4) where location 2 is in deep water, thus

$$H_s = K_R K_S H_{so} \quad (5)$$

The wave orthogonals were stopped at the shoreline when the wave height H was related to the water depth, d , by the breaking condition (Munk, 1949)

$$H_s = H_{sb} = 0.78d \quad (6)$$

The breaking wave height H_{sb} , and direction of wave orthogonal approach relative to a positive x-axis, θ_b , were stored. The final wave orthogonal co-ordinates could be adjusted by changing the co-ordinates of the orthogonal at its point of origin in deep water.

It was a simple procedure to change the method of forward progression of wave orthogonals to a back-tracking process. A series of wave orthogonals radiating from a particular point could be transferred in a "fan" to deep water. This enabled wave heights recorded at the Waverider Buoy site to be hindcast using refraction and shoaling coefficients to a deep water wave height for a particular offshore approach angle.

6 COMPARISON WITH AERIAL PHOTOGRAPHS

A number of organisations were approached with regard to obtaining aerial photographs of the region under study. The only available photographs were the property of the Ministry of Defence and, after inspection, it was apparent that only three flights had yielded recognisable wave patterns from a reasonable portion of the Bays. These had been flown on the 7th July 1959, 6th July 1960 and 20th November 1962. Specimen photographs for 7th July 1959 are shown in Figs. 8 and 9.

The offshore wave approach direction and period were required to simulate the wave patterns on the computer. Since no directional wave data was available it was necessary to estimate this value from wind data, assuming that wind waves would follow the path of the wind.

The mean hourly speed and direction during the day of the flights was available from the Meteorological Office wind station at Calshot, located as shown in Fig. 5. As an example, on 7th July 1959 winds were approximately 12 knots (6 m/s) from a direction of 150° from a positive x-axis for seven hours centred about mid-day. The wave approach angle in deep water was assumed to be from this direction. The significant wave height was estimated using an expression relating U to H_s as described by Henderson and Webber (1979(b)) for this particular site and given by:

$$H_s = 8.26 \times 10^{-3} U^{1.627} \quad (7)$$

for onshore winds greater than 9 knots (4.5 m/s) where U is the wind speed in knots and H_s is in metres.

A scatter diagram (Henderson and Webber 1979(c)) was used to show that the estimated value of H_s of 0.5 m, in this case, was associated with an upward zero crossing wave period, T_z , of 4.5 s.

Fig. 10 shows the computer simulated wave orthogonals for a wave period of 4.5 s and an offshore approach angle of 150° from a positive x-axis.

When Figs. 8 and 9 are compared with Fig. 10 reasonable comparability can be seen at locations where wave crests can be identified on the aerial photographs. The wave direction throughout the modelled area and at the shoreline are well depicted by the refraction diagram with the exception of the "shadow region" in Christchurch Bay. In this area, wave diffraction has occurred at the Needles bringing more energy into the Bay than is shown on the refraction diagram which ignores the effects of diffraction. Regions of crossed wave orthogonals can be identified from the aerial photographs in approximately the same positions as those in the refraction diagram.

A comparison of the results of 6th July 1960 and 20th November 1962 for approach angles from the south-west give similar results. Fig. 11 shows the refraction diagram modelling conditions on 6th July 1960 and it is evident that, without diffraction, no disturbances in

Fig. 8 Aerial photograph for 7th. July 1959 (British Crown Copyright Reserved / D.O.E. Photograph)

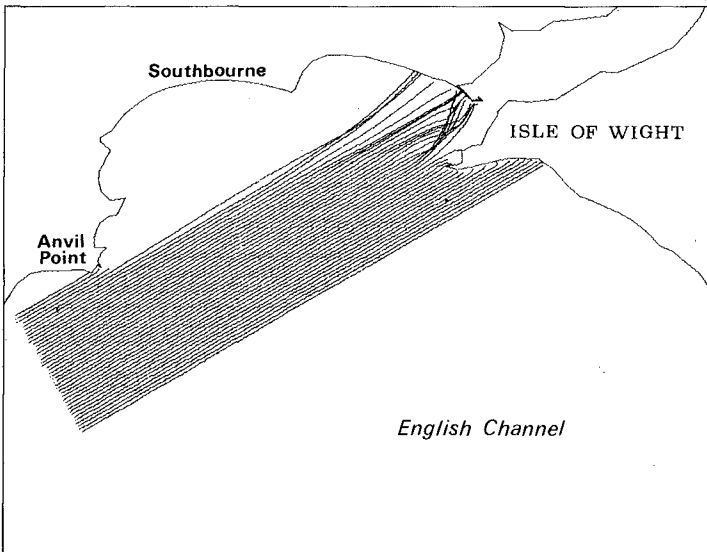

Fig. 11 Computer simulated wave orthogonals for 6th. July 1960

the lee of the headland at Anvil Point are predicted - a feature contrary to actual conditions shown in the aerial photographs.

Although the general conclusions noted above are useful, no detailed analysis has been possible. The aerial photographs are difficult to interpret because the sea surface is reasonably calm and no information is given concerning the variation of the angle at the shoreline as compared with those predicted in the model. In addition, as noted above, no indication of the comparison of wave height values is given. The aerial photographs have, therefore, provided little confidence in the refraction diagram especially in the important region at the shoreline.

7 VERIFICATION UTILISING RECORDED AND OBSERVED WAVE DATA

The aerial photographs having provided only some general indications as to the applicability of the wave refraction model and with no radar observations available, it was necessary to verify the refraction model using some alternative procedure. The method adopted made use of the recorded Waverider Buoy data, the observed breaking wave data and wind information from local Meteorological Office Stations as well as observed winds from coastguards and other personnel.

Listed tables of recorded wave parameters from the Waverider Buoy were inspected on a daily time basis. To avoid the difficulties of simulating swell waves with regard to offshore direction and in an attempt to select unidirectional wind wave trains only, limitations were placed on data that was considered of use in the present analysis. These were:

- (1) Consecutive values of H_s must be rising from a sea state with H_s less than 0.5 m. Values of H_s must return to below 0.5 m before data is considered.
- (2) The values of H_s must exceed 1 m.
- (3) It was evident that the maximum available water depth at the beach site, taking into account tidal variation, was 2.5 m. Hence the value of H_s should be less than 2.0 m.
- (4) A beach observation of breaking waves must have been made at approximately the same time as the data recording from the Waverider Buoy.

A total of 76 records were classified as having satisfied these conditions. The data available for each record for a known day and time consisted of the values of H_s and T_z at the Waverider Buoy site and the observed breaking wave height, H_{bo} and breaking wave angle, θ_{bo} .

At the particular time of each of these records, wind data from six sources was considered in detail as shown in Fig. 5. Portland Bill, Hurn and Calshot Spit are authoritative Meteorological stations recording mean hourly wind speeds and directions. Anvil Point wind data, recorded at the Lighthouse Station, consisted of direction estimated by compass and speed measured by an anemometer at three hourly intervals corresponding to the recording of wave data by the Waverider Buoy. The Bournemouth Pier data consisted of an estimated direction and speed at

approximately mid-day. The Southbourne data was recorded by the wave observer and comprised wind direction and speed.

Utilising this wind data a fairly comprehensive picture of the wind field was available. With consideration given to the fluctuation of wind direction over the preceding six hours, it was possible to estimate the offshore approach angle of the wind to the nearest 10° . With the conditions listed above, the waves were assumed to follow the wind thus providing the vital offshore wave approach direction, θ_o .

For a particular comparison, the recorded H_s was hindcast to deep water using values of K_R and K_S , and to correspond to the correct angle θ_o . The wave period was assumed constant and equal to T_z . This yielded the deep water significant wave height H_{s0} . The grid depths were adjusted to be equivalent to the tidal level at the time of the comparison. For some of the more acute angles (e.g. $\theta_o = 30^\circ$) it was impossible to track the wave orthogonals towards the shoreline from deep water and obtain sufficient refraction for the waves to impinge at the correct location. In such cases the wave orthogonals were started within the Bays and so the resulting waves would be more locally generated.

With values of H_{s0} , T_z and θ_o wave orthogonals were run at an offshore spacing of 50 m until they were stopped at the breaking condition. Provided they had reached the correct location at the shoreline, a region of 250 m width at the Southbourne beach observer site, the values of H_{sb} and θ_b were stored and averaged.

These wave parameters were compared with the observed values of breaking wave height, H_{b0} (equivalent to the significant wave height at breaking) and the breaking wave approach angle θ_{b0} .

8 COMPARISON OF BREAKING ANGLES

The observed (θ_{b0}) and computed (θ_b) breaking angles made by the wave orthogonals with a positive x-axis at the shoreline have been plotted in Fig. 12.

There are three interesting portions to the graph:

- (1) For angles of θ_{b0} between 76° and 100° there is reasonable agreement between the two values with differences of 3° at the most.
- (2) For angles of θ_b less than 90° the value of θ_b is less than θ_{b0} by an average of 3.6° , although variations of up to 14° are illustrated. This suggests that the real sea waves undergo greater deviation than is predicted in the model, such that the wave crests are more parallel to the shoreline at breaking.
- (3) For angles of θ_b greater than, or equal to 90° , the value of θ_b is greater than θ_{b0} by an average of 7.2° although individual points differ by as much as 20° . A similar implication to that in (2) can be made in that the modelled orthogonals are more perpendicular to the coastline at breaking.

Fig. 12 A Comparison of observed and predicted breaking approach angle

Fig. 13 A Comparison of observed and predicted breaking wave height

Fig. 14 The difference between predicted and observed breaking wave height as a function of predicted breaking approach angle

These results may indicate that the omission of diffraction effects produce modelled wave orthogonals which undergo less movement than is recorded in the field. This is most apparent when wave orthogonals enter the Bay area at oblique angles, there being only minor deviations for approach angles close to due south. It appears that wave orthogonals are modelled more accurately with westerly than easterly components, probably because of the more complex bed topography and greater occurrence of shoals for waves from easterly directions.

It should, of course, be noted that the method of verification is subject to certain inaccuracies, especially with regard to the prediction of the offshore approach angle θ_0 which was approximated to the nearest 10° .

9 COMPARISON OF BREAKING WAVE HEIGHTS

Fig. 13 shows a plot of the observed (H_{b0}) and computed (H_{sb}) breaking wave heights. There is a fair degree of scatter of the points but, on average, values of H_{sb} are 0.05 m greater than H_{b0} .

In Fig. 14 variations between H_{sb} and H_{b0} have been plotted against θ_b . Also shown is the mean of the wave height difference and the standard deviation. The graph shows that for values of θ_b close to due south the wave height values are more comparable but that greater deviations occur as the approach angles become more oblique. This confirms the comments already made in that for approach angles close to due south when diffraction effects are least, the model reasonably predicts conditions at the shoreline. However, for orthogonal approach directions with westerly or easterly components there is a lateral shedding of wave energy, resulting in a smaller wave height at the shoreline than is predicted by the model.

10 DISCUSSION

Already a number of possible inaccuracies have been suggested but it is considered that the model input data was expressed as precisely as was possible without additional instrumentation. One of the major sources of error was in obtaining an offshore approach angle. The method described using incident wind direction appears to have provided a reasonably good value but there are no data to confirm this.

A further study was undertaken to give an indication of the effect of grid size on the angle of approach of the breaking waves. The inshore grid was made sixteen times coarser by increasing the element size from 125 m by 31.25 m to 1000 m by 250 m. The effect for a variety of offshore approach angles and wave periods was that the breaking wave orthogonal approach angle was increased by less than one degree using the coarser grid. In addition, the same angle showed much smaller differences for a grid four times coarser than the one employed for the analysis. Thus, it seems that the wave refraction model is not unduly affected by changes in grid size for the region considered.

The verification has been undertaken for only a small portion of

the modelled area at a relatively exposed position. An indication has been given of possible correction factors to breaking wave direction and height to bring the model more in line with real wave conditions. However, it would be very difficult to predict similar correction factors for other locations in the modelled region. Certainly the situation in Christchurch Bay would be more complex because water depths are less and a number of shoals exist offshore.

It is, however, evident that wave heights and approach angle parameters could be obtained more accurately which would be of benefit to calculations such as those for longshore drift using the C.E.R.C. formula.

In the present analysis, care has been taken to select recorded and observed data pertaining to unidirectional wave trains. For the more complex situation of superimposed waves from varying directions, no conclusions can be drawn concerning the breaking wave height and direction - apart from the fact that the wave refraction model itself cannot reproduce such conditions.

Although swell waves were not considered in the present analysis it would be possible to undertake a similar comparison provided an offshore approach angle can be assumed or recorded. This is often a fairly simple task since swell waves are unidirectional and, in addition, would be modelled more realistically by the refraction analysis.

Finally, the major criticism of the present model is the omission of diffraction. This is because other phenomena which would change wave height and direction in shallow water are considered to be relatively unimportant in the present case. Friction and percolation effects are probably small and currents, which rarely exceed 0.5 m/s, would cause only minor modifications.

11 CONCLUSIONS

There are few references to the verification of wave refraction models using field data in the published literature, despite the fact that such models are widely used in engineering practice.

A study of aerial photographs show that some general comparisons of wave patterns with refraction diagrams can be made, but that specific details cannot be examined.

A method of verification of such wave refraction models has been described in this paper. It utilises recorded and observed wind and wave data, and could be readily applied in other regions of the world.

At the site it is evident that for unidirectional southerly waves, the observed and computed breaking height and angle are reasonably comparable. For waves approaching with westerly or easterly components, the effects of diffraction are such that the actual wave crests impinge more parallel to the shoreline than is predicted in the model and with slightly lower wave heights. The mean variation in wave breaking angle

is 3.6° and 7.2° for westerly and easterly waves, respectively and a breaking wave height difference of 0.5 m is suggested.

The authors would like to stress the importance of such verifications if wave refraction models are to be used with confidence. There is also a need to verify such models using field data in areas of shoals and complex bed topography where caustics may be formed.

ACKNOWLEDGEMENTS

The authors are indebted to Dr. A.H. Brampton of the Hydraulics Research Station for kindly making available the refraction program and for his subsequent advice. The helpful guidance of Mrs. G. Jewell of the DATS 11 computer section in the Institute of Sound and Vibration Research at Southampton University is gratefully acknowledged.

The Ministry of Defence kindly made available a number of aerial photographs of the region. The Department of the Environment, the consulting engineers, Sir William Halcrow and Partners and Bournemouth Corporation are thanked for permission to utilise data obtained in wave recording and shoreline observation.

There is grateful acknowledgement of the financial support received from the British Council and the Royal Society enabling this paper to be presented.

CHAPTER 6

WAVE SHOALING CALCULATED FROM COKELET'S THEORY.

T. Sakai¹⁾ and J.A. Battjes²⁾

ABSTRACT

Cokelet's numerical non-linear theory for progressive, periodic gravity waves is applied to the two-dimensional shoaling of finite amplitude waves on a beach up to breaking. The shoaling curves so obtained are compared with existing shoaling curves calculated from different finite amplitude wave theories, and with existing experimental data. It was found that the shoaling curves calculated from Cokelet's theory predict higher wave height ratios than other curves. The agreement between the present curves and the experimental results is good except near the breakpoint, where the wave height of the present curves is larger than the experimental wave height.

INTRODUCTION

In recent years, significant developments have taken place in the field of non-linear theories for progressive, periodic gravity waves of constant form.

Schwartz (1974) derived recurrence relations between successive coefficients in a Stokes-type power series, which made it possible to find computer-generated solutions of very high order.

Cokeket (1977) modified the procedure developed by Schwartz. He calculated the wave parameters with great precision, for arbitrary depth-length ratio and arbitrary wave steepness up to the highest wave of permanent form.

For all practical purposes, Cokelet's work can be seen as giving an exact solution to the classical nonlinear irrotational gravity wave problem addressed first by Stokes. It is worthwhile to apply it in situations involving highly nonlinear waves. One such application is given in the present paper, in which Cokeket's results are being used to calculate the two-dimensional shoaling of finite-amplitude waves on a beach, up to breaking.

Shoaling calculations have been made previously by several authors, using one or another approximate non-linear theory of the Stokes type or the cnoidal type, or a semi-numerical theory. The majority of these theories is for periodic waves of permanent form in water of uniform depth.

 - 2) Professor, Dept. of Civil Engineering, Delft University of Technology, Stevinweg 1, Delft, The Netherlands

They are applied locally in water of gradually varying depth on the assumption that the rate of change of the wave parameters is sufficiently small so that its effect on the local wave behaviour is negligible.

While it is difficult to make an a priori assessment of the errors resulting from this assumption, it is reasonable to expect that the approximation improves with decreasing value of the relative depth change within an interval of one wavelength. Thus, provided that the bed slope is sufficiently small, depending on the depth-to-wavelength ratio, it seems reasonable to expect also that the calculated wave height variation in the shoaling process is more nearly exact when it is based on a more nearly exact theory for waves of permanent form in water of constant depth.

The paper is made up as follows. Some relevant points of Cokelet's theory are summarized first. This is followed by an outline of the shoaling calculations, and by a presentation of the results. Finally, a comparison is made with previously published shoaling curves and with experimental data.

The presentation in this proceedings paper is kept rather brief. The reader is referred to Sakai and Battjes (1980) for more details and quantitative formulations.

COKELET'S THEORY

Cokelet (1977) deals with the classical problem of two-dimensional irrotational periodic gravity waves of constant form in a fluid of constant density (ρ) and uniform mean depth (h) and with a stress-free upper surface. The equations describing these conditions are well known and will not be repeated here. Neither shall we describe in detail the method of solution employed by Cokelet.

For given values of ρ and g , the motion is specified entirely by the wave length λ (or, equivalently, the wave number $k = 2\pi/\lambda$), the wave height H (or, equivalently, the semi-wave height $a = H/2$), and the mean depth h . Cokelet makes all quantities dimensionless in terms of k , ρ and g .

An orthogonal system of rectilinear axes is used, with Ox horizontal, positive in the direction of wave advance, and with Oy vertical, positive upward. The reference plane $y = 0$ is chosen near but not in the mean water level. The elevation of the free surface is given by $y = \eta(x,t)$, and that of the sea bed by $y = -d$, so that $d + \bar{\eta} = h$, the mean depth (an overbar denotes a time average).

The Oxy frame of reference is chosen such that the Eulerian mean velocity is zero in all points below the level of the wave troughs. A consequence of this choice is that the mean mass transport in this reference frame is not zero.

A Fourier series development was assumed for the complex velocity potential as a function of the complex coordinate. The Laplace equation and the kinematic boundary conditions at the bottom and the free surface can be made to be satisfied exactly. Satisfaction of the condition of constancy of pressure at the free surface leads to a set of nonlinear algebraic equations which determine the Fourier coefficients completely.

The values of these could be computed on a digital computer up to very high order (>100) and with great accuracy (4 to 6 significant figures). In his calculations, Cokelet used a perturbation parameter ε , whose value ranges from zero for waves of vanishing steepness to 1 for waves of limiting height.

Cokelet has tabulated numerical values of several dimensionless dependent wave parameters as function of ε^2 and the relative depth kd . These parameters include the semi-wave height (a), the square of the phase speed (c^2), and a number of integral properties, such as the mean densities and fluxes of mass, momentum and energy.

For constant relative depth (kd), the wave steepness ka was found to be a monotonic function of ε^2 , but the phase speed and the integral properties appeared to have a maximum for some value of ε^2 a little less than 1, that is, for waves slightly less high than the highest wave possible for the given value of kd . This had been discovered earlier for the solitary wave by Longuet-Higgins and Fenton (1974), and for deep-water waves by Longuet-Higgins (1975).

CALCULATION OF WAVE SHOALING

Assumptions

We consider the classical, idealised wave shoaling problem: a purely periodic, two-dimensional wave motion, an impermeable, rigid sea bed of gentle slope and ending in a dry beach, zero reflection, and zero dissipation. As stated in the introduction, the bed slope is supposed to be sufficiently gentle for the local applicability of a theory for progressive waves of constant form in uniform depth.

The preceding assumptions imply a zero mean mass transport, and constancy of wave frequency and of onshore energy flux.

Adaptations of Cokelet's results

The conditions stated above required an adaptation of Cokelet's results in two ways.

First, we have transformed the results to a new reference frame by adding a vertically uniform mean counter-current, such that the mean mass flux would be zero. The transformed variables are indicated by a prime (e.g. σ' , the wave frequency, and F' , the mean onshore energy flux per unit span).

Secondly, we have non-dimensionalised the results with respect to ρ , g and σ' , instead of ρ , g and k , which had been used by Cokelet. The latter set is less suitable since k varies in the shoaling process, while σ' does not. Variables which have been made non-dimensional in terms of ρ , g and σ' are indicated by an asterisk.

Procedure of shoaling calculation

The onshore energy flux F' , suitably normalized for our purposes, is expressed entirely in terms of dimensionless quantities tabulated by Cokelet as functions of ε^2 and kd . We can write therefore

$$\bar{F}' = \bar{F}'(\epsilon^2, kd) . \quad (1)$$

Since the (dimensional) frequency σ' and energy flux F' are constant in the shoaling process, so is \bar{F}' . It is everywhere equal to its value in deep water, designated with a subscript "o":

$$\bar{F}'(\epsilon^2, kd) = \text{constant} = \bar{F}'_o . \quad (2)$$

The procedure of the shoaling calculation is broadly as follows. A deep-water steepness $H/\lambda = \pi^{-1}ka$ is chosen; this determines the deep-water value ϵ_o^2 , and subsequently all other dimensionless parameters of the motion in deep water, including \bar{F}'_o . For a chosen value of kd , Eq. 2 can be solved for ϵ^2 , as illustrated in Fig. 1. The local values of ϵ^2 and kd in turn determine the local values of all other dimensionless parameters, including ka , $k\bar{\eta}$, and k/k_o , so that the wave height ratio $H/H_o = a/a_o$ is known as a function of relative depth $h/\lambda_o = (d+\bar{\eta})/\lambda_o$, with the chosen value of H_o/λ_o as a parameter.

The variation of \bar{F}' with ϵ^2 and kd was found to be qualitatively similar to that of F of Cokelet's theory itself, in the sense that for each relative depth (kd) it has a maximum (\bar{F}'_m , say) for some value of ϵ^2 less than 1 (see Fig. 1). Eq. 2 has (one) real root(s) for sufficiently large kd -values only, such that the associated maximum of \bar{F}' is at least as large as the given deep-water value \bar{F}'_o (see Fig. 1). In smaller relative depths, where $\bar{F}'(kd) < \bar{F}'_o$, the waves cannot deliver the required energy flux. The point where $\bar{F}'_m(kd) = \bar{F}'_o$ (whose position is determined entirely by \bar{F}'_o , or by the deep-water wave steepness H/λ_o) is provisionally called the breakpoint. The shoaling calculations have been performed only up to that point. In the range of kd where Eq. 2 has two distinct roots in ϵ^2 , the smallest one was taken for reasons of continuity (see Fig. 1).

The numerical values of the functions referred to above were read from Cokelet's tables. In each of these, kd is constant, and ϵ^2 is varied, from 0 to 0.8 with increments of 0.1, and from 0.8 to 1 with increments of 0.01. The tables are given for ten values of e^{-kd} , ranging from 0 (deep water) to 0.9, with increments of 0.1. This grid proved to be too coarse for our shoaling calculations. Using cubic splines (Ahlberg et al, 1967), interpolated values were calculated first with respect to ϵ^2 , with a constant increment of 0.01, subsequently with respect to kd , with a constant increment of 0.02. This was necessary (and sufficient) to obtain a well-defined curve through the calculated points. However, near the breakpoint still greater accuracy with respect to kd is required because of the rapid variation of the wave parameters in that region. To locate the breakpoint, the equation $\bar{F}'_m(kd) = \bar{F}'_o$ was solved for kd to an accuracy of 10^{-4} , using cubic spline interpolations, after which a conventional shoaling calculation yielded the wave height at the breakpoint.

RESULTS

The calculations were performed for different values of the deep-water steepness H/λ_o , ranging from 0.001 to 0.1. The calculated values of H/H_o were plotted versus h/λ_o and a smooth curve was drawn through the points.

Fig. 1 Sketch illustrating procedure of shoaling calculation

The results are presented in Fig. 2 with a full line. The curve for $H_o/\lambda_o = 0$ is for the linear wave theory. The breakpoints of the non-linear shoaling curves have been connected by a smooth curve. Dashed lines indicate extrapolations.

It should be noted that the quantity λ_o is defined as the wave length in deep water, including non-linear effects. It must be distinguished from the deep-water wave length L_o in the linear approximation. Values of the ratio between the two as calculated by Cokelet (1977), are presented in Table 1, for those values of H_o/λ_o for which the shoaling curves were calculated.

Table 1 Non-linear effect on deep-water wavelength

H_o/λ_o	$0 \leq H_o/\lambda_o \leq 0.02$	0.04	0.06	0.08	0.10
λ_o/L_o	$1 \leq \lambda_o/L_o \leq 1.01$	1.02	1.04	1.07	1.10

DISCUSSIONS

The behaviour of the shoaling curves near the breakpoint deserves a special comment. The curves are seen to have a very steep gradient there. This is a consequence of the fact that (by definition) the energy flux has a maximum (in ϵ^2) at the breakpoint (see Fig. 1). This implies that an infinitesimal variation of ϵ^2 from its value at the breakpoint, at constant value of the energy flux \bar{F} , gives zero variation of kd . Since for constant kd the wave steepness is a monotonically increasing function of ϵ^2 , it follows that the gradient of the shoaling curve becomes infinite at the breakpoint.

The foregoing conclusion contrasts with the assumption of very gradual variation of the wave parameters, which was the justification for the use of a theory for waves of constant form in the calculation of wave shoaling. Notice also that it holds regardless of how small the bed slope is. The use of Cokelet's theory for wave shoaling calculation therefore leads to an internal inconsistency as the breakpoint is approached. Consequently, the behaviour of the waves near that point cannot be inferred from that theory, no matter how small the bed slope may be.

Comparisons with existing shoaling curves

There are several theoretical shoaling curves, calculated by using different finite amplitude wave theories.

Le Méhauté and Webb (1964) calculated shoaling curves of Stokes waves of the third order. Their curves are limited to rather large deep-water wave steepness due to the limitation of applicability of Stokes waves. Iwagaki and Sakai (1967) calculated shoaling curves for rather small deep-water wave steepness and small depth-length ratio. They used an approximate expression of Laitone's cnoidal wave theory of the second approximation which is called "hyperbolic waves". Fig. 2 shows the comparison of the shoaling curves calculated from Cokelet's theory with the above mentioned two kinds of shoaling curves. It is clear that the wave height ratio H/H_o of the present curves increases more rapidly with decreasing relative

Fig. 2 Full lines: shoaling curves based on Cokelet's theory; values of H/λ_0 are shown.
 Dashed lines, $h/\lambda_0 > 0.04$: shoaling curves after Le Méhauté and Webb (1964); values of H/λ_0 are shown.
 $h/\lambda_0 < 0.04$: shoaling curves after Iwagaki and Sakai (1967); values of H_0/λ_0 are shown.

depth than that of the other two kinds of curves. In general, the difference between the values of the present and other curves becomes large with decreasing water depth. The breaking wave height of the present curves is much larger than that of the other two kinds of curves.

Svendsen and Brink-Kjaer (1972) presented shoaling curves of cnoidal waves. They used Laitone's cnoidal waves of the first approximation (1963). Fig. 3 shows the comparison with their shoaling curves. (The values were read from a table in Skovgaard, Svendsen, Jonsson and Brink-Kjaer, 1974.) In their shoaling curves, the small-amplitude deep-water wave length (L_0) was used, for which reason we have replotted our curves as H/H_0 vs. h/L_0 ; however, we have not found it worthwhile to re-calculate a set of curves so as to obtain slightly different values of the deep-water steepness. The H/H_0 -values given by Svendsen and Brink-Kjaer are considerably smaller than those of the present paper. It must be pointed out in this respect that the former were obtained by matching the calculated energy flux values of the cnoidal theory and the linear theory at $h/L_0 = 0.1$, which gives a discontinuity in wave height. If the wave heights are matched instead, then the calculated H/H_0 -values increase significantly (Svendsen and Buhr-Hansen, 1976).

Shuto (1974) derived several practically useful formulae for wave shoaling from an equation of non-linear long waves including effects of dispersion and variable depth. The trend of Shuto's curves is found to be nearly the same as that of Iwagaki and Sakai's curves. The values of H/H_0 of Shuto's curves (not shown here) are smaller than those of the present shoaling curves.

Yamaguchi and Tsuchiya (1976) calculated shoaling curves from several kinds of finite amplitude wave theories. Their shoaling curves, calculated from Chappellear's (1962) cnoidal wave theory of the second approximation, which predict the highest wave height among their calculated curves, were compared with those of the present paper. The trend of these shoaling curves (not shown here) is also found to be nearly the same as that given by Iwagaki and Sakai.

All of the curves based on approximate shallow-water theories display a smaller rate of wave amplification as the breakpoint is approached, than the curves based on Cokelet's theory. But, as has been pointed out, the application of Cokelet's theory gives an inconsistency near the breakpoint. Therefore, although it may be an exact theory for waves of constant form, its use for the calculation of wave shoaling does not necessarily give more reliable results near the breakpoint than does the use of an approximate theory. Ironically, the inconsistency noted above has not appeared in the existing shoaling calculations, based on more approximate theories for waves of constant form, because in all of these theories the energy flux is an increasing function of wave height, up to the highest wave.

Comparison with experimental data

The theoretical shoaling curves calculated from Cokelet's theory are compared with experimental data. We have selected data published by Svendsen and Buhr-Hansen (1976), since these were obtained in waves which were relatively free from undesired disturbances. Svendsen and Buhr-Hansen's experiments were carried out on a plane beach of 1:35 slope. Six cases of

Fig. 3 Full lines: shoaling curves based on Coker's theory; values of H_0/λ_0 are shown.
 Dashed lines: shoaling curves after Svendsen and Brink-Kjaer (1972); values of H_0/L_0 are shown.

variation of wave height were discussed in their paper. These were used for the present comparison. The data were read from data tables which were kindly provided to the present authors.

From the experimental values of wave period, wave height and mean water depth at the toe of the slope, a deep-water steepness (H_0/L_0) was calculated on the basis of the shoaling theory of the present paper.

To estimate the damping due to boundary layers on the bed and the sidewalls, we used Hunt's theory (1952). Although this theory is based on the assumptions of small amplitude and laminar boundary layers, it is thought to be sufficient for an estimate of the damping, which is relatively small anyway. A damping factor C_d (ratio of local damped wave amplitude to local undamped amplitude) was calculated at several points on the slope up to the breakpoint. Its value was found to range from 2% to 7%. The theoretical wave height H was then calculated as

$$H = C_d \cdot H_0 \cdot (H/H_0)_t,$$

where $(H/H_0)_t$ is the wave height ratio of the present theoretical curves, and H_0 is the deep-water wave height determined in the calculation of H_0/L_0 . The still water depth was corrected for wave set-down.

Fig. 4 shows the comparisons between the theoretical wave height variation and experimental results obtained by Svendsen and Buhr-Hansen. The theoretical curve ends at its breakpoint. It is clear that in all cases the agreement with the experimental results is good except near the breakpoint. The theoretical wave height increases more rapidly near the breakpoint than the experimental wave height. The reason for this rapid increase has already been explained.

For completeness' sake, it is noted that Svendsen and Buhr-Hansen (1976) have compared Svendsen and Brink-Kjaer's shoaling curves (1972) to their data. The agreement was found to be very good even near the breakpoint, but only after the original curves were shifted upwards so as to have continuity in wave height at the point of matching with the (linear) theory for deeper water, at the expense of continuity in calculated energy flux.

CONCLUSIONS

Wave shoaling curves were calculated by using Cokelet's (1977) non-linear theory for progressive, periodic gravity waves of constant form in arbitrary uniform depth.

It was found that the shoaling curves calculated from Cokelet's theory show a rapid amplification as the theoretical breakpoint is approached, and that they have an infinite slope at their breakpoints. The reason for this is that the wave energy flux in Cokelet's theory has an intermediate maximum before the highest wave is reached. The rapid variation of wave height is inconsistent with the basic assumption of gradually varying wave parameters. In this meaning, the accuracy of the present curves near the breakpoint is poor.

Fig. 4, (1) Comparison of shoaling curves based on Cokelet's theory (corrected for viscous damping) with experimental results of Svendsen and Buhr-Hansen (1976)

Fig. 4,(2) Comparison of shoaling curves based on Cokelet's theory (corrected for viscous damping) with experimental results of Svendsen and Buhr-Hansen (1976)

The shoaling curves calculated from Cokelet's theory were compared with five kinds of existing shoaling curves calculated from different finite amplitude wave theories: Le Méhauté and Webb (1964), Iwagaki and Sakai (1967), Svendsen and Brink-Kjaer (1972), Shuto (1974), and Yamaguchi and Tsuchiya (1976). The curves of the present paper showed the largest amplification for all initial steepnesses and relative depths. However, except for the region near the breakpoint, the differences between most of the existing curves used in the comparison, and those from the present paper, are relatively minor.

ACKNOWLEDGEMENTS

The authors wish to express their gratitude to Dr. E.D. Cokelet, who kindly provided tables of interpolated values of quantities of his theory, which were useful in the first stage of this study, and to Dr. Ib.A. Svendsen, who gave unpublished tables of experimental data. Acknowledgement is also due to Mr. S. de Boer of the Department of Civil Engineering, Delft University of Technology, who assisted in the computer work. Finally, the first author wishes to thank the Delft University of Technology for granting him a Research Fellowship.

CHAPTER 7

A SURVEY OF "RANDOM" WAVE GENERATION TECHNIQUES

by J. Ploeg* and E.R. Funke**

Techniques of producing waves in hydraulic models and laboratory flumes have evolved from the simple electrical-mechanical technique of some 15 years ago, to the present sophisticated hydraulic-electric servo systems, controlled by on-line computers and capable of producing a large number of different types of sea states. An accurate definition of the required sea state has become very important, since it has been shown that different types of wave trains, although all having the same significant wave heights and periods, can produce large differences in the results of model tests. Even a specification of the input spectrum, including all relevant spectral parameters, is not sufficient. The occurrence of wave groups, for instance, has to be defined separately. Table 1 illustrates which sea state parameters (A-E) need to be defined and controlled in the laboratory for different types of model studies (1-9). This is just shown as an example, and does not pretend to be a definitive statement.

There exists presently a great variety of different techniques and methods to produce irregular waves and there is no assurance that testing the same model in different laboratories will give similar results. As a first step to address this problem, it was thought to be useful to determine the variety (or perhaps similarity) of all laboratory wave generation systems presently used. A discussion with representatives of a number of hydraulics laboratories and ship towing tanks in the spring of 1979 led to the organisation of a survey of wave generation and analysis systems. The results of the survey are shown in the same format as the questionnaire. A list of all institutes which participated is also included.

Summarizing the results of the survey is impossible within the text of this paper. A general conclusion to be drawn is, that there is a surprisingly large uniformity in the equipment and facilities used for modelling waves. Also, for the suggested definition of sea state, it would not be difficult to list the generally accepted parameters:

$$(S_I(f), S_R(f), f_p, H_{m0}, \epsilon_s, Q_p \text{ and } H_{z,max}, T_{H_{z,max}}, H_{1/3}, \bar{T}_z)$$

Many laboratories mention wave grouping, but only three institutes suggest a definition of the grouping parameter.

It appears that the next logical step has to be a draft proposal of a standard set of methods of wave generation techniques and data analysis methods, based on the results of this survey. The discussion of this presentation at the conference seemed to suggest to involve an existing international organisation, such as the IAHR, to produce such a draft. Other laboratories will hopefully perceive the need for an agreement on standard wave generation techniques and analysis methods, and actively cooperate with this project.

*Head and **Senior Research Officer, Hydraulics Laboratory, National Research Council of Canada, Ottawa, Canada.

SEA STATE PARAMETERS IN COASTAL AND MARINE ENGINEERING STUDIES

DATA REPORT OF QUESTIONNAIRES ON
WAVE GENERATION AND ANALYSIS SYSTEMS

GENERAL

Total number of questionnaires sent out to Hydraulics Lab: 184
 Total number of replies received from Hydraulics Labs: 98 (53%)
 Total number of questionnaires sent out to Ship Towing Tanks: 74
 Total number of replies received from Ship Towing Tanks: 44 (59%)
 Number of institutes included in replies which reported
 not having wave making facilities: Hydraulics Labs: 15
 Ship Towing Tanks: 9

The 83 Hydraulics Labs with wave making facilities reported a total of:

176 flumes equipped for regular waves
 79 flumes equipped for irregular waves
 15 flumes equipped for transient waves
 112 basins equipped for regular waves
 39 basins equipped for irregular waves
 7 basins equipped for transient waves.

The 35 Towing Tanks with wave making facilities reported a total of:

51 flumes equipped for regular waves
 31 flumes equipped for irregular waves
 13 flumes equipped for transient waves
 22 basins equipped for regular waves
 18 basins equipped for irregular waves
 6 basins equipped for transient waves.

A. TANKS AND WAVE MACHINES

Note: A distinction was made between wave flumes and wave basins in analyzing the questionnaires. When the length of a tank is larger than 5X the width it was classified as a "Flume"; when the length of a tank is smaller than 5X the width, it was classified as a "Basin". Also, the ranges of tank dimension were set at different limits for Hydraulics Laboratories and Ship Towing Tanks.

The Measurement of Incident and Reflected Spectra
Using a Least Squares Method

by

E.P.D. Mansard* and E.R. Funke**

ABSTRACT

A least squares method to separate the incident and reflected spectra from the measured co-existing spectra is presented. This method requires a simultaneous measurement of the waves at three positions in the flume which are in reasonable proximity to each other and are on a line parallel to the direction of wave propagation.

Experimental investigations have shown that there is good agreement between the incident spectra calculated by the least squares method and the incident spectra measured concurrently in a side channel.

1.0 INTRODUCTION

As a large number of hydraulic laboratories now have the capability of generating irregular sea states for their experimental investigations, the necessity for computing reflections in an irregular sea state has become urgent. The presently available technique for this purpose is a 2-point method advanced by Thornton and Calhoun (1972), Goda and Suzuki (1976), and Morden et al (1976), which consists of measuring simultaneously the co-existing wave spectra at two known positions on a line parallel to the direction of wave propagation and deriving from this the incident and reflected spectra. This method has, however, certain limitations.

This paper presents a 3-point method which uses a least square analysis for decomposing the measured spectra into incident and reflected spectra with greater accuracy and range. This method originally derived by Marcou (1969) was used extensively for reflections with periodic waves (Mansard, 1976) and yielded reliable results.†

Assistant* and Senior** Research Officers, Hydraulics Laboratory, National Research Council of Canada, Ottawa.

† A recently proposed method by Gaillard et al (1980) also employs a 3-point measurement and contains some similarity to the method described here.

This paper describes the extension of this method to irregular waves and presents some experimental results obtained with a rubble mound breakwater.

2.0 REFLECTION MEASUREMENTS FOR IRREGULAR WAVES

The main assumption underlying the analysis of reflections in an irregular sea state is that the irregular waves can be described as a linear superposition of an infinite number of discrete components each with their own frequency, amplitude and phase. Another assumption, which is also of importance, is that these components travel at their own individual phase velocities described by the dispersion relationship. The first assumption is a widely accepted axiom in irregular wave studies while the second one has been found, through experimental investigations, to be a good approximation for finite and infinite depths of water (Funke and Mansard, 1980).

2.1 The 2-point Method

This method consists of measuring simultaneously the co-existing waves (two progressive wave trains moving in opposite direction) at two known positions in the flume, in a line parallel to the direction of wave propagation. Fourier analysis of these two signals will then produce the amplitudes and phases of the wave components at these two positions, by means of which the standing wave can be resolved into incident and reflected waves. This method described in detail by Thornton et al (1972) and Goda et al (1976) was developed by applying linear wave theory to monochromatic waves.

The above 2-point method has, however, certain limitations:

1. Limited Frequency Range
 - a) If the spacing between the probes is too great, the coherency factor which estimates the relative phase stability in each spectral frequency band decreases as the frequency increases, thus making the calculations of reflections less reliable.
 - b) If the spacing is too short, then there is a loss of contrast in cross spectral analysis.
2. Critical Probe Spacing

If the probe spacing "x" is such that $x/L = n/2$ ($n=0,1,2 \dots$, $L =$ wave length), the values of reflections become indeterminate because the proposed equa-

tions have singularities at these values.

3. High sensitivity to errors in the measurement of waves due to:
 - a) Transversal waves in the flume,
 - b) Non-linear wave interactions,
 - c) Harmonics due to non-linearities,
 - d) Signal noise, measurement errors, etc.

In order to overcome the above limitations, a 3-point method using a least squares method was developed.

2.2.1 The Least Squares Method

A definition sketch for this analysis is presented in Fig. 1.

Let us assume that waves are travelling in a channel in a longitudinal direction and reflections from some arbitrary structure or beach are travelling in the opposite direction. Assume also that it is possible to measure simultaneously the linear superpositions of these waves at m points $p = 1, 2, 3$ to m , which are in reasonable proximity to each other and are on a line parallel to the direction of wave propagation.

The wave profile observed at any one of these probe positions may be given as a summation of discrete, harmonically related Fourier components, i.e.

$$\eta_p(t) = \sum_{k=1}^N A_{p,k} \cdot \sin\left(\frac{2\pi \cdot k \cdot t}{T} + \alpha_{p,k}\right) \quad (1)$$

where $A_{p,k}$ is the Fourier coefficient for frequency k/T ,
 T is the length of the wave profile which is being observed; thus the fundamental frequency is $f_0 = 1/T$,
 $\alpha_{p,k}$ is the phase relative to the time origin of the record,
 N is an upper limit of summation which depends on the maximum significant frequency component in the series.

The Fourier coefficients and their phases are obtained from a Fourier transform of the function

$$\eta_p(t), \quad 0 \leq t \leq T \quad (2)$$

and are given in polar form as:

$$B_{p,k} = A_{p,k} \cdot e^{i\alpha_{p,k}} \quad (3)$$

or in rectangular form as:

$$B_{p,k} = [A_{p,k} \cdot \cos(\alpha_{p,k}) + i \cdot A_{p,k} \cdot \sin(\alpha_{p,k})] \quad (4)$$

Since the spacing between the various probes is known and since it is established that (except for locked harmonics) individual frequency components in a composite wave train travel at their own celerity (Funke and Mansard, 1980; Goda and Suzuki, 1976), it is possible to calculate the phase relationships between the wave trains as observed by each of the three probes. The general equation for a progressive wave is:

$$\eta_x(t) = \sum_{k=1}^N C_k \cdot \sin \left(-\frac{2\pi \cdot k \cdot t}{T} + \frac{2\pi x}{L_k} + \theta_k \right) \quad (5)$$

where θ_k is some arbitrary phase related to the space and time origin of the function,
 x is a space variable measured from the space origin of the function in a direction of wave propagation,
 L_k is the wave length of frequency k/T .

The observation of wave activity made at point p can now be stated in terms of a summation of

- a) an incident wave $C_{I,k}$
- b) a reflected wave $C_{R,k}$
- c) a noise signal which may be caused due to
 - cross-nodal activity
 - locked harmonics
 - non-linear interactions
 - measurement errors.

Let the distance from the wave source to the probe at $p=1$ be $X1$ and let the distance from the probe at $p=1$ to the reflecting structure be $XR1$, then the wave profile as observed at the probe may be written as:

$$\begin{aligned} \eta_{p=1}(t) = & \sum_{k=1}^N C_{Ik} \cdot \sin \left(-\frac{2\pi \cdot k \cdot t}{T} + \frac{2\pi \cdot X1}{L_k} + \theta_k \right) \\ & + \sum_{k=1}^N C_{Rk} \cdot \sin \left(-\frac{2\pi \cdot k \cdot t}{T} + \frac{2\pi \cdot (X1+2 \cdot XR1)}{L_k} + \theta_k + \phi_k \right) \quad (6) \\ & + \Omega_1(t) \end{aligned}$$

FIG. 1
SET-UP FOR WAVE REFLECTION MEASUREMENT

where $\Omega_1(t)$ is the cumulative effect of all the corrupting signals at probe $p=1$ and ϕ_k is a phase change due to the reflecting structure. The second probe at $p=2$, which is displaced by a distance X_{12} from the probe at $p=1$ in the direction of incident wave propagation (see Fig. 1), will record a similar wave profile as Eq. 6 except the phase angles will now be

$$\left(-\frac{2\pi \cdot k \cdot t}{T} + \frac{2\pi \cdot (X_1 + X_{12})}{L_k} + \theta_k \right) \quad (7)$$

for the incident wave and

$$\left(-\frac{2\pi \cdot k \cdot t}{T} + \frac{2\pi \cdot (X_1 + 2 \cdot X_{r1} - X_{12})}{L_k} + \theta_k + \phi_k \right) \quad (8)$$

for the reflected wave. A similar argument will define the wave angles for other probe positions which are displaced by distances X_{1p} from the first probe.

Fourier transformation of the composite signal, as

described by Eq. 6, over the interval $0 < t < T$ yields:

$$\begin{aligned}
 F[\eta_{p=1}(t)] = B_{1,k} = & C_{I,k} \cdot \exp\left\{i \cdot \frac{2\pi \cdot X1}{L_k} + i \cdot \theta_k\right\} \\
 & + C_{R,k} \cdot \exp\left\{i \cdot \frac{2\pi \cdot (X1+2 \cdot XR1)}{L_k} + i(\theta_k + \phi_k)\right\} \\
 & + Y_{1,k} \cdot \exp \cdot i(\rho_{1,k})
 \end{aligned} \quad (9)$$

where $\exp(\alpha) = e^\alpha$.

Similarly the observed signal for the other probes can be given in terms of their Fourier transforms as:

$$\begin{aligned}
 F[\eta_p(t)] = B_{p,k} = & C_{I,k} \cdot \exp\left\{i \cdot \frac{2\pi \cdot (X1+X1P)}{L_k} + i \cdot \theta_k\right\} \\
 & + C_{R,k} \cdot \exp\left\{i \cdot \frac{2\pi \cdot (X1+2 \cdot XR1-X1P)}{L_k} + i(\theta_k + \phi_k)\right\} \\
 & + Y_{p,k} \cdot \exp \cdot i(\rho_{p,k})
 \end{aligned} \quad (10)$$

Since one is only interested in the phase differences between the various probes, Eqs. 9 and 10 may be simplified in such a manner that the relevant phase differences are revealed. Therefore, let:

$$\begin{aligned}
 Z_{I,k} &= C_{I,k} \cdot \exp\left\{i \cdot \frac{2\pi \cdot X1}{L_k} + i \cdot \theta_k\right\} \\
 Z_{R,k} &= C_{R,k} \cdot \exp\left\{i \cdot \frac{2\pi \cdot (X1+2 \cdot XR1)}{L_k} + i(\theta_k + \phi_k)\right\} \\
 Z_{N,p,k} &= Y_{p,k} \cdot \exp \cdot i(\rho_{p,k})
 \end{aligned} \quad (11)$$

Consequently one obtains for the first three probes:

$$B_{1,k} = Z_{I,k} + Z_{R,k} + Z_{N,1,k} \quad (12)$$

$$B_{2,k} = Z_{I,k} \cdot \exp\left\{i \cdot \frac{2\pi \cdot X12}{L_k}\right\} + Z_{R,k} \cdot \exp\left\{-i \cdot \frac{2\pi \cdot X12}{L_k}\right\} + Z_{N,2,k} \quad (13)$$

$$B_{3,k} = Z_{I,k} \cdot \exp\left\{i \cdot \frac{2\pi \cdot X13}{L_k}\right\} + Z_{R,k} \cdot \exp\left\{-i \cdot \frac{2\pi \cdot X13}{L_k}\right\} + Z_{N,3,k} \quad (14)$$

The Z_N terms cannot be measured, but for the purpose of solving for Eqs. 12, 13 and 14, a least squared error method may be employed as follows:

For convenience define

$$\psi_{p,k} = \frac{2\pi \cdot X1P}{L_k} \quad (15)$$

where $X1P$ is the distance between probe 1 and probe 'p'.

In particular let

$$\begin{aligned} \beta_k &= \psi_{2,k} = \frac{2\pi \cdot X12}{L_k} \\ \gamma_k &= \psi_{3,k} = \frac{2\pi \cdot X13}{L_k} \end{aligned} \quad (16)$$

Eqs. 12 to 14 may now be restated thus:

$$\begin{aligned} Z_{I,k} + Z_{R,k} - B_{1,k} &= \epsilon_{1,k} \\ Z_{I,k} \cdot e^{i\beta_k} + Z_{R,k} \cdot e^{-i\beta_k} &= B_{2,k} = \epsilon_{2,k} \\ Z_{I,k} \cdot e^{i\gamma_k} + Z_{R,k} \cdot e^{-i\gamma_k} - B_{3,k} &= \epsilon_{3,k} \end{aligned} \quad (17)$$

where

$$\epsilon_{p,k} = -Z_{N,p,k} + f_e(Z_{I,k}, Z_{R,k}) \quad (18)$$

By applying a least squares method one may find those values of Z_I and Z_R for which the sum of squares of $\epsilon_{p,k}$ for all 'p' is minimum. This should correspond to those values of $Z_{I,k}$ and $Z_{R,k}$ for which

$$f_e(Z_{I,k}, Z_{R,k}) = 0.$$

It is therefore required that

$$\sum_{p=1}^3 (\epsilon_{p,k})^2 = \sum_{p=1}^3 \left(Z_{I,k} \cdot e^{i\psi_{p,k}} + Z_{R,k} \cdot e^{-i\psi_{p,k}} - B_{p,k} \right)^2 \quad (19)$$

= a minimum.

It is assumed that this minimum is reached when both partial derivatives are zero, i.e.

$$\frac{d \left(\sum_{p=1}^3 (\epsilon_{p,k})^2 \right)}{d Z_{I,k}} = \frac{d \left(\sum_{p=1}^3 (\epsilon_{p,k})^2 \right)}{d Z_{R,k}} = 0 \quad (20)$$

Differentiating Eq. 19, one therefore obtains:

$$\sum_{p=1}^3 \left(Z_{I,k} \cdot e^{i\psi_{p,k}} + Z_{R,k} \cdot e^{-i\psi_{p,k}} - B_{p,k} \right) \cdot e^{i\psi_{p,k}} = 0 \quad (21)$$

and

$$\sum_{p=1}^3 \left(Z_{I,k} \cdot e^{i\psi_{p,k}} + Z_{R,k} \cdot e^{-i\psi_{p,k}} - B_{p,k} \right) \cdot e^{-i\psi_{p,k}} = 0 \quad (22)$$

Eqs. 21 and 22 may now be written as follows:

$$Z_{I,k} \cdot \left(1 + e^{i \cdot 2 \cdot \beta_k} + e^{i \cdot 2 \cdot \gamma_k} \right) + 3 Z_{R,k} = B_{1,k} + B_{2,k} \cdot e^{i\beta_k} + B_{3,k} \cdot e^{i\gamma_k} \quad (23)$$

$$Z_{R,k} \cdot \left(1 + e^{-i \cdot 2 \cdot \beta_k} + e^{-i \cdot 2 \cdot \gamma_k} \right) + 3 Z_{I,k} = B_{1,k} + B_{2,k} \cdot e^{-i\beta_k} + B_{3,k} \cdot e^{-i\gamma_k} \quad (24)$$

where β and γ were defined by Eq. 16. From these, the solu-

tions for Z_I and Z_R may be derived, namely:

$$Z_{I,k} = \frac{1}{D_k} \cdot \left[B_{1,k} \cdot (R1 + i \cdot Q1) + B_{2,k} \cdot (R2 + i \cdot Q2) + B_{3,k} \cdot (R3 + i \cdot Q3) \right] \quad (25)$$

and

$$Z_{R,k} = \frac{1}{D_k} \cdot \left[B_{1,k} \cdot (R1 - i \cdot Q1) + B_{2,k} \cdot (R2 - i \cdot Q2) + B_{3,k} \cdot (R3 - i \cdot Q3) \right] \quad (26)$$

where:

$$\begin{aligned} D_k &= 2 \cdot (\sin^2 \beta_k + \sin^2 \gamma_k + \sin^2 (\gamma_k - \beta_k)) \\ R1_k &= \sin^2 \beta_k + \sin^2 \gamma_k \\ Q1_k &= \sin \beta_k \cdot \cos \beta_k + \sin \gamma_k \cdot \cos \gamma_k \\ R2_k &= \sin \gamma_k \sin (\gamma_k - \beta_k) \\ Q2_k &= \sin \gamma_k \cdot \cos (\gamma_k - \beta_k) - 2 \cdot \sin \beta_k \\ R3_k &= -\sin \beta_k \sin (\gamma_k - \beta_k) \\ Q3_k &= \sin \beta_k \cdot \cos (\gamma_k - \beta_k) - 2 \cdot \sin \gamma_k \end{aligned} \quad (27)$$

2.2.2 Analysis Technique

The two equations (25 and 26) are solved independently for each frequency component (using the Fourier transform technique) or for each frequency band (using the technique of spectral analysis by the method of averaged periodogram) and then squared and scaled to give the incident and reflected spectra.

The parameters D_k , $R1_k$, $R2_k$, $R3_k$, $Q1_k$, $Q2_k$ and $Q3_k$ can be obtained easily from the trigonometric relations of the probe spacings. The characteristics of the co-existing wave profiles $B_{p,k}$ which can be expressed as:

$$B_{p,k} = [A_{p,k} \cdot \cos(\alpha_{p,k}) + i \cdot A_{p,k} \cdot \sin(\alpha_{p,k})] \quad (28)$$

are given by one of the above two techniques. The values of $A_{p,k}$ and $\alpha_{p,k}$ can be calculated directly from the Fourier transform, while in the case of spectral analysis they are

obtained by auto and cross spectral density analysis respectively.

By applying a suitable averaging window for spectral density analysis, a representative value of $B_{D,k}$ for each frequency band rather than for every frequency component is obtained. This technique significantly reduces the erratic variations of the reflection coefficient spectrum and, at the same time, reduces the computational task.

The different steps involved in calculating the solutions for the above Eqs. 25 and 26 are described below:

1. The outputs from the three probes are denoted as $\eta_1(t)$, $\eta_2(t)$ and $\eta_3(t)$. Execute auto-spectral density analysis on each record, yielding:

$$S1(k \cdot \Delta f), S2(k \cdot \Delta f) \text{ and } S3(k \cdot \Delta f)$$

Apply band-limiting, if required and provide spectral smoothing to obtain reliable estimates for each frequency bandwidth.

2. From the auto-spectra compute the amplitude spectra as follows:

$$A1(k \cdot \Delta f) = \sqrt{2 \cdot S1(k \cdot \Delta f) \cdot \Delta f} \quad (29)$$

and similarly for A2 and A3.

3. Obtain the cross-spectral density in polar form for $\eta_1(t)$ with $\eta_2(t)$ and $\eta_1(t)$ with $\eta_3(t)$. Apply band-limiting and smoothing identical to that applied under (1).
4. From the cross-spectra, extract the phase spectra

$$PH12(k \cdot \Delta f) \text{ and } PH13(k \cdot \Delta f)$$

Also set $PH11(k \cdot \Delta f) = 0$ for all k .

5. Pair up the amplitude and the phase spectra in polar form as follows:

$$\begin{aligned} A1(k \cdot \Delta f) & \text{ with } PH11(k \cdot \Delta f) \\ A2(k \cdot \Delta f) & \text{ with } PH12(k \cdot \Delta f) \\ A3(k \cdot \Delta f) & \text{ with } PH13(k \cdot \Delta f) \end{aligned}$$

6. Convert from polar to rectangular form so that

$$B1(k \cdot \Delta f) = \text{REC}\{A1(k \cdot \Delta f) \cdot \exp(PH11(k \cdot \Delta f))\}$$

etc.

7. For all k evaluate the angles $\beta(k \cdot \Delta f)$ and $\gamma(k \cdot \Delta f)$ as per Eq. 16. The wave length L_k must be evaluated in terms of the depth of water which may be considered average for the region in which the probes are located.
8. For all k evaluate all the terms of the set of Eq. 27.
9. Evaluate $Z_I(k \cdot \Delta f)$ and $Z_R(k \cdot \Delta f)$ according to Eqs. 25 and 26.
10. From Z_I and Z_R compute the spectral densities S_I and S_R by

$$S_I(k \cdot \Delta f) = |Z_I(k \cdot \Delta f)|^2 / (2 \cdot \Delta f)$$

and

$$S_R(k \cdot \Delta f) = |Z_R(k \cdot \Delta f)|^2 / (2 \cdot \Delta f)$$

11. The reflection coefficient is then evaluated from

$$R(k \cdot \Delta f) = |Z_R(k \cdot \Delta f)| / |Z_I(k \cdot \Delta f)|$$

12. The coherency factor should also be computed in order to evaluate the degree of significance of the incident and the reflected spectrum. Thus

$$CF_{12}(k \cdot \Delta f) = |S_{12}(k \cdot \Delta f)| / (S_1(k \cdot \Delta f) \cdot S_2(k \cdot \Delta f))^{1/2}$$

and

$$CF_{13}(k \cdot \Delta f) = |S_{13}(k \cdot \Delta f)| / (S_1(k \cdot \Delta f) \cdot S_3(k \cdot \Delta f))^{1/2}$$

3.0 EXPERIMENTAL SET-UP AND TEST RESULTS

Experimental investigations were carried out to determine the reflective characteristics of a rubble mound breakwater subject to irregular wave action. The set-up used for this purpose (Fig. 2) consists of a flume of dimensions 67 m x 1.8 m x 1.25 m, equipped with a hydraulically driven random wave generator. This wave generator, controlled by an on-line computer, can reproduce a variety of simulated natural sea states in the flume (Funke et al, 1980; Funke and Mansard, 1979).

As shown in Fig. 2, the width of the flume was subdivided into three sections: a centre channel of 0.9 m wide and two side channels of 0.45 m wide. The breakwater was placed in the centre channel while beaches with a mild slope of 1:20 ensured a good dissipation of the incident wave energy in the side channels. This particular set-up reduced the secondary reflections from the wave board since half of the secondary reflections were dissipated in the side channels.

FIG. 2 WAVE FLUME WITH PROBE LOCATIONS

The primary reflections in the side channels being very small (lower than 5% for long waves), the waves therein were considered more or less as pure incident waves. This allowed a direct comparison between the calculated and the actual incident wave spectra.

The waves were sampled simultaneously by the on-line computer at four probe positions (three in the central channel and one in the side channel). The probes used for this purpose are a variation of the Robertshaw capacitance probe which has proved to be quite reliable. The sampling of data, which was initiated only after the reflections had stabilized, was carried out for at least one cycle length of the time series (about 200 s in the model).

Tests were carried out using JONSWAP spectra and the results corresponding to two different peak frequencies are presented below in Figs. 3 and 4. Additional examples can be found in Mansard and Funke (1980).

These results show that the co-existing spectra measured at the three probe positions differ to a certain extent; the values of their characteristic wave height (H_{m0}) and their maximum wave height ($H_{z,max}$) vary. These variations, which could be attributed to the standing wave pat-

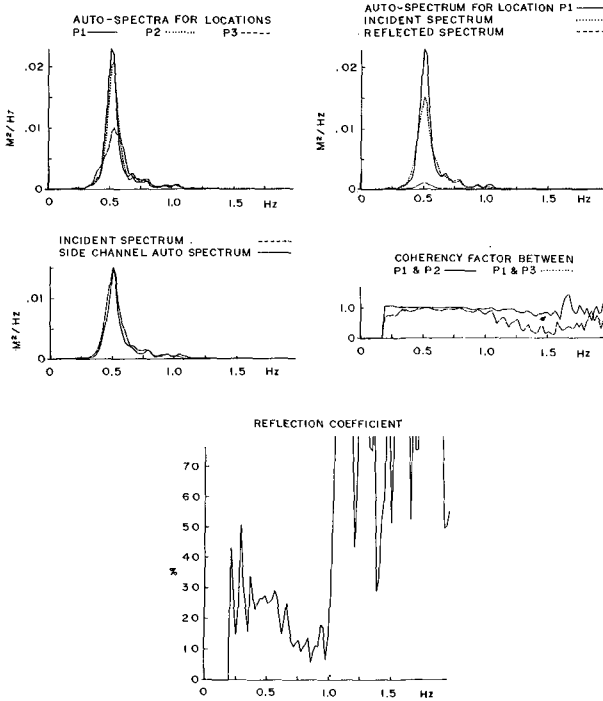

FIG.3 SEPARATION OF INCIDENT AND REFLECTED SPECTRA
FOR A RUBBLE MOUND BREAKWATER
($F_p = 0.51$ Hz)

tern, are found to be higher than 10% for many cases of the rubble mound breakwater study.

The incident spectra calculated by the least squares method are found to agree reasonably well with the spectra measured in the side channel thereby validating this technique as a useful tool in the decomposition of the co-existing spectra.

The reflection coefficients in each band of the spectrum are presented in terms of percentage of the corresponding incident wave height. Their variations do not exhibit any specific trend with respect to frequency. It can be shown, however, that their scatter is partly due averaging applied during spectral analysis.

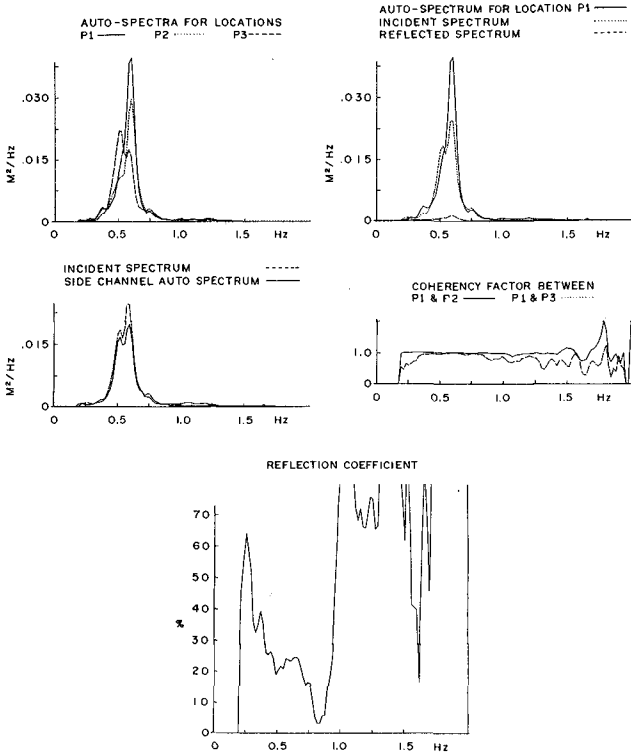

FIG.4 SEPARATION OF INCIDENT AND REFLECTED SPECTRA
FOR A RUBBLE MOUND BREAKWATER
($F_p = 0.60$ Hz)

Another important factor worth noting is the dependency of the reflection phenomenon on wave steepness. Therefore, the reflection coefficient spectrum is highly dependent on the incident spectrum and can only be considered an average value of reflection for each frequency band over the duration of the sample record.

It must also be considered quite likely that the reflection phenomenon leads to a transfer of energy between different frequency bands and not just to its attenuation. Some incident energy at frequency f_a may therefore be radiated back at frequency f_b and appear consequently as an amplification of reflected energy at f_b .

In the range of frequencies where the incident spectrum is very low, the signal to noise ratio is very low. As a result the estimation of reflection coefficients is subject to errors and therefore produces spurious variations.

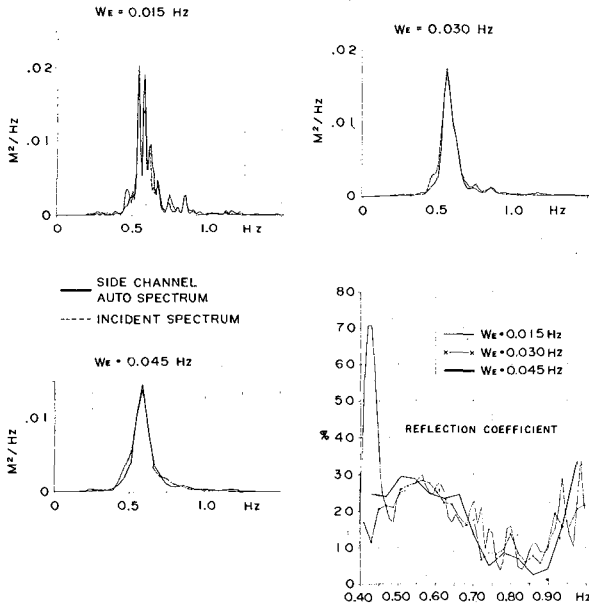

FIG. 5 EFFECT ON THE CALCULATION OF REFLECTIONS
DUE TO SMOOTHING WINDOW SIZE
($F_p = 0.57$ Hz)

The coherency factor $CF(f)$, presented in these figures, gives an indication of the relative phase stability in each frequency band between cross-correlated records. This is therefore a direct measure of the degree of confidence which could be attributed to the reflection coefficient in each band. When $CF(f)$ is close to unity, the records are said to be well correlated and the opposite applies when it approaches zero. Results show that $CF(f)$ decreases with an increase in frequency or with an increase in probe spacings. Where the spectrum has almost zero energy, $CF(f)$ appears to exceed 1. This is clearly incorrect and can be attributed to low signal to noise ratios.

3.1 Effect of Smoothing Spectra

The smoothing of spectra in the analysis of prototype wave data is generally performed in order to improve the reliability of estimating power within a certain band of frequencies. This operation may be performed implicitly, by applying so-called "data windows" in the time domain, or explicitly, by using various frequency windows or filters in the frequency domain. In either case, the net effect is the averaging of several weighted power estimates within a frequency bandwidth defined by the particular window function chosen.

The price to be paid for improved reliability is a loss of resolution or fidelity of analysis (Jenkins and Watts, 1968). Fidelity is the ability of an analysis to reveal the true characteristics or details of a process. A low fidelity analysis would lead to a blurring or smearing of those details which may or may not be a true characteristic of the process under investigation.

The statistical techniques for the choice of window bandwidth in the analysis of prototype wave data are based on the assumption that each individual contributing component within the width of the window is a member of a stochastic process. It is important to realize that this situation does not generally apply to the analysis of wave data under laboratory conditions. If, as is usually the case, the waves were generated by some deterministic process, then the process is also deterministic in the frequency domain and the question of statistical reliability must only be answered in relation to the noise which is added to the wave data by the various mechanisms which were identified in section 2.1.

As the mixture of noise and deterministic signal is not known at this time, the question of a best choice of window bandwidth cannot be answered. Instead it may be better to experiment with different windows and compare the results. A more formal procedure along this line is known as "window closing" and is described by Jenkins and Watts (1968).

For the purpose of this report three separate explicit Hanning windows (Blackman and Tuckey, 1958) were used on laboratory generated wave data with bandwidth of 0.015, 0.03 and 0.045 Hz respectively. The results are shown in Fig. 5. The relatively small differences in results suggest that the solution is fairly stable.

3.2 Effect of Probe Spacings

Past studies using monochromatic waves (Marcou, 1969) have shown that the estimation of the incident and reflected waves are not influenced by the choice of probe spacings. However, there is one critical combination of the probe spacing for which the reflection analysis will be invalid.

The main expression used for the estimation of incident and reflected waves (Eqs. 25 and 26) will become indeterminate if its denominator D_k is equal to zero (one of these equations is given below for easy reference).

$$Z_{I,k} = \frac{1}{D_k} \cdot \left(B_{1,k} \cdot (R1+i \cdot Q1) + B_{2,k} \cdot (R2+i \cdot Q2) + B_{3,k} \cdot (R3+i \cdot Q3) \right)$$

where $D_k = 2 \cdot (\sin^2 \beta_k + \sin^2 \gamma_k + \sin^2 (\gamma_k - \beta_k))$

D_k is equal to zero if

$$\sin \beta_k = \sin \gamma_k = \sin (\gamma_k - \beta_k) = 0$$

$$\text{or } \sin \beta_k = \sin \gamma_k = 0$$

$$\text{or } \sin \left(\frac{2\pi \cdot X12}{L_k} \right) = \sin \left(\frac{2\pi \cdot X13}{L_k} \right) = 0$$

This occurs when

$$X12 = \frac{jL_k}{2} \text{ and } X13 = \frac{m}{n} \cdot X12$$

where j , m , n and m/n are integers and L_k is the wave length for the frequency components ($k \cdot \Delta f$) under consideration. In other words the reflection calculations become indeterminate when:

1. the distance $X12$ is equal to half wave length of the frequency component under consideration or even multiples of half wave length .AND.
2. the distance $X13$ is an integer multiple of the distance $X12$.

More research may be carried out to determine the optimum probe spacing for greatest accuracy and widest bandwidth. The coherency function and, perhaps the spectrum of residues as given by equation 19 could probably be used as a criterion.

On the basis of experience gained at the Hydraulics Laboratory at the National Research Council, and experiments carried out by Marcou (1969) using monochromatic waves, the following range of probe spacings are recommended:

$$X_{12} = L_p/10$$

$$L_p/6 < X_{13} < L_p/3 \quad \text{and} \quad X_{13} \neq L_p/5 \quad \text{and} \quad X_{13} \neq 3L_p/10$$

Another parameter which is of similar importance is the distance of probes from the reflective structure (test structure and wave paddle). It has been shown by Ishida (1972) and Goda et al (1976) that the co-existing wave height fluctuates to a certain extent near the reflective structures. However, these fluctuations become negligible beyond a distance of one wave length. Hence it is suggested that the probes be located at least one wave length (wave length corresponding to peak frequency) away from the reflective structures.

4.0 CONCLUSIONS

A satisfactory technique based on least squares analysis is described whereby the incident and reflected spectra are resolved from the measured co-existing spectra.

There is good agreement between the incident spectrum calculated by the least squares method and the corresponding spectrum measured concurrently in the side channel.

This method can be considered as superior to the 2-point method since it has:

- a) wider frequency range,
- b) reduced sensitivity to noise and deviations from the linear theory and,
- c) lesser sensitivity to critical probe spacing.

The effect of varying the size of smoothing window in the calculation of the incident spectrum has been found to be relatively small. However a relationship between the best smoothing window and the general properties of the wave spectrum is still a subject of continuing research.

Suitable locations of probes are recommended. Probe spacings which must be avoided to eliminate singularities are also defined.

CHAPTER 9 .

ORBITAL VELOCITIES IN IRREGULAR WAVES

by

F.C. VIS

Project Engineer

Delft Hydraulics Laboratory

The Netherlands

1 ABSTRACT

Experimental and theoretical study to determine the applicability of linear wave theory for the description of the velocity field in irregular waves. A comparison between theory and measurement was executed both in frequency and in time domain. In frequency domain by means of the experimentally and theoretically determined frequency response functions of wave motion to orbital velocity, and in time domain by means of the measured and computed time records of the velocities. The time records for the velocities were computed from the measured waterlevel fluctuations by using the impuls response function method. The orbital velocities were measured contactless with laser-doppler equipment.

2 INTRODUCTION

In order to determine the applicability of linear wave theory for conversion of irregular wave motion to wave induced orbital velocities near the bottom, the Delft Hydraulics Laboratory has carried out in the past experimental investigation where the velocities were measured by means of a propeller-type flowmeter. The results of this study were used for the computation of wave forces on submarine pipelines. Although in general a reasonable agreement was found between theory and measurement, also significant discrepancies were observed. However, these discrepancies had to be ascribed to the distortion of the flow by the flowmeter.

The development of the laser-doppler velocity meter made it possible to measure accurately the orbital velocities in an extremely small area, without influence of the meter. With this accurate instrument new experiments in irregular waves were carried out, where apart from the bottom velocity also the horizontal and vertical orbital velocities at half water depth and just beneath the deepest trough were measured. The program

comprised waves of moderate steepness at intermediate depth/wavelength ratios ($0.008 < h/g T_p^2 < 0.069$, $0.0009 < H_s/g T_p^2 < 0.0064$). It appeared that the discrepancies mentioned above were indeed due to inaccuracies of the flowmeter and that the agreement with linear wave theory was even better than was found in the first set of experiments.

3 NOTATION

a	distance from the bottom where the velocities were measured
a_{cs}	significant crest of the waves
a_{c1}	crest exceeded by 1% of all the crests of the wave record
a_{ts}	significant trough of the waves
a_{t1}	trough exceeded by 1% of all the troughs of the wave record
g	acceleration of gravity
h	water depth
$H(\omega)$	computed frequency response function
$\hat{H}(\omega)$	"measured" frequency response function
$h(\tau)$	impuls response function
H_s	significant wave height
H_1	wave height exceeded by 1% of all the heights of the wave record
i	$\sqrt{-1}$
k	wave number
$S_{xy}(\omega)$	cross-spectrum
$S_{xx}(\omega)$	auto-spectrum
u_{cs}	significant crest velocity of the horizontal velocity component u
u_{c1}	crest velocity exceeded by 1% of all the crest velocities of the record of the horizontal velocity component u
u_{ts}	significant trough velocity of the horizontal velocity component u
u_{t1}	trough velocity exceeded by 1% of all the trough velocities of the record of the horizontal velocity component u
v_{cs}	significant crest velocity of the vertical velocity component v
v_{c1}	crest velocity exceeded by 1% of all the crest velocities of the record of the vertical velocity component v
v_{ts}	significant trough velocity of the vertical velocity component v
v_{t1}	trough velocity exceeded by 1% of all the trough velocities of the record of the vertical velocity component v
ϵ	relative error

4 THEORETICAL APPROACH

In Appendix A it is shown that according to the linear wave theory the water level fluctuations $\eta(t)$ and the horizontal and vertical orbital velocity components $u(t)$ and $v(t)$ at distance a from the bottom are mutually related by

$$u(t) = \int_0^{\infty} h_u(\tau) \{ \eta(t-\tau) + \eta(t+\tau) \} d\tau \quad (1)$$

$$v(t) = \int_0^{\infty} h_v(\tau) \{ \eta(t-\tau) - \eta(t+\tau) \} d\tau, \quad (2)$$

where $h_u(\tau)$ and $h_v(\tau)$ are impuls response functions. The corresponding frequency response functions are given by

$$H_u(\omega) = \frac{\omega \cosh ka}{\sinh kh} \quad (3)$$

$$H_v(\omega) = i \frac{\omega \sinh ka}{\sinh kh} . \quad (4)$$

The "measured" frequency response functions $\hat{H}_u(\omega)$ and $\hat{H}_v(\omega)$ can be obtained from the measured data by using the relation

$$\hat{H}(\omega) = \frac{S_{xy}(\omega)}{S_{xx}(\omega)}, \quad (5)$$

where $S_{xy}(\omega)$ is the cross-spectrum of input (wave motion) and output (orbital velocity component) and $S_{xx}(\omega)$ is the auto-spectrum of input (see e.g. Bendat and Piersol, 1971).

5 MEASUREMENTS

5.1 Experimental Set-up

The tests were carried out in the 2 meter wide windwave flume of the Delft Hydraulics Laboratory. In this flume irregular waves can be generated up to a height of 30 cm by means of wind and/or a hydraulically driven wave generator. A detailed description of the wave generator is given in (DHL, 1976). For the actual tests no wind was applied. The water level fluctuations were measured by means of a resistance type wave height meter, consisting of two vertical metal rods, and the orbital velocities were measured by means of a laser-doppler equipment which could simultaneously measure horizontal and vertical component. A description of the laser-doppler velocity meter is given in (Godefroy, 1978). In order to measure the undisturbed velocities with this instrument, the walls of the flume had to be translucent for transmitting the laser beams. As this was not the case, the flume was partially provided with an inner flume with perspex walls (see Figure 1). For absorption of the waves, beaches were used with a slope of 1:10 for minimal reflection.

Wave motion and orbital velocities were simultaneously measured in the same cross-section of the flume at a mutual distance of 20 cm. This distance proved to be sufficient for avoiding disturbance of the velocity measurement by the wave height meter. As the waves were long-crested this solution could be used.

For elaboration with the computer the measured signals were digitized with sample frequency of 25 Hz.

5.2 Test Program

The test program comprised irregular waves of moderate steepness at intermediate depth/wave length ratios, which are the normal working conditions for offshore structures. The wave parameters are given in Tables I and II. The wave heights, defined as the maximum difference of the record between two succeeding zero-down crossings, appeared to be nearly Rayleigh distributed. As an example the energy density spectrum of a wave record and the corresponding cumulative frequency distribution of the wave heights at test 16 are presented in Figures 2 and 3. Velocities were measured at three locations along the vertical: the horizontal bottom velocity just outside the boundary layer, and the horizontal and vertical components at mid-depth and just beneath the deepest trough (see Tables I and II).

6 COMPARISON OF THEORY AND MEASUREMENT

The comparison of the measured velocities in irregular waves with the linear wave theory has been carried out in frequency domain and, except for the bottom velocities, also in time domain.

In frequency domain theory and measurement were compared by defining a relative error ϵ by

$$\epsilon = \frac{1}{N} \sum_{i=1}^N \left| \frac{|\hat{H}(\omega_i)| - |H(\omega_i)|}{|H(\omega_i)|} \right|,$$

where the "measured" frequency response functions $\hat{H}(\omega_i)$ were determined by (5), and $H(\omega_i)$ by means of (3) or (4). The notation $|\cdot|$ denotes the

amplitude of the (complex) number. The relative errors ϵ have been evaluated only for those frequencies ω_i for which both the spectral density functions of input and output were greater than 10% of their peak value, as for smaller values the spectral densities are relatively inaccurate. All spectra were computed using a Fast Fourier Transform method. The relative errors are given in Tables I and II. The indices u and v have been attached for distinction between horizontal and vertical velocity.

Figure 4 presents most amplitudes of the "measured" and computed frequency response functions.

A comparison in time domain was executed for the velocities above the bottom by computing the time records of the orbital velocity components, for which either (1) or (2) was used, and by comparing them with the measured ones. The significant and the 1% crest and trough velocities are presented in Tables III and IV. Crest and trough velocities are defined in accordance with crests and troughs of the wave motion by the maximum positive and maximum negative velocity between two succeeding zero-down crossings. A positive velocity means for the horizontal velocity a velocity in direction of propagation of the waves, and for the vertical velocity a velocity in upwards direction.

An example of measured and computed time record is presented in Figure 5 and in more detail in Figure 6.

7 DISCUSSION OF THE RESULTS

It is remarkable to see from the comparison in frequency domain that the velocities near the free surface match linear wave theory better than the velocities at mid-depth, whereas in view of test results in regular waves (see e.g. Le Méhauté, Divoky and Lin, 1968) just the opposite would be expected. This phenomenon was observed for both the orbital velocity components. The bottom velocities were indeed in more agreement with linear wave theory than the velocities at mid-depth. However, from the comparison in time domain, as far as executed, these tendencies could not be observed.

From Table III it appears that for the horizontal velocities the trough velocities are greater in magnitude than the crest velocities, contrary to the wave motion where the crests are higher than the troughs. The vertical velocities appeared to be distributed more symmetrically. It is important to note that these tendencies are followed by linear wave theory in most cases. However, when a higher order wave theory, such as the fifth order Stokes' method of De (1954), would be used for description of the velocity field in the individual waves of the irregular sea (the so-called deterministic approach) just the opposite would be found, apart from the fact that with respect to the crests of the waves only a "symmetrical" velocity distribution would be found. Also when linear wave theory is used in the random phase model, these tendencies will not be found, just as a consequence of the random phases by which equal crest and trough velocities will be found.

8 CONCLUSIONS AND RECOMMENDATIONS

In the present study low to moderately steep irregular waves have been

investigated, and it appeared that linear wave theory gives a reasonable description of the velocity field, in particular for the velocities near the free surface just beneath the deepest trough.

In view of these results it is advised to carry out further investigation of the applicability of linear wave theory to more severe wave conditions and to the velocities in the crests of the waves.

It will also be interesting to check linear wave theory for a spatial description of the velocity field. As for long-crested waves the correlation between water level fluctuations and orbital velocities in the same vertical has now been shown, this investigation can then be restricted to a check of the correlation in space of the wave motion at different locations. This was already investigated by Lundgren and Sand (1978), who found that the dispersion of the waves over limited distance is well described by linear wave theory, but that deviations increase with increasing distance. For directional seas research of the velocity field is necessary.

APPENDIX A. THEORY OF LINEAR SYSTEMS

Suppose that $x(t)$ is the input and $y(t)$ the output or response of a linear system and that $X(\omega)$ and $Y(\omega)$ are the corresponding Fourier transforms. Put $H(\omega)$ equal to the ratio $Y(\omega)/X(\omega)$; thus

$$Y(\omega) = H(\omega) \cdot X(\omega) \quad (A.1)$$

Inverse Fouriertransform of this relation yields the well-known convolution expression

$$y(t) = \int_{-\infty}^{+\infty} h(\tau) x(t-\tau) d\tau, \quad (\text{A.2})$$

where $h(t)$ is the inverse Fouriertransform of $H(\omega)$, given by

$$h(t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} H(\omega) e^{i\omega t} d\omega \quad (\text{A.3})$$

Often $h(t)$ is denoted by impuls response function, as

$$h(t) = \int_{-\infty}^{+\infty} h(\tau) \delta(t-\tau) d\tau,$$

and $H(\omega)$ by frequency response function.

Expression (A.1) yields the relation between input and output of the linear system in frequency domain and (A.2) in time domain. Thus if the frequency response function $H(\omega)$ of the linear system is known, then the response $y(t)$ on any arbitrary input can be computed, either by using (A.3) followed by (A.2), or by using (A.1), in which case first the input has to be Fouriertransformed, resulting in $X(\omega)$, and the output $Y(\omega)$ has to be Fourier inverted in order to obtain $y(t)$.

The frequency response function between wave motion and orbital velocity component at distance a from the bottom (both in the same cross-section of the flume) can be found with linear wave theory by putting as input of the linear system the wave motion in frequency domain

$$X(\omega) = e^{i\omega t} = \cos\omega t + i \sin\omega t. \quad (\text{A.4})$$

(Note that $e^{i\omega t}$ is the Fouriertransform of the impulse on time $-t$; t has to be considered as a parameter.)

According to linear wave theory the response $Y(\omega)$ is then given by

$$Y(\omega) = \frac{\omega \cosh ka}{\sinh kh} e^{i\omega t} \quad (\text{A.5})$$

for the horizontal orbital velocity component, which is defined positive in wave direction, and by

$$Y(\omega) = i \frac{\omega \sinh ka}{\sinh kh} e^{i\omega t} \quad (\text{A.6})$$

for the vertical orbital velocity component, which is defined positive in upwards direction.

Then by using (A.1) the frequency response functions can be determined to be

Fig. 7 Impuls response function for the horizontal orbital velocity component at test 14 and 16.
 $\omega_0 = 15 \text{ rad/s}$, $t_0 = 4.0 \text{ s}$

$$H_u(\omega) = \frac{\omega \cosh ka}{\sinh kh} \tag{A.7}$$

$$H_v(\omega) = i \frac{\omega \sinh ka}{\sinh kh}, \tag{A.8}$$

where indices u and v have been attached for distinction. With the aid of (A.3) it follows that

$$h_u(t) = \frac{1}{\pi} \int_0^\infty \left\{ \frac{\omega \cosh ka}{\sinh kh} \cos \omega t \right\} d\omega, \tag{A.9}$$

$$h_v(t) = \frac{1}{\pi} \int_0^\infty \left\{ \frac{\omega \sinh ka}{\sinh kh} \sin \omega t \right\} d\omega, \tag{A.10}$$

where also use was made of the property that the impuls response of a physical system is real. From these expressions it can be seen that $h_u(t)$ is an even and $h_v(t)$ an odd function of t. With these properties it follows from (A.2) that the horizontal and vertical orbital velocity components u and v at distance a from the bottom are respectively given by

$$u(t) = \int_0^\infty h_u(\tau) \{ \eta(t-\tau) + \eta(t+\tau) \} d\tau \tag{A.11}$$

$$v(t) = \int_0^\infty h_v(\tau) \{ \eta(t-\tau) - \eta(t+\tau) \} d\tau \tag{A.12}$$

It is remarkable to see from these relations that the response on time t depends on the wave motion $\eta(t)$ before and after t. Thus, not only the past but also the future of $\eta(t)$ determines the velocities at time t. Physically seen this is rather strange. However, it has to be realized that these relations are based on linear wave theory where it is assumed that the sinusoidal wave motion is present from $t = -\infty$ to $t = +\infty$. In view of this basic assumption, the results (A.11) and (A.12) could be expected.

In order to achieve existing integrals in (A.9) and (A.10), the constituent functions $H_u(\omega)$ and $H_v(\omega)$ have been put equal to zero for $\omega > \omega_0$, which implies that the response on input in this frequency range is zero. However, this interference is no limitation if ω_0 is chosen such that for higher frequencies the input signal does not contain energy.

For numerical computation of the integrals in (A.11) and (A.12), the functions $h_u(t)$ and $h_v(t)$, which approach to zero for $t \rightarrow \infty$, have been put equal to zero for $t > t_0$, where t_0 is chosen such that for $t > t_0$

$$|h(t)| < \epsilon \cdot \max_p |h(p)|$$

(e.g. is 0.01). An example of $h_u(t)$ is presented in Figure 7.

CHAPTER 10

INVESTIGATIONS ON IRREGULAR WAVES IN HYDRAULIC MODELS

by

Karl-Friedrich Daemrich, Wolf-Dietrich Eggert

Sören Kohlhasse

Franzius-Institut, University of Hannover, Germany

ABSTRACT

The first part of the paper deals with some aspects of wave generation by mechanical wave-generators, especially with hydraulic transfer functions for pusher movement of the paddle, and the influences of signal characteristics and analysis methods. In the second part, results of measurements of orbital velocities and pressures in irregular waves are presented, together with some results from theoretical simulation methods in the frequency and time domain, based on linear wave theory.

SCOPE OF INVESTIGATIONS AND INSTRUMENTATION

The possibility of the generation of predictable and reproducible irregular waves with servo-controlled wave-machines extends considerably the validity of hydraulic models and also allows an effective basic research for the improvement of dimensioning methods.

To get an impression of the transformation process of paddle-generated waves, hydraulic transfer functions between pusher movement of the board and generated wave trains are measured in different water depths, using as well noise spectra as natural wave trains as a basis for control signal calculations.

The investigations on orbital velocities and pressures in irregular waves are presented mainly under the aspect of the applicability of special analysis and simulation methods within investigations with irregular waves.

The investigations were performed in a wave basin of the "SONDERFORSCHUNGSBEREICH 79" and in a wave channel at the FRANZIUS-INSTITUTE of the University of Hannover (Table 1).

	wave basin	wave channel
length	45 m	118 m
width	18 m	2.2 m
max. water depth	0.6 m	1.5 m
max. wave height	0.4 m	0.5 m

Table 1: Dimensions of the hydraulic models

Both facilities are equipped with servo-controlled hydraulically driven wave generators and allow predefined partial flap/partial piston motions of the wave board.

Control signals were generated with a "WAVE SYNTHESIZER" as developed at the "HYDRAULIC RESEARCH STATION WALLINGFORD" and with a "WAVE SIGNAL GENERATOR" consisting of a tape-reader, a Digital to Analog Converter and some more electronic equipment, as produced by the "DANISH HYDRAULIC INSTITUTE".

The "WAVE SYNTHESIZER" generates pseudo-random signals with selectable power spectra and different sequenth lengths. However, the generated signals do not consider special wave characteristics like flat troughs and peaked crests or a definite wave grouping. The "WAVE SIGNAL GENERATOR" reads digitized data from punchtape and converts them to analog signals. With this instrument it is possible to generate control signals with arbitrary characteristics. The input signal may be converted with a built in approximate transfer function for pushertype motion. This allows to generate wavetrains - which are numerically described by the punch tape - at the wave board without any further calculations.

INVESTIGATIONS ON WAVE GENERATION

To generate a suitable spectrum in a basin or a channel the following transfer functions have to be considered:

- the mechanical transfer function of the wave-generator
- the hydraulic transfer function between paddle movement and generated wave at the paddle or near the paddle
- the transfer function for the transformation of the waves with increasing distance from the wave-generator.

The characteristics of the mechanical transfer function of the wave generator depend on the type of the generator and the settings of the servo-amplifiers and shall not be discussed here.

To prove the validity of the theoretical hydraulic transfer functions, several test series were performed. Fig. 1 shows a comparison of measured and theoretical transfer functions for a deepwater wave spectrum with noise characteristics.

Fig. 1 Measured and theoretical hydraulic transfer functions for different wave steepnesses in deepwater ($d/(g \cdot T_m^2) = 0.058$)

a) $H_{1/3}/(g \cdot T_m^2) = 0.0051$ (nonbreaking waves)

b) $H_{1/3}/(g \cdot T_m^2) = 0.0077$ (slight breaking of high waves)

The wave probe was located in a distance of 5 m from the wave board. The transfer function was calculated from one sequence length of the pseudo-random signal (1024 data) without any averaging in this case, while the spectrum was smoothed by a moving average (11 data) in the frequency domain.

There is a rather good agreement between theory and measured values, even for slight breaking conditions, and it can be seen that it may be possible, to measure transfer functions very effective also with such an unrealistic wave spectrum.

As a next example results from waves in more transitional water are used to demonstrate the influence of the control signal characteristics.

From former tests in smaller water depths it could be expected, that transformation processes influence the quality of the hydraulic transfer functions.

Transformation process is called the changing of the wave train from a simple irregular water level fluctuation without any typical characteristics - for instance generated by a band-limited noise signal - to a wave train with distinct characteristics (peaked crests and flat troughs) depending on the relative water depth. We therefore selected a natural wave train as a basis for control signal generation of this example (Fig. 2).

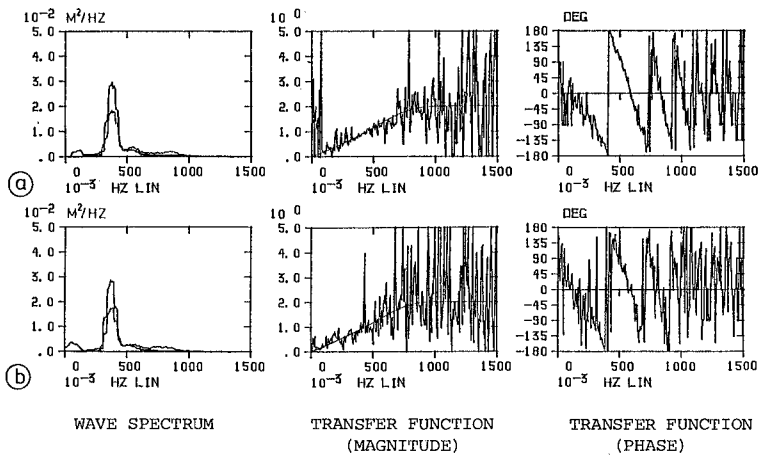

Fig. 2 Measured and theoretical hydraulic transfer functions for different signal characteristics in transitional water depths ($H_{1/3}/(g \cdot T_m^2) = 0.0056$); $d/(g \cdot T_m^2) = 0.025$)

- a) natural wave train
- b) random wave train with same amplitude spectrum, but random phase spectrum

Fig. 2a shows the measured transfer function using a wave train which was generated according to the natural wave train. This wave train includes all characteristics typical for the water depth and the period-range.

Contrarily, Fig. 2b shows the transfer function measured with an artificial wave train with the amplitude spectrum corresponding to the natural wave train, but with random

phase values of the frequency components.

The distinct minor scatter of the first transfer function may be seen as an indicator for the optimization of the control signal i.e., the transformation of the wave train from random-noise characteristics to the suitable and necessary characteristics for this waterdepth is indicated clearly by an increased scatter in the transfer function.

The next example shows hydraulic transfer functions in different water depths for wave spectra, generated with pseudo random control signals (Fig. 3).

Fig. 3 Measured and theoretical hydraulic transfer functions for different water depths d (pseudo random control signals)

To make clearer the increasing losses, the transfer functions were smoothed in the frequency domain for this example.

The differences between measured and theoretical transfer functions are increasing with decreasing water depths. This may be explained by the stronger transformation processes.

These examples lead to the conclusion that for deepwater and to some extent also for transitional water depths the theoretical transfer functions are sufficient to calculate control signals for spectrum generation, but that corrections are necessary in small relative water depths, especially if bandlimited random noise signals are used as control signals.

Finally, the problem of generating special wave trains in a definite distance from the wave board shall be mentioned.

Some tests were performed, simulating a self-correcting system with the DHI-WAVE SIGNAL GENERATOR. The desired wave train was used as an input signal and corrected with the measured transfer function. This correction was repeated several times. It was found that with a well characterized wave train as a first input signal the first correction leads to rather good results (Fig. 4). However, this work is only at the beginning and demands more experience.

Fig. 4 Simulation of a self-correcting system with the DHI-WAVE SIGNAL GENERATOR

SOME REMARKS ON THE CALCULATION OF TRANSFER FUNCTIONS

As shown for demonstration before, the transfer functions were generally calculated from wave trains with pre-defined repetition periods and always the complete sequenth-length was analyzed as one data block. Sometimes a frequency smoothing was performed.

Calculation in that way was done, because the distance between the wave board and the wave probe leads to unrealistic values of the measured transfer functions, if the time series is shared into small time cycles, and the final results were calculated from the averaged auto-power and cross-power spectra. The following example may demonstrate this (Fig. 5).

Fig. 5 Influence of the calculation method on the magnitude and phase of a transfer function

- a) averaged auto- and cross-spectrum
- b) without averaging but with equivalent frequency smoothing of the magnitude

Fig. 5a shows a transfer function calculated from eight parts of the time series using the averaged auto- and cross-power spectra; Fig. 5b shows the transfer function calculated from the same time series without averaging, but with an equivalent frequency-smoothing.

The tendency can be seen clearly. The averaged transfer function (Fig. 5a) does not describe the change in the wave spectrum sufficiently.

DEVELOPMENT OF THE WAVE SPECTRUM WITH INCREASING DISTANCE

Fig. 6 shows two examples of measured transfer functions between 5 and 12.5 m from the wave board (Fig. 6a) and between 15 and 22.5 m (Fig. 6b).

The change in the spectrum, expressed by the magnitude of these transfer functions, is not very important.

In addition, the development of some wave parameters from 2.5 to 30 m from the wave board in intervals of 2.5 m was calculated for this example (Table 2).

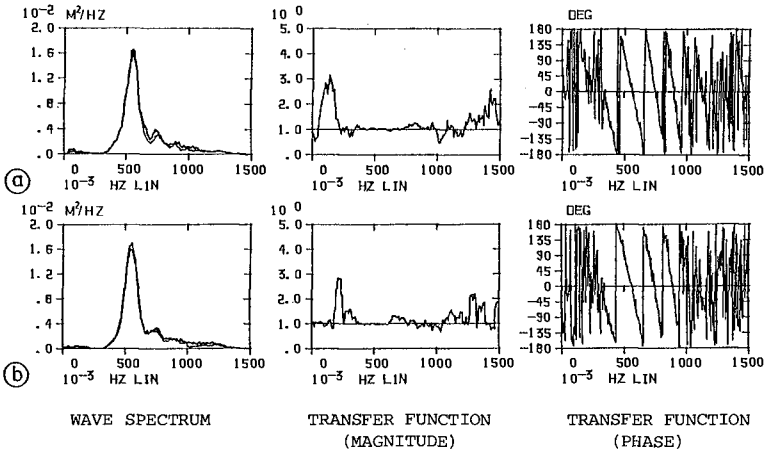

Fig. 6 Changes of the wave spectra with increasing distance and transfer functions

- a) 5.0 m to 12.5 m from the wave board
- b) 15.0 m to 22.5 m from the wave board

distance [m]	H_s [cm]	$H_{1/3}$ [cm]	$H_{1/10}$ [cm]	H_{max} [cm]	$T_{m0,1}$ [sec]	T_m [sec]	Q_p -
2.50	16.1	14.9	18.3	23.3	1.59	1.50	3.46
5.00	15.7	15.3	19.1	22.8	1.53	1.51	3.43
7.50	15.9	15.3	18.4	23.8	1.57	1.60	3.58
10.00	15.7	15.5	18.6	22.0	1.57	1.58	3.44
12.50	16.1	15.8	19.3	24.6	1.57	1.60	3.47
15.00	15.9	15.3	18.2	22.3	1.55	1.49	3.59
17.50	15.7	15.0	18.2	22.0	1.58	1.52	3.54
20.00	15.6	15.2	17.9	23.2	1.55	1.57	3.65
22.50	15.8	14.9	17.5	20.7	1.59	1.62	3.77
25.00	16.0	15.4	18.1	22.9	1.56	1.53	3.90
27.50	16.1	15.5	19.1	22.0	1.56	1.59	3.95
30.00	15.7	15.2	18.3	21.6	1.57	1.61	3.91

Table 2: Wave parameters in different distances from the wave board

It can be seen that characteristic wave parameters, e. g. significant wave heights or mean periods, derived from the spectrum or from the time series did not change with a clear tendency over this distance.

Only the peakedness factors Q_p show a slight trend from about 3.4 at the first wave gauge^B to 3.9 in a distance of 30 m.

ORBITAL VELOCITIES IN IRREGULAR WAVES

Velocities and pressures, the actual values causing the load of a structure, are used as an input for many dimensioning methods dealing with wave forces on structures.

It was the purpose of the investigations to check simulation methods with respect to the prediction of velocities and pressures, especially the maximum positive and negative values in every single irregular wave.

Inductive type and impeller type probes were used to measure horizontal and vertical velocity components. However, transfer functions were only calculated from signals of the inductive type probe.

The spectra were mostly JONSWAP-spectra, generated with the "WAVE SYNTHESIZER", but additionally a natural wave train and a random noise spectrum were investigated for comparison.

The significant wave heights ranged from 10 to 25 cm, the water depth was 1.0 m in most of the tests; the velocities were measured in different depths (- 0.25 m, - 0.50 m, - 0.85 m).

The first step of the analysis was the calculation of the transfer function between wave spectrum and velocity spectrum and the comparison with the theoretical transfer function according to linear wave theory.

Fig. 7 shows exemplarily some typical results for velocity components measured in a depth of 25 cm below "still water level".

It can be stated, that there are no significant differences between the transfer functions of the different wave spectra, and even or just the spectrum in Fig. 7b yields to a good agreement with the theory.

However, it was the purpose of the investigation, to predict maximum positive and negative velocities in every wave of a given wave train. Therefore, three simulation methods on the

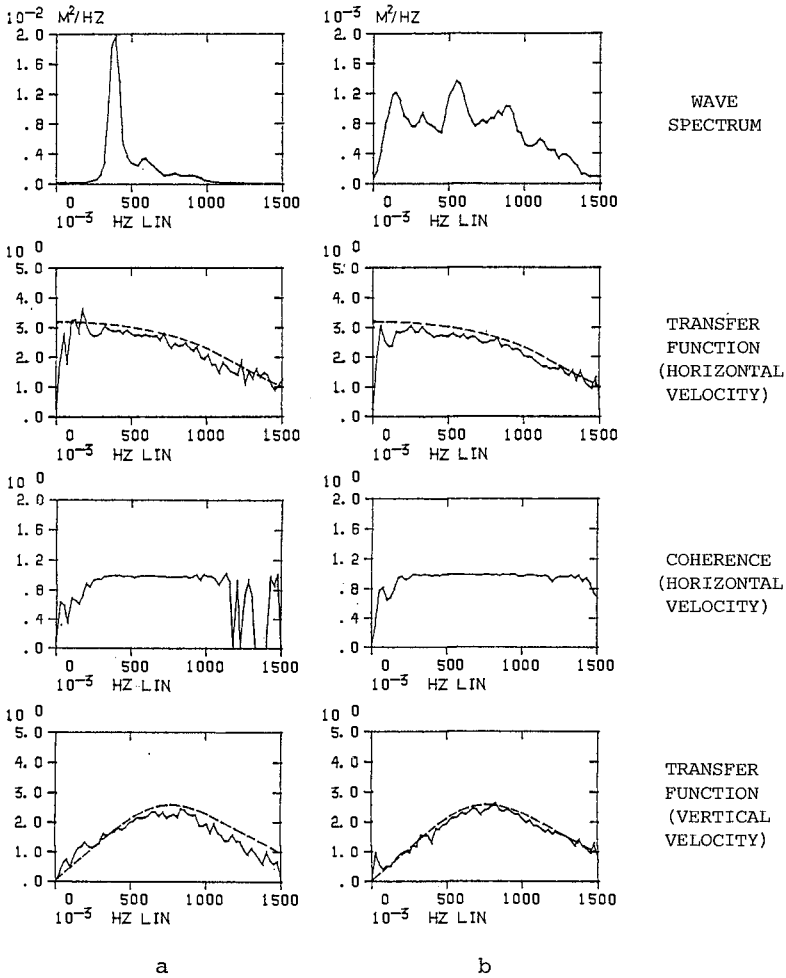

Fig. 7 Transfer functions and coherence functions of orbital velocities
 a) natural wave train
 b) random noise control signal

basis of linear wave theory were applied, one in the frequency domain and two in the time domain.

For the superposition method with theoretical transfer functions the FOURIER-transformation of the measured wave train was calculated, each frequency component was multiplied with the pertinent value of the theoretical transfer function according to linear wave theory. The time series of the velocities was then recalculated or superimposed from this FOURIER-components. The maxima of the measured velocity time series were now compared with the maxima of the simulated velocities (Fig. 8).

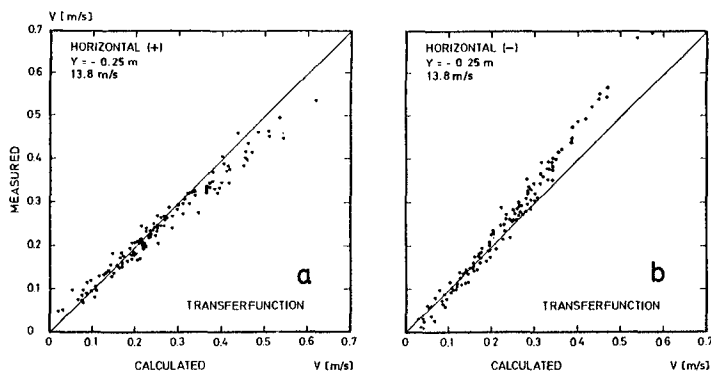

Fig. 8 Comparison of measured and with the theoretical transfer function predicted horizontal velocities (JONSWAP spectrum, $\gamma = 3.3$, $U = 13.8$ m/sec, scale 1 : 20)

- a) positive maxima
- b) negative maxima

The scatter of the data is relatively small, but the tendency is generally, that the measured horizontal velocities are lower than the predicted ones under a wave crest, and higher than the predicted ones under a wave trough.

The next two simulation methods are based on analysis methods in the time domain. Such methods have to be used, because it is not always possible to calculate a FOURIER-transformation, for instance when measurements are available only on recording chart, when signals are distorted or if there is no suitable computer equipment available. For these methods regular wave parameters must be defined for every irregular wave of the wave train.

A common method to define a wave parameter in the time domain is the zero-crossing method. For these examples the zero-down-crossing parameters were used to calculate velocities with the linear wave theory.

A typical result from the same test as Fig. 8 is shown by Fig. 9.

Fig. 9 Comparison of measured and predicted horizontal velocities according to zero-down crossing definition

- a) positive maxima
- b) negative maxima

The scatter of the data is remarkably wider in comparison to the superposition method.

A better definition for the physical efficient part of the wave was found by comparing the measured wave train and the pertinent velocity time series visually (Fig. 10).

The similarity of the both time series is evident. It seems that, for instance the velocity in the positive region has the same trend as the positive part of the wave. This effect, which is independent on the shape of the preceding wave trough leads to the following definition of the wave parameters for this special problem.

It was proved to take no longer the wave height and period of the whole wave, according to zero-crossing-definition, but to take the height and period of the pertinent halve wave to calculate the maximum velocities with linear wave theory.

Fig. 10 Example of time series of waves and pertinent measured horizontal velocities

Fig. 11 shows a sketch of this definition, which is called "complementary method" in the following.

Fig. 11

Definition sketch for determination of wave parameters according to complementary method (horizontal velocities)

This - in the physical sense - efficient part of the wave was completed to a full sine wave for calculation.

Comparative results from the simulation of horizontal velocities with the complementary method are shown in Fig. 12, again for the same test as shown by Fig. 8 and 9.

The scatter of the results is of the same order as the scatter of the results from the much more comprehensive superposition method and remarkably smaller than the results according to zero-crossing method.

In the following, two more examples of measurements of positive horizontal velocities are given.

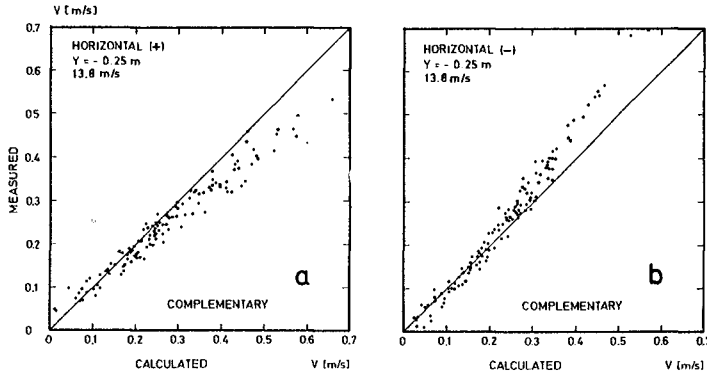

Fig. 12 Comparison of measured and predicted horizontal velocities according to complementary method

- a) positive maxima
- b) negative maxima

Fig. 13 shows results derived from measurements in a natural wave train with wave heights and periods similar to the preceding example.

For all simulation methods the scatter is of the same order as in the example before.

Finally, Fig. 14 shows results from a test with a wave time-series similar to the first example, but with amplitudes of only 50 %.

The scatter is very small in comparison to the examples before, but still the same tendency can be seen.

The velocities under the wave crest are generally smaller than the predicted values and, under the wave trough, they tend to be higher or equal to the predicted values.

The three simulation methods were also used to determine vertical velocities theoretically. For the complementary method it was proved to take the pertinent wave height as sketched in Fig. 15.

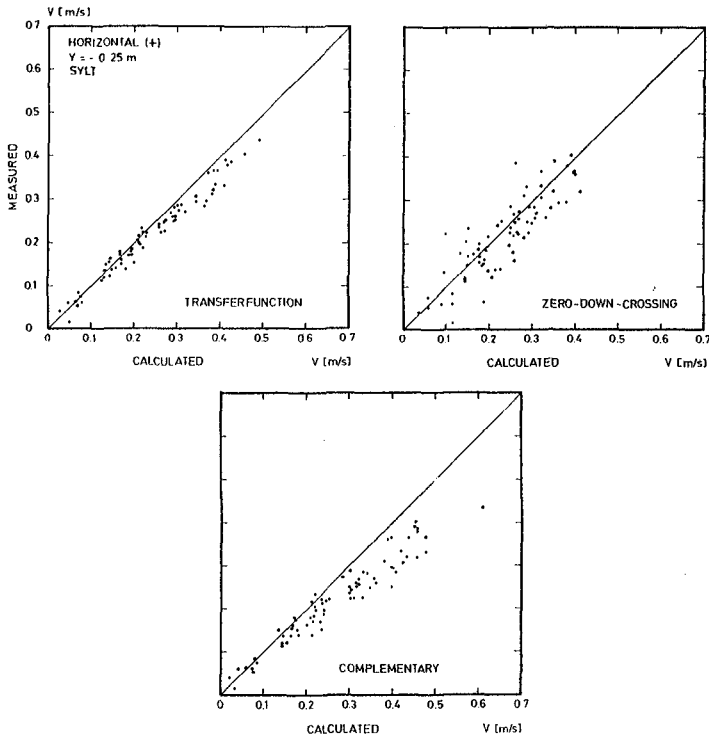

Fig. 13 Comparison of measured and predicted positive horizontal velocities according to different simulation methods (natural wave train)

For calculations of the positive maximum of the vertical velocity the wave height between the preceding trough and the crest was used and the wave height between the crest and the following trough for the calculation of the negative maximum of the vertical velocity respectively. The corresponding wave periods were defined as shown in Fig. 15.

Some results from the measurements of vertical positive and negative velocities are presented in Fig. 16.

The scattering of the data using the complementary method and superposition method (with theoretical transfer function) is of the same order but, contrarily to the results from horizontal velocity components, there is no remarkable difference between the positive and negative velocities.

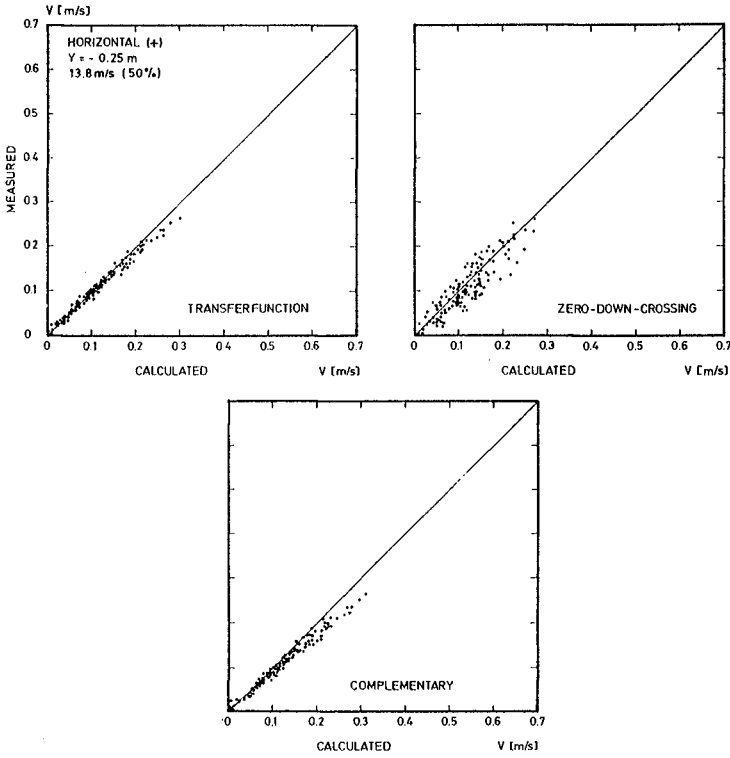

Fig. 14 Comparison of measured and predicted positive horizontal velocities according to different simulation methods (JONSWAP spectrum, $\gamma = 3.3$, $U = 13.8$ m/s, scale 1 : 20, halved amplitude)

Fig. 15

Definition sketch for determination of wave parameters according to complementary method (vertical velocities)

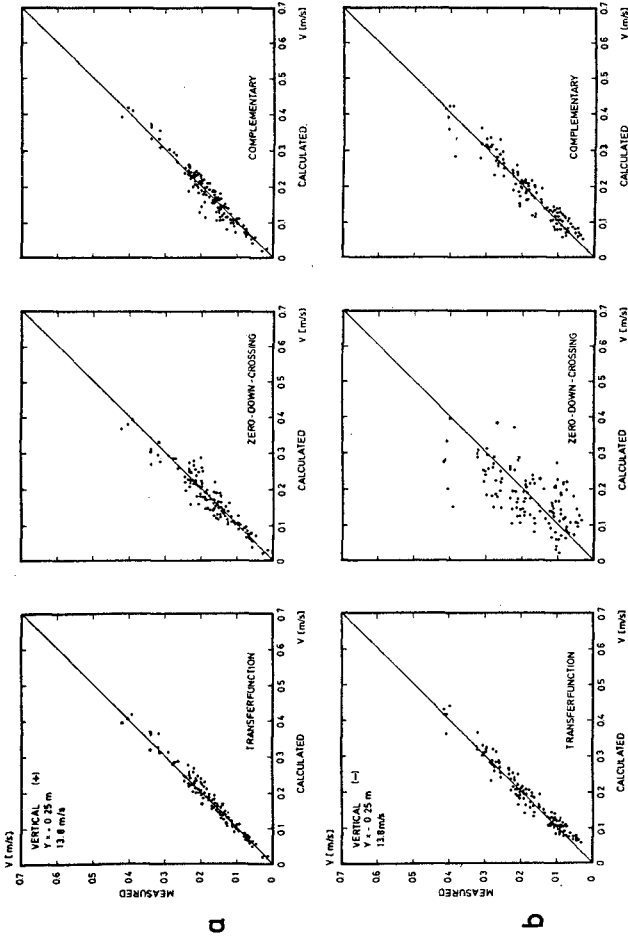

Fig. 16 Comparison of measured and predicted vertical velocities according to different simulation methods (JONSWAP spectrum, $\gamma = 3.3$, $U = 13.8$ m/sec, scale 1 : 20)

- a) positive maxima
- b) negative maxima

In this case the zero-down crossing method leads to good results for the positive values too, because nearly the same part of the wave is used to calculate the velocity components. However, for the negative velocities the scatter is remarkably wide.

The investigations on the pressure in irregular waves can only be mentioned in the scope of this paper. Theoretical simulations were done similarly to the simulations of the velocities. Results from the superposition method with theoretical transfer functions were still better than for the velocities. The scatter of the results simulated by the complementary method was less than the scatter from zero-crossing simulation. There is the same tendency too, that the predicted pressure under the wave crest is higher than the measured pressure and the predicted negative pressure is lower than the measured pressure in the wave trough.

ACKNOWLEDGEMENTS

This investigation was carried out as a part of the research programme of the Sonderforschungsbereich 79 at the Franzius-Institut für Wasserbau und Küsteningenieurwesen, Technical University of Hannover and was financed by the Deutsche Forschungsgemeinschaft. The authors gratefully acknowledge for having provided the facilities to conduct the investigations presented in this paper.

CHAPTER 11

METHOD OF ANALYSIS OF RANDOM WAVE EXPERIMENTS WITH REFLECTING COASTAL STRUCTURES

by

Pierre Gaillard, Michel Gauthier and Forrest Holly
Sogreah, Grenoble, France

ABSTRACT

A method of evaluation of the incident and reflected wave spectra in laboratory experiments or field investigations, based on the analysis of wave records obtained with a three-gauge array, is presented.

Results of a laboratory investigation with a rubble-mound breakwater and with a special type of sea-wall (ARC system) are given to illustrate the applications of the method.

INTRODUCTION

Random wave experiments performed with reflecting coastal structures require calibration of the wave generator movement in order to obtain incident waves conforming to specified characteristics. This calibration raises a problem because of multiple wave reflections from the structure and the wave paddle.

A technique often used in such cases, as well as in field investigations, consists in measuring the water level variation in front of the structure and in applying a method of analysis which estimates the incident and reflected waves.

Several methods of analysis based on measurements with two wave-gauges have formerly been published by Kajima (3), Thornton and Calhoun (5), Goda and Suzuki (2), Morden, Richey and Christensen (4). In these methods, however, the incident wave spectral density cannot be estimated correctly in the vicinity of a discrete number of critical frequencies, for which the distance between the two wave-gauges is a multiple of half the corresponding wave-length.

In this paper a different method, based on the analysis of wave records obtained with a three gauge array is presented. With this method, it is possible to estimate the incident and reflected wave spectra for the whole range of frequencies of interest.

BASIC ASSUMPTIONS

The incident waves are considered as a stationary, ergodic random process with gaussian properties. The water surface level variations related to waves propagating along the positive x axis are accordingly represented by:

$$\eta_I(x, t) = \text{Re} \left\{ 2 \int_0^{\infty} e^{i(2\pi ft - mx + \phi)} \sqrt{S_I(f)} df \right\} \quad (1)$$

with:

$$4\pi^2 f^2 = mg \tanh(mh) \quad (2)$$

f = wave frequency
 m = wave number
 h = Water depth at rest
 ϕ = random phase with constant probability density
 S_I = two-sided power spectral density of the incident waves

We shall consider a coastal structure in the wave tank, with its longitudinal axis parallel to the wave fronts. The structure section is assumed uniform so that diffraction effects are negligible. The reflected waves can thus be represented by:

$$\eta_I(x, t) = \text{Re} \left\{ 2 \int_0^{\infty} T(x, f) e^{i(2\pi ft - mx + \phi)} \sqrt{S_I(f)} df \right\} \quad (3)$$

The transfer function $T(x, f)$ related to the wave reflection, is a function of the location of the point of observation, and of frequency. In the following, we consider as reference the abscissa x_s of the seaward face of the structure, where the transfer function takes the value:

$$T_s = T(x_s, f) = C_R(f) e^{i\phi_s(f)} \quad (4)$$

$C_R(f)$: reflection coefficient of the structure

$\phi_s(f)$: phase lag due to wave reflection.

Provided that there is no wave damping or breaking along the wave flume, the transfer function T_k associated with any abscissa x_k is related to T_s by:

$$\begin{aligned} T_k &= T(x_k, f) = T_s \cdot e^{i2\theta_k} \\ \theta_k &= m(x_k - x_s) \end{aligned} \quad (5)$$

The objective of the analysis is to estimate from records of water level variations three unknown functions of frequency: the incident wave power spectral density S_I , the reflection coefficient $C_R(f)$ and the phase lag $\phi_s(f)$ due to this reflection.

Let us now consider the relationship between the incident waves and the partially or totally standing waves observed in front of the structure. Since the observed water level variations are simply a linear superposition of the incident and reflected waves given by (1) and (3), the relationship between incident waves and observed waves is defined by the transfer function:

$$T\eta_K\eta_I = 1 + T(x_k, t) \quad (6)$$

and the relationship between the spectrum of the observed waves $S_K(f)$ and the spectrum of the incident waves $S_I(f)$ is:

$$S_K(f) = S_I(f) \cdot T\eta_K\eta_I \cdot T\eta_K\eta_I^* \quad (7)$$

Where T^* stands for the complex conjugate of T .

From equations (4) to (7), the following expressions result:

$$S_K(f) = S_I(f) \cdot (1 + 2\text{Re}(T_s) \cos 2\theta_K - 2\text{Im}(T_s) \sin 2\theta_K + |T_s|^2) \quad (8)$$

$$S_K(f) = S_I(f) \cdot (1 + 2C_R(f) \cdot \cos(2\theta_K + \phi_s) + C_R^2(f)) \quad (9)$$

ANALYSIS WITH TWO WAVE GAUGES

From measurements of water level variations η_j, η_k at two locations x_j, x_k , it is possible to estimate the spectra $S_j(f)$ and $S_k(f)$, which are related to the unknown functions S_I, C_R and ϕ_s by equations similar to (8) and (9). It is also possible to obtain the cross-spectrum:

$$S_{jk}(f) = C_{jk}(f) - i Q_{jk}(f) = \int_{-\infty}^{+\infty} R_{jk}(t) e^{-i2\pi ft} dt \quad (10)$$

$$R_{jk}(\tau) = E(\eta(x_j, t) \cdot \eta(x_k, t - \tau))$$

The following relationship holds between the cross-spectrum $S_{jk}(f)$ and the incident wave spectrum $S_I(f)$:

$$S_{jk} = S_I(f) T\eta_j\eta_I \cdot T\eta_k\eta_I^*$$

$$S_{jk} = S_I(f) \cdot (1+T_j) \cdot (1+T_k^*)$$

$$S_{jk} = S_I(f) \cdot (1+T_s e^{i2\theta_j}) \cdot (1+T_s^* e^{-i2\theta_k}) \quad (11)$$

By separating the real and imaginary parts of (11), we obtain the co-spectrum and quad-spectrum:

$$C_{jk}(f) = S_I(f) \{ (1+|T_s|^2) \cdot \cos(\theta_j - \theta_k) + 2 \text{Re}(T_s) \cos(\theta_j + \theta_k) - 2 \text{Im}(T_s) \sin(\theta_j + \theta_k) \} \quad (12)$$

$$Q_{jk}(f) = S_I(f) (1 - |T_s|^2) \cdot \sin(\theta_j - \theta_k) \quad (13)$$

For simplicity, we shall write hereafter:

$$\theta_{jk} = \theta_j - \theta_k = m(x_j - x_k) \quad (14)$$

With the expressions of $S_j(f)$, $S_k(f)$ given by (8) and the expressions of the co and quad-spectra given by (12) (13), we have a set of four linear equations with three unknown functions of frequency $\text{Re}(T_s)$, $\text{Im}(T_s)$ and $|T_s|^2$. A necessary and sufficient condition for having a non zero solution of this set of equations is:

$$\begin{vmatrix} 2 \cos 2\theta_j & -2 \sin 2\theta_j & 1 & S_j/S_I - 1 \\ 2 \cos 2\theta_k & -2 \sin 2\theta_k & 1 & S_k/S_I - 1 \\ 2 \cos(\theta_j + \theta_k) & -2 \sin(\theta_j + \theta_k) & \cos \theta_{jk} & C_{jk}/S_I - \cos \theta_{jk} \\ 0 & 0 & -\sin \theta_{jk} & Q_{jk}/S_I - \sin \theta_{jk} \end{vmatrix} = 0 \quad (15)$$

This condition gives the following expression of the incident wave spectrum:

$$S_{Ijk}(f) = \frac{S_j + S_k - 2(C_{jk} \cos \theta_{jk} - Q_{jk} \sin \theta_{jk})}{4 \sin^2 \theta_{jk}} \quad (16)$$

The subscript jk is added to indicate that this is an estimate of $S_I(f)$ derived from the wave records at abscissas x_j and x_k .

The spectra of the incident and reflected waves are related by:

$$S_R(f) = C_R^2(f) \cdot S_I(f) = |T_s|^2 \cdot S_I(f) \quad (17)$$

From (16) and (17) we get the following expression of the reflected wave spectrum:

$$S_{Rjk}(f) = \frac{S_j + S_k - 2(C_{jk} \cos \theta_{jk} + Q_{jk} \sin \theta_{jk})}{4 \sin^2 \theta_{jk}} \quad (18)$$

Expressions (16) and (18) are similar to those used by Kajima (3). Differences come only from the orientation of the positive x axis in opposite directions. From the preceding set of equations we can also derive the following expression for the transfer function:

$$T_{Sjk}(f) = \frac{-S_j e^{-2i\theta_k} - S_k e^{-2i\theta_j} + 2C_{jk} e^{-i(\theta_j + \theta_k)}}{4S_I(f) \cdot \sin^2 \theta_{jk}} \quad (19)$$

which can also be written as:

$$T_{Sjk}(f) = \frac{-S_j e^{-2i\theta_k} - S_k e^{-2i\theta_j} + 2C_{jk} e^{-i(\theta_j + \theta_k)}}{S_j + S_k - 2(C_{jk} \cos \theta_{jk} - Q_{jk} \sin \theta_{jk})} \quad (20)$$

CRITICAL FREQUENCIES

Formula (9) shows that the power spectral density of the actually observed waves is a periodic function of space, for a given frequency, with a period equal to one half of the wave length associated with this frequency.

For a given pair of wave gauges, there is a discrete number of frequencies f_{cjk} , for which the distance between the wave gauges is a multiple of half the corresponding wave length $L(f_{cjk})$.

$$x_j - x_k = \pm p \frac{L}{2} (f_{cjk}) \quad p = 1, 2, 3... \quad (21)$$

For those critical frequencies, the following properties should hold:

$$\left. \begin{aligned} S_j(f) &= S_k(f) \\ C_{jk}(f) &= \pm S_k(f) \\ Q_{jk}(f) &= 0 \\ \sin(\theta_j - \theta_k) &= 0 \end{aligned} \right\} C_{jk} \cos(\theta_j - \theta_k) > 0 \quad f = f_{cjk} \quad (22)$$

As a result the numerator and denominator of (16) and (18) tend towards zero and the incident and reflected wave spectra cannot be evaluated with these formulae for these specific frequencies.

Because of round-off errors and background noise the numerator does not actually vanish, and it is observed in numerical computations that the absolute value of S_I and S_R increases considerably in the vicinity of the critical frequencies. This behaviour has been observed with all the methods of analysis based on measurements with two-gauge arrays.

Because of this difficulty, the distance between the wavegauges must be chosen carefully, with due consideration to the frequency range (f_{min} , f_{max}) over which the wave spectrum extends. Goda and Suzuki (2) suggest the following rule for this choice.

$$x_j - x_k = 0.05 L(f_{min}) = 0.45 L(f_{max}) \quad (23)$$

ANALYSIS WITH THREE WAVE GAUGES

From simultaneous measurements of water level variations with a three-gauge array, nine functions of frequency are derived i.e. the three spectra S_1, S_2, S_3 corresponding to the observed partially standing waves at the gauge locations, the three co-spectra C_{21}, C_{31}, C_{32} and quad-spectra Q_{21}, Q_{31}, Q_{32} associated with the different couples of gauges.

With each of these functions, is associated an equation such as (8), (12) or (13). We thus have a set of nine equations for three unknown functions only. Since there are more data available than unknown parameters many different formulae can be derived for evaluating the incident wave spectrum and the transfer function representing the wave reflection from the structure. Many of these formulae are inappropriate because they cannot be applied for critical frequencies associated with some or all of the gauge intervals.

A theoretical analysis developed in (1) led us to the following formulae for evaluating the incident and reflected wave spectra:

$$\begin{aligned} S_I(f) &= \alpha_{21} S_{I21}(f) + \alpha_{31} S_{I31}(f) + \alpha_{32} S_{I32}(f) \\ S_R(f) &= \alpha_{21} S_{R21}(f) + \alpha_{31} S_{R31}(f) + \alpha_{32} S_{R32}(f) \end{aligned} \quad (24)$$

$$\alpha_{21} + \alpha_{31} + \alpha_{32} = 1 \quad \alpha_{jk} \geq 0 \quad (25)$$

S_{Ijk} and S_{Rjk} are estimates of the incident and reflected wave spectra obtained from (16) and (18) for the different possible associations of gauges by pairs.

The weighting factors α_{jk} are positive functions of frequency, defined in such a way that (24) be valid for all frequencies, of interest, including for the critical values associated with the different gauge intervals. For this to be true, the gauge locations must be chosen so as to avoid any coincidence of the critical frequencies associated with the different gauge spacings; otherwise, effects similar to those observed with a two-gauge array would be encountered for these frequencies.

For critical frequencies f_{c12} , S_{I12} cannot be computed from (16) as shown in the preceding section, so α_{21} should vanish for this frequency. By an analysis of equations (8), (12), (13), it can be shown that solutions given by (16) for S_{I32} , S_{I31} and by (18) for S_{R32} , S_{R31} are theoretically equivalent for these critical frequencies. However, since slight differences may result from background noise $S_I(f)$ and $S_R(f)$ are estimated by:

$$\begin{aligned} S_I(f_{C12}) &= 0.5 (S_{I31} + S_{I32}) \\ S_R(f_{C12}) &= 0.5 (S_{R31} + S_{R32}) \end{aligned} \quad (26)$$

Similar formulae are used for the critical frequencies f_{C31} , f_{C32} associated with the other gauge intervals. The weighting functions are thus subject to the conditions:

$$\begin{aligned} \alpha_{jk}(f) &\rightarrow 0 \\ \alpha_{j1}(f) &\rightarrow 1/2 \quad \text{for } f \rightarrow f_{cjk} \\ \alpha_{k1}(f) &\rightarrow 1/2 \end{aligned} \quad (27)$$

We use the following functions, which satisfy conditions (25) and (27):

$$\begin{aligned} \alpha_{jk}(f) &= \frac{\sin^{2n}\theta_{jk}}{S_\alpha^{(n)}} \quad n = 1, 2, 3 \dots \\ S_\alpha^{(n)} &= \sin^{2n}\theta_{21} + \sin^{2n}\theta_{31} + \sin^{2n}\theta_{32} \end{aligned} \quad (28)$$

Insertion of these functions in (24), for $n = 1$ and 2 , leads to:

$$\begin{aligned} S_I(f) &= \frac{\bar{S}^{(n)} - \bar{C}^{(n)} + \bar{Q}^{(n)}}{2 S_\alpha^{(n)}} \\ S_R(f) &= \end{aligned} \quad (29)$$

$$\bar{S}^{(1)} = S_1 + S_2 + S_3$$

$$\bar{C}^{(1)} = C_{21} \cos \theta_{21} + C_{31} \cos \theta_{31} + C_{32} \cos \theta_{32} \quad (30)$$

$$\bar{Q}^{(1)} = Q_{21} \sin \theta_{21} + Q_{31} \sin \theta_{31} + Q_{32} \sin \theta_{32}$$

$$\bar{S}^{(2)} = 0.5(S_1+S_2)\sin^2\theta_{21}+0.5(S_1+S_3)\sin^2\theta_{31}+0.5(S_2+S_3)\sin^2\theta_{32}$$

$$\bar{C}^{(2)} = C_{21}\cos\theta_{21}\sin^2\theta_{21}+C_{31}\cos\theta_{31}\sin^2\theta_{31}+C_{32}\cos\theta_{32}\sin^2\theta_{32} \quad (31)$$

$$\bar{Q}^{(2)} = Q_{21}\sin^3\theta_{21}+Q_{31}\sin^3\theta_{31}+Q_{32}\sin^3\theta_{32}$$

The transfer function associated with the wave reflection on the coastal structure is estimated by means of:

$$T_S(f) = \frac{N_{21}\sin^2\theta_{21}+N_{31}\sin^2\theta_{31}+N_{32}\sin^2\theta_{32}}{D_{21}\sin^2\theta_{21}+D_{31}\sin^2\theta_{31}+D_{32}\sin^2\theta_{32}} \quad (32)$$

with:

$$\begin{aligned} N_{jk} &= -S_j e^{-i2\theta_k} - S_k e^{-i2\theta_j} + 2 C_{jk} e^{-i(\theta_j+\theta_k)} \\ D_{jk} &= S_j + S_k - 2 (C_{jk} \cos \theta_{jk} - Q_{jk} \sin \theta_{jk}) \end{aligned} \quad (33)$$

N_{jk} and D_{jk} are the terms involved in (20) when estimating the transfer function from each pair of gauges.

The reflection coefficient of the structure can be estimated by two possible methods:

- the first is by the use of (17) with the expressions of S_I and S_R given by (24), i.e. by (29) (30) (31) for the two lowest orders of the weighting functions.
- the second is by the use of (4) with the transfer function given by (32) and (33).

In the following we refer to these two estimates as $C_R(f)$ and $C'_R(f)$ respectively.

APPLICATION TO LABORATORY EXPERIMENTS

Examples of application of the present method to random-wave experiments conducted at Sogreah's laboratory will now be given.

EXPERIMENTAL SET-UP

The experiments were performed in a wave tank of 39 m length, 1.40 m depth and 0.60 m width, with the set-up indicated in figure 1. The bottom profile conforms to an actual situation for which breakwater stability tests were required. Two kinds of structures were considered at a scale of 1/50:

- a) a rubble mound breakwater with a two layer tetrapod covering on a seaward slope of 4/3.
- b) a vertical sea-wall with an anti-reflection chamber (ARC system), as described in (6)

Though a three-gauge array is generally sufficient for applying the present method, a four-gauge array was used in these particular experiments, in order to compare the results provided by the four different combinations of gauges by triplets. Water level variations were measured with capacitance-type wave gauges.

Figure 1 shows one of the wave-gauge arrangements used. In this case, gauges 1 and 4 are located respectively at the third anti-node and third node of the partially standing waves corresponding to the spectral peak frequency.

Data retrieval and digitization of water level measurements were performed on a General Automation GA220 minicomputer of 16 Kwords capacity. A Fortran computer code based on the previously described method, is implemented on this computer for current experiments.

Fig.1 EXPERIMENTAL SET-UP

Model 1: BREAKWATER WITH TETRAPODS

Model 2: SEA-WALL WITH ARC SYSTEM

Fig. 2 Incident and reflected wave spectra obtained with model 1

For processing the data of the four-gauge array and for comparing the results of the four different triplets, a special code was implemented on an ITEL AS 6 computer.

Wave records were analysed over a period of 160 s, with a time step of 0.1 s. Auto and cross-covariance functions were computed with a maximum lag of + 10 s. This analysis provided values of the 16 following functions with a frequency interval of 0.02 Hz at model scale, i.e. of 0.0028 Hz at prototype scale:

- the spectra of waves observed at the gauge locations S_1, S_2, S_3, S_4
- the six co-spectra $C_{21}, C_{31}, C_{41}, C_{32}, C_{42}, C_{43}$
- the six quad-spectra $Q_{21}, Q_{32}, Q_{41}, Q_{32}, Q_{42}, Q_{43}$

The number of degrees of freedom associated with the preceding parameters is approximately 40, with a Hamming spectral window. From the Chi-square law it is concluded that the 80% confidence interval lies between 73% and 130% of the estimated power spectral density.

INCIDENT AND REFLECTED WAVE SPECTRA

Figure 2 shows the incident and reflected wave spectra derived from the wave records of gauges 2, 3, 4 of figure 1, with the first type of structure, by application of formulae (29) and (31).

Figure 3 gives a simultaneous plot of the incident wave spectra obtained by analysis of the four different combinations of wave gauges (O stands for gauges 1, 2, 3; v for gauges 1, 2, 4; x for gauges 1, 3, 4 and * for gauges 2, 3, 4). As this graph results from a printer output, coincident values of the power spectral densities are plotted by a single symbol. The four estimates of the incident wave spectrum are in excellent agreement.

Figure 4 gives a simultaneous plot of the incident wave spectra obtained by analysis of the four gauges with the two lowest orders of weighting functions (28) (* stands for $n=1$ and O for $n=2$). No significant difference appears here between the two procedures of estimation of the incident wave spectrum.

The same conclusions were drawn from tests with the second type of structure.

With this technique, the gauge locations should be chosen so as to avoid too proximate values of the critical frequencies associated with the different intervals. Figure 5 refers to a particular wave gauge arrangement, 1, 2, 4, where critical frequencies associated with the gauge intervals are very nearly coincident, so that $S_{\alpha}^{(n)}$, defined by (28), drops to a very low value for frequencies near $f=1.55$ Hz at model scale and $f=0.22$ Hz at prototype scale. This situation leads to undesirable effects shown in figures 6 and 7.

Fig. 5 Weighting functions with nearly coincident critical frequencies

Fig. 6 Comparison of results in the situation of Fig. 5, for gauges 1-2-4

Fig. 7 Effect of weighting parameter n in the situation of fig. 5

Fig. 8 Reflection coefficients and phase lag for model 1

In figure 6, it is seen that the incident wave spectrum estimated from gauges 1, 2, 4 exhibits a small hump in the vicinity of the previously mentioned frequency, while this is not observed with the spectra estimated from the three other gauge associations.

Figure 7 is a graph similar to figure 4. It shows that the weighting functions of order 1 gives a hump of greater magnitude than those of order 2, in the frequency interval where critical frequencies are nearly coincident, while results are almost the same for other frequencies. Because of this, preference should be given to (31) for evaluating the incident and reflected wave spectra.

Another point should be stressed about the presentation of wave spectra derived through this analysis. The frequency $f=0$ is a critical frequency whatever the choice of the gauge intervals, since $\sin \theta_{jk}$ vanishes for this value. For this reason, a sharp rise in the absolute value of $S_I(f)$ and $S_R(f)$ is observed at very low frequencies, with a three-gauge array as well as with a two-gauge array. This effect was illustrated in (1) with numerically simulated random waves, for which it was clear that no energy was actually present in the low frequency range. This spurious effect affects a frequency interval equal to the width of the specific spectral window used for smoothing wave spectra. A cut-off frequency equal to this bandwidth is introduced in the computations.

REFLECTION COEFFICIENTS

Figures 8 and 9 show the variation with frequency of the reflection coefficients $C_R(f)$, $C'_R(f)$ for the two structures previously mentioned, together with the phase lag $\phi_S(f)$. $C_R(f)$ is derived here by means of the weighting functions of order 2.

It was shown in (1), with numerically simulated water waves, that a good estimate of the reflection coefficients cannot be obtained for frequencies where the power spectral density is very low. A threshold value dependent on the peak spectral density, was accordingly chosen for selecting the frequency range over which these parameters are computed. Results are presented here for a threshold value of 10%.

The two procedures described for evaluating the reflection coefficient of the structure versus frequency, though theoretically equivalent, give slightly different estimates of this parameter. Both procedures give the same general trend which is typical of the structures considered. The rubble-mound breakwater exhibits a progressive decrease in reflection as frequency increases, due to higher dissipation as waves impinge on the artificial blocks. The ARC system on the other hand exhibits a U-shaped curve, with minimum reflection for a frequency dependent on the dimensions of the anti-reflection chamber, which acts as a resonator.

Fig. 9 Reflection coefficients and phase lag for model 2

Fig. 10 Reflection coefficients $C_R(f)$ resulting from different gauge arrays with $n = 1$ & 2

As shown on figures 8 and 9 $C_R(f)$ has generally a more regular variation as a function of frequency than $C'_R(f)$. The reason for this behaviour has not yet been fully understood. From our experiments, the differences between $C_R(f)$ and $C'_R(f)$, did not seem to be connected with non-linear effects, as they did not increase with the significant wave height of the waves considered.

Figure 10 compares the reflection coefficients $C_R(f)$, associated with the first and second order weighting functions (28): * stands for $n=1$, 0 for $n=2$. As this graph results from a printer output, coincident values of $C_R(f)$ by both methods are plotted by a single symbol. Results shown here come from the analysis of the four combinations of gauges. A generally good agreement is observed between results of different triplets, and between the two methods of estimations of $C_R(f)$ for frequencies where wave energy is high. The scatter of experimental points increases on the boundaries of the wave spectrum.

CONCLUSION

In conclusion, the method of analysis just described has proven to be a valuable tool for estimating incident and reflected wave spectra in instances where wave reflection on structures has to be accounted for. Examples of application of the method to flume experiments have been given here. The method should also be applicable to field investigations, provided that the incoming waves are directed normally to the reflecting structure.

The numerical and experimental tests have shown that the incident wave spectrum is estimated accurately, provided that the gauge spacings are properly selected, so as to avoid too small a frequency interval between critical frequencies. The incident wave spectrum is practically insensitive to the order of the weighting functions used, except when critical frequencies are nearly coincident.

The method also proves to be an interesting means of studying the reflection coefficient (and the associated phase lag) of coastal structures as a function of frequency. It enables a better assessment of the efficiency of wave absorbing devices, such as the ARC system.

Two procedures of evaluation of the reflection coefficient have been investigated, one directly connected with the incident and reflected wave spectral densities by equations (17) and (29), the other derived from the theoretical transfer function (32). The first one is considered preferable since it showed a more regular variation of the reflection coefficient versus frequency.

CHAPTER 12

WAVE HEIGHT DISTRIBUTION AROUND PERMEABLE BREAKWATERS

BY

Shintaro Hotta*

ABSTRACT

A phase lag phenomenon in which waves are delayed in transmission through a permeable breakwater⁸ was considered in an approximate calculation method using the superposition principle of Sommerfeld. Experimental verifications were carried out for a semi-infinite permeable breakwater. In addition, a field observation of wave height distribution around a small detached breakwater is reported.

PART 1

APPROXIMATE CALCULATION METHOD FOR WAVE HEIGHT DISTRIBUTION AROUND A PERMEABLE BREAKWATER WITH A PHASE LAG

INTRODUCTION

At the 16th International Conference on Coastal Engineering at Hamburg, 1978, the author reported a calculation method for the wave height distribution around permeable breakwater using the superposition method of Sommerfeld. The cases dealt with were a semi-infinite breakwater, a single relatively large gap in a long breakwater and an insular breakwater (or a single detached breakwater). As discussed in the last paper (Chapter 39, Proc. 16th ICCE, pp 695-714, hereafter referred to as I), the weak point of this method is that it is not strictly correct theoretically, that is, the boundary conditions are not completely satisfied, and the wave height becomes discontinuous on the x and y axis and on the lines which divide the calculation region considered. However, this method has some advantages, that is, the wave height distribution can be calculated very easily by addition and subtraction, if we have the Fresnel Integrals. Another advantage is that if the waves have a phase lag due to a time lag upon transmission through a permeable breakwater, the influence of this time lag can easily be taken into consideration in the equations, without any complication. That is, we can replace y with $(y \pm \Delta L)$ in the term which represents the transmitted waves. Here ΔL is related to the phase lag between the transmitted and free waves. In this paper, the equations with the phase lag are given,

* Research Associate, Dept. of Civil Engineering, Tokyo Metropolitan University, Setagaya-ku, Tokyo, JAPAN

and the experimental verification of this method for semi-infinite permeable breakwaters are shown together with the case of no phase lag.

NUMERICAL CALCULATION OF WAVE HEIGHT DISTRIBUTION IN TRANSMISSION THROUGH THE PERMEABLE BREAKWATERS WITH PHASE LAG

As mentioned before, if waves are delayed in transmission through a breakwaters, the phase lag on the shoreside of the breakwaters can be expressed by replacing y with $(y \pm \Delta L)$ in the terms which represent the transmitted waves, namely

$$\alpha \{ e^{-ik(y + \Delta L)} f(u) + e^{-ik(y - \Delta L)} g(u) \} \text{-----} \quad (1)$$

Calculations will be done using the same figures, symbols and coordinate systems described in reference I.

(1) A semi-infinite permeable breakwater

By replacing y with $(y \pm \Delta L)$ in the terms which represent the transmitted waves (See Fig. 5 - (3) in reference I) we have the final forms of these equations, with a phase lag accounted for in regions A and B1, as follows:

Region A $x > 0, y > 0$

$$\begin{aligned} F_{2t}^A &= F_0^A + \alpha F_{1t}^A \\ &= e^{-iky} f(u_1) + e^{iky} g(-u_2) + \alpha \{ e^{-ik(y+\Delta L)} f(-u_1) + e^{ik(y-\Delta L)} g(-u_2) \} \\ &= (S_1 + S_2) \cos ky + (W_1 - W_2) \sin ky \\ &\quad + \alpha \{ (1 - S_1) \cos(k(y+\Delta L)) + S_2 \cos(k(y-\Delta L)) \\ &\quad \quad + (-W_1) \sin(k(y+\Delta L)) + (-W_2) \sin(k(y-\Delta L)) \} \\ &+ i \{ (W_1 + W_2) \cos ky + (-S_1 + S_2) \sin ky \\ &\quad + \alpha \{ (-W_1) \cos(k(y+\Delta L)) + W_2 \cos(k(y-\Delta L)) \\ &\quad \quad + (-1 + S_1) \sin(k(y+\Delta L)) + S_2 \sin(k(y-\Delta L)) \} \} \text{-----} \quad (2) \end{aligned}$$

Region B₁ $x < 0$, $y > 0$

$$\begin{aligned}
 F_{2t}^{B1} &= F_0^{B1} + \alpha F_{2t}^{B1} \\
 &= e^{-iky} f_r(u_1) + e^{iky} g_r(-u_2) + \alpha \{ e^{-ik(y+\Delta L)} f_r(-u_1) + e^{ik(y-\Delta L)} g_r(-u_2) \} \\
 &= (1-S_1+S_2) \cos ky + (-W_1-W_2) \sin ky \\
 &\quad + \alpha \{ S_1 \cos(k(y+\Delta L)) + S_2 \cos(k(y-\Delta L)) \\
 &\quad \quad + W_1 \sin(k(y+\Delta L)) + (-W_2) \sin(k(y-\Delta L)) \} \\
 &\quad + i [(-W_1+W_2) \cos ky + (-1+S_1+S_2) \sin ky \\
 &\quad \quad + \alpha \{ W_1 \cos(k(y+\Delta L)) + W_2 \cos(k(y-\Delta L)) \\
 &\quad \quad \quad + (-S_1) \sin(k(y+\Delta L)) + S_2 \sin(k(y-\Delta L)) \}] \quad \text{-----} \quad (3)
 \end{aligned}$$

To indicate the cases with a phase lag, a suffix t is added to the equivalent equations for no phase lag.

If we put $\Delta L = 0$ in Eqs. (2) and (3), they become Eqs. (23) and (24) in reference I, respectively.

(2) A single relatively large gap in a long permeable breakwater

As in section (1), replacing y with $(y \pm \Delta L)$ in the transmitted wave terms (See Fig. 6-(4) in reference I) the final forms of the equations in regions A1 and A2 for an opening in a breakwater become:

Region A₁ $0 < x < b/2$, $y > 0$

$$\begin{aligned}
 F_{3pt}^{A1} &= F_3^{A1} + \alpha [F_{1t}^{B1} + F_{0t}^A] \\
 &= e^{-iky} f_r(u_1) + e^{iky} g_r(-u_2) + e^{-iky} f_l(u_1) + e^{iky} g_l(-u_2) - e^{-iky} \\
 &\quad + \alpha [e^{-ik(y+\Delta L)} f_l(-u_1) + e^{ik(y-\Delta L)} g_l(-u_2) \\
 &\quad \quad + e^{-ik(y+\Delta L)} f_r(-u_1) + e^{ik(y+\Delta L)} g_r(-u_2)] \\
 &= (1-S_{r1}-S_{l1}+S_{r2}+S_{l2}) \cos ky + (-W_{r1}-W_{l1}-W_{r2}-W_{l2}) \sin ky \\
 &\quad + \alpha \{ (S_{r1}+S_{l1}) \cos(k(y+\Delta L)) + (W_{r1}+W_{l1}) \sin(k(y+\Delta L)) \\
 &\quad \quad + (S_{r2}+S_{l2}) \cos(k(y-\Delta L)) + (-W_{r2}-W_{l2}) \sin(k(y-\Delta L)) \} \\
 &\quad + i [(-W_{r1}-W_{l1}+W_{r2}+W_{l2}) \cos ky + (-1+S_{r1}+S_{l1}+S_{r2}+S_{l2}) \sin ky \\
 &\quad \quad + \alpha \{ (W_{r1}+W_{l1}) \cos(k(y+\Delta L)) + (-S_{r1}-S_{l1}) \sin(k(y+\Delta L)) \\
 &\quad \quad \quad + (W_{r2}+W_{l2}) \cos(k(y-\Delta L)) + (S_{r2}+S_{l2}) \sin(k(y-\Delta L)) \}] \quad \text{-----} \quad (4)
 \end{aligned}$$

Region A2 $x > b/2, y > 0$

$$\begin{aligned}
 F_{3t}^{A2} &= F_3^{A2} + \alpha [F_{1t}^A + F_{2t}^A] \\
 &= e^{-iky} f_r(-u_1) + e^{iky} g_r(-u_2) + e^{-ky} f_l(u_1) + e^{iky} g_l(-u_2) - e^{-iky} \\
 &\quad + \alpha [e^{-ik(y+\Delta L)} f_l(u_1) + e^{ik(y-\Delta L)} g_l(-u_2) \\
 &\quad + e^{-ik(y+\Delta L)} f_r(-u_1) + e^{ik(y-\Delta L)} g_r(-u_2)] \\
 &= (S_{r1} - S_{l1} + S_{r2} + S_{l2}) \cos ky + (W_{r1} - W_{l1} - W_{r2} - W_{l2}) \sin ky \\
 &\quad + \alpha \{ (1 - S_{r1} + S_{l1}) \cos(k(y+\Delta L)) + (-W_{r1} + W_{l1}) \sin(k(y+\Delta L)) \\
 &\quad + (S_{r2} + S_{l2}) \cos(k(y-\Delta L)) + (-W_{r2} - W_{l2}) \sin(k(y-\Delta L)) \} \\
 &\quad + i [(W_{r1} - W_{l1} + W_{r2} + W_{l2}) \cos ky + (-S_{r1} + S_{l1} + S_{r2} + S_{l2}) \sin ky \\
 &\quad + \alpha \{ (-W_{r1} + W_{l1}) \cos(k(y+\Delta L)) + (-1 + S_{r1} - S_{l1}) \sin(k(y+\Delta L)) \\
 &\quad + (W_{r2} + W_{l2}) \cos(k(y-\Delta L)) + (S_{r2} + S_{l2}) \sin(k(y-\Delta L)) \}] \quad \text{-----} \quad (5)
 \end{aligned}$$

Letting $\Delta L = 0$, Eqs. (4) and (5) become Eqs. (32) and (33) in reference I.

(3) A single insular permeable breakwater

Similar to the above, replacing y with $(y \pm \Delta L)$ in the transmitted wave terms (See Fig. 8 in reference I) the equations for regions A1 and A2 become:

Region A1 $0 < x < b/2, y > 0$

$$\begin{aligned}
 F_{1t}^{A1} &= (S_{r1} + S_{l1} + S_{r2} + S_{l2}) \cos ky + (W_{r1} + W_{l1} - W_{r2} - W_{l2}) \sin ky \\
 &\quad + \alpha \{ (1 - S_{r1} - S_{l1}) \cos(k(y+\Delta L)) + (-W_{r1} - W_{l1}) \sin(k(y+\Delta L)) \\
 &\quad + (S_{r2} + S_{l2}) \cos(k(y-\Delta L)) + (-W_{r2} - W_{l2}) \sin(k(y-\Delta L)) \} \\
 &\quad + i [(W_{r1} + W_{l1} + W_{r2} + W_{l2}) \cos ky + (-S_{r1} - S_{l1} + S_{r2} + S_{l2}) \sin ky \\
 &\quad + \alpha \{ (-W_{r1} - W_{l1}) \cos(k(y+\Delta L)) + (-1 + S_{r1} + S_{l1}) \sin(k(y+\Delta L)) \\
 &\quad + (W_{r2} + W_{l2}) \cos(k(y-\Delta L)) + (S_{r2} + S_{l2}) \sin(k(y-\Delta L)) \}] \quad \text{-----} \quad (6)
 \end{aligned}$$

Region A2 $x > b/2, y > 0$

$$\begin{aligned}
 F_{2t}^{A2} &= (1 + S_{r1} - S_{l1} + S_{r2} + S_{l2}) \cos ky + (W_{r1} - W_{l1} - W_{r2} - W_{l2}) \sin ky \\
 &\quad + \alpha \{ (-S_{r1} + S_{l1}) \cos(k(y+\Delta L)) + (-W_{r1} + W_{l1}) \sin(k(y+\Delta L)) \\
 &\quad + (S_{r2} + S_{l2}) \cos(k(y-\Delta L)) + (-W_{r2} - W_{l2}) \sin(k(y-\Delta L)) \} \\
 &\quad + i [(W_{r1} - W_{l1} + W_{r2} + W_{l2}) \cos ky + (-1 - S_{r1} + S_{l1} + S_{r2} + S_{l2}) \sin ky \\
 &\quad + \alpha \{ (-W_{r1} + W_{l1}) \cos(k(y+\Delta L)) + (S_{r1} - S_{l1}) \sin(k(y+\Delta L)) \\
 &\quad + (W_{r2} + W_{l2}) \cos(k(y-\Delta L)) + (S_{r2} + S_{l2}) \sin(k(y-\Delta L)) \}] \quad \text{-----} \quad (7)
 \end{aligned}$$

With $\Delta L = 0$, Eqs. (6) and (7) become Eqs. (39) and (40) in reference I.

EXPERIMENTAL FACILITIES AND PROCEDURES

Experiments were carried out using a small wave basin which was 2.4 meters in width, 6.0 meters in length and 0.5 meters in depth. The dimensions and the arrangement of the experimental facilities are shown in Fig. 1. Because of the limited wave basin width, only the case of a semi-infinite breakwater was treated.

As a model of a breakwater, a vertical homogeneous crib-style wall of 8 cm thickness, filled with 17 mm diameter glass balls, was used. Wave heights were measured with 18 capacitance-type wave gauges. Three of these were placed on a line extending from the breakwater axis ($x < 0$, $y = 0$) to measure the incoming waves and to synchronize three 6-channel paper oscillographs. The remaining 15 gauges were mounted on an arm having wheels at both ends, and which moved on rails fixed to both side walls of the basin. Using these wave gauges, wave heights at 15 locations could be simultaneously measured across the basin. To avoid wave interactions between the incoming waves and the waves reflected from the basin walls (of course a wave absorber was placed along the basin walls; See Fig. 1), the third wave height of each wave train generated was adopted as the height for comparison with the calculations. So, waves were generated from the still water state for each measurement on different transects parallel to the x-axis.

First, the experiments with no phase lag were carried out using wave periods of 0.7 and 1.2 seconds, and a water depth of 0.2 meters. Similar to the above, the experiments where the transmitted waves suffered a phase lag, due to the breakwater, were carried out using only one wave period (0.7 second) and the same water depth. In these experiments, it was difficult to obtain transmitted waves under the conditions of a phase lag. Instead of this, the waves generated in the region of the gap were forced to propagate ahead of the waves arriving at the breakwater by increasing the thickness of the wave generator flap in the former region. Then, to avoid the wave interaction between the two regions, the partition was placed as shown in Fig. 1.

Fig. 1 Experimental facilities

EXPERIMENTAL RESULTS AND DISCUSSION

Figure 2 shows the experimental results for no phase lag. The transmission coefficient was about 0.25. The water depth was 0.2 meters. In Fig. 2, the solid lines are the calculated values from equations (23) and (24) in reference I, and the solid and empty triangles show the experimental values for wave periods of 0.7 and 1.2 seconds, respectively. These figures show that the calculations agree with the experiments qualitatively. The experimental wave heights at the antinodes of the superimposed waves were a little smaller than the those in the calculations, and the experimental wave heights at the nodes became larger than those in the calculations. It is inferred that this is due to the interaction between the two waves, the transmitted and diffracted waves. Deviation of the experimental results from the calculations becomes larger according to the progress of the waves, especially in the case of the 0.7 second period. Perhaps this effect is due to an energy loss, since it is considered that the energy loss is greater for shorter waves.

Figure 3 shows the experimental results when the transmitted waves suffered a phase lag due to the breakwater. The wave period was 0.7 seconds and the water depth was 0.2 meters. In this experiment, the phase lag was 0.2 wave length, about 15 cm. In Fig. 3, the solid, dotted and broken lines show the calculated values from equations (2) and (3) for phase lags of $\Delta L = 0.1L$ and $\Delta L = 0.2L$, respectively. Here ΔL is the phase lag and L is the wave length. Solid rectangles show the experimental results for no phase lag and solid circles show the experimental results for a phase lag of $\Delta L = 0.2L$. From these figures, you can see a similarity with the experimental results for the case of no phase lag previously discussed. That is, first of all, the calculation agrees with the experiments qualitatively. Second, at the antinode the calculated wave heights are smaller than those in the experiments, and at the nodes we find the contrary. Thirdly with continued propagation, the wave interaction becomes larger, and the wave heights become constant.

From these results, we feel this method may be acceptable to roughly predict the wave heights distribution around permeable breakwaters. Furthermore, if we accept this method, then we have the possibility of expressing the wave height distribution around permeable breakwaters for irregular waves, by superimposing waves which have different incident wave angles and heights.

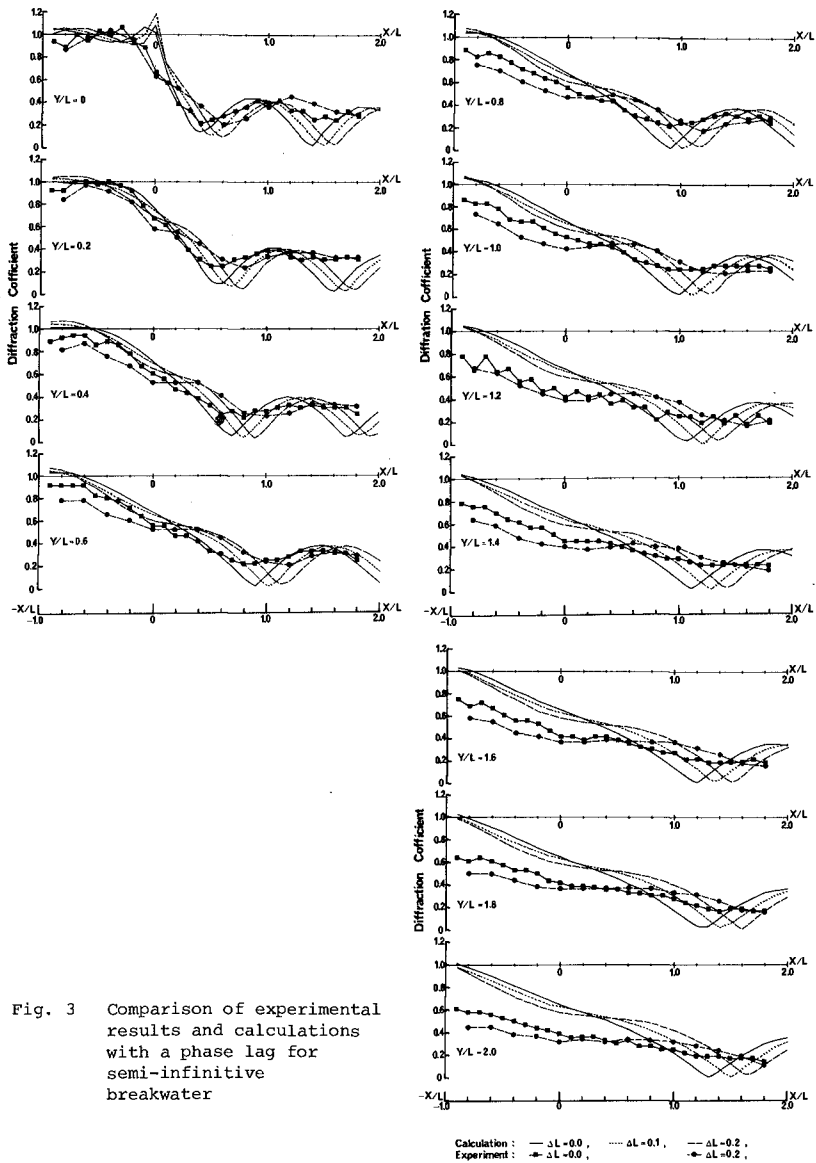

Fig. 3 Comparison of experimental results and calculations with a phase lag for semi-infinite breakwater

• PART II

A FIELD STUDY OF WAVE HEIGHT DISTRIBUTION
AROUND A SMALL DETACHED PERMEABLE BREAKWATER

FORWARD

The field observation was carried out on September 4, 1979 at Oharai beach (See Fig. 4). Data are presently still under analysis. However, a part of the results are described and discussed here because of their interest which still remains to be expanded upon in a more detailed analysis and discussion. In the preceding section, the calculation and experiments were dealt with assuming regular waves, no breaking waves and a constant water depth. The field observation which will be described here was under the conditions that waves were irregular, had already broken and were on a sloping sea bottom. Because of these idealized constraints, this field observation is not considered as a verification of the calculation or experiments in the preceding section. However, it is expected that field wave data will give important information about the applicability of these calculations, or suggest an improvement of these calculation methods or development of new calculation methods in the future.

Fig. 4 Location of field observation site

FIELD OBSERVATION SITE AND INSTRUMENTATION

Field observation was carried out at Oharai beach where eleven small detached breakwaters had been constructed of hexalegs on the front of the seawall for defense from beach erosion. The detached breakwaters are about 20 m in length and situated with a 30 m spacing between each other, parallel to and 50 m from the seawall. Observation of wave height was done around the 5th detached breakwater counting from the North.

The wave height distribution at the shoreside of the detached breakwater was observed using a pole array and a 16 mm memo-motion camera system. This system is a photographic method of measuring waves on the sea water surface at poles placed in the sea, using several synchronized cameras. In this observation, 5 cameras were used and 25 poles were photographed. The arrangement of poles (station Nos.) shown in Fig. 5.

The tidal range of this beach was 1.1 m at the time, and at low tide the water depth of the breakwater site was about 0.2 - 0.3 m. At low tide, poles were erected in the sandy bottom using water jets, and wave heights were observed at high tide.

The data from 16 mm photographs of the water surface variations were transferred to paper tapes by using a 16 mm film analyzer and sonic digitizer graf pen system. Data on paper tapes were again transferred to magnetic tapes for convenient analysis by computer. Data station Nos. 12, 31, 32 and 63 were not recorded because it happened that these stations were out of the field of view. Three electromagnetic current meters were used to measure the current. However, the author has no intention of describing the current data in the present study.

Fig. 5 Sea bottom topography and position of poles

DEFINITION OF WAVES

How are waves defined? The zero-up or zero-down crossing methods are one of the ways generally accepted at present. The field studies of waves in the surf zone being carried out by the author and coworkers (Hotta, Mizuguchi, and Isobe (1978, 1979, 1980)), using the same pole array and a 16 mm memo-motion camera system, have shown that many small amplitude waves could be defined by the zero-up or zero-down crossing methods for the waves in the surf zone. As a result, these small amplitude waves had small values of the representative wave statistics, for example, the one-tenth wave height and period ($H_{1/10}, T_{1/10}$) or the significant wave height and period ($H_{1/3}, T_{1/3}$). The same thing was found in this field observation. In studying the characteristics of the waves in the field it does not appear reasonable to take into consideration small amplitude waves. However, we have no evidence that smaller waves should be ignored. We have still not reached a conclusion yet, though we have extensively scrutinized and investigated this problem. One of the guidelines which the author wants to state, at least, is that the waves which have heights smaller than 3 times the minimum scale unit in reading water surface variations, should be ignored. This is concluded from checking the accuracy of our data (Hotta et al.(1980)). In this study the minimum scale unit was 2 cm, and time interval of photographing was 0.2 second. Then, the minimum wave which could be defined in this study was 6 cm in height and had a 0.6 second period.

We have other problem in the definition of waves. That is, as just mentioned above, we have ignored waves which were smaller than 6 cm and had period of less than 0.6 second. The problem is in choosing which way is more reasonable to add the small wave which we have ignored, to the main wave: to the previous main wave or to the next main wave? (See Fig. 6) This does not influence the height of the main wave, but influences the wave period. We have no idea which choice should be made. It seems that the zero-down crossing method might be good for defining waves in the surf zone, because it is considered that the elevation between the top of the propagating wave crest and the sea surface in front of the crest would characterized waves in the surf zone. Then, profiles of the waves defined by the zero-down crossing method would look good if the small waves ignored could be added to the trailing part of the main wave.

In this study waves were defined using the zero-down or zero-up crossing methods with W as shown in Fig. 6.

Fig. 6 Definition of waves

FIELD OBSERVATION RESULTS AND DISCUSSION

(1) Wave height distribution at the shoreside of the breakwater.

Figure 7A shows the significant wave height and period around a small detached breakwater. Fig. 7B shows a graph the same values along the section A-A, B-B and two other sections parallel to the former ones. From Fig. 7 we can point out the following. The significant wave height along section A-A, near the leeside of the breakwater, becomes smaller from the tip of the breakwater towards the center of the breakwater and at the center the wave height decreases by about 75% of that at the tip. Contrarywise, wave heights along section B-B, about 10 m from the breakwater, are getting large towards the center of the breakwater. This might depend on the superposition or convergence of waves, i.e. transmitted waves and waves diffracted from both sides of the breakwater.

Figure 8 shows part of the experimental results for wave height distribution around a permeable breakwater carried out by Horikawa, Isobe and Shiozaki (1980). Wave heights are shown in cm units. Experiments were carried out on a 1/20 sea bottom slope and the water depth at the site of the breakwater was 5.8 cm. The wave length at the site of breakwater and the length of the breakwater were about 72 cm and 90 cm, respectively. Noticing that this experiment and the field conditions were almost the same, we find the following fact. That is, we can see wave heights of 1.4 and 1.9 cm at the leeside of the breakwater and at positions about one-fourth of the breakwater length from both ends of the breakwater. These positions might be considered as nodes of three dimensional partial standing waves which were formed by the transmitted and diffracted waves. In the experiments described in part I, it was shown that the wave height at nodes of the partial standing waves became larger than the calculated values and it was imagined that this depended on energy transfer from antinodes to nodes by interaction of the two waves: transmitted and diffracted waves.

The same thing might have occurred the experiments of Horikawa et al. Comparing Fig. 7 and Fig. 8, we recognize that the energy transfer from the antinodes to the nodes of the partial standing waves in an irregular wave in the field becomes larger than that in regular waves in laboratory experiments. That is, to wave height averages at the leeside of the breakwater for regular waves is smaller than that for irregular waves. This is natural.

The significant wave period (See Fig. 7B) shows a tendency to become smaller at the leeside of the breakwater.

(2) Waves at the offshoreside of the breakwater.

Significant wave heights and periods at stations 91 and 92 were 113 cm and 8.7 sec. and 70 cm and 5.0 sec using the zero-up crossing method; and 119 cm and 9.4 sec, and 79 cm and 6.4 sec using the zero-down crossing method, respectively. The number of waves defined were 123 and 166. From the big difference between these two stations, we can predict that at the offshoreside of the breakwater, the partial

standing waves were formed by incoming waves and reflected waves. At the node the number of waves defined becomes larger than that at the anti-node, and the wave period becomes smaller. (See Fig. 9)

(3) Wave height distribution at one location as a function of time.

Figure 10 shows the wave height and period distribution as a function of time at stations on the leeside of the breakwater. Fig. 10A shows the wave heights and period distribution at section C-C in Fig. 7. It is considered that waves on this section suffer little influence from the breakwater, and are almost the same as on a natural beach. Fig. 10B, 10C and 10D show the wave height distribution at each station on sections B-B, C-C and D-D, respectively.

In these Figures, histograms show the nondimensional wave heights, the ratio of wave heights and average wave height, H/\bar{H} . Solid circles show the nondimensional period, the ratio of wave periods and average period, T/\bar{T} . The distribution graph to the left side is that derived from the zero-up crossing method, and that to the right side is the one derived from the zero-down crossing method. These are distinguished by UP and DOWN, respectively.

Glancing at these figures, you can readily see that the nondimensional wave height distributions completely differ with the definitions of waves. Distributions defined by the zero-up crossing method become unimodal distributions, and those defined by the zero-down crossing method result in bi-modal distributions, except at stations 21, 41 and 51. This tendency is especially evident on section C-C. As mentioned before, waves on this section are not influenced by the existing breakwater so much, and we may consider that waves in this section are almost the same as on beaches with no structures. This phenomenon has often been observed by the author and his coworkers (1979 and 1980) on natural beaches.

The facts that the wave height distribution become uni-modal with its peak in the neighborhood of $H/\bar{H} = 1.0$, if we define the waves by the zero-up crossing method, and that the wave height distribution becomes bi-modal with two peaks located to the right and left side of $H/\bar{H} = 1.0$, if we define the waves by the zero-down crossing method, can be interpreted as follows. We shall consider defining waves for a case in which a relatively small wave follows a big wave, as shown in Fig. 11. Clearly, a large and a small wave are defined by the zero-down crossing method and two waves of almost the same height are defined by the zero-up crossing method. In addition to this, the average wave height and number of waves defined are the same in spite of the two different methods of definition. It is probable that these facts take place in the distributions shown in Fig. 10. No doubt, waves as shown in Fig. 11 exist very much in the surf zone on natural beaches. We can guess that the distribution for stations on the leeside of the breakwater change due to their dependence on the different positions of the waves.

Another thing to be pointed out from Fig. 10 is that the distribution of nondimensional wave periods roughly agrees with the wave height distribution. This means that the wave periods are roughly proportional to the wave heights. This is not inconsistent with the general concept.

- (4) Difference of representative waves statistics due to wave definitions.

Table-1 shows the wave heights and periods of the one-tenth and significant waves, and the number of waves defined. Wave heights show no difference between the zero-up and down crossing methods. However, wave periods defined using the zero-up crossing method become less large than those defined using the zero-down crossing method. This means that waves defined using the zero-down crossing method become steeper than those from the zero-up crossing method. There are relatively large differences in the numbers of waves defined. This relates to the differences of wave positions of the transmitted and diffracted waves, but this is not all. We can not offer exact answers or interpretations for the above results. Many things remain to be discussed in the future.

ACKNOWLEDGEMENTS

The experiment was carried out with the wave basin belonging to Dr. M. Mizuguchi, Associate Professor, University of Chuo. The author gratefully acknowledges the help of Dr. Mizuguchi. The author acknowledges the permissions given by Drs. K. Horikawa, M. Isobe and Mr. M. Shiozaki for reproduction of their data and figures. The author also thanks staffs of Nearshore Environment Research Center for their assistance in the field observations and analysis.

A part of this study was supported by The Grant in Aid for Co-operative Research A 435026, (1979) "Study of Dynamics in the Surf Zone" given to Dr. Kiyoshi Horikawa, Professor, Dept. of Civil Eng., University of Tokyo. The Grant is offered by the Ministry of Education, Science and Culture.

CHAPTER 13

NON-RESONANT WAVE AGITATION IN SMALL CRAFT HARBOURS

by

J.W. Kamphuis ¹⁾ and D.A.Y. Smith ²⁾

ABSTRACT

A model study of wave agitation in small craft harbours was performed using a square and a rectangular marina basin subjected to monochromatic waves. Wave agitation was measured in up to 273 points within the marina basin and overall wave energy levels were calculated from these measurements for 4 different wave periods, 6 different entrances and 5 different lengths of energy absorbing sections along the perimeter walls. These values were compared and found to correspond well with a rather simple theoretical expression.

INTRODUCTION

Ancient harbours were small craft harbours and their design was already very sophisticated (2,9)³. The development of harbour design from the early Minoans, Phoenicians and Romans, however, has not been a linear process. First, the same mistakes were often repeated throughout history (and indeed are repeated today). Secondly, with increase in the size of ships, design was mainly concerned with harbours for large vessels. Around 1900, a parting of the ways is evidenced and two distinct types of harbour designs are found — the large harbour for large vessels and the smaller craft harbour, mainly for fishing vessels. Not until the 1960's can the concept of "small craft harbour" or "marina" be found regularly in the literature and the design of these small craft harbours is very often simply a scaled down version of design for large commercial harbours.

Two examples of scaled down design may suffice.

It makes good sense when designing a harbour for large vessels, not to obstruct navigation unnecessarily and hence to design a relatively straight, open entrance, directed away from the predominant wave direction. Only "small waves", which do not unduly affect the stability of the large vessels, are permitted to enter the harbour. But this design criterion is anathema for small craft which are terribly disturbed by these so-called "small waves".

-
1. Professor of Civil Engineering, Queen's University, Kingston, Canada.
 2. Engineer, Jamaica Bauxite, Kingston, Jamaica.
 3. Numbers in brackets refer to the Reference section.

Applying the same entrance design criterion to both types of harbours is therefore ludicrous, especially in view of the fact that small craft are very easily maneuverable and can negotiate more complicated entrance configurations quite easily. An additional entrance design criterion for small craft harbours is that the entrance prevent penetration of waves generated by other small craft passing the entrance.

Vertical perimeter walls around a harbour also constitute sensible design for harbours with large vessels. The vessels can easily come alongside. Vertical sheetpile walls are inexpensive compared to the alternatives. Loading and unloading platforms can be constructed immediately adjacent to the vessels. The fact that wave energy is reflected by these walls, resulting in ever-present chop within the harbour and along the docks is of no concern to the large vessels. But in a small craft harbour reflected and re-reflected waves present an unacceptable level of motion. Hence vertical, reflecting perimeter walls constitute very poor design for small craft harbours.

It is possible to quote many examples of small craft harbours with open entrances and vertical, reflecting perimeters. Portsmouth Olympic Harbour, reconstructed for the 1976 Olympic games, is shown as one such example in Figure 1. The unacceptable energy levels in this marina basin prompted the Queen's University Coastal Engineering Laboratory to begin investigation of agitation in small craft harbours.

A literature search indicated very little work directly applicable to small craft harbour design — especially with respect to non-resonant agitation (as opposed to studies on resonance — so important for larger harbours containing large vessels). Hence a series of very basic research tests was initiated. So far, one earlier paper was published (5). The work discussed in this paper may be found in detail in the junior author's Ph.D. thesis (8). It consists of

- a. Obtaining some basic data with respect to wave penetration, diffraction, reflection, etc.
- b. Testing a simple theory to explain (overall average) energy levels in simple harbour configurations.

The program has been continued to investigate

- c. Local wave energy levels in sections of the harbour
- d. Energy absorber location design
- e. Entrance design,

and will in the future also focus on

- f. Arrangement of "furniture" (docks, piers, boats, etc.) within the harbour
- g. Effects of irregular waves
- h. Construction of a Finite Element Model based on the above experimental data.

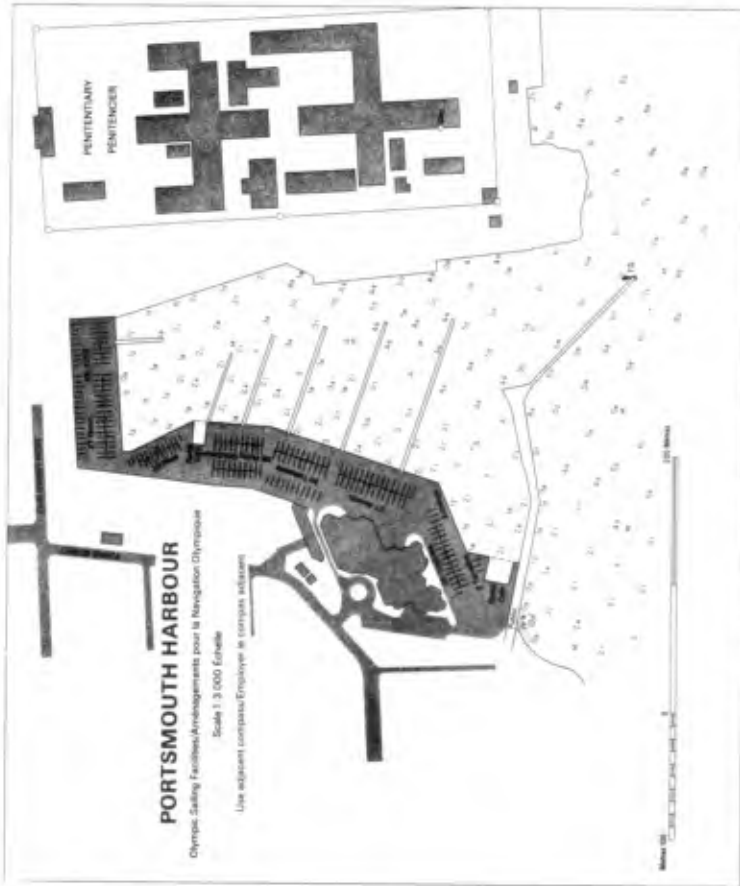

FIGURE 1: EXAMPLE OF SMALL CRAFT HARBOUR DESIGN BY SCALING DOWN LARGE HARBOUR DESIGN CONCEPTS.

Some work on marina and harbour agitation has been published by others such as the Danish Hydraulics Institute and their System 21 (1), Daenrich and Kohlhase (6) and others. Their work consists of rather sophisticated mathematical and theoretical analysis, but is based on very limited data. The purpose of the work discussed in this paper is:

- a. to provide an experimental data base on which to construct mathematical models,
- b. to provide some simple relationships that can be used in preliminary engineering design.

The last point is very important since many small craft harbours are never really designed, but are evolved from committee meetings, etc. using available space and money as the basic design criterion, while hard technical study is only of secondary importance. A simple expression and indications of trends give the harassed engineer something in hand to plead his case.

THE EXPERIMENTS

The experimental facility is shown in Figure 2. Regular waves were generated in a 3-dimensional wave basin and two harbour models, a 6.1 m square and a 4.25 x 6.1 m rectangular one, were tested. Heavy wave filters were used and energy absorbing material was placed along the front face of the model to prevent coupling and secondary reflections between the model and the wave generator.

The testing procedure was as follows: after the generator was started, a period of approximately 20 minutes was found to be sufficient to damp long waves resulting from generator start-up. The square harbour was tested with fully reflecting vertical walls all around the perimeter for six different entrance widths ($b = 0.61, 1.07, 1.60, 2.13, 2.67$ and 3.23 m). These tests were repeated using a horsehair, beach type absorber¹, first along the back wall, then along the back and one side, the back and both sides and all around the perimeter — each time testing for six entrance widths. Such complete series of tests were run for each of four wave periods ($T = .985, 1.152, .858$ and $.69$ seconds) and the whole program was completely repeated for the rectangular harbour. Wave measurements were taken by a bank of seven capacitance wave gauges, which moved to locations outside the harbour and to locations spaced at .15 m inside the harbour resulting in 189 to 273 individual wave height measurements within the harbour per test.

Because of the monochromatic nature of the incident wave, it was entirely possible to choose wave periods which caused very large agitations in the models without energy absorbing perimeters. A deliberate attempt was made to de-tune the model, i.e. to adjust the wave period slightly to cause agitation to be a minimum for the harbours without absorber. This method yields conservative results when

¹ The absorber exhibited reflection coefficients between 7 and 18%, depending on the incident wave period and would be comparable to prototype sloping rubble walls, launching ramps, etc.

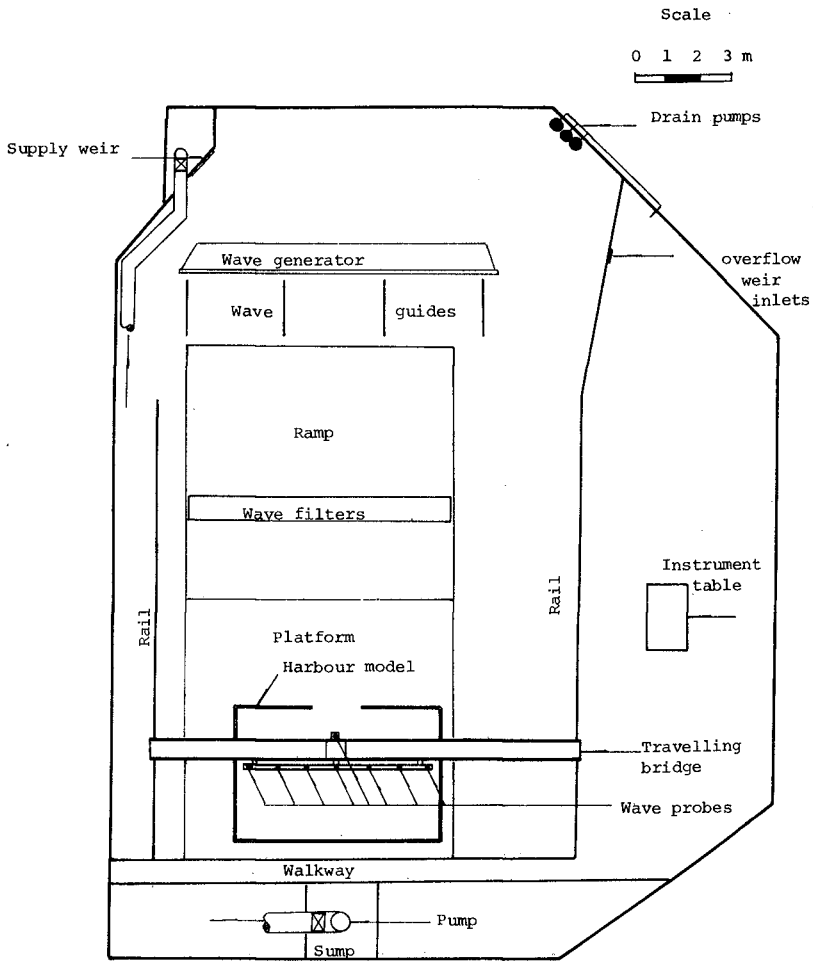

FIGURE 2: EXPERIMENTAL FACILITY.

discussing reduction in wave agitation by perimeter absorbers. Changes in wave period of 1/100 of a second showed remarkable impact on the wave action. This is frightening since the prototype waves contain all sorts of wave frequencies and could respond to any one of these frequencies rather violently.

EXPERIMENTAL RESULTS

The readings from the wave gauges were reduced in the first analysis to normalized wave height plots, of the variety shown in Fig. 3. Normalized wave height is defined as the ratio of local wave height (H) to the incident wave height (H_i). Figure 3(a) with the vertical, reflecting walls shows pronounced reflection patterns in spite of all efforts to de-tune the model. Comparison with Fig. 3(b) shows the influence of an absorbing perimeter. A decrease in overall energy level may be noted, but also a very marked decrease in local agitation, i.e. the internal reflection pattern is gone and the energy is more evenly distributed throughout the harbour. The latter is a particularly important consideration which is not studied in this paper but will be studied in future work. Also in Fig. 3(b), the measured wave agitation is compared with the output of a diffraction program, indicating that wave heights may essentially be determined from diffraction analysis if reflection from the perimeter is minimum. Figures 3(c) and 3(d) show the effect of increased entrance width.

It was also seen from the tests that the absorber was much more efficient when placed along the back wall than when placed along the sides and Fig. 4 shows some examples of overall energy level reduction, clearly indicating that absorber along the back wall only and absorber all around are almost equally effective at decreasing the overall energy level, while the former costs only 30% of the latter. This optimisation of absorber location is under further investigation and the topic of another paper.

THEORY

Assuming conservation of energy, it is possible to state:

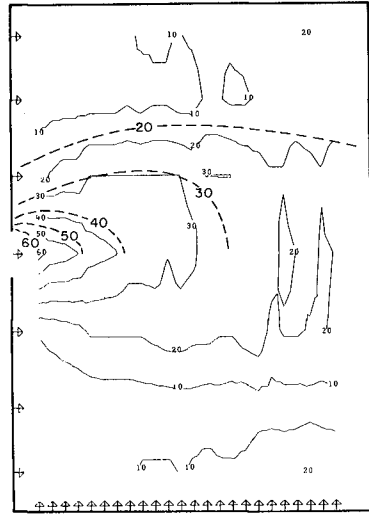

$$A \frac{dE(t)}{dt} = P_i - P_o - P_a - P_f - P_d \quad (1)$$

where A is the harbour area,

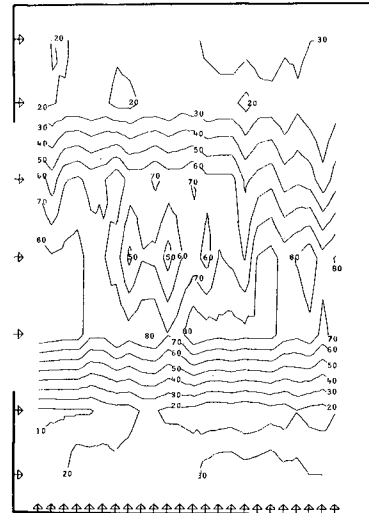

E(t) is the energy density in the harbour as a function of time,

P_i is the rate of energy input (Power in) through the harbour entrance,

P_o is the rate at which energy radiates out (Power out) through the harbour entrance,

a. VERTICAL REFLECTING WALLS. ($b = 0.61$ m) b. ABSORBER ON ALL WALLS.

c. $b = 1.60$ m d. $b = 3.23$ m
 ABSORBER ALL AROUND.

FIGURE 3: NORMALIZED WAVE HEIGHT PLOTS.

a. $T = 0.985$ s.

b. $T = 0.69$ s.

FIGURE 4: REDUCTION IN OVERALL ENERGY LEVEL BY ABSORBERS.

P_a is the rate at which energy is absorbed
(Power absorbed) by the perimeter,

P_f is the rate of energy dissipation by bottom friction,

P_d is the rate of energy dissipation by internal friction.

There are additional terms such as energy dissipated by the docks, boats, etc. which will be included at a later stage of the work.

The term $E(t)$ in Eq. 1 describes the overall average energy density for the complete harbour in this particular study. In subsequent studies, the harbour will be divided to study energy buildup in particular sections individually. In either case, it is possible to define an RMS wave height for the harbour or particular section as:

$$E(t) = \frac{1}{8} \rho g \{ H_{\text{rms}}(t) \}^2 \quad (2)$$

for ease of comparison with the experimental results. Experimentally H_{rms} is simply the RMS value of all the wave heights measured by the probes within the harbour or within a particular section and this value of course corresponds to $t = \infty$.

The rate at which energy enters the harbour may be expressed as

$$P_i = bnC \frac{\rho g H_1^2}{8} \quad (3)$$

where b is the entrance width,

C is the phase velocity of the waves,

ρ is the density of the water,

g is the gravitational acceleration,

n is the ratio of group velocity to phase velocity

$$n = \frac{1}{2} \left\{ 1 + \frac{2kd}{\sinh 2kd} \right\}$$

where k is the wave number ($2\pi/L$),

L is the wave length,

d is the depth of water.

In actual fact, Eq. 2 should use H_1^1 , the incident wave height immediately inside the harbour entrance since the entrance causes energy losses. Work by Unluata and Mei (10) and Murakami and

Noguchi (7) states:

$$H'_i = H_i - K_e \frac{\hat{u}_e |\hat{u}_e|}{2g} \quad (4)$$

where K_e is an entrance loss coefficient
 \hat{u}_e is the maximum velocity in the entrance.

The value used for K_e was 1.5 and this will be verified in some later research. Equation 3 must therefore be rewritten as:

$$P'_i = bnC \frac{\rho g H_i'^2}{8} = bnCR^2 \frac{\rho g H_i^2}{8} = R^2 P_i \quad (5)$$

where

$$R = \frac{H'_i}{H_i}$$

If complete and even diffusion of wave energy is assumed, it is possible to write:

$$P_a = \left(k_a^2 \frac{\epsilon}{S} \right) P'_i \quad (6)$$

where k_a is the absorption coefficient for the perimeter absorbers,
 ϵ is the length of absorber,
 S is the length of harbour perimeter.

In actual fact diffraction takes place and Eq. 6 needs to be modified as:

$$P_a = \left\{ \sum_{j=1}^J k_{a_j}^2 k_{D_j}^2 \frac{\Delta S_j}{b} \right\} P'_i \quad (7)$$

Here the perimeter, S , has been divided into J incremental lengths ΔS_j ,

k_{a_j} is the absorption coefficient for incremental perimeter length ΔS_j ,

k_{D_j} is the diffraction coefficient for the waves reaching section ΔS_j .

Finally, the waves that are incident on the absorber have been modified by bottom friction and hence to be totally correct, Eq. 7 should be rewritten as:

$$P_a = \left\{ \sum_{j=1}^J k_{a_j}^2 k_{D_j}^2 \frac{\Delta S_j}{b} \right\} (P'_i - P_f) \quad (8)$$

where it is assumed that energy dissipation by friction occurs evenly throughout the harbour.

The weakest link in this rather simple analysis is the expression for radiation of energy outward through the entrance. It is assumed that the waves reflected from the face directly opposite the entrance radiate outward through the entrance completely. Any other reflected waves are assumed to re-reflect and remain in the harbour. Essentially a balance in error is assumed between ignoring dispersion of the waves involved in the outward radiation and ignoring the portion of wave energy escaping after secondary reflection. Thus

$$P_o = \left(\sum_{m=1}^M k_r^2 k_{D_m}^2 \frac{\Delta S_m}{b} \right) (P'_i - P_f) \quad (9)$$

where k_r is the reflection coefficient of perimeter length ΔS_m and the summation is only over a width of perimeter b , directly across the harbour entrance consisting of M incremental lengths of perimeter ΔS_m . Energy dissipation by friction for the return journey of the waves from the backwall to the entrance is also ignored in Eq. 9.

The rate of energy dissipation is based on work done earlier at Queen's and summarized in Ref. 4.

$$P_f = \frac{0.18 \rho \omega^2 H_{rms}^3}{8n \sinh^3 kd} f_w \quad (10)$$

where ω is the wave frequency ($2\pi/T$),

T is the wave period,

f_w is the wave friction factor defined in Refs. 3 and 4.

The dissipation by internal friction, P_d , was found to be insignificant.

Introducing P'_i instead of P_i into Eq. 1 and integrating yields:

$$E = \frac{t}{A} (P'_i - P_o - P_a - P_f) \quad (11)$$

where the expression has been averaged over several wave periods.

Substitution of Eqs. 2 to 10 now yields:

$$\frac{H_{rms}}{H_i} = \sqrt{\frac{t}{A} \left[bnCR^2 - \frac{0.18 \omega^2 H_{rms}^3}{ngH_i^2 \sinh^3 kd} \right] \left[1 - \sum_{j=1}^J k_{a_j}^2 k_{D_j}^2 \frac{\Delta S_j}{b} - \sum_{m=1}^M k_r^2 k_{D_m}^2 \frac{\Delta S_m}{b} \right]} \quad (12)$$

Note that to solve Eq. 12 requires both diffraction analysis and iteration.

Figure 5, based on calculations using the above equations, shows the influence of the individual terms in Eq. 11 as well as the development of the ratio H_{rms}/H_i . It may be seen that when the perimeter consists of reflecting walls, P_o is the important energy sink, as expected, while P_a is the dominant energy sink when absorbing perimeter walls are present. It may also be seen that the harbour takes a relatively short time to build up its wave energy to an asymptotic value. The dimensionless time scale used simply means time divided by the time it takes the wave to reach the back wall of the harbour (D is the depth of the harbour).

COMPARISON OF THEORY WITH EXPERIMENT

The relatively simple theoretical development of the previous section was compared with the experimental results and sample plots are shown in Figs. 6,7,8 and 9 (B is the width of the harbour). These figures indicate very good agreement except when the perimeter walls are reflecting. There are two possible reasons for this discrepancy:

- a. Local values of H deviate very far from H_{rms} but on a rather regular reflection pattern (Fig. 3(a)). The seven wave probes shown in Fig. 2 can therefore consistently measure values of H which result in substantially high or low values of H_{rms} depending on the reflection pattern present in the harbour.
- b. In the case of reflecting walls, the dominant energy sink in Eq. 11 is P_o , which is defined in the least reliable fashion.

CONCLUSIONS

1. The average, overall energy level in a harbour may be adequately calculated using a relatively simple theoretical expression such as Eq. 1 or Eq. 11. For the simple square or rectangular harbour used in this paper, the expressions reduce to Eq. 12.
2. The fit of the theoretical expression improves with the absorption qualities of the perimeter.
3. It was further seen from the tests that:
 - a. absorbing perimeter sections are valuable for reducing overall energy levels in a small craft harbour (Fig. 4).
 - b. absorbing perimeter sections reduce local wave energy peaks or locally large wave heights drastically, spreading the energy more evenly throughout the harbour (Fig. 3(a) and (b)).

FIGURE 9: NORMALIZED RMS WAVE HEIGHT COMPARISON WITH THEORY
 $T = 0.985$ s SQUARE HARBOUR.

- c. absorbing perimeter sections can be located judiciously in order to bring about maximum attenuation of wave action per unit length of absorber, (Fig. 4).
- d. Energy levels in the harbour build up rapidly until the main energy sinks begin to function. In any case, response of a marina to outside agitation is rapid — of the order of the time taken for a wave to cross the marina and reflect back to the entrance, (Fig. 5).

Much more work needs to be done. This is only one building block which is useful in solving a rather pressing problem.

CHAPTER 14

EXPERIMENTAL INVESTIGATIONS OF PERIODIC WAVES NEAR BREAKING

J. Buhr Hansen*

ABSTRACT

The results presented are from a series of experiments of periodic waves approaching breaking on a gently sloping beach.

The recorded surface profiles are compared with a cnoidal theory taking into account the effect of the bottom slope. In both theory and experiments a skewness of the profile is observed. A fair agreement is found within certain limits of the wave height to water depth ratio and when the slope is sufficiently gentle. The change in water depth over a wave length must be sufficiently small.

The detailed analysis of the surface profiles including the skewness element shows good agreement with the cnoidal theory in cases where the wave height variation is as predicted by cnoidal wave shoaling.

The recorded surface profiles together with the recorded phase velocities are further used in computing the wave energy flux based on the theoretical relations from linear and cnoidal theories. Reasonable constancy is observed over the whole length covered by the experiments.

Finally the recorded wave set-down is compared with the results of linear and cnoidal theories. When approaching breaking neither of the theories can apparently predict the recorded water level changes.

1. INTRODUCTION

An extensive series of experiments with periodic waves approaching breaking on a 1:34.26 plane sloping beach were carried out from 1975 through 1978.

In these experiments were studied the wave transformation on a gentle slope up to the point of breaking, and the measurements supplied information about height, speed of propagation, and variation of mean water level, as well as the shape and deformation of the surface profiles. In particular the wave profiles differ significantly from those reported in literature because the waves generated were nearly free of free second harmonic components, which so seriously have hampered other investigations.

Much of the raw data from 17 different wave conditions is published in Buhr Hansen and Svendsen (1979). This report further contains a detailed description of the experimental set-up and data acquisition system.

*Assoc. Prof., Inst. Hydrodyn. and Hydraulic Engrg. (ISVA),
Technical University of Denmark, Building 115, DK-2800 Lyngby.

Some of the results extracted from the measurements have already been published in journals and at conferences:

Svendsen and Buhr Hansen (1977 and 1976 a) compared the observed wave height variation over the sloping bottom with the theoretical shoaling of the waves as predicted by sinusoidal and cnoidal wave theories. A good agreement between experiments and theory was observed for waves of relatively small deep water steepnesses (Svendsen and Buhr Hansen, 1976 a, Fig. 4).

In case of rather steep waves, deviations between experiments and theory become pronounced (Svendsen and Buhr Hansen, 1976 a, Fig. 5). However, the shoaling assumption requires that the relative change in water depth, h , over a wave length, L , is small. This indicates that, in case of very long waves, other deviations between experiments and theory might be observed. This is in Svendsen and Buhr Hansen (1977) expressed in terms of a bottom slope parameter $S \equiv h_x L/h$, where h_x is the bottom slope. To fulfill the shoaling assumption, linear theory requires that S is of the same order of magnitude (or smaller) as the wave steepness, H/L , and Svendsen (1974) showed that for (first order) cnoidal waves S must be small compared to $(h/L)^2$. Further, H/h must be sufficiently small ($\ll 1$).

In this paper a detailed analysis of wave surface profiles will be presented, and the results will be compared with a cnoidal theory covering cases from very long waves with low steepness to shorter waves with a considerable steepness.

The analysis of the surface profiles includes a comparison with a cnoidal theory taking into account the distortion (skewness) of the profile due to the sloping bottom as given in Svendsen and Buhr Hansen (1978). A preliminary comparison between some measured wave profiles and the above mentioned theory is included in Svendsen and Buhr Hansen (1976 a, 1978).

Further, the wave energy flux, as calculated from the experimental data, will be analysed for the influence of profile skewness and phase velocity. Svendsen and Buhr Hansen (1976 a) contains some preliminary comparison between the measured and the theoretical phase velocities.

Finally this paper will include a comparison of wave set-down near breaking between the experiments and different theoretical approaches. Svendsen and Buhr Hansen (1976 b) contains some cnoidal wave approximations for the wave set-down and a comparison with two experiments.

2. THE EXPERIMENTAL SET-UP

The waves are generated by a piston type wave generator in a flume 32 m long, 60 cm wide, with a plane beach sloping 1:34.26 (see Fig. 1). The motion of the wave generator is controlled by a PDP 8 mini-computer, which generates a command signal of the form

$$\xi = e_1 \sin \omega t + e_2 \sin(2\omega t + \beta) \quad (1)$$

(Buhr Hansen and Svendsen, 1974). The recording system is described in details in Buhr Hansen and Svendsen (1979).

Fig. 1 Experimental facility

The resulting wave profiles on the horizontal bottom are in Svendsen and Buhr Hansen (1977, 1978) compared with a Stokes' second order wave for rather short waves ($U = HL^2/h^3$ is about 2 and 7, respectively), indicating the generation of waves with almost no free second harmonic components.

It appears that even for waves with U as large as 40 (which is far up in the cnoidal region), the waves generated remain of clean and constant form. In Fig. 2 the recorded surface profiles of three wave conditions are compared with theoretical cnoidal profiles, and a good agreement is observed.

Fig. 2 Surface profiles on horizontal bottom. Measurements compared with first order cnoidal theory. a) $T = 1/3$ s, $U = 32.2$; b) $T = 1/5$ s, $U = 10.7$; c) $T = 1/6$ s, $U = 17.5$

For the longest of these waves the wave height variation over the sloping bottom is clearly not predicted by theoretical cnoidal wave shoaling (see Fig. 3), indicating that the bottom is not 'sufficiently gently sloping' in this case.

Fig. 3 Variation of wave height for 'long' waves with low steepness $T = 1/.3 s, H_0/L_0 = .0019$

Table 1 includes the basic dimensionless parameters for the wave conditions analysed in this paper. In the following the waves will be characterized by their period, T, and deep water steepness H_0/L_0 .

Period T(s)	H_0/L_0	Gener- ated height H(mm)	At $h \approx 360$ mm			At breaking ($\lambda (H/h)_{max}$)			
			U	S	$T\sqrt{g/h}$	h(mm)	U	S	$T\sqrt{g/h}$
1/.3	.0019	40	32.2	.50	17.4	89	1800	1.30	35.0
1/.4	.0038	40	17.5	.37	13.1	85	1000	.93	26.9
1/.4	.0064	71	30.6	.37	13.1	129	650	.74	21.8

3. SURFACE PROFILES ON SLOPING BOTTOM

The deformation of waves passing over a sloping bottom is evaluated theoretically by Svendsen and Buhr Hansen (1978). Their theoretical result is based on a two-scale expansion of the cnoidal theory in which

it is essential that the bottom slope is so small that the shoaling condition is fulfilled, $S \ll (h/L)^2$, but still so steep that the deformation (skewness) due to the slope is an order of magnitude greater than the second order terms of the constant depth solution, $S \gg (h/L)^4$. Simultaneously H/h must be sufficiently small. Under these assumptions the surface profile is given by

$$\eta = \eta^{(0)} + \eta^{(1)} \tag{2}$$

where $\eta^{(0)}$ is the constant depth, first order cnoidal solution

$$\eta^{(0)} = \eta_{\min} + H \operatorname{cn}^2(\theta, m) \tag{3}$$

and $\eta^{(1)}$ is the skewness term given by

$$\eta^{(1)}/H = 3 (L/h)^2 h_x T \sqrt{g/h} G(\theta, U) \tag{4}$$

where g is the acceleration of gravity, and the function $G(\theta, U)$ is given in Fig. 4.

Fig. 4
 $G(\theta, U)$ as function
of phase angle.
Each curve marked
with the value of
 $U = HL^2/h^3$
(From Svendsen and
Buhr Hansen, 1978)

Recorded surface profiles: In analysing the experimental re-sults, the total recorded η is assumed to be a sum of two contributions as given by (2). Knowing the basic features of each of the two terms, $\eta^{(0)}$ and $\eta^{(1)}$ may be separated through

$$\eta_{\theta}^{(0)} = \frac{1}{2} (\eta_{\theta} + \eta_{-\theta}) \quad \text{and} \quad \eta_{\theta}^{(1)} = \frac{1}{2} (\eta_{\theta} - \eta_{-\theta}) \tag{5 and (6)}$$

with $\theta = 0$ at the wave crest.

A direct comparison between the measured and the theoretical profiles as well as the $\eta^{(0)}$ and $\eta^{(1)}$ are given in Fig. 5. The theoretical profiles are computed using the recorded horizontal-bottom-wave height $H^{(0)}$, determined from the $\eta^{(0)}$ profile, and the actual h as input values to the computations.

The four profiles in Fig. 5 are for two different wave conditions, and for each of these are shown the recorded profiles halfway between the toe of the slope and the point of breaking and the last profile recorded before the point of breaking. The recorded $\eta^{(0)}$ -profiles are

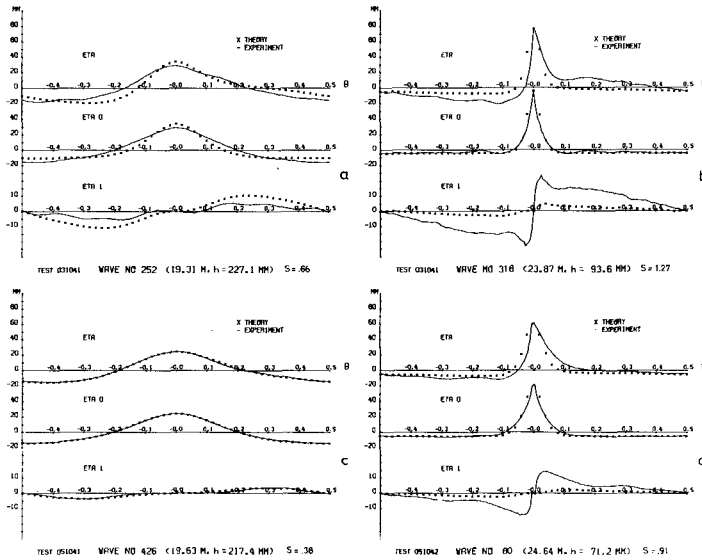

Fig. 5 Surface profiles on sloping bottom. Measurements compared with cnoidal theory. a) and b) $T = 1/3 s$, $H_0/L_0 = .0019$; c) and d) $T = 1/5 s$, $H_0/L_0 = .0060$

seen to agree fairly well with the theoretical profiles even for relatively high H/h values. On the other hand, the observed skewness of the profiles close to breaking is obviously not predicted by the theory. This might, of course, be expected since neither the slope parameter S nor the H/h ratio are within the limits of the theoretical approximation.

Analysis of observed wave skewness: The figures 6 through 9 show the variation of the maximum relative skewness $\eta_{max}^{(1)}/H^{(0)}$ (abbreviated to MRS) with $H^{(0)}/h$ for six different wave conditions. The characteristic feature of the theoretical variation with H/h showing a maximum MRS is clearly reproduced in the tests with waves of low deep water steepness, Figs. 6, 7, 8 and 9 a. Only in case of the shortest of the waves (Fig. 9 a) is the maximum MRS observed at the same H/h as predicted by the theory. When the wave period is increased (Figs. 8, 7 and 6) the maximum MRS should according to the theory be found at decreasing H/h ratios, but this is not observed in the experiments.

Inspection of the figures further shows that the development of the skewness from the toe of the slope is as predicted by the theory in Fig. 8, and with a reasonable accuracy in Figs. 7 and 9 a. In Fig. 6 the skewness is obviously developing gradually over a considerable range of $H^{(0)}/h$ from the toe of the slope, indicating - presumably - that the slope is too steep for this long wave to adjust itself to the local water depth instantaneously as assumed in the theory. This further supports the observation in Fig. 3 indicating that the wave height

Fig. 6 Max. relative skewness $T = 1/3.3$ s, $H_0/L_0 = .0019$

Fig. 7 Max. relative skewness $T = 1/4.5$ s, $H_0/L_0 = .0038$

Fig. 8 Max. relative skewness $T = 1/5.5$ s, $H_0/L_0 = .0060$

Fig. 9 Maximum relative skewness for waves with $T = 1/6$ s
a) $H_0/L_0 = .0093$, b) $H_0/L_0 = .0167$, c) $H_0/L_0 = .0241$

does not vary as predicted by cnoidal wave shoaling. In the case of relatively short waves with greater steepness, Fig. 9 b and c, the characteristic feature of the theoretical MRS variation with a maximum and subsequent decrease of MRS for increasing $H^{(0)}/h$ is not observed in the tests. However, if not only the maximum recorded $\eta^{(1)}$ - which may obviously be greatly influenced by small disturbances of the waves recorded - but the entire $\eta^{(1)}$ profile is included in this analysis, the maximum and subsequent decrease of relative skewness is hardly observed in any of the tests. In Fig. 10 is shown the variations of $\text{RMS}\{\eta^{(1)}\}/\text{RMS}\{\eta^{(0)}\}$ for the same tests as reported in Figs. 6, 8 and 9 a. For the not too long waves the skewness development up to the theoretical maximum is still seen to be reproduced in the experiments, but the subsequent decrease is hardly noticeable. This may indicate that the shape of the recorded $\eta^{(1)}$ profile deviates more from the theoretical shape than the observed maximum value alone, which may be due to the presence of small reflected waves and parasitic waves. For two tests one measure of the shape of the $\eta^{(1)}$ profile is compared with the theory. In Fig. 11 is plotted $\text{MS}\{\eta^{(1)}/\eta_{\text{max}}^{(1)}\}$ versus $U = (H^{(0)}/h)^2 L^2/h^3$.

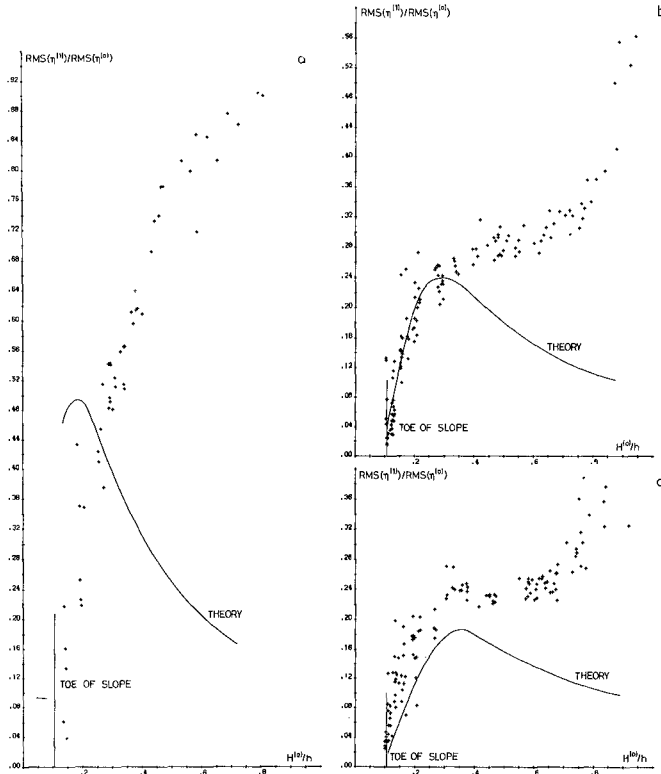

Fig. 10 Relative skewness in terms of $\left\{ \frac{\overline{\eta^{(1)2}}}{\overline{\eta^{(2)2}}} \right\}^{1/2}$
 a) $T = 1/3$, $H_0/L_0 = .0019$; b) $T = 1/5$, $H_0/L_0 = .0060$
 c) $T = 1/6$, $H_0/L_0 = .0093$

Fig. 11
 Shape of $\eta^{(1)}$ profile
 compared with theory

The measurements show a considerable scatter around the theoretical curve calculated from the $G(U, \theta)$ function given in Fig. 4, but the general trend of the theory is reproduced in the tests.

Having determined the $\eta^{(1)}$ profile from the experiments, it is from eq. (4) possible to compare an experimentally determined G function with the theoretical function. In Fig. 12 this comparison is shown in terms of RMS (G), indicating that the general trend is the same in theory and experiments, but also that for $U > 100$ all experiments show an experimental value above the theoretical one, and with a constantly increasing ratio between the measured and the theoretical values for increasing U . It is further observed that for $U > 100$ the experiments yield higher values for higher deep water wave steepness. Both these observations indicate the increasing importance of $H^{(0)}/h$, which in this region cannot really be regarded as small.

Fig. 12 Skewness function G . Comparison between theory and experiments

It is interesting to observe that the experimental G-values continue to decrease when the waves approach breaking, indicating the possibility of establishing a higher order theory valid for $H < h$ rather than the present theory requiring $H \ll h$.

Waves close to breaking: The skewness is seen to increase rapidly just prior to breaking (see Figs. 6 through 9). This might indicate the commencement of the irreversible deformation of the waves eventually leading to the actual breaking. For those tests, where the MRS shows a clear maximum and subsequent minimum for increasing $H^{(0)}/h$ (e.g. Figs. 6, 7, 8 and 9 a), the minimum MRS is observed at an $H^{(0)}/h$ which is very close to the theoretical H/h for the highest stable wave at horizontal bottom according to Ridler (1979), see Fig. 13. This may be taken as support of the idea that this indicates the commencement of the breaking process. Fig. 13 also includes the total wave height to water depth ratio, H/h , at the observed minimum MRS and the $(H/h)_D$ at the breaking point defined as $\max(H/h)$. Close to the breaking point

Fig. 13 Theoretical and observed $(H/h)_{\max}$

the skewness yields a significant change in the wave height recorded, which is not accounted for in the theory. For waves with very low deep water steepness - which in the tests are at the same time 'long' waves - the total wave height may be more than 20% higher than the horizontal bottom wave height, $H^{(0)}$. For the 'shorter' waves with higher deep water steepness the total wave height is only 5 - 10% higher than $H^{(0)}$. This may again support the previous observations indicating incomplete shoaling conditions for the long waves of periods 1/.3 and 1/.4 s, since the $H^{(0)}$ variation if plotted in Fig. 3 would indicate greater discrepancy from the theory than the plotted H variation.

4. ENERGY FLUX FOR WAVES ON SLOPING BOTTOM

One of the basic assumption in wave shoaling is that the wave energy flux through a vertical section remains constant when the water depth is changing.

The basic expression for the energy flux, E_f , as function of time, t , is

$$E_f(t) = \int_{-h}^{\eta} \left(p^+ + \frac{1}{2} \rho (u^2 + w^2) \right) u \, dz \tag{7}$$

where p^+ is the excess pressure due to the wave motion, u and w are the horizontal and vertical particle velocities, and ρ the density of the water.

When (7) is evaluated to the second order in η/h and averaged over a wave period, it reduces to

$$E_f = \rho g h^2 c \left\{ \overline{\left(\frac{\eta}{h}\right)^2} + \frac{1}{2} \overline{\left(\frac{\eta}{h}\right) \left(\frac{\eta}{h+\eta}\right)^2} + \frac{1}{3} \overline{\eta \eta_{xx}} \right\} \quad (8)$$

Using the KdV equation, the last term may be expressed in terms of η

$$\frac{1}{3} \overline{\eta \eta_{xx}} = 2 \left(\frac{c}{c_0} - 1 \right) \overline{\left(\frac{\eta}{h}\right)^2} - \frac{3}{2} \overline{\left(\frac{\eta}{h}\right)^3} \quad (9)$$

where $c_0 = \sqrt{gh}$, and c is the cnoidal approximation to the phase velocity

$$c = c_0 \sqrt{1 + A H/h} \quad (10)$$

$A = A(U)$ is given by the cnoidal theory, see e.g. Skovgaard et al. (1974). When further η is assumed to be a sum of the horizontal bottom profile, $\eta^{(0)}$, and a small skewness component, $\eta^{(1)}$, (8) may be written

$$E_f = \rho g H^2 c B \quad (11)$$

with

$$B = \overline{\left(\frac{\eta^{(0)}}{H}\right)^2} + \overline{\left(\frac{\eta^{(1)}}{H}\right)^2} + 2 \left(\frac{c}{c_0} - 1 \right) \overline{\left(\frac{\eta^{(0)}}{H}\right)^2} - \overline{\left(\frac{\eta^{(0)}}{H}\right)^3} \frac{H}{h} \quad (12)$$

In B the first term is the first order horizontal bottom component

$$B_{01} = \overline{\left(\frac{\eta^{(0)}}{H}\right)^2} \quad (13)$$

which is a function of U only. Of the remaining three terms the first one is the skewness term, while the last two terms are the second order horizontal bottom terms. The direct influence of the skewness on the B value can be seen in Fig. 10 which shows directly the square root of the skewness term relative to the B_{01} term.

While the skewness term is obviously positive, the second order terms of the horizontal bottom profile will be negative for $U < \sim 390$. This is seen when (10) is introduced in the last two terms in (12) yielding an overall negative result for

$$A < \frac{\overline{\eta^{(0)^3}}}{\eta^{(0)^2 H} \quad (14)$$

(A is positive for $U > 47$ and a negligible influence of the second order horizontal bottom terms is observed for $U > \sim 250$).

Experimental results for B_{01} : In Fig. 14 is shown the comparison between the theoretical B_{01} and the value obtained from the recorded $\eta^{(0)}$ profiles. (The theoretical wave length is used in computing U).

While the experiments with not too long waves and a low deep water steepness plotted in Fig. 14b and one test in Fig. 14c show a good agreement with theory up to $U \sim 700$ (corresponding to $H^{(0)}/h \gtrsim .75$) the same agreement is not found neither in Fig. 14a nor in the other two

Fig. 14 Experimental values of $B_{01} = \overline{\eta(0)^2}/H(0)^2$ compared with cnoidal theory

tests included in Fig. 14 c. Fig. 14 a shows experimental values greater than the theoretical values, which is yet another indication of the incomplete shoaling of these long waves. Within $50 < U < 300$ the experimental values would agree with the theory if they had been recorded at a 15% greater water depth, indicating that the shape of the profile corresponds to a greater - earlier - water depth.

For waves with greater deep water steepness (Fig. 14 c) the experimental values are all below the theoretical curves. In this case only the change in wave height can explain the deviation from theory, indicating the importance of the $H^{(0)}/h$ ratio when this is not really small. For increasing wave steepness, a constant U will reflect increasing H/h ratios seen in Fig. 14 c to cause increasing discrepancy between theory and experiments.

Experimental results for B : The combined influence of the skewness and the second order horizontal bottom terms on the energy flux may be analysed through analysis of B given by (12) compared with B_{01} given by (13).

The theoretical B is from (12), (3) and (4) seen to be a function of U , but at the same time dependent on $h_x T \sqrt{gh}$. Theoretically this causes B to be generally greater than B_{01} for long waves of low steepness, and smaller than B_{01} for shorter waves of considerable steepness.

In Fig. 15 is compared the experimental values for B with the theory for three experiments. For all experimental values are plotted two different B values based on both the theoretical and the recorded phase velocities.

The general trend of all three tests is that the combined skewness and second order influence on B is more pronounced in the experiments than predicted by the theory. This is especially pronounced in Fig. 15 a for the long waves with low steepness, and in this case the difference between measured and theoretical phase velocities is seen to be of minor importance.

As seen in previous comparisons, the test in Fig. 15 b shows a very close agreement with theory over the whole range of U values with measured and theoretical phase velocities plotting on either side of the theoretical curve. For the short, steep waves plotted in Fig. 15 c the trend is the same as in the comparison of B_{01} term in Fig. 14 c.

A comparison between measured and theoretical phase velocities is included in Svendsen and Buhr Hansen (1976 a) indicating a fair agreement with cnoidal theory. However, a closer analysis shows that for high values of H/h , the measured phase velocities are in general 5-10% below the theoretical values.

Energy flux: Having determined B , the total energy flux may be computed from (11), now taking into account the combined effect of wave height, phase velocity and the shape of the surface profile. It should be noticed that (11) is valid in linear wave theory as well with

$$B = \frac{1}{16} (1 + G) \quad (15)$$

and

$$G = \frac{2 kh}{\sinh 2kh} \quad (16)$$

Fig. 15 Experimental values of B compared with cnoidal theory

Fig. 16 E_f calculated from experimental results

Fig. 17 E_f for short waves calculated from experimental results

The figures 16 and 17 show for three tests the energy flux determined from (11) using recorded data.

In front of the sloping bottom the recorded H and c values are applied together with an average B determined from the profile recordings available in this region. For the tests in Fig. 16 with rather long waves, B is determined from (12) with no skewness component. For the short waves dealt with in Fig. 17, B is determined from the linear theory (eqs. (15) and (16)).

Over the sloping bottom, on the other hand, $H^{(0)}$, the height of the horizontal bottom part of the profiles is used in determining E_f both in case of a cnoidal computation, Fig. 16, and in case of linear theory computations, Fig. 17.

The scatter about the - by eye placed - regression line is in both figures considerable, mainly due to variation in the recorded phase velocities. However, the two tests in Fig. 16 show some evidence of the presence of a small reflected wave, but with an overall constant energy flux. In Fig. 17 both cnoidal and linear computations of E_f are performed for $U > \sim 15$. As expected, the linear theory yields too high E_f values in this region, but the cnoidal theory on the other hand seems to underestimate E_f . The energy flux is in this case clearly decreasing by the distance from the wave generator (at $x = 0$). The rate of decrease corresponds to a rate of decrease in wave height of $\Delta H/H = .0054$ pr. m, which agrees well with the direct measured attenuation of the wave heights, see Fig. 18. The same agreement is obviously not observed for the tests analysed in Fig. 16.

Fig. 18
 Recorded attenuation of wave heights. Water depth 36 cm, flume width 60 cm (Buhr Hansen and Svendsen, 1979)

5. WAVE SET-DOWN NEAR BREAKING

The last topic to be discussed in this paper is a comparison between recorded and theoretical wave set-down.

From linear theory the wave set-down is given by the well-known expression

$$b = -\frac{1}{16} \frac{H^2}{h} \frac{2kh}{\sinh 2kh} \quad (17)$$

Close to breaking, however, the H/h ratio is not small, and usually the L/h is so large that (17) is a poor approximation, as indicated in both examples given in Fig. 19, where (17) is evaluated using the recorded $H^{(0)}$ and $L (= cT)$ values.

The first approximation to b in cnoidal theory is (Svendsen, 1974)

$$b = -\frac{\eta^2}{2h} \quad (18)$$

In Svendsen and Buhr Hansen (1976 b), (18) is shown to be as poor an approximation to the experimental results as the linear theory. This is confirmed in Fig. 19 where (18) is evaluated using the recorded η values.

Fig. 19
Wave set-down
a) $T = 1/.4 \text{ s}$, $H_0/L_0 = .0038$
b) $T = 1/.5 \text{ s}$, $H_0/L_0 = .0102$

When taking into account the non-linearity of the bottom particle velocity and the vertical accelerations, Svendsen and Buhr Hansen (1976 b) obtain the following approximation to b in cnoidal theory

$$b = -\frac{c^2}{2g} \left[\left(2 \frac{c}{\sqrt{gh}} - 1 \right) \frac{\eta^2}{h^2} - \frac{\eta}{2} \frac{\eta^3}{h^3} \right] \quad (19)$$

When (19) is evaluated from the recorded η and c values, this is in Fig. 19 seen to underestimate the set-down close to breaking where (17) and (18) overestimate b .

Svendsen and Buhr Hansen (1976 b) develop (19) further through certain approximations. (The approximation op. cit. eq. (11) stated to be 'correct within a few per cent for $0 < \eta/h < 1$ ' is, however, only correct within 7% for $\eta/h > .4$. For $\eta/h = .1$ it is incorrect by 35% yielding a severe underestimate of the wave set-down at the toe of the slope in the present experiments, where (17) and (19) yield almost identical results.) The final equation given by Svendsen and Buhr Hansen (1976 b, eq. (14)) based on the above mentioned approximation is

$$b = -\frac{c^2}{2g} \left[\left(\frac{c^2}{gh} - .35 \right) \frac{\bar{\eta}^2}{h^2} - 1.9 \frac{\bar{\eta}^3}{h^3} \right] \quad (20)$$

In Fig. 19 this is to some extent seen to reflect the shape of the measured set-down but at a different elevation, when (20) is evaluated from recorded η and c values.

Compared to the observations in the previous chapters of this paper it is remarkable to observe that, while the surface profiles and the energy flux seem to be reasonably well predicted by the cnoidal theory, this is certainly not the case for the set-down.

An Heuristic Model of Wave Height Distribution in Surf Zone

Masaru MIZUGUCHI

 Kasuga, Bunkyo-ku
 Tokyo, JAPAN

INTRODUCTION

Until now, almost every study on coastal processes has considered the basic type of two-dimensional beach profile as being of constant slope. However, as our knowledge on this problem advances, we realize the importance of the influences of the bottom configuration on the hydrodynamic phenomena in a given area.

Figure 1 shows a recent experimental result on the longshore current profile on a step type beach. (Here the step type beaches are defined as those which have a step in the bottom profile, whether the beaches are of accretion type or not.) The wave height and mean water

Figure 1 Longshore current on a step type beach [Mizuguchi & Horikawa (1978)]

level distribution are also plotted in this figure. The current velocity profile exhibits a different pattern from the one expected on a uniformly sloping beach. The difference is mainly due to the wave height distribution in the surf zone, which contributes to the radiation stress gradient and to generating the current. On uniformly sloping beaches, the wave height in the surf zone is almost proportional to the water depth, and thus the external force to generate the current is a monotonous function of the onshore or offshore direction. The wave height distribution after breaking at the step in Fig. 1 is not proportional to the local water depth but, rather, is unique to the step type beach, showing exponential-like decay after the first breaking, recovery at the uniform depth area, second breaking on the inner slope and linear decay on the uniformly sloping beach. The long-shore current velocity tends to increase shoreward where the wave height decreases, being modified by the turbulent viscosity. Therefore it is absolutely essential to be able to calculate the wave height distribution in a surf zone with a non-uniform bottom profile. And the beach profile usually observed in field experiments is not a uniformly sloping one, but a much more complex profile.

Outside the surf zone the energy equation, combined with a theory of permanent wave, is capable of giving the wave height change with good approximation, if the beach slope is not very steep. Inside the surf zone, turbulence induced by wave breaking plays an important role. At present, we have both experimental results and semi-empirical theories based on the energy conservation equation to evaluate the wave height (or energy) decay on a constant depth beach [for example, Horikawa & Kuo (1966)]. The most sophisticated but still gross treatment of that problem originates with the work of LeMehaute (1962), where the energy dissipation process is assumed to be similar to that in the hydraulic jump. Following this line, Battjes & Janssen (1978) treated the change of the r.m.s. value of the irregular wave height in the surf zone and succeeded in adjusting their theory to the experimental results, which included the case of a non-uniformly sloping beach.

In the above mentioned theories the energy dissipation depends on the wave height itself. This means that the wave height decays until reaching zero. However, suppose that the water depth after the wave breaking is constant; the broken wave will recover somewhere and start to propagate as a reformed wave in the constant depth area, if the energy dissipation due to the bottom friction is negligible.

In this paper an heuristic model is developed by employing the simplest formulation, that is, an eddy viscosity assumption. In order to construct the model, two limiting conditions were taken into account, namely, 1) wave breaking on a constant depth beach and 2) wave breaking on a uniformly sloping beach. These will be shown to be well described by the model.

DERIVATION OF THE MODEL

Four major assumptions are employed to derive the model as are now listed.

1) The following wave energy equation can be applied in the surf zone.

$$\frac{d}{dx}(Ec_g) = -\epsilon \quad (1)$$

with expressions

$$E = (1/2)\rho ga^2 \quad (2)$$

and

$$c_g = \sqrt{gd} \quad (3)$$

where E: wave energy per unit area, c_g : energy propagation velocity, ρ : fluid density, g : gravity acceleration, a : wave amplitude, ϵ : energy dissipation rate, d : water depth. In a strict sense, these expressions are inadequate to describe wave motion in the surf zone. The validity of Eq. (1) depends on the dissipation rate ϵ . Equation (2) can be used if the ratio of the wave height squared to the wave energy is constant through the surf zone. The unknown constant ratio will be included in the dissipation rate. In the surf zone the wave energy propagation velocity may be the same as the phase velocity, and is well approximated by that of the solitary wave theory [Mizuguchi (1979)].

$$c_g = \sqrt{g(d+2a)} \quad (4)$$

Equation (3) can be considered to be a first approximation to Eq. (4).

2) When applying the idea of turbulent eddy viscosity, ν_e , the rate of energy dissipation is given by

$$\epsilon = 2\rho g\nu_e(ka)^2 \quad (5)$$

where k : wave number. Here the energy dissipation due to the bottom friction is neglected. Equation (5) is obtained by replacing the molecular viscosity ν by the turbulent eddy viscosity ν_e in the final expression of the wave energy dissipation in irrotational flow. Ijima, Takahashi & Nakamura (1956) introduced Eqs. (1) and (5) to treat wave height decay in a surf zone of uniform depth with constant eddy viscosity. It should be noted that the eddy viscosity is not equivalent to that proposed by Battjes (1975), which is introduced through a discussion of energy dissipation due to (isotropic) turbulence induced in wave breaking.

3) Then the eddy viscosity is modeled in the following way. First, when the depth in the surf zone is constant, the broken wave should recover (or reform) as mentioned before. This suggests that the energy dissipation rate or the eddy viscosity should be a function of the difference between the real wave height and the reformed wave height. Secondly, the dissipation rate may also be related to the ratio of the real wave height to the possible maximum wave height at any location. On uniformly sloping beaches the waves are considered to be continuously breaking and the state of the maximum wave height is always realized. Then the possible maximum wave height may be expressed by $\gamma'd$, where

γ' is the constant wave amplitude to water depth ratio in the surf zone on a uniformly sloping beach. These hypotheses result in the following expression for v_e :

$$v_e = v_{eB} [(a-c'd)/\gamma'd]^m \quad (6)$$

where c' is the ratio between the wave amplitude and the water depth in the wave recovery zone on a constant depth beach, and m is a constant to be determined later. The subscript B denotes quantities evaluated at the breaker line.

Then the nondimensional equation describing the wave height distribution in the surf zone is

$$\frac{d}{dX} (A^2 D^{1/2}) = -N_B (AD^{-1} - c_0)^m A^2 D^{-1} \quad (7)$$

where

$$N_B = 4v_{eB} \sigma / (g d_B) \quad (8)$$

and $c_0 = c'/\gamma'$, $A = a/a_B$, $D = d/d_B$, $X = k_B x$ and σ : angular frequency. In Eq. (7) the constant m should be less than 1.0, since the broken wave should recover in a finite distance in a constant depth surf zone. Here we take m as 0.5, for the advantage of easy handling.

4) The nondimensional eddy viscosity N_B can be calculated as follows from the experimental fact that the ratio γ' is constant on uniformly sloping beaches.

$$N_B = 5(1-c_0)^{-1/2} s_B / (2k_B d_B) \quad (9)$$

Here s_B is a representative beach slope (including the expected wave set-up_B) outside the breaker line, so that

$$s_B = s'_B / (1 + 3\gamma'^2/2) \quad (10)$$

where s'_B is a representative beach slope for wave breaking. Actually Eq. (9) is derived by equating the wave height decay ratio at the breaking point with the mean decay ratio a_B/x_B , where x_B is the surf width.

The wave set-up $\bar{\eta}$ in the surf zone is usually given by the following nondimensional equation,

$$\frac{dH}{dX} = -(3/2)\gamma'^2 AD^{-1} \frac{dA}{dX} \quad (11)$$

where the radiation S_{xx} is assumed to be given by $3E/2$ with Eq. (2), and $H = \bar{\eta}/d_B$. Combining Eqs. (7) and (11), we can calculate both the wave height and the wave set-up distribution in the surf zone for arbitrary bottom profile $d(x)$. The flowchart to solve Eqs. (7) and (11) numerically is shown in Fig. 2, for the case of no second wave recovery. The differential equations are solved numerically by the Runge-Kutta-Gill method. The calculation converges within two or three

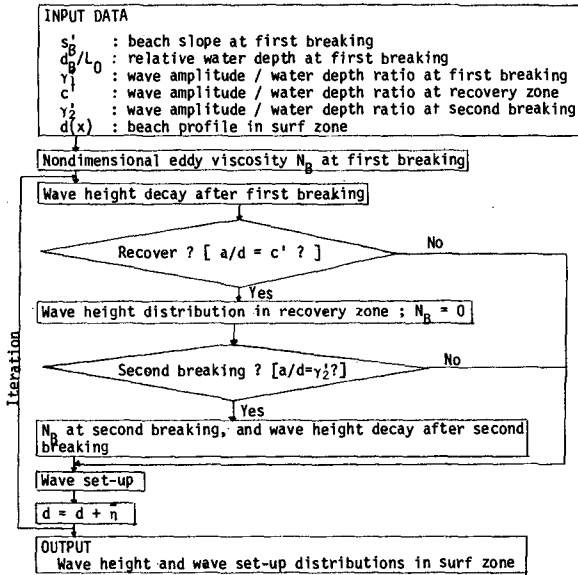

Figure 2 Flowchart to calculate wave height and wave set-up in the surf zone (no second wave recovery)

iterations as described in the flowchart.

As shown in Fig. 2, the unknowns are the breaker depth, the breaker height, the wave amplitude to water depth ratio, c' , in the recovery zone, and the bottom topography $d(x)$. The second wave breaking criterion γ'_2 may be chosen as 0.4, which is an approximate value for breaking solitary wave, because once-broken waves may be better expressed by solitary wave theory. Any kind of breaker index can be used to predict the breaker depth and the breaker height (or the ratio γ'_1) for uniformly sloping beaches [for example Goda (1970)]. The next simple empirical relation was given by Sunamura & Horikawa (1974):

$$a_B/H_0 = 0.5s'_B{}^{0.2}(H_0/L_0)^{-0.25} \quad (12)$$

$$0.01 < s'_B < 0.1$$

$$0.003 < H_0/L_0 < 0.07$$

Equation (12) was obtained by using the collected (and also corrected) data in Goda (1970). The following relation may also be derived from

the same data:

$$a_B/d_B (= \gamma'_1) = 0.75s_B'^{0.3} (d_B/L_0)^{-0.1} \quad (13)$$

$$0.03 < s_B' < 0.1$$

$$0.01 < d_B/L_0 < 0.05$$

In Eqs. (12) and (13), H_0 and L_0 denote deepwater wave height and deepwater wave length respectively. These equations provide full information for a wave to break. The ratio γ'_1 has two limiting conditions. It tends to a constant as the slope s_B' goes to zero when the relative water depth is small, and the wave steepness should be limited when the relative water depth is large. Then Eq. (13) can hold only in the indicated range. The ratio c' is expected to be determined by the intensity of wave breaking. The values obtained in laboratory experiments [Mizuguchi, Tsujioka & Horikawa (1978) and Nagatoh & Ohishi (1979)] centered on the range from 0.21 to 0.28, slightly decreasing with increase of wave steepness.

If wave set-up is neglected, Eq. (7) can be solved in closed form for the case of a constant depth surf zone.

$$A = c_0 \sec^2 \left(-\sqrt{c_0} N_B X/4 + \arctan \sqrt{(1-c_0)/c_0} \right) \quad (14)$$

Figure 3 show calculated curves for various values of N_B . The distance X_R to the recovery point where $A = c_0$ is given by

$$X_R = 4 \arctan \sqrt{(1-c_0)/c_0} / (N_B \sqrt{c_0}). \quad (15)$$

Figure 3 Wave height decay in a constant depth surf zone

COMPARISON WITH EXPERIMENTS

Figures 4 - 7 show the comparisons of the predicted results (solid lines) with the experimental results. The broken lines will be explained later. In the calculation the constant c' is roughly chosen as noted in the figures to give the best fitted curve in the recovery or almost recovery zone. In the case of uniformly sloping beaches as in Fig. 5, the value of c' does not affect the results.

Figure 4 Comparison with experiment (constant depth beach)

Figure 5 Comparison with experiment (uniformly sloping beach)

Figure 6 Comparison with experiment (step type beach)

Figure 7 Comparison with field experiment

Generally the agreement is good enough. However, the model shows a tendency to underestimate the wave height decay near the first breaking, except in Fig. 6. In figs. 5 and 6, it is also seen that the wave set-up is also overestimated. The overestimated wave set-up increases the water depth, so that the wave height decay is relaxed. These are mainly caused by the fact that the wave energy is overestimated in the form given by Eq. (2). The delay of the wave set-up starting point from the wave breaking point, which is usually defined by the point of the maximum wave height, is also responsible for the results in Fig. 5.

Figure 8 shows the relation of the wave set-up $\bar{\eta}_R$ in the recovery zone to the wave breaking height on step type beaches. The solid line is from the next relation.

$$H_R (= \bar{\eta}_R/d_B) = 0.75(\gamma'^2 - c'^2) \tag{16}$$

which follows immediately from Eq. (11). The fitted line is

$$H_R = 0.25(\gamma'^2 - c'^2) \tag{17}$$

and indicates that the wave energy (or radiation stress) should be estimated by the following relation:

$$E = (1/6)\rho g a^2 \tag{18}$$

Here it is worth noting that the data plotted in Fig. 8 were obtained by changing the wave height while keeping the water depth fixed in the step region. Figure 8 also suggests that the value of c' is approximately 0.25.

In Figs. 5 and 6, the nondimensional r.m.s. values of the water surface fluctuation η_{rms}/η_{rmsB} are also plotted. Taking the long wave or small amplitude wave assumption, we have the next relation.

$$E = \rho g \eta_{rms}^2 \tag{19}$$

Therefore, in a sense, the ratio of the wave height to η_{rms} denotes the unknown factor mentioned in the derivation of the model. The difference between η_{rms}/η_{rmsB} and a/a_B is within the

Figure 8 Wave set-up in recovery zone (constant depth or step type beach)

error of the allowance for surf zone phenomena. Then the relation (18) is expected to hold through the surf zone and should be taken into consideration in evaluating the wave energy from the wave height. Actually the ratio of a^2 to n_{rms}^2 is calculated from the experimental data for the cases in Figs. 5 and 6. In and near the surf zone the values are about 3 to 4, which is much larger than the value 2 for small amplitude waves but almost half of that expected from Eq. (18).

The broken lines in Figs. 4 - 7 are the results obtained by using the empirical relation (18). Then Eq. (10) is also modified. They agree better with the experimental results. A typical wave height transformation over a step type beach is shown in Fig. 6; decay after the first breaking, recovery at the uniform depth area (marked by "R"), increase due to the decrease in water depth, second wave breaking ("S.B.") after which the wave height linearly decreases to zero at the mean water shoreline. However, this time, the wave set-up is a little underestimated. It reflects the above-mentioned experimental results that the ratio a^2 to n_{rms}^2 should be smaller than 6. In addition, the broken line shows the overestimation of the wave height decay just after the first breaking in Fig. 6. This is connected with the determination of the representative beach slope for the wave breaking. The step part of the bottom profile in the case of Fig. 6 was made of bent plate, which was placed on the uniformly sloping (1/10) beach. The slope just before the wave breaking was about 1/5, which was used to calculate the predicted curve. The slope might be steeper than the value which really governs the process of the wave breaking and gives too rapid decay of the wave height after breaking.

DISCUSSION

The model developed herein is an expedient, although it predicts rather well the experimental results over a wide range of conditions. There are two points which one should treat carefully when applying this model. The first point is how to choose the representative beach slope s'_B before wave breaking. In laboratory experiments, it should be pointed out that the beach slope s'_B is not equal to a real slope, unless the uniformly sloping beach section extends to a sufficient deep region. When the water is not so deep in the uniform depth region, waves may deform while travelling in that region and easily break. Then the breaking phenomena cannot be considered to depend only on the beach slope just before wave breaking. We suggest that Eq. (13) is to be applied to determine the beach slope s'_B , once the wave amplitude - water depth ratio γ'_1 at the breaking point is given independently. This ratio may be considered to indicate how the wave is deformed before breaking, representing the wave's history. The second point is how to give the value of c' . In this respect our knowledge on wave breaking phenomena is still unsatisfactory. Well-controlled experiments are required to give the proper value of the c' in this model.

Finally it should be pointed out that the eddy viscosity assumption in the energy equation is physically obscure, although it could be more easily modeled as in Eq. (6) than that proposed by Battjes (1975). This model reflects the present state of the study on wave

properties in the surf zone and reveals some problems to be investigated in the future. For example, on uniformly sloping beaches where the waves are considered to be continuously breaking, why is the wave height always proportional to the water depth through the surf zone and why does the wave set-up delay its start from the point of the maximum wave height? How is the turbulence generated and how does it affect the wave height decay? How should the constant c' be determined? What is the best expression for breaking or broken waves in and near the surf zone? The investigation to answer such questions will lead to a more complete modeling of the wave breaking process. The work by Sawaragi & Iwata (1974) and Svendsen, Madsen & Hansen (1978) are along these lines, but still further progress must be made before one can reach a firm understanding of the wave transformation in the surf zone.

ACKNOWLEDGEMENT

I appreciate the assistance of Mr. K. Tsujioka and Prof. K. Horikawa in carrying out this study. A portion of this paper was authored with them and published in Japanese in the Proceedings of 25th Japanese Conference on Coastal Engineering held in November, 1978, [Mizuguchi, Tsujioka & Horikawa (1978)].

CHAPTER 16

Resonances of Coastal Waters Between Perth and Geraldton (Western Australia)

H. ALLISON, Ph.D. M.Sc., MIE Aust., M.R. Soc (Vic. & W.A.), Senior Research Scientist, CSIRO, Div. of Land Resources Management, Wembley, 6014.

A. GRASSIA, Dr. Math. & Phys., B.A. Principal Research Scientist, CSIRO, Div. of Mathematics and Statistics, Wembley, 6014.

R. LITCHFIELD, CSIRO, Div. of Mathematics and Statistics, Wembley, 6014.

SUMMARY Sea-level oscillations along the Western Australian coast, with periods in the range of 20-40 mins, have considerably greater amplitudes between Perth and Geraldton than at other locations along the coastline. It is shown that amplification of these oscillations is due to resonance in the near shore basin formed by the shore and a submerged reef-chain parallel to and 5 km from the shore.

The rigorous analytical solution for the resonance frequencies is obtained for the two-dimensional hydrodynamic model. Comparison with results from spectral analysis of recorded oscillations indicates a satisfactory agreement with the theory. Statistical estimation of damping of the observed oscillations indicates that the predominant resonance in the first mode is sharp, having the quality factor $Q=10$.

1 Introduction

Nearshore sea-level oscillations, apart from tides, are observed at many locations. The oscillations have periods ranging from several minutes (surf beat, nearshore edge waves, harbour seiches) through several hours (continental shelf waves) to hundreds of days (planetary waves) (Le Blond and Mysak, 1978). Research on continental shelf waves in Western Australia (Hamon, 1966) initiated world-wide theoretical and experimental study of the subject. Later studies by Hamon (1976) indicated that the shelf waves in Australia were generated by wind, supporting the point of view of Gill and Schumann (1974). Recently sea-level oscillations along the Western Australian coastline, with periods in the range 20-40 min, were reported by Allison and Grassia (1979) to be attributed to the presence of a reef-chain parallel and 5 km from the Western Australian shore (Fig. 1).

The new results are reported below, including the spectral analysis of sea-level oscillations, theoretical solutions for the two-dimensional hydrodynamic model, which in particular indicates the presence of oscillating currents near the coastline.

2 Long-term statistics

Western Australian tidal records for the last 15 years were analysed. On many of them, short period (relative to tidal period) oscillations

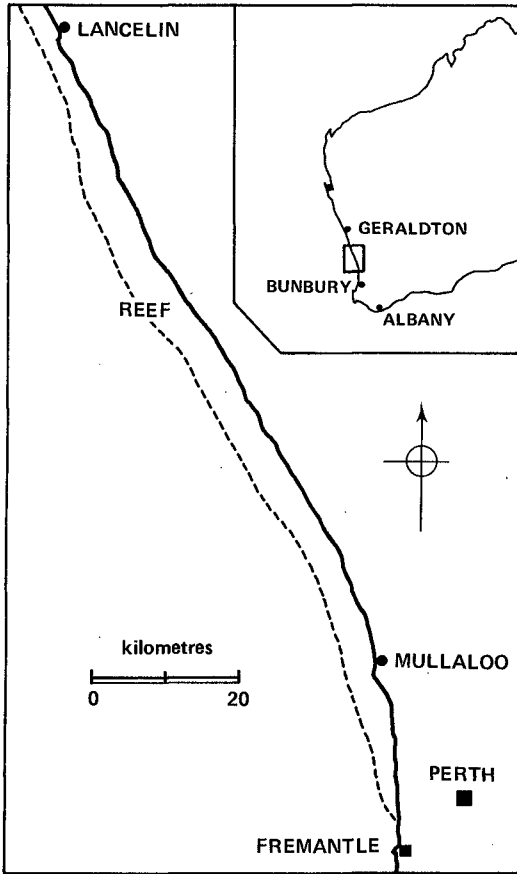

Figure 1. Submerged Reef Chain Off Western Australian Coast

were present. These oscillations usually were of small amplitudes, of the order of several centimetres. However, occasionally large amplitude oscillations occurred and lasted several hours, sometimes persisting for one or two days (with corresponding smaller amplitudes). A typical such sporadic oscillation is presented in Figure 2.

In the following any sea-level oscillation, having its amplitude ≥ 10 cm is called an event. In total, 219 such events were observed between 1963 and 1978.

To characterise the intensity of the event we have used its energy E, which was calculated on the basis of the following formula:

$$E = \frac{\rho g A^2 \tau}{4T} \quad (1)$$

which follows from the familiar expression of a maximum energy of a standing wave per unit surface and per one cycle of oscillations of the period T:

$$E_T = \frac{1}{4} \rho g A^2 \quad (2)$$

Here ρ is the mass density of water, g is a gravity acceleration, A was taken as a maximum amplitude during the sea-level oscillation event, and τ is a duration of the oscillation event, which was taken as a length of time during which amplitudes of oscillations exceeded the threshold value of 10cm.

Estimate of energy obtained by (1) is, of course, exaggerated, because the formula is valid, strictly speaking, only for waves, sinusoidal in time, while the recorded oscillations decay with time (Fig. 2). A justification of its use is however simple: we are interested only in relative variation of the energy of the events in the long term, rather than in the absolute value of the energy.

To characterise the probability of occurrence of large sea-level oscillation events we used their frequency of appearance, meaning number of events occurring during a certain selected interval, such as a month or a year. (Notice that on the following pages we shall also use the word 'frequency' in the physical sense, such as 'resonance frequency', not to be confused with the statistical frequency of occurrence).

The results of calculations of seasonal and yearly variations of event frequencies and energies are shown in Fig. 3 and 4. (In Fig. 4 the yearly averages of Zürich sunspot numbers are shown for comparison).

The monthly averages (Fig. 3) indicate that more events and events with larger energy occur in the Southern Hemisphere winter. This may indicate that observed events are possibly caused by long waves, generated by winter storms in the Indian Ocean, but we do not possess any independent proof of this.

Figure 2. Tidal Record Geraldton, W.A.

Figure 3.

Figure 4. Monthly and Yearly Frequencies of Events

The yearly averages demonstrate a remarkable resemblance to the solar activity pattern (in fact, our calculations had shown a statistically significant correlation of the energies and frequencies of occurrence of events to solar activity). However, in spite of some recent claims about solar-terrestrial relationship (see, for example, Currie, 1976) we are reluctant to speculate here on the subject, leaving room for further study, which might, possibly, indicate the correlation between storms in the Indian Ocean and solar activity.

3 Short-term statistics - spectral analysis

The large sea-level oscillation event, described above, usually occur on the background of small amplitude oscillations. These small oscillations, (with the amplitudes below threshold of 10cm) are persistent practically always, and generate permanently present oscillating currents in the nearshore zone of Western Australia.

An example of such small amplitude oscillations is shown in Fig. 5.

Figure 5 Small Oscillations of East-West Current, Mullaloo, W.A.

While it has been proved (Allison and Grassia, 1979) that large sea-level oscillations events are associated with the standing waves between the shore and the reef-chain, no such proof has been made for small amplitude background oscillations. We present here some evidence in support of the point of view, that these always persistent small amplitude oscillations originate in the same way as the large ones. To this point, let us consider the results of spectral analysis of both large sea-level oscillations and small-amplitude background. These results are presented correspondingly on Fig. 6a,b.

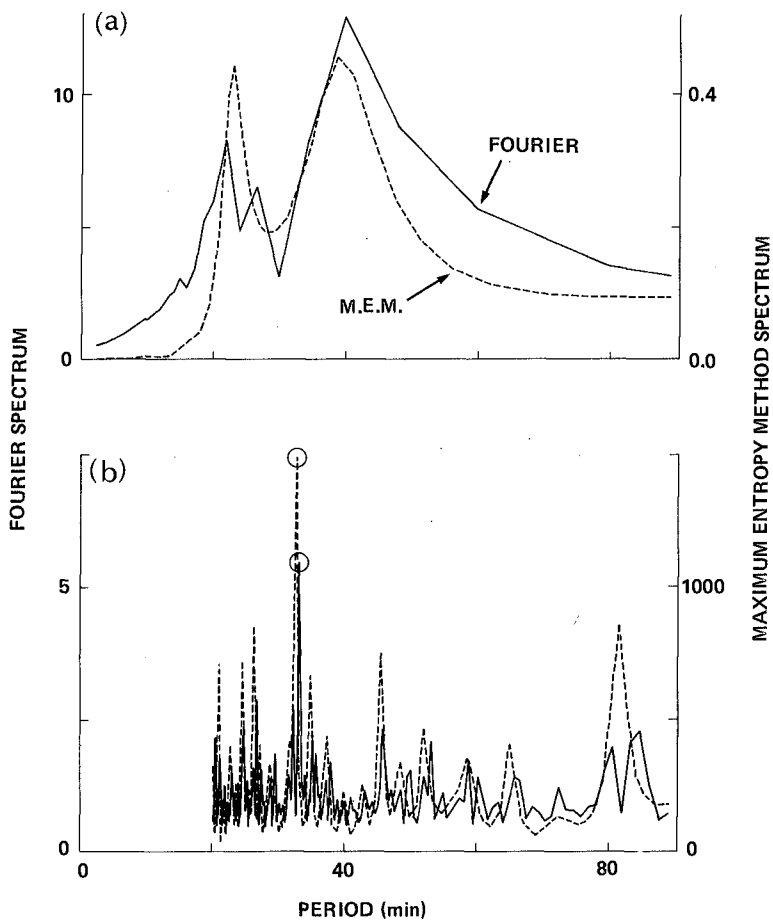

Figure 6. Period Spectrum of:

(a) Large Oscillations (b) Small Oscillations

The solid lines on both parts (a) and (b) of Fig. 6 correspond to the modulus of the Fourier Spectrum of the oscillations, the dashed lines show the Maximum Entropy Method spectra. It is seen, first of all, that the Maximum Entropy Method gives results, closely corresponding to the ordinary Fourier Analysis, although some spurious peaks, given by Fourier Analysis are effectively suppressed by the Maximum Entropy Method. Most important, however, is the presence of considerably sharp resonance peaks on both spectra.

The comparison of computed resonance periods for large sea-level oscillation events and small-amplitude background is given in Table 1.

Table 1

	Distance from reef to shore	Dominant Period	Non-dimensional Frequency
	ℓ (km)	T (mins)	$R = \frac{2\pi}{T} \frac{\ell}{\sqrt{gh}} \dots (18)$
Large oscillations Geraldton, W.A.	5	40	1.32
Small oscillations Mullaloo, W.A.	4.5	33	1.44

As seen from Table 1, the non-dimensional frequencies of large and small oscillations are in reasonable agreement, thus substantiating the point of view, that both types of oscillations are, in essence, resonances in a hydrodynamic system, namely, the basin formed by the shore and nearshore reef chain. We consider now the analytical treatment of the resonances.

4 Analytical Development

The bottom topography of the nearshore basin is represented by the dashed area in Fig. 7. We approximate this profile by the parabolic expression

$$h(x) = h_0 \left[1 - \left(\frac{x}{\ell} \right)^2 \right] (1-\alpha) \quad (3)$$

where h_0 refers to the depth at $x=0$, ℓ being the length of the basin (in our case the width of the channel) and α is a non-dimensional parameter, describing the fact that the reef-chain is submerged. For the values $h_0 = 10\text{m}$; $\alpha = 0.3$ the graph of expression (3), shown by a solid line in Fig. 7, provides an idealised smooth representation of the bottom profile. The chief advantage of using (3) is that it allows us to obtain a rigorous analytical solution of the equation of water motion in the basin partly open to the ocean. One may notice that variation in the parameter α permits also consideration of various cases of submergency of the reef.

Figure 7 Typical Bottom Topography in W.A. (normal to shore)

When $\alpha = 1$ the basin has a uniform depth with one end ($x=0$) closed and the other end ($x=l$) opened into the deep ocean, being the classical problem, for which the exact solutions are known (Lamb, 1932). When $\alpha = 0$, we have the closed basin with a parabolic bottom profile, being the other classical case (Chrystal, 1904).

We give below the rigorous solution for the intermediate case of a partly open basin with the parabolic bottom for $0 \leq \alpha \leq 1$: the classical problems, considered by Chrystal and Lamb emerging as the limiting cases of the solution that follows. As the depth is in the order of 10m, while length of the basin (width of the channel) is in the range 4-6 km, we accept as a starting point the familiar shallow water equation:

$$g \frac{\partial}{\partial x} [h(x) \frac{\partial \eta}{\partial x}] = \frac{\partial^2 \eta}{\partial t^2} \quad (4)$$

where g is a gravity acceleration and $\eta(x,t)$ represents the elevation of the free surface of water above its undisturbed surface level.

Considering free oscillations with frequency ω , we, as usual, represent $\eta(x,t)$ as a product of two functions, one describing the shape of water motion $\xi(x)$ and the other being a time-dependent term $e^{-i\omega t}$.

$$\eta(x,t) = \xi(x)e^{-i\omega t} \quad (5a)$$

The second time derivative becomes:

$$\frac{\partial^2}{\partial t^2} \eta(x, t) = -\xi(x) e^{-i\omega t} \omega^2. \quad (5b)$$

After the separation of variables, and substitution of $h(x)$ as in (3), eq. (4) takes the form:

$$\frac{d^2 \xi}{dx^2} \left[1 - \left(\frac{x}{\ell} \right)^2 (1-\alpha) \right] - \frac{d\xi}{dx} \left[\frac{2x}{\ell^2} (1-\alpha) \right] + \frac{\omega^2}{gh_0} \xi = 0. \quad (6)$$

Introducing the new variable

$$z^2 = \left(\frac{x}{\ell} \right)^2 (1-\alpha) \quad (7)$$

we obtain the following sequence of simple formulae:

$$z = \left(\frac{x}{\ell} \right) (1-\alpha)^{1/2} ; \quad \frac{dx}{dz} = \ell (1-\alpha)^{-1/2} \quad \} \quad (8a)$$

$$x = z\ell (1-\alpha)^{-1/2} ; \quad \frac{d^2 x}{dz^2} = 0 \quad \}$$

$$\frac{d\xi}{dx} = \left(\frac{dx}{dz} \right)^{-1} \frac{d\xi}{dz} = (1-\alpha)^{1/2} \ell^{-1} \frac{d\xi}{dz} \quad \} \quad (8b)$$

$$\frac{d^2 \xi}{dx^2} = \left(\frac{dx}{dz} \right)^{-2} \frac{d^2 \xi}{dz^2} - \left(\frac{d^2 x}{dz^2} \right) \left(\frac{dx}{dz} \right)^{-3} \frac{d\xi}{dz} = (1-\alpha) \ell^{-2} \frac{d^2 \xi}{dz^2} \}$$

Substitution of (8a), (8b) and (7) in (6) leads to the following equation:

$$(1-z^2) \frac{d^2 \xi}{dz^2} - 2z \frac{d\xi}{dz} + \frac{\omega^2 \ell^2}{gh_0 (1-\alpha)} \xi = 0 \quad (9)$$

which has the familiar form of a Legendre equation, if we put

$$\frac{\omega^2 \ell^2}{gh_0 (1-\alpha)} = n(n+1) \quad (10)$$

where the integer n , being a mode number, takes the values 1, 2, 3, ...

The general solution of (9) with the notation (10) has a form:

$$\xi(z) = AP_n(z) + BQ_n(z) \quad (11)$$

where A and B are arbitrary constants and $P_n(z)$ and $Q_n(z)$ are the Legendre functions, of which $P_n(z)$ is always a polynomial, but $Q_n(z)$ is not. Let us consider initially the boundary condition at the shore side of the basin, where no current is possible. This can be written as a condition on the first derivative of the vertical displacement ξ , at the point $x = z = 0$:

$$\left. \frac{d\xi}{dz} \right|_{z=0} = 0 \quad (12)$$

which, after substitution of (11) into (12) becomes:

$$\left. \frac{d\xi}{dz} \right|_{z=0} = AP_n'(0) + BQ_n'(0) = 0 \quad (13)$$

We can utilize now the useful properties of the Legendre functions, given in the Table 2.

Table 2

For even n	For odd n
$P_n'(0) = Q_n'(0) = 0$	$P_n'(0) = Q_n'(0) = 0$
$P_n(0) \neq 0 ; Q_n(0) \neq 0$	$P_n(0) \neq 0 ; Q_n(0) \neq 0$

Substituting the values from Table 2 into eq. (11) we obtain that the solutions, satisfying the boundary condition (12) are:

$$\xi = AP_n(z) \quad (n \text{ even}) \quad (14a)$$

$$\xi = BQ_n(z) \quad (n \text{ odd}) \quad (14b)$$

Explicit expressions for the first six solutions are given below:

$$\begin{aligned} P_0(z) &= 1 \\ Q_1(z) &= \frac{z}{2} \ln \frac{1+z}{1-z} - 1 \end{aligned} \quad (15)$$

$$P_2(z) = \frac{1}{2} (2z^2 - 1) \tag{15 cont.}$$

$$Q_3(z) = \left(\frac{5z^3}{4} - \frac{3z}{4}\right) \ln \frac{1+z}{1-z} - \frac{5}{2} z^2 + \frac{2}{3}$$

$$P_4(z) = \frac{1}{8} (35z^4 - 30z^2 + 3)$$

$$Q_5(z) = \left(\frac{63}{16} z^5 - \frac{70}{16} z^3 + \frac{15}{16} z\right) \ln \frac{1+z}{1-z} - \frac{63}{8} z^4 + \frac{49}{8} z^2 - \frac{8}{15}$$

$$P_6(z) = \frac{1}{16} (231z^6 - 315z^4 + 105z^2 - 5)$$

These solutions and also the solutions of any desirable higher orders can be obtained by use of the recurrence relations (Abramowitz and Stegun, 1975).

$$(n+1)P_{n+1}(z) = (2n+1)zP_n(z) - nP_{n-1}(z) \tag{16a}$$

$$(n+1)Q_{n+1}(z) = (2n+1)zQ_n(z) - nQ_{n-1}(z) \tag{16b}$$

by starting from $P_0(z)$, $Q_1(z)$ as in (13) and using:

$$P_1(z) = z; \quad Q_0(z) = \frac{1}{2} \ln \frac{1+z}{1-z} \tag{17}$$

The domain of definition of the functions (15) in our problem is within $0 \leq z \leq (1-\alpha)^{1/2}$, as it follows from eq. (8). The solutions (15) within the mentioned domain of definition give for any selected n the shape of possible modes of oscillations of water in the basin, the corresponding angular frequencies being determined from (10) depending once again on the integer n .

It is convenient to introduce the non-dimensional frequency parameter R , which, as follows from (10), is equal:

$$R = \frac{\omega \ell}{(gh_0)^{1/2}} = [(1-\alpha)n(n+1)]^{1/2} \tag{18}$$

If the basin would be of constant depth h_0 , the parameter R will take the following values:

$$R_0 = \{ \pi/2; 3\pi/2; 5\pi/2 \dots (2k-1) \pi/2 \} \tag{19a}$$

$$R_c = \{ \pi; 2\pi; 4\pi; \dots 2k\pi \} \tag{19b}$$

Here R_0 refers to the basin open to the ocean ($\alpha = 1$); R_c refers to the closed basin ($\alpha = 0$).

In our case of a parabolic bottom the parameter R can be calculated by the use of (18). The results, giving R as a function of α and various values of n , are plotted in Fig. 8, where the values of R , as in (19), for constant water depth are shown by horizontal dashed lines. Open dots on the graphs $R_n(\alpha)$ indicate the positions of the first and second zeroes of the Legendre P_{2j}, Q_{2j-1} ($j=1,2,3$) functions, the solid lines marked Z_1 and Z_2 , joining the zeroes, show the tendency of the zeroes to approach the limiting values of $R = \pi/2; 3\pi/2$ for $\alpha \rightarrow 1$, as from (19a), for $n \rightarrow \infty$. This indeed must be the case, because when $\alpha = 1$, our basin in Fig. 7 is becoming a constant depth basin, fully open to a deep ocean. Hence, one of limiting cases, that of a fully opened basin, appears naturally as a limiting case of the present theory. The values of R for the other limiting cases, a closed basin ($\alpha = 0$), with parabolic bottom, discussed by Chrystal (1905), can be seen in Fig. 8. There are no zeroes of the Legendre functions for $\alpha = 0$, due to the fact that in the closed basin there is a vertical displacement of water at the end $x = l$.

The shapes of the modes of oscillations corresponding to $\alpha = 0$ are presented as the top graphs in Fig. 9. It is seen that the solutions, corresponding to Q_2 and Q_4 are finite, while the solutions given by Q_1 and Q_3 tend to infinity at $x = l$. The last two solutions were described by Chrystal (1904) as "paradoxical seiches" and, indeed, they can not be present in any real situation, because they involve the infinite water displacement at the right end of the basin.

However, these "paradoxical seiches" become finite in amplitude and, hence, very real when the basin is not fully closed. For example, when $\alpha = 0.06$ the modal shape given by Q_3 has a zero vertical displacement at $x = l$, and Q_1 does not tend to infinity because for $\alpha = 0.06$ our domain is $[0, \sqrt{1-0.06}]^{1/2}$ where all values for Q_1 are finite.

We assign a particular significance to the modal shapes, giving zero (or nearly zero) vertical displacement at the sea side end ($x = l$ in Figure 7) when $\alpha > 0$ for the following reason.

In the outer region ($x > l$ in Fig. 7) there must exist the outgoing wave, propagating into the ocean, away from the basin, and carrying some energy of oscillations within the basin with the wave. The amplitude of this outgoing wave has to be matched to the amplitude of water oscillations in the basin at the point $x = l$. The higher is the amplitude of the modal shape at $x = l$, the larger will be the amount of seiche energy radiated to the ocean, hence, the more severe will be the damping of oscillation within the basin. The energy radiated towards the ocean will be minimal when amplitudes of modes at $x = l$ equal zero, hence the resonances within the basin will be the sharpest. Obviously, as the parameter α is approaching unity, the modal shapes of strong resonances are becoming very close to those for the fully open basin with constant depth. (Compare the cases of $\alpha = 0.8$ and $\alpha = 1$ on Fig. 9).

Figure 8. Non-dimensional Frequency of Oscillations R vs Relative Opening α

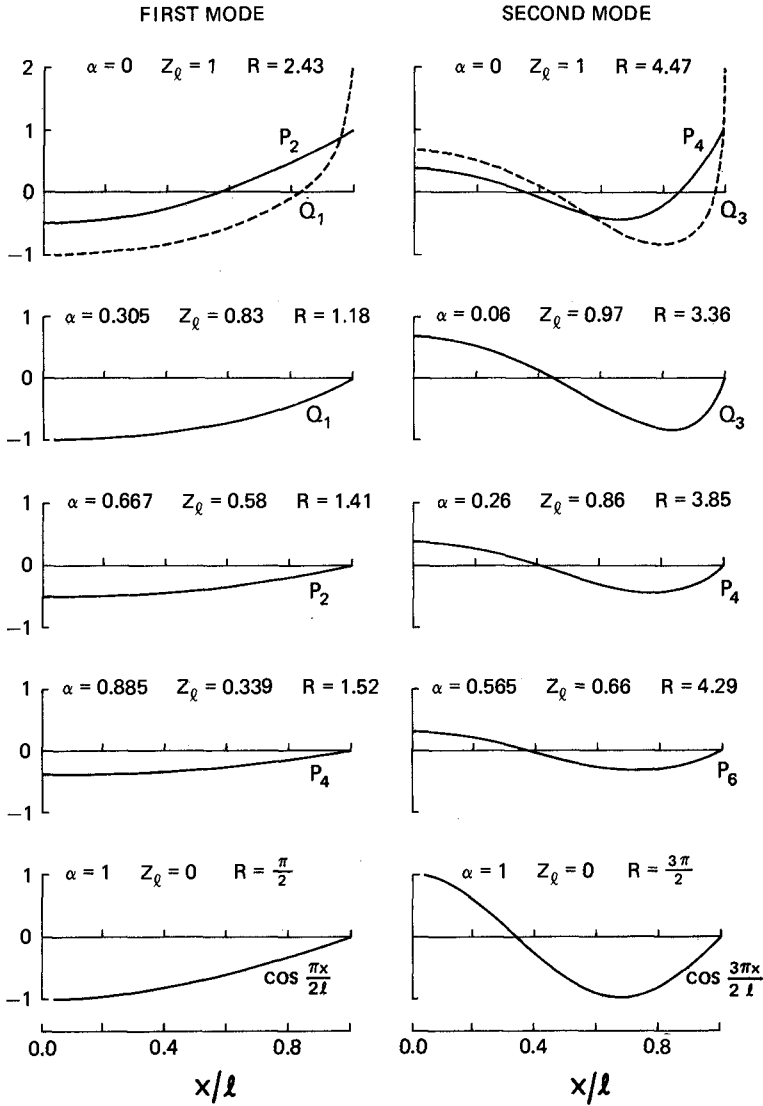

Figure 9. Modes of Water Oscillations in the Basin for Various Values of the Relative Opening α .

Returning back to Fig. 8, one can see, that the point $\alpha = 1$ is the point of condensation for zeroes of Legendre functions, hence for any $\alpha \approx 1$ there exist a strong resonance plus an infinitely increasing number of weak resonances, also condensing near $\alpha = 1$.

It is clear now, that the second boundary condition, which we deliberately avoided to discuss so far, is:

$$\xi = 0 \quad \text{at } x = l \quad (z = \sqrt{1-\alpha}) \quad (20a)$$

for strong resonances and

$$\xi < \infty \quad \text{at } x = l \quad (z = \sqrt{1-\alpha}) \quad (20b)$$

for weak resonances.

In the Figure 9 the frequencies of strong resonances (in terms of non-dimensional values of R) together with the corresponding modal shapes are given. The case of a completely closed basin is also classified as a strong resonance, because there is no radiation of energy to the ocean when $\alpha = 0$.

Consulting again Fig. 8, we can see, that solid lines joining the zeroes display the interesting tendency to decrease, when α is decreasing from $\alpha = 1$. This means the frequencies of strong resonances are decreasing while the basin is becoming more closed. This result is in agreement with Tuck, (1980), who predicts a similar tendency for the basin of a constant depth with an infinitely thin barrier of a variable height ($0 < \alpha < 1$) at the point $x = l$. However, the essential difference is that in our case there exists a set of discrete parameters α , for which strong resonance is possible, while for the basin of a constant depth the strong resonances exist for any α within the continuum $0 \leq \alpha \leq 1$, if the outer basin (ocean) is deeper, than the inner basin.

5 Periods and damping of the strong resonances for the Western Australian Coastline

The average value of a reef height for the coastline corresponds to a value $\alpha = 0.3$. It is seen from Fig. 8, that this particular value is near the zeroes of the Legendre functions Q_1 and P_4 , thus being capable of producing the two strong resonances, the modal shapes of which are depicted on Fig. 9.

The values R for $\alpha = 0.3$ are, as taken from Fig. 8, $R_1 = 1.18$; $R_2 = 3.84$, correspondingly for the first and second strong resonances. The average distance from reef chain to the shore can be taken as 5000 m, the periods of resonance oscillations are then, as follows from (18):

$$T = \frac{2\pi}{\omega} = \frac{2\pi l}{R(gh_0)^{1/2}} \quad (21)$$

Taking $h_0 = 10\text{m}$ and substituting the above values for R_1 and R_2 one finds: $T_1 = 2688 \text{ sec} = 44.8 \text{ min}$; $T_2 = 826 \text{ sec} = 13.8 \text{ min}$. In the spectral analysis of the large sea-level oscillations the period prominent was 40 min.

The current measurements were taken in the Mullaloo area, where the average distance of the reef chain from the shore is about 4500 m. Using the same values of R_1 , R_2 as above, we would obtain from (21) the following periods: $T_1 = 40.3 \text{ min}$, $T_2 = 12.4 \text{ min}$. The last value is too small to be verified by our experimental data as the current meter records were sampled at 10 minute intervals. The results of the spectral analysis of currents gave a prominent period of 33 mins.

The difference of about 20% between the theoretical and experimental results is not bad when taking into account the crude estimates of water depth h and distance l and the uneven bottom topography.

Our theoretical analysis gives consequently, reasonable prediction of the periods of sea-level oscillations. However, the damping was not considered in the theory and when the term "strong" resonance is used it does not give a quantitative idea yet of how strong the resonance is.

The quantitative measure, by which the resonance capabilities are usually judged, is the so-called "quality factor", denoted as Q (e.g. Miles and Munk, 1961). Resonances are considered sharp when $Q \gg 3-5$. Sometimes the values Q up to 18 occur (e.g. Gill and Schumann, 1974). We give below an estimate of this factor for the recorded sea-level oscillations.

Considering one of the normal modes with a wave-length λ , we can write the maximum potential energy in this mode as

$$W = \frac{1}{4} \rho g \lambda A^2 \quad (22)$$

Let the amplitude A during one period T of free oscillations decrease by the value ΔA . The new value of maximum potential energy is

$$W - \Delta W = \frac{1}{4} \rho g \lambda [A^2 - 2A \cdot \Delta A + (\Delta A)^2] \quad (23)$$

Neglecting the second-order term $(\Delta A)^2$ and subtracting eq (22) from eq (23) one obtains a loss in potential energy:

$$\Delta W = \frac{1}{2} \rho g \lambda A \cdot \Delta A \quad (24)$$

From eq (24) and eq (22), it follows that the relative energy loss ψ is twice the relative amplitude decrease δ during one cycle of oscillations.

$$\psi = \frac{\Delta W}{W} = \frac{2\Delta A}{A} = 2\delta \quad (25)$$

The values of ψ and δ are independent of λ , and hence independent of the shape and order of the normal modes. This means that damping of water oscillations can be studied without any knowledge of normal modes.

Let us denote by A_T the amplitude of sea-level oscillations after one period T has elapsed and consider the following supplementary relationship, which holds for small values of δ :

$$\ln \frac{A}{A_T} = \frac{\Delta A}{A} = \delta \quad (26)$$

From eq (26) it follows immediately the exponential law for the amplitude decay of free sea-level oscillations in the basin:

$$A_T = A \exp(-\delta) \quad (27)$$

The damping coefficient δ was estimated on the basis of the relationship (27) for the nine largest sea-level oscillation events recorded in Geraldton during the years 1963-1978.

Letting i be the event number and j be the order number of an amplitude with respect to the maximum, we can rewrite (27) as

$$A_{ij} = A_i \exp(-K_{ij} \delta_i) \quad (28)$$

where K_{ij} is the order number of j th amplitude in the event i and has the values 1, 2, 3... Taking the logarithm of (28), one obtains:

$$Y_{ij} = \ln A_{ij} - \ln A_i = -K_{ij} \delta_i \quad (29)$$

Linear regressions through the origin were fitted to individual sea-level oscillation events and estimates of the δ_i 's were obtained from

$$\delta_i = - \frac{\sum_j K_{ij} Y_{ij}}{\sum_j K_{ij}^2} \quad (30)$$

The estimated values of δ_c , ranged from 0.22 to 0.57, with a pooled value δ_c , obtained from combining sums of squares and cross products over events, of 0.29. From eq(25) it follows that the average relative energy loss ψ during one cycle of oscillations equals twice the value of δ_c , i.e. $\psi = 0.58$. The average resonance amplification factor Q can be estimated as:

$$Q = \frac{2\pi}{\psi} = \frac{6.28}{0.58} = 10.8 \quad (31)$$

with a range from 5.5 to 14.3 in the individual sea-level oscillation events. The large value of Q obtained indicates that observed water oscillations are caused by resonance of the coastal waters in the nearshore basin between Perth and Geraldton, and the resonances are sharp indeed.

6 Conclusions

- 1) Sea-level oscillations between Perth and Geraldton, Western Australia, with periods of the order of 10-40 min. are caused by resonance of local waters in a basin between a shore and submerged reef chain.
- 2) The theory presented gives a reasonable agreement between observed and theoretical values of resonance periods.
- 3) Statistical analysis of recorded oscillations gives the average value of $Q = 10.8$, indicating that the resonances are sharp.

CHAPTER 17

A CLOSELY RESPONDING, VERSATILE WAVE TUNNEL

ABSTRACT

A new wave tunnel is presented as has been recently built at the Delft Hydraulics Laboratory. Several design aspects of the wave tunnel will be discussed and special attention is drawn to the required force and power diagrams.

1. INTRODUCTION

It is often emphasized that wave asymmetry and the corresponding orbital velocities have a dominating influence on the behaviour of bed material i.e. on the geometry and stability of ripples, on the concentration and on the transport of sand, see e.g. Russell and Dyke (1963) and Kamphuis (1973). Yet hardly any systematic investigation has been reported so far. An important reason for this is the very nature of the wave: the free surface wave form cannot be controlled in detail due to its continuous adaptation to bed geometry changes. As a matter of fact, the near-bed orbital velocity rather than the wave surface history determines the sediment transport.

In order to study the effect of different orbital velocity regimes on onshore-offshore sand transport, preliminary tests were carried out in a simple pulsating water block, affirming the very close systematic dependence of direction and rate of sand transport on slight changes in the asymmetry of the orbital velocity (Hulsbergen, 1974). It has been concluded that fundamental research on sand/water interaction required a facility in which prescribed water motions can be exactly generated. This research will be performed in the here presented wave tunnel.

2. DESIGN CONSIDERATIONS

The water motion to be generated should meet the following requirements:

- i Exact reproduction should be possible of any water motion as occurring in the existing laboratory channels.
- ii The complete range of sand ripple evolution should be covered, including the phenomenon of "sheet flow".
- iii A relatively high amount of high frequency components should be available.

Further some general requirements were formulated:

- iv The facility should serve as a pilot model for possible future tests in a larger facility.
- v Access to the test section should be easy for visual inspection, for measuring devices and for changing the sand bed.
- vi The whole system should be automatized to a high degree in order to facilitate efficient research.

It was decided to construct a tunnel because a "pulsating bottom apparatus" or a "pulsating water block" would not meet all of these requirements. A water tunnel has the important advantage that it can be composed of various sections. These sections can have different shapes, different cross section areas and can even contain different fluids, in order to most properly meet the specific requirements for their function in the system. The only thing which is constant throughout the tunnel is the instantaneous rate of flow. Through this constancy the flow history can be controlled and programmed exactly according to a given signal, provided that the leakage is nihil and the driving power is sufficient. Once the requirements i, ii and iii are specified in terms of amplitudes, velocities and accelerations (Chapter 4), the dimensions of the test section (Chapter 5) and the rest of the apparatus (Chapter 6) can be determined, and thence the required power of the driving mechanism (Chapter 7).

3. LAY-OUT OF THE WAVE TUNNEL

As the tunnel contains both water and oil, and is aiming at simulating certain aspects of wave motion, it is called a "wave tunnel" rather than a "water tunnel". In principle it is a U-shaped tunnel (Fig. 1) with a horizontal test section between large-diameter vertical legs. The test section and one of these tanks contain water, the other tank contains oil. In order to separate both fluids there is a third tank in between, which contains a large-diameter rubber diaphragm. The driving piston, which is forced by a programmable hydro-power unit, moves in oil in a horizontal cylinder section located between the diaphragm tank and the vertical oil tank. Superimposed on the oscillatory mode, a mean flow may be induced by a pump in the by-pass circuit.

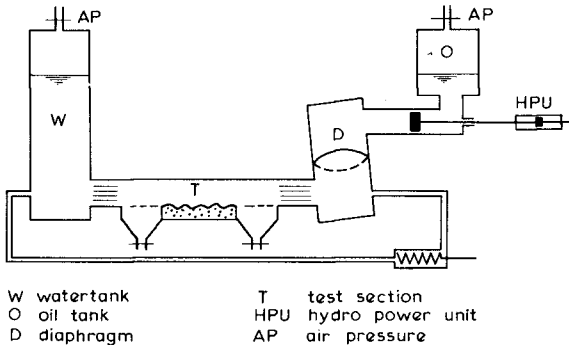

Figure 1 Schematic lay-out of the DHL wave tunnel

4. THE DESIGN WATER MOTION

In order to meet requirement i), viz. the exact reproducibility of any orbital motion as measured in laboratory wave channels (outside the surf zone), the following steps were made:

- determine the maximum near-bed orbital velocity, $(\hat{u}_b)_{\max}$, as a function of the wave period T,
- select the design wave condition in terms of T and $(\hat{u}_b)_{\max}$
- add some fraction of higher harmonic components,
- add some mean flow capacity (see Chapter 8).

The relation between $(\hat{u}_b)_{\max}$ and T has been determined on the basis of first order wave theory and a breaking criterion as follows. The orbital peak velocity near the bed, in a progressive first order gravity wave with period T, height H, length L and in a water depth d is written as

$$\hat{u}_b = \pi H/T \sinh(2\pi d/L) \quad (1)$$

The question is now: what is the maximum value, $(\hat{u}_b)_{\max}$, for a given wave period T? In shoaling waves \hat{u}_b increases until there is a limit, set e.g. by the breaking criterion of Miche (1944):

$$(H/L)_{\max} = 0.142 \tanh(2\pi d/L) \quad (2)$$

from which

$$H_{\max} = 0.142 L \tanh(2\pi d/L) \quad (3)$$

Further,

$$L = 1.56 T^2 \tanh(2\pi d/L) \quad (\text{in metres, secs}) \quad (4)$$

Substituting equations (3) and (4) into (1) yields for $(\hat{u}_b)_{\max}$

$$(\hat{u}_b)_{\max} = \left[0.696 T \tanh^2(2\pi d/L) / \sinh(2\pi d/L) \right]_{\max} \quad (5)$$

The quotient \tanh^2/\sinh has a maximum value of 0.50 for $d/L = 0.141$ or $d/L_0 = 0.10$, so that

$$(\hat{u}_b)_{\max} = 0.348 T \quad (\text{in metres, secs}) \quad (6)$$

Further, at the breaker location as defined above where $d/L_0 = 0.10$, the following relations apply:

$$\left. \begin{aligned} \sinh(2\pi d/L) &= 1.00 \\ d &= 0.156 T^2 \quad (\text{in metres, secs}) \\ H_{\max} &= 0.111 T^2 \quad (\text{in metres, secs}) \\ H_{\max}/d &= 0.71 \\ H_{\max} &= A_b, \text{ where } A_b \text{ is the near-bed water particle} \\ &\quad \text{stroke (= } 2 \times \text{near-bed particle amplitude)} \\ \text{max. acceleration} &= 2.2 \text{ m/s}^2 \end{aligned} \right\} \quad (7)$$

The equations (6) and (7) are tabulated for some values of T in Table 1.

T (seconds)	d (m)	$(\hat{u}_b)_{\max}$ (m/s)	$H_{\max} = A_b$ (m)
0.8	0.10	0.28	0.07
1.4	0.31	0.49	0.22
2.0	0.62	0.70	0.44
3.0	1.40	1.04	1.00
5.0	3.90	1.74	2.77
10.0	15.60	3.48	11.08

Table 1 Conditions at $d/L_o = 0.10$, where $(\hat{u}_b)_{\max}$ occurs.

From this range of periods, strokes and velocities the condition of $T = 2$ seconds was adopted as a design basis. The design water motion has been composed of this sinusoidal motion, with period = 2 seconds and amplitude = 0.22 m, plus a second harmonic motion with an amplitude ratio of 0.333, plus a third harmonic motion with an amplitude ratio of 0.20, all in arbitrary phase relationship to each other. This combines to the following maximum values in the test section for the oscillatory mode:

maximum stroke = 0.69 m
 maximum velocity = 1.60 m/s
 maximum acceleration = 9.1 m/s^2

These maximum values do not appear simultaneously, but they may be reached within the course of a single oscillation. It is noticed that the acceleration rate of 9.1 m/s^2 is more than 4 times the acceleration rate in sinusoidal waves at maximum steepness, as given in equation (7), reflecting the requirement iii of Chapter 2. Also, the maximum velocity of 1.60 m/s should be enough to generate "sheet flow" conditions as was stated in requirement ii of Chapter 2.

5. THE TEST SECTION

The test section accommodates the 0.2 m thick sand bed with sand traps at both ends. The width of the test section was chosen at 0.3 m as a compromise between small side wall effects and small power consumption. The height above the sand bed was chosen at 0.4 m, high enough to accommodate suspended sediment concentrations and ripple formation as expected under the design water motion. The length of the sand bed was taken as 3 times the maximum stroke, or 2.0 m. Each sand trap has a length of 1.5 times the maximum stroke, or 1.0 m. The sand bed can be extended over the sand traps and is then 4.0 m long. Also, the sand may be replaced by dummy bottom plates. The test section consists of a steel framework with glass side panels and steel top hatches. Special attention has been paid to the details of the ceiling in order to facilitate de-aeration. Through the hatches instruments can be inserted via pivoting connections every 0.3 m over the entire test section. On both ends of the test section 1.0 m long tunnel sections are installed with flow straighteners.

6. THE OIL SECTION

The requirement that the water motion in the test section should very closely respond to the programmed signal means that virtually no leak is allowed along the driving piston. Thus absolutely no sediment should reach the piston in order

to prevent wearing of the cylinder. By means of a separating diaphragm, and by having the piston moving in oil, these requirements were met. The position of the diaphragm is continuously monitored, and it is integrated in the automatic control system of the tunnel. Extreme positions of the diaphragm are defined by two perforated steel plates. For practical reasons the piston stroke is limited to 0.50 m, so its cross section area is 1.36 times the area of the test section and its velocity is 0.74 times the velocity in the test section.

7. THE DRIVING MECHANISM

Acceleration/velocity

The combined acceleration and velocity, stemming from the design water motion as defined in Chapter 4, can be easily calculated. However, the analytical form of the maximum acceleration rate as a function of the simultaneous velocity is rather complex. Therefore this relation is shown in graphical form in Fig. 2.

Forces

The forces on the piston stem from different sources which are in general not in phase:

- Inertial forces due to the accelerated mass of the piston and of the fluids. This is by far the dominant force.
- Forces proportional to the squared velocity due to fluid friction.
- Forces proportional to the piston excursion, due to hydrostatic pressure differences and air pressure differences in both vertical legs.
- Other sources such as friction between the piston and the cylinder.

Figure 2 The maximum acceleration rate as a function of the simultaneous velocity in the test section, both as required (r) and as measured in tests (t)

Figure 3 The maximum required force (F) and power (P) as a function of the velocity in the test section.

The maximum total required force is depicted in Fig. 3 as a function of the velocity in the test section.

Power

The required power is found as the product of the force applied by the piston, and the piston velocity. Hence the required power-velocity diagram follows from the force-velocity diagram. In Fig. 3 the power is depicted as a function of the water velocity in the test section. The nett maximum power required at the piston is about 11 kWatt. The gross power of the installed hydro-power unit is 22 kWatt.

8. VARIOUS DESIGN ASPECTS

Apart from the programmable oscillating motion, a nett flow can be induced. A special pump has been chosen with a discharge virtually unaffected by the large fluctuations in head over the test section. The maximum discharge is 20 litres/second, generating an average velocity of 0.17 m/second in the test section of 0.12 m² cross section area. The pump is driven by a 15 kWatt electric engine. The instantaneous discharge is measured with an electromagnetic flow meter.

As can be seen from Fig. 2, quite large acceleration rates may occur in the tunnel. Consequently large pressure drops may result. The low water pressure might cause air intrusion, or even an inward collapse of the windows. In order to prevent this, the whole system is 100 kPa (= 1 bar) overpressurized by controlling the air pressure above the fluids in both vertical tanks.

The tunnel is remotely controlled by a programmable operation panel to perform operations such as quick emptying and filling from a reservoir, air pressure control, definition of piston and diaphragm starting conditions, etc. This panel also includes complete safety-guarding of the whole system while in operation.

9. VARIOUS PERFORMANCE ASPECTS

The full range of acceleration rates in its relation to the simultaneous velocity, as observed during tests in the wave tunnel, is shown by curve (t) in Fig. 2. For purely sinusoidal motion the maximum amplitude of water motion that could be generated within 5% distortion is shown in Fig. 4.

The amplitude upper limit of 0.34 m for frequencies below about 0.8 Hz is imposed by the limits of the piston movement. For these conditions there is enough power at hand to increase the water velocity and the stroke in the test section, by decreasing the cross section area of the test section.

For frequencies over 3 Hz the attainable amplitude is quite small because of the very high inertial forces. A frequency of 2.5 Hz has shown to be a very effective mode to flatten a rippled bed after a sand transport test, so that a whole series of experiments can be done without opening the hatches. One of the design considerations was to create sheat flow conditions, which indeed has been observed during some preliminary tests.

Among other tunnels, the DHL wave tunnel is certainly not outstanding for its size, but for its ability to generate any prescribed motion within quite strict margins of accuracy, e.g. purely sinusoidal motion, regular motion with any prescribed sort of skewness, and irregular motions, with or without a nett

flow. Also, special flow conditions can be generated, e.g. a prescribed fluctuating head over a model of a soil structure, packed in a module box in the test section. In this case a digital driving signal can be calculated, based on the resistance characteristics of the specific structure. These must be determined by correlating the measured pressure head and the simultaneous velocity and acceleration of the piston.

Figure 4 Maximum amplitude of water displacement in pure sinusoidal motion as a function of frequency, as measured in the test section

Measurements may be performed with any probe through the hatch connections (velocity, pressure, sand concentration). As standard velocity measuring system, a laser doppler velocimeter is mounted on a x, y, z frame on rails, covering the entire test section.

10. CONCLUSIONS

The presented wave tunnel has shown to operate quite satisfactorily. Hence it is expected to be a powerful tool for future experiments on the interaction between a well-defined velocity field and movable bed material.

The DHL wave tunnel

Conditional Simulations of Ocean Wave Properties.

Leon R. Borgman¹

1. INTRODUCTION

Computer simulation is a convenient procedure to produce artificial data with specified statistical properties. The usual procedure in ocean wave simulations is to take the ensemble or theoretical mean and spectral relations as given by selected formulas and to produce with pseudo-random numbers and various statistical techniques a long Gaussian (multi-variate normal) time series which is one realization of the stochastic population. The simulation may be constructed directly in time, or (usually, more rapidly) in frequency domain with subsequent reversion to time by the fast Fourier transform algorithm (Borgman, 1969, 1980).

A number of such simulated time series are ordinarily generated, and used, as typical realizations of the sea state for vibration or fatigue studies. The sample mean and sample spectra computed for a given realization will differ from the theoretical values initially assigned in accordance with the random structure of the process. Thus, the fatigue or vibrational behavior produced is not that associated with the theoretical spectral density initially assigned but rather with the particular sample spectral density which was, by accident, present in that realization. If one has an actual sequence of sample spectra and mean water levels, and wishes to study the vibration or fatigue behavior which might have been associated with that particular sequence, standard simulation procedures will not suffice. Rather, constrained simulations are necessary, with the randomness being restricted so as to produce the required sample mean and spectra for each time interval. Any simulation, whose randomness is restricted so that the sample function satisfies some specified behavior, will be referred to as a constrained simulation.

The concept of constraints may be extended to sets of statistically interrelated time series. Suppose that the first time series represents the water level elevations as measured by a wave staff at a specified location on a drilling

¹/Professor of Geology and Statistics, University of Wyoming, Laramie, Wyoming.

platform. Let the other time series represent velocity or acceleration time series at loading points down the legs of the platform. Simulations of the velocity and acceleration sequences would be produced by the computer, conditional on the wave profile having the assigned values. Such sequences will be called conditional simulations.

2. FOURIER RELATIONS

Although the development of simulated sequences directly in time is intuitively more obvious and easily understood, it is much slower in terms of computer operations than indirect procedures starting in the frequency domain and later reverting to the time domain. Therefore, it is worthwhile to briefly enumerate the statistical properties which Fourier coefficients must have in order that the time-domain inverse will form a real-valued stationary, Gaussian process (Borgman, 1976). Let $\{X_n, n=0,1,2,\dots,N-1\}$ be the time-domain series and $\{A_m, m=0,1,2,\dots,N-1\}$ be the frequency domain sequence which is related to the X_n by the equations

$$A_m = \Delta t \sum_{n=0}^{N-1} X_n e^{-i2\pi mn/N} = U_m - i V_m \quad (1)$$

$$X_n = \Delta f \sum_{m=0}^{N-1} A_m e^{i2\pi mn/N}, \quad \Delta f = 1/N\Delta t \quad (2)$$

where $i = \sqrt{-1}$, Δt is the increment in time, and Δf is the frequency increment.

The following properties hold. (All sums run from 0 to $N-1$ unless otherwise noted. The asterisk denotes complex conjugation.)

$$A_0 = \Delta t \sum_n X_n \quad (3)$$

$$A_{N-m} = A_m^* = U_m + iV_m \quad (4)$$

$$X_0 = \Delta f \sum_m U_m \quad (5)$$

$$E(U_m) = E(V_m) = 0, \quad 0 \leq m < N, \quad \text{if } E(X_n) = 0 \quad (6)$$

$$\text{Variance}(U_m) = \text{Var}(V_m) = S_m N \Delta t / 2, \quad \text{for } 0 < m < N/2 \quad (7)$$

$$\text{Var}(U_m) = S_m N \Delta t, \quad \text{if } m=0 \text{ or } m=N/2 \quad (8)$$

(U_m, V_m, U_m^i, V_m^i) are independent and normally distributed for $0 < m < m^i < N/2$. In the above,

$$S_m = \Delta t \sum_k C_k e^{-i2\pi km/N} \quad (9)$$

and

$$C_k = \text{Covariance}(X_n, X_{n+k}) \quad (10)$$

where X_n is repeated periodically for n outside $(0, N-1)$.

3. TWO TIME SERIES

All of the Fourier properties reported in Section 2 hold separately for two time series, X_n and Y_n . In addition, the Fourier coefficients are independent for different subscript values, $0 < m < N/2$. However, the Fourier coefficients for the two series at the same m value are multivariate normal with covariance matrix

$$\text{Cov} \begin{bmatrix} U_m \\ V_m \\ U'_m \\ V'_m \end{bmatrix} = \frac{N\Delta t}{2} \begin{bmatrix} S_m & 0 & c_m & q_m \\ 0 & S_m & -q_m & c_m \\ c_m & -q_m & S'_m & 0 \\ q_m & c_m & 0 & S'_m \end{bmatrix} \quad (11)$$

In this formula, c_m and q_m are the co- and quad-spectral densities defined as

$$c_m - iq_m = \Delta t \sum_k C_{XY,k} e^{-i2\pi km/N} \quad (12)$$

where

$$C_{XY,k} = \text{Covariance}(X_n, Y_{n+k}) \quad (13)$$

Also U_m and V_m are the FFT coefficients for X_n while U'_m , V'_m are the corresponding coefficients for Y_n .

The generalization to more than two time series is straightforward. The matrix in (11) is just enlarged to include the additional spectra and cross-spectra.

4. UNCONDITIONAL FREQUENCY-DOMAIN SIMULATIONS

The simulation of j simultaneous time series reduces to the development of $2j$ multivariate normal variates independently for each $0 < m < N/2$. The Fourier coefficients for $m > N/2$ are obtained by complex conjugation (see(4)). Usually the coefficients at $m=0$ are set equal to zero (a constrained simulation producing exactly zero mean water level) and $N\Delta t$

is chosen large enough so that there is no energy left of any consequence for frequencies approaching $N\Delta t/2$. This forces $A_{N/2} = 0$.

Various schemes can be used to produce the multivariate normal random deviates approximating wave properties (Borgman, 1980). One procedure based on multiplication of independent standard normal random deviates is given by Scheuer and Stoller (1962).

5. CONSTRAINED AND CONDITIONAL SIMULATIONS

A constrained simulation is a simulation in which the resulting artificial sample functions are adjusted to have specified sample properties. The simplest example would be a sequence of standard normal independent pseudo-random numbers, $\{Z_0, Z_1, Z_2, \dots, Z_{N-1}\}$ which are adjusted by subtracting the sample average and dividing by the sample standard deviation. The resulting sequence will exactly will exactly have mean zero and variance one. The original sequence $\{Z_n\}$ was a sample from a population with theoretical mean zero variance one, but its sample values will deviate slightly from these theoretical values due to the randomness and finite extent of the sample.

Correlated simulated sequences may be constrained to have other specified sample properties. For example, a specified sample covariance function or sample spectral density can be forced onto the simulated sequence. It is not always clear if the resulting sequence has the same distribution as the original one. In fact, in general it will not. The original example above of a sequence of independent normal random numbers will have a weak correlation between successive values after the sample mean is subtracted from each term. Nevertheless, it is occasionally useful to work with simulated time series which have been constrained.

What type of questions may be answered with constrained time series simulations? Generally such questions are related to behavior which pivotally are concerned with a given sample property. Consider the following two questions:

1. What is the vibrational behavior of an oil-drilling structure which is experiencing ocean waves for one hour whose theoretical spectral density is specified?
2. What is the vibrational history of the same structure when it experiences waves for one hour whose sample spectral density is a specified function?

In a simulation for the first question, the actual sample

spectra for the one hour of data will not equal the theoretical function. In fact, it may differ quite a bit from the theoretical value which holds for the population. A simulation for the second question will force the spectra for the one hour record to equal the specified function. One source of variation, the sample fluctuation, will have been removed. Several simulations will all have exactly the same sample spectral density.

There are many unresolved theoretical questions connected with constrained simulations. The foregoing is intended only to be a brief introduction to the problem. However, it is common engineering practice to introduce constraints on simulations, at least for some types of studies.

Conditional simulations are less theoretically questionable. In a conditional simulation, one or more of the simulated values are assigned numerical values, and the rest are obtained from distribution theory and pseudo-random numbers. For example, suppose $\{X_0, X_1, X_2, \dots, X_{N-1}\}$ are a multivariate Gaussian sequence and it is known, a priori, that X_0 and X_{N-1} are both zero. The sequence $\{X_1, X_2, \dots, X_{N-2}\}$ can be simulated conditionally given $X_0 = X_{N-1} = 0$. If the original sequence was highly positively correlated, the simulated X_1 will not differ appreciably from $X_0 = 0$. That is, the correlation will be preserved between the given and the simulated values. Techniques of conditional simulation have been used in geological problems (Journal, 1974). The concept appears to be very promising for coastal engineering applications.

The concept can be extended to several simultaneous time series. One or more of the time series can have specified values and the remaining time series can be simulated conditionally. Thus the sea surface elevation time series could be set equal to a measured wave record, and the inter-correlated bottom pressure which was occurring simultaneously could be simulated conditionally. This latter type of conditional simulation (one or more time series specified, the remaining ones simulated) will be given the primary attention in the following.

Conditional simulations may be generated either by matrix multiplication or filtered white noise. (At the present time, it is not clear how the random phase procedures could be used.) Only matrix multiplication procedures will be presented here. Two basic theorems for the matrix multiplication technique are as follows:

Let \underline{W} be a normal random (column) vector with n components,

which has mean vector $\underline{\mu}$ and covariance matrix C . Let \underline{W} be partitioned into two vectors \underline{W}_1 and \underline{W}_2 with n_1 and n_2 components respectively. The vector $\underline{\mu}$ and the matrix C are similarly partitioned. Thus

$$n = n_1 + n_2 \quad (14)$$

$$\underline{W} = \begin{bmatrix} \underline{W}_1 \\ \underline{W}_2 \end{bmatrix} \quad (15)$$

$$\underline{\mu} = \begin{bmatrix} \underline{\mu}_1 \\ \underline{\mu}_2 \end{bmatrix} \quad (16)$$

$$C = \begin{bmatrix} C_{11} & C_{12} \\ C_{12}^T & C_{22} \end{bmatrix} \quad (17)$$

where the superscript "T" denotes the matrix transpose.

Theorem A

The conditional probability law for \underline{W}_2 , given $\underline{W}_1 = \underline{w}_1$, is multivariate normal with conditional mean of

$$\underline{W}_2 = \underline{\mu}_2 + C_{12}^T C_{11}^{-1} (\underline{w}_1 - \underline{\mu}_1) \quad , \text{ and} \quad (18)$$

conditional covariance matrix

$$\underline{W}_2 = C_{22} - C_{12}^T C_{11}^{-1} C_{12} \quad (19)$$

Proof. (See Anderson, 1958, pp. 27-29)

Theorem B

Let \underline{W} be an unconditional simulation of the random vector. That is, \underline{W} follows a multivariate normal probability law with mean $\underline{\mu}$ and covariance matrix, C . The vector $\underline{\tilde{W}}_2$ defined by

$$\underline{\tilde{W}}_2 = C_{12}^T C_{11}^{-1} (\underline{w}_1 - \underline{W}_1) + \underline{W}_2 \quad (20)$$

will be a conditional simulation of \underline{W}_2 , given $\underline{W}_1 = \underline{w}_1$.

The mean vector and covariance matrix for \underline{W}_2 are the same as the conditional mean and covariance relations specified in Theorem A and \underline{W}_2 is a multivariate normal random vector.

Proof

Since every linear combination of multivariate normal is also multivariate normal (Anderson, 1958), \underline{W}_2 is a multivariate normal vector. Also

$$E[\underline{\tilde{W}}_2] = C_{12}^T C_{11}^{-1} (\underline{w}_1 - \underline{\mu}_1) + \underline{\mu}_2 \quad (21)$$

$$\begin{aligned} \text{Cov}(\underline{\tilde{W}}_2) &= E[\{\underline{\tilde{W}}_2 - E(\underline{\tilde{W}}_2)\}\{\underline{\tilde{W}}_2 - E(\underline{\tilde{W}}_2)\}^T] \\ &= E[\{(\underline{W}_2 - \underline{\mu}_2) - C_{12}^T C_{11}^{-1} (\underline{W}_1 - \underline{\mu}_1)\}\{(\underline{W}_2 - \underline{\mu}_2) \\ &\quad - C_{12}^T C_{11}^{-1} (\underline{W}_1 - \underline{\mu}_1)\}^T] \\ &= C_{22} - C_{12}^T C_{11}^{-1} C_{12} \quad \text{Q.E.D.} \quad (22) \end{aligned}$$

For a time domain simulation by matrix multiplication, \underline{W}_2^T would contain the given values and \underline{W}_1^T would be simulated as a normal with the mean and covariance matrix listed in the theorem. Either of the previous techniques (triangular matrix or eigenvector) could be used to generate \underline{W}_1^T . A mean zero version of \underline{W}_1^T would be developed first, and then the appropriate mean vector as listed in the theorem would be added on.

It is usually easier to do the conditional simulation in frequency domain by matrix multiplication. The unknown and the given time series each have Fourier coefficients which are uncorrelated from frequency to frequency ($0 < m < N/2$), and have the covariance matrix for each m as previously discussed. The Fourier coefficients for the given time series can be easily developed by a fast Fourier transform computation. The coefficients for the unknown (i.e., to be simulated conditionally) time series are normally distributed with mean vector and covariance matrix as specified by the theorem. The simulation of these unknown coefficients, for each m , can be done by matrix multiplication. At each frequency, only a $2L$ -component vector is involved if L is the number of unknown time series. This is a much smaller operation than the corresponding time-domain simulations.

6. EXAMPLE A

Suppose a wave profile is represented by a time series with 32 values spaced over a wave period of $T=14$ sec. That is,

$$\begin{aligned}\Delta t &= 14/32 \text{ seconds} \\ N &= 32, \quad \Delta f = 1/N\Delta t = 1/14 \text{ Hertz} \quad (23) \\ \eta_n &= \eta(n\Delta t) = \text{water level elevation above mean} \\ &\quad \text{water level.}\end{aligned}$$

Let $\eta_0 = \eta_{16} = \eta_{32} = 0$, $\eta_8 = 18$ ft., and $\eta_{24} = -12$ ft. Then the wave will have a height at least as large as 30 ft. and the crest elevation to height ratio will be around 18/30. What are reasonable simulated values for the other unspecified η_n values assuming the following spectral density and covariance values?

$$S(m\Delta f)\Delta f = (0, 5.446, 6.990, 1.184, .279, .090, .036, .020, .005, 0,0,0,0,0,0,0) \quad (24)$$

$$C(n\Delta t) = (28.1, 26.1, 20.7, 13.3, 5.4, -1.9, -7.7, -11.6, -13.5, -13.5, -12.0, -9.5, -6.5, -3.5, -1.0, .6) \quad (25)$$

The convention used here is that the values in the parenthesis represent the sequences for $m = 0,1,2,\dots,15$ and $n = 0,1,2,\dots,15$ for the two functions.

Theorem B provides the theory for the simulation of the profile passing through the specified points.

$$\underline{w}'_1 = (\eta_0, \eta_8, \eta_{16}, \eta_{24}) = (0, 18, 0, -12) \quad (26)$$

$$\begin{aligned}\underline{w}'_2 &= (\eta_1, \eta_2, \eta_3, \eta_4, \eta_5, \eta_6, \eta_7, \eta_9, \eta_{10}, \eta_{11}, \eta_{12}, \eta_{13}, \\ &\quad \eta_{14}, \eta_{15}, \eta_{17}, \eta_{18}, \eta_{19}, \eta_{20}, \eta_{21}, \eta_{22}, \eta_{23}, \eta_{25}, \\ &\quad \eta_{27}, \eta_{28}, \eta_{29}, \eta_{30}, \eta_{31}) \quad (27)\end{aligned}$$

Since the profile is periodic, $\eta_{32} = \eta_0 = 0$, and it is not necessary to specifically introduce the constraint that $\eta_{32} = 0$. The covariance matrix C_{11} will be the 4x4 array of covariances for $(\eta_0, \eta_8, \eta_{16}, \eta_{24})$. The covariance matrix C_{22} will be the 28x28 matrix of covariances for the other η_n , excluding $n = 0, 8, 16$, and 24.

The application of theorem B proceeds in two steps. First

an unconditional simulation of a wave profile for η_n with the specified theoretical covariance function and spectral density is prepared by any convenient procedure. This simulation is not constrained to pass through the specified η_n values. It is an ordinary unconstrained or unconditional simulation. This simulation produces random values for

$$\underline{W}'_1 = (\eta_0, \eta_8, \eta_{16}, \eta_{24}) \quad (28)$$

and for \underline{W}'_2 . By theorem B, the conditional or constrained simulation of \underline{W}_2 (denoted by \tilde{W}_2) given $\underline{W}_1 = \underline{w}_1$ (the assigned values) is provided by

$$\tilde{W}_2 = C_{12}^T C_{11}^{-1} (\underline{w}_1 - \underline{W}_1) + \underline{W}_2 \quad (29)$$

since $\underline{\mu}_1 = \underline{0}$ and $\underline{\mu}_2 = \underline{0}$. Two graphical examples of such a constrained simulation are given in Fig. 1.

7. EXAMPLE B

Suppose now that the complete wave profile is specified and one wishes to simulate the time series for the horizontal water particle velocity components $v_x(t)$ (in-line) and $v_y(t)$ (transverse) at still water level. Let $T=14$ sec., $H=30$ ft., and $d=100$ ft. For convenience, suppose the period is subdivided into 32 increments as in example A. The same spectra and covariance function used in the first example will be assumed here. However, a spreading function with equivalent standard deviation of 20° will be taken as holding for all frequencies. The wave profile will be taken from Table 1 for the assumed H , d , and T values. This gives the wave profile listed in the second column of Table 2.

It is convenient to perform the conditional simulation in the frequency domain. Let the real and imaginary parts for the Fourier coefficients (FFT coefficients) for η , v_x , and v_y be specified by

$$U_m - iV_m = \text{FFT coeff. for } \eta \quad (30)$$

$$U_{m,vx} - iV_{m,vx} = \text{FFT coeff. for } v_x \quad (31)$$

$$U_{m,vy} - iV_{m,vy} = \text{FFT coeff. for } v_y \quad (32)$$

By properties of the discrete Fourier transform, these six random values for a given m ($0 < m < 16$) are independent of the corresponding values at other $0 < m < 16$. Thus the frequency domain version of the time series can be constructed independently for each frequency between 0 and the Nyquist frequency. For convenience the Fourier coefficients at zero

and at the Nyquist frequency are set to zero (no DC component and the spectra dies to zero before reaching the folding frequency).

At a given frequency, the four random variables U_m, v_x , V_m, v_x , U_m, v_y , and V_m, v_y are to be simulated conditionally on U_m and V_m having the values specified by the discrete Fourier transform of the wave profile at that same frequency. For this example, it is perhaps easiest to use theorem A applied to each frequency. In this case $\underline{w}_1^T = (U_m, V_m)$ and $\underline{w}_2^T = (U_m, v_x, V_m, v_x, U_m, v_y, V_m, v_y)$. C_{11} is the 2x2 covariance matrix for (U_m, V_m) and C_{22} is the 4x4 covariance matrix for \underline{w}_2 . C_{12} is the 2x4 matrix of cross covariances. The three matrices C_{11} , C_{22} , and C_{12} change value from frequency to frequency. The random vector \underline{w}_2 , as conditioned on $\underline{w}_1 = \underline{w}_1$, will have a 4x4 conditional covariance matrix given by $C_{22} - C_{12} C_{11}^{-1} C_{12}$. The mean vector will equal $C_{12}^T C_{11}^{-1} \underline{w}_1$ since it has been assumed that $\underline{\mu}_1 = 0$ and $\underline{\mu}_2 = 0$. Thus, the conditional simulation of the FFT coefficients for v_x and v_y involves producing a 4-component multivariate normal with the specified conditional covariance matrix and mean for each frequency. The FFT coefficients are then inverted back to the time domain by the fast Fourier transform to produce a conditional simulation of v_x and v_y consistent with the assumed wave profile.

The present example is substantially simplified in that it can be shown that the velocity FFT coefficients have the structure

$$U_m, v_x = aRZ_1 + \text{cond. mean} \quad (33)$$

$$V_m, v_x = aRZ_2 + \text{cond. mean} \quad (34)$$

$$U_m, v_y = bRZ_3 + \text{cond. mean} \quad (35)$$

$$V_m, v_y = bRZ_4 + \text{cond. mean} \quad (36)$$

where Z_1 , Z_2 , Z_3 , and Z_4 are standard normal independent random variables. The R value is the appropriate attenuation factor for the distance down in the water where the velocities are taken as occurring. Actually the different Z_i values could be used simultaneously to produce simulations at any number of depth positions vertically. The constant a and b can be selected to provide the proper conditional covariance matrix.

A conditional simulation for v_x and v_y is given in Table 2.

8. CONCLUSIONS

Techniques are outlined for efficient conditional and/or constrained simulations of wave properties in the frequency domain. Through the speed of the fast Fourier transform algorithm and the directness of conditional simulations in producing targeted results, substantial savings in computer time are possible.

WIND WAVES TRANSMISSION THROUGH
POROUS BREAKWATER

by

Stanisław R. Massel¹ and Piotr Butowski²

INTRODUCTION

Rubble - mound breakwaters are designed to protect exposed marine areas from excessive wave activity. The resulting interaction of the incident waves with the rubble units is extremely complex due to the variable reflective and frictional properties of the permeable structure. In the past decade considerable effort has been expended to derive rational methods for of such type structure. The theoretical and experimental investigations have been focused especially on the prediction of the reflection and transmission of regular waves incident to breakwater. Sollitt and Cross /1972/ presented the analytical approach to the problem based on the assumption that the original nonlinear governing equation of the wave motion into porous media may be replaced by a linear one so as to give the same average rate of dissipation/Lorentz approximation/. Under the assumption that severe wave conditions for most breakwaters correspond to relatively long waves, the considerably simple solutions were developed by Kondo and Toma /1972/ and in series of papers by Madsen and co-authors /1974, 1977, 1978/. Madsen's solutions follows rather a physical than mathematical rigorous approach to the problem. The momentum equation evaluated him explains the influence of the inertia force associated with the unsteady flow around the solid particles. Very careful analytical examination of this problem for the long waves past the narrow gaps and holes has been presented by Mei et al. /1974/. The study indicate that apparent mass term can be ignored in most practical cases. The number of studies concerning reflection and transmission of waves by breakwaters conducted in the field are

¹Asst. Prof., ² Res. Asst., Institute of Hydroengineering of the Polish Academy of Sciences, Gdańsk, Poland.

very few. Thoratou and Calhoun /1972/ reported the results of the field measurements at the rubble - mound breakwater in Monterey Harbor, California. The incident wave motion was measured at two locations in front of the breakwater in order to resolve the incident and reflected wave components; the transmitted wave was measured at one point behind the breakwater. The incident, reflected and transmitted power spectra were next calculated using the linear wave theory. This model is not truly predictive in that it relies on the knowledge of the wave records at the three locations near the breakwater in any particular case.

For more realistic representation of the interaction between ocean - wind waves and the rubble - mound breakwater, the consideration of the random character of the wave motion is needed.

Thus, the probability theory is the natural frame of reference for the description of such time - varying quantities. For the incident wave the Gaussian model involving superposition of linear waves predicts all the probability properties of the sea surface. Unfortunately, the wave motion into porous media cannot be considered linear.

Massel and Mei /1977/ presented the analytical theory for random waves passing a perforated and porous breakwater. However, these theories are approximate for the shallow coastal zone where the energy of the incident wave is concentrated in the long - wave part of the spectrum. The quadratic damping term is treated by the stochastic equivalent linearization technique. They defined the statistical transmission and reflection coefficients in terms of the standard deviations and the wave spectra.

In this paper an extension of previous work is given. The various aspects of the rectangular porous breakwater - wave interaction are considered under the assumption that the incident wave spectrum is arbitrary. To simplify the analysis the damping terms in the body of breakwater will be replaced by an equivalent linear term. The standard deviations for both wave velocity components are then calculated assuming that they are non - correlated random functions with zero mean values. Results obtained from this analysis are compared with the field measurements of reflection and transmission characteristics of porous breakwater and numerical examples are given.

We consider the motion of an incompressible inviscid fluid and Cartesian axes x, z ; with z increasing vertically upward. The homogeneous, rectangular breakwater is subjected to normally incident wind - induced waves. The depth of the water is constant.

ANALYSISGoverning Equations

Fig. 1: Definition Sketch

Three different computational regions are identified in Fig. 1.

In the region I, the random incident wave is assumed to be Gaussian with zero mean and is represented by the following Fourier - Stjeltjes integral:

$$\zeta_i = \int_{-\infty}^{\infty} dA(\omega) e^{i(kx - \omega t)} \quad /1/$$

where $\omega^2 = gk \cdot \tanh(kh)$

For a stationary and homogeneous process, the amplitude spectrum dA satisfies:

$$E[dA(\omega) \cdot dA^*(\omega')] = \frac{1}{2} \cdot S(\omega) \cdot \delta(\omega - \omega') \cdot d\omega d\omega' \quad /2/$$

The wave motion in region I consists of an incident and a reflected wave. Thus, the resultant velocity potential takes the form

$$\Phi_1(x, z, t) = \operatorname{Re} \int_{-\infty}^{\infty} \frac{-ig}{\omega} \cdot e^{-i\omega t} \cdot \left[e^{ik(x+l)} - e^{-ik(x+l)} \right] \cdot \frac{\cosh k(z+h)}{\cosh kh} + \sum_{\alpha} M_{\alpha}(\omega) \cdot e^{\alpha(x+l)} \cdot \frac{\cos \alpha(z+h)}{\cos \alpha h} \cdot dA(\omega) \quad /3/$$

in which the wave number α must satisfy the following dispersion relation

$$\frac{\omega^2}{g} + \alpha \cdot \operatorname{tg}(\alpha h) = 0 \quad /4/$$

In the region III, the wave motion is simply transmitted wave. The velocity potential may be expressed as

$$\Phi_3(x,z,t) = \operatorname{Re} \int_{-\infty}^{\infty} \frac{ig}{\omega} \cdot e^{-i\omega t} \cdot \sum_{\alpha} \left\{ N_{\alpha}(\omega) \cdot e^{\alpha(l-x)} \cdot \frac{\cos \alpha(z+h)}{\cos \alpha h} \right\} dA(\omega) /5/$$

A complete mathematical description of flow through a coarse granular material in the region II would be a very difficult and tedious task. A more reasonable approach to the problem is to determine the important physical and hydraulic properties of the media and then evaluate the macroscopic flow field in terms of these properties. The analysis yields the velocities and pressures which are averaged over the small but finite pore volumes. Thus, for porous media ($-h \leq z \leq 0, -l \leq x \leq l$), we write the equation of motion in the form

$$\frac{\partial \vec{u}_2}{\partial t} = -\frac{1}{\rho} \cdot \nabla(p_2 + \gamma z) + \text{resistance forces} \quad /6/$$

in which \vec{u}_2 - the "seepage velocity", p_2 - water pressure.

In order to specify the resistance forces, the equation proposed by Forchheimer is adopted in the form

$$\frac{\partial \vec{u}_2}{\partial t} = -\frac{1}{\rho} \nabla(p_2 + \gamma z) - \frac{\nu \cdot n}{K} \cdot \vec{u}_2 - \frac{C_f \cdot n^2}{\sqrt{K}} \cdot |\vec{u}_2| \cdot \vec{u}_2 \quad /7/$$

where ν - kinematic viscosity of fluid, K - intrinsic permeability, n - porosity, C_f - coefficient dependent on properties of porous media.

According to Arbbabhirama and Dinoy /1973/

$$C_f = 100 \left[d_m \left(\frac{n}{K} \right)^{1/2} \right]^{-3/2} \quad /8/$$

in which d_m - particle mean diameter of porous media. Although the damping term in Eq. /7/ is derived from steady state concepts it is assumed that it accounts for the damping due to the instantaneous velocity occurring at all phases of the wave cycle. Thus, the linear term dominates when velocities are low and the turbulent term dominates when velocities are high. The assumptions which limit the application of the expression /7/ are that convective accelerations be and that the motion be periodic with frequency low enough to maintain the validity of the damping term. Thus, Eq./7/ applies when the wave lengths of the particular spectral components are long with respect to wave amplitudes and media grain size.

An analytical solution to Eq.7 is possible after its linearization. It is done using a technique that approximate the turbulent damping condition inside the porous media. The dissipative nonlinear stress term in Eq. 7 is

replaced by an equivalent stress term linear in \vec{u}_2 , i.e.

$$\frac{\nu \cdot n}{K} \vec{u}_2 + \frac{C_f \cdot n^2}{\sqrt{K}} \cdot |\vec{u}_2| \cdot \vec{u}_2 \longrightarrow f_e \cdot \omega_p \cdot n \cdot \vec{u}_2 \quad /9/$$

in which f_e is a dimensionless friction /damping/ coefficient and ω_p is the peak frequency. To evaluate f_e in terms of the known damping law in the deterministic case, we choose f_e such that the total rate of energy dissipation, integrated over the breakwater cross section and averaged over period is unchanged. Alternatively, for random waves one may minimize, the mean square error ϵ^2 when the mean is taken over time in the stochastic sense as well as space. The relation between f_e and the physical parameters of motion is developed in Appendix A. As a motion inside the porous media is a result of the harmonic excitation, it may be written as

$$\vec{u}_2(x, z, t), p_2(x, z, t) = [\vec{u}_2^{\sim}(x, z), \tilde{p}_2(x, z)] \cdot e^{-i\omega t} \quad /10/$$

Combining Eqs. 7 and 10 and taking into account Eq. 9 and the equation of continuity $\nabla \vec{u}_2 = 0$, gives

$$\frac{\partial \Phi_2}{\partial t} + \frac{1}{g} (p_2 + \gamma z) + f_e \cdot \omega_p \cdot n \cdot \Phi_2 = 0 \quad /11/$$

in which Φ_2 - velocity potential in the porous media. Eq. 11 yields the surface displacement in the form

$$\zeta_2 = -\frac{1}{g} \left(\frac{\partial \Phi_2}{\partial t} + f_e \cdot \omega_p \cdot n \cdot \Phi_2 \right)_{z=0} \quad /12/$$

Substituting the above expression into the kinematic free surface condition leads to its final form in the term of potential function

$$g \cdot \frac{\partial \Phi_2}{\partial z} - \omega^2 \left(1 + i \cdot n \cdot f_e \cdot \frac{\omega_p}{\omega} \right) \cdot \Phi_2 = 0 \quad /13/$$

At the bottom ($z = -h$), the foundation is taken to be impervious, i.e.

$$\frac{\partial \Phi_2}{\partial z} = 0 \quad /14/$$

Finally, in the region II we adopte the potential Φ_2 in the form

$$\Phi_2(x, z, t) = \mathcal{A} e \int_{-\infty}^{\infty} \frac{g \cdot e^{-i\omega t}}{\omega (i - n f_e \frac{\omega_p}{\omega})} \cdot \sum_{\psi} \left\{ [P_{\psi} \cdot e^{-\psi(x+l)} + Q_{\psi} \cdot e^{\psi(x-l)}] \cdot \frac{\cos \psi(z+h)}{\cos \psi h} \right\} \cdot dA(\omega) \quad /15/$$

in which γ - complex wave number being a solution of the following dispersion relation

$$\omega^2 \left(1 + i \cdot n \cdot f_e \cdot \frac{\omega_p}{\omega} \right) + g \cdot \gamma \cdot \operatorname{tg}(\gamma h) = 0 \quad /16/$$

Eq. 16 has an infinite number of complex roots.

Matching Conditions

For the moment we assume that porosity n , permeability K and the linearization coefficient f_e are known. The general solutions developed in the proceeding section then contain 4 unknown functions of frequency: M_α , N_α , P_ψ and Q_ψ . To determine the functions the general solutions for the horizontal mass flux and pressure are matched at $x = \pm l$. This yields 4 equations from which the 4 unknowns may be determined.

It is of interest to note that the matching conditions may be expressed in the form of set of two equations with an infinite number of solutions for coefficients M_α and N_α /Massel, Butowski 1980/.

Solving this set by the standard Galerkin's method we obtain the following expressions for coefficients P_ψ and

$$Q_\psi \quad P_\psi + e^{-2\psi l} \cdot Q_\psi = \sum_{\alpha} L_{\psi\alpha} \cdot M_\alpha \quad /17/$$

$$e^{-2\psi l} \cdot P_\psi + Q_\psi = \sum_{\alpha} L_{\psi\alpha} \cdot N_\alpha$$

in which

$$L_{\psi\alpha} = \frac{1 + i \cdot n \cdot f_e \cdot \frac{\omega_p}{\omega} \cdot \cos(\psi h)}{B_\psi^2 \cdot \cos(\alpha h)} \cdot \int_{-h}^0 \cos\psi(z+h) \cdot \cos\alpha(z+h) dz \quad /18/$$

and

$$B_\psi = \left\{ \frac{h}{2} \left[\frac{\sin(2\psi h)}{2\psi h} + 1 \right] \right\}^{1/2} \quad /19/$$

Transmission and reflection coefficients

Taking the analogy to the deterministic waves we adopted the following expressions for the statistical transmission and reflection coefficients

$$K_r = \frac{\sigma_r}{\sigma_i} = \left[\frac{\int_0^\infty S_r(\omega) d\omega}{\int_0^\infty S(\omega) d\omega} \right]^{1/2} \quad /20/$$

$$K_t = \frac{\sigma_t}{\sigma_i} = \left[\frac{\int_0^\infty S_t(\omega) d\omega}{\int_0^\infty S(\omega) d\omega} \right]^{1/2} \quad /21/$$

where $S_r(\omega)$ - spectrum of reflected waves, $S_t(\omega)$ - spectrum of transmitted waves, $S(\omega)$ - incident wave spectrum.

The reflected wave spectrum can be expressed as

$$S_r(\omega) = S_{1r}(\omega) = \left[\hat{M}_k(\omega) \right]^2 \cdot S(\omega); \quad \hat{M}_k(\omega) = \left| M_k(\omega) - 1.0 \right|_{\alpha = -ik/22/}$$

and for the transmitted wave spectrum we have

$$S_t(\omega) = S_3(\omega) = \left[\hat{N}_k(\omega) \right]^2 \cdot S(\omega); \quad \hat{N}_k(\omega) = \left| N_k \right|_{\alpha = -ik} / 23/$$

The spectrum $S_1(\omega)$ for the total wave on the incidence side ($x < -l$) is

$$S_1(\omega, x) = \left\{ \left[1 + \hat{M}_k^2(\omega) \right] + 2 \cdot \hat{M}_k(\omega) \cdot \cos[2k(x+l) - \varphi_k] + \left(M_{\Sigma_1}(\omega, x) \right)^2 + 2 \cdot M_{\Sigma_1}(\omega, x) \cdot \cos[k(x+l) - \varphi_{\Sigma_1}] + 2 \cdot \hat{M}_k(\omega) \cdot M_{\Sigma_1}(\omega, x) \cdot \cos[k(x+l) - \varphi_k + \varphi_{\Sigma_1}] \right\} \cdot S(\omega) \quad /24/$$

in which

$$M_{\Sigma_1}(\omega, x) \cdot e^{i\varphi_{\Sigma_1}} = \sum_{\alpha} e^{\alpha(x+l)} \cdot \hat{M}_{\alpha}(\omega) \cdot e^{i\varphi_{\alpha}}, \quad /25/$$

$\hat{M}_{\alpha}(\omega)$, φ_{α} - absolute value and phase angle of the complex M_{α} , respectively. \sum_{α} denotes summation over all the real values of α ; i.e. $\alpha = -ik$ is omitted from the sum.

It is of special interest to note that the spectrum $S_1(\omega)$ is also the function of distance from front face of the breakwater.

The transmitted waves at the arbitrary distance from the lee face are described by the spectrum in the form

$$S_3(\omega, x) = \left| \sum_{\alpha} N_{\alpha}(\omega) \cdot \exp \alpha(l-x) \right|^2 \cdot S(\omega) \quad /26/$$

When $x \rightarrow \infty$, we obtain $S_3(\omega, x) \rightarrow S_t(\omega)$.

It is easy to demonstrate that when $f_e = 0$ /no break-water/, Eqs. 20 and 21 reduce to

$$K_r = 0 \quad \text{and} \quad K_t = 0 \quad /27/$$

NUMERICAL RESULTS

The application of the semi - empirical theory in the previous section is illustrated first for the porous breakwater of thickness $2l = 15$ m. Let the water depth be $h = 10$ m. Assume that the wind velocity is $U_{10} = 20$ m/sec and the fetch $X = 100$ km. The frequency at the spectral peak is $\omega_p = 0.821$ rad/sec and the mean wave height is $H = 2.23$ m. The incident wave energy distribution let to be represented by the JONSWAP formula /Hasselmann et al., 1973/. For a prototype rubble diameter $d = 1$ m/,

Fig.2 Spectra of the incident $S(\omega)$ and transmitted $S_3(\omega)$ and reflected $S_{1r}(\omega)$ waves.

Fig.3 Frequency dependence of the transmission, reflection and dissipation energy.

the permeability and porosity is estimated from the model tests /see Appendix A/ to be

$$K = K_m \left(\frac{d}{d_m} \right)^2 = 5.52 \cdot 10^{-4} \text{ m}^2, \quad n = 0.437, \quad C_f = 0.228 \quad /28/$$

From the Appendix A follows that equivalent linear friction coefficient is $f_e = 4.2654$. Finally by performing the numerical integration in Eqs. 20 and 21 the statistical transmission and reflection coefficients are found, $K_t = 0.255$ and $K_r = 0.460$. In the Fig.2 the spectra of the incident wave, and the reflected and transmitted wave are shown.

Fig.3 shows the frequency dependence on the respected energies. From this Figure it is evident that almost 73 % of the mean value of incident energy is dissipated within the body of breakwater. The transmitted energy varies considerably with frequency from a maximum at low frequency and decreasing with increasing frequency. The reflection part of energy is almost constant in the band of frequency under consideration. Small maximum of reflected energy is observed at the frequency of spectral peak in $S(\omega)$ function. Both energies are decreasing for high frequencies.

The measurements and calculations performed by Thornton and Calhoun /1972/ in California represent of some opportunity to check the developed theory against the prototype data. In the fig. 4 the cross section of the Monterey Breakwater is shown.

Fig. 4 Monterey Breakwater cross section

As the preceding analysis is limited to permeable structure of rectangular form only, we adopte the equivalent rectangular cross section to the Monterey Breakwater which has approximately the same submerged volume /see Fig.4/. The hydraulic properties of the breakwater /permeability and porosity/ are roughly estimated taking into account that the structure is a mound of stones of different sizes and shapes, mainly of "C" type. The averaged total weight of the stone equal to $\sim 10^4$ N with specific gravity $\gamma \approx 26 \cdot 10^3 \text{ N/m}^3$ is used in the calculation. Then, the mean diameter of the stone is approximately $d_m \approx 0.8$ m.

Assuming that the prototype stone angularity and packing are the same as in the small scale rubble investigated by Sollitt and Cross /1972/ we can calculate the permeability K and the coefficient C_f . The incident wave spectrum is specify as in field investigation for December 1, 1970 at 2330 hr /see Tabl.1 in Thornton and Calhoun paper/.

Performing the numerical calculation of the K_t and K_r coefficients we obtain:

$$K_r = 0.448, K_t = 0.344, K_d = [1 - (K_r^2 + K_t^2)]^{1/2} = 0.825 \quad /29/$$

While the field measurement yields

$$K_r = 0.52, K_t = 0.11, K_d = 0.84 \quad /30/$$

The above numbers suggest that the transmission rate of energy in the field is higher than that predicted by theory. The reflection rate of energy is almost the same in both methods. The coefficient K_d represents the rate of energy which is dissipated in the body of breakwater. A possible explanation for this discrepancy is probably associated with the rectangular shape and value of permeability introduced in the analysis. Especially, the knowledge of the hydraulic properties of the porous material of Monterey Breakwater is rather poor. It is worthwhile to note that the experimental results for the reflection coefficient and dissipation rate are in good agreement with the theoretical values.

CONCLUSIONS

The present analysis was undertaken in order to extend a previous simplified theory for the determination of transmission and reflected characteristics of porous breakwaters subjected to the action of the wind - induced waves. The extension consisted of a more rigorous analysis of wave motion inside the breakwater space

when the incident wave spectrum may be arbitrary. The original nonlinear equation of motion into porous structure was linearized using statistical linearization technique. The computed output consists of the spectral density functions for the reflected and transmitted waves. The statistical transmission and reflection coefficients are introduced in terms of the standard deviations and the wave spectra.

From a comparison with experimental data it appears that the method may be valuable in practical applications. Probably more good quality experimental data is needed for the determination of the applicability range of the method.

APPENDIX A

Equivalent friction coefficient

Let the error between nonlinear and linear resistance forces be

$$e(x, z, t) = \frac{\gamma n}{K} \vec{u}_2 + \frac{C_f \cdot n^2}{\sqrt{K}} |\vec{u}_2| \cdot \vec{u}_2 - \int e \cdot \omega_p \cdot n \cdot \vec{u}_2 \quad /31/$$

Upon minimizing the mean square error

$$\frac{1}{2lh} \int_{-h}^l \int_{-l}^l E[e^2] dx dz \quad /32/$$

one gets

$$f_e = \frac{1}{n \cdot \omega_p} \left[a + b \cdot \frac{\int_{-l}^l \int_{-h}^l E[|\vec{u}_2| \cdot \vec{u}_2^2] dx dz}{\int_{-l}^l \int_{-h}^l E[\vec{u}_2^2] dx dz} \right] \quad /33/$$

in which

$$a = \frac{\gamma n}{K}, \quad b = \frac{C_f \cdot n^2}{\sqrt{K}} \quad /34/$$

The symbol $E[]$ represents the statistical average.

In order to calculate the statistical moments in Eq. 33 we assume that in the breakwater space the both wave velocity components u_2 and v_2 are the independent random values with gaussian probability density. The mean values are zero and the standard deviations are equal to σ_{u_2} and σ_{v_2} , respectively.

Thus, the probability density function for $U = |\vec{u}_2| = (u_2^2 + v_2^2)^{1/2}$ takes the form /Papoulis/

$$p(U) = p(|\vec{u}_2|) = \frac{U}{\sigma_{u_2} \cdot \sigma_{v_2}} \cdot I_0(m_1 \cdot U^2) \cdot \exp(-m_2 \cdot U^2) /35/$$

where I_0 - modified Bessel function and

$$m_1 = \frac{1}{4} \cdot \frac{\sigma_{u_2}^2 - \sigma_{v_2}^2}{\sigma_{u_2}^2 \cdot \sigma_{v_2}^2}, \quad m_2 = \frac{1}{4} \cdot \frac{\sigma_{u_2}^2 + \sigma_{v_2}^2}{\sigma_{u_2}^2 \cdot \sigma_{v_2}^2} \quad /36/$$

It can be easily demonstrated that

$$p_2(u_2) = p_2(\vec{u}_2^2) = \frac{1}{2 \cdot \sigma_{u_2} \cdot \sigma_{v_2}} \cdot I_0(m_1 \cdot u_2) \cdot \exp(-m_2 \cdot u_2) \quad /37/$$

and

$$p_3(u_3) = p_3(\vec{u}_2^2 | \vec{u}_2) = \frac{1}{3 \cdot \sigma_{u_2} \cdot \sigma_{v_2} \cdot u_3^{1/3}} \cdot I_0(m_1 \cdot u_3^{1/3}) \cdot \exp(-m_2 \cdot u_3^{1/3}) \quad /38/$$

By virtue of the definition of the mean of the random value we obtain

$$E[\vec{u}_2^2] = \sigma_{u_2}^2 + \sigma_{v_2}^2$$

$$E[\vec{u}_2^2 | \vec{u}_2] = \frac{12 \cdot \sqrt{\pi} \cdot \sigma_{u_2}^4 \cdot \sigma_{v_2}^4}{(\sigma_{u_2}^2 + \sigma_{v_2}^2)^{5/2}} \cdot \left(\Gamma(5/4) \cdot \Gamma(7/4) \right)^{-1} \quad /39/$$

$$\sum_{n=0}^{\infty} \frac{\Gamma(5/4+n) \cdot \Gamma(7/4+n)}{(n!)^2} \cdot \left(\frac{\sigma_{u_2}^2 - \sigma_{v_2}^2}{\sigma_{u_2}^2 + \sigma_{v_2}^2} \right)^{2n} \quad /40/$$

Substituting Eqs. 39 and 40 into Eq. 33 we are able to calculate the equivalent friction coefficient f_e . To initiate the solution, a value for f_e is assumed / $f_e \approx 1.0$ is suitable/. Then the appropriate potentials are evaluated. The standard deviations of the velocity components are extracted and substituted into linearization condition to compute f_e . If the result is different from the assumed value it is necessary to iterate in order to obtain next value for f_e .

CHAPTER 20

FIELD MEASUREMENTS OF WIND WAVE KINEMATICS

by

J.A. Battjes¹⁾ and J. van Heteren²⁾

ABSTRACT

Measurements of surface elevations and three orthogonal subsurface velocity components have been performed from a platform in the southern North Sea, off the Dutch coast, in order to check linear spectral transfer functions relating subsurface velocities to surface elevations, to obtain information about the directional properties of the waves, and to investigate the velocity statistics. The data obtained as far do not cover a sufficiently wide range of conditions to permit general conclusions. Some preliminary results are presented in the paper.

1. INTRODUCTION

Routine instrumental measurements of wind wave parameters are usually restricted to the free surface fluctuation. However, in applications in offshore and coastal engineering one needs information about the internal wave kinematics. Examples are the calculation of the loads on a structure due to a given wave field, or the calculation of densities and fluxes of energy and momentum, which are needed in problems of wave shoaling and refraction, and the prediction of nearshore currents.

Transforming data on surface elevations into velocity data can be accomplished in different ways. These can broadly be classified into two groups, that of a quasi-deterministic non-linear, individual wave analysis, and that of a random linear spectral approach. The principal advantage of the latter is its superiority in dealing with aspects of randomness in time and space (short-crestedness) of the wind waves. Its main drawback is the restriction to linear problems, but there are developments towards the inclusion of some degree of nonlinearity in the formulations (see for example Sharma and Dean, 1979).

- 1) Professor, Department of Civil Engineering, Delft University of Technology, The Netherlands
- 2) Staff Member, Hydraulic Division, Deltadepartment, Rijkswaterstaat, The Hague, The Netherlands.

Until a few years ago, there have been rather few published experimental verifications of the linear spectral approach, and those were typically in waves of rather low steepness (Thornton and Krapohl, 1974). It was then decided to initiate a research project in The Netherlands, aimed at such verification, to be based on measurements off an available platform in the southern North Sea. More specifically, the aims were to test the validity of linear spectral transfer functions relating internal velocities to surface elevations, to check the applicability of the model of a Gaussian process to the velocities, and, in addition, to obtain data on the short-crestedness of wind waves.

Due to a variety of causes related to equipment and personnel, progress in this work has been below expectations. Meanwhile, a number of studies by others has been published in which aims were pursued similar to those of the present investigation, and in which significant results were obtained (Cavaleri et al, 1977; Forristall et al, 1978; Guza and Thornton, 1980). It was nevertheless deemed useful to continue the present work, inasmuch as it gives independent additional data, obtained in different geographical conditions, with different sensors, and in part analysed differently. However, due to the delays referred to above, the measurements do not yet cover a wide range of conditions, so that no general conclusions can be drawn. For that reason this paper is kept rather brief. It is planned to give a more extensive presentation elsewhere, after additional data have been obtained and analysed.

The contents of this paper are as follows. Section 2 contains a description of the platform used for the measurements, and of its location. In section 3 the sensors, the data logging system and the transmission are described. The data available at the moment of writing are described in section 4. The methods of estimation of the transfer function, wave direction and short-crestedness are dealt with in section 5. Examples and some results of the estimated transfer functions are presented in section 6, those of the wave directions and short-crestedness in section 7, and those of the statistical properties in section 8. Section 9 gives some preliminary conclusions.

2. LOCATION AND DESCRIPTION OF THE PLATFORM

The measurements were made from a platform (MPN) located in the southern North Sea, about 10 km off the Dutch Coast (see figure 1). The local depth is about 17 m below M.S.L., and the local mean tidal range is approximately 1.80 m.

The platform has been built on a jacket construction, made from tubular elements which are up to 0.80 m in diameter. At three of the four corners of the platform, vertical sensor supports have been mounted (figure 2). These supports are space trusses

consisting of tubes with diameters up to 0.15 m. They can be lifted out of the water for attachment, inspection and cleaning of sensors.

Figure 1: Location of the platform (MPN)

3. INSTRUMENTATION

The velocity meter used for the measurements described in this paper is based on the principle of travel time of acoustic pulses. A meter of this type designed for use in tidal rivers has been described by Botma (1978), who also designed the meters used in the present study.

At first the velocity meter consisted of only one pair of transducers/responders. The distance between this pair of transducers/responders was 1.71 m and they were mounted with the axis in the vertical position so that the vertical velocity component (w) could be measured. The calibration factor of this instrument was calculated using a nominal value of the speed of sound in sea water, and an effective travel distance which was 10 cm less than the actual distance between the sensors, to allow for wake effects.

The wave gauge used for these measurements of the surface elevation, a Baylorgauge, is based on the conductivity of water and it consists of two vertically tensed wires with a length of about 20 m. The distance between the two wires is 22.5 cm. Deviations from linearity and variations in calibration factors were both less than 0.5 %.

Both sensors were fixed to the sensor support situated at the

south west side of the platform, with the wave gauge in the centre of the sensor support and the velocity meter at the west side of the sensor support. The horizontal distance between the two sensors was 1.20 m. The elevation of the velocity meter was 5.70 m below M.S.L.

Figure 2: side-view of MPN (north-side)

Afterwards this velocity meter has been extended in such a way that three mutually orthogonal velocity components (u,v,w) could be measured. To that end three pairs of transducers/responders were mounted in a glued frame, see figure 3. This frame consists of copper pipes (outer diameter 50.4 mm) to minimize marine fouling. It was mounted outside the sensor support with one of its axes in the vertical position. The orientation of the other axes is arbitrary.

The distance from the vertical axis of the velocity meter to the center of the sensor support has been increased from 1.20 m to 1.75 m so as to decrease the influence of the sensor support and platform piles.

In contrast to the one-dimensional meter, the three-dimensional version compensates for variations in the speed of sound due to variations in temperature and salinity of the sea water. The calculated calibration factor was checked experimentally by oscillating the frame rectilinearly in a laboratory basin. It was found to be correct within 5%, except when the meter was oscillated exactly in line with two sensors measuring one component, in which case the

deviation was up to 10%. This phenomenon is ascribed to the wake development. Since in the field the flow is not rectilinear, this deviation in the calibration is not taken into account in the analysis.

The wave gauge used for the measurements with the extended velocity meter is a stiff step gauge with a length of 15 m. It measures the number of wet electrodes of known mutual distance (0.1 m), so that the calibration is trivial.

The horizontal distance between the two sensors is 1.75 m. The elevation of the velocity meter has been 4.91 m below M.S.L. and 7.94 m below M.S.L.

Figure 3: the three-dimensional velocity meter

Through a data logging system the measured quantities can be scanned at intervals of 0.25 s (per quantity). Because the different channels are scanned successively there is a time interval between two successive channels of 0.25 s divided by the number of channels of the data logging system, in this case 32.

The data are transmitted by an F.M. radio-link to a shore station where they are recorded on magnetic tape. At intervals of 5 min. the significant wave height and the total energy of the frequencies lower than .1 Hz are recorded as well (as part of another project).

4. DATA

The time of recording is normally chosen to be near slack water in order to minimize disturbances due to the wake of the platform and sensor piles.

With the original one-dimensional velocity meter 31 measurements have been made, simultaneous with measurements of the surface elevation, distributed over three days with different climatologic conditions.

With the extended velocity meter two sets of measurements have been performed at the time of writing. First, 26 measurements of the three velocity components only were made, distributed over 6 days. The depth of the centre of the frame was 4.91 m below M.S.L. Later, velocity measurements have been made simultaneous with those of the surface elevation. At the moment of writing 32 such measurements have been made, distributed over 6 days with different climatologic conditions. During the second set of measurements the depth of the sensor was larger, namely 7.94 m below M.S.L.

5. CALCULATIONS

The respective transfer functions are calculated by auto- and cross spectral analyses, which also yield phase and coherence information. Standard procedures as described by Bendat and Piersol (1971) and Jenkins and Watts (1968) have been used based on an F.F.T. algorithm. The length of the analyzed records has been taken 1800 s. For the calculations of the spectra the records are divided in 30 segments, each with duration of 60 s. Because no data window has been used the number of degrees of freedom is 60 and the resolution 0.0167 Hz.

The auto- and cross spectra of the vertical velocity w and the surface elevation ζ , written as S_{ww} , $S_{\zeta w}$ and $S_{\zeta\zeta}$, have been used to calculate the transfer function

$$H_{\zeta w} = |S_{\zeta w}|/S_{\zeta\zeta},$$

the phase function

$$\phi_{\zeta w} = (\arg S_{\zeta w})/S_{\zeta\zeta}$$

and the squared coherence function

$$\gamma_{\zeta w}^2 = |S_{\zeta w}|^2 / (S_{\zeta\zeta} S_{ww}).$$

The procedure sketched above cannot be used for the relation between the surface elevation and the horizontal velocity $\vec{u} = (u, v)$, because of the short-crestedness of the waves. Assuming the system to be free of noise, a transfer function can be estimated as

$$H_{\zeta \vec{u}} = \{(S_{uu} + S_{vv})/S_{\zeta\zeta}\}^{1/2}$$

Transfer functions calculated from the measurements as indicated above will in the following be referred to as "measured" transfer functions.

Assuming the water motion and the measurements to be linear and noise-free, the calculated auto- and crossspectra for (u, v, ζ) or (u, v, w) can be used to estimate directional properties of the waves by standard procedures (see Borgman, 1979, for a review). Via the auto spectra and cross spectra the truncated Fourier series and the parameters of the \cos^2 -model of the directional spectrum have been calculated, for different frequencies. From these results, short-crestedness parameters can be calculated, again as a function of frequency.

In addition to the spectrally resolved short-crestedness parameters referred to above, an overall (i.e. non-spectral) measure of the short-crestedness of the waves can be defined.

Generally the mean squares and the mean product of u and v are non-zero. Let (u_x, v_x) denote the values of (u, v) in a reference frame in which $\overline{u_x v_x} = 0$. The axes of this reference frame then define the principal directions, and $(\overline{u_x^2}, \overline{v_x^2})$ represent the principal values of the velocity product tensor. An overall measure of the short-crestedness of the waves can then be defined as:

$$\Gamma = \frac{\overline{v_x^2}}{\overline{u_x^2}},$$

such that by definition $0 \leq \Gamma \leq 1$. Values of this short-crestedness parameter have been calculated from the data.

From the mean squares and the mean product of u and v , an overall principal wave direction can be obtained, e.g. by using the Mohr circle.

In addition to these calculations the statistical properties of the surface elevation and the velocity components are investigated. The distributions of the instantaneous values are compared with the normal distribution.

6. COMPARISON WITH LINEAR THEORY

6.1. The transfer function of the vertical velocity component and the surface elevation.

As indicated in section 4, the first set of measurements (31) was carried out with a one-dimensional velocity meter, which was so aligned that it measured the vertical velocity component. The results will not be presented here, with one exception. The average of the 31 ratios of the measured transfer function ($H_{\zeta w}$) to the theoretical (linear) one, at the peak frequency of $S_{\zeta \zeta}$, was about 0.87. If the effects of possible density variations of the sea water are considered, this ratio is estimated to vary between 0.87 and 0.92, with a standard deviation of 0.04. (Note: in an example given in the Conference preprint of this paper, said ratio was 0.75. However, it later turned out that the calculation procedure con-

tained an error; the corrected values are those mentioned above.)

At the moment of writing a series of simultaneous measurements have been made of (ζ, u, v, w) , using a wave gauge and the three-dimensional velocity meter. They have not yet been analysed fully. Some results of one measurement will be shown here by way of illustration. The data were recorded on Jan. 16, 1980, from 17 h.10 min. GMT to 17 h.40 min.

In figure 4 the wind- and sea conditions prior to and during the time of recording are shown. Figure 5 shows the surface elevation spectrum ($S_{\zeta\zeta}$), and figure 6 the coherence function between surface elevation and vertical velocity. The dashed lines indicate the 90% confidence bands. In the frequency interval which contributes most to ζ^2 , the squared coherence appears to be nearly 1. This indicates that the relation between ζ and w is approximately linear and noise-free in that interval.

In figure 7 the measured transfer function $H_{\zeta w}$ is compared with the corresponding transfer function based on the linear theory. For the range where the coherence is nearly one the calculated transfer function corresponds well with the theoretical one.

Figure 8 shows the ratio of the measured transfer function to the theoretical (linear) one as a function of frequency. This ratio does not vary significantly from the 100% value. A comparison of the measured velocity spectrum (S_{ww}) and the corresponding spectrum calculated from the linear transfer function and the measured elevation spectrum is given in figure 9. As expected from the results contained in the figures 7 and 8, the discrepancies are small in the region where most of the energy is located.

Figure 4: the wind- and sea conditions prior to the time of recording on Jan. 16, 1980, 17.10h - 17.40h.

Figure 5: surface elevation spectrum, with peak frequency f_m and area m_0 .

Figure 6: squared coherence function

Figure 7: measured (—) and theoretical (---) transfer function

Figure 8: measured transfer function as a percentage of the theoretical transfer function

Figure 9: auto spectrum of the vertical velocity; measured (---); calculated via the linear transfer function and the measured surface elevation spectrum (—)

The phase difference between surface elevation and vertical velocity is shown in fig. 10. It is seen to vary approximately linearly with frequency; if extrapolated to $f = 0$ Hz, the phase difference is 90° , as expected in the linear approximation for all frequencies.

The observed phase function indicates a constant (with respect to frequency) time shift (0.83 s in the example of fig. 10) between elevation and vertical velocity, in addition to the predicted 90° phase difference. This seems very unrealistic physically, and it gave rise to suspicions about the system of instrumentation and data handling. However, search efforts in that direction have so far not given evidence of the source of the "observed" shift. Another contributing factor may be the horizontal separation between the two sensors, but the effect of that would be too small to explain the 0.83 s. At the moment of writing the response times of the instruments are being re-investigated. No further results about phase differences will be reported in the present paper.

In the context of observed phase lags which seem to be unrealistic, in the sense that they cannot be explained by known processes, reference is made to Cavaleri et al (1977), who found good agreement in the observed and predicted phase difference between elevation and vertical velocity, but not for the horizontal velocities. The fact that horizontal and vertical velocities in their results were not in quadrature implies a net vertical transfer of horizontal momentum, which however could not be balanced with other physical processes such as wind stress at the water surface.

Figure 10: phase lag between surface elevation and vertical velocity component.

6.2. The transfer function of the vertical velocity component and the horizontal velocity component.

Figure 11 shows a comparison of the measured transfer function $H_{w\vec{u}}$, defined as $\{(S_{uu} + S_{vv})/S_{ww}\}^{1/2}$, to the theoretical one. Since this transfer function is estimated via the auto-spectra, possible noise is not eliminated. In the case of the relation between vertical velocity and surface elevation, the noise level was found to be negligible in the frequency band where most of the energy is concentrated (see figures 6 and 9). Assuming the same for the relation between vertical and horizontal velocities, the transfer function $H_{w\vec{u}}$ was calculated in the frequency range in which S_{ww} is at least 5% of its maximum value. In the lower - frequency part of this range there is a good agreement between the measured and predicted transfer functions, but the measured values show irregularities in the higher - frequency part, which suggests the presence of velocities not related to surface waves.

6.3. The transfer function of the surface elevation and the horizontal velocity component.

A comparison of the measured transfer function $H_{\zeta\vec{u}}$ to the theoretical one is shown in figure 12, within the range where $S_{\zeta\zeta}$ is at least 5% of its maximum value. In most of this range there is a good agreement between the calculated transfer function and the theoretical one according to the linear theory.

Figure 13 shows three sequences of ratios of measured transfer functions to the linear prediction, at the peak frequency of the auto-spectrum of the input (ζ in case of $H_{\zeta\vec{u}}$ and $H_{\zeta\vec{w}}$; w in case of $H_{w\vec{u}}$). The sequences were obtained from a series of 30 min. measurements in one day, with mild and almost-constant wind and sea conditions (see figure 4). The

average value of each of the three ratios is very nearly 100%. Additional data, including some taken in more severe conditions, are being analyzed so as to obtain a broader base for conclusions.

Figure 11: transfer function of the vertical velocity and the horizontal velocity; measured (—), theoretical (---).

Figure 12: transfer function of the surface elevation and the horizontal velocity; measured (—); theoretical (---).

Figure 13: ratios of measured to theoretical transfer function values near the peak of the auto-spectra, for some successive 30 min. measurements on Jan. 15 and 16, 1980.

7. WAVE DIRECTION AND SHORT-CRESTEDNESS

Via the auto spectra and the cross spectra of the surface elevation and the two horizontal velocity components two components of the truncated Fourier series per frequency and the parameters of the \cos^{2s} -model per frequency can be calculated. This can also be done via the auto spectra and cross spectra of the vertical velocity component and the two horizontal velocity components. Because the resolution of this truncated Fourier series is very low (72° , Longuet Higgins, 1963) and because the \cos^{2s} -model only gives one main direction per frequency, interpretation of the results of these calculations is very difficult. Therefore only an indication of the principal wave directions can be obtained. Some typical results will be given in the following, without going into the details.

For the frequencies round 0.10 Hz the calculated main wave directions are found to be in agreement with the direction of swell coming from the northern part of the North Sea if refraction is taken into account (Holthuysen, 1973). For the frequencies round 0.30 Hz the calculated wave direction is about the same as the direction of the wind. Between these frequencies the direction of the waves changes slowly from the direction of the swell near $f = 0.10$ Hz to the wind direction near $f = 0.30$ Hz. It may be that in this range there are two main directions per frequency of which for the lower frequencies the direction of the swell dominates and for the higher frequencies the direction of the sea.

In figure 14 an example is given of the determination of the overall measure of the main wave direction and of the overall short-crestedness, using the Mohr circle. Measured values of $\overline{u^2}$, \overline{uv} and $\overline{v^2}$ are plotted, from which the principal values ($\overline{u_*^2}$, $\overline{v_*^2}$) and the principal directions ($\theta, \theta + \frac{\pi}{2}$) can be obtained. The angle θ is referred to the direction of the u -component, from which the angle θ' is calculated, which is referred to North.

As can be seen from the example, the overall principal direction calculated from $\overline{u^2}$, \overline{uv} and $\overline{v^2}$ ($\theta' = 277^\circ$) has about the same

Figure 14: the calculation of the main wave direction and short-crestedness using the Mohr circle.

value as the main directions in the $\cos^{2\alpha}$ -model for frequencies near the spectral peak.

For the example shown the value of the short-crestedness parameter Γ is $\overline{v_x^2}/\overline{u_x^2} \approx 0.34$. The measurements were made in a mild sea state following about 20 hours of almost constant wind direction, so that this value of the short-crestedness parameter is expected to be typical for wind waves in an ideal, steady generation situation. The value of 0.34 is in accordance with an indirect result by Forristall et al (1978), who found that a value of the ratio $\overline{u_x^2}/(\overline{u_x^2} + \overline{v_x^2})$ of about 0.75 gave the best fit of the theoretical distribution of the magnitude of the horizontal velocity to the observations (said ratio is a parameter of this distribution). These measurements were made in a hurricane. Lastly, it is noted that a value $\Gamma = 1/3$ is consistent with a $\cos^2\alpha$ - directional spectrum, which has often been used in the past as a rough approximation.

Although this paper does not deal with applications, it is pointed out that the overall short-crestedness is important in the determination of the radiation shear stresses, which are proportional to $(\overline{u_x^2} - \overline{v_x^2})$, in a wave field of given total energy, which is proportional to $(\overline{u_x^2} + \overline{v_x^2})$ (Battjes, 1972). The radiation shear stress is the driving force for longshore currents.

8. STATISTICAL PROPERTIES

Figure 15 shows a histogram of instantaneous values of a horizontal velocity component and the best fitting Gaussian probability density function. Based on visual observations from results such as shown in figure 15, it appears that for engineering purposes, the three velocity components and the surface elevation are normally distributed. However, it should be borne in mind that the measurements so far have taken place in rather mild to moderate sea conditions.

Figure 15: example distribution of instantaneous values of a velocity component

9. CONCLUSIONS

The measurements available at the time of writing do not cover a sufficiently wide range of conditions to permit very general conclusions. The following tendencies have been observed.

In the first series of measurements, in which a one-dimensional (vertical) velocity meter was used together with a Baylor-type surface wave staff, the measured vertical velocities were found to be on the average about 10% below the predictions using linear theory and measured elevation spectra. No significant deviation has been found in the analysis of the simultaneous measurements of the three mutually orthogonal velocity components and the surface elevation. A reason for these different results has not yet been firmly established.

The observed phase spectra for the relations between elevation and velocity show a linear dependence on frequency, which indicates a constant time shift between the two signals. Although it is believed that this shift is not physically realistic, efforts to locate its origin in the system of instrumentation and data handling have so far not been successful.

The principal wave directions calculated via the auto spectra and cross spectra of the surface elevation and the two horizontal velocity components show for the low frequencies a direction which corresponds with the direction of swell coming from the northern part of the North Sea if refraction is taken into account and for the high frequencies a direction which corresponds with the direction of the local wind. Between these two ranges the calculated main wave direction changes slowly.

From the mean squares and the mean product of the two horizontal velocity components an overall (i.e. non-spectral) short-crestedness parameter and an overall main wave direction have been calculated. It appears that there is a good agreement between the direction of the waves calculated in this way and the directions calculated by conventional spectral methods for the frequencies near the spectral peak.

From the investigation of the statistical properties of the three velocity components it appears that for engineering purposes, the distribution of these components can be accepted as being normally distributed.

ACKNOWLEDGEMENTS

The work described in this paper was carried out as part of the Coastal Research Program (TOW-K) of the Department of Public Works of The Netherlands.

CHAPTER 21

HF-RADAR MAPPING OF EXTENSIVE OCEAN WINDFIELDS

by

P.E. Dexter

Physical Research Section, Bureau of Meteorology,
Melbourne, Australia

and

R.C. Casey

Physics Department, James Cook University,
Townsville, Australia

1 INTRODUCTION

The possibility of deriving parameters of sea wave spectra remotely from characteristics of radio waves at high frequency (HF) scattered from the sea surface was first raised when Crombie (1955) correctly deduced that Doppler frequency shifts in the signal returned from short range in his HF radar resulted uniquely from components of the sea wave spectrum having wavelengths exactly one-half the radio wavelength, and travelling radially with respect to the radar. Since then the technique has been expanded in two directions:

- (a) The use of ionospherically propagated HF radio waves ('Skywave' HF radar) to examine extensive ocean areas out to some 4000 km from the observing site, to obtain oceanographic and meteorological data suitable for input to synoptic observation systems. This approach has been developed through the experimental work of Tveten (1967) and Ward (1969), and the empirical technique proposed by Long and Trizna (1973) to allow the simple extraction of sea surface wind vectors from Doppler spectra of the backscattered radio signals.
- (b) The determination of directional sea wave spectra and sea surface currents at short ranges with HF radars operating in the ground-wave propagation mode, based on theoretical analyses of the scattering process such as those of Barrick (1972).

The HF Skywave radar constructed and operated at Townsville by the Physics Department of James Cook University has been employed for some years now on research into the possibilities for mapping sea states and sea surface winds over ocean areas surrounding Australia (Ward, 1969; Ward and Dexter, 1976; Dexter and Casey, 1978).

While the high spatial resolution necessary for the accurate mapping of such meteorological systems as tropical cyclones with a Skywave radar (Maresca and Carlson, 1979) can be achieved with extensive aerial arrays, these arrays are necessarily fixed, and the spatial coverage which may be obtained is thus limited. The James Cook University radar employs a fully rotatable aerial array, thus enabling a full 360° azimuthal cov-

erage of the sea surface, out to ranges approaching 4000 km from the coastline. The limited physical size of the array in this case in turn limits spatial resolution, although the resolution obtainable is sufficient to delineate most large-scale meteorological systems (Dexter and Casey, 1978).

The present paper will describe briefly the James Cook University radar, and discuss recent results involving the mapping of sea surface wind vectors over extensive ocean areas to the east and south of Australia. It will also examine some of the limitations imposed on data collection and analysis by a moving ionosphere, and will argue that the resolution and coverage of the James Cook University radar are well suited to the input data requirements of numerical meteorological analysis and forecast systems currently in use for the southern hemisphere.

2 RADIO THEORY

The backscatter of HF radio waves from the sea surface is interpreted, to first order, as a Bragg resonant interaction between the incident radio waves and ocean waves of one half the radio wavelength propagating along the radar radial. The backscattered radio wave has a Doppler frequency shift imposed by the moving ocean waves, and its frequency spectrum contains discrete components at

$$\omega = \omega_0 \pm (2gk_0)^{1/2} = \omega_0 \pm \omega_B \quad (1)$$

where k_0 and ω_0 are the wave number and frequency of the incident radiation (wavelength g_0) and g is gravitational acceleration. These components, the Bragg lines, correspond to advancing and receding ocean waves, respectively. The ratio r of the amplitudes of the two Bragg lines is directly related to the relative proportions of advancing to receding waves and, through a directional model of the sea wave spectrum, may be interpreted in terms of surface wind direction. For the James Cook University radar, operating at 21.84 MHz, Bragg scatter occurs from ocean waves of 6.9 m wave length. These waves will be in equilibrium with the local wind for all wind speeds above about 4 m/s.

Unfortunately, this saturation of the resonant ocean wave components means that the Bragg lines can supply no information on state of development of the sea (in simple terms, wave heights or ultimately surface wind speeds). For this information recourse must be made to second and higher order scattering, which produces lower-level sidebands in the frequency spectrum of the backscattered signal. Various empirical and theoretical techniques have been developed to extract relevant information from the second order Doppler spectrum. For a full discussion of radio scatter theory, to both first and second order, see Barrick (1972, 1977, 1978), Johnstone (1975) and Lipa (1977).

3 RADAR FACILITY

The James Cook University HF skywave radar has been described in detail by Ward and Dexter (1976), Dexter and Casey (1978) and Dexter (1979). Some of the characteristics of the facility are summarised in Table 1.

TABLE I

JAMES COOK UNIVERSITY HF SKYWAVE RADAR

Transmitter	
Operating frequency	21.840 MHz
Peak power	20 kW
Pulse repetition frequency	25 Hz
Pulse length	0.5-1.0 ms
Receiver	
Bandwidth	1-4 kHz
Antenna (monostatic)	
Gain	+13 dB over free space dipole
Front/back ratio	+20 dB
Beamwidth	24 ⁰ (-3 dB points)
Sidelobes	-15 dB
Targets	
Range coverage	1000-4000 km
Range resolution	0.5 ms group delay ≅ 75 km
Angle coverage	360 ⁰ of azimuth
Angle resolution	Of the order of ±7 ⁰ (700 km at 3000 km range)
Expected Bragg Doppler	±0.475 Hz
Doppler resolution	0.04 Hz system, 0.14 Hz due to ionosphere
Range accuracy - relative	30-40 km
- absolute	around 50 km
Angle accuracy	±0.5 ⁰

4 OBSERVATIONS, ANALYSIS AND INTERPRETATION

A quasi-operational test of system performance was conducted on 26 October 1978. Observations were made during the 3 hour period 0130Z to 0430Z (the optimum time as determined by Ward (1972) and Heron and Rose (1978(a)) to minimise mean ionospheric Doppler shifts), with 102.4s data blocks being obtained from scattering areas selected at group delays of from 9 ms to 25 ms (ground ranges approximately 1200 to 3700 km) on azimuths from true bearing 050⁰ from Townsville to true bearing 190⁰. Radar coverage was thus fairly uniform over a total sea area of some 2 × 10⁷ km² in the Coral Sea, Tasman Sea and Southern Ocean (Fig 2).

Figure 1 Doppler spectrum from 102.4s of data recorded near 0230Z on 26 October 1978. Scattering area located on true bearing 070° from Townsville, at a ground range of 2800 km. Bragg peaks (exhibiting multipath) occur at ± 0.475 Hz. Peaks at Doppler frequency shifts of 0 Hz and 2 Hz represent transmitter frequency leakage and a reference signal, respectively.

The 102.4s data blocks for each scattering cell were digitised at 10/s. The resulting 1024 data points were divided into four sets of 256 points, spectral analysis performed on each with an FFT, and the resulting raw spectral estimates incoherently averaged to give spectral resolution of 0.04Hz and approximate 90 per cent confidence limits of +2.0 and -3.1 dB (Dexter and Casey, 1978; Dexter 1979).

An example of the resulting Doppler spectrum for a single scattering cell (true bearing 070° , range 2800 km from Townsville) is shown in Fig 1. There was some leakage of transmitter frequency into the processor circuitry during this experiment, and this has resulted in the peak at zero Doppler frequency. The spectral line near +2Hz is a locally injected reference.

The frequency spectrum exhibits both positive and negative first-order lines, with the dominant positive line indicating approaching waves (and winds). Wind direction analyses were performed on this and similar spectra for all scattering cells using the technique of Stewart and Barnum (1975). Briefly, this assumes a wave directional spectrum of the form

$$g(\theta) = \cos^s (\theta/2) \quad (2)$$

where θ is the angle between mean wind and radio propagation direction, and s is a parameter related to wind speed (Tyler et al., 1974). The ratio of advancing to receding waves is thus $\tan^s (\theta/2)$. However, this is also the ratio of the advance to recede Bragg line amplitudes, A^+ and A^- respectively. Thus

$$\theta = 2 \arctan \left\{ \left(\frac{A^+}{A^-} \right)^{\frac{1}{s}} \right\} \quad (3)$$

In practice, for reasons discussed by Dexter and Casey (1978), a uniform wind speed of 10 m/s was adopted in this analysis. Full results of the direction analysis are shown in Fig 2. The fit to the meteorological mean sea level (MSL) pressure analysis for 0300 Z (1300 h local time) on 26 October is obviously good, particularly when allowance is made for cross-isobar flow. A similar direction analysis using the technique of Long and Trizna (1973) was also performed, with inferior results (although this technique has been used with success in the North Atlantic by Shearman et al. (1977)).

Most of the Doppler spectra obtained in this experiment (including that shown in Fig 1), display features characteristic of an unstable ionospheric propagation mode. Of most significance are:

- (a) ionospheric multipath, manifest as a splitting of the Bragg lines into three or more distinct peaks;
- (b) broadening of the Bragg lines due to small scale and random ionospheric movements, imposing a spectral resolution limit of the order of 0.14 Hz (at 21.840 MHz), as found by Heron and Rose (1978(b)).

Neither of these phenomena affects wind direction determinations, but both interfere substantially with wind speed computations. The approach employed in this case was again that of Stewart and Barnum (1975), in which the width (B) of the principal Bragg line, at a level 10 dB below the peak, is related empirically to surface wind speed. The approach can only be applied to spectra which do not exhibit multipath, and the particular empirical relationship employed has been that derived by Dexter and Casey (1978). The few wind speeds which could be computed in this way are also displayed in Fig 2. Comparison with available surface observations is reasonable.

Absolute ground ranges have been computed for all scattering cells using ionospheric data supplied by the Australian Ionospheric Prediction Service for Brisbane, applied to a technique devised by Dexter (1979). These ranges could only be confirmed where identifiable land features occurred in a scattering cell, but errors are unlikely to be greater than system range resolution.

5 DISCUSSION

While the low spatial resolution (average scattering cell for 'almost independent' observations of the order of 150 km × 470 km) of the James Cook University radar makes it unsuitable for the detailed observations of such small-scale atmospheric features as fronts and tropical cyclones as have been attained with the high resolution radar of Barnum et al. (1977) and Maresca et al. (1978), its flexibility of operation and large scanning area do afford other advantages. In particular, a total potential sea area coverage of some 5×10^7 km² makes this radar an attractive possibility for the observation of surface wind vectors over a significant portion of the data sparse southern hemisphere oceans. An illustration of the areal coverage for the radar when sited at Townsville and near Alice Springs is shown in Fig. 3. It remains to be seen whether such data is compatible with required meteorological synoptic analyses.

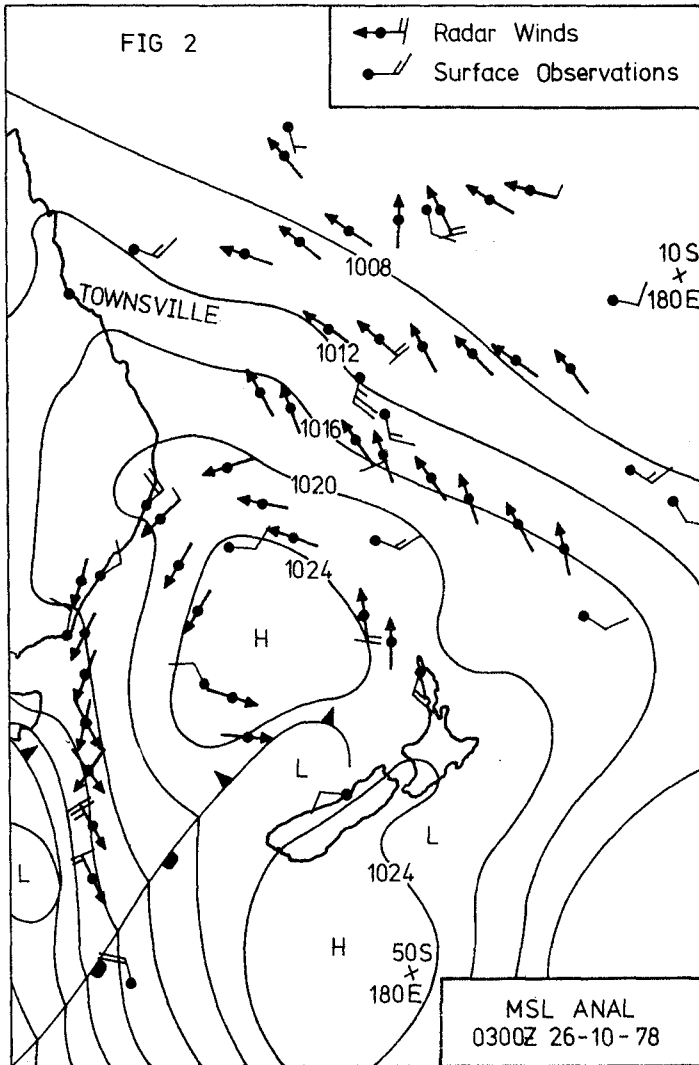

Figure 2 Surface meteorological analysis for 0300Z on 26 October 1978, with radar-derived winds superimposed. Solid arrows are radar wind directions, with feathers in wind speed intervals of 2.5 m/s. Measured surface winds are also shown, where available.

FIG 3

Figure 3 Standard meteorological chart for Australian region, polar stereographic projection (true at 60°S), with relevant portion of 47 x 47 grid superimposed. Also shown is approximate areal coverage of the James Cook University radar in its present site, and when more conveniently sited near Alice Springs. Dots represent meteorological synoptic observing station.

Numerical meteorological analysis and prognosis models currently in use with the Australian Bureau of Meteorology are hemispheric in scope and based on a rectangular grid, either 61×61 (grid spacing approximately 330 km at 60°S), or 47×47 (grid spacing approximately 490 km at 60°S (Fig. 3)). Both grid spacings are comparable with the average spacing between observations for the radar winds, of around 300-400 km. Seaman (1977) has analysed the optimum density of an observational network in terms of such observational parameters as spatial correlation of observational errors, observational error variance, and the scale size of particular meteorological systems required to be observed and forecast. If it is assumed that this latter scale size is approximately twice the numerical grid spacing, this analysis shows that the point of diminishing return for the rms analysis error in the absolute value of a particular meteorological element is reached for an observational network spacing between 1.0 and 1.4 of the grid spacing. Thus the density of 'almost independent' observations attainable by the radar is well matched to the operational numerical grid, and the maximum system resolution.

In addition, a complete Australian region coverage can be made by the radar in a 2 to 3 hour period at least once per day. While this is not ideal, it is at least similar to the observational frequency in the Australian region from orbiting meteorological satellites.

Similar considerations apply to numerical wave forecast models for southern hemisphere oceans with the additional factors: (a) in the absence of extensive sea state observations, initial wave fields must be computed from analysed surface wind fields. Thus direct observations of these wind fields over the ocean assume even greater significance. (b) The low success rate for wind speed extraction (around 15% of all observations) to date could limit utility in this regard. While the problems of multipath and peak broadening are always likely to be present for a skywave radar of this configuration, work is currently underway to develop a more reliable technique for wind speed determination from observed Doppler spectra, and hopefully this will raise the success rate to better than 60%. This work is to be reported on separately at a later date.

6 ACKNOWLEDGMENTS

We thank Professor J.F. Ward for his continued interest in, and support for, the skywave radar project. This paper is published by permission of the Director of Meteorology, Australia.

SOURCES OF MEASURED WAVE DATA

by

Laurence Draper
Institute of Oceanographic Sciences
Wormley, Godalming, Surrey GU8 5UB, U.K.

ABSTRACT

A Catalogue listing 550 known sources around the world of instrumentally-measured wave data has been prepared by the Marine Information and Advisory Service under the auspices of the Intergovernmental Oceanographic Commission of UNESCO.

A source of good wave data is a prime requirement of the coastal engineer. "Perhaps I exaggerate the importance of the wave climate but from my own experience I rate it as the most frustrating gap in the kit of tools available to the coastal engineers..." so said Dean Morrough P. O'Brien, Chairman, Coastal Engineering Research Council A.S.C.E., in his opening address to the 13th Conference on Coastal Engineering, Vancouver, 1972.

Since that time there have been significant developments in a number of aspects. Existing wave climate measurement programmes have been extended and new ones have been started, so that the world-wide effort has increased considerably. The International Waves Commission of PIANC (Larras 1973) (which was already in operation in 1972) developed its proposals for a wave data inventory, and the Intergovernmental Oceanographic Commission (IOC) of UNESCO accepted an offer by the Marine Information and Advisory Service of the Institute of Oceanographic Sciences to establish what is in effect a wave data centre, a Responsible National Oceanographic Data Centre for Waves (RNODC (Waves)). A world-wide network of Area Representatives has been established; each representative provides the RNODC (Waves) with information on instrumental wave measurements in his area. Data are not transmitted at this stage. The information is in a standard format so that a potential user can assess the value of the data to his own project; negotiations for use of the data then proceed between owner and potential customer.

It is not planned to publish the complete Master Catalogue, because of its bulk, but a condensation entitled Catalogue of Wave Data has been published and is available

from MIAS at the Institute of Oceanographic Sciences. An example of one page of this catalogue, showing two stations, is given in Figure 1. A list of Area Representatives as of April 1980 is given as an Appendix to this paper, and the countries involved are shown in Figure 2, which also gives the number of entries published for each area. The most intensively covered areas are those around the British Isles, and a larger scale map showing actual locations is given in Figure 3. Maps of eastern Australia (Figure 4) and eastern Canada and north eastern USA (Figure 5) are also given to indicate the coverage in these areas.

Although Area Representatives provide reasonable coverage of the world's coastlines, seas and oceans (see Figure 2), additional offers of help would be appreciated at any time. These should be addressed to the author, who is Scientific Co-ordinator RNODC (Waves), at the Institute of Oceanographic Sciences, Wormley.

The establishment of such an organization has been needed for many years. The first two years of its life have shown great promise, both in the number of people eager to help and the enormous effort they have shown in tackling the major task of completing the questionnaire forms for data already in existence. So far, nearly 600 forms have been received and many more have been promised. It looks as though Dean O'Brien will soon need a larger toolbox.

CHAPTER 23

VISUALLY OBSERVED WAVE DATA AT PT. MUCU, CALIF.

Christine Schneider¹

J. Richard Weggel², M. ASCE

Abstract

A Littoral Environment Observation (LEO) Program was established along the West Coast of the United States in 1968. This program provides for visual observations of waves and surf conditions to be made systematically on a daily basis. The data addressed in this report were collected at three LEO sites (as shown in Figure 1) at Pt. Mugu California, located 50 miles northwest of Los Angeles.

In order to evaluate the reliability of wave heights and periods collected using the LEO techniques, comparisons of visual observations and measured wave gage records were made.

The study revealed that individual visual observations of breaker height can deviate significantly from measured wave heights even when the gage wave heights had been corrected for shoaling effects. On the average the LEO observations gave a fair estimate of prevailing wave heights.

LEO estimates of wave period tended to overpredict the period of maximum energy density. It is presumed that this occurred because observers often fail to count smaller waves when making this measurement. Statistics of the gage measurements of wave height and LEO wave heights are reasonably close.

Introduction

In an effort to provide low-cost coastal information for the planning, operation and maintenance of coastal structures and projects, the U.S. Army Coastal Engineering Research Center (CERC) in cooperation with coastal states and other public entities, established the Littoral Environment Observation (LEO) program. This program has been in operation since 1968, and provides a data bank of wind, wave and current statistics which have been collected on a repetitive and systematic basis by volunteer observers. (BERC, 1968)

Presently fifteen pieces of information are gathered during each observation; included are: the wave period, height, angle and type of breaker; wind speed and direction; foreshore slope; surf zone width; current and direction; and rip current and beach cusp spacings.

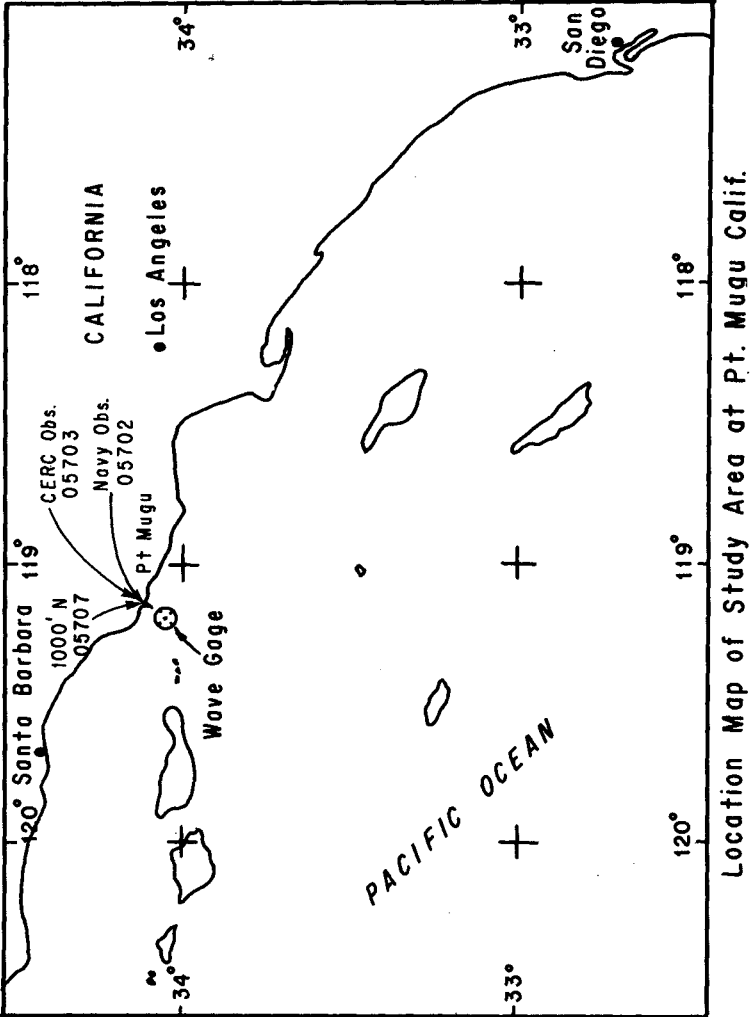

Fig. 1. Location map of study area at Pt. Mugu, California.

LEO data have been collected primarily at sites where little or no wave data existed or where resources are not available for installation of wave recording instruments. This report presents comparisons between LEO observations of wave characteristics and gage measured characteristics made for the period from March to December 1972 at Pt. Mugu, California where a 5-gage array and several LEO Sites were operated simultaneously. At the Pt. Mugu site, LEO observations were obtained by two separate observers, a CERC observer and a Navy observer. In addition, CERC observations were made at two adjacent locations 1000 ft. upcoast (northwest) and 1000 ft. downcoast (southeast) from the primary site. The primary site was located at a pier constructed across the surf zone and thus the observers at this location were not constrained to make observations from the beach. All of the Navy observations were made from the deck of the pier while most of the CERC observations were made from the beach. At the adjacent sites, the CERC observer made estimates of breaker height, surf zone width, breaker period, etc. from the beach. It is thus possible to look at differences between two independent observers at a given site and to look at spatial variations introduced by a single observer making observations at three sites spaced 1000 ft. apart. Only data from the pier site and the upcoast were analysed for this study and thus only results from these two sites are presented herein. For observations made by a single observer at two separated sites, it is not known how much influence the observation at one site has on the same observer's estimate of wave conditions 1000 ft. away. Presumably, the observations are independent and describe real spatial variations; however, it seems reasonable to assume that observations made at one site may have some influence on what the observer reports from an adjacent site.

DATA ANALYSIS

Comparisons were made of wave heights obtained visually at three LEO stations (two sites) with the significant wave heights obtained from a pressure wave gage located in about 30 ft of water. The gage was about 2.5 feet above the bottom and pressure readings were corrected to obtain water surface elevations including the effect of tide. Additionally, comparisons were made of wave periods obtained by timing the passage of 11 breaker crests and the period of maximum energy density obtained from the wave spectrum. The comparison was made for the gage observations taken closest to the time the LEO observation was made. Since gage measurements were taken every six hours the greatest time between gage measurement and corresponding LEO observation was 3 hours.

Figure 2, shows scatter plots of the LEO estimated wave heights for both the Navy observer and CERC observer at the pier and 1000 ft upcoast, respectively, and how they compare with the significant wave heights measured in 30 ft of water.

No corrections for refraction and shoaling between the gage and breaking were applied to the gage data for these plots. The lines shown on the plots are (a) the line of equality, (b) a least-squares best-fit straight line and (c) a least-squares-best-fit straight line constrained to pass through the origin. Comparing this latter line for the three sets of observations, it appears that the Navy observations

Figure 2. LEO observations of breaker height versus uncorrected wave gage heights, 1972.

of breaker height most closely approximate the gage values while the CERC observations at both the pier and 1000 feet upcoast are generally greater than the significant wave height as recorded at the gage. The least-squares best-fit line suggests that there is a tendency for both observers to overestimate the height of smaller waves and underestimate the height of larger waves. Obviously, the effects of shoaling and refraction between the gage and breaker line need to be considered.

Two shoaling models were applied to the gage data to estimate breaker heights that could be compared with LEO breaker height observations. Recognizing that the transformation of a wave spectrum across the nearshore area is a complex phenomenon, a crude approximation to the shoaling process was made by characterizing the spectrum as monochromatic waves having height and period equal to the significant height and the period of maximum energy density. No correction for refraction was applied. The first shoaling model used linear wave theory with the assumption that the group velocity and phase velocity were the same at breaking. From linear theory,

$$\frac{H_{bl}}{H_{gage}} = \sqrt{\frac{(C_G)_{gage}}{(C_G)_b}} = \sqrt{\frac{(nC)_{gage}}{(C_G)_b}} \quad (1)$$

$$\text{where } (C_G)_b \approx \sqrt{g(d_b + H_{bl})} \quad (2)$$

$$\text{and } d_b = 1.28 H_{bl} \quad (3)$$

where H_{bl} is the breaker height

H_{gage} is the gage wave height in 30 ft of water

$(C_G)_{gage}$ is the wave group velocity at the gage

$(C_G)_b$ is the wave group velocity at breaking, and

n = ratio of wave group velocity to phase velocity

Combining these expressions gives, for H_{bl} as a function of H_{gage} , the explicit relationship

$$H_{bl} = \left\{ H_{gage} \sqrt{n \frac{L_{gage}}{T}} (0.1167) \right\}^{4/5} \quad (4)$$

where L_{gage} is the wave length at the gage of a wave with period T equal to the period of maximum energy density. Applying this shoaling adjustment to the gage data results in the scatter plots of figure 3 for the Navy observer, the CERC observer at the pier and the CERC observer 1000 feet upcoast of the pier, respectively. The approximate shoaling correction results in higher gage wave heights and better comparison with the LEO observations. Comparing the least-squares-best-fit lines passing through the origin, the Navy observations now generally underpredict the corrected gage heights while the CERC

Figure 3. LEO observations of breaker height versus wave gage heights corrected for shoaling (shoaling model 1).

observations at both the pier and 1000 ft. upcoast, on the average, predict the measured values rather well.

The second shoaling model used was an iterative solution to the linear shoaling relationship and the breaker height to water depth ratio (equation 3.) This implicit scheme makes no a priori assumptions about the relationship between the wave group velocity and phase velocity at breaking, nor does it require that the shallow water approximation be made to determine the wave phase velocity. This second shoaling model resulted in higher breaker heights than the first model (figure 4.) As a result, the LEO observations by both the Navy and CERC observer are quite a bit lower than the transformed significant wave height obtained from the gage. If the root-mean-square wave height is used instead of the significant height (assuming that $H_{rms} = 0.71 H_S$) the equations on figure 4 become,

$$H_{leo} = 0.86 (H_{b2})_{rms} \quad (\text{Navy Observer, pier})$$

$$H_{leo} = 0.96 (H_{b2})_{rms} \quad (\text{CERC Observer, pier})$$

$$H_{leo} = 0.92 (H_{b2})_{rms} \quad (\text{CERC Observer, 1000 ft upcoast})$$

where H_{b2} is now the breaker height determined from the second shoaling model using the rms wave height measured at the gage.

The statistical distribution of wave heights was estimated for the LEO observations at the three sites and compared with the distribution of heights obtained from the gage and from the gage as corrected by the two shoaling models. Comparisons between the LEO observations and the wave gage heights are shown on figure 5 plotted on a log-normal probability scale. Probabilities were estimated by ranking the individual observations and using the plotting position formula,

$$P(X \geq x) \approx \frac{m}{N+1} \quad (5)$$

where m is the rank of the observation (m=1 for the largest) and N is the number of observations in the sample. The distribution of gage heights shown on figures 5a, 5b, and 5c are essentially identical; any small differences are due to a slightly different sample size. These differences are most apparent at the extreme ends of the distribution (near the largest and smallest observations.) The Navy observations (5a) compare favorably with the uncorrected gage heights whereas the CERC observations at both sites overestimate the significant wave height at the gage.

Figure 6 shows the probability distribution of the gage wave heights transformed by the two shoaling models. In both cases the curve is shifted upward for shoaling-corrected wave heights. Shoaling model 1 applied to the significant wave height gives the best comparison with the LEO observations. If the H_{rms} wave height is assumed to characterize the wave spectrum at the gage, the second shoaling model and the

Figure 4. LEO observations of breaker height versus wave gage heights corrected for shoaling (shoaling model 2).

Figure 5. Probability a given wave height is exceeded, LEO breaker heights compared with uncorrected wave gage heights.

Figure 6. Probability a given wave height is exceeded, wave gage data corrected using shoaling models 1 and 2.

LEO observations are comparable. No firm conclusions can be reached regarding which wave of the spectrum an observer sees when he estimates the breaker height. It appears to be some wave between the root-mean-square height and the significant height; however, the scatter of individual observations about the line of best fit indicates that any individual visual observation may be in significant error. Statistically, however, the data appear to give comparable results. Data on observed wave periods and the measured period of maximum energy density are compared on figure 7 for each of the three data sets. In each case the tendency is for the observer to overestimate the wave period especially for lower wave periods. For larger periods there is some tendency for the LEO observer to underestimate the period. This apparent bias is presumably due to the observer's failure to count the smaller waves that pass a given point when timing the passage of 10 waves. This leads to a bias toward recording longer wave periods. Also, during times when there is a local sea which may dominate the wave energy spectrum, long period waves may continue to dominate in the breaker zone.

Table 1 compares the coefficients (ratio of LEO observation to gage measurement) of the best-fit line through the origin for (a) uncorrected gage heights, (b) the two shoaling models and (c) for wave period. All gage heights are significant heights or transformed significant heights. The gage period is again the period of maximum energy density in the spectrum and the LEO period is the time for 11 wave crests (10 wave lengths) to pass a fixed point in the surf zone.

TABLE 1: COMPARISON OF COEFFICIENTS OF BEST FIT LINE THROUGH ORIGIN

Conclusions

When using the LEO method to collect wave data, the breaker height can deviate from measured heights, even after models had been applied to correct the information for shoaling effects. On the average, the LEO observations are a fair estimate of prevailing breaker heights.

Again the LEO estimates of breaker period tend to overpredict the period of maximum energy density, presumably because of the observer's failure to count smaller waves.

Figure 7. LEO observations of wave period versus period of maximum energy density from wave gage.

These conclusions are not general, as the capability of each observer is a real factor. Periodic visits and checks of observers are needed to insure data are collected conscientiously. Recognizing the shortcomings of visual observations, they still represent a useful and inexpensive source of coastal information, but data that must be used carefully with full recognition of its limitations.

ACKNOWLEDGEMENTS

The authors wishes to extend special thanks to Mr. Mike Leffler and Dr. Todd Walton for their assistance during the data analysis.

The analysis and results presented in this paper, unless otherwise noted, were based on research conducted at the Coastal Engineering Research Center under the Coastal Engineering Research Program of the U.S. Army Corps of Engineers. Permission to publish this information is appreciated.

WAVE HINOCASTS AND MEASUREMENTS
BASS STRAIT

By

M. N. Silbert*, T. P. Barnett**, O. J. H. Peters† and R. C. Hamilton††

1.0 INTROOUCTION

The Bass Strait of Australia is the location of significant offshore oil and gas production. At the time of this writing eight self-contained drilling and production platforms as well as many miles of submerged pipeline comprise the Esso Australia Ltd. (EAL) and Broken Hill Proprietary Company Ltd. (BHP) operation in the Bass Strait. During the course of the next five years significant additional development and platform construction will take place in this offshore oil and gas area.

Observation of offshore wind and wave conditions are greatly facilitated by the presence of fixed platforms from which to collect data. Visual observations of waves along with measurements of wind speed and direction and barometric pressure from Bass Strait Platforms have been routinely recorded and reported to the Australian Bureau of meteorology for more than ten years. Close cooperation between EAL and the Meteorological Bureau has resulted in continuous weather forecasts for the Bass Strait region.

In March of 1977 EAL decided to upgrade the instrumentation on two of the platforms in the Bass Strait. The purpose of this was to reduce the subjectivity of visual wave observations and to eliminate the uncertainty of such observations at night and during inclement weather. Additionally it was felt that by instrumenting both a deep water (250 feet) and a shallow water (150 feet) platform the data collected would help quantify the observation that the storm waves seemed to be larger in deeper water than in shallow water. It was felt that use of the data along with a computer based wave hindcast model would aid in the development of an understanding of the Bass Strait wave environment.

Two platforms were chosen for instrumentation. The Barracouta (BTA) platform in 150 feet of water, located about 20 miles from shore, was instrumented with a wavestaff. The Kingfish B (KFB) platform in 250 feet of water, located about 50 miles southeast of BTA, was instrumented with a wave staff, electromagnetic current meters, anemometer, barometer and air temperature sensor. Figure 1 shows the location of these platforms in the Bass Strait. The design, fabrication and installation of the data station was performed by Evans-Hamilton Inc. of Houston, Texas.

Section 2 of this paper provides an overall summary of the Bass Strait weather. This is followed, in Section 3, by a review of the data acquired in the Bass Strait through the first six months of 1978. The wave hindcast model used is described in Section 4. Comparisons between measured and predicted sea conditions are detailed in Section 5.

2.0 AN OVERVIEW OF BASS STRAIT WEATHER AND WAVE CONDITIONS

During most of the year, the general atmospheric circulation in the region surrounding Tasmania and southeast Australia can be characterized as a steady procession of anticyclones moving from west to east with intervening troughs of low pressure. These troughs are usually accompanied by unsettled weather which often lasts for several days.

Low pressure systems track eastward across the southern Indian Ocean, south of 50° south latitude. Cold or occluded fronts associated with these systems usually extend northwestward from the storm center and track rapidly eastward through the Bass Strait region. Secondary low centers often form along these trailing fronts and move eastward or southeastward toward New Zealand. There are two favored areas for the formation of the secondary low centers: (1) the Great Australian Bight, and (2) the western Tasman Sea. On rare occasions one of these low centers will intensify enough to generate very strong wind (≥ 50 knots) in the Bass Strait. These storm events can be classified in one of three categories: (1) southwest storms, (2) southeast storms, and (3) southeast/southwest storms.

When intense cold fronts approach the Bass Strait, prefrontal winds blow from the northwest. Immediately after frontal passage, the wind direction shifts to the southwest, with strong wind speeds accompanied by high seas. The most intense southwest storms can generate winds as high as 50 to 60 knots.

The second class of severe storms are those that traverse or develop in the Tasman Sea. As these systems move into the central portion of Tasman Sea, they generate strong east to southeast winds (up to 60 knots).

Typical surface synoptic chart representations of these two types of storms are presented in Figures 2a and b. Note the classical closed circulation of the southeast storm (2a) typical of large extra-tropical storms. The southwest storm (2b) on the other hand presents a more complicated synoptic situation.

The final class of severe storms is similar to the southeast type. That is, they develop in or traverse the Tasman Sea. However, at some point near the peak (highest wind speeds) of the storm, a trough forms in the Bass Strait, generating south to southwest winds (waves) throughout most of the Strait. At the same time, very strong southeast winds are present just outside of the Bass Strait, extending well into the

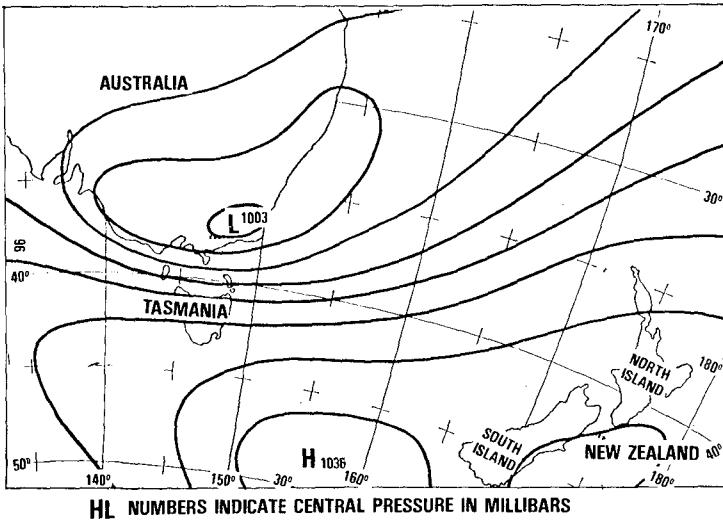

Figure 2a. Typical Southeast Storm

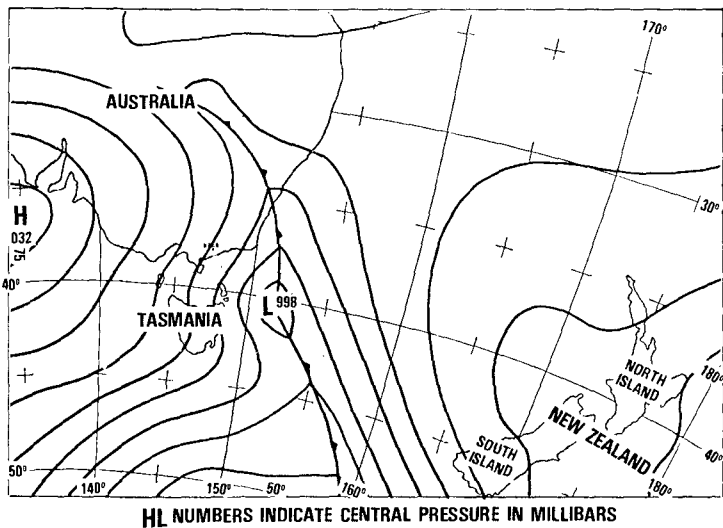

Figure 2b. Typical Southwest Storm

Tasman Sea. These southeast winds generate waves that propagate into the Bass Strait from the southeast.

3.0 SUMMARY OF OATA COLLECTED

Both data stations were made operational in early January of 1978. Since that time a large amount of "operational" (day-to-day normal conditions) data have been gathered. While these data are of great interest, the remainder of this paper will only discuss data collected during storms and the modeling of these storms.

3.1 STORM OATA (WIND AND WAVES)

During the period between January 1978 and June 1978, four storms occurred which were suitable for our analysis. Three of these storms were "southeasters" and one was a "southwester". Maximum significant wave heights ranged between 13.5 feet at BTA during a southwest storm in February to 29 feet at KFB during a June storm. For the sake of brevity we will present details of only two of these storms. However model comparisons have been made, and they will be discussed for all four storms.

3.1.1 SOUTHEAST STORM: Jan. 27-29, 1978

This storm developed on the east coast of Australia near 33°S latitude. The storm tracked to the southwest across Bass Strait and then southeast across the Tasman Sea. Maximum sustained wind speeds of 40 kts and largest significant wave heights of 21 feet were noted.

The measured H_s vs. time during this storm is shown in Figure 3a for the KFB location and in Figure 3b for the BTA location. Plots showing the measured average zero crossing wave period vs. time for KFB and BTA are shown in Figures 4a and b. The measured wind speed vs. time at KFB is shown in Figure 5.

3.1.2 SOUTHEAST STORM: JUNE 1-4, 1978

Initial development occurred over the interior of Australia near 28°S latitude, 147°E longitude. The storm moved off the east coast of Australia and tracked south near Bass Strait. It then moved east across the Tasman Sea. Maximum sustained winds reached 50 kts and significant wave heights as high as 29 feet were measured. A single zero crossing wave in excess of 60 feet was measured at KFB.

Significant wave height (H_s) time history plots for this storm are shown in Figure 6a and b for KFB and BTA respectively. Zero crossing period plots are shown in Figure 7a and b. Measured wind speed and direction vs time are shown in Figure 8a and b for the KFB location.

As shown in Figures 7-8, for some reason the KFB data station was not recording for a 10 hour period during this storm.

Figure 7. Wave Periods—June 1978

3.2 CURRENT DATA

One of the original goals of the instrumentation installed on KFB was to obtain data from the electromagnetic current meters that would enable determination of a directional wave spectrum. Due to various problems with the current meters and their mountings this goal was not achieved during the storms mentioned above.

4.0 DESCRIPTION OF THE WAVE HINCAST MODEL

We approach hindcasting the storms described above in two steps. First we treat the general problem of the generation of waves by wind in deep water. The wave model used in this part of the study was a spectral model based on the equation of radiative transfer (Barnett, 1968; Barnett, et al, 1969). In this model, propagation of wave energy is accounted for by the method of characteristics and is highly accurate numerically. Wave growth and decay are accounted for by atmospheric source terms that are based on theory (Miles, Phillips) and on empirical fits of observed wave generation cases. The wave-wave interaction terms are parameterized from the theoretical results of Hasselmann. The dissipation in deepwater is partially empirical and partially theoretical, relying on the concept of an equilibrium range in the high frequency portion of the spectrum.

The model is easily adjustable to arbitrary grids in physical space, as well as frequency-direction space. Thus it has been easy to test the model in both open ocean environments (e.g., North Atlantic, North Pacific) and enclosed bodies of water (South China Sea, Lake Superior) against actual observation. In all cases the average significant wave height hindcast error has been less than 3 feet rms. Recently the model has been applied to several storms in the North Sea with notable success in comparison with measured wave data.

The second step in our modeling procedure was to account for effects due to the interaction between the waves and the sea bottom. We have used a model based on the work of Hasselman and Collins (1968) to account for wave energy dissipation due to interaction with the sea bottom. This model does not account for shallow water generation, nor does it consider other forms of dissipation. It does provide an order of magnitude estimate of energy loss. Results of the dissipation calculations along with the difference between the results of the deep-water modeling at both KFB and BTA are used to estimate the wave energy at BTA.

4.1 WIND FIELD SPECIFICATION

Three basic marine wind field analysis methods are available for use in hindcasting severe storms:

- a. parametric wind models
- b. objective analysis schemes
- c. manual wind field analysis

Parametric models have been utilized (with considerable success) in modeling the surface wind field associated with tropical cyclones. However, these models have not been successfully applied to the complex wind fields associated with severe extratropical cyclones (Bretschneider, 1972).

Various objective analysis schemes are available for use in the specification of surface marine wind fields. These schemes range from computer-based routines that utilize surface pressure fields and marine wind observations, to complex planetary boundary layer (PBL) models that relate the surface pressure gradient, air-sea temperature difference and thermal advection to the local wind speed and direction (see Overland and Gemmill, 1977; Mooers and Partagas, 1976; Druyan, 1973, 1972; and Cardone, 1969). Provided a reasonably dense network of marine observations is available, the objective analysis schemes will yield results suitable for use in hindcasting severe extratropical storms.

The third analysis method (c above) is a technique in which experienced meteorologists derive the surface wind field distribution based on manually analyzed surface pressure fields and available marine wind observations. Although this method is very time consuming and therefore costly, a skilled, patient, meteorologist can produce very accurate results. The manual method has obvious advantages in that questionable data can be screened out more effectively, and observations not recorded at synoptic time periods can be easily incorporated into the evaluation.

4.1.1 DATA BASE

The marine areas surrounding Australia, Tasmania and New Zealand (like most marine areas) can be characterized as data sparse regions, where surface pressure analyses are based on a very limited number of ship observations. On the average, there are only 3 or 4 marine observations contained on the Australian Weather Service charts over the entire area of interest both east and west of the Bass Strait. Therefore, it was decided that the manual wind field analysis method would be the most appropriate technique to use in this hindcast, as it would provide the most accurate input data.

The Australian maps were reanalyzed OSI (Oceanographic Services Inc.) meteorologists based on: 1) additional observational data derived in a data search (through the National Climatic Center in Asheville North Carolina), and 2) prior experience in analyzing marine wind fields for the purpose of wave hindcasting in all areas of the world. In many cases existing historical surface pressure analyses can be improved by reanalysis, thereby improving the accuracy of hindcast wind fields.

4.1.2 SELECTION OF WIND SPEEDS AND DIRECTIONS

An appropriate grid system was developed for each storm type analyzed. Grid points were densely spaced within the Bass Strait with spacing increasing outside the Bass Strait. The grid system was

designed so that all regions of potential wave generation could be covered.

Hindcast wind speeds (10-minute average, 10-meter/standard level) and directions were derived at each grid point from horizontal pressure gradients, as reanalyzed from the Australian maps. Wind observations, recorded by ships operating in the basins during the hindcast time periods (acquired from the National Climatic Center) were also used in conjunction with the pressure analyses in selecting wind parameters.

In addition, observations from drilling units, and locally analyzed pressure maps (analyzed by OSI meteorologists in Sale, Australia during forecast projects in the Bass Strait) were used by OSI to augment the wind field analysis. During this earlier work, OSI found good correlation between wind speeds for various Bass Strait locations and pressure gradients between selected Australian and Tasmanian coastal stations. These relations were used as initial guidance in selecting wind parameters at grid points in the Bass Strait. OSI's choice of the wind field analysis method made it easier to incorporate these relations into the hindcasting scheme.

Finally, hindcast wind speeds and directions were compared with wind parameters reported at Australian and Tasmanian coastal stations. Reported coastal winds were adjusted to compensate for differing frictional effects as well as observed topographical effects.

The final wind field analyses were derived using all sources of available data. We believe that these analyses were as accurate as possible, within the limitations of the available data.

4.1.3 TIME INTERPOLATION OF WIND SPEEDS AND DIRECTIONS

It was necessary to provide wind input for each time step (one hour) of the model integration. Therefore, wind data were interpolated between available input map times. A linear interpolation scheme (for both wind speed and direction) was chosen as the best approximation for this hindcast after careful analysis of the wind speed time histories recorded at two marine measurement stations in the Bass Strait during the severe storms under consideration.

5.0 COMPARISON BETWEEN MEASURED AND CALCULATED CONDITIONS

To date we have compared calculated conditions with measurements for four storms at two locations. In general the results of this comparison have been very encouraging. Figure 9 shows a summary of the comparison between maximum measured H_s and maximum hindcast H_s . The discrepancy between model and data was unbiased while the rms deviation was less than 3 feet. Comparisons of this type have been reported elsewhere (Cardone et. al. Ewing et. al.) and allow a gross level of agreement to be established.

Figure 9. Measured and Calculated Maximum Sea States

Figure 10. Wave Spectrum Comparison—Jan. 1978

More detailed comparisons between the measured data and the wave model have been made. These comparisons are useful in determining areas in which the modeling process can be improved. A more detailed model comparison for the two storms discussed earlier (January and June 1978) is given below.

5.1 STORM OF JANUARY 1978

During the peak of this storm the maximum measured wind speed at KFB reached 36 kts while the maximum hindcast winds reached 40 kts. The resulting maximum significant wave heights were 21 feet (measured) and 19.5 ft (hindcast) respectively. Figure 10 shows a comparison (for KFB) between the maximum measured and maximum hindcast wave spectra during the peak of this storm. Subjectively this comparison is excellent both in terms of total energy and frequency distribution.

Figure 11 presents a comparison of the sea state intensity (H_s) as the storm passes at KFB. It is clear from this plot that the general character of the storm development has been depicted by the model results. However, Figure 11 also illustrates the fact that there is a several hour shift in the time of occurrence of the peak seas. Given the 6 hour synoptic interval this fact is not surprising. A similar result was obtained at BTA with the agreement between measured and hindcast sea states being even better than it was at KFB. Numerical calculations convinced us that shallow water dissipation would not be evident in a storm of this intensity in these water depths.

5.2 STORM OF JUNE 1978

The results of our comparison of the measured and hindcast storm of June 1978 illustrate several interesting problems that can enter studies such as ours, but which are not usually reported.

5.2.1 DEEP WATER RESULTS

The maximum hindcast significant wave height for this storm at KFB was 32 feet. The maximum measured significant wave height for this storm at KFB was 29 feet (for a 40 minute period). The spectral comparison for this storm is shown in Figure 12. The maximum hindcast windspeed at KFB was 50 kts while the maximum measured wind speed was 46 kts. The wind/wave comparison stated in this way appears extremely good. However, if we look at the overall storm profile of H_s shown in Figure 13, several points become clear:

- o The duration of the storm was underestimated
- o The buildup of the seas was not reproduced
- o The period of sustained high waves for the hindcast storm was substantially different from the measured storm

Figure 11. Measured and Hindcast Storm Profiles—Jan. 1978
KFB

Figure 12. Wave Spectrum Comparison—June 1978

Figure 13. Measured and Calculated Storm Profiles

Figure 14. Measured and Calculated Storm Profiles

BTA

The reasons behind the above mentioned shortcomings, in this particular hindcast, can almost certainly be traced to the weather map construction. Due to the fact that the wave hindcast was conducted almost immediately following the construction of the weather charts, there was insufficient time to include any post analysis in this particular hindcast. It is the opinion of the authors that the shortcomings in this case are more indicative of weather forecast limitations than wave model inadequacy.

5.2.2 SHALLOW WATER EFFECTS

As mentioned previously we have used a shallow water computational algorithm to help quantify the reduction in wave intensity between KFB and BTA. The hindcast deepwater spectra at KFB were input to the model and the resulting spectra at BTA were computed. Since the shallow water model did not account for wave energy input from local winds, these computed values were further adjusted (somewhat arbitrarily) by the difference between the "deepwater" values at KFB and BTA. The purpose of this adjustment was to account for the spacial variability in the hindcast wind field in an order-of-magnitude way. In this case the adjustment led to a reduction in the calculated BTA sea intensities of approximately 2 feet. The results of this operation are shown in Figure 14. Once again, the peak sea intensity is reasonably represented by our model but the overall storm characteristics are not well represented. We again believe that the major influence for this storm is the inaccuracy in the weather analysis.

6.0 MODEL COMPARISON CONCLUSIONS

In general we have demonstrated that the numerical hindcast techniques discussed herein can be used to adequately estimate storm sea state characteristics. The model was applied to four storms at two locations yielding estimates of maximum significant wave height that on the average were within 3 feet of the measured values. Detailed comparison of model results with data indicate that the primary limitation in model capability is associated with the windfield description.

Furthermore we have documented the fact that significant differences in sea state intensity can exist between KFB and BTA during large storms with wind and waves from the southeast. Some of this difference can be attributed to bottom dissipation while some can likely be attributed to windfield variations. Additional studies along these lines that quantify the various influences more precisely (Shemdin et al.,) would be worthwhile.

7.0 ACKNOWLEDGEMENTS

The authors would like to thank Henry Gerlach, Ian Edwards and Alan Lunghusen of EAL for their help in this project. We would also like to thank the Royal Australian Navy Research Laboratory for their interest

and help in maintaining the equipment. The Australian Bureau of Meteorology is to be thanked for their cooperation in providing synoptic weather charts. Special thanks are directed to R. E. Haring of Exxon Production Research for his help and encouragement during the almost 2 years that this project spanned.

REALTIME WAVE ANALYSIS, NEWCASTLE, AUSTRALIA

N.V. Lawson, Director, Lawson and Treloar Pty. Ltd.
P.H. Youll, Planning Engineer, The Maritime
Services Board of N.S.W.

1. INTRODUCTION

The Port of Newcastle, N.S.W., Australia, is being deepened from 11m to 15.2m below chart datum to permit the navigation of 120,000 D.W.T. bulk coal vessels. Part of this project, which is expected to reach a cost of approximately A\$90 million, involves the removal of two million cubic metres of rock, some of which is located outside the breakwaters and exposed to ocean waves (see Fig. 1).

Drilling and blasting of rock in the area subjected to ocean wave activity is being carried out by two self elevating platforms. On completion of drilling and prior to blasting the platform must make a transition from being supported by its legs to floating so it can be removed from the blasting area. While the two self elevating platforms have been built with a very fast jacking rate of 6m/minute, with a sophisticated shock absorbing system connecting the legs to the platform, the rigs cannot be jacked up or down when wave conditions exceed a certain limit. Even though the rigs can survive worse conditions than those allowable for jacking down by remaining on their legs at a sufficient height above the water, this would entail loss of drilling time, and the presence of the rigs in the channel could close the port to shipping.

Thus from an operational point of view it is vital that present wave conditions are reliably described. Estimation of wave height by observation is difficult enough during daylight hours but is virtually impossible in darkness (drilling operations are carried out 24 hours/day). The dredging contractor (WestHam Dredging Co. Pty. Ltd.) therefore decided that a real time wave analysis system should be established and co-operated with The Maritime Services Board of N.S.W. in a joint project for this purpose.

2. THE SYSTEM HARDWARE

A block diagram of the system hardware is shown in Fig. 2. Because of the large investment that the system is designed to protect it has been designed for maximum reliability.

Three Waverider buoys are used as the water surface elevation sensing instrument. The location of these buoys is shown in Figure 1. The offshore buoy and one inshore buoy were part of a traditional type Waverider installation which had been operating since 1975 (Lawson and Youll, 1977). The second inshore buoy (closest to the shore) was installed to add reliability to the system and to ensure that at least two buoys were always operating.

The Waverider buoy signal is received at a shore based station. Each buoy has its own receiver/ phaselock loop/digitiser circuit with an additional spare set of circuits to ensure minimum down time.

Each buoy is continuously monitored and the signal is digitised once every $\frac{1}{2}$ second to indicate the average position of the buoy over the previous $\frac{1}{2}$ second. An arbitrary datum is established 2000cm below mean water level and the position of the buoy in elevation is resolved to 1cm. A multiplexor samples all three channels and sends the 3 x 4 ASCII characters through the leased line, prefaced by a status character which indicates which buoys are not in position.

The characters are collected from the leased line by a PRIME 400 minicomputer running under a real time operating system. The Prime performs the required calculations and interpretations and sends these results back through the leased line to the WestHam site office. Input data is stored in a buffer while the calculations are performed so that no input data is lost, and all raw data and results of analysis is stored on disc, to be dumped to magnetic tape at fortnightly intervals.

FIG 1 LOCATION PLAN FOR NEWCASTLE HARBOUR

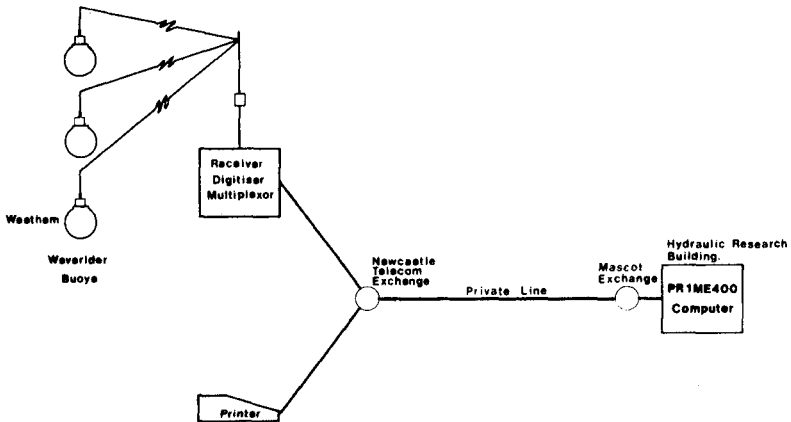

FIG 2 REALTIME WAVE ANALYSIS SYSTEM-NEWCASTLE

3. THE SYSTEM SOFTWARE

The system software performs the following functions :-

- (a) Collects the data from the leased line and checks for errors in line transmission, parity errors and for a Waverider buoy being hit or spun, which is usually indicated by a large displacement.
- (b) If it is recognised that the buoy has been hit or spun, a message is immediately sent to Newcastle with advice as to which buoy has been tampered with, and the appropriate action which should be taken.
- (c) Every 10 minutes, calculates for the previous 20 minutes of data, a wave-by-wave routine analysis and an auto-correlation type spectral analysis yielding the parameters of significant wave height (H_s), maximum wave height in 15 minutes (H_{max}) and peak period in the energy spectrum (T_p) (Abernethy and Lawson, 1973, Lawson and Abernethy 1975).
- (d) Following calculation H_s , H_{max} and T_p values are sent to Newcastle with H_s and T_p also being represented graphically.
- (e) If the value of H_s for any buoy has exceeded 1.75m since the previous computation, a message to that effect is sent to Newcastle with a warning bell to alert WestHam personnel.
- (f) The programme also checks the amount of energy at 0.0 Hertz. If the value is large, a message is sent to Newcastle indicating that a buoy is faulty, either due to interference or a twisted accelerometer suspension.

The system is in continuous operation, producing 144 analyses per day. CPU demand is very low at about 2 minutes/hour for data logging and analysis.

4. RECENT DEVELOPMENTS

While the system has been able to provide the dredging contractor with sufficient warning on most occasions, the provision of information from the waverider system at Botany Bay, 160Km to the south, would give earlier notice of waves arriving from the south. This addition to the system is at present being installed.

5. EXAMPLES

In the examples shown in Figures 3 and 4, the isobar spacing is 4mb. The two examples have been selected to show the two types of wave conditions which can occur off Newcastle :-

- (a) where Newcastle is within the wave generation area (Fig. 3).
- (b) where the swell generation area is some distance away from Newcastle (Fig. 4).

In Figure 3 a reasonably intense high pressure system and associated front formed over south eastern Australia during the early hours of 23rd September, 1979. Prior to its formation, low background type swell conditions existed from a weak high pressure system to the east of Newcastle. The significant wave height was about 1.1m while the peak period about 12 seconds. With the arrival of the locally generated waves from the south the amount of energy in these shorter period waves soon became larger than the underlying swell reducing the peak period from about 12 seconds down to 5 seconds. As the locally generated waves became larger the peak period became longer. In this example the warning that waves were going to get larger would have been accepted at about 1200 hrs. on 23rd September, 1979 providing more than the required 2 hours notice that waves inshore were likely to rise above 1.75m.

Figure 4 illustrates a classic example of swell waves arriving from a distant generation area. In this case the low pressure system is moving south east from Tasmania towards New

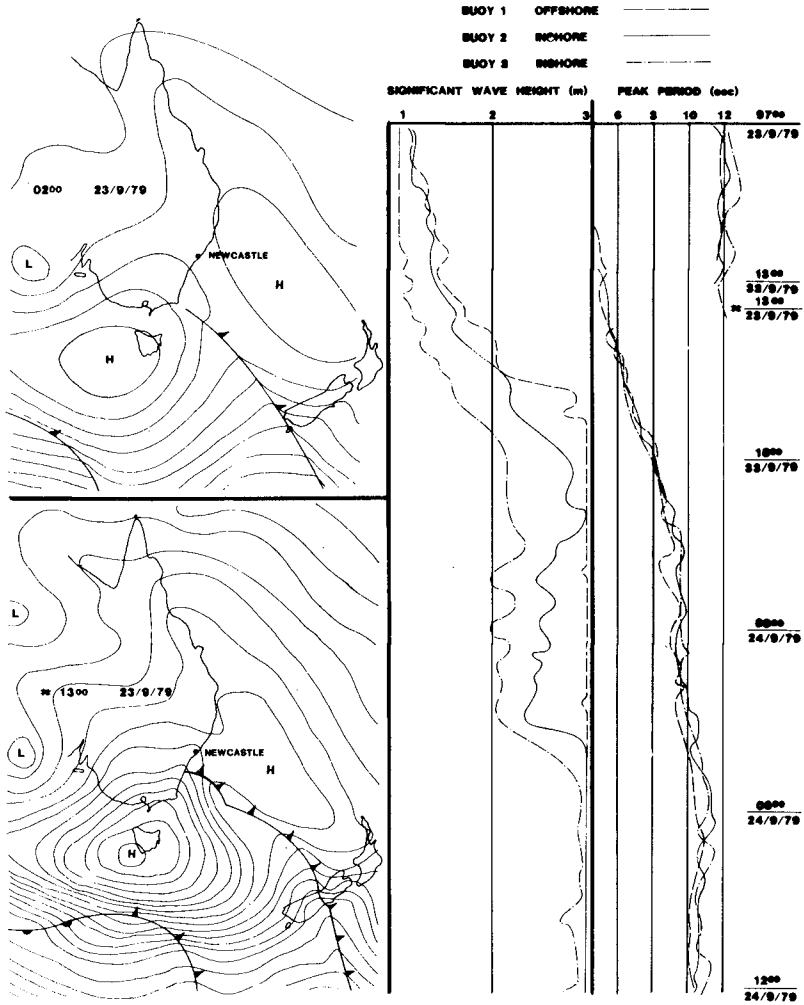

FIG 3 WAVE ANALYSIS OUTPUT

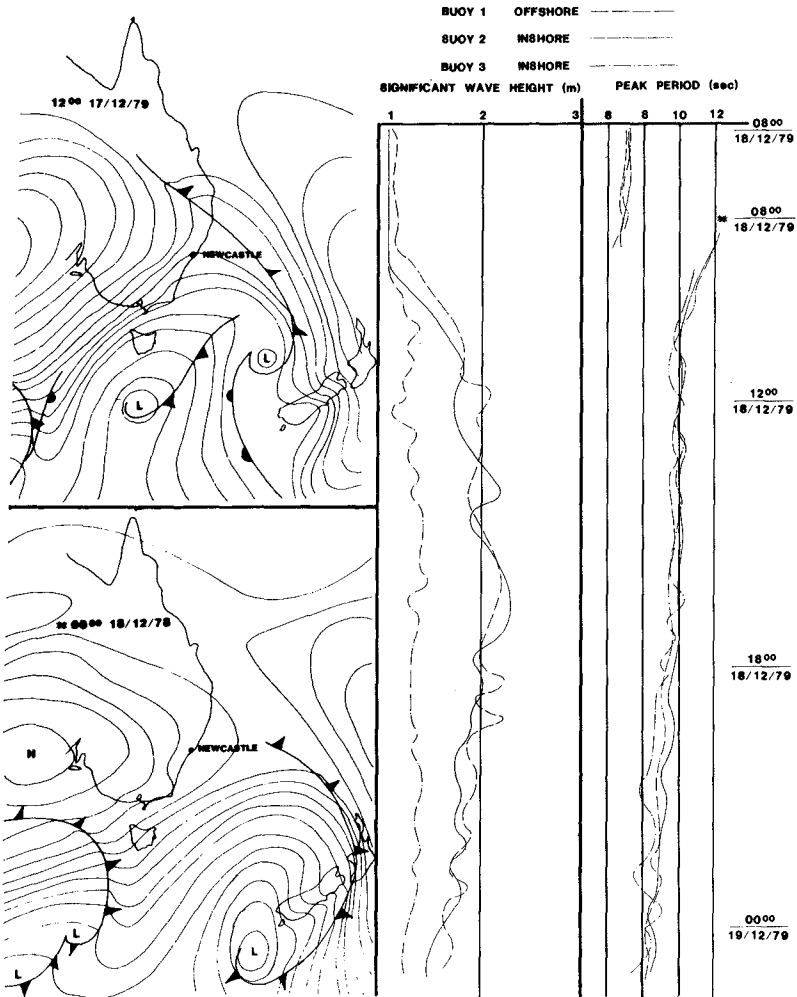

FIG 4 WAVE ANALYSIS OUTPUT

Zealand. The longer period waves of low wave height arrive first resulting in an abrupt change in peak period with no apparent immediate increase in wave height. However, this change is a clear indication that larger waves will follow within the next few hours. In this case the warning of increasing waves would have been accepted just after 0800 hours on 18th December, 1979, again providing at least the required 2 hours notice.

Situations similar to these two examples have been repeated on numerous occasions since the installation of the system during April 1979. The output format was chosen to provide clear results, requiring no interpretation. All the operator has to look for is a sudden change in peak period, either up or down, associate the change with the synoptic situation from a Facsimile (Fax) receiver, and issue a warning. It would be possible to provide more warning if the amount of energy in discrete period bands had been investigated, but this approach was rejected because of the additional interpretation required. With the system chosen all the operator needs to do is look for a change in peak period.

6. CONCLUSIONS

The system has now operated with good reliability for over 12 months. The most unreliable section of the system has proven to be the leased telephone line between Newcastle and Mascot. The system has provided the dredging contractor with a reliable warning system which on the great majority of cases has provided at least 2 hours notice that waves will rise above 1.75m.

This system has real advantages over traditional methods of wave data collection and analysis :-

- (a) There is an increase in reliability of the total system resulting from the early warning of a Waverider being hit or tampered with.

- (b) Data collection and analysis is a one step process rather than 2 or 3 steps resulting in less manhours in wave analysis and data storage.
- (c) There are significant benefits in the description of storm events. This type of recording will eventually allow more reliable and rational methods of describing and predicting return intervals of storms.

7. ACKNOWLEDGEMENTS

The authors wish to thank WestHam Dredging Co. Pty. Ltd. and their electronics sub-contractors Summit Electronic Systems, without whose assistance the system would not have been established, and the Engineer-in-Chief of The Maritime Services Board for permission to publish this paper.

FLORIDA COASTAL DATA NETWORK

Gary Howell
Coastal and Oceanographic Engineering Department
University of Florida, Gainesville, Florida

1. INTRODUCTION

The application of wave and tide data to coastal engineering problems has been demonstrated frequently by university and government research organizations. However, problems faced by practicing coastal engineers are often solved without recourse to such data, since it is frequently not available for the required location. The high cost and low reliability of long term wave measurement is the primary factor limiting the wider application of analysis techniques requiring wave energy and wave direction parameters. In order to improve this situation several organizations, notably the Army Corps of Engineers, Coastal Engineering Research Center (CERC), Peacock (1974), and the California Department of Navigation and Ocean Development, Seymour (1976), have employed advanced electronics and computer techniques to reduce the cost of wave measurement. The Florida Coastal Data Network (CDN) is a similar effort which due to the special problems of Florida wave climate has employed advanced instrumentation not only to reduce cost, but to provide additional capability. Like other tropical and sub-tropical regions, Florida's coastal environment is characterized by relatively infrequent but severe tropical storms. In many coastal engineering applications, the specification of the hurricane-associated storm surge and storm waves will be the major design criteria. The Florida CDN was created in order to provide field measurements of waves and tides year-around as well as during hurricanes.

A measurement program of this nature must respond to both the immediate needs of practicing engineers as well as to research needs. Since it is unrealistic to hope for measurements of hurricane conditions at every location, the long term goal of research is to produce better models of storm waves and surge. Field measurements are required to assist in the formulation and validation of models. In the near term, actual measurements of both normal and severe waves and tides are the most reliable design input for the shallow and intermediate water depths.

Unfortunately, the severity of hurricanes, which makes them of interest to coastal engineers, also creates problems for instruments. Very few standard instrumentation installations have survived hurricanes. Most successful hurricane wave measurements have been made by either large, deep water

buoys or from oil production platforms in intermediate or shallow water depths. Most tide records of storm surge are from sheltered gages in bays or estuaries. Since large, offshore structures such as oil platforms are unavailable in Florida coastal waters, other strategies were investigated. Mounting instruments on existing piers was rejected due to the historically low survivability of such structures. Consistent with the low cost goals, a completely bottom-mounted instrument in a survivable structure was chosen. In order to gain as much benefit as possible from the high cost of installing and maintaining an installation, multiple purposes were defined. Each station was required to transmit wave and tide data over telephone lines to a central location. Additionally a self-contained power and recording capability was required for hurricane conditions.

Measurement sites were chosen at approximately equally spaced intervals around the coast (Figure 1). Specific locations were determined by considerations such as regular bathymetry, absence of nearby obstructions or inlets, and logistics. A target water depth of ten meters was specified in order to guarantee survivability during storm conditions and to provide measurements in the transition region between deep and shallow water. This water depth generally corresponds to distances of about one kilometer offshore on the East coast and over two kilometers on the Gulf coast.

2. INSTRUMENTATION

Absolute reading pressure transducers are bottom mounted on a completely self-contained electronics cylinder. The cylinder contains a microcomputer controlled data acquisition system (Howell, 1978) which can operate according to an internally stored program or upon commands received from shore. The shore connection supplies power to continuously charge internal batteries as well as two-way data communications using a standard computer interface (Figure 2).

A digital cassette recorder controlled by the microcomputer completes the underwater instrumentation.

The instrument cylinder is mounted inside a large steel tripod which is anchored at each apex to steel pipes jettied into the bottom sediment. The cylinder may be easily installed or removed by divers (Figure 3).

Two types of shore boxes are available. The first, a real time shore station, consists of a power supply and a telephone connected modem (Figure 4). Using the shore box, a central computer in Gainesville may interrogate the underwater microcomputer, and record a time series of water pressure in real time. The second type of shore box, the

PRESENT and PROPOSED FIELD STATIONS

REAL TIME SHORE STATION

Figure 4

buffered data shore station, consists of a high performance microcomputer with 0.5 megabytes of disc storage, and a high speed modem (Figure 5). This shore station may be programmed to record data internally at scheduled intervals and has a limited analytical capability to record more data when certain parameters exceed a preset threshold. It is primarily employed to reduce long distance telephone charges by as much as a factor of 50 over the real time station.

At present, all CDN stations are programmed to operate in two modes. The first, a field station mode, allows data to be recorded in Gainesville over standard dial-up telephone lines. During these calls, a complete check of the underwater system is carried out by inspecting status indicators and exercising test routines. The second, called storm mode, is entered on command from Gainesville. Once entered, the underwater microcomputer automatically records (on the internal cassette) a seventeen minute data record and a four minute data record every hour for six days. The long and short records are spaced to give equal off-times during the hour. Once storm mode has been entered, data recording will continue even if the shore station and cable are lost.

3. DATA ANALYSIS

Just as important in reducing costs as a wave gage system are the data analysis techniques employed. Spectral analysis by digital computer has made a significant contribution to cost reduction, however most real systems still require significant time from skilled technicians to process all data records. This is due to inevitable errors and artifacts inherent in any instrumentation system. For the CDN a significant effort has been made to automate data analysis, achieving a goal that 90% of all records are analyzed without human intervention, and a minimum amount of effort required for the remainder.

The central computer at Gainesville can generate power spectra statistics of any recorded file immediately after the data has been recorded. This capability is useful for applications requiring real time data for operational purposes or in following the development of storms. A sample report output is shown in figure 6.

Figure 7 shows the routine procedure used for acquiring daily data from each station. Monthly summaries of recorded data are produced regularly and spectrally analyzed data are stored in archival files for long term statistical analysis.

4. RESULTS

CDN has successfully recovered regular wave data from the oldest stations for a period of three years. Data sets are now large enough that a variety of analysis projects are feasible. In addition hurricane David which moved up the Atlantic coast in September 1978 passed directly over two measurement sites. Data from these stations were obtained as planned and are now being analyzed. Figure 8 shows composite plots of tide and significant wave height from one station. A contour plot of constant spectral energy density lines as a function of time is also shown. These data were calculated using spectral analysis techniques and depth attenuation correction by linear wave theory assumptions. Thus, some error can be anticipated in the most severe time periods.

5. CONCLUSIONS AND FUTURE DEVELOPMENTS

A combination of advanced instrumentation with designed in maintenance features and improved data analysis procedures have improved the economy and reliability of single point wave measurements. Progress still needs to be made in the area of wave direction measurements both in the area of instrumentation and data analysis. The tools and techniques developed by the Florida CDN, can readily take advantage of the rapid cost-performance increases of microelectronics. The time is approaching when coastal engineers may have reliable and economical long term measurements of basic parameters for site-specific and problem-specific applications. Finally a new breed of small, intelligent instruments based on the microcomputer is already under development. These instruments will bring analytical capability, decision making, and flexibility to previously passive observers of coastal phenomena.

CHAPTER 27

A MEASUREMENT OF SLOPE, CURVATURE, AND DIRECTIONAL SPECTRA OF WIND WAVES IN LAKE MICHIGAN

Paul C. Liu, M. ASCE¹

1. INTRODUCTION

Wave recording activity among coastal and oceanic engineers has increased rapidly in recent years, and ample wave data covering a large number of gage stations are now available. Directional wave spectra, however, are relatively scarce. The detailed knowledge of directional wave characteristics that correlate with the simultaneously recorded wind field is needed immediately for a proper understanding of the generation, growth, and propagation of a wave field. The data are necessary for engineering design, for verification and improvement of wave prediction models, and for provision of appropriate ground truth for calibrating remote sensing measurements. This paper represents the results of an effort to fulfill this need.

2. MEASUREMENTS

From July to October 1977, the Great Lakes Environmental Research Laboratory (GLERL) installed a light-weight, solar-powered research tower in Lake Michigan to provide a stable platform for supporting wind anemometers, temperature sensors, and an array of four wave staffs to measure meteorological and directional wave variables. The tower was located 2 km offshore from Muskegon, Mich., in 16 m of water (Fig. 1). The wave staffs, 6 m Kelk, Model P116, Zwarts gages (Zwarts, 1974), were placed at the center and vertices of an equilateral triangle of 3.05-m sides. The wave data were recorded digitally at 0.5-s sampling intervals for 30 minutes during each hour. The wind data used in this paper were recorded from an anemometer installed at 10 m above water level. A detailed description of the tower instrumentation data collection and reduction systems are given in Schwab *et al.* (1980).

3. DATA ANALYSIS

Conventional analysis for calculating the directional wave spectrum with a gage array usually yields poor directional resolution unless a large number of wave gages are used (e.g., Borgman, 1978). In order to

¹2939 Renfrew St., Ann Arbor, MI. 48105

Fig. 1. GLERL research tower and its location.

Fig. 2. An example of a fitted wave surface. The wave staffs are 6-m long.

improve the resolution with merely four wave staffs, the present study analyzes the data by fitting a cubic surface through the wave measurements. The fitted surface provides cubic spline approximations to the slopes and curvatures of the waves. Analysis was performed with the six quantities ζ , ζ_x , ζ_y , ζ_{xx} , ζ_{yy} , and ζ_{xy} , where ζ is the surface fluctuation at the center wave staff and the subscripts x,y indicate partial differentiations in the east-west and north-south directions, respectively. In addition to directional spectra, which can be calculated readily using these quantities in the method developed by Longuet-Higgins *et al.* (1963) and extended by Cartwright and Smith (1964), this method also provides an opportunity to examine characteristics and statistical distributions of wave slope and wave curvature. An example of a fitted cubic surface is shown in Fig. 2.

4. WAVE SLOPES

Perhaps because of a lack of practical measuring instruments, there have been very few field measurements of surface wave slope except for those reported by Cox and Munk (1956) and Longuet-Higgins *et al.* (1963). A number of laboratory measurements have been conducted by Schoolley (1954), Cox (1958), Wu (1971, 1977), and Long and Huang (1976), among others. These previous studies have shown that the statistical distribution of the wave slopes is approximately normal and the mean square surface slope increases as a function of wind speed. The data from this study basically agree with these results.

Fig. 3 presents a typical set of histograms for the statistical distribution of the east-west and north-south components of surface wave slope. They show essentially normal distributions. These histograms represent conditions during a southerly, 5 m s^{-1} wind, and skew is not evident. However, under stronger and growing wind speeds, an appreciable skew toward the windward direction indicated by Cox and Munk (1954) can also be found. The correlation of the mean square slope with wind condition is shown in Fig. 4. The data covered a wide range of wind conditions including both growing and decaying winds. The line drawn through the scattered points is representative of the mean square slope as proportional to the square of 10-m-level wind speed. The points away from the line are those under decaying winds. While the magnitude of the mean square slopes is similar to those oceanic cases calculated by Longuet-Higgins *et al.* (1963), it is much smaller than laboratory results. This is because laboratory measurements are for short dominant waves that contribute more toward mean square slopes than the long dominant waves found in the field and the instruments used in the field are not capable of measuring short waves.

5. WAVE CURVATURES

The study of wave curvatures is important in understanding the optical properties of the sea surface. Surprisingly few measurements have been made other than those made in the laboratory studies of Wu (1971, 1972, 1977). Theoretical studies (e.g., Kepr, 1969) have shown

Fig. 3. Typical histograms of the distribution of x- and y-components of surface wave slope.

Fig. 4. Mean square surface slopes as a function of wind speed.

that if the surface is represented in the form

$$z = \zeta(x,y) \quad (1)$$

where (x,y) are horizontal coordinates and z is measured vertically upwards, the mean curvature J of the surface is given by

$$J = \frac{(1 + \zeta_y^2)\zeta_{xx} - 2\zeta_x\zeta_y\zeta_{xy} + (1 + \zeta_x^2)\zeta_{yy}}{(1 + \zeta_x^2 + \zeta_y^2)^{3/2}} = \zeta_{xx} + \zeta_{yy} \quad (2)$$

and its total curvature, Ω , is given by

$$\Omega = \frac{\zeta_{xx}\zeta_{yy} - \zeta_{xy}^2}{(1 + \zeta_x^2 + \zeta_y^2)^2} = \zeta_{xx}\zeta_{yy} - \zeta_{xy}^2 \quad (3)$$

The simplified versions in (2) and (3) are obtained by neglecting the squares of the surface slopes since they are much smaller than 1. In general, the statistical distribution of the components ζ_{xx} , ζ_{yy} , and ζ_{xy} are normal, as shown in Fig. 5. Therefore the mean curvature J , being the sum of two normal variates, is also normally distributed (Fig. 6). Longuet-Higgins (1958) derived a strikingly non-normal distribution for the total curvature Ω . This distribution was found to be asymmetrical with positive skewness; its distribution function satisfies a linear differential equation depending on two parameters derived from the moments of the surface energy spectrum. A comparison of Longuet-Higgins' distribution with histograms from the present data is shown in Fig. 6. It is seen that the histogram does exhibit an asymmetrical character with positive skewness. However, its fit with the theoretical distribution is by no means close. Further examination shows that the theoretical distribution has a maximum skewness of 1.15, while the skewness obtained from the data is consistently greater than 1.15 by a factor of 2 or more. One possible explanation is that the statistical characteristics of the variates ζ_{xx} , ζ_{yy} , and ζ_{xy} are assumed to be similar in the theoretical derivations. In the data, however, it has been found that the moments of ζ_{xy} are consistently an order of magnitude smaller than those of ζ_{xx} and ζ_{yy} 's.

The variations of curvature with wind have also been examined. Fig. 7 represents mean square values of J and Ω plotted against wind speed. From the data obtained under varied wind fields, the mean square of total curvature appears to be proportional to U_{10}^2 , while the mean square of mean curvature is proportional to the square root of U_{10} .

6. DIRECTIONAL WAVE SPECTRA

Previous studies of directional wave spectra have been concerned mostly with single instances of time. The continuous measurements available from the GLERL research tower provide an opportunity to study directional characteristics of waves episodically. In the present

Fig. 5. Typical histograms of the distribution of component curvatures.

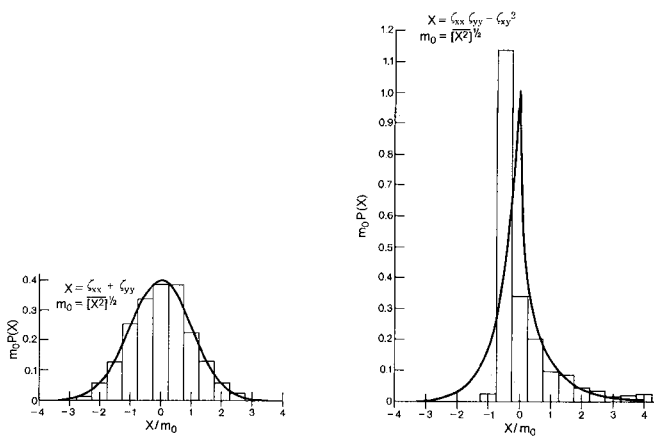

Fig. 6. Typical histograms of the distribution of mean and total curvatures. The non-normal distribution curve represents Longuet-Higgins' theory.

Fig. 7. The mean square values of mean and total curvatures as a function of wind speeds.

Fig. 8. Two episodes of wind and wind fields for directional spectral study, August 31, 1977, and August 16, 1977.

study two episodes, each with a characteristic wind field, were selected for illustration. Fig. 8 presents the wind and wave fields of the two episodes.

The episode of August 31, 1977, has a constant southerly wind direction with increasing wind speed that generates steadily growing waves. Five sets of single and directional wave spectra at 2-hour intervals between 0600 and 1400 hours, as shown by the tick marks in Fig. 8, are presented in Fig. 9. The directional spectra were plotted on a polar graph with frequency as the radial axis. The contours represent equal spectral energy densities. While contour levels were not indicated, in order to avoid crowding in the figure, it should be noted that the outside contours had the lowest magnitude and remained the same for all the figures. The contour levels increased logarithmically toward the hill, which corresponded to the spectral peak in the single spectrum. It can be seen that as waves grow the contours spread toward lower and higher frequencies and higher spectral density develops around the hill. The directional spectra are unimodal with some skewness toward higher frequency, especially when waves grow higher.

These results also show that the directional spreading tends to be narrow only around the spectral peak and wide for both higher and lower frequencies. This is consistent with the $\cos^2\theta$ model, where a higher s indicates narrower spreading. It has been shown by Mitsuyasu et al. (1975) that s is the highest at the spectral peak and decreases toward both higher and lower frequencies.

The episode of August 16, 1977, on the other hand, shows a wind direction changing from south to northwest, with a somewhat fluctuating wind speed. The five directional spectra shown in Fig. 10 were between 1500 and 1900 hours during periods of increasing wind speed, while waves decayed because of the changing wind direction. At 1500 hours, the spectrum was clearly northward owing to previously southerly wind. At 1600 and 1700 hours the waves decayed, the hill remained northward even though the wind direction had changed. There were indications that the contours at both the higher and lower frequency sides tended to spread toward the new wind direction. At 1800 hours an interesting bimodal picture had developed. A new hill showed up in the new south-southwest wind direction, but an old hill remained northward with diminishing magnitude. It was also interesting to note that with the bimodal directional spectrum, there were corresponding two peaks in the single spectrum. Finally, at 1900 hours, the waves conformed to the direction of the prevailing wind. The actual duration to which the wind switched from a steady south to a steady northwest direction lasted over 8 hours. The directional spectra carried the memory of northward direction during most of this time.

Changing wind direction is a familiar and common phenomenon. Hence the response of waves should also be familiar and common. However, the process of direction is also extremely varied; hence a knowledge of these responses is difficult to assess. The results shown in Fig. 10 represent a first look into one of these interesting and intriguing common occurrences.

7. CONCLUDING REMARKS

By fitting a cubic surface through the measurements of the four wave staffs, the result of this paper has shown that wave slope, curvature, and directional spectra can be readily calculated with improved resolution over conventional array measurements. Direct measurement of wave slope and curvature in the field has been extremely rare. This study was able to provide these data indirectly and an examination of their statistical characteristics. The results are generally consistent with previous studies. The continuous measurements made from the research tower provided an opportunity for interesting episodic case studies, which is an improvement over previous directional wave analysis that studies mostly single instances in time. This paper represents a first step toward filling the need for definitive directional wave information. Efforts to quantify these results by parameterization, correlation, and modeling are presently under way at GLERL.

CHAPTER 28

WAVE ATTENUATION AND WAVE SET-UP ON A COASTAL REEF

by

Franciscus Gerritsen
Professor of Ocean Engineering
University of Hawaii at Manoa
Honolulu, HI 96822

ABSTRACT

In attempting to specify criteria for the design of structures on coastal reefs, it was found that no adequate method existed to derive those criteria from the deep water wave conditions.

In order to fill the gap, a program of measurements and analysis was initiated at the University of Hawaii.

The program consisted of prototype and laboratory measurements. Great emphasis was placed on reliable field data, which were collected on Ala Moana Reef, in Honolulu.

Laboratory investigations on the behavior of waves on shallow reefs are subject to scale effects; verification from field observations is required to obtain reliable results. As a result of this study, a mathematical model was developed for the calculation of wave attenuation and wave set-up on a shallow reef, using the incident waves in the ocean as boundary conditions.

This paper discusses the general behavior of waves approaching a shallow reef and presents some essential characteristics of the mathematical model. The study is limited to waves approaching the shoreline at right angles.

The results of this study can be extended to breakwaters with wide, submerged berms.

1. INTRODUCTION

In Hawaii many coastal areas have a relatively low elevation and require protection against wave attack by storm waves. In some of these areas a shallow coral reef extends between the shoreline and the deeper water. The reef may be biologically alive or dead. Such coastal reef offers significant protection to the coast; the large ocean waves will break on the edge of the reef and the wave that reaches the coastline is of reduced magnitude. Not only is wave energy lost in the breaking process but attenuation of wave height also takes place due to friction along the bottom.

After the breaking of waves on the reef's seaward edge, regeneration of waves may occur over the reef, creating waves of lower height and shorter period. If wind blows over the reef in shoreward direction, wind energy is transferred into wave energy but the growth of wind generated waves over the shallow reef is limited by the depth of the water.

The effect of wave breaking and wave attenuation on a shallow reef, however, also has another aspect: it generates a setup of the mean water level over the reef and near the coastline. The increased water

depth in turn results in greater wave heights near the shoreline. Onshore winds may further increase the depth of water near the shoreline and in this way also contribute to a potentially greater wave height.

The depth over a reef usually varies in the direction parallel to the shoreline, giving rise to differences in setup along the coast. The resulting gradients of the mean water level drive a mean current system. Such currents are of major importance with regard to the transportation of coastal sediments, and also for the onshore-offshore mixing of the water leeward of the reef and the ocean waters. Quantitative knowledge of the setup is required for a prediction of these currents and their effects.

Knowledge of the setup and the wave characteristics leeward of a reef is furthermore necessary in numerous engineering endeavors, such as the assessment of beach stability or the design of coastal structures, as well as the prediction of the dynamic response of ships or the design of marine terminals in waters partly protected by a reef. The existing grave uncertainties with regard to the design parameters mentioned above has led to a widespread practice of producing conservative results, which needless to say, results in unnecessarily high costs.

In view of the preceding discussion it was proposed to carry out a study on the attenuation of ocean waves on a reef and of the associated wave setup.

In addition to a theoretical analysis of the problem the study would consist of a field study and a laboratory study.

It was believed that a scale model study in a wave flume would in itself not be conclusive and that data from the field, properly analyzed, would be required to arrive at reliable answers.

A comparison between field and model data would furthermore provide interesting information regarding possible scale effects.

2. WAVE TRANSFORMATION ON A SHOALING BOTTOM AND A HORIZONTAL OR SLIGHTLY SLOPING REEF

Waves moving from deep into shallow water are subject to transformation, which may take different forms, whether the waves are monochromatic or random and whether they are breaking or not breaking.

The following general characteristics have been documented.

- a. Periodic waves propagating into shallow water are likely to demonstrate cnoidal characteristics (Svendsen and Buhr Hansen, 1976).
- b. A solitary wave progressing over a sloping bottom onto a shelf or reef, with no breaking occurring, demonstrates a remarkable behavior in that the initial wave disintegrates into a train of solitary waves of decreasing amplitude. These are called solitons. (Madsen and Mei, 1969; Johnson, 1972).
- c. For waves approaching a beach or a shallow reef, breaking occurs when the wave height over depth ratio assumes a

critical value. The behavior of breaking waves has been documented by many experimental studies (e.g. Galvin, 1968). Battjes (1974) found that the similarity parameter

$$\xi_o = \frac{\tan \alpha}{\sqrt{\frac{H_o}{L_o}}},$$

in which α represents the slope and H_o and L_o re-

spectively the deep water wave height and wave length is a characteristic parameter useful in describing breaking wave characteristics.

- d. The behavior of random waves after breaking over a sloping bottom or on the edge of a natural reef is not well documented in the literature. These are the type of waves that are particularly relevant to this study. At the study site incident waves usually have a narrow-band spectrum, often showing distinct wave group behavior.

As the waves shoal and break, secondary waves are typically formed and are indicative of a nonlinear wave process. Because of the wave height variation in the (random) waves the zone in which initial breaking occurs extends over a certain width; a consequence of this is that the fraction of breaking or broken waves in a wave record varies over the breaking zone.

Energy dissipation leading to a reduction in wave height is primarily due to bottom friction and breaking. When the bottom is porous, percolation losses may become important. The wave attenuation is primarily at the expense of the energy near the peak frequency of the spectrum. At the same time nonlinear energy transfer takes place from the peak frequencies to higher and lower frequencies.

The lower frequency energy components demonstrate themselves in the surf beat which is induced by the height modulation of the breaking waves and the corresponding variation in shoreward mass transport. The higher frequency waves are generated in the breaking process in the form of secondary waves riding on the crests of the primary waves.

As a result of these transformations, the mean period of the waves inside the reef is considerably lower than the period of the incident waves outside the reef.

The decrease in wave energy is associated with a rise in the mean water level over the reef (wave set-up). Low frequency waterlevel variations may be observed as the dynamic part of the wave set-up.

It has been the objective of this study to quantify the above processes and to provide the design engineer with the tools to calculate the relevant design conditions.

For a mathematical model to adequately describe the behavior of random waves after breaking, the following aspects need consideration:

- energy losses due to wave bottom friction and percolation;
- energy losses due to wave breaking;
- the fraction of breaking waves in a wave record, as a function of location

- exchange of energy from medium to lower and higher frequency components of the wave spectrum;
- wave set-up and wave set-down.

Within the framework of this paper it will not be possible to give adequate coverage to all aspects of these transformations. Most attention will be given to wave energy dissipation and wave set-up.

Empirical coefficients from the mathematical model are verified from the analysis of the field and model observations. The experimental set-up is described in the following section.

3. EXPERIMENTAL SET-UP

3.1 Field Experiments

The field experiments were conducted on a shallow reef at Ala Moana Park, in Honolulu, Hawaii. Site conditions, bathymetry, and measurement stations are shown in Fig. 1. In all stations, except Station 6, waves were measured with a capacitance wave gage (Black, 1978). In Station 6 where heavy breaking occurred, wave heights were obtained by filming the motion of a tethered buoy from a location offshore.

For the determination of wave set-up best results were obtained from visual readings of the mean water level using five separate manometers, fixed to the reef bottom and carefully levelled from a bench mark on shore (Wentland, 1978). At the study site the offshore bottom consists of a stable coral reef, whereby the (dead) coral heads produce a rough surface.

3.2 Model Experiments

The model experiments were conducted in the outdoor wave flume of the J.K.K. Look Laboratory. The flume is 54 m long and 1.22 m wide. Maximum water depth is about 1.0 m. Waves are generated with a parabolically shaped plunger type wave generator; the maximum wave height is about 0.3 m, whereas wave periods range from 0.5-4.0 sec. Only regular waves can be generated. The vertical walls partly consist of glass panels, which allow visual inspection of the wave phenomena from outside.

The size of the tank allowed the construction of a 1:12 scale model of the outdoor reef site, whereby 130 m of the actual reef could be simulated. Waves were measured with capacitance wave gages in positions corresponding to the field stations. The waves were recorded on two channel wave recorders and on magnetic tape.

For the measurement of wave set-up in the tank best results were obtained by visual readings of manometers, attached to the outside of the flume and connected with 3 mm plastic tubes mounted inside to the side-wall of the tank, with their openings close to the bottom.

4. RESULTS OF INVESTIGATIONS

4.1 Background

Prototype measurements were taken at Ala Moana Reef, Honolulu, at a site where the bottom consists of coral reef. It has been assumed that energy losses due to percolation are negligible at this site and need not be taken into consideration. Energy losses therefore are limited to losses due to bottom friction and to breaking.

Observations at the study site furthermore show that under most conditions waves approach the shoreline at near right angles. The effect of refraction on changes in wave heights can then be ignored. Consequently in all our analysis the waves were treated as a two-dimensional problem.

Because of variations in reef elevation some wave refraction did occur across the reef. Since the experimental set-up did not provide quantitative information on these three-dimensional effects they could not be taken into consideration in the analysis. It was found, however, that at times, certain observations were adversely affected by this aspect of the problem.

For waves moving perpendicular to the coast the process of wave attenuation is governed by the equation:

$$\frac{dF}{dx} = -(\epsilon_f + \epsilon_b) \quad (1)$$

where F is the energy flux per unit of width,
 x is the direction of wave propagation
 (perpendicular to coastline),
 ϵ_f is the rate of energy dissipation per unit of (horizontal)
 area due to friction, and
 ϵ_b is the rate of energy dissipation per unit of (horizontal)
 area due to breaking.

Equation (1) assumes a steady state condition where the variation of the mean energy with time equals zero.

In monochromatic waves (laboratory conditions) variations in wave height can be directly obtained from Eq. (1); however because of strong nonlinearities, values for mean energy and energy flux have to be used as they apply to nonlinear waves. Both the value of the mean energy and of the velocity of propagation of the waves near and after breaking are affected by the nonlinearity of the waves, so that linear expressions need to be modified.

In random waves the situation is even more complicated; besides nonlinearity, the variation in wave heights and wave period pose additional problems to define dissipation parameters. (Gerritsen, 1980).

One of the objectives of the study is to evaluate the numerical values of ϵ_f and ϵ_b so that a mathematical model for wave attenuation can be developed.

The wave set-up on the reef is governed by the equation (Battjes, 1974):

$$\frac{dS_{xx}}{dx} + \rho g (h_0 + \bar{\eta}) \frac{d\bar{\eta}}{dx} + \bar{\tau} = 0 \quad (2)$$

where S_{xx} is the radiation stress component, perpendicular to the shoreline,
 h_0 is the mean depth,
 ρ is the density of the water,
 g is the acceleration of gravity,
 $\bar{\eta}$ is the time-averaged value of the wave set-up, and
 $\bar{\tau}$ is the mean value of the bottom shear stress.

In the above expression for wave set-up it is assumed that the mean mass transport velocity equals zero.

In most previous studies (Battjes, 1974, Van Dorn, 1976) the authors have neglected the contribution of $\bar{\tau}$ to the wave set-up.

From analyzing wave set-up on a reef, there is some evidence that the contribution of $\bar{\tau}$ is not entirely negligible, and needs to be taken into consideration.

In the calculation of S_{xx} , the linear formulation is usually accepted, although the nonlinearity of the waves will also have an effect on the value of the radiation stress.

In this study we have also used the linear expression of S_{xx} for the analysis of data.

4.2 Energy Losses Due to Bottom Friction

In the literature extensive information is available in the bottom friction in low amplitude, harmonic waves. (Jonsson, 1963, 1966; Riedel, et al., 1972; Kajiura, 1964, 1968).

The concepts introduced by these authors have been extended to waves under shoaling and breaking conditions, whereby the assumption was made that even under breaking waves the orbital velocities near the bottom retain oscillatory characteristics (Gerritsen, 1979).

It can be shown, that both the nonlinearity of the waves and the turbulence induced by breaking will affect the numerical value of the bottom friction coefficient, if the latter is based on a linear wave formulation. (Gerritsen, 1979).

The wave bottom shear stress coefficient f_w is here defined by the equation

$$\tau = f_w \frac{1}{2} \rho U_b |U_b| \quad (3)$$

where U_b is the instantaneous value of the orbital velocity near the bottom. Linear assumptions give the following value for the energy dissipation rate ϵ_f :

$$\epsilon_f = \frac{2}{3} f_w \frac{\rho}{\pi} \left(\frac{\pi H}{\bar{\tau} \sinh kh} \right)^3 \quad (4)$$

where k is the wave number. From field and model data, numerical values of the friction coefficient f_w have been obtained.

It appears that the results follow the general trends established by Jonsson and others surprisingly well. (Gerritsen, 1979) The values of the bottom friction coefficient seem to be only slightly larger than for linear waves, possibly with the exception of plunging breakers where turbulence affects the wave boundary layer and higher values of f_w may be expected.

Values of f_w for prototype conditions usually ranged between 0.1 and 0.5, indicating that the role of friction in energy dissipation in the breaking zone is of considerable significance.

4.3 Energy Losses in Breaking and Broken Waves

The problem of energy dissipation in breaking waves is highly complex and so far no completely satisfactory solution has been proposed.

A number of investigators have used the similarity between a breaking wave and a bore as a model for energy dissipation. (e.g. LeMéhauté, 1962, Battjes and Jansen, 1978). Such approach has also been followed in this study. Utilizing an analysis on bore propagation by Schönfeld (1955) the following expression for the rate of energy dissipation can be derived (Gerritsen, 1979)

$$\epsilon_b = \frac{\zeta}{8\pi\sqrt{2}} \rho g \omega H^2 \quad (5)$$

In this expression ω is the angular wave frequency, and ζ is a dimensionless energy dissipation coefficient, which is a function of the Froude number, the ratio between wave height and depth in front of the breaker and of the fraction of energy dissipated by turbulence. The latter is highest for a plunging breaker and lowest for a spilling breaker.

Expected values of the coefficient ζ range between 0.3 and 0.6, which is in agreement with experimental results.

4.4 Energy Losses in Random Breaking Waves

For monochromatic waves a breaking point can be defined using conventional methods. This in turn defines the width of the breaking zone, over which energy dissipation due to breaking occurs. In this analysis,

the similarity parameter $\xi_o = \frac{\tan \alpha}{\sqrt{\frac{H_o}{L_o}}}$ plays an important role. Battjes

(1974) has shown that there is a relationship between the value of ξ_o , the ratio between wave height and depth at the breaking point. The value of ξ_o is also indicative of the type of breaker that can be expected.

In random waves the above analysis is useful for a wave-by-wave analysis of wave dissipation when wave observations are available at successive stations. Such approach has been used to experimentally determine the values of f_w and ζ .

For prediction purposes, however, this approach is less useful because of lack of wave data across the surf zone.

For the calculation of energy dissipation in breaking waves in a predictive manner two methods can be considered:

- (1) Calculation of the transformation of the wave spectrum when waves move into shallow water and across the reef after breaking. Utilizing this method the effects of shoaling, and energy dissipation and of energy shifts in the wave spectrum must be considered. (Gerritsen, 1980)
- (2) A simplified method, which is based on the mean energy of the wave spectrum, appears to give adequate results for engineering purposes. This method is based on the attenuation of the root mean square wave height and does not take into account energy shifts between frequency components.

In this paper the discussion will be limited to the second method. In order to calculate the energy dissipation due to breaking, the fraction of breaking waves at various locations in the breaking zone must be predicted. Battjes and Jansen (1978) developed a method, based on the truncated Rayleigh distribution, to describe the frequency distribution of waves in the surf zone. This model assumes that the wave height at the point of breaking is limited by depth and that the higher waves of the distribution are reduced to the maximum possible wave height corresponding to that depth.

In evaluating Battjes and Jansen's model to describe our experimental data a difficulty emerged in relation to the assumed truncated distribution. In reality wave heights in the breaker zone do not conform to such a distribution. The distribution is continuous rather than truncated and may be described by a two parameter Weibull distribution.

The concept of a maximum wave height for a certain depth has been verified. Indeed the presence of such maximum could be assumed to exist and could be expressed by

$$H_m = \gamma_m h \quad (6)$$

where H_m is the maximum wave height and γ_m a proportionality parameter, depending on ξ_0 . The prototype experiments showed γ_m to vary between 0.46 and 1.11 with mean values for each station (see section 3) varying gradually from $\gamma_m = 0.81$ for station 5 to $\gamma_m = 0.60$ to station 1.

Because of the difference between the actual distribution (Weibull) and the assumed distribution (Truncated Rayleigh) the probability of occurrence of H_m was expectedly much smaller in reality than predicted in Battjes and Jansen's model for the same value of H_m . A correction is therefore required.

For random waves Eq. (5) is modified to:

$$\epsilon_b = Q \frac{\xi^2}{4\sqrt{2}} \rho g \bar{f} H^2 \quad (7)$$

where Q is the fraction of broken waves at a given location and \bar{f} a mean frequency of the waves obtained from the first order moment of the wave spectrum.

The reduction parameter Q is related to the ratio $\frac{H_{rms}}{H_m}$, and may be calculated from Battjes and Jansen's model, if a correction factor is applied. (Gerritsen, 1980)

The modified equation is:

$$\frac{1-Q}{y^2 \ln Q} = - \left(\frac{H_{rms}}{H_m} \right)^2 \tag{8}$$

where y is the correction factor involved; the latter may be obtained from

$$y = 0.71(Q-1)^2 + 1 \tag{9}$$

Equations (8) and (9) are to be seen as being of empirical nature fitted to observed data.

Results of some measurements and calculations are shown in Figs. 2 and 3. The observations were made on August 25, 1976. The location of the measurement stations is shown in Fig. 1.

Figure 2 Calculated Wave Spectra for Stations on Ala Moana Reef

Figure 3 Root Mean Square Wave Heights from Measurements and Calculations

Figure 2 shows calculated wave spectra for the various measurement stations. It shows the sharp decline in energy densities around the peak frequencies, and the shift of energy to low and high frequencies.

Part of the shift is an apparent shift and may not be real; it is due to the Fourier analysis applied to nonlinear wave forms.

The higher frequency components may not represent free harmonics, but they may be bound in phase to the principal wave.

Figure 3 shows the results obtained from the above described dissipation model. Calculated values of H_{rms} , obtained directly from the wave records, and obtained from the dissipation model are both shown. For the latter the root mean square wave height at the offshore station was used as input for the calculations.

Satisfactory agreement between the data from observations and from the model is obtained if the correct values of the dissipation coefficients are introduced into the calculations.

4.5 Wave Set-Up

Analysis of model investigations

Measurements on wave set-up were carried out in the field as well as in a hydraulic model (scale 1:12), allowing a comparison between the two types of measurements. However waves in the laboratory were restricted to the monochromatic type which made the comparison less than ideal.

The range of test conditions in the field measurements was limited, therefore the broader scope of the model data was used as the basis of verification.

An overall view of the test results indicated that both the mean relative waterdepth over the reef $\frac{h_s}{H_1}$ and the wave steepness parameter $\frac{H_1}{gT^2}$ were playing a role in the wave set-up phenomenon. In these parameters H_1 is the incident wave height and T the incident wave period. These values were taken at the offshore station. An attempt was made to define a single parameter (most likely a combination of the two other parameters mentioned), that would function as a governing parameter for the wave set-up on a reef.

A suitable parameter of this kind is:

$$\chi = \frac{gT^2 H_1}{h_s^2}$$

which appears to be a modified Ursell parameter, for shallow water.

In Fig. 4 the dimensionless maximum wave set-up on the reef $\frac{\bar{\eta}_{\max}}{H_1}$ is plotted against χ . Although there is considerable scatter the solid line may represent a unique relationship. Much of the scatter is probably due to inaccuracies in the reading of the manometers, particularly for low values of the wave set-up. As the values of the wave set-up get larger the scatter seems to become smaller.

It may be noted that χ is related to relative reef depth and wave steepness:

$$\chi = \frac{gT^2 H_1}{h_s^2} = \frac{1}{\frac{H_1}{gT^2} \cdot \left(\frac{h_s}{H_1}\right)^2}$$

so that

$$\frac{\bar{\eta}_{\max}}{H_1} = \text{fct} \left[\frac{H_1}{gT^2}, \frac{h_s}{H_1} \right] \quad (10)$$

A graphical representation of (10) can be accomplished in two manners:

Figure 4 Maximum dimensionless wave set-up on reef versus χ

- (1) $\frac{\bar{\eta}_{max}}{H_1}$ as function of $\frac{h_s}{H_1}$, with $\frac{H_1}{gT^2}$ as a variable parameter;
- (2) $\frac{\bar{\eta}_{max}}{H_1}$ as function of $\frac{H_1}{gT^2}$, with $\frac{h_s}{H_1}$ as a variable parameter.

In view of the space limitations for the paper only the second representation is shown. (Figure 5)

The scatter that was observed in Fig. 4 is visible again in Fig. 5.

Figure 5 Maximum Dimensionless Wave Set-Up on Reef as a Function of the Wave Steepness Parameter

Verification of hydraulic model with theory

For the verification of the model with theory, a numerical integration of (2) was used. The computations were carried out in two different ways: by letting the mean shearstress $\bar{\tau}$ be equal to zero and by letting it be different from zero. In the latter case its value was adjusted until satisfactory agreement between observation and theory was obtained.

For the numerical integration of Eq. (2) the gradient in mean wave energy must be known in order to determine $\frac{dS_{yx}}{dx}$. For this the dissipation equations developed in the previous sections, were applied.

The results of this analysis indicated that a positive shearstress $\bar{\tau}$ must be introduced to obtain satisfactory agreement between observation and theory. If this positive shearstress is not applied theoretical values are too high and do not agree with observed values.

A positive shearstress is indicative of a resultant watermotion toward the coast in the bottom layers. The nature of this will have to

be investigated in future studies. The analysis further showed that reasonable agreement between observation and theory was usually obtained when a shearstress proportional to the (negative) gradient of the radiationstress

$$\bar{\tau} = -B \frac{dS}{dx} \quad (11)$$

was introduced.

B is a numerical coefficient for the model for which a mean value $B_m = 0.36$ was found.

Comparison between field and model data

It is unfortunate that the extensive 1976 field measurements provided inaccurate information on wave set-up.

Improved measurements were taken in 1978, although without the simultaneous wave data that characterized the measurements in 1976. In 1978 wave measurements were limited to the offshore wave station.

Over a total of about 14 days of measurement the maximum wave set-up on the reef was found to be 10.7 cm.

Wave set-up values were found from the difference in waterlevel elevation on the reef and in the small harbor behind the reef. The latter is connected with the ocean by a 6 m deep channel. (It was assumed that the wave set-up inside the harbor, compared to the instantaneous mean sealevel in the ocean, would be negligible).

Utilizing available field data and comparing measurements with theory, the coefficient B of Eq. (11) for field conditions could be determined. It was found that $B_p = 0.17$ which is less than the value found for the model.

This difference suggests a difference in resultant bottom shear stress between model and prototype possibly related to a difference in circulatory water movement.

In the field surface drift velocity measurements near reef stations showed low and variable currents (between 0.03 and 0.1 m/sec) usually westerly in longshore direction, occasionally directed shoreward. Onshore mass transport, is expected to have been very small. However velocities near the bottom were not measured and consequently no information is available regarding the resultant current conditions near the bottom.

In the model resultant mass transport to the shore must necessarily be zero, but a resultant shoreward bottom current may nevertheless still be present. An imperfection of the model: return ground waterflow through a not completely sealed bottom, and a porous reef may have had some lowering effect on the wave set-up, which consequently may have increased the value of B_m .

The difference in the values of B for the model and prototype may be considered as a scale effect of the model, and may be used to calculate corrections on the model data.

The results are presented in Fig. 6. In this figure the average of four field observations under approximately equal conditions is also shown, which plotting fits the corrected model data well.

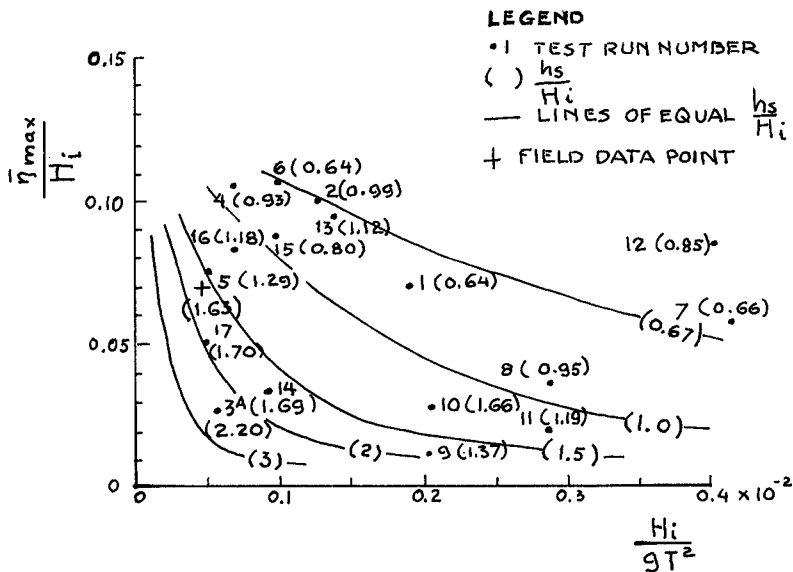

Figure 6 Dimensionless maximum wave set-up on reef versus wave steepness parameter from model, corrected for scale effect

5. CONCLUSIONS AND RECOMMENDATIONS

1. Waves breaking on a coral reef are subject to energy dissipation due to bottom friction losses and breaking losses.
2. The linear wave bottom friction coefficient is affected by the nonlinearity of the waves and by near bottom turbulence.
3. In spilling breakers the wave friction coefficient is of the same order of magnitude as the value of this coefficient in nonbreaking waves.
4. In plunging breakers the overturning jet affects the turbulence of the near bottom fluid motion, and a considerably higher friction coefficient may be expected.
5. Wave friction coefficients in the breaking zone, obtained from the reef measurements are usually between 0.1 and 0.5.

6. The similarity with the bore is utilized to define a breaking loss coefficient ζ . Its value is usually between 0.3 and 0.6 depending on the type of breaker.
7. The randomness of broken waves is an important element in the calculation of wave energy dissipation. A modified Battjes-Jansen model gives adequate results.
8. Wave set-up on a shallow reef is governed by a dimensionless parameter

$$\chi = \frac{gT^2 H_1}{h_s^2}$$

which may be considered as a modified Ursell parameter.

9. Experimental evidence suggests that the resultant shearstress $\bar{\tau}$ cannot be neglected in the calculation of wave set-up.
10. More research is required to obtain a full understanding of the physical phenomena. The study of the resultant shearstress $\bar{\tau}$ in the wave set-up equation is particularly recommended.

6. ACKNOWLEDGMENTS

This work was sponsored by the University of Hawaii Sea Grant College Program under institutional grant nos. 04-6-158-44026 and 04-6-158-44114 from NOAA Office of Sea Grant, U.S. Department of Commerce and the State of Hawaii. Many individuals contributed to the planning, the measurements, and the analysis of the data: T.T. Lee, J.A. Battjes, E. Thornton, K. Black, L. Brower, T.C. Hwang, G. Zee, D.A. Wentland, H.L. Kaul and K.G. Weber. Their contributions and cooperation are gratefully acknowledged.

CHAPTER 29

LONGSHORE CURRENT FLOWS IN A WAVE BASIN

by P.J. Visser *)

ABSTRACT

This paper describes the investigation into a method how to adjust the proper longshore current in a wave basin. In this method the basin geometry and the proper recirculation flow (outside wave guides) are determined by minimising the circulation flow (between wave guides). Using one wave field and one uniform beach the length of the downstream wave guide wall, the distribution of the recirculation flow at the upstream wave guide wall and the recirculation flow were varied. The investigation shows that the adjustment of the longshore current has to be done carefully in order to get uniformity along the beach and the correct magnitude and distribution normal to the beach.

1 INTRODUCTION

Since the introduction of the concept of radiation stresses by Longuet-Higgins and Stewart (1964) considerable progress has been made in the understanding of the physics of longshore currents induced by obliquely incident breaking waves on beaches. The investigation of the uniform (along the straight shoreline) longshore current profile has been first undertaken by Bowen (1969), Thornton (1969) and Longuet-Higgins (1970). The investigation has been continued by, among others, Battjes (1974) using irregular waves, Jonsson, Skovgaard and Jacobsen (1975), Liu and Dalrymple (1978) and Skovgaard, Jonsson and Olsen (1978). Although some assumptions done in above mentioned studies are rather crude, the achievements obtained by these authors are considerable and call for an accurate comparison with experimental results. Moreover, most of above mentioned models comprise coefficients which, for the present state of knowledge, have to follow from experiments. Comprehensive experiments, in which the longshore current profile was measured are, however, scarce.

In most of the published laboratory and field experiments of longshore currents, see for instance the reviews of Galvin (1967) and Komar (1975), the "longshore current velocity" was measured. In general this longshore current velocity is defined as the averaged (over the width of the surf zone) current velocity. In fact only Galvin and Eagleson

*) Scientific Officer, Department of Civil Engineering, Delft University of Technology, The Netherlands.

(1965) measured the variation of the longshore current across the surf zone in extensive series of laboratory experiments. Unfortunately the measured currents were not uniform along the beach. Therefore care must be taken in comparing these experiments with theoretical longshore current profiles.

Dalrymple, Eubanks and Birkemeier (1977), see also Kamphuis (1977), measured circulation streamlines and "longshore velocities along surf zone" in the three commonly used wave basin configurations:

- (1) A basin as used by Brebner and Kamphuis (1963) with surf zone openings in both wave guide walls to allow recirculation outside the wave guide walls. The recirculation flow takes place behind the wave generator or through a pipe under the beach.
- (2) The completely enclosed wave basin: used by Putnam, Munk and Traylor (1949) and Saville (1950).
- (3) A basin as used by Galvin and Eagleson (1965) with an opening in the downstream wave guide wall and with an opening under the wave board to allow recirculation.

Dalrymple et al. (1977) concluded in their paper that if a working recirculation procedure could be devised for the type (1) basin that this would reduce the amount of return flow in the offshore region. It has been the objective of the investigation described in this paper to develop such a procedure, resulting in a uniform longshore current, for a basin similar to that of type (1) but equipped with a pump to effect the recirculation and with longshore current openings in the wave guides rather than surf zone openings. This investigation is a first step to a theoretical and laboratory study of longshore current and wave set-up induced by obliquely incident breaking waves on beaches. The longshore current study will probably be followed by a laboratory investigation of sediment transport caused by this current.

2 CRITERION FOR PROPER LONGSHORE CURRENT FLOW

To approximate the longshore current flow generated by a uniform (along the shoreline) wave field on an infinitely long and uniform (along the shoreline) beach, a wave basin configuration was chosen with longshore current openings in both wave guide walls and with a recirculation outside the wave guide walls which is effected completely by a pump (fig. 1). Very likely the choice of such a wave basin is the only way to obtain a uniform longshore current in a wave basin, it also yields, however, the following unknown quantities:

- the width of the longshore current openings in both wave guide walls,
- the recirculation flow rate.

These quantities have to be determined preceding to a longshore current or littoral transport investigation in a basin as shown in fig. 1, preferably in a relatively short period of time.

The criterion for the proper longshore current flow generated by a uniform wave field is that the profile is uniform along the beach, or also that the slope of the mean water in longshore direction is zero.

Figure 1 - Wave basin configuration.

It is, however, impossible to optimise the recirculation procedure from measurements of mean water level in longshore direction. This is caused by the inevitable small variation along the shoreline of wave set-up and set-down and the limited length of a wave basin. This paper describes the investigation into an alternative method. In this method the wave basin geometry and the proper recirculation flow (outside wave guides) Q_{ru} are determined such that the circulation flow (inside wave guides) Q_c is minimised (fig. 1). Q_{ru} is the recirculation flow Q_r which yields the uniform longshore current flow Q_u . This method is based on the physical consideration that in an optimised wave basin geometry Q_c is minimal if $Q = Q_u$: because if $Q_r < Q_{ru}$ the shortage returns offshore in Q_c and Q_c will increase and if $Q_r > Q_{ru}$ the surplus generates a circulation flow, also yielding an increase of Q_c .

To verify the method outlined above, experiments were carried out in which the following quantities were varied:

- the width of the longshore current opening in the downstream wave guide wall,
- the distribution of the recirculation flow in the longshore current opening of the upstream wave guide wall,
- the recirculation flow Q_r .

The completely enclosed wave basin and the basin with surf zone openings in both wave guide walls and a recirculation achieved outside the wave guide walls without a pump were also investigated. The wave field quantities and beach slope and beach roughness were not varied as yet.

3 EXPERIMENTAL PROCEDURE

The experiments were done in a $16.60 * 34.00 \text{ m}^2$ wave basin (fig. 1) equipped with a snake-type wave generator. Opposite to the (regular wave) generator a smooth concrete 1 : 10 slope was constructed in the basin. The wave guide walls were composed of concrete elements and installed at an angle of 31 degrees with the normal of the wave board. The recirculation has been effected through a $\varnothing 0.80 \text{ m}$ pipe by means of a pump. The adjustment of the desired recirculation flow Q_r was done with the help of an orifice plate.

Figure 1 shows the position of the 7 sections in which measurements of current velocity were performed. In each experiment the current velocity was measured in section 2, which extends from the wave board to the wave set-up line. In some experiments the velocity was also measured in sections 5 and 6 perpendicular to the wave guide walls and/or in the "longshore current zone" in sections 0, 1, 3 and 4 parallel to section 2. The distance along a section between two measuring points was 0.20 m in and near the surf zone and 0.40-0.60 m in the other region.

In the measuring points the current velocity was measured near the surface, at mid-depth (with exception of sections 5 and 6 and the shallow zone between plunge line and wave set-up line) and near the bottom. The current velocities were measured by timing the travel (along 0.80 m, 0.50 m or 0.30 m, depending on the velocity) of dye (KMnO_4) perpendicular to a measuring section. To this end, near each measuring section strings were stretched parallel to the section and just above the waves. In the surf zone dye was followed over a distance of 0.80 m and not longer because of the rather fast spreading of dye by turbulence in this zone. To serve accuracy, the number of readings giving one measurement result (that is a velocity at a certain depth) was increased and the measurements were conducted by two persons in this zone. Outside the surf zone, the spreading of dye was rather small and there the measured travel time of dye was at least 3 seconds. The number of readings which gave one measurement result are as follows:

- in the surf zone : at least 20,
- near the surf zone: at least 10,
- remaining region : at least 5.

To eliminate the influence of the orbital velocities on the measurement results, the velocities were measured in different phases of the waves. Dye was chosen in accordance with the choice of dye by the Delft Hydraulics Laboratory (1977) after a series of experiments in which the application of floats, dye, the propeller-type miniature current meter and the Ott propeller-type current meter was investigated.

Wave set-up and set-down were measured in sections 1 and 2 with tappings, flush-mounted in the beach. The horizontal distance between 2 tappings was 0.10 m in the surf zone, and 0.20 m outside the surf zone. The tappings were connected with pots, in which the static head was measured.

Measurements of wave heights were performed with resistance wave probes. The distance between two measuring points was 0.10 m in the surf zone and 0.20 m outside this zone. In the constant depth part of the basin wave heights were measured in 5 sections (yielding a number of 100 measuring points). In the slope zone wave heights were measured in sections 1 and 2 and, to measure the position of the breaker line and the mean breaker height, in 3 sections parallel to the wave board at and near the breaker line, each section containing 29 measuring points on a mutual distance of 0.20 m.

Measurements of angles of incidence were done:

- in the constant depth part of the basin with wave probes directly after the start of the wave generator,
- on the breaker line by photograph.

The results of the measurements of wave heights, breaker depths, angles of incidence, wave set-up and set-down are listed in table 1. These wave field quantities were measured in the optimised wave basin geometry with the uniform longshore current flow. The breaker line is defined here as the averaged (along the shoreline) position of the measured breaker points. A breaker point is defined here as the point

wave period	= 2.01 sec	sloping beach with $\text{tga} = 0.101$
still water depth	= 39.9 cm	
mean wave height	= 7.1 cm	} in constant depth part of the wave basin
adjusted angle of incidence	= 31.1°	
measured angle of incidence	= 31.6°	
mean breaker depth	= 10.4 cm	mean breaker height = 10.5 cm
mean maximum set-up	= 4.2 cm	mean max. set-down = 0.32 cm
mean width surf zone (from wave set-up line to breaker line)	= 1.45 m	
angle of incidence on breaker line	= 20.9°	
mean wave run-up	= 7.2 cm	

Table 1 - Measured wave field quantities.

in which the wave height is maximal (in a section normal to the coast) : at the shoreward side of this point the wave height decreases (more or less) continuously.

The velocity measurements which are described in this paper can be summarized as follows:

A. first series of experiments in which

- width opening in upstream wave guide (= 1.90 m) = 1.3 * width surf zone,
- width opening in downstream wave guide varied from 1.0 * width surf zone to 2.0 * width surf zone (ratios of 0.97, 1.17, 1.31, 1.45 and 2.00),
- recirculation flow Q_r varied from 0 l/sec to 59 l/sec.

B. second series of experiments in which

- distribution system in longshore current opening of upstream wave guide wall,
- width opening in downstream wave guide wall varied from 1.0 * width surf zone to 1.6 * width surf zone (ratios of 0.97, 1.17, 1.31, 1.45 and 1.59),
- recirculation flow varied from 25 l/sec to 50 l/sec.

C. measurements in completely enclosed wave basin.

D. measurements in wave basin with surf zone openings in both wave guides rather than longshore current openings and a free recirculation (no pump).

The distribution system in the longshore current opening of the upstream wave guide wall is 1.20 m long (in longshore direction) and 2.40 m wide (in the direction normal to the wave board) and consists of 12 channels each 1.20 m long and 0.20 m wide. With gates, slide-valves, etc., it is possible to vary the rate of flow in each channel.

4 EXPERIMENTAL RESULTS

The mean velocity in a measuring point was calculated from the measured current velocities as follows

$$\bar{v} = \frac{1}{4} (v_{\text{surface}} + 2 v_{\text{mid-depth}} + v_{\text{bottom}}).$$

The rate of flow between two adjacent measuring points followed from the mean velocities and mean water levels measured in these points. The enumeration of these flow rates between adjacent points gave the longshore current flow Q and the circulation flow Q_c , as defined in fig. 1. By comparing the difference $Q - Q_c$ with the adjusted flow rate of the pump Q_r an indication of the accuracy of the experiments was obtained. At the end of this chapter the accuracy of the experiments will be discussed.

In the first series of experiments (A) the width of the longshore

Figure 2 - Longshore current flows Q and circulation flows Q_c measured in section 2' in first (A) series of experiments.

current opening in the upstream wave guide was constant, namely $1.3 * w_s$ (w_s = width surf zone), which after the completion of these experiments turned out to be a fortunate choice. The width w_d of the longshore current opening in the downstream wave guide and the recirculation flow Q_r were varied. Figure 2 gives a graphical representation of the longshore current flows Q and circulation flows Q_c measured in section 2 (25 measurements) in the first series of experiments. From this figure it can be seen that Q_c is more or less a parabolic function of Q_r for a given w_d/w_s -ratio. The locus of the minima of these parabolas gives a graphical relation between w_d/w_s and Q_r (such that Q_c is minimal for a given Q_r or w_d/w_s -ratio). In the first series of experiments the circulation flow Q_c is minimal for $w_d/w_s = 1.31$ and $Q_r = 35$ l/sec : $Q_c = 13.6$ l/sec and $Q = 48.4$ l/sec. In this situation (here labeled as \hat{A} -experiment) also velocity measurements were done in sections 5 and 6 and, to examine the uniformity along the beach, in sections 0, 1, 3 and 4. The results of these measurements and of the measurements in section 2 are shown in fig. 3. From this figure it can be seen that from section 2 to section 0 the longshore current profile is uniform, but that almost half a wave basin length is necessary to establish this uniform longshore current. In order to increase the length of uniformity, a distribution system was installed in the longshore current opening in the upstream wave guide wall after the completion of the first series of experiments.

The distribution of the recirculation flows Q_r in this system was adjusted according to the measured distribution of the longshore current flows Q in the first series of experiments. In the second series of experiments (B) the number of measurements in section 2 was restricted to 11 : 6 with $w_d/w_s = 1.31$ and a Q_r -range from 25 to 50 l/sec, 5 with a varying w_d/w_s -ratio (according to the locus of the minima in fig. 2) and a Q_r also ranging between 25 and 50 l/sec. The longshore current flows Q and circulation flows Q_c measured in this series of experiments are shown in figure 4. Also in the second series of experiments the circulation flow Q_c is minimal for $w_d/w_s = 1.31$ and $Q_r = 35$ l/sec : $Q_c = 19.2$ l/sec and $Q = 52.1$ l/sec. The results of the velocity measurements in section 2 and the results of the measurements in sections 0, 1, 3, 4, 5 and 6, which were also performed in this situation (here labeled as \hat{B} -experiment), are shown in figure 5. This figure shows that the longshore current is uniform from section 3 to section 0: due to the distribution system the distance along which the longshore current is uniform increases substantially.

The smallest Q_c in the second series of experiments is $Q_c = 19.2$ l/sec, in the first series of experiments: $Q_c = 13.6$ l/sec. The influence of

Figure 3 - Depth averaged longshore current and circulation velocities (A-measurements).

Figure 4 - Longshore current flows Q and circulation flows Q_c measured in section 2 in second series of experiments (B).

the distribution system on the rate of circulation flow Q_c does not follow from a comparison of these circulation flow rates due to the fact that not only a distribution system was installed but also some small (but not unimportant) leaks in the wave guides were closed. To investigate this influence an additional experiment was performed without the distribution system, with $Q_r = 35$ l/sec and with $1.31 * w_s$ wide openings in both wave guides. The result of this experiment: $Q_c = 29.4$ l/sec and $Q = 62.2$ l/sec.

The depth averaged velocities resulting from the measurements in the completely enclosed wave basin are shown in figure 6. The longshore current is clearly non-uniform; the profile is strongly disturbed by the significant large circulation flow ($Q_c \approx 128$ l/sec).

Figure 7 shows the depth averaged velocities which follow from the velocities measured in the type (1) basin, that is a basin with surf zone openings in both wave guides and with a recirculation outside the wave guides without the use of a pump. Also the longshore current measured in this type wave basin is clearly non-uniform. In this experiment the return flow took place directly alongside of the longshore current, yielding an anti-clockwise circulation in the offshore region. The "free recirculation flow" was also measured: $Q_r = 12.4$ l/sec, which is about one third of the proper Q_r .

Table 2 - Some results of the measurements along the shoreline.

The flows along the coast in the surf zone (Q_s) and in a section with a width of 2 times the width of the surf zone (Q_{2s}) measured in the four experiments \hat{A} , \hat{B} , C and D are given in table 2. The table presents also the depth averaged maximum velocities along the coast and the depth averaged velocities on the breaker line. Table 2 shows again the uniformity and non-uniformity of the measured longshore currents which is already depicted in figures 3 and 5-7. The depth averaged longshore current velocities measured in section 2 in the experiments \hat{A} , \hat{B} (both with practically the same uniform longshore current profile), C and D are shown in figure 8. The differences between the uniform longshore current profiles and the non-uniform longshore current profiles near the middle (in longshore direction) of the sloping beach in the completely enclosed wave basin and the type (1) basin are clear, especially near the breaker line. Deviations from the uniform longshore current profile can become also considerable in the

Figure 8 - Depth averaged longshore current velocities.

fig. 1 type basin, especially if the rate of recirculation flow differs substantially from the proper recirculation flow. This is demonstrated in figure 8 with the help of the longshore current profile measured in the first series of experiments with $Q_r = 59$ l/sec and $w_d/w_s = 2.00$.

Adding all recirculation flows Q_r , all longshore current flows Q and all circulation flows Q_c of the experiments described in this paper gives respectively:

$$\sum Q_r = 1253 \text{ l/sec,}$$

$$\sum Q - \sum Q_c = 2320 - 1080 = 1240 \text{ l/sec.}$$

The difference of 13 l/sec is for 70% due to the experiment with the completely enclosed wave basin (with the large circulation flow) and only 1% of $\sum Q_r$. So it can be concluded that the systematic error in the longshore current and circulation velocity measurements is small. The random error of one measurement result was restricted as far as the experimental time this permitted by the number of readings (5, 10 or 20) which gave this measurement result. From the above and from the smooth longshore current profiles reflected in the figures 3, 5, 6, 7 and 8 it can be concluded that rather accurate measurements of longshore currents are possible.

5 DISCUSSION

The investigation described in this paper shows that the adjustment of the correct longshore current flow in a wave basin has to be done conscientiously. Deviations from the uniform longshore current profile can become considerable

- in non-optimised wave basin geometries and/or if
- the adjusted recirculation flow deviates substantially from the proper recirculation flow.

One of the most important aims of this investigation is to set-up a method for the adjustment of the uniform longshore current flow (or profile) in a wave basin and to verify this experimentally. From the previous chapters it can be concluded that this objective has been attained, at least for the wave field/wave basin combination which was used for the experiments described in this paper. From this investigation a "wave basin prescription" will be set-up. With this wave basin prescription it has to be possible to create a uniform longshore current flow in a wave basin for given wave field and beach quantities in a rather short time. To verify this wave basin prescription the experiments will be continued with other wave fields on the same slope.

ACKNOWLEDGEMENTS

The author is greatly indebted to Mr. D.C. Post for his assistance with the velocity measurements in and near the surf zone and for his performance of the remaining measurements. The author also wishes to thank Prof. J.P.Th. Kalkwijk for his critical comments during the investigation.

ABSTRACT

A detailed discussion is made on the dynamic characteristics of waves and wave-induced currents in the nearshore area by using the laboratory and field investigation data collected during the last few years. The main purposes of this paper are to get the insight on the precise mechanism of the nearshore dynamic phenomena and to evaluate critically the applicability of the various assumptions commonly applied by the previous researchers.

INTRODUCTION

During the last several years, the research group supervised by the senior author have carried out the series of field and laboratory investigations on the nearshore dynamic phenomena. The final target of the research works is to understand precisely and more deeply the coastal sediment processes, which must be governed by the nearshore dynamics. However, in the present paper, the authors would like to focus their discussions on the several subjects which are closely related to the detailed mechanism of nearshore dynamics.

Since the radiation stress concept was presented by Longuet-Higgins and Stewart (1960, 1964), various important phenomena in the nearshore area have been analyzed extensively. Wave set-down and wave set-up, longshore current velocity distribution, and nearshore circulation must be typical examples in these phenomena.

Generally speaking, the phenomena in the nearshore area are extremely complex due to the complicated action of breaking waves. Therefore, in the previous treatments, some appropriate assumptions have been introduced to formulate the dynamical equations. These assumptions are that, for example, the small amplitude wave theory is applicable to the wave motion in the nearshore area, the wave height in the surf zone is proportional to the local water depth, and the bottom and lateral frictional terms are expressed in specified forms.

These previous works contributed very much to the advancement of coastal engineering research in the 1970s. On the other hand the instrumentation techniques have been developed extensively during these days. These facts encourage the scientists to carry out the detailed investigations to clarify the fine structures of nearshore phenomena, such as wave characteristics and current fields in the nearshore area.

Reflecting the above fortunate circumstances, the staffs at the Coastal Engineering Laboratory, University of Tokyo, have continued the extensive field and laboratory investigations during the last three years. Based on the data obtained up to the present stage, the authors' concept or understanding on the dynamic characteristics of waves and wave-induced currents in the nearshore area will be introduced in the following sections.

GOVERNING EQUATIONS

Figure 1 indicates the definition sketch. By using these terms, the dynamic equations, such as the total mass conservation equation, and the total momentum conservation equation, can be written down as shown in the following forms after Phillips (1977).

1) Conservation of total mass:

$$\frac{\partial}{\partial t} [\rho(h+\bar{z})] + \frac{\partial}{\partial x_\alpha} \hat{M}_\alpha = 0 \quad (1)$$

2) Conservation of total momentum:

$$\frac{\partial}{\partial t} \hat{M}_\alpha + \frac{\partial}{\partial x_\beta} [\hat{U}_\alpha \hat{M}_\beta + S_{\alpha\beta}] = T_\alpha + R_\alpha \quad (2)$$

where $\hat{U}_\alpha = \hat{M}_\alpha / \rho(h+\bar{z}) = U_\alpha + M_\alpha / \rho(h+\bar{z})$, $S_{\alpha\beta} = \int_{-h}^{\bar{z}} (\rho u_\alpha u_\beta + p \delta_{\alpha\beta}) dz$

$$- \frac{1}{2} \rho g (h+\bar{z})^2 \delta_{\alpha\beta} - M_\alpha M_\beta / \rho(h+\bar{z}), \quad T_\alpha = -\rho g (h+\bar{z}) \frac{\partial}{\partial x_\alpha} \bar{z}, \quad \text{and}$$

$$R_\alpha = \int_{-h}^{\bar{z}} \frac{\partial}{\partial x_\beta} \tau_{\beta\alpha} dz + \bar{\tau}_{z\alpha} - \bar{\tau}_{h\alpha} = -\frac{\partial}{\partial x_\beta} (S'_{\alpha\beta}) + \bar{\tau}_{z\alpha} - \bar{\tau}_{h\alpha}$$

Here t is the time, x_α the horizontal axis, z the vertical axis taken above the still water level, p the pressure intensity, u_α the horizontal component of wave orbital velocity, ρ the fluid density, g the acceleration due to gravity, $\delta_{\alpha\beta}$ the Kronecker delta, $\tau_{\beta\alpha}$ the Reynolds stress and $\bar{\tau}_{z\alpha}$, $\bar{\tau}_{h\alpha}$ are the mean shear stresses at the free surface and at the bottom respectively. The term $S_{\alpha\beta}$ is the so-called radiation stress which corresponds to the excess momentum flux tensor, T_α the horizontal force per unit surface area induced by the free surface gradient, and R_α the frictional term consisting of the lateral and boundary frictional terms. The term $S'_{\alpha\beta}$ introduced here may be expressed by $\int_{-h}^{\bar{z}} \rho u'' v'' dz$, where u'' and v'' are the horizontal components of turbulent velocity.

As stated previously, it is very common to apply the small amplitude wave theory in evaluating the radiation stress tensor $S_{\alpha\beta}$ which is given by

$$S = \bar{E} \begin{pmatrix} \frac{c_g}{c} \cos^2 \theta + \frac{1}{2} \left(\frac{2c_g}{c} - 1 \right) & \frac{1}{2} \frac{c_g}{c} \sin 2\theta \\ \frac{1}{2} \frac{c_g}{c} \sin 2\theta & \frac{c_g}{c} \sin^2 \theta + \frac{1}{2} \left(\frac{2c_g}{c} - 1 \right) \end{pmatrix} \quad (3)$$

where the wave profile ζ is assumed to be expressed by $\zeta = \frac{H}{2} \cos(x_1 k \cos\theta + x_2 k \sin\theta - \sigma t)$, in which H is the wave height, k the wave number, σ the angular frequency, θ the wave direction angle, and $\bar{E} = \frac{1}{8} \rho g H^2$ the average wave energy per unit water surface.

TWO DIMENSIONAL CASE

WAVE SET-DOWN AND WAVE SET-UP

As a first step of the present discussion, the following simple case will be taken. That is to say, the waves are coming perpendicularly to the shoreline, hence the wave direction angle θ is equal to zero. In addition to the above it is assumed that the phenomenon is in the steady state, and the bottom contour lines are parallel to the shoreline. In such a case, the basic equation is simply expressed by

$$\frac{d}{dx} S_{xx} = -g(h + \bar{\zeta}) \frac{d}{dx} \bar{\zeta} + R_x \quad (4)$$

where x is taken in the onshore-offshore direction.

The nearshore area is usually separated into two regions; the first one is the outside of the surf zone, and the other one is the inside of the surf zone. The reason is that there exists a remarkable difference in wave characteristics in these two regions. The treatments given by Eqs. (5) and (6) in the following are the very common ways to evaluate the amount of wave set-down as well as that of wave set-up.

- 1) Outside the surf zone:

$$\bar{\zeta} = -\frac{H^2}{8} \frac{k}{\sinh 2kh} \quad (5)$$

under the conditions of $R_x \approx 0$ and $\bar{\zeta} \ll h$.

- 2) Inside the surf zone:

$$\bar{\zeta} = K(h_b - h) + \bar{\zeta}_b$$

$$K = [1 + (8/3\gamma^2)]^{-1} \quad (6)$$

under the conditions of $R_x \approx 0$ and $H \approx \gamma(h + \bar{\zeta})$, where the subscript b indicates the value at the breaking point.

It has been realized that these equations give the curves of mean water level which agree well with the laboratory data except in the vicinity of the breaking point.

Figure 2 demonstrates a result of comparison among the mean water level measured in a wave flume and those calculated by using any one of the small amplitude wave theory, the linear long wave theory, the stream function theory (Dean, 1967), and the radiation stress S_{xx} obtained from the measured velocity field through an approximate expression (Isobe, Fukuda & Horikawa, 1979). Here it should be mentioned that these calculations except the last one were made by using the measured wave profile at each location. That is to say, in the case of the small amplitude wave theory the measured wave height only

$$u_\alpha = U_\alpha + u_\alpha'$$

$$\hat{M}_\alpha = \int_{-h}^{\zeta} \rho u_\alpha dz = \hat{M}_\alpha + M_\alpha$$

$$\hat{M}_\alpha = \int_{-h}^{\zeta} \rho U_\alpha dz = \rho(h + \bar{\zeta}) U_\alpha$$

$$M_\alpha = \int_{-h}^{\zeta} \rho u_\alpha' dz$$

Fig. 1 Definition sketch (adapted from Phillips, 1977).

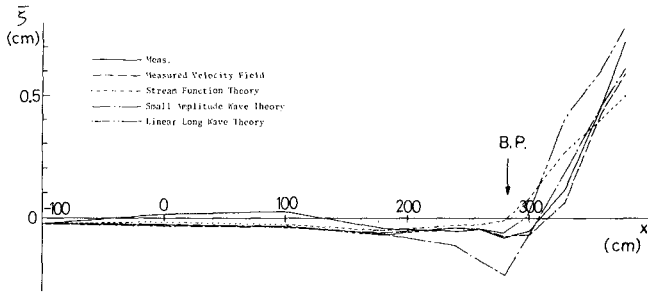

Fig. 2 Comparison between the measured and predicted wave set-down and wave set-up curves.

was used for the computation, while in the case of the linear long wave theory the instant horizontal velocity component was calculated by using the well-known relationship of $u = \sqrt{g/h} \zeta$, where u is the horizontal velocity component and ζ is the surface wave elevation above the mean water level. On the other hand, the stream function theory contains in it the non-linear effect of wave characteristics.

From this diagram, it is realized that the curve calculated by using the values of S_{xx} stated above fits best in the measured mean water level. However the curve based on the small amplitude wave theory deviated extremely from the measured one especially in the vicinity of breaking point.

EVALUATION OF RADIATION STRESS

The fact stated above indicates that the radiation stress S_{xx} outside the surf zone evaluated here on the basis of the small amplitude wave theory seems to be inadequate for the present purpose. Figure 3 demonstrates the above surmise; that is to say, the small amplitude wave theory seems to have a tendency to overestimate the value of $S_{xx}/\rho g$ especially near the breaking point. This conclusion is quite natural, because the non-linearity of waves is normally intensified in the shallow water region. In addition to the above, it should be mentioned that the actual wave height change on the gently sloping beach up to the breaking point differs from the curve calculated by using the small amplitude wave theory as shown in Fig. 4. Here the predicted curve is based on the simple rule of energy flux conservation, and only the wave height in deep water is given in the present computation. Due to the double fault stated above, it is quite possible that the onshore-offshore distribution curve of $S_{xx}/\rho g$ outside the surf zone can be predicted a little more closer to the reference curve from the deep water wave height on the basis of the small amplitude wave theory.

On the other hand, the wave height inside the surf zone, H , is well expressed by the relationship of $H = \gamma (h + \bar{\zeta})$, where h is the still water depth, $(h + \bar{\zeta})$ is the local water depth, and γ is a proportionality constant. However, the field and laboratory data indicate that the above proportional relationship between the wave height and the local water depth holds good only on a uniformly gently sloping beach (Hotta & Mizuguchi, 1978, Mizuguchi, Tsujioka & Horikawa, 1978, and Mizuguchi & Horikawa, 1978).

The wave set-down and wave set-up are closely related to the gradient of radiation stress, while the radiation stress has a close connection with the local wave pattern. That is why the stream function theory predicts well the radiation stress, thus the mean water level, at least outside the surf zone.

WAVE CELERITY

From the above discussion, it is clear that the small amplitude wave theory is not powerful to predict the wave height change on a gently sloping beach. However the wave celerity is in a little different situation from the wave height. Figure 5 show the comparison between the measured wave celerity curve and the theoretical curves based either on the small amplitude wave theory or on the solitary wave theory. From this diagram it is realized that the discrepancy between the measured one and the theoretical one based on the small amp-

Fig. 3 Radiation stress curves predicted by the various methods.

Fig. 4 Comparison between the measured and predicted wave height change.

Fig. 5 Comparison between the measured and predicted wave celerity change.

litude wave theory is not large in the offshore region, but becomes large in the nearshore region. However in the surf zone, the wave celerity can be predicted fairly well by the solitary wave theory.

CORRELATION BETWEEN SURFACE PROFILE AND VELOCITY FIELD

In order to investigate the detailed mechanism of wave-induced velocity field, the surface fluctuation and the fluid velocity components were measured at numerous locations in a laboratory flume (Fig. 6). Table 1 gives the conditions of laboratory experiments carried out for the present investigation. Figure 7 shows sample records of wave profile and the horizontal velocity component taken simultaneously. For the comparison, the stream function method and the 5th order Stokes wave theory were applied to the wave profile, and the time history of velocity components were calculated by these methods. In addition to these, the linear filter method was applied to calculate the velocity component from the wave profile. As for the wave profile, it is quite natural that the curves based on the stream function method agree well with the measured ones both outside and inside the surf zone. The 5th order Stokes wave theory gives fairly good results in the offshore region. As for the velocity component, the curves obtained outside the surf zone agree well with those based on either the Stokes wave theory or the stream function method. The linear filter is also applicable to calculate the velocity component near the bottom from the surface profile. On the other hand, the velocity component inside the surf zone has the following remarkable tendency. The velocity near the free surface measured at the location just after breaking differs largely from the predicted one, but the velocity near the bottom agrees well with the one predicted by using the stream function theory.

That is to say, in the region just after the breaking the turbulent fluctuation is very strong, therefore the simple prediction methods stated above are not powerful for our purposes, but the turbulent fluctuation does not penetrate down to the sea bottom. Of course, such situation is strongly dependent on the breaking type and the distance to the questioned point measured shoreward from the breaking point. The above fact indicates that the Reynolds stress of the turbulent fluctuation induced by breaking phenomenon should play an important role in the nearshore dynamics.

In the ordinary treatment on the wave set-up in the surf zone, the frictional term is conventionally neglected as shown in Eqs. (5) and (6). The frictional term consists of the bottom frictional and the lateral frictional terms, in which the latter term is the depth integral of the Reynolds stress. Based on the laboratory investigation data, the authors have the insight that the bottom frictional term averaged over many wave cycles does not contribute significantly to the wave set-up phenomenon due to the time-dependent oscillatory motion, while the lateral frictional term must have an important influence on the stated phenomenon. At the present stage, the data on this subject are extremely scarce, hence the further effort to accumulate laboratory and field data seems to be of essential importance.

FIELD OBSERVATION

In the foregoing discussion, the laboratory data were only used. In order to confirm the stated results, a part of the field observation data will be presented in the following.

Fig. 6 Location diagram of the measuring points.

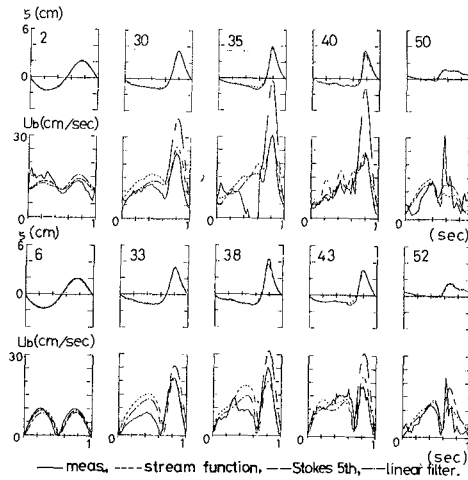

Fig. 7 Comparison of the measured time histories of wave profile and of corresponding absolute velocity with those predicted by the various methods (Case I).

A number of poles were installed closely in a row perpendicular to the shoreline inside the surf zone on Ajigaura coast, Ibaragi Prefecture, Japan, and the data of sea surface fluctuations at these poles were collected by using simultaneously operated 16mm memo-motion cameras. In some cases a frame was set in the surf zone. On this frame a certain number of electromagnetic current meters were attached in order to measure the vertical distribution of wave-induced current velocities. Hence the surface fluctuation and the corresponding velocity fluctuations were measured simultaneously.

Two records of surface fluctuations obtained at two points 2m apart in the direction perpendicular to the shoreline in the surf zone were picked up. The wave direction angle was negligibly small, hence the wave celerity could be calculated by the phase shift between these two records. The abscissa of the diagram shown in Fig. 8 is the frequency in Hz and the ordinate is the phase shift. Therefore the wave celerity is proportional to the slope of the curve. The plotted points fall on the theoretical curve based on the solitary wave theory, and this fact confirms the conclusion obtained in the laboratory investigations.

Figures 9 (a), (b), and (c) show the serial comparison between the time history of measured velocity components and those predicted by the various methods using the corresponding surface profiles. From these figures, it can be said in general that the stream function method is useful in field also for the prediction of velocity components outside the surf zone. However, the predicted velocity curves by the various methods are not always fit to the measured ones inside the surf zone. Especially it is remarkable that there is time lag between the calculated and measured velocity components.

Figures 10 (a) and (b) give the power spectra of water surface fluctuations at two points, one is located outside and the other is inside the surf zone. Figures 11 (a) and (b) indicate the power spectra of wave induced velocity components at the corresponding locations in Figs. 10 (a) and (b), where u_2 and v_2 are the onshore-offshore and alongshore components of velocity measured near the water surface, while u_4 and v_4 are near the sea bed. From these diagrams it can be observed that the turbulent velocity fluctuation is very weak outside the surf zone, but it is strong just after the breaking point especially near the surface. Looking at these data, the authors have tried to construct the following conceptual model of turbulent fluctuation in the nearshore area.

The turbulent fluctuation in the nearshore area is primarily generated by the wave breaking, therefore the turbulence outside the surf zone is negligibly small but that inside the surf zone is remarkably strong especially in the vicinity of the breaking point. The disturbance induced by the breaking waves penetrates into the body of water, and reaches slightly to the bottom. Therefore the distribution of the Reynolds stresses is negligibly small outside the surf zone, but is large enough to be considered inside the surf zone. It is needless to say that the wave-induced turbulence depends upon the breaker type, the running distance of breakers, and the depth below the water surface.

In addition to the above, it should be mentioned that the power spectra of velocity fluctuation inside the surf zone contain tremendously big spectral density in the low frequency part as shown in Fig. 11 (b) comparing with

Table 1 Experimental conditions.

Case	Incid. Wave Height H_i (cm)	Wave Period T (s)	H_o I_o	Breaker Type
I	3.5	1.0	0.025	Plunging
II	5.5	1.0	0.039	Plunging

Fig. B Wave celerity in the surf zone observed in field.

Fig. 9 Time history of horizontal velocity component. Comparison between the measured and predicted curves, where z is taken upward from the sea bottom, d the mean water depth at the measuring site, and \bar{u} the shoreward mean constant velocity. Thus u is the value subtracted the \bar{u} value from the actual velocity.

those for the outside of the surf zone as shown in Fig. 11 (a). This fact indicates that the low frequency (that is, long period) oscillation is predominant inside the surf zone as reported by Sasaki and Horikawa (1978).

THREE DIMENSIONAL CASE

LONGSHORE CURRENT VELOCITY DISTRIBUTION

In order to proceed the present discussion to the three dimensional case, longshore current velocity distribution will be treated. As Longuet-Higgins (1970) pointed out in his paper, the longshore current velocity is used to have its maximum at a certain point located between the shoreline and the breaker line. The velocity distributions in a wave basin have so far been measured under the various conditions of bottom slope, wave approaching angle, and wave characteristics. Through the analysis of these data, it was realized that the shoreward pattern of velocity distribution in the surf zone on a uniformly sloping beach fits very well with the one calculated under an appropriate value of P on the basis of the Longuet-Higgins analytical result. Here P is defined by Longuet-Higgins as a non-dimensional parameter representing the relative importance of horizontal mixing and lateral friction. However, the seaward pattern of the measured velocity distribution curve drops abruptly comparing with the theoretical one. One example is shown in Fig. 12. The above discrepancy is presumably caused by the following two reasons. The first reason is that the value of S_{xy} used for the calculation was derived by using the small amplitude wave theory. The second reason is that the expression for the lateral friction outside the surf zone was estimated to be too large comparing with the actual one. In addition to these, the effect of wave approaching angle can be pointed out as discussed independently by Liu & Darliple (1978) and Kraus & Sasaki (1979).

INTERNAL CHARACTERISTICS OF SURF ZONE

Izumiya, Isobe, Watanabe & Horikawa (1980) reported recently a detailed laboratory measurement of the internal characteristics of waves and wave-induced current in the surf zone. Their measurement was performed under such a simple condition as the longshore current being predominant on a fixed uniform slope of $1/20$ in a wave basin. The characteristic conditions of the waves are as follows: the wave height at the uniform water depth $h=25\text{cm}$ is 4.1cm , the wave period is 0.87s and the wave angle at the breaker line is 15° .

The fluctuation of velocity components were measured directly by using hot-film anemometers. Based on these laboratory data, they tried to evaluate how well the radiation stresses outside and inside the surf zone can be evaluated by using the appropriate theory, and to find out how much the lateral frictional term contributes to the balance in the dynamical equation.

The governing equation of the present case is expressed by

$$\frac{d}{dx} S_{xy} = R_y = -\frac{d}{dx} S_{xy} + \overline{\tau_{xy}} - \overline{\tau_{hy}} \quad (7)$$

where x and y are taken perpendicular and parallel to the shoreline respectively. In order to predict precisely the spatial velocity distribution of

longshore current, the characteristics of the two terms S_{xy} and R_y should be clarified in more detail. Equation (7) can be rewritten in the next form;

$$\frac{d}{dx} (S_{xy} + S_{xy}^{\prime}) = \overline{\tau_{xy}} - \overline{\tau_{hy}} \quad (8)$$

Here the new term $S_{xy}^{\prime} = S_{xy} + S_{xy}^{\prime}$ will be defined for the convenience of the following discussion.

It is quite natural that the record of current velocity components taken inside the surf zone is the superposition of the turbulent fluctuation generated by the breaking wave action on the wave orbital and steady current velocity components. In the forgoing treatment, the vertically uniform steady current is assumed, however the actual current must have a certain vertical distribution which is not yet clearly known. Considering the above fact, it should be noticed that the term S_{xy} in the paper reported by Izumiya, Isobe, Watanabe & Horikawa (1980) is not exactly equal to the radiation stress or the excess momentum flux defined by Longuet-Higgins & Stewart (1964). However, they reported that the calculated term S_{xy} is well expressed by the 5th order Stokes wave theory outside the surf zone.

Figure 13 indicates the variations of S_{xy}^{\prime} and S_{xy} from offshore to onshore. From this diagram, it is clearly seen that the $S_{xy}^{\prime} = S_{xy}^{\prime} - S_{xy}$ is zero outside the surf zone but is large enough to be considered inside the surf zone. In Eq. (8) the shear stress along the water surface $\overline{\tau_{xy}}$ is negligibly small, therefore the gradient of S_{xy}^{\prime} must be balanced with the bottom shear stress $\overline{\tau_{hy}}$.

The lateral frictional stress is used to be expressed simply to be proportional to the gradient of the longshore current velocity. However, it seems to be unreasonable that the proportionality constant becomes negative just after breaking as seeing from Figs. 12 and 13.

Here it should be noticed that the term S_{xy} takes its maximum at the location a little offshoreward from the breaking point. That is to say, the gradient of S_{xy} between that point and the breaking point determines the velocity distribution of longshore current outside the surf zone. The above mechanism is quite important to understand the real longshore current pattern.

Figure 14 demonstrates the spatial distribution of Reynolds stress $-\overline{u''v''}$ from which the statement made in the previous section can be confirmed.

CONCLUSIONS

The main conclusions of the present paper are summarized in the following:

- (1) It is quite naturally true that the small amplitude wave theory is not powerful to take the insight of the detailed mechanism of nearshore dynamics.
- (2) Therefore some appropriate theory or method should be applied to evaluate the dynamic characteristics of waves outside and inside the surf zone.

Fig. 12 Longshore current velocity distribution ($\tan\beta = 1/20$) (adapted from Izumiya, Isobe, Watanabe & Horikawa, 1980).

Fig. 13 Distribution curves of \bar{S}_{xy} and S_{xy} (adapted from Izumiya, Isobe, Watanabe & Horikawa, 1980).

Fig. 14 Distribution pattern of $pu''v''$ (adapted from Izumiya, Isobe, Watanabe & Horikawa, 1980).

- (3) The precise calculation of radiation stresses is of essential importance to predict the phenomena actually happening in the nearshore area,
- (4) The Reynolds stresses are negligibly small outside the surf zone, but is large enough to be taken into consideration inside the surf zone due to the strong breaking wave disturbance. Therefore the evaluation of Reynolds stresses in the surf zone is also needed to understand the various phenomena in the surf zone.
- (5) In order to clarify the detailed mechanism of nearshore phenomena, more data should be accumulated in laboratory as well as in field.

ACKNOWLEDGEMENTS

The authors would like to express their appreciation to the personnel at the Coastal Engineering Laboratory, University of Tokyo, for their effort to carry out the laboratory and field measurements. The present research was supported by the research grant of the Ministry of Education of Japan.

VELOCITY FIELD IN A STEADY BREAKER

by

J.A. Battjes¹⁾ and T. Sakai²⁾

ABSTRACT

An experimental investigation is described of the velocity field in a steady, spilling-type breaker, generated on a steady current by a submerged hydrofoil. Velocities have been measured with a laser-doppler system, and analysed with respect to mean and rms-values as well as Reynolds stresses. The results indicate that the turbulent flow field downstream of the initiation of the separation at the surface resembles that in a turbulent wake.

INTRODUCTION

Peregrine and Svendsen (1978) have proposed a model for the flow field in a class of steady and quasi-steady breaking flows such as hydraulic jumps, bores, and spilling breakers. They concluded from visual observations that the turbulent flow, immediately following the breaking, resembles a turbulent mixing layer, which arises because the smooth flow from upstream meets the relatively slowly moving water in the toe of a surface roller. This roller, which is small compared to the region of high-intensity turbulence, is believed not to play an important role in the dynamics of the wave, other than that it triggers the turbulence.

In Peregrine and Svendsen's model, the region of turbulent flow following breaking is supposed to spread downstream and downward as in a mixing layer; at some distance downstream the upper region becomes affected by gravity, and for waves in shallow water the lower region by the bottom. Still further downstream there is a so-called wake or decay region.

The usefulness of a model such as this is that it enables one to describe the main features of the turbulence induced by breaking in terms of better known classes of turbulent flows. However, the model is partly hypothetical. It is based on visual observations, which are largely qualitative. A more quantitative verification is still needed. It is the purpose of the present study to contribute to such verification, through the measurement and analysis of the mean flow, the turbulent intensities, the turbulent shear stresses, and their decay with distance downward and downstream.

The contents of the paper are as follows. The experimental arrangement and procedure are described first. This is followed by a presentation of the main results. These are subsequently discussed and compared with the model of a turbulent mixing layer and a turbulent wake. The conclusion is that the observed flow field appears to be predominantly like a turbulent wake.

This proceedings paper is kept rather brief. A more extensive presentation will be given in a forthcoming paper.

EXPERIMENTAL ARRANGEMENT AND PROCEDURES

Flow conditions

As stated in the introduction, the purpose of the present study is to investigate the turbulence induced by a breaking water surface, with special reference to the model proposed by Peregrine and Svendsen (1978) for the flow field in a class of steady or quasi-steady breakers. A partial check of the validity of that model can be obtained in a breaker in which the mean (non-turbulent) motion is steady. Such type of flow was used in this study, because its investigation is experimentally much simpler than that of non-steady flows, while at the same time it should yield useful information about the flow characteristics in quasi-steady breakers.

We have set out to obtain a steady breaker, which should be relatively unaffected by a bottom boundary layer, and the geometry of which should resemble that of a spilling breaker or a post-breaking bore on a beach. We have created such a flow condition by inserting a hydrofoil below the free surface of a steady flow in a laboratory flume (Fig.1).

Fig.1 - Sketch indicating flow condition and definition of reference frame

Under these conditions, there is no need for the entire upstream flow to be supercritical, or even to have a Froude number near 1. We could therefore choose a relatively large depth (larger than the critical

depth for the given maximum discharge), so as to obtain an extensive region in which the post-breaking turbulent flow near the free surface would not be affected by the proximity of the bottom. The maximum discharge in the flume is $0.50 \text{ m}^3\text{s}^{-1}$, and the flume width is 0.80 m; the corresponding critical depth is 0.34 m. The experiments were performed with a mean undisturbed flow depth (h) of 0.58 m.

Our ultimate interest is in "full-size" breakers, with high Reynolds numbers and intensive air entrapment. We have therefore chosen for as large dimensions and discharge as could be achieved in the available flume, so as to minimize scale effects. These experiments will be referred to as "full scale". The cross-sectionally averaged undisturbed flow velocity in these runs was 1.08 ms^{-1} . In addition, a few measurements were made in a so-called "half scale" run, which was a Froudian model of the full-scale situation, with a length scale of about 1:2, with the purpose of obtaining insight into possible scale effects. The numbers given in the following refer to the full-scale experiments.

The hydrofoil was chosen to have a relatively full profile. A NACA 6024 profile was used, with a maximum thickness of 4.8cm and a chord of 20.0cm.

In preliminary runs, the depth of the center of the hydrofoil below the undisturbed mean water level (d) and its angle with respect to the horizontal (α) were varied, in order to find conditions which appeared suitable to our purpose (as described above). For the values of mean depth and discharge mentioned above, useable flows were obtained for values of d from about 0.15 m to 0.30 m, and for values of α from about 5° to 20° . The final full-scale experiments were performed with $d = 0.21 \text{ m}$ and $\alpha = 15^\circ$ (see Fig.1).

Velocity measurements

Velocities were measured by means of a laser-doppler velocity (LDV) meter. Such meter works on the principle of measuring the Doppler frequency shift of a laser beam scattered by small particles in a moving fluid. It measures some average velocity value for a volume with a characteristic linear dimension of the order of 1 mm. In what follows these dimensions are ignored, and we shall refer to the measurements as "point" measurements.

The LDV system which was used operates in the reference beam mode. Laser beams were transmitted transversely through the flume (through the glass-panelled side-walls) and the water in it. The components radiating and detecting the signals were mounted in a fairly rigid frame over the flume, to maintain proper alignment. This frame could be moved in its entirety, along the flume as well as vertically.

If no light scattering is detected by the laser-doppler system, the output signal contains no information about the flow velocity. This situation is called "signal drop-out". In this experiment, the signal drop-out is most often induced by air bubble interruption of the laser beam near the breaking surface. The occurrence of drop-outs was accounted for in the data analysis.

The LDV system is capable of measuring two velocity components in one point simultaneously. We have measured the downstream component (u) and the vertical component (w , positive upward).

The outputs of the LDV were recorded simultaneously in an analog magnetic tape recorder (Bell Howell adr 1000). The recording time was 2 minutes per measurement point.

The velocity signals (u, w) were separated in their mean values (\bar{u}, \bar{w}) and the fluctuations about these means, (u', w') = (u, w) - (\bar{u}, \bar{w}). (Here and in the following, an overbar denotes a time average.) Estimates of $\bar{u}, \bar{w}, u'^{\text{rms}} = (\overline{u'^2})^{1/2}, w'^{\text{rms}} = (\overline{w'^2})^{1/2}$ and $\overline{u'w'}$ in all the measurement points were obtained using standard analog equipment. The procedures which were used in the analyses will be described in more detail in a forthcoming paper.

RESULTS

Measurements of (u, w) have been made in a number of points in the central verticals of flume cross-sections, at various distances (x) downstream of the center of the hydrofoil. The minimum distance used was $x = 0.33$ m, in the cross-section of the toe of the breaker (Fig.1). The maximum distance was 4 m. It was believed that beyond that too much bottom influence would occur.

A number of points in each vertical were used, with a height (z) above the flume bottom varying from 0.21 m (the minimum possible with the frame supporting the LDV apparatus) to somewhat below the free surface, where the signal drop-outs were judged to become too severe. Measurements were also made in the undisturbed flow, i.e. in absence of the hydrofoil.

The results have been plotted in two ways, vz , as a sequence of vertical profiles, and as isolines in the x, z -plane. For brevity, only the profiles of \bar{u}, u'^{rms} and $\overline{u'w'}$ are given here (Figs. 2, 3 and 4), as well as isolines of $\overline{u'w'}$ (Fig.5).

Data points of the full-scale experiments are indicated by crosses, and those of the half-scale experiments by open circles. The latter points have been scaled up from the measured values. The lengths have been multiplied with a factor 2. With a strict Froude scaling, the velocities should have been multiplied with a factor $2^{1/2}$. In fact, the ratio of the actually measured upstream mean velocities was used, which was about 1.6. The difference is due to a mal-adjustment of the discharge.

The full-scale data points have been connected by full-drawn straight-line segments for purposes of visualisation.

DISCUSSION

General trends

The half-scale results are in general in good agreement with the full-scale results. Significant deviations are present in all three profiles at $x = 0.47$ m, and in the $\overline{u'w'}$ - profile at $x = 0.60$ m as well. This matter has not been pursued in the present study, so that no conclusions concerning scale effects can be drawn other than that these appear to be absent in the region downstream of the cross-sections mentioned above.

The profiles in the lower right-hand corner of the Figs. 2 through 4 refer to the undisturbed flow conditions. It can be seen by inspection that the corresponding mean-velocity profile (Fig. 2) is virtually uniform in the upper part of the flow, while the turbulent shear stresses there do not deviate visibly from zero, when drawn on the same scale as the profiles for the flow with a hydrofoil (Fig. 4). This indicates a virtual absence of any influence of a bottom boundary layer in the upper flow region.

It is clear from Fig. 2 that the profiles of \bar{u} in the presence of the hydrofoil exhibit a strong defect near the breaking surface. This defect penetrates into the deeper region of the flow with increasing distance downstream, while at the same time it diminishes in magnitude. However, even at $x = 4$ m it is still clearly present, as can be seen by

comparing that profile with the one for the flow in absence of the hydrofoil.

At the most upstream cross-section, a slight velocity defect can be discerned at a height $z \approx 0.3$ m, which is an indication of the wake generated behind the hydrofoil.

Fig.3 shows that the turbulence has its greatest intensity near the toe of the breaking surface, from where it decays downward and downstream. At $x = 4$ m, the station farthest downstream, it is still significantly in excess of its value in the undisturbed flow. The wake of the hydrofoil shows up in Fig.3 as a slight excess of u'_{rms} .

The quantity $\overline{u'w'}$, which is proportional to the turbulent shear stress, has significant non-zero values only in a fairly well-defined upper layer downstream of the toe of the breaker. It is virtually zero in the cross-section of this toe ($x \approx 0.33$ m); no evidence of a wake behind the hydrofoil is present in this profile.

Altogether, the results shown in the Figs.2 through 5 clearly indicate the presence of a region of relatively high shear on top of a more or less undisturbed flow. The thickness of the shear layer increases in the downstream direction, while the mean-velocity defect and the turbulent intensity and shear stress decrease.

Comparison with wake and mixing layer

In the classical theory of turbulence a number of freely evolving shear flows has been studied, such as mixing layers, jets and wakes. In this section, the question will be considered to which extent the observed flow is similar to one of these.

A mixing layer forms the transition between two uniform parallel flows of different velocity, while a jet and a wake can be seen as laterally limited regions of velocity surplus and velocity deficit, respectively, relative to the undisturbed flow. In a mixing layer the cross-stream variation in mean flow velocity is constant in the downstream direction (if the two external flows have a sufficient lateral dimension), while this quantity decreases downstream in jets and wakes.

It follows from the above that the flow observed in our experiment, which is characterized by having a velocity deficit with respect to the undisturbed flow, which deficit is decreasing downstream, is qualitatively most nearly like a flow in a wake. This can be checked quantitatively, or at least semi-quantitatively, by estimating the values of some characteristic parameters and their variation downstream, and comparing this with the corresponding results for a typical wake flow. This is done in the following. We have also concluded some theoretical results for a mixing layer, since this was taken by Peregrine and Svendsen as a model for the initial phase of the post-breaking flow.

The quantities to be considered in the comparison are the mean velocity defect (\bar{u}_d), a characteristic value for the turbulent velocity magnitude (\bar{u}'), and a lateral length scale (l).

Asymptotic theoretical relations have previously been derived

between these quantities and their variations downstream, assuming a high Reynolds number (Re) and a nearly parallel, self-preserving flow, away from bounding surfaces. The results are asymptotic in the sense of $Re^{1/2} \gg 1$ and $l \ll L$, in which L is a longitudinal length scale, as well as in the sense that only the far field is considered, sufficiently far downstream from the physical origin of the shear layer, so that the flow has settled down to self-preservation. Some such results, taken from Tennekes and Lumley (1974), have been collected in Table 1, in which the symbol \sim indicates a proportionality, and $x = x - x_0$ is the downstream distance to some reference point $x = x_0$. (This point is near the physical origin of the shear layer. However, a theory for self preserving flow in the far field cannot predict the location of $x = x_0$ in terms of the details of the physical origin of the shear flow, since by definition a self preserving flow has no "memory" of those details.)

Table 1 - Downstream variation of characteristic parameters in free shear layers

	Mixing layer	Plane wake
\bar{u}_d	const.	$\sim x^{-1/2}$
l	$\sim x$	$\sim x^{1/2}$
\hat{u}'	$O\{(l/L)^{1/2}\}\bar{u}_d$ = const.	$O(\bar{u}_d) \sim x^{-1/2}$

Experimental values of \bar{u}_d , \hat{u}' and l were determined as follows. The mean velocity defect was calculated as $\bar{u}_d = \bar{u}_1 - \bar{u}_f$, in which \bar{u}_1 is the value of \bar{u} in the lowest point of measurement ($z = 0.21$ m), and \bar{u}_f the value of \bar{u} at the mean free surface elevation, as estimated by linear extrapolation of the upper part of the measured profile (see Fig.2). For \hat{u}' the maximum value of u'_{rms} in the vertical profile was taken, and l was defined as the depth of the shear layer, from the mean free surface elevation down to the region where there is a fairly abrupt transition between the region of high shear above and the more or less homogeneous flow beneath. The locations of these transition zones were estimated from the vertical distributions of $u'w'$; they have been indicated in Fig.4 by vertical arrows.

The most upstream cross-sections where meaningful estimates could be made were $x = 0.60$ m for \bar{u}_d and l , and $x = 0.90$ m for \hat{u}' (see Figs. 2, 3 and 4).

For a comparison of the observed downstream variations of \bar{u}_d , \hat{u}' and l with the theoretical ones, it is necessary to have an estimate of the location of the reference point for the downstream distance, $x = x_0$. This point is expected to be near the point of initiation of breaking, $x = x_b \approx 0.33$ m (see Fig.1). A more exact estimate is not necessary if one considers points far downstream ($x-x_0 \gg |x_0-x_b|$), but since our measurement points may not fulfill this condition it is worthwhile to

allow x_0 to differ from x_b .

A value of x_0 can be determined so as to optimize the fit of the data points to some theoretical model. We have not done this numerically; we found by visual inspection that $x_0 = 0.5$ m gives results (see Fig.6) which appear to be consistent with the asymptotic theory for a plane wake: u_d and u' both vary approximately as $(x-x_0)^{-1/2}$ and l varies approximately as $(x-x_0)^{1/2}$ (excluding the most upstream measurement of l). Based on these results, we conclude that the flow downstream of the breaking surface is not only like a wake flow in a qualitative sense, but also in a more quantitative sense.

A quantitative comparison of our observations with the theoretical model of a mixing layer was not attempted in view of the observed downstream decrease of u_d and u' , which is absent in the classical mixing layer model.

CONCLUSIONS

Measurements have been made of horizontal and vertical velocities, including turbulent fluctuations, in a steady mean flow with a breaking surface, similar to a so-called spilling breaker in shallow water. These measurements have given rise to the following conclusions:

- (1) A region downstream of the initiation of breaking can be recognized in which the flow evolves as in a free self-preserving turbulent wake. This conclusion rests on the observed downstream variation of mean velocity defect, turbulence intensity, and shear layer thickness.
- (2) The region mentioned in (1) is bounded above by the free surface, which is more or less horizontal because of gravity. The lateral (= vertical) spreading of the shear layer occurs mainly in the downward direction. The flow can therefore be compared to that in one half of a symmetric wake.
- (3) The measurements of the flow in the region mentioned in conclusion (1) appear to be free of scale effects if scaled up according to Froude's law.
- (4) If -as hypothesised by Peregrine and Svendsen (1978)- there exists a region immediately downstream of the initial breakpoint, in which gravity is unimportant, and in which the flow is similar to that in a mixing layer, then such region is small compared to the overall vertical dimensions of the breaker. The model of a mixing layer does not appear to be useful for the prediction of the downward and downstream spreading of the turbulence induced by the breaker, over distances of the order of the breaker height or layer.

CHAPTER 32

THE FLUID MECHANICS OF WAVES APPROACHING BREAKING

by

D. H. Peregrine¹

E. D. Cokelet²

P. McIver³

Abstract

Numerical computations of water waves deforming until an overhanging, incipient jet has formed near the crest are studied in detail. Velocity and acceleration plots lead to the identification of three regions in the water which appear to be significant in the approach to breaking. In particular there is a region with particle accelerations greater than the acceleration of gravity.

1. Introduction

The initial stages of a plunging breaker are described from calculations by Longuet-Higgins and Cokelet (1976). They succeeded in computing the motion of particles on the surface of deep-water waves which are periodic in space. Similar computations are the basis of the present work which considers the flow properties in more detail.

The mathematical model is for irrotational flow. The viscosity, the surface tension and the density of the fluid above the free surface are all taken to be zero. The only physical quantities which are present in the flow are the fluid's inertia and gravity. This appears to be quite sufficient since realistic looking results are obtained up to a time when a portion of the surface near the wave crest has been projected forward as an overhanging incipient jet. The numerical scheme then loses accuracy rapidly, apparently because the surface curvature has become too large for the method to resolve without more points along the wave profile.

Waves can be forced to break in several different ways. For these deep-water waves Longuet-Higgins and Cokelet (1978) describe how a small growing, normal-mode perturbation grows until waves break, and Cokelet (1979) shows how sinusoidal waves of sufficient initial amplitude also break, even if their energy density is less than that of the highest wave. Longuet-Higgins and Cokelet (1976) used a pressure distribution

Figure 1. Surface profiles for $\pi \leq t \leq 22\pi/15$, $p_0 = 0.20$.

imposed on the free surface for a limited time to drive the waves to break, and the same set of solutions are considered in more detail here. Full details of the method are to be found in that paper.

Details relevant to this work include the units used and the particular initial and forcing conditions. Units are made dimensionless using the fluid density, the acceleration due to gravity and the wave number of the waves. That means the waves have wavelength, $L = 2\pi$, and the phase velocity and radian frequency of infinitesimal waves of that wavelength are equal to one. The infinitesimal wave period is 2π . The initial conditions are an accurate, steadily-progressing wave of steepness $H/L = 0.13$, or $ak = 0.40$, which may be compared with the values 0.14, or 0.43, for the steepest wave.

The wave forcing is by a sinusoidal pressure pattern travelling at the same speed as the initial wave, in quadrature with the wave profile to give an energy growth and smoothly applied for $0 < t < \pi$. The value, p_0 , of the maximum pressure used is a useful parameter for identifying particular cases.

2. Surface Profiles and the Flow Field

Some profiles of the surface for $p_0 = 0.0729, 0.100, 0.126$ and 0.146 are given by Longuet-Higgins and Cokelet (1976). A sequence of profiles for $p_0 = 0.200$ are shown in Figure 1. This figure shows a succession of wave profiles in the reference frame which has water at depth at rest. The paths of surface particles are indicated by dotted lines. The extra partial profile indicates the last calculations which we consider to be reliable for both particle displacements and velocities (see Sec. 3).

A good way to illustrate the velocity field of an irrotational flow is by the use of equipotentials and streamlines. Cokelet (1979) outlines how to calculate these inside the fluid from surface-evaluated quantities using Cauchy's theorem. Figure 2 shows such isolines for a full wave profile with the fluid at rest at great depth, and Figure 3 gives details near the crest at a slightly later time. These are not as informative as such diagrams for steady flows since the approach to breaking is unsteady. The fluid does not travel along fixed streamlines, but rather the flow is instantaneously tangent to changing streamlines.

Clearly it would be an improvement to consider flow in a reference frame moving with the wave crest. However there is no unique velocity that can be chosen. Any particular feature of the wave could be used to define a velocity, but that velocity would be unsteady. In Figures 4 and 5 we have chosen to view the flow of Figures 2 and 3 in a reference frame moving with the speed of the original steady wave. This gives another, possibly clearer, picture of the motion, and there are some indications that this particular reference frame is of especial relevance. This aspect is being studied further.

Figure 2. Equipotentials (dashed) and streamlines (solid) at $t = 4.61$ for $p_0 = 0.146$ in a frame of reference with water at great depth at rest. The box at upper right represents contour spacing corresponding to a dimensionless velocity of 1.

Figure 3. As for Figure 2 but near the crest at $t = 4.82$.

Figure 4. Equipotentials (dashed) and streamlines (solid) at $t = 4.61$ for $p_0 = 0.146$ in a frame of reference moving with speed $c = 1.082$ relative to water at great depth.

Figure 5. As for Figure 4 but near the crest at $t = 4.82$.

3. The Hodograph Plane

The search for a relevant reference frame leads to consideration of the hodograph plane. That is the (u,v) plane where u and v are, respectively, the horizontal and vertical components of velocity. A change of reference frame by a Galilean transformation (i.e. involving only a uniform constant relative velocity) corresponds only to a change of origin in the (u,v) plane. Thus the character of the (u,v) trajectory for any particle, or of the (u,v) "profile" of surface particles at any instant is unchanged. For a motion which is steady in some Galilean reference frame the trajectory of surface particles is the same as the profile of those particles at any instant. For example, it is a circle for infinitesimal waves on deep water.

To help the reader appreciate the hodograph plane in this context Figure 6 shows the surface particle trajectory/profile for the initial steady wave. The origin in this example corresponds to water at depth. Different portions of the wave are labelled. The crest-trough asymmetry is clear.

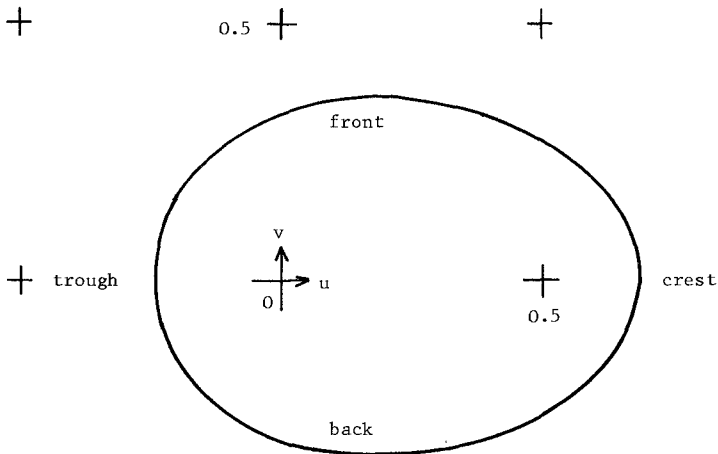

Figure 6. The hodograph plane for surface particles on a steady wave, $H/L = 0.13$, $ak = 0.40$.

The (u,v) profiles of the surface of waves approaching breaking are shown in Figures 7 and 8 together with some of the (u,v) trajectories of surface particles.

There are several features to note in these figures. Firstly each successive profile differs from its predecessor, especially on the front and crest of the wave. Secondly the magnitude of the maximum velocities continually increases. In particular the maximum horizontal velocity component soon exceeds one, the phase velocity of infinitesimal waves, and also 1.093 the maximum phase velocity of waves of this wavelength.

Further, the rate of increase of velocity also increases. That is, the acceleration of some particles increases. These particles are on the front of the wave. The dynamical importance of particle acceleration leads us to draw the corresponding profiles and trajectories in the acceleration plane (see the next section).

The last profile illustrated is not smooth. This indicates that the numerical method becomes inaccurate probably because the surface curvature is too great to be resolved by 60 points along the wave profile. This happens only in the region where a jet is beginning to form. Further development in time can be computed. The particle positions in the (u,v) plane, and eventually in space, become more irregular but do follow a general pattern similar to that which is to be expected for a jet. That is, particles converge towards a free fall trajectory which has a constant horizontal velocity component and a uniformly accelerating downward velocity component.

An envelope of trajectories and profiles is a prominent feature of Figure 8. It cannot be considered as typical since it does not occur in Figure 7. However, one point of that envelope is noteworthy. From the smoothness and continuity of the curves it is easy to deduce that one particle trajectory approaches the envelope and then recedes away from it without any tangential component along the envelope at the instant it touches. This is clear since some particles move to the left and some to the right. At the instant this particular particle is at the envelope it has zero acceleration. As may be seen in the next section there is nothing special about the value zero, but it is representative of a region of water of low acceleration.

Figure 7. The hodograph plane for $p_0 = 0.10$. The full lines are surface profiles for $\pi \leq t \leq 5\pi/3$, the dotted lines are trajectories of surface particles and the broken line is the initial profile.

Figure 8. The hodograph plane for $p_0 = 0.20$, $\pi \leq t \leq 3\pi/2$.

4. The Acceleration Plane and Pressure

The hodograph plane indicates both large and small particle accelerations. It is particle accelerations that are important in dynamics and it has proved instructive to draw surface profiles and particle trajectories in the particle acceleration plane (Du/Dt , Dv/Dt). As a guide Figure 9 shows the surface profile and particle trajectories of the initial progressing wave. These are coincident as in the hodograph plane. The crest-trough asymmetry is also clear.

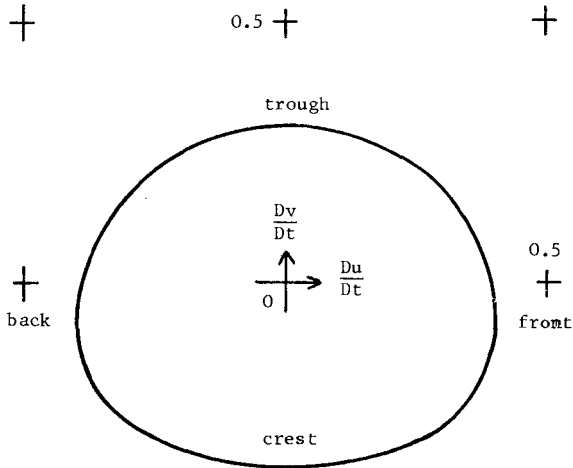

Figure 9. The particle acceleration frame for surface particles on a steady wave, $H/L = 0.13$, $ak = 0.40$.

For the approach to breaking the particle trajectories and surface profiles of acceleration show very large departures from the steady-state, as Figures 10 and 11 show. These are for the same two examples as the hodograph plane of Figures 7 and 8. The greatest reliably computed accelerations are so large, e.g. (4.3, -2.0) for Figure 11 that they have been left beyond the margins of the figures rather than reduce the scale of the more complex region illustrated.

The region of high accelerations, i.e. accelerations greater than gravity, is the dominant first impression from these figures. The region in (x,y) space which has these accelerations is the steep front portion of the wave just below the crest. In that region, water which was originally in the trough travelling towards the crest is accelerated in a relatively short time until it is travelling with or faster than the crest. It is thus not surprising that the largest component of acceleration is in a horizontal direction.

Figure 10. The particle acceleration plane for $p_0 = 0.1$. The full lines are surface profiles at times $\pi \leq t \leq 8\pi/5$. The dotted lines are particle trajectories, the broken line is the initial profile.

Figure 11. The particle acceleration plane for $p_0 = 0.2$, $\pi \leq t \leq 43\pi/30$.

In all these cases the direction of large accelerations is such that it is directed away from the surface. This implies there is no tendency to a Rayleigh-Taylor instability which occurs if the total acceleration field is directed into the fluid. The downward accelerations which are greater than gravity are for overhanging parts of the free surface so they do not contradict this statement.

For water to receive a large acceleration there must be a corresponding large pressure gradient. At all surface points the pressure gradient is normal to the surface and directed inwards since the pressure is zero at the free surface. Figure 12 is a vector diagram of the equation of motion,

$$\rho \frac{Du}{Dt} = -\nabla p + \rho g$$

to illustrate this.

Figure 12. The equation of motion at the free surface.

The quantity $p + \rho gy$ is a good indicator of acceleration since it is a particle-acceleration potential,

$$\rho \frac{Du}{Dt} = -\nabla(p + \rho gy).$$

Figure 13 shows a contour plot of $p + \rho gy$ near the crest of the wave of Figures 2 and 4. The large gradients below the crest are clear. The direction of acceleration is perpendicular to the contours and is directed away from the closed contour. When the jet reaches a state of free-fall the particles must be at $(0, -1)$ in the acceleration plane.

A region of low acceleration shows clearly at the crest and its back in Figure 13 which includes a point of zero acceleration, and the same feature is also clear in Figures 10 and 11. Figure 11 includes the zero-acceleration point passing through the surface profile but also indicates that it has no special place in the acceleration plane.

Figure 13. Lines of constant acceleration potential at $t = 4.61$ for $p_0 = 0.146$. The pair of parallel lines at upper right indicate the spacing for an acceleration equal to that of gravity.

Figure 14. The pressure distribution at $t = 4.82$ for $p_0 = 0.146$.

The low acceleration region has a pressure distribution little different from hydrostatic. This particular region might be thought of as providing a "support" for the strong pressure gradient accelerating the front of the wave.

The pressure distribution for much of the flow at one time is shown in Figure 14. One aspect of it is relevant to the interpretation of pressure measurements beneath waves. The maximum of pressure at any level shows a significant variation of phase with depth. This means that the usual deductions about free-surface shape from pressure measurements are likely to be in serious error for waves at or near breaking.

5. Concluding Discussion

Analysis of the velocities and accelerations of a wave approaching breaking indicates three features that may be important in its dynamics. These are regions with:

- (i) a velocity greater than the maximum phase velocity for that wavelength,
- (ii) water particle accelerations greater than gravity,
- (iii) low particle accelerations.

All these three regions become evident well before breaking is indicated by the presence of a projecting jet. The extent of these regions at the time at which the wave face becomes vertical is indicated in Figure 15. The development of the regions in time is indicated in Figure 16.

Figure 15. The crest of a wave at $t = 4.61$ for $p_o = 0.146$.
 Region (i) $u > 1.09$, (ii) $|\underline{Du}/Dt| > 1$,
 (iii) $|\underline{Du}/Dt| < 0.33$.

Figure 16. Properties of wave approach to breaking $37\pi/30 \leq t \leq 46\pi/30$, $P_0 = 0.146$.

Each of these regions could be defined slightly differently, and although with a given set of bounding conditions the appearance of one may precede another there is no clear indication that any one appears first. For example, for $p_0 = 0.146$ at $t = 3.87$, the horizontal velocity has just exceeded 1.10, the maximum acceleration has reached 0.98 and the minimum acceleration is 0.30.

Some surprise has been felt at the maximum accelerations calculated, though once the flow is considered carefully they are entirely consistent. It would be interesting to have confirmation from experiments or observations of water waves, but accelerations are difficult quantities to measure in a difficult environment for instruments. A small, freely floating accelerometer may be the best direct approach to measuring them.

The influence of the high accelerations on any fixed object in the path of a breaking wave could also be important. Not only is there a drag force due to the velocity but also an inertial force due to the strong pressure gradient. In addition both these forces act in nearly the same direction, whereas for a steadily progressing wave the accelerations and velocities are more or less perpendicular to each other.

Only a few examples of waves approaching breaking have been examined in detail, and it is certain that the features described here do not occur in all breaking waves. However, for plunging breakers we have examined other examples and found reasonable agreement with the above description.

1. INTRODUCTION

In fluid mechanics, a powerful tool known as the similarity model has been applied successfully to describe velocity and pressure fields in steady boundary layer flows, jet flows and wake flows. These flows, with the exception of a few laminar cases, are quite complex and are usually not amenable to theoretical analysis. The similarity analysis offers an alternative and often provides useful engineering information on the mean flow characteristics. The present work explores the possibility of applying the similarity concept to describe the flow field of breaking waves in the surf zone.

Before presenting the similarity solution, a non-dimensional surf zone parameter is examined. This parameter, in addition to its many implications of characterizing surf zone properties, is pertinent to defining the region of validity of the similarity solutions. Solutions on mean flow characteristics are then established based upon a similarity hypothesis which states that the profiles of flow properties such as velocity and wave form preserve geometrical similarity downstream from the source of the disturbance and, therefore, can be defined by a few local characteristic parameters. Conditions required to preserve similarity are examined. Finally, laboratory results from a number of studies (Flick, 1978; Svendsen et al., 1978; Sakai and Iwagaki, 1978) and those from the authors are used to test the validity of the proposed model.

2. SURF PARAMETER

Considering a single long-crested wave breaking on a beach of uniform slope, say $\tan \alpha$, the cyclic breaking process can be approximately divided into three stages as illustrated in Fig. 1. The developing stage covers the period when the wave begins incipient breaking at the crest until it collapses on the beach in the vicinity of the water level unit. During this stage, the shape of the wave evolves from a highly asymmetric curled form to a triangular form with numerous white caps. Its potential energy is converted into kinetic energy which in turn is partially dissipated as the remaining portion preserved to stage the upwash. In the second stage, the flow surges

up to its runup limit similar to a solid element moving up-slope while the kinetic energy is being converted back to potential energy. In the last stage, the flow washes down as a thin sheet to the breaking point to complete the cycle.

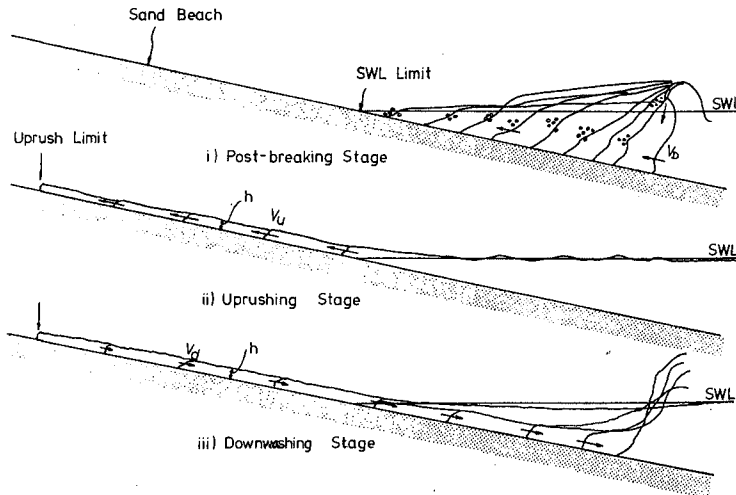

FIGURE 1. ILLUSTRATION OF BREAKING PROCESS.

The time required to complete each respective stage can be estimated based upon a simple energy model shown in Fig. 2. This energy

FIGURE 2. ENERGY CONSIDERATION OF BREAKING WAVE.

model is based upon the premise that the fluid element at the crest of the wave during breaking remains at the crest and is the same element that reaches the runup limit. This condition is clearly observed from recorded slow-motion films.

If the kinetic energy of the fluid element at the wave crest at the breaking point is assumed to be proportional to the breaking height, say $k_1 H_b$, then the kinetic energy in the developing stage can be expressed as

$$KE(x) = k_1 H_b + (S_2 - S_1)x \quad (1)$$

where S_2 and S_1 are the slopes of the total energy line and potential energy line, respectively. The velocity of the fluid element is

$$v_D(x) = \sqrt{2g[k_1 H_b + (S_2 - S_1)x]} \quad (2)$$

and the corresponding time required for the element travelling from the breaking point to the water level limit is

$$\begin{aligned} t_D &= \int_0^{x_D} \frac{dx}{v_D(x)} \\ &= \frac{\sqrt{2}(\sqrt{k_2} - \sqrt{k_1})}{k(k_2 - k_1)} \frac{H_b^{1/2}}{g^{1/2} \tan \alpha} \end{aligned} \quad (3)$$

where k_2 and k are constants of proportionality as defined in Fig. 2.

During the uprush and downwash stages, the crest element can be treated as a solid body moving on a sloped plan. In such cases, we have the following relationship on the basis of Newton's second law:

$$\mp Mg \sin \alpha - \rho f A_o \frac{v|v|}{8} = M \frac{dv}{dt} \quad (4)$$

where f is a frictional coefficient and A_o is the contact surface area; the "-" sign corresponds to the uprush condition and the "+" sign the downwash case. If we let $M = \rho t_h A_o$ the above equation simplifies to

$$\mp g \sin \alpha - \rho f \frac{v|v|}{8t_h} = \frac{dv}{dt} \quad (5)$$

where t_h is the thickness of the runup water sheet. Equation (5) can be integrated to obtain the uprush and downwash time which are, respectively,

$$t_u = \left(2\sqrt{\frac{k_2}{\beta}} \tan^{-1} \sqrt{\frac{\beta}{2}}\right) \frac{H_b^{1/2}}{g^{1/2} \tan \alpha} \quad (6)$$

and

$$t_d = 2\sqrt{\frac{k_2}{\beta}} \exp\left(\frac{\beta}{4} \frac{k_3 + \frac{1}{k_2}}{k_2}\right) \frac{H_b^{1/2}}{g^{1/2} \tan \alpha} \quad (7)$$

where

$$\beta = \frac{fV_0^2}{4t_h \sin \alpha}$$

and k_3 is a runup coefficient as shown in Fig. 2.

Based upon Eqs. (3), (6), and (7), the swash period of a single wave can be determined:

$$T_n = K \frac{H_b^{1/2}}{g^{1/2} \tan \alpha} \quad (8)$$

where

$$K = K_1 + K_2 + K_3$$

with

$$K_1 = \frac{\sqrt{2}(\sqrt{k_2} - \sqrt{k_1})}{k(k_2 - k_1)}$$

$$K_2 = 2\sqrt{\frac{k_2}{\beta}} \tan^{-1} \sqrt{\frac{\beta}{2}}$$

$$K_3 = 2\sqrt{\frac{k_2}{\beta}} \exp\left(\frac{\beta}{4} \frac{k_3 + \frac{1}{k_2}}{k_2}\right)$$

Therefore, the natural swash period is found to be a function of

$\frac{H_b^{1/2}}{g^{1/2} \tan \alpha}$. We now define a non-dimensional surf zone parameter as the

ratio of natural swash period to the incoming wave period (T):

$$I_w = \frac{T_n}{KT} = \frac{H_b^{1/2}}{g^{1/2} T \tan \alpha} \quad (9)$$

This non-dimensional parameter has the same form as the one suggested by Iribareu and Nogales (1949) to define breaking criterion. Battjes (1974), through dimensional reasoning, came to a similar non-dimensional parameter, which he amplified its significance to a variety of surf zone phenomena, including breaking type classification, set-up and set-down, etc. In here, we add another physical implication which can be explained as follows:

The I_w is the surf zone interference index. When I_w is small, each individual wave will complete the swash cycle with little or no interference from the successive waves. The flow in the swash zone is mainly oscillating and the breaker is of the plunging type. When I_w increases, the degree of interference from successive waves also increases; a circulatory motion is gradually developing which will result in a return flow in the main water column; the breaking phenomenon gradually transforms from plunging to spilling. This sequence of events is illustrated in Fig. 3.

This surf parameter also seems to play an important role in the similarity model to be presented in the following sections.

FIGURE 3. BREAKER CLASSIFICATION BASED UPON I_w .

3. BREAKING WAVE SIMILARITY

For a wave train of single frequency shoaling on a beach, a more or less amount of energy is being transferred from the primary wave component to its higher harmonics. The amplitude dispersing among harmonics coupled with phase lags developed due to differential shoaling of each harmonic component results in a highly asymmetric wave form upon breaking.

After breaking, as the wave travels further inshore, the wave form tends to stabilize although it remains asymmetrical. The conventional higher order wave theories are no longer adequate to describe these asymmetrical wave forms. A variation would be the introduction of phase angles among harmonic components such that the water surface fluctuation is expressed as

$$\eta(t) = \sum_{n=1}^{\infty} a_n \sin(n\sigma t + \phi_n') \quad (10)$$

where a_n is the nth harmonic amplitude; ϕ_n' is the nth harmonic phase and σ is the fundamental frequency.

Equation (10) most certainly can be used to prescribe the wave form of any particular set of breaking waves. Yet, it serves little useful engineering purpose if the solution cannot be generalized. If we assume that (1) each harmonic amplitude is limited by the local water depth, and (2) the phase velocity of each harmonic is also depth limited, then, we have

$$a_n = \alpha_n (d + \bar{\eta}) \quad (11)$$

and

$$c_n \propto \sqrt{g(d + \bar{\eta})} \quad (12)$$

where $\bar{\eta}$ is wave setup. Equation (10) can now be expressed as:

$$\frac{\eta(t)}{d + \bar{\eta}} = \sum_{n=1}^{\infty} \alpha_n \sin(n\sigma t + \phi_n) \quad (13)$$

where α_n 's are non-dimensional coefficients and ϕ_n 's are constant phase angles. Thus, the wave profile remains similar and its magnitude is affected only by a local parameter $(d + \bar{\eta})$.

In shallow water, if we express the depth averaged horizontal velocity in terms of η , we have

$$u(t) = \frac{C\eta(t)}{d} + \text{higher order terms of } \eta \quad (14)$$

recognizing that the net contribution of the higher order terms is a

mean return flow in the water column, Eq. (14) becomes

$$u(t) = \frac{C\bar{\eta}(t)}{d} - \bar{U}_R \quad (15)$$

The fact of having a similarity solution of $\eta(t)$, leads to the following similarity solutions for $u(t)$:

$$\frac{u(t) + \bar{U}_R}{C(1 + \frac{\bar{\eta}}{d})} = \sum_{n=1}^{\infty} \beta_n \sin(n\sigma t + \psi_n) \quad (16)$$

where β_n and ψ_n are constant coefficients.

Since C can be approximated by

$$C = \kappa\sqrt{g(d + \bar{\eta})} \quad (17)$$

we have

$$\frac{u(t) + \bar{U}_R}{\kappa\sqrt{g(d + \bar{\eta})} (1 + \frac{\bar{\eta}}{d})} = \sum_{n=1}^{\infty} \beta_n \sin(n\sigma t + \psi_n) \quad (18)$$

The solution $u(t)$ now depends only upon certain local parameters d , $\bar{\eta}$ and \bar{U}_R .

4. LABORATORY EXPERIMENT

To check the validity of the similarity solutions, experiments were conducted in a wave tank shown in Fig. 4. Water surface variations and horizontal particle motions were measured at four stations inside the surf zone on a smooth beach with a slope $m = 0.1$. The waves were measured by motion pictures and the horizontal particle velocity was measured by an air bubble system following the same principle as the hydrogen bubble system for flow visualization (for detailed measurement techniques see Yang, 1980). Since the wave flow field is unsteady, the dynamic response of an air bubble is established as shown in Fig. 5.

A total of ten sets of experiments were conducted. The test conditions are summarized in Table 1.

5. RESULTS

The wave amplitude coefficients, α_n , and wave phase coefficients, ϕ_n , of the first five harmonics are shown in Fig. 6 plotted against the surf parameter, I_w . The phase angles are adjusted so that $\phi_1 = 0$. These data are quite scattered but the trend is clear. Both α and ϕ become constant when I_w becomes large. Since a large I_w corresponds to a spilling breaker, the results seem to indicate a similarity solution,

if exists, would be in the spilling breaker region where I_w is larger than 0.9. In the case of horizontal velocity, the amplitude and coefficients are plotted against I_w as shown in Fig. 7. These data reveal that the similarity solution also yields reasonable approximations for large I_w . In fact, the similarity approximations for velocity seems to extend to regions of smaller I_w than the corresponding region where the similarity solution of η becomes valid, i.e. velocity profile approaches similar form as early as the transition flow zone, whereas the surface profile will not become similar until spilling breaker condition is attained.

Figure 8 plots the non-dimensional surface variation for various experiments. In there, data from Svendsen et al. (ISVA, 1978) and Sakai and Iwagaki (1978) are also shown. Both Svendsen's and Sakai's data are well within the spilling breaker region (I_w ranging from 1.12 to 2.27). Their test conditions are listed in Table 1. All the data sets seem to exhibit a gross similarity feature. A closer examination of these profiles reveals that the fine features of similarity vary for data sets obtained by different investigators. These variations can best be explained with the aid of Table 2 where the statistics of the coefficients in the similarity solution are tabulated. First of all, the standard deviations of the amplitude coefficients are all very small (no more than 4% from the mean), which means the similarity solution is good in the region specified. On the other hand, the absolute value of α 's are different. The present laboratory value data and Sakai and Iwagaki's values are very close. They both differ somewhat from ISVA's values. The relative importance of each harmonic component can be assessed from the values listed under $\alpha/\Sigma\alpha$. For instance, the fundamental component has a value of 0.4 to 0.5. The total contribution due to harmonics higher than third is usually less than 20%. In terms of wave height, the effect of these higher harmonics is insignificant because of the phase shift. In terms of energy, their contributions are even less. The relative importance of the first three harmonic components is quite consistent among the three sets of data. The results of phase angle are somewhat unexpected. All the data show that the second harmonic leads the first harmonic and the third harmonic leads both first and second. One would expect the other way around as the higher harmonics should have smaller phase velocities. The values of phase coefficients are very close for the Delaware and ISVA data. They both differ from Sakai and Iwagaki's value. This point is further examined later.

Figure 9 illustrates the non-dimensional velocity profiles. The statistics of velocity harmonics are also tabulated in Table 2. In here, the fundamental component dominates the others. The higher component lags the successive lower component as expected. However, these phase lags are all very small. The combined effects of dominant fundamental components and small phase shift result in a more symmetrical profile than that of wave forms. The same kind of results have been obtained by Flick (1978) and Thornton (1976). A tentative explanation has been offered on the reasoning that bottom and internal frictions tend to dampen the higher wave components at a fast rate. The experimental data also show here that the peak horizontal velocity always lags the peak water surface variation such as illustrated by an example in Fig. 10.

FIGURE 10. COMPARISONS OF SURFACE AND VELOCITY PROFILE.

As the wave breaks on a slope, the motion appears to be quite disorderly. When the breaking wave proceeds up-slope, it gradually regains its regular appearance. The question is how far shoreward from the breaking point beyond which the similarity solution can be considered adequate. For this purpose, the phase angles are plotted against the non-dimensional depth d/d_b and d_b the depth at the breaking point. Four sets of data from different investigators are defined in terms of cosine phase lag, i.e.,

$$\eta = \sum_{n=1}^{\infty} \alpha_n \cos(n\omega t + \zeta_n) \tag{19}$$

FIGURE 11. VARIATIONS OF PHASE COEFFICIENTS AS A FUNCTION OF d/d_b .

The relationship between ζ_n and ϕ_n , which is defined as the sine phase lag, is

$$\zeta_n = (n - 1) \frac{\pi}{2} + \phi_n \quad (20)$$

These phase coefficients are shown to vary slowly with d/d_b and approach limits at $\pi/2$ intervals when $d/d_b \rightarrow 0$. Since the profiles measured by Sakai and Iwagaki are near the breaking point, the results in this figure explain why they differ from that of the present experiment and that of ISVA; both were carried out in the inner zone where $d/d_b < 0.7$.

To utilize the similarity equations to describe the breaking wave properties one must have knowledge of \bar{U}_R and κ as appeared in Eq. (18). At present, we are unable to predict either. The experimental results of these quantities are, however, shown in Figs. 12 and 13 respectively. It appears that the return flow strength increases with increasing I_w but gradually reaches a constant in the spilling breaking region. The κ value, on the other hand, decreases with increasing I_w . Since κ is actually the ratio of wave celerity and \sqrt{gd} , the results are the consequence that spilling breakers travel slower than plunging breakers.

6. CONCLUSIONS

Assuming both the water surface variations and the depth-averaged horizontal particle velocities in the surf zone can be expressed by the summation of Fourier components, similarity solutions are proposed here. These solutions are based upon a pair of rather restrictive conditions; namely, both the amplitude and the phase velocity of each harmonic component are depth limited. The solutions, however, offer the advantage of being simple and completely defined by a few local flow parameters.

Laboratory data from a number of investigators including those obtained by the authors are used to test the validity of the proposed solutions.

The results seem to suggest that the similarity solution is not universally applicable. However, if the wave is of the spilling type and is far inshore in the inner breaking zone, the similarity solution becomes suitable to describe the mean flow characteristics. These

conditions can be defined in terms of a surf parameter $I_w = \frac{H^{1/2}}{g^{1/2} T \tan \alpha}$

and a relative depth parameter d/d_b . The region of suitability is found to be when $I_w > 0.9$ and $d/d_b < 0.6$. In this region, both surface profile and horizontal velocity can be adequately described by the first three harmonics. The velocity profile is found to be less asymmetric than the surface profile.

For surface profile, the higher harmonics lead the lower ones whereas the contrary is true for the velocity profile.

CHAPTER 34

VELOCITY AND PRESSURE FIELD OF SPILLING BREAKERS

M.J.F. Stive¹⁾

ABSTRACT

The internal velocity and pressure fields of quasi-steady spilling breaking waves have been investigated experimentally. The internal flow fields are shown to be in qualitative agreement with a model proposed by Peregrine and Svendsen (1978). Furthermore a quantitative comparison is made with non-breaking wave theories. Measurements of the pressure field are presented, and interpreted semi-quantitatively using the vertical momentum balance. Finally, it is shown how the integral properties can be obtained and analysed.

1. INTRODUCTION

The surfzone water motion is a topic that deserves and receives a lot of theoretical and experimental investigation. However, in experimental studies of the surf zone measurements have generally been restricted to the external characteristics, i.e. the instantaneous and time mean surface elevations. It is conspicuous that the internal kinematics of breaking waves have received little experimental attention. It is also conspicuous that the experimental study of the energy dissipation and the momentum flux variation is literally "superficial". Based on measurements of the internal kinematics and dynamics a more fundamental approach is possible, e.g. gradients in the momentum flux can be related to variations in mean water level, and gradients in the energy flux can provide the local energy dissipation. At the same time it may be possible to relate the turbulence intensity to the energy dissipation (Battjes, 1975).

Along the lines indicated above an experimental study was initiated of the internal velocity and pressure field of waves breaking on a gentle slope. The experimental data from this study are analysed in two consecutive phases. The first phase concentrates on instantaneous values. The second phase concentrates on integral properties, i.e. the densities and fluxes of momentum and energy, and on the energy dissipation in relation to the measured turbulence.

This paper presents an indication of the results obtained so far. A more extensive presentation of the results will follow.

Following Svendsen et al (1978) a characteristic description of the surfzone water motion is given in § 3. The kinematics are described in § 4, in which the model for the flow field of a quasi-steady breaking wave as proposed by Peregrine and Svendsen (1978) is shown to agree with the experimental results. Furthermore the measurements are compared to non-breaking wave theories. A semi-quantitative description of the dynamics is given in § 5. Finally, the planned evaluation of the integral properties is outlined in § 6 and illustrated with a preliminary result.

¹⁾Project Engineer, Harbours and Coasts Branch, Delft Hydraulics Laboratory, The Netherlands.

2. EXPERIMENTS

Arrangements

The experiments were conducted in a wave flume of the Delft Hydraulics Laboratory. The flume is 55 m long, 1 m wide and 1 m high.

Regular waves without free second harmonic components were generated in a water depth of 0.85 m. To obtain a control signal for the wave generator which resulted in a maximum suppression of the free second harmonics a simple trial and error procedure was applied, using Fontanet's theory (see e.g. Hulsbergen, 1974) as a first approximation.

To enable the construction of instruments in the bottom of the horizontal section a false, concrete floor was made, which reduced the water depth of the horizontal section to 0.70 m. The waves broke on a plane, concrete beach of a 1:40 slope (see Fig. 1a).

Figure 1a Experimental set-up

Figure 1b Detail experimental set-up

Measurements

The surface variations, i.e. the time mean and instantaneous vertical elevations of the surface, were measured over the whole length of the flume at positions with an interval of 1 m by means of resistance type wave gauges. Velocities of propagation were determined from the time of propagation of characteristic points of the wave surface between these positions.

It must be noticed, that resistance type wave gauges in principle cannot be used in the aerated region of breaking waves. Awaiting the results of a study of this aspect the conclusions of the study of Svendsen et al (1978) were used, i.e. (1) the wave gauges measure solid water and (2) the actual air content in the most densely entrained laboratory wave is only 2-4 percent. Thus, in view of the required accuracies the measured surface elevations are regarded as the elevation of water with normal density.

The horizontal and vertical component of velocity were measured by means of a laser doppler velocimeter, which is described elsewhere (Godefroy, 1978). The measurements were concentrated on the breaking and the near-breaking zone (see Fig. 1b). They were conducted at different levels between bottom and surface elevation.

It must be noticed, that during measurements the doppler signal may drop out temporarily for several reasons, such as the presence of air bubbles or large opacities. When the doppler signal drops out the last detected doppler frequency is held until the next doppler burst of about the same frequency is detected. Consequently these drop-outs occur when measuring above the level of the wave troughs and in water with entrained air as found in the front of breaking waves. Concerning the latter case it can be remarked that in view of the procedure of signal processing measurements are meaningless if the time scale of the drop-outs exceeds the time scale of the turbulent fluctuations. The time scale of the drop-outs increases with the density of the aeration. As a consequence measurements are only possible up to lightly aerated regions.

Pressures were measured by means of differential pressure transducers (0.8 cm diameter) at only four positions in the breaker zone (see Fig. 1b). In each of these positions the transducers were mounted at different elevations in a transparent, dummy side wall.

Symbol and sign conventions are as follows. The surface elevation is denoted η , the horizontal velocity component u , the vertical velocity component w and the pressure p . The horizontal x -axis is positive in the direction of wave propagation. The vertical z -axis is positive upwards, while the z -origin is chosen at the still water level.

Because of the exploratory nature of the investigation the experiments were restricted to two wave conditions, which are referred to as test 1 and test 2. The wave characteristics are as follows:

	H_o (m)	$H_{hor. section}$ (m)	$T_{wave maker}$ (m)	$H_{breaker}$ (m)	H_o/L_o (-)
test 1	0.159	0.145	1.79	0.178	0.032
test 2	0.142	0.145	3.00	0.226	0.010

The breaking behaviour at the breaking point of test 1 falls in the category "spilling breaking", while that of test 2 falls in the category "plunging breaking".

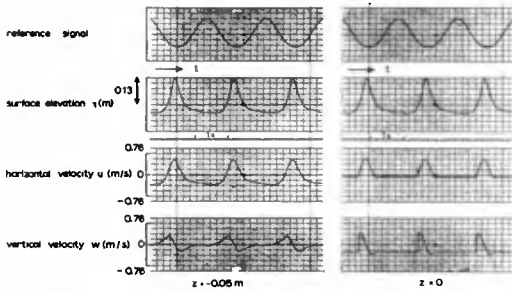

Figure 2a Typical recording near-breaking region (test 1, $x = 34.5$ m)

Figure 2b Typical recording breaking region (test 1, $x = 38.5$ m)

Procedures

Typical recordings of the surface elevation and the velocity components in the near-breaking and the breaking region (see Fig. 2a and 2b) show that the non-breaking wave motion is a purely periodic quantity, and that the breaking wave motion is a fluctuating quantity with a quasi-periodic character. To describe the breaking motion it is considered as the sum of a purely periodic component (indicated by a tilde) and a non-periodic residual component (indicated by a dash). The periodic component is obtained by averaging the signals at a fixed phase of the reference signal, i.e. the command signal of the wave generator. This procedure may be described as ensemble averaging. The major part of the residual component is formed by the turbulent fluctuations of the breaking process and is therefore termed the turbulent component. These fluctuations are non-stationary in time. Because of their time-scale a recording over say n waves may be considered as n independent recordings of the turbulent process. From this ensemble an estimate of e.g. the r.m.s.-value at a fixed time may be obtained.

Summarising, the non-breaking wave motion can be fully described just by a periodic component, i.e. $\eta = \tilde{\eta}$, $u = \tilde{u}$, $w = \tilde{w}$ and $p = \tilde{p}$. The breaking wave motion can be described as the sum of a periodic and a "turbulent" component, i.e. $\eta = \tilde{\eta} + \eta'$, $u = \tilde{u} + u'$, $w = \tilde{w} + w'$ and $p = \tilde{p} + p'$.

The periodic components are obtained as the ensemble mean over a minimum of 20 waves. The r.m.s.-value of the turbulent component at a fixed phase is obtained from the ensemble of minimum 20 "recordings" of the turbulent process. The time mean value of the turbulent component is zero by its definition. Consequently, the time mean value of the wave motion is equal to the time mean value of the periodic wave motion, i.e. $\bar{\eta} = \bar{\tilde{\eta}}$, $\bar{u} = \bar{\tilde{u}}$, $\bar{w} = \bar{\tilde{w}}$ and $\bar{p} = \bar{\tilde{p}}$, where an overbar indicates time-averaging over an integral number of wave periods. Furthermore, for points above the level of the wave troughs which are not always submerged, u , w and p are zero by definition when $z > \eta(x,t)$, while their time mean value is the time mean over an integral number of full wave periods.

At each of the indicated positions the velocities and the pressures at the different levels were measured consecutively, i.e. non-simultaneously. Simultaneously with a velocity or pressure measurement at a certain level the command signal of the wave generator and the surface elevation were recorded. Using these signals as a reference it is possible to couple the non-simultaneous measurements in one cross-section. This procedure of composing the velocity and pressure fields introduces inaccuracies due to the determination of the wave motion from an ensemble of a limited number of waves. These inaccuracies are found to be of the order of $\pm 2-3\%$ of the maximum periodic value. They exceed the instrumental inaccuracies, with the exception of inaccuracies due to drift of the laser doppler velocimeter and the pressure transducers, amounting to ± 1 cm/s and ± 0.2 cm (H_2O) respectively.

3. CHARACTERISTIC DESCRIPTION

This study is restricted to the kind of breaking waves that are usually found on gently sloping, sandy beaches with relatively wide breaker zones. A characteristic description of the breaking wave motion on these beaches is given by Svendsen et al (1978). They differentiate between a so-called outer and inner region (see Fig. 3). In the outer region the initial, chaotic breaking (ranging from spilling to plunging) takes place over a relatively short horizontal distance of several times the waterdepth at the breaking point. In the inner region soon a relatively well organized motion develops. The breaking motion is fully turbulent, while the mean motion is quasi-steady. A definition of a quasi-steady wave is given by Peregrine and Svendsen (1978): "one which changes little during the time a water particle takes to pass through it, excluding water particles which may become trapped in a surface roller". At this stage of its breaking motion a breaker on a beach may be described as a spilling breaker or bore. In case the depth continues to decrease the quasi-steady breaking motion is maintained until the shoreline is reached.

Indeed, the remarkable feature of the inner region is that the wave shapes throughout this region are very similar, as a comparison of the dimensionless surface profiles of the inner region shows (see Fig. 6 and 8). This conservation of wave shape is also illustrated by the tendency of the velocities

of propagation of characteristic points of the wave front to coincide as the waves propagate into the inner region (see Fig. 4). Comparison of the wave shapes for test 1 and test 2 shows that the similarity also holds for waves at the same position originating from different deep water conditions.

Figure 3 Wave characteristics in the surfzone (after Svendsen et al, 1978)

Figure 4 Velocities of propagation

From the surface variations it can be concluded that the water motion at each depth seems to be strongly locally controlled. Local depth and bed slope determine the characteristics of flow and hence the shape of the wave, including the energy flux, the energy dissipation and consequently the decrease in wave height. This hypothesis finds support in the nearly constant ratio of

wave height over mean water depth H/d for both tests (see Fig. 5), which is used to define the extent of the inner region.

In the next paragraph it is shown that the flow fields of the inner breaking region confirm the hypothesis of similarity with regard to the water motions.

Figure 5 Variation of wave height to water depth ratio

4. HORIZONTAL VELOCITY FIELD

The measured velocity fields presented and analysed in this paragraph belong to the inner breaking region. Because of the quasi-steady motion in this region it is possible to interpret the measured motion as being of waves of constant form. Virtually no velocity measurements were conducted in the relatively small outer region. The violent variation of the water motions in this region prohibits a constant form interpretation, so that for an analysis detailed spatial measurements would be required.

Comparison with non-breaking wave theories

The measured periodic velocity fields are compared to the theoretical fields for non-breaking waves of constant form to check the applicability of these theories, since they are commonly used for lack of breaking wave theories.

The selection of the theories used for the comparison is mainly based on the recommendations of the study of LeMéhauté et al (1968), because the experimental wave characteristics of their study are close to the experimental characteristics at the different measuring positions of both tests of this

study. In the study by LeMéhauté et al (1968) a number of theories were used for comparison with measured horizontal velocities under the wave crest. Dean (1974) extended the comparison with the stream function method. Of the 12 theories included in the comparison the stream function theory provided the best agreement followed in order by Goda's empirical formula, the cnoidal theory of Keulegan and Patterson and linear theory. Since Dean's stream function theory requires interpolation from tables and since Goda's formula is empirical, it was at this stage of the study decided to use the third and fourth best theories, viz. the cnoidal theory of Keulegan and Patterson (Masch and Wiegel, 1964) and the linear theory.

Firstly, the measured horizontal periodic velocity fields for test 1 are compared with the theoretical cnoidal fields (see Fig. 6). Secondly, the measured maximum (shoreward) and minimum (seaward) horizontal periodic velocities for both tests are compared with the extreme velocities following from the cnoidal and linear theory (see Fig. 7). Thirdly, in the same figure the measured time mean horizontal velocities are compared to the cnoidal and linear time mean velocities.

For both tests a number of representative results for the breaking waves in the inner region is presented. For comparison also a near-breaking wave is included. Vertical distances are made dimensionless by the local mean water depth, horizontal distances by the wave length and time by the wave period. It is noticed that the origin of the vertical z-axis is at the still water level. The horizontal lines indicate the levels at which the measurements were conducted. On the basis of these measurements fields with lines of equal velocities are constructed. The positive time axis of the measured velocity fields is directed to the right, so the wave profiles "propagate" to the left. It is stressed that the measured velocities are Eulerian velocities.

For both the cnoidal and linear theory two different formulations are used. The unbracketed values in Figure 6 and the full curves in Figure 7 are for the usual formulation in which the frame of reference is chosen such that the mean horizontal momentum or mass flow under the level of the wave troughs is zero: $-\int_{-h}^{\eta} \rho u \, dz = 0$. The in-phase relation of surface elevation and horizontal velocity introduces a net mass flow or Eulerian mass transport in the region above the level of the wave troughs. Since the measurements were conducted in a closed wave flume in a stationary situation the total mean mass flow is zero: $-\int_{-h}^{\eta} \rho u \, dz = 0$. Therefore a second formulation is chosen, such that the net shoreward mass flow in the region above the wave troughs equals the net seaward mass flow in the region below the troughs. This formulation is simply found by changing the speed of the frame of reference by the amount $-\eta_t$ $\int_{-h}^{\eta} \rho u \, dz / \rho d$. The results are given by the bracketed values in Fig. 6 and the dashed curves in Fig. 7.

It is noticed that for an irrotational wave motion, which is spatially homogeneous (apart from phase differences), the mean mass flow under the wave troughs is essentially constant. The "conduction solution" of Longuet-Higgins (1953) for rotational wave motion in a viscous fluid of finite depth predicts a mean mass flow which is maximum seaward right below the level of the wave troughs but which changes to a shoreward mass flow near the bottom.

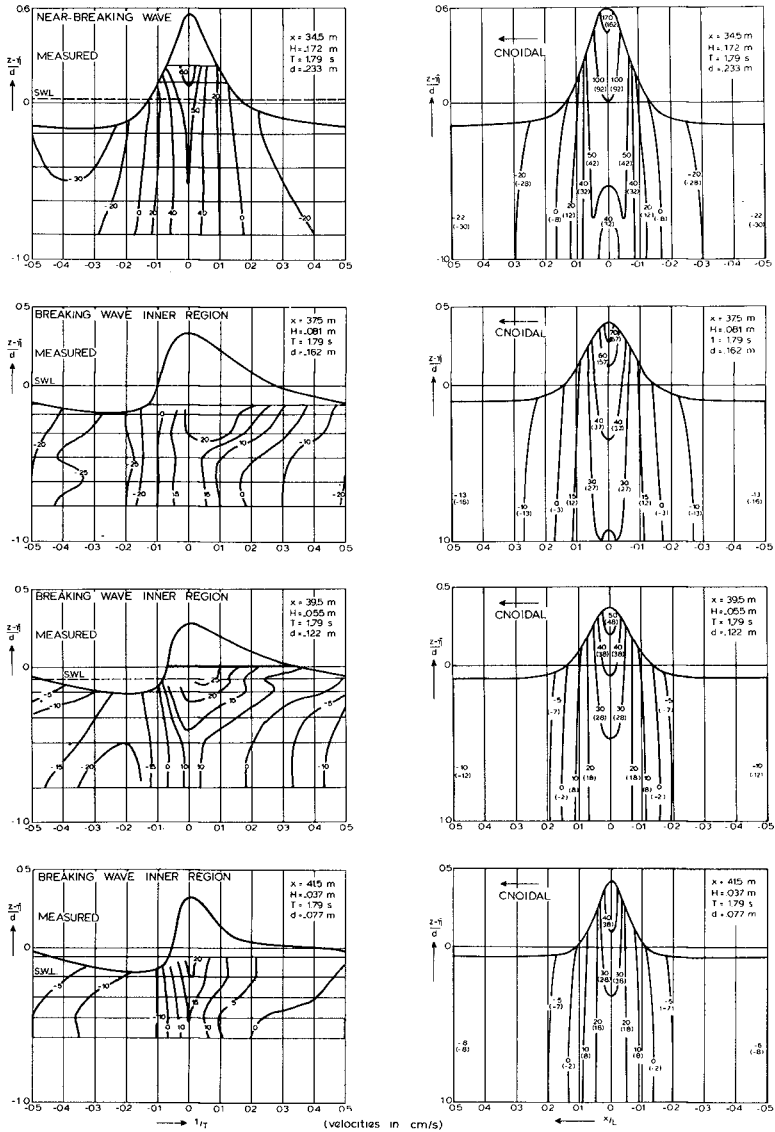

Figure 6 Comparison of measured and theoretical (cnoidal) horizontal periodic velocity fields of test I (see text for explanation)

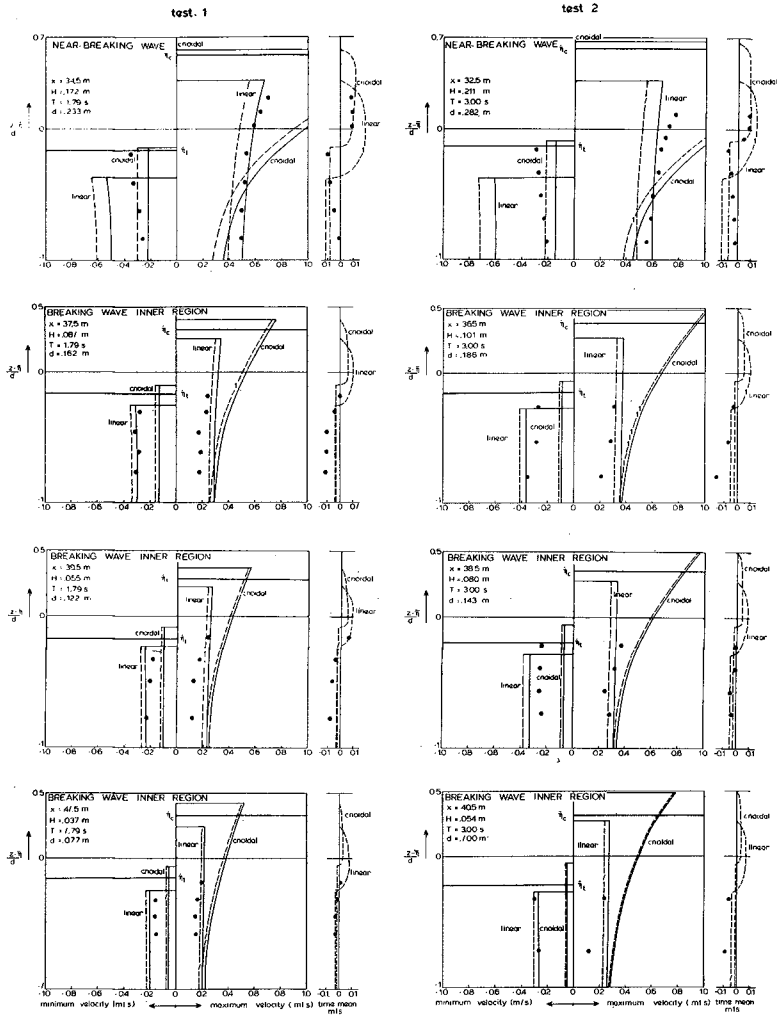

Figure 7 Comparison of measured and theoretical extreme horizontal periodic velocities for both tests (see text for explanation)

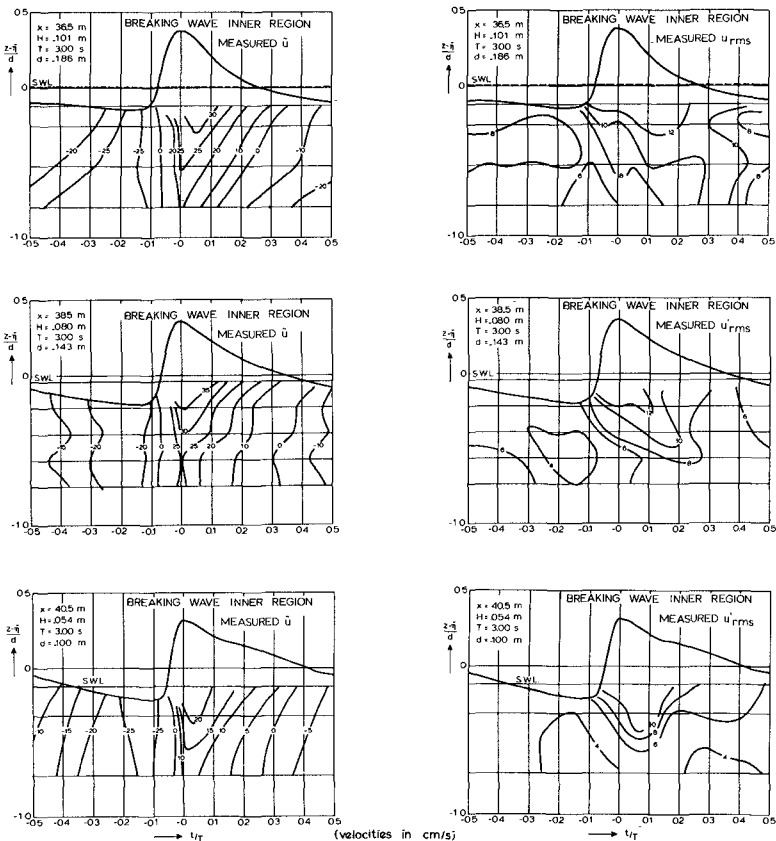

Figure 8 Measured horizontal periodic and turbulent velocities of test 2

Lagrangian measurements of Russell and Osorio (1958) in a closed wave flume confirmed this picture for non-breaking waves and found it to hold even for a sloping bottom.

From the comparison relating to the near-breaking waves (top of Fig. 6 and 7), it can be noted that:

- the surface elevation and the orbital wave motion remain quite symmetric horizontally,

- the surface elevation is well predicted by the cnoidal theory,
- the horizontal velocity is qualitatively and, with the exception of the upper crest region, quantitatively well predicted by the cnoidal theory,
- the discrepancies between the theoretical and measured maximum and minimum velocities are of the same order of magnitude as found by LeMéhauté et al. (1968),
- the time mean horizontal motion shows the tendencies as described by Longuet-Higgins' "conduction solution" (1953).

From the comparison relating to the breaking waves of the inner region (lower part of Fig. 6 and 7) it can be noted that

- the surface elevation and the orbital water motion are quite asymmetric horizontally and vertically,
- the cnoidal theory (for symmetric waves) is not able to predict the horizontal velocity field,
- the linear maximum and minimum horizontal velocities compare favourably to the measured extreme velocities,
- the net seaward flow below the wave troughs does not tend to zero or to shoreward flow near the bottom.

Figures 6 and 8 show that the horizontal periodic velocity fields of the inner breaking region for both tests and for different positions show a similar pattern that can be characterised as follows: in the regions just before the bore front arrives and in the lower regions a vertically homogeneous orbital motion exists which shows a horizontal asymmetry as can be expected from a non-breaking wave theory based on a similar asymmetric wave profile. Just behind the bore front a disturbed region exists, which seems to restore itself to a smooth velocity profile just before the next wave front arrives. The nature of these flow fields is described by the following model.

A model for the flow field

Based on visual observation Peregrine and Svendsen (1978) developed a model of a quasi-steady breaking wave (see Fig. 9a), which is briefly outlined below. The flow fields resulting from this model are compared to the measured flow fields of the inner breaking region.

At the front face of a spilling breaker an aerated surface layer can be observed, which is rapidly mixed into an increasing volume of aerated flow by the strong turbulence. The aerated flow commences at the toe of the aerated surface layer and forms a wedge. Longuet-Higgins and Turner (1974) describe the surface layer as a roller, falling down the front face of the wave. It is doubted, whether the surface layer can be treated as a roller separate from the region of highly turbulent flow. Peregrine and Svendsen (1978) hypothesize that it acts as a trigger to initiate the turbulence and that the initial volume of turbulent flow resembles a turbulent mixing layer.

The influence of gravity limits the development of the mixing layer region strongly, due to the absence of an upper fluid. A substantial part of the aerated, turbulent flow is found behind the mixing region, where the flow is like that in a wake. In this wake region the turbulence spreads and decays.

The horizontal velocity field resulting from this model is sketched in Figure 9b, for a frame of reference moving with the wave. The uniform flow approaching the breaking wave meets the toe of the surface roller, which has a velocity not very different from zero. In the moving reference frame the uniform velocity of the undisturbed flow is of the order of the propagation velocity c to which the oscillatory motion of order of $0.1 - 0.2 c$ is added. The mixing layer region develops in which the uniform velocity of the lower fluid changes to the zero velocity of the surface layer until the influence of gravity becomes dominant. In the wake region the uniform velocity of the undisturbed lower regions is slowly restored over the whole depth.

In figure 9c the velocity field described above is translated to a field with isolines of horizontal velocity for a fixed frame of reference. Comparison of this typical velocity field with the presented measured periodic flow fields (Fig. 6 and 8) shows that the model of the flow field agrees encouragingly well with the measured flow fields. However, the lack of measurements in the most aerated regions restricts this conclusion to the far wake region and the lower boundaries of mixing region and initial wake region.

Turbulent mixing layers grow linearly with distance in a wedge. The growth rate depends primarily on the velocity difference of the meeting flows. Brown and Roshko (1974) present values for the visually observed growth rate for a range of velocity differences including the case where the upper fluid velocity is zero. The measured flow fields (Fig. 6 and 8) give an indication of the lower boundary of the mixing layer. Since the model assumes the surface elevation to be the upper boundary, it is possible to obtain the growth rate of the mixing regions of the flow fields measured at the different positions in the inner breaking region. These growth rates are compared (see Fig. 10) to the values which Brown and Roshko present for their cases $u_2 = 0$, $\rho_2/\rho_1 = 1$ and $u_2 = 0$, $\rho_2/\rho_1 = 1/7$, in which the subscripts 1 and 2 stand for the lower and upper fluid respectively. Although the measurements on which these values are based show a considerable scatter, which is also true for the presented growth rates, it is concluded that there is a fair order of magnitude agreement. The density difference that Brown and Roshko introduced in their experiments appears to create only quantitative differences. Because of the scatter in the measured growth rates presented in Fig. 10 it is not possible to perceive any effects of a lower mean density of the surface layer due to air entrainment.

Finally, it is shown that also the measured horizontal turbulent velocity field ($u_{r.m.s.}$) is in agreement with the model. For positions corresponding to the measured periodic velocity fields of Figure 8 some typical examples are given in the same figure. The lower boundary of the mixing region is indicated by the spreading of the high intensities of the turbulence. In the wake region behind the mixing zone a decay of the turbulent intensities is clearly observed. It is noticed that the velocity fluctuations in the initial wake region are of the same order of magnitude as the mean velocity defect. This is typical for wakes (Tennekes and Lumley, 1974). A clear indication of the wake type flow in the region behind the crest is also found from the measurements of Battjes and Sakai (1980) in a steady breaking wave.

Figure 9a Model of a quasi-steady breaking wave (after Peregrine and Svendsen, 1978) for a reference frame moving with the wave

Figure 9b Horizontal velocity field of a quasi-steady breaking wave for a reference frame moving with the wave

Figure 9c Horizontal velocity field of a quasi-steady breaking wave for a fixed frame of reference

Figure 10 Growth rate of mixing regions

Summarizing, it is concluded that the measured horizontal periodic and turbulent velocity fields are at least in qualitative agreement with the model of a quasi-steady breaking wave as proposed by Peregrine and Svendsen (1978).

5. PRESSURE FIELD

In this paragraph a semi-quantitative description of a typical, measured periodic pressure field of the inner breaking region is presented. As will be shown, the magnitude and gradients of the vertical velocity and the surface elevation control the dynamic pressure field. From the comparison with the theories in §3 it is clear that the cnoidal theory is unable to predict the magnitudes of the velocity field. Linear theory is not able to describe the gradients in the velocity fields and surface elevation. Therefore a quantitative comparison with the cnoidal and linear theory is not considered appropriate at this stage of the study.

In Figure 11a the periodic dynamic pressure $\tilde{p}/\rho g + z$ measured at different levels in the inner region is given, along with the surface elevation or equivalently the dynamic hydrostatic pressure head, i.e. the dynamic pressure head that would result from a hydrostatic pressure distribution. The test conditions differ from the conditions of test 1 only in the presence of the dummy side wall, which is the cause of a surface elevation profile slightly different from test 1. Figure 11b shows the measured periodic vertical velocity at different levels and the surface elevation of test 1. The following description is based on the balance of vertical momentum (Dorrestein, 1961). Consider a fixed control volume of length δx extending between a level $z = z_1$ and the surface $z = \eta$. The dynamic equation reads:

$$\left(\frac{p}{\rho g} + z \right) \Big|_{z=z_1} = \eta - \frac{1}{g} w^2 \Big|_{z=z_1} + \frac{1}{g} \frac{\partial}{\partial t} \int_{z_1}^{\eta} w \, dz + \frac{1}{g} \frac{\partial}{\partial x} \int_{z_1}^{\eta} uw \, dz$$

From the measurements it is concluded that the magnitude of the last term on the right hand side, representing the advective gain of vertical momentum through the side boundaries, is at all times small, i.e. less than 10%, relative to the second and third term. The second term represents the advective gain of vertical momentum through the base of the control volume and the third term represents the gain due to the difference of vertical momentum at time t and $t + \delta t$. These terms are responsible for the deviation of the pressure $\bar{p}/\rho g$ from the hydrostatic pressure $\bar{\eta} - z$. A schematic representation of the magnitude and gradients of these two terms is given in Figure 11c in which 3 zones are distinguished. In zone A \bar{w} and $z \int \bar{\eta} \bar{w} dz$ are small in magnitude and gradients, resulting in a hydrostatic pressure distribution. In zone B at first a strong gradient in $z \int \bar{\eta} \bar{w} dz$ and small \bar{w} result in a pressure higher than the hydrostatic value. The magnitude of w increases strongly and w^2 tends to cancel out $\frac{\delta}{\delta t} z \int \bar{\eta} \bar{w} dz$. In zone C both terms contribute negatively to the right hand side of the equation, so at the crest a pressure lower than the hydrostatic pressure results.

The measured periodic pressure field as presented in Figure 11a appeared to be typical not only for the breaking waves of the inner region but also for the breaking waves in the outer region. Nearer to the breaking point the pressure fields show qualitatively the same deviations though more pronounced. The opposite effects are found nearer to the shoreline.

These findings are in agreement with measurements of crest and trough pressure in breaking waves of van Dorn (1976), who found a hydrostatic pressure under the troughs and a pressure lower than hydrostatic pressure under the crests, increasing substantially nearer to the breaking point.

6. INTEGRAL PROPERTIES

As described in the introduction the integral properties are evaluated in the second phase of this study. The planned approach is outlined hereafter and illustrated with a preliminary result for the mean momentum balance.

Time averaging of the vertically integrated density and flux of horizontal momentum and energy yields the so-called integral properties, which enables the following analyses. Firstly, local values of the integral properties can be compared to accepted theoretical expressions. Secondly, a check is possible on the theoretical and measured relation between gradients in the time and depth integrated momentum flux and gradients in the mean water level. Thirdly, the mean energy dissipation can be obtained from gradients in the time and depth integrated energy flux, so that dissipation models can be checked.

To quantify the integral properties the ensemble mean values of u , p , u^2 , w^2 , u^3 , uw^2 and pu must be integrated over time and depth. Since u and p were not measured simultaneously the term pu is approximated by $\bar{p}\bar{u}$, thus neglecting the turbulent pu -interaction and the joint contribution of waves and turbulence. However, because of the air entrainment velocity measurements were only possible up to lightly aerated regions. For a full time and depth integration it is therefore necessary to make extrapolations in the crest regions of the breaking waves. For the most essential extrapolation of the horizontal velocity u it is

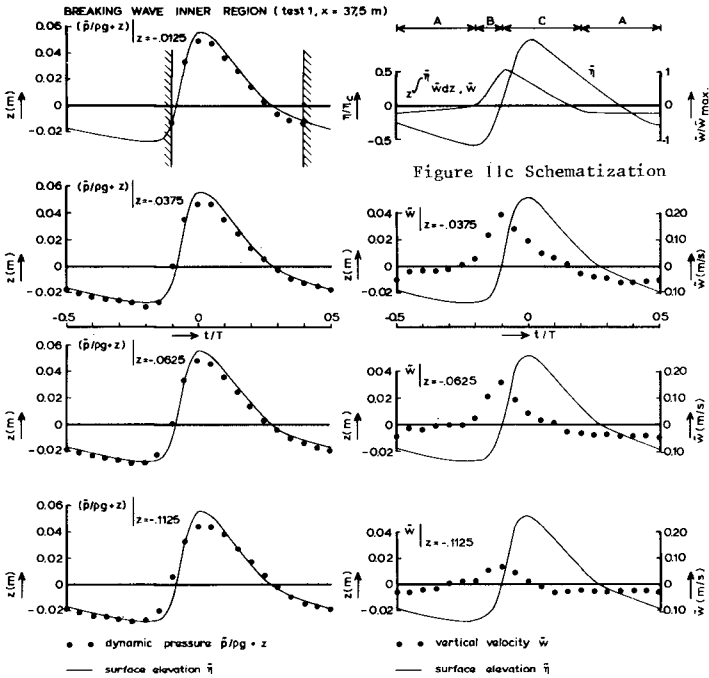

Figure 11a Dynamic pressure distribution

Figure 11b Vertical velocity distribution

possible to use the continuity equation and the constant form assumption - as suggested by the measurements - as follows. For constant form $\frac{\delta}{\delta t} = -c \frac{\delta}{\delta x}$ so the continuity equation can be written:

$$-c \frac{\delta}{\delta x} \int_{-h}^{\eta} \rho dz + \frac{\delta}{\delta x} \int_{-h}^{\eta} \rho u dz = 0$$

Using $\int_{-h}^{\eta} \rho u dz = 0$ it follows: $\int_{-h}^{\eta} \rho u dz = \rho c (\eta - \bar{\eta})$.

From the measurements the velocity of propagation c and the surface elevation $\eta - \bar{\eta}$ are known. The value of the velocity integral so obtained yields a constraint that can be used for the extrapolation. A check on the validity of this expression in the trough regions where $-\int_{-h}^{\eta} \rho u dz$ can be determined, showed it to be a valid relation.

A preliminary result of the analysis of the integral properties is given by the following evaluation of the mean momentum balance.

For a number of stations in the surfzone the time mean horizontal momentum flux $I_{xx} = -h \int_{-h}^{\eta} (\rho + \rho u^2) dz$ is determined using the measured (and extrapolated) p and u . Gradients in the excess time mean horizontal momentum flux due to the presence of waves or radiation stress induce a variation of mean water level, $\bar{\eta}$, as follows from the mean momentum balance (Longuet-Higgins and Stewart, 1962):

$$\frac{dS_{xx}}{dx} + \rho g (h + \bar{\eta}) \frac{d\bar{\eta}}{dx} = 0$$

in which:

$$S_{xx} = I_{xx} - \frac{1}{2} \rho g (h + \bar{\eta})^2$$

The measured mean water level is compared (Fig. 12) with

- the mean water level calculated from the measured I_{xx} using the equation above and
 - the mean water level calculated from the measured wave height, H_{rms} , using the linear approximation of $S_{xx} = (2n - \frac{1}{2})E$ and the equation above.
- The comparison shows that a fair agreement exists between the measured mean water level and the mean water level calculated from the measured momentum flux. This is not unexpected because the derivation of the mean water level from the measured momentum flux using the momentum balance is nearly exact, since only the bottom shear stress is neglected. Use of the linear approximation of the radiation stress gives strong deviations in magnitude and gradients of the calculated mean water level around the breaking point.

Figure 12 Comparison of measured and calculated mean water level

7. CONCLUSIONS

The internal velocity and pressure fields of quasi-steady spilling breaking waves have been investigated experimentally. So far the following conclusions can be drawn:

- The flow fields in the inner breaking region show a similarity not only from point to point for a particular wave condition, but also at corresponding points for different deep water wave conditions (see Fig. 6 and 8). This is a generalisation of the conclusions made by Svendsen et al (1978) on the basis of the similarity of the surface profiles in the inner region.
- A comparison of the horizontal periodic velocity fields with the non-breaking cnoidal (Keulegan & Patterson) and linear theory shows that:
 - a) the cnoidal theory fails to predict the horizontal velocity field qualitatively and quantitatively;
 - b) linear theory predicts the order of magnitude of the maximum and minimum horizontal velocities quite well, which is probably due to the full wave profiles.
- The model of a quasi-steady breaking wave as proposed by Peregrine and Svendsen (1978) is - at least qualitatively - shown to be in agreement with the measured horizontal periodic and turbulent velocity fields.
- The periodic pressure field deviates from hydrostatic pressure at the breaking wave front and at the wave crest. Shortly behind the wave crest and at the trough region the periodic pressure field is hydrostatic. The deviations can be explained semi-quantitatively from the vertical velocity distribution using the vertical momentum balance.
- The integral properties can in principle be quantified from the measured internal velocity and pressure field. This makes a valuable check possible on known relations, such as the mean momentum balance. It also allows for a fundamental study of the energy dissipation.

8. ACKNOWLEDGEMENT

This study was suggested by dr. J.A. Battjes as a part of the coastal research program (TOW) of the Public Works Department of the Netherlands (Rijkswaterstaat). The author gratefully acknowledges the encouragement and valuable suggestions of dr. Battjes.

ABSTRACT

A realistic description of the kinematics of hurricane waves requires that the directional spectrum of the sea be known. Models for hindcasting the directional spectrum have existed for some time, but there has been a dearth of data available for checking the directional characteristics of the hindcasts. Hurricane Carmen in 1974 and hurricane Eloise in 1975 passed reasonably close to platforms in the Gulf of Mexico which were instrumented with wave staffs and electromagnetic current meters. The maximum recorded significant wave height was 29 feet. The simultaneous measurements of wave height and water particle velocity permitted estimates of the directional spectra to be made. The estimated directional spectra are complicated and often bimodal in frequency and direction. Swell from the center of the storm can propagate in directions over 90 degrees away from the direction of the shorter waves which are in local equilibrium with the wind. The hindcast model reproduces these directional features remarkably well. The measurements of wave kinematics also permitted tests of the accuracy of wave theories in high and confused storm waves. All of the unidirectional theories tested showed a bias toward overpredicting the velocity under the highest waves. However, the kinetic energy in the velocity components and the velocity probability distribution could be found to within a ten percent scatter using directional spectral concepts and linear wave theory.

INTRODUCTION

Hurricane waves are steep, confused, and short-crested. The directional spectrum provides a concise description of this chaos by giving the most important statistical measures of the motion of the sea surface. Knowledge of the directional spectrum is of obvious practical importance in predicting ship motions. Using wave height and velocity measurements made in tropical storm Delia, Forristall et al. (1978) showed that the details of the directional spectrum can also be important when the subsurface kinematics of the wave motion are needed, as for predicting wave forces on slender members of a structure. For the short-crested waves in that data set, unidirectional wave theories consistently overpredicted the subsurface velocities while linear directional theory came close to matching the observed velocity spectra.

Measurements of directional spectra in the most severe conditions are unlikely to be available, and hindcasts of historical storms are needed to establish design conditions. The hindcast models can be of either a discrete or parametric type, as discussed in the review by Vincent and Resio (1979). At the present state of development, the discrete models such as the one developed specially for hurricanes by Cardone et al. (1976) offer more flexibility in handling variable wind directions. However, parametric models based on the work of Hasselman et al. (1976) are well suited to fetch limited generation cases, and with the addition of discrete swell bands as discussed by Gunther et al. (1979), they may be extended to situations with rapidly changing winds.

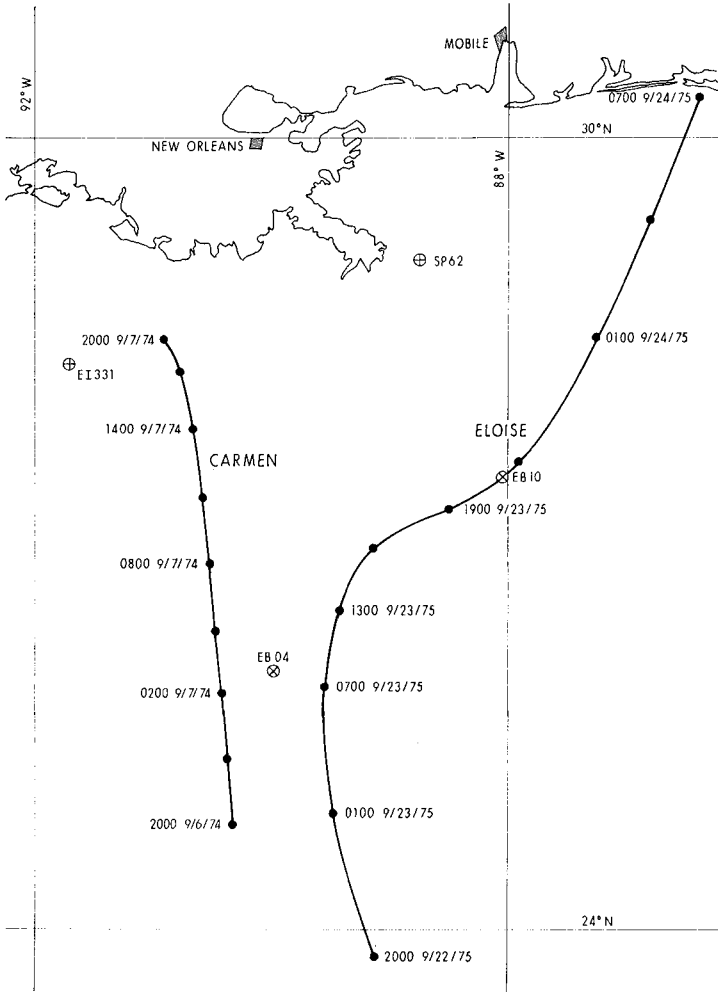

Wave hindcast models have been reasonably well verified with wave height measurements, but there has been little data on the directional characteristics of storm waves available for verification of the hindcast directional spectra. The main purpose of this paper is a description of directional spectra estimated from wave staff and electromagnetic current meter measurements made in hurricanes Carmen in 1974 and Eloise in 1975. The measurements compare reasonably well with hindcasts made using the model of Cardone et al (1976).

The measurements of particle velocities under the waves were compared with the predictions of various wave theories and general confirmation of the results of Forristall et al. (1978) was obtained. That is, all unidirectional theories tested, including irregular and nonlinear theories, overpredicted the measured velocity. In contrast, the kinetic energy spectra and statistical distributions of the velocity were predicted to within a reasonable scatter using linear theory.

DATA AND METHODS OF ANALYSIS

The measurements were made in the northern Gulf of Mexico at the oil and gas production platforms designated EI331 and SP62 in Figure 1. The water depth at EI331 is 246 feet and the depth at SP62 is 315 feet. At both stations, continuous analog recordings were made from a Baylor wave staff and a string of cylindrical electromagnetic current meters manufactured by Marsh-McBirney, Inc. The current meters were hung from pairs of taut wires designed to hold them as rigidly as possible with minimum interference to the flow. Forristall and Hamilton (1978) give a more complete description of the instrumentation and suspension system.

Tank testing has shown that the cylindrical electromagnetic current meters respond linearly to the flow speed but that their response to flow 45° from an electrode axis is down by eight percent. It was easy to correct for this feature during the analysis. The meters included an internal calibration circuit which was switched on automatically once a day to provide a check on the gain of most of the amplifiers in the circuitry, and which was used to give the calibration to engineering units during the analysis. The 0.80 Hz low pass output filter used on the meters was squared off by applying the inverse filter during the spectral analysis.

77-0291-21

Fig. 1 - Storm tracks of hurricanes Carmen and Eloise, with OCMF stations and NOAA data buoy sites.

All the signals were transformed to the frequency domain using an FFT over 2048 samples. Power spectra and co-spectral estimates were formed by multiplying the Fourier transforms together and averaging over ten raw frequency lines. The estimates thus have 20 degrees of freedom and a resolution of 0.0098 Hz.

The information on wave direction available from a wave staff and current meter is equivalent to that from a pitch and roll buoy, and does not provide very sharp directional resolution. However, it is sufficient to determine the mean direction of travel and degree of directional spreading for waves in each frequency band. The co-spectra were thus used to find the best estimates for the parameters in the function

$$H(\theta) = N(s) \cos^{2s}(\theta - \theta_0) \quad (1)$$

where θ_0 is the mean direction of travel, s is a spreading parameter which increases as the directional spread becomes narrower, and $N(s)$ is included to normalize the area to unity. The details of the calculations, including a correction for the Doppler shift caused by steady currents, are given by Forristall et al (1978).

The hindcasts of directional spectra in the storms were made using the discrete model described by Cardone et al (1976). The processes of wave growth, dissipation, and propagation are simulated on a hexagonal grid system which covers the Gulf of Mexico with a grid spacing of 35 kilometers. At each grid point, the directional spectrum is resolved into 13 frequency and 24 directional bands. The growth of spectral components by linear and exponential mechanisms is limited by the Pierson-Moskowitz fully developed spectral form. Propagation of spectral components is accomplished by a simple Lagrangian scheme. For comparison with the measurements, the hindcast results were fit to equation (1) with a nonlinear least squares program.

The quality of a wave hindcast depends to a great extent on the accuracy of the wind field used as input. For hurricanes, it is possible to use a model storm approach since the similarity of hurricane pressure fields allows their description with relatively few parameters. Once the pressure field is specified, the wind speed and direction can be found by solving the equations of motion averaged over the atmospheric boundary layer.

HURRICANE CARMEN

Carmen was a rather severe storm with minimum central pressure of 937 mb and estimated peak gusts of 140 miles/hr. Figure 1 shows her track past EI331 and SP62 on her way to landfall near Vermillion Bay on the Louisiana coast. The NOAA data buoys shown in the figure were not operational during Carmen. Hope (1976) gives a description of the meteorological conditions in the storm.

The wave hindcast for Carmen was performed as part of an extensive study of waves generated by historical hurricanes in the Gulf of Mexico (Ward et al., 1978). For consistency, only the type of meteorological information available in the historical records was used in the windfield analysis. This limitation gives an indication of the accuracy of the historical hindcasts, but a better windfield could probably have been constructed using the additional data available for a storm in 1974. In particular, the modeled wind direction early in the storm at EI331 and SP62 was considerably clockwise from the measured directions. This discrepancy is probably due to a poor specification of the large scale pressure field.

Figure 2 shows the comparison between the measured and hindcast significant wave heights at EI331 as estimated from the total variance of the spectra. The solid line shows the half-hour maximum wave height, the dashed line shows the measured significant wave height, and the dotted line shows the hindcast significant wave height. The hindcast results are available for only a rather short stretch of the storm and the hindcast waves are slower in reaching their maxima than the measured waves. However, the eventual fit of the maxima is excellent. The conditions during this storm were the most severe during the measurement program, with the maximum spectral significant wave height equal to 29 feet and a maximum zero downcrossing 46 feet high.

There were several current meter failures at the measurement sites which affected the usefulness of the data for calculating directional spectra. In particular, the boat deck clamps holding the current meter taut wire assembly broke at both stations, making the particle velocity data completely unusable after 0930 at EI331 and after 1300 at SP62. Even before then, only the data from Current Meters 2 and 3 at EI331 and Current Meters 1 and 2 at SP62 could be used.

Despite the problems with the instrumentation, some interesting directional spectra are available for comparison with the hindcasts. Figure 3 shows a comparison for EI331 and Figure 4 shows data from SP62. The hindcast for EI331 at 0900 shows too little energy at all frequencies as would be expected from Figure 2. The hindcast energy is not spread as much as the measurements, which may be related to noise in the data. The mean direction of the hindcast energy at the higher frequencies is in error by about 30° in the same sense as the wind direction errors noted above. At later times in the storm, when only the power spectrum was measured, the total hindcast energy was nearly correct, but the peak frequency was considerably lower than that measured.

As shown in Figure 4, the hindcast compares much more favorably with the measurements at SP62. The fit of the power spectrum and the mean direction of travel is very good for all frequencies. The energy is more directionally spread in the measured spectrum, but the difference is slight.

HURRICANE ELOISE

The track taken by hurricane Eloise in September 1975 is shown in Figure 1. After heading northward in the direction of SP62, she was forced eastward by a cold front which had been moving southeast over Texas and Louisiana and made landfall near Fort Walton Beach, Florida. The minimum pressure recorded near landfall was 955 mb and wind gusts to 155 miles/hr were recorded. A review of the storm meteorology is given by Hebert (1976). Withee and Johnson (1975) summarize the measurements made from the data buoys located in Figure 1, and Friese (1977) used that data to discuss the oscillations of the thermocline caused by the storm. The Corps of Engineers (1976) has prepared a report describing the coastal damage caused by the storm.

The large amount of meteorological information available for Eloise permitted a detailed investigation of the windfield. Aircraft and satellite reconnaissance, shore radar, buoy data, and data recorded at EI331 and SP62 were all used in a determination of the storm track and pressure history. The storm winds were unusually asymmetric due to the intruding high pressure ridge, and thus the tangential pressure distribution was fit to a five-term Fourier series. The resulting wind field solution had several unusual features which were corroborated by the available data. There was very sharp inflow in the right rear and left front quadrants, pronounced outflow in the left rear quadrant, and a sharp almost front-like wind shift line extending to the south of the center.

Although the model wind field is very good, it does not perfectly match all the details of the observed winds. The model misses small scale variations due to individual rain bands, and the wind speed is underpredicted early in the storm at EI331 when the wind was dominated by the high pressure ridge intruding before the hurricane.

The underpredicted wind speeds at EI331 led to underpredicted significant wave heights until about midnight on September 22. The hindcast wave heights at SP62, shown in Figure 5, also began a bit low, but they followed the observed buildup quite well and were within a few feet of the observed peak. Some of the most interesting measurements during Eloise were made by National Data Buoy Office at EB-10 which was directly under the storm track. Figure 6 shows a comparison between the peak wave spectrum measured by an accelerometer on the buoy and the spectrum hindcast for the same time. The fit is quite good, and the hindcast would be well within the 90 percent confidence limits for the measured spectrum.

Figures 7 and 8 show measured and hindcast directional spectra at EI331 and SP62, respectively. At 1800 CDT on September 22 at EI331, the measured spectrum is strongly bimodal, with the swell component clearly separated from the locally generated sea. The directions of travel of the two components are over 90° different. The hindcast spectrum shows good qualitative agreement with the measurements, but the amount of energy is too low in every frequency band, in large part

due to the underspecification of the local wind speed. The transition in wave direction between sea and swell is much sharper in the measurements.

Throughout most of the storm at SP62, the spectra were also bimodal. This bimodality cannot always be recognized from consideration of the frequency spectrum alone, but in both the measurements and hindcasts there is a sharp break in the direction of travel at about 0.10 Hz, as shown in Figure 8. The error in the direction of travel of the high frequency waves is due to a small scale shift in wind direction at SP62 which persisted for a few hours and was not modeled.

Black (1979) used the EI331 and SP62 data sets to determine the wave power spectrum and mean direction of travel of waves in each frequency band. In general, his results are consistent with those presented here. However, at 2400 CDT, September 23 at SP62, he finds high frequency energy propagating upwind while we do not. The discrepancy could be due to the considerable difference in the methods of analysis or to the possibility that a calibration mark on the data tape was inadvertently included in Black's analysis.

The measured directional spectra show that the sea state in a hurricane is typically very complicated. Different frequencies can have greatly different mean directions of travel and directional spreads. The discrete model used for the wave hindcasts is well suited to accounting for the development and propagation of the energy in the various frequency bands, and the hindcasts generally agree well with the measurements. In fact, the directional parameters often seem to be more accurately hindcast than the power spectrum, although this is in part associated with the natural statistical variability in measured power spectra. Many details of the errors in the hindcasts can be ascribed to errors in the details of the local wind specifications, which again emphasizes the importance of the wind field specification to wave hindcasting.

WAVE KINEMATICS

The calculation of wave kinematics in confused seas is of considerable importance in the specification of wave forces on ocean structures. Forristall et al. (1978) showed that unidirectional wave theories consistently overpredicted measured velocities during tropical storm Delia, and this result was confirmed in the data sets considered here. Figure 9 shows a comparison between measured horizontal velocities and those predicted by Stokes' fifth-order theory for SP62 during Eloise. Data from the top current meter 16 feet below mean sea level are given, and each data point represents the highest wave in a half-hour segment of data. The measured velocity is the maximum resultant of the two horizontal measured components during the wave. The wave height and period for the Stokes' calculation were determined by the zero down-crossing method. The scatter in the comparisons and the bias toward overprediction are both quite large and both can be explained by the directional spreading of the confused waves.

COMPARISON OF MEASURED VS PREDICTED VELOCITIES
(EXISTING WAVE THEORIES)

Fig. 9 - Measured compared to Stokes wave kinematics at SP62 during Eloise.

Linear wave theory can be extended to directionally spread seas since linear waves with different frequencies and directions can be combined by superposition. However, the applicability of linear theory is questionable for the high and steep waves of a hurricane. It is possible to check the theory by comparing the measured and theoretical horizontal kinetic energy. The measured kinetic energy is found by adding the spectra from the two horizontal axes of the current meter, and the theoretical energy is found by attenuating the measured wave height spectra by the factor given by linear wave theory. An amplitude ratio of measured-to-theoretical velocity may then be found by taking the square root of the ratios between the spectra. This process is complicated somewhat by the Doppler shift due to steady currents as described by Forristall et al. (1978), but for the moderate currents measured during the storms, the change in the ratios is slight.

The amplitude ratios of measured over theoretical velocity for SP62 during Carmen and EI331 during Eloise are shown in Figures 10 and 11, respectively. The ratio for the top meter at SP62 was about 0.9 at the peak of the wave spectrum, rising to 1.1 at the higher frequencies. In contrast, the ratio at the top meter at EI331 was about 1.1 throughout the energetic part of the spectrum. Note that the rise to a higher ratio at about 0.10 Hz corresponds to a notch in the wave spectrum. The meter at the 47-foot depth at EI331 had a ratio near 1.0 for all frequencies, while the deeper meters at both stations showed wide variations due in part to the very small predicted velocities at these levels. For high frequencies, electronic noise or turbulent fluctuations in the flow can overwhelm the signal from the wave induced oscillations.

Similar amplitude ratios were calculated for many hours of each storm at each station. The results were nearly constant for a given storm and current meter, but varied as noted between storms and meters. The meter at the 47-foot depth at EI331 during Carmen had a ratio of about 0.95 while the meter at the 16-foot depth at SP62 during Eloise had a ratio of only 0.85. There does not seem to be any consistent pattern of change in velocity amplitude ratio with different sea states, and it seems most likely that the observed changes are due to changes in the response of the instrumentation systems.

There have been several other field studies of wave kinematics in recent years and it is interesting to compare results. The results were not all presented as amplitude ratios, but they can easily be discussed in that form. Thornton and Krapohl (1974) used electromagnetic meters to measure the kinematics of a moderate swell off the coast of California. The amplitude ratio for the horizontal velocity was 0.94. Cavalieri et al. (1978) made measurements using electromagnetic meters mounted on a tower in the Adriatic Sea and found a ratio of 0.9. Battjes and Heteren (1980) used acoustic travel time meters in the North Sea and found a ratio of only 0.85. Our previously reported measurements during tropical storm Delia (Forristall et al., 1978) showed ratios of 1.1, decreasing to 0.9 at frequencies twice that of the spectral peak.

Our interpretation of the variability of results, both in our work and that of other investigators, is that present instrument

technology is capable of making field measurements of wave kinematics with an accuracy of about ten percent. This accuracy is sufficient to determine that unidirectional wave theories perform poorly in confused seas, but it is not sufficient to enable any conclusions to be made about the nonlinearity of storm waves.

The results also indicate that it is appropriate to make engineering calculations of forces on structures using wave kinematics derived from the superposition of directionally spread linear waves. A kinematic field for a given directional spectrum can be generated using a Monte Carlo simulation of wavelet phase angles and the fast Fourier transform, and we are presently developing and testing design programs using this approach.

ACKNOWLEDGEMENTS

R. C. Hamilton and T. E. Long contributed greatly to the success of the measurement program. A. M. Reece and M. E. Thro made helpful comments on an earlier version of the manuscript. The measurements were made by Shell Development Company with financial support from Amoco Production Research, Chevron Oil Field Research, Exxon Production Research, and Mobil Research and Development.

PREDICTION OF THE SEVEREST SIGNIFICANT WAVE HEIGHT

Michel K. Ochi* and Joseph E. Whalen**

ABSTRACT

This paper presents a method to statistically estimate the severest sea state (significant wave height) from the observed data. For the estimation of extreme significant wave height, a precise representation of the data by a certain probability function is highly desirable. Since we do not have any specific technique to meet this requirement, this situation seriously affects the reliability of the current method of predicting the severest sea condition. The author's method is to express asymptotically the cumulative distribution of the significant wave height as a combination of an exponential and power of the significant wave height. The parameters involved are determined numerically by a nonlinear minimization procedure. The method is applied to available significant wave height data measured in the North Sea, the Canadian coast, and the U.S. coast. The results of the analysis show that the data are well represented by the proposed method over the entire range of the cumulative distribution.

INTRODUCTION

For the design of coastal and ocean structures, it is necessary to obtain the severity of sea over a period of time on the order of 50 years, sufficiently long enough to cover the lifetime of the structure. The severity of the sea is most commonly expressed in terms of significant wave height. Therefore, if the probability law which governs the significant wave height is found, then the statistical prediction of the severest sea in the long-term can be achieved.

It should be noted that the probability distribution function of the significant wave height is derived empirically from analysis of data accumulated over a certain period of time, and that there is no way to theoretically derive the probability distribution function, in contrast to the probability function applicable for wave height in a given sea severity. Observations (or measurements) of the significant wave height are usually made several times a day, each for 15 to 20

* Professor, University of Florida

** Senior Scientist, Operations Research, Inc.

minutes duration. Since the observations (or measurements) of the significant wave heights are made intermittently, the information on the sea severity is given as a discrete phenomenon, although in reality the sea severity is continuously changing with time.

The results of analysis made on available data have indicated that statistical properties of the significant wave height appear to follow the log-normal probability law, in general, but not to the extent that this probability law can be used for the estimation of extreme values. On the other hand, when the data are plotted on the Weibull probability paper, it is the general trend that the higher significant wave heights are fit reasonably well to the Weibull distribution, but the representation over the entire range of the significant wave height by the (two-parameter) Weibull distribution is substantially poor.

It should be noted that the data of severe seas (significant wave heights) are always sparse; on the order of one to two percent of the total number of observations are spread over the range of higher significant wave heights. Hence, the question always remains as to how reliable the prediction technique is if we estimate the extreme significant wave height by extending the line plotted on either the log-normal or the Weibull probability paper taking into account the higher significant wave heights which are extremely unreliable data.

For the estimation of extreme significant wave height, a precise representation of the data by a certain probability function is highly desirable. The precise representation implies that the data shall be represented by a probability function over the *entire* range of the cumulative distribution except data points of very high cumulative distribution such as 0.999 or higher due to the reason discussed in the foregoing paragraph.

In order to represent the measured data with sufficient accuracy for estimating extreme values, this paper presents a method to express the cumulative distribution function as a combination of an exponential and power of the significant wave height.

The method is applied to available significant wave height data measured in the North Sea, the Canadian coast, and the U.S. coast. The extreme significant wave heights expected in 50 years estimated by the proposed method are presented.

PROBABILITY DISTRIBUTION FUNCTION FOR THE SIGNIFICANT WAVE HEIGHT

For the probability density function applicable to the significant wave height, the Weibull distribution and the log-normal distribution have often been considered to date. The Weibull probability density function is given by,

$$f(x) = c\lambda^c x^{c-1} e^{-(\lambda x)^c} \quad 0 \leq x < \infty \quad (1)$$

where x is the significant wave height for the present problem, and c and λ are parameter to be determined from observed data. Since the probability density function given in (1) carries two parameters, it may be called the two-parameter Weibull distribution.

It has been claimed that some data of significant wave heights can be represented very well by the three-parameter Weibull distribution which is given by,

$$f(x) = c\lambda^c (x-a)^{c-1} e^{-\{\lambda(x-a)\}^c} \quad a \leq x < \infty \quad (2)$$

It is noted, however, that the three-parameter Weibull distribution carries the minimum non-zero value, a , as one of its parameters. If this is the case, it is not possible to explain the physical meaning of this minimum significant wave height associated with the distribution. The sea state of significant wave height zero, which represents the calm sea, is an important part of the distribution. The sample space of significant wave height has to be chosen between zero and ∞ for the probability distribution of the significant wave height. For this reason, it is not appropriate to use the three-parameter Weibull distribution for the analysis of the significant wave height data.

The log-normal probability function is another distribution that has been used to represent the statistical properties of the significant wave height. The density function is given by,

$$f(x) = \frac{1}{\sqrt{2\pi} \sigma x} e^{-\frac{(\ln x - \mu)^2}{2\sigma^2}} \quad 0 \leq x < \infty \quad (3)$$

where, μ and σ are parameters to be determined from the observed data.

An example of data of significant wave height measured at the location 53.5° N, 4° E in the North Sea is shown in Table 1 (Bouws 1978). A total of 5,412 measurements of significant wave heights were made in three years. This information implies that the significant wave heights were measured at every 5-hour interval, as an average. Hence, the data provide information on the significant wave height at 5-hour intervals, just to cover all severe sea conditions expected to occur at the site. It should be noted here that the observed (or measured) data of significant wave height obtained in a relatively long time interval may not provide sufficient information on severe seas that do not persist for a long period.

Figures 1 and 2 show the cumulative distribution function of the data given in Table 1 plotted on log-normal probability paper and Weibull probability paper, respectively. As can be seen in these figures, the data appear to follow the log-normal distribution for the cumulative distribution up to 0.99, and the data also may be represented by the Weibull probability distribution except for small significant wave heights.

Table 1 Significant wave height data obtained from measurements in the North Sea (from Bouws 1978)

SIGNIFICANT WAVE HEIGHT (M)	NUMBER OF OBSERVATIONS
0 - 0.5	1,280

7.0 - 7.5	1
TOTAL	5,412 in 3 Years

Figure 1 Cumulative distribution function of significant wave height plotted on log-normal probability paper (data from Bouws 1978)

Figure 2 Cumulative distribution function of significant wave height plotted on Weibull paper (data from Bouws 1978)

Figure 3 Comparison between histogram of significant wave height and log-normal and Weibull probability distributions (data from Bouws 1978)

In order to see the difference between the histogram constructed from the original data and the two probability functions, Figure 3 is prepared. As seen in this figure, the difference between Weibull probability function and the data is pronounced when the probability density functions and histogram are compared. It is noted that the Weibull probability paper is usually constructed by taking the logarithm of the cumulative distribution function twice. Hence, a small difference between data and the cumulative distribution function drawn on the Weibull probability paper may result in a substantial difference between the histogram and theoretical probability density function.

As another example, Figure 4 shows the comparison between the histogram of significant wave height and Weibull and log-normal probability density functions for the data observed at Tiner Point, Canada (Khanna and Andru 1974). The figure shows that the log-normal probability density function agrees well with the histogram over the entire range of significant wave height. On the other hand, the Weibull probability density function agrees well with the histogram for large significant wave heights, but the agreement is rather poor for small significant wave heights.

Although these examples show that the data are represented satisfactorily by the log-normal distribution, this may not always be the case. Some other significant wave data may be better fitted by the (two-dimensional) Weibull distribution depending on the geographical location, depth of the water, frequency of occurrence of the storm, etc. In principle, as was mentioned earlier, there is no scientific basis for selecting any particular probability distribution to characterize the significant wave height.

It may be noted, however, that the representation of significant wave height by the log-normal probability distribution results in a significant benefit for the derivation of the joint probability distribution of the significant wave height and wave period (Ochi 1978).

Since our goal is to statistically predict the extreme significant wave height from the observed data, a precise representation of the data by a certain probability function is highly desirable. However, we should consider the fact that the data of severe significant wave heights are always sparse, and hence the frequency of occurrence is extremely unreliable. For example, the data given in Table 1 show that the largest significant wave height of 7-7.5 meters was observed once in three years, and that 99 percent of the data are significant wave heights less than 4.5 meters. This implies that, on the order of one percent of the total number of observations are spread over the range of higher significant wave heights, which are most interesting for us from the view point of statistical estimation.

It is appropriate, therefore, to establish a probability function which represents the significant wave height data over the entire range for the cumulative distribution up to about 0.99. Then, the extreme significant wave height will be estimated based on this probability function. For this, let us express the cumulative distribution function

Figure 4 Comparison between histogram of significant wave height and log-normal and Weibull probability density functions (data from Khanna and Andru 1974)

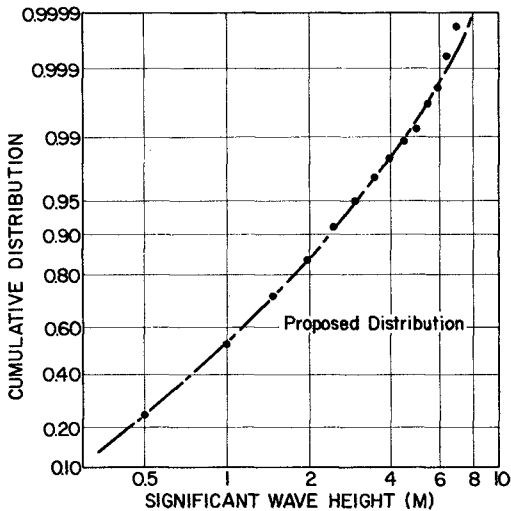

Figure 5 Cumulative distribution function based on Equation (6) plotted on log-normal probability paper (data from Bouws 1978)

in the following form,

$$F(x) = 1 - e^{-q(x)} \quad (4)$$

where, $q(x)$ is a monotonically increasing, real-valued function. Then, it can be proved that, for a large number of observations, the probable extreme value in n -observations, denoted by \bar{Y}_n , is given as the inverse function of $q(x)$. That is,

$$\bar{Y}_n = q^{-1}(\ln n) \quad (5)$$

The probable extreme value can also be obtained graphically by equating the return period, $1/\{1 - F(x)\}$, to the number of waves expected in a specified period of time, 10 years, 50 years, etc.

The authors' method is to express $q(x)$ as a combination of an exponential and power of the significant wave height. That is,

$$q(x) = a x^m \exp\{-px^k\} \quad (6)$$

The parameters involved in $q(x)$ are determined numerically by a nonlinear minimization procedure. The form used in the procedure is given by,

$$G = \ln\{-\ln(1 - F)\} = \ln a + m \ln x - px^k \quad (7)$$

The parameters are optimized such that the sum of the difference between G and the corresponding observed values squared is minimal. The procedure is iterative, and thus requires a single set of priori estimates for the parameters. It was found through results of many numerical examples, the value of each parameter converges to a fixed value, individually, irrespective of the priori estimates, if sufficient many number of iterations, approximately 100 iterations, are carried out.

As an example, the method is applied to significant wave height data observed in the North Sea. For this example, values of the four parameters involved in (6) are obtained as,

$$\begin{aligned} a &= 0.908 \\ m &= 1.101 \\ p &= 0.181 \\ k &= -1.328 \end{aligned}$$

The cumulative distribution function evaluated by using these values are plotted on the log-normal probability paper as shown in Figure 5 together with data points, while Figure 6 shows those plotted on the Weibull paper. As can be seen in these figures, the data are

Figure 6 Cumulative distribution function based on Equation (6) plotted on Weibull probability paper (data from Bauws 1978)

Figure 7 Prediction of extreme significant wave height by using the proposed cumulative distribution function (data from Bauws 1978)

well represented by the proposed probability distribution over the entire range of the cumulative distribution function. It can be seen, from these figures together with the results shown in Figures 1 and 2, that the log-normal distribution substantially overestimates, while the Weibull distribution underestimates the magnitude of the extreme significant wave height for this example.

Figure 7 shows the return period in the logarithmic scale. Given that 5,412 observations are made in 3 years, the magnitude of significant wave height most likely to occur in 10 years and 50 years are estimated from the figure as 8.8 meters and 10.0 meters, respectively.

As another example, presentations similar to those shown in Figures 5 and 6 are made using the significant wave height data observed at Tiner Point, Canada, and results are shown in Figures 8 and 9. Again, the data are well represented by the proposed distribution over the entire range. Given that 2,304 observations were made in one year, the magnitudes of extreme significant wave height expected in 10 years and 50 years are estimated from Figure 10 as 19.0 ft (5.8 meters) and 22.2 ft (6.8 meters), respectively.

Figure 11 shows another example of application using the significant wave height data observed at Port Hueneme, California (Thompson 1977). As can be seen in the figure, the data follow fairly well the log-normal distribution; however, the log-normal distribution appears to underestimate the extreme significant wave height for this example. The data are represented well by the cumulative distribution function obtained by the proposed method. The extreme significant wave heights estimated by the proposed method are shown in Figure 12.

CONCLUSIONS

This paper discusses a method to statistically predict the severest sea state (significant wave height) from the observed data. For the estimation of extreme significant wave height, a precise representation of the data by a certain probability function is highly desirable. For the probability distribution function applicable to the significant wave height, the log-normal distribution and the Weibull distribution have often been considered to date. Although it is a general trend that the data appear to follow the log-normal probability law, but not to the extent that this probability law can be used for the estimation of extreme values. In principle, there is no scientific basis for selecting any particular probability distribution (either the log-normal or the Weibull) to characterize the significant wave height.

The authors' method is to express asymptotically the cumulative distribution function of the significant wave height as a combination of an exponential and power of the significant wave height. The parameters involved are determined numerically by a nonlinear minimization procedure.

Figure 8 Cumulative distribution function based on Equation (6) plotted on log-normal probability paper (data from Khanna and Andru 1974)

Figure 9 Cumulative distribution function based on Equation (6) plotted on Weibull probability paper (data from Khanna and Andru 1974)

Figure 10 Prediction of extreme significant wave height by using the proposed cumulative distribution function (data from Khanna and Andru 1974)

Figure 11 Cumulative distribution function based on Equation (6) plotted on log-normal probability paper (data from Thompson 1977)

Figure 12 Prediction of extreme significant wave height by using the proposed cumulative distribution function (data from Thompson 1977)

The proposed method is applied to significant wave height data obtained in the North Sea, Tina Point, Canada, and Port Hueneme, California. The results of analysis show that the data are well represented by the proposed method over the entire range of the cumulative distribution. Thus, it is believed that a more accurate estimation of the severest sea state (significant wave height) can be achieved based on the proposed cumulative distribution function.

CHAPTER 37

PREDICTION OF DOMINANT WAVE PROPERTIES AHEAD OF HURRICANES

by

Omar H. Shemdin¹

ABSTRACT

A method is proposed for predicting properties of dominant waves in the forward region of hurricanes where the waves are found to propagate predominately in the direction of hurricane forward travel. An extended fetch concept is used in which each wave component is exposed to the action of wind over a fetch length that is determined by wave group speed, hurricane forward speed, and location with respect to eye. Maximum extended fetches are found to the right of the eye (with respect to direction of hurricane travel) in the northern hemisphere. The method correctly predicts dominant wave frequencies and significant wave heights. The prediction method utilizes recently developed concepts in wave generation and energy transfer among wave spectral components; the predicted values are compared favorably with observations

Introduction

There is substantial interest in techniques that can predict properties of waves generated by hurricanes. Considerable damage results in the coastal zone when hurricane-generated waves impact a coast even when the hurricane eye is located far offshore. The damage is most dramatic when the hurricane eye crosses the shoreline (land fall) because of flooding generated by both storm surge and wave-induced set-up. The hurricane windfield is complex but has been successfully described in terms of a translating vortex. For the purpose of this investigation it is assumed that the wind field can be adequately described and that information on the wind field is available as input. This paper outlines a procedure which uses the wind field as input to predict properties of dominant waves which are found ahead of hurricanes (see King and Shemdin, 1978).

Up to 1970 the available hurricane wave measurements were not of sufficient quantity or quality to promote either understanding of the wave generation process or to achieve verification of the empirical predictive techniques available. An organized program was instituted by a consortium of oil companies in the late 60's and early 70's to amend this deficiency (see Ward, 1974). The results were used to develop and verify models that predict the significant wave height (Bea, 1974) and others that provide two-dimensional wave spectral properties (Cardone, Pierson and Ward, 1976).

¹Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, and University of Florida, Gainesville, Florida.

Additional valuable data sets on several hurricanes were collected by buoys operated by the NOAA-Data Buoy Office and by our airborne Synthetic Aperture Radar (SAR) which was operated by Jet Propulsion Laboratory (JPL). These data sets were reviewed by King and Shemdin (1979); a condensed summary of measured hurricane parameters is given in Table 1.

The numerical wave spectral model of Cardone, Pierson and Ward (1976) has been shown to predict satisfactorily the significant wave height in hurricanes. Because of the dearth of directional wave measurements the model wave direction predictions have not been verified completely by comparison with measurements. Such measurements have only become available recently through the use of airborne synthetic aperture radars such as discussed by King and Shemdin (1978). Empirical models for predicting the significant wave height have also been advanced by Bretschneider (1972) and Ross (see Cardone and Ross, 1979). The Ross model does not recognize the influence of hurricane forward speed in wave generation and for that reason it is limited in application to very slow moving hurricanes. The Bretschneider model does account for the hurricane forward speed; however, the model is strictly empirical and does not incorporate recent advances in wave generation physics and consequently does not provide insight on the wave generation process in hurricanes.

The purpose of this paper is to propose a method that adequately predicts the frequency and significant wave height of dominant waves which are found in the forward region of the hurricane (ahead of the eye in the direction of forward travel). The model is consistent with known mechanisms of wave generation and incorporates the hurricane forward speed as a central factor in our ability to correctly predict dominant wave properties in moving hurricanes.

Wave Prediction Model

King and Shemdin (1978) presented SAR images showing waves in different hurricane sectors for several hurricanes. The wave images contained valuable information on dominant wave lengths and directions. A striking asymmetry was observed in the wave field when the wave images were assembled in location with respect to the hurricane eye. The asymmetric wave generation was attributed to two mechanisms: (1) the cyclonic wind speed is greater on the right hand side of a moving hurricane (in the northern hemisphere), and (2) the waves generated on the right side of the moving storm propagate in the same general direction as the storm and therefore remain in the wind generation zone longer than those generated on the left side of the storm. The residence time of a wave component in the wind generation area to the right of the storm is inversely proportional to the difference between the wave group velocity in the direction of hurricane forward travel and the hurricane forward speed. In a wind generation setting various wave frequencies are generated in various directions. The waves which propagate in the same direction as that of hurricanes forward travel are

5. Duration of linear travel

expected to grow fastest. Of those the wave spectral components which travel slower or equal to the storm forward speed grow rapidly and saturate in the wave generation zone. Very low frequency waves travel faster than the storm and consequently have small residence duration in the wind generation zone. The intermediate wave frequencies which correspond to wave group velocities slightly larger than the hurricane forward speed remain in the wind generation zone long enough to achieve substantial wave heights. These waves eventually overcome the hurricane intense region and appear as dominant waves ahead of the hurricane as shown in the images presented by King and Shemdin (1978). It was shown that these dominant waves have group velocities 1.3 to 2.5 times greater than the hurricane forward speeds.

The above observations also suggest that the dominant waves ahead of the hurricane are primarily generated by a fetch system to the right of the eye that translates with the speed of the storm. In a stationary fetch situation the duration of a wave component in the fetch area is related to the fetch length by the wave group velocity. When a fetch translates in the direction of wave travel the duration of a wave in the fetch area is determined by the difference between the wave group velocity and the forward speed of the fetch.

In a fetch-limited wave generation setting Hasselmann et al (1973) obtained a relationship for the dominant frequency, f_m , in terms of fetch length, X , and wind speed at 10m above the mean sea level, U_{10} , given below:

$$f_m = 3.5 \left(\frac{g^2}{X U_{10}} \right)^{1/3}, \quad (1)$$

where g is gravitational acceleration. For the same conditions, they found the mean squared surface displacement, ϵ , to be:

$$\epsilon = 1.6 \times 10^{-7} \left(\frac{X U_{10}^2}{g} \right), \quad (2)$$

where ϵ is related to the significant wave height, H_s , by

$$H_s = 4 \sqrt{\epsilon}. \quad (3)$$

In a translating fetch setting such as in a hurricane the following transformation is proposed:

$$X U_{10} = \left(\frac{K U_m}{1 - (V/C_g)} \right), \quad (4)$$

where U_m is the maximum hurricane wind speed reduced to 10m elevation, K is an equivalent fetch which is established empirically, V is the hurricane forward speed and C_g is the wave group velocity in the direction of hurricane forward travel. Substituting Equation (4) into Equation (3) yields:

$$f_m = 3.5 \left(\frac{g^2 - 4\pi f_m g V}{K U_m} \right)^{1/3} \quad (5)$$

King and Shemdin (1979) used the available data, from several hurricanes, on f_m , V and U_m , shown in Table 1, to establish that an equilibrium wave generation condition exists in hurricanes when the hurricane forward travel remains along a linear path over a period specified by time required for waves to propagate through the fetch area. For those hurricanes satisfying the equilibrium condition they empirically determined the equivalent fetch length, K , to be 80 Km. Using this value of K in Equation (5) it was possible to predict f_m from available values of U and U_m . As a test of this procedure, predicted f_m values were compared with observed f_m values as shown in Figure 1. As can be seen the agreement is satisfactory for equilibrium hurricanes and unsatisfactory for non-equilibrium hurricanes.

The wave prediction model is now extended to predict the significant wave height. Substituting Equation (4) into Equation (2) and adopting a scaling factor, α , between U_{10} and U_m ($U_{10} = \alpha U_m$):

$$\epsilon = 1.6 \times 10^{-7} \left(\frac{\alpha U_m^2 K}{g - 4\pi f_m V} \right) \quad (6)$$

Alternatively, ϵ may be expressed in terms of the dominant frequency, f_m ,

$$\epsilon = 6.86 \times 10^{-6} \left(\frac{\alpha U_m^2 K}{f_m^3} \right) \quad (7)$$

Predicted significant wave height, H_s , values derived from Equations (6) and (7) are compared with observed values in the following section.

Comparison with Observations

The comparison between f_m values predicted from the hurricane wind parameters and those observed f_m are shown in Figure 1. The favorable comparison substantiates the relatively simple process with which waves are generated in a translating hurricane wind field. The prediction model extends the usefulness of wave length measurements obtained from airborne SAR images to provide estimates of the significant wave height ahead of the hurricane.

Figure 1. Comparison of observed and predicted f_m values of dominant waves.

The available observations for verifying Equation (7) are summarized in Table 2; only equilibrium hurricanes are included in this table. As shown, significant wave height measurements are available only for three of the seven equilibrium hurricanes listed. The observed wave heights are those measured with NOAA-NDBO buoys. The observed f_m values refer to direct measurements from the buoys or inferred from wave length values in aircraft SAR images. The SAR does not provide wave height measurements. The H_s values predicted with Equation (7) using observed f_m and U_m values are also shown in Table 2. The scaling parameter α was assumed to be one. The H_s comparison is displayed graphically in Figure 2. Because of the limited number of observations no further analysis was pursued to determine the optimum scaling factor α . Clearly, this will become useful as more wave height measurements become available. The favorable comparison shown in Figure 2 provides substantiation for the usefulness of the proposed method for predicting the significant wave height of the dominant waves ahead of the hurricanes.

Summary and Conclusions

The insight gained from the observed asymmetrical distribution of waves in the various hurricane sectors and the proposed model for describing and predicting the dominant wave properties ahead of hurricanes can be summarized in the following:

1. The dominant and most energetic waves generated in a translating hurricane wind field are found immediately ahead of the storm. These waves propagate in the same general direction as that of hurricane forward travel.
2. The dominant waves are generated by a translating fetch system that is of order 80 km in length and located to the right of the hurricane eye (in the northern hemisphere). The fetch translates with the speed of hurricane forward travel.
3. The hurricane forward travel speed plays a central role in determining the properties of the dominant waves. Fast traveling hurricanes are expected to generate longer and more energetic waves ahead of the hurricane compared to stationary hurricanes.
4. The above description of wave generation is substantiated by favorable comparisons between predicted and measured dominant wave frequencies ahead of hurricanes. The comparisons are only favorable in equilibrium hurricanes.
5. The proposed model predicts the significant wave height, H_s , of dominant waves from either the observed or predicted values of the dominant frequency, f_m . The model is considered valid only for equilibrium hurricanes.

TABLE 2

Comparison of predicted and observed H_S values for equilibrium hurricanes.

Hurricane	Observed Values			Predicted H_S (m) from Eq. (7)*
	$f_m(H_z)$	U_m (m/s)	H_S (m)	
Camille	0.072	64	13.8	13.6
Belle I	0.075	31	7.5	8.9
Emmy II	0.085	24		6.5
Frances	0.080	32		8.2
Gloria I	0.106	23		4.6
Gloria II	0.075	34		9.3
Anita	0.090	37	6.7	7.4

* $\alpha = 1$ assumed in these calculations.

6. The proposed model is suitable for statistical studies of dominant wave properties in hurricanes. It can be applied productively when complex and costly numerical procedures are not needed such as in predicting H_s or f_m values of dominant waves. Detailed directional wave properties in various sectors of the hurricane require detailed numerical procedures, however.

ACKNOWLEDGEMENT

The research described in this paper was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under NASA Contract NAS 7-100. The author acknowledges the valuable support of Dr. R. Sheets of the NOAA-National Hurricane and Environmental Meteorological Laboratory.

LONG PERIOD DISTURBANCES DUE TO WAVE GROUPS
by
E.C.BOWERS, Ph.D, HYDRAULICS RESEARCH STATION, ENGLAND

SUMMARY

Measurements of long period disturbances associated with wave groups are compared with theoretical predictions. The experiments were carried out in a wave flume with an absorbing beach at one end. Tests were carried out using both regular wave groups (made up of two wave frequencies so that groups occur at a single beat frequency) and a random sea. The theoretical predictions are based on a Stokes expansion of the basic wave equations up to second order. The results are consistent with having three components in the long period disturbance at wave group periods. The first is set-down beneath wave groups, a disturbance that is tied to the wave groups travelling towards the beach. The second is a surf beat, a free long wave propagating back from the beach that is generated by reflection of the set-down from the beach. The third component is a secondary wave, a free long wave propagating towards the beach, that is generated by the wave-maker when it is only programmed to produce the primary wave system without its associated set-down beneath wave groups. The experimental results show that this third component can be minimised for both regular wave groups and a random sea by adding an appropriate long period movement of the wave-maker. Also, results are presented that indicate that long cycles of truly random waves, lasting many hours in model terms, are required to obtain reliable estimates of the effect of wave grouping on marine structures.

1 INTRODUCTION

Long wave disturbances with periods of the order of minutes are of importance to large moored vessels since the natural periods of horizontal oscillation of such vessels on their moorings are typically within the range of 30 seconds to 2 minutes depending on the displacement of the vessel and the stiffness of the moorings. As hydrodynamic damping of these oscillations is low, a significant resonant response of the vessel on its moorings can be produced by relatively small amplitude long period wave motions. Such disturbances with average heights of 0.3m to 0.4m are known to cause moorings to part (Hydraulics Research Station Report, 1976 and Stammers et.al., 1977). The problem can be compounded for vessels moored inside harbours when long period wave motions are amplified through harbour resonance.

One source of long wave energy, described by Longuet-Higgins and Stewart (1964) arises from disturbances generated by wave grouping. A group of large waves will tend to cause a depression in the mean water level with a corresponding rise in level between groups of large waves. This effect, sometimes known as set-down beneath wave groups, has a periodicity that is associated with the groups but it differs from a free long wave because it is tied to the wave groups. Therefore, it propagates at the group velocity which is less than the phase velocity of a free long wave of the same period as the set-down. Even so, it has been shown both theoretically and experimentally by Bowers (1977) that set-down behaves much like an ordinary long wave when it excites the resonant modes of harbours. This result indicates that in situations where wave diffraction occurs, the energy contained in disturbances that are tied to the wave envelope can be released as free long waves. This is similar to the effect described by Biesel (1966) where diffraction of a regular wave around a breakwater is accompanied by the emission of free waves at twice the regular wave frequency. The energy for these free waves, clearly visible in the shelter of the breakwater, comes from the second order disturbances that cause the regular wave to have sharper crests and more shallow troughs than a sine wave, ie disturbances at twice the primary frequency that are tied to the waves incident on the breakwater.

Tucker (1950) reported a correlation, which occurred off a beach in Cornwall, between fluctuations of period of the order of minutes and the envelope of incoming waves. This correlation occurred with a depression in the long wave lagging behind a group of high waves by 4 to 5 minutes. It was suggested by Longuet-Higgins and Stewart (1964) that the time lag in these long waves or surf beats correspond to the time taken for the ordinary waves with their associated set-down beneath wave groups to propagate from the wave recorder position into the breaker zone and for the set-down to be reflected back past the recorder as free long waves. This mechanism of surf beat generation is consistent with the experimental results reported in this paper. It is to be expected that in many situations part of the energy in the incoming set-down will be trapped by the coastline in the form of edge waves (Gallagher, 1971; Bowen and Guza, 1978).

In physical model studies of harbours and moored ships a wave generator which produces a good representation of the primary wave system is used to produce irregular waves. Since this wave system is irregular it naturally contains wave groups and therefore it should also contain set-down beneath wave groups. If the wave generator is not programmed to produce this set-down then it can be appreciated that the expected long period water particle movement will not occur. Experiments carried out as part of the research programme of the Hydraulics Research Station (Bowers, 1976 and 1977) have demonstrated that the result of not programming the wave generator to produce set-down is to introduce long waves with the same period and approximately the same amplitude as set-down. These secondary long waves arise so that their water particle movement near the wave-maker tends to cancel the water particle movement of set-down in such a way that the boundary condition of no long period movement on the face of the wave-maker is satisfied. This mechanism of secondary wave generation is similar to that reported by Fontanet (1961). As the primary wave system propagates away from the generator it carries with it the set-down associated with wave groups and propagating with the system are secondary long waves. As mentioned before, set-down propagates more slowly than the free secondary long waves. As they are exactly out of phase at the wave generator they will gradually come into phase with one another with increasing distance from the generator. As distance increases further the two will again go out of phase with one another, and so on. Thus, in physical models the response of harbours and moored ships sensitive to long period disturbances could depend on their distance from the wave-maker. For this reason a programme of research was started at HRS into methods of adding in the necessary movement of the wave-maker to produce set-down at the generator. By this means it should be possible to minimise secondary long waves from the generator

Summarising, we see that wave diffraction, wave breaking and model wave generation are three mechanisms whereby free long waves are produced in irregular seas. It is a description of an effort to minimise the third kind, free secondary long waves produced by the wave-maker, that forms the main body of this paper.

2 THEORETICAL MODEL

The basic equation describing irrotational motions is

$$\nabla^2 \phi = 0 \quad \text{.....(1)}$$

Here, water particle motion in the vertical x, z plane of a right handed orthogonal co-ordinate system with velocity \underline{v} (horizontal component u and vertical component w) is related to the velocity potential ϕ by

$$\underline{v} = (u, w) = -\nabla\phi$$

The boundary conditions to be satisfied by surface waves are, on the bottom ($z = -d$)

$$w = 0 \quad \text{.....(2)}$$

on the free surface ($z = \eta$)

$$\eta_t + u\eta_x - w = 0 \quad \text{.....(3)}$$

$$\frac{1}{2} v^2 + g\eta - \phi_t = 0 \quad \text{.....(4)}$$

Here, ϕ_t indicates the partial derivative of ϕ with respect to time with corresponding meanings for the other variables with a suffix

The usual assumption made in describing surface waves is that the product terms in (3) and (4) are small in comparison with the other terms in the equations. Thus, the following set of equations is obtained

$$\nabla^2 \phi^{(1)} = 0 \quad \dots(5)$$

where

$$\underline{v}^{(1)} = (u^{(1)}, 0, w^{(1)}) = -\nabla \phi^{(1)}$$

and the boundary conditions are,

on $z = -d$

$$w^{(1)} = 0 \quad \dots(6)$$

on $z = 0$

$$\eta_t^{(1)} - w^{(1)} = 0 \quad \dots(7)$$

$$g\eta^{(1)} - \phi_t^{(1)} = 0 \quad \dots(8)$$

(5) to (8) are the first order set of equations in a Stokes expansion of the basic equations (1) to (4). This is why the variables have been given a super script of one.

To second order we obtain

$$\nabla^2 \phi^{(2)} \approx 0 \quad \dots(9)$$

where the boundary conditions are

on $z = -d$

$$-\phi_z^{(2)} = 0 \quad \dots(10)$$

on $z = 0$

$$\phi_{tt}^{(2)} + g\phi_z^{(2)} = \eta^{(1)} (w_{tt}^{(1)} + gw_z^{(1)}) + 2\underline{v}^{(1)} \cdot \underline{v}_t^{(1)} \quad \dots(11)$$

Here, (11) is obtained by expanding (3) and (4) to second order and eliminating the second order surface elevation

Fig 1 Experimental layout

3 EXPERIMENTAL AND THEORETICAL RESULTS FOR REGULAR WAVE GROUPS

The experimental layout (Fig 1) consisted of a wave flume about 7m long, 0.6m wide and 0.18m deep. To establish the feasibility of generating set-down with the wave-maker it was decided to work with regular wave groups. The primary wave system consisted of two frequencies (f_1 and f_2) so that wave groups occurred at a single beat frequency ($f'' = f_2 - f_1$). Wave heights were measured with twin wire wave probes and the horizontal movement of the face of the piston type wave-maker was measured with a transducer. The data were analysed with a fast Fourier transform (FFT) computer program to give spectra of the waves and the wave-maker. The three peaks of interest in the spectra occur at the difference frequency (f'') and at the primary wave frequencies (f_1 and f_2). The amplitude (a) of each component was obtained from the area (A) under each peak by using

$$\frac{1}{2} a^2 = A$$

It was established that measurements were accurate to within 0.2mm. The beach at the end of the flume resulted in reflection coefficients of less than 10% for the primary wave system so that the assumption that the primary system is purely progressive is a reasonable one. Equations (5) to (8) can be used to give a mathematical representation of the two progressive primary waves.

3.1 Progressive secondary wave system

To second order (9) to (11) can be used to solve for $\phi_s^{(2)}$ say, representing set-down beneath the regular wave groups. From (11) we see that a surface perturbation (the product of first order terms on the right-hand side of (11)) is the forcing term leading to set-down (terms involving $\phi_s^{(2)}$ on the left-hand side of (11)).

It was clear from experiment that although the beach was an efficient absorber of the primary waves it was not such a good absorber of disturbances at the beat frequency. This resulted in secondary long waves travelling back towards the wave generator. It can be appreciated that such waves will tend to reflect from the face of a wave-maker board as though reflecting from a vertical wall. Therefore, long waves travelling back from the beach will give rise to a standing wave system with nodal points at distances of $L/4, 3L/4, 5L/4$ etc from the face of the wave-maker. Here, L is the wavelength of a free long wave at the beat frequency. Thus, a wave probe placed at these nodal points will not register the long wave system caused by reflection from the beach. This allows a comparison to be made between theory and experiment for a progressive secondary wave system.

The second order velocity potential found so far ($\phi_s^{(2)}$) would result in set-down at the wave generator but as explained in the introduction, the predicted long period water particle movement does not occur in the absence of an appropriate movement of the wave-maker at the group period. The boundary condition on the face of the wave-maker is

$$u = \xi_t$$

Table I

where u is the horizontal water particle velocity and ξ is the horizontal deviation of the paddle from its equilibrium position $x = 0$

To second order this boundary condition becomes

$$-\phi_{xx}^{(2)} - \phi_{xx}^{(1)} \xi^{(1)} = \xi_t^{(2)} \quad \text{at } x = 0 \quad \dots(12)$$

In the absence of secondary paddle movement ($\xi^{(2)} = 0$) experiments have shown that secondary free waves are formed in addition to set-down. Denoting the velocity potential of the free waves by $\phi_L^{(2)}$ we obtain from (12) an equation determining the secondary free waves

$$-\phi_{Lx}^{(2)} = \phi_{Sx}^{(2)} + \phi_{xx}^{(1)} \xi^{(1)} \quad \dots(13)$$

Here $\phi_L^{(2)}$ satisfies the usual equations for a surface wave ie (9) (10) and (11) with the right-hand side set to zero.

Experimental values of the amplitude of the surface elevation at the beat frequency are compared with theoretical values, obtained using (9),(10),(11) and (13), in column (a) of Table I. In this table a comparison between theory and experiment for a progressive secondary wave system can only be made at wave probe positions $L/4, 3L/4$ or $5L/4$. This table shows results for six different pairs of primary wave frequencies. The first three pairs each have a difference frequency of 0.3 c/s and the last three each have a difference frequency of 0.17 c/s. As expected, the theoretical results in column (a) predict that the amplitude of the beat frequency disturbance at nodal points should vary with distance from the wave-maker depending on the phase relationship between set-down and secondary wave. Example 2 is a good illustration. Theory predicts that at $3L/4$ the set-down and secondary wave from the wave-maker are in phase, resulting in an enhanced amplitude of 2.8mm. Then, at a greater distance from the wave-maker the two are no longer in phase giving a reduced disturbance of 1.2mm at $5L/4$. In general, qualitative agreement is obtained between theory and experiment at nodal positions in column (a) of Table I in that increasing and decreasing trends measured in the amplitude of the beat frequency disturbance at various distances from the wave-maker are much as predicted by theory

If the secondary free wave from the wave-maker is to be eliminated we see from (12) that a secondary paddle movement $\xi^{(2)}$ is required such that

$$\xi_t^{(2)} = -\phi_{Sx}^{(2)} - \phi_{xx}^{(1)} \xi^{(1)} \quad \dots(14)$$

In the absence of secondary waves only set-down should be present and so the amplitude of the beat frequency disturbance should not vary with distance from the wave-maker. In the experiments an appropriate movement of the wave-maker based on (14) was applied until the beat frequency disturbance became equal at nodal points. The results are given under column (b) of Table I. They show that an appropriate secondary movement of the wave-maker can almost eliminate secondary waves from the generator. The column giving amplitude of secondary paddle movement also shows that the amount of secondary movement required is much as predicted by (14).

To appreciate what these model results represent in prototype terms we can assume that Froude scaling applies at I to 100. Then primary wave periods cover the range 7s to 20s with wave heights up to 5m. The heights of the disturbance at the beat frequency are about 0.2m with periods of about 30s or 60s.

Summarising, we see that the results indicate that secondary long waves from the wave-maker can be minimised for regular wave groups by adding an appropriate movement of the wave-maker at the group period.

3. 2 Surf beats

The presence of a surf beat, ie a reflection of set-down from the beach as a free long wave, is demonstrated by the results in column (b) of Table I. If set-down were dissipated on the shingle beach along with the primary waves, the amplitude of the surface elevation at the beat frequency would be the same at all positions in the flume. But, it is clear from the experimental results in column (b) of Table I that there are considerable variations in this amplitude particularly when the primary waves are of short period (see cases 1,2 and 4). From the description of results in Section 3.1 we know that secondary waves from the wave-maker are not the cause of these variations because such waves have been minimised by an appropriate movement of the wave-maker.

In an effort to explain these variations we can assume that part of the energy in set-down is reflected as a free long wave or surf beat and that this surf beat is perfectly reflected from the face of the wave-maker. One method of proceeding is to estimate the magnitude of the reflection coefficient for set-down. This estimate was obtained in the following way. The coefficient of reflection from the beach (R_L) of a free wave at the beat frequency was measured by carrying out monochromatic long wave tests. If we then assume that R_L is equal to the ratio of horizontal water particle movement in the surf beat to the horizontal water particle movement in set-down, we have

$$R_L = \frac{Ka}{k^2 a^2}$$

Here, K and a are the wave number and amplitude, respectively, of the surf beat and k and \bar{a} are the wave number amplitude of the set-down; all these quantities being evaluated in the depth of water at the toe of the slope. If \bar{a}/a the reflection coefficient of set-down, is denoted by R , then

$$R = \frac{k}{K} R_L = c/cg R_L$$

Here, c is the phase velocity of the surf beat and cg is the group velocity. Since $c > cg$ we see that this relationship produces an enhancement in the reflection coefficient of set-down. The shorter the primary waves, the smaller the group velocity and the larger this enhancement becomes. This trend is illustrated by the experimental results in column (b) of Table I in that variations representative of the presence of a surf beat are larger when the primary waves are short. Having estimated the magnitude of R , the actual point of reflection on the shingle beach was chosen such that theoretical and experimental values of the resultant amplitude at the beat frequency agreed at one position in the flume for each pair of frequencies. This position is indicated in Table I by a line under the experimental and theoretical values. Of course, in obtaining the theoretical values given under column (a) in Table I it was necessary to include a free secondary wave from the wave-maker together with its reflection from the beach.

Fig 2 Long wave results for a random sea

Summarising, we see from the results given in Table I for positions in the flume other than nodal points that the somewhat rough and ready theoretical model for surf beat generation does predict the increasing and decreasing trends measured in the amplitude of the beat frequency disturbance at various distances from the wave-maker. These results indicate that the energy in set-down beneath wave groups can be released in the form of free long waves when the primary waves are dissipated

4 EXPERIMENTAL AND THEORETICAL RESULTS FOR A RANDOM SEA

To make theoretical calculations more tractable it was decided to work with a Gaussian shaped wave spectrum. This is shown in Fig.2 which is drawn to a scale of 1 to 80. The spectrum can be considered representative of swell waves. With the same experimental layout as that already described (Fig 1) the primary wave system was essentially progressive. The measuring instruments and the method of data analysis were also the same

Two experimental results for the spectrum of set-down are compared with a theoretical result in Fig 2. We see that theory and experiment are in reasonable agreement only when the set-down generator is used, ie, an appropriate long period movement of the wave-maker is used to produce set-down at the wave generator. The small amount of energy at low frequencies measured without the set-down generator indicates that secondary long waves from the wave-maker were cancelling the set-down at the positions in the flume used for measurement. The long period spectra are only plotted for periods of less than 70 seconds since the time constants in the set-down generator limited its effectiveness to that range for these tests. The theoretical prediction for the spectrum of set-down is in fact Gaussian with its maximum spectral density at zero frequency.

To avoid measuring the effect of surf beats in the flume the following procedure was used. The spectral density for a particular low frequency (f) band was measured at a distance from the wave-maker that was a nodal point for the secondary waves (at frequency f'') caused by reflection from the beach and re-reflection from the wave-maker. This meant that the spectral density for different low frequency bands was obtained from spectral measurements at different positions in the flume. This allowed an experimental estimate of the low frequency spectrum to be obtained for a purely progressive wave system.

A theoretical estimate of the spectrum of set-down associated with a progressive random sea was obtained in the following way. The first order surface elevation ($\eta^{(1)}$) was represented by a sum of sine waves with random phases. The products of first order quantities on the right-hand side of (11) were then evaluated and the equation solved to give the second order velocity potential. Expanding (4) to second order and substituting for the second order velocity potential results in an expression for the second order surface elevation, $\eta^{(2)}$ say.

Denoting the slowly varying part of $\eta^{(2)}$ by $\tilde{\eta}^{(2)}$ we find

$$\tilde{\eta}^{(2)} \cong A \tilde{\eta}^{(1)2} \dots(15)$$

where

$$A = - \frac{\omega^2 n^2}{2k^2 d(1-n^2 \tanh kd)} \left[\frac{\omega^2}{g^2 n \sinh^2 kd} (2 - 2kd \tanh kd - n) + \frac{2k^2}{\omega^2} (1 + \tanh^2 kd) \right] + k \tanh kd - \frac{gk^2 \cosh 2kd}{2\omega^2 \cosh^2 kd}$$

$$n = \frac{cgk}{\omega}$$

Here, it has been assumed that the primary wave spectrum is sufficiently narrow band to approximate A (a function of frequencies in the primary wave spectrum) by its value at the frequency at which the peak occurs in the primary spectrum. It has also been assumed that for the depths of interest the wave group lengths are much greater than the water depth. It can be shown (Bowers 1976) that the spectrum of $(\eta^{(1)})^2$ is given by

$$2 \int S(f) S(f + f^-) df$$

where $S(f)$ is the primary wave spectrum. Hence from (15) we obtain the following estimate of the spectrum of set-down

$$S(f^-) = 2A^2 \int S(f) S(f + f^-) df \quad \dots(16)$$

Using (16) for the Gaussian wave spectrum shown in Fig 2 resulted in the predicted long wave spectrum shown in that figure.

5 REQUIREMENT FOR A GOOD ESTIMATE OF THE EFFECT OF WAVE GROUPS IN PHYSICAL MODELS

Here, it is demonstrated by using an example, that long cycles of truly random waves, lasting many hours in model terms, are required to obtain reliable estimates of the effect of wave groups on marine structures.

Equation (15) shows that set-down and surf beats are related to the slowly varying part of the square of the wave elevation. It is clear that an adequate representation of the spectrum of $(\eta^{(1)})^2$ is required if wave grouping effects are to be well represented. Table II gives values for the area under the spectrum of $(\eta^{(1)})^2$ for ten records of random data each containing about 350 waves. Each record represented a surface elevation with the same wave spectrum $S(f)$. The predicted value for the area under this spectrum was obtained from the following (Bowers, 1976)

$$[\int S(f) df]^2 + 4 \int df^- \int S(f) S(f + f^-) df$$

When the predicted value of 35.83 is compared with the corresponding values obtained from individual records it can be seen that fluctuations of up to +15% and -24% occur. However, the average for the ten records is well within 10% of the predicted value.

These results illustrate the large variability in the response of structures to wave grouping effects found by many observers when short repeating cycles of random data are used in physical model studies. However, the results given here also show that a result closer to the predicted value will be obtained if the cycle of random data used is of long enough duration. This requirement may well result in model tests lasting the equivalent of many times the duration of the design condition of interest. The results of such long tests can be interpreted by considering the following example. Suppose the design condition has a return period of 10 years. If this design condition only lasts 3 hours, say, then the response of a structure sensitive to wave grouping may vary considerably each time the design condition occurs.

Record No.	Area under η^2 spectrum
1	29.12
2	41.29
3	33.9
4	35.15
5	31.36
6	37.75
7	31.35
8	32.34
9	27.01
10	31.76
	Average value = 33.3
	Predicted value = 35.83

However, if a good average estimate of the structure response can be obtained by running a scale model for the equivalent of 30 hours, or 10 times the duration of the design condition, then it appears reasonable to attach a return period of 10 years to that good average estimate of structure response. This technique is particularly appropriate if one is interested in obtaining the standard deviation of the long period response of harbours and moored vessels to wave grouping effects. In such cases long runs are required to obtain reasonable estimates of the standard deviation. Of course, the average maximum response, over the duration of the design condition, can also be obtained from such long model tests.

It is clear from the above that if a structure is sensitive to wave grouping then it is important in physical model tests to carry out sufficiently long tests using random waves. This means that the method of random sea generation used in the laboratory must be capable of producing long cycles of truly random waves lasting many hours in the model.

6 CONCLUSIONS

- (a) Experiments carried out with regular wave groups show that secondary long waves introduced by the wave-maker can be minimised by the addition of a secondary movement of the wave-maker at wave group periods. These experiments also provide evidence for the existence of surf beats, ie reflections of set-down as free seaward going long waves.
- (b) Secondary long waves from the wave-maker can also be minimised for the general case of a random sea.
- (c) Evidence is given to show that in physical model studies long cycles of truly random waves, lasting hours in model terms, are required to obtain reliable estimates of wave grouping effects.

7 ACKNOWLEDGEMENTS

I am grateful to Mr D Fryer who designed the electronic equipment used to generate set-down beneath wave groups. The work is part of the research programme of the Hydraulics Research Station, Wallingford and the paper is published by permission of its Director.

TWO-DIMENSIONAL SURF BEAT

by

Reinhard E. Flick¹
 Douglas L. Inman²
 Robert T. Guza³

ABSTRACT

Surface elevation and velocity measurements in shallow water on beaches show large fluctuations known as surf beat in the long period range from approximately 20s to 2000s (Munk, 1949; Tucker, 1950). A laboratory study was conducted to determine if two shoaling primary waves of nearly equal frequency would generate two-dimensional surf beat at their difference frequency. The experiments, carried out in the Scripps Institution of Oceanography Hydraulics Laboratory 30 m glass walled wave channel, show that the beat frequency motion in the channel consists of the sum of a forced progressive wave and two free standing waves. The progressive wave is forced by the local nonlinear interaction of the primary waves and grows sharply in shallow water. One of the free standing waves is generated directly by the wavemaker. The data is consistent with the hypotheses that the second, much larger, free wave is generated in shallow water as the reflection of the long, forced progressive wave, leading to the observed standing wave surf beat pattern.

Introduction

Surf beat was first observed by Munk (1949) and by Tucker (1950) who noted from field records of swell in shallow water that the envelope of wave amplitude was correlated with wave energy at the envelope, or beat, period. Longuet-Higgins and Stewart (1962) derived the result that the difference interaction of the incoming swell nonlinearly generated forced waves ("set-down" wave) at the difference frequency and wavenumber with some properties like those observed by Munk and Tucker. However, the nonlinear forcing hypotheses could not explain the observed

lag between the envelope of the swell offshore and the arrival of the difference frequency wave. This discrepancy led to the idea that the nonlinearly forced wave was reflected from the shore line as a free wave (Tucker, 1950; Longuet-Higgins and Stewart, 1962), but a plausible mechanism for this was not proposed.

At about the same time, Munk et al (1964) showed that low frequency energy on the continental shelf was mostly in the form of trapped, three-dimensional edge waves. Furthermore, Gallagher (1971) was able to show that resonant growth of edge waves due to nonlinear difference interaction of incoming waves was theoretically possible and consistent with field data. Inman et al (1976) presented field data suggesting that beat period edge waves can be trapped and grow because of longshore discontinuities in topography such as headlands and submarine canyons. Recently, Bowen and Guza (1978) showed in the laboratory that difference interactions of obliquely incident waves caused resonant edge wave growth according to the Gallagher (1971) hypotheses.

With all the interest in edge waves, however, it still remained to show whether or not two-dimensional free long waves existed as a consequence of reflection or surf zone forcing. It was suggested by Tait and Inman (1969) that special surf zone widths and bars and other slope discontinuities could lead to enhancement effects in the surf zone which would amplify runup at special frequencies. Observations by Inman and Tait (unpublished manuscript) show that large runup amplitudes may be observed at certain frequencies. However, it was found that some of the runup peaks appeared at resonant frequencies of the channel, while some did not, thus still leaving the problem unresolved.

A long wave channel conveniently suppresses three-dimensional motions such as edge waves which have longshore dependence. Thus, on-offshore processes can be measured without interference. For example, the upper panel of Figure 1 shows two superposed spectra taken from two single frequency wave experiments at primary frequencies σ_1 and σ_2 run separately. Only the harmonics of each primary appear as secondary peaks. The lower panel of Figure 1 shows the spectrum resulting from measurements made when the two primary waves appear together. Note the energy present at sum and difference frequencies, particularly $\sigma_2 - \sigma_1$.

Wave channels introduce a completely different set of problems which complicate the interpretation of data, especially long wave measurements. These problems are essentially associated either with the wavemaker or with reflection and dissipation in the flume, or in some cases with both (Ursell, et al, 1960; Fontanet, 1961; Madsen, 1971; Hansen and Svendsen, 1974; Bowers, 1977; Flick and Guza, 1980).

It was the purpose of the experiments outlined in this paper to clarify the role of free, two-dimensional surf beat in light of reflection and wavemaker effects peculiar to wavechannels. The measurements were conducted in the Scripps Institution of Oceanography Hydraulics Laboratory. Figure 2 illustrates schematically the 30 m glass wall wave channel, the high-pressure servo-hydraulic wavemaker system and the high resolution resistance wire wavestaff system (Flick, et al, 1979) used in the study.

Figure 1. Upper panel shows superposed spectra of single frequency (σ_1 and σ_2) wave experiments. Note harmonics of each primary. Lower panel shows spectrum of run with both primaries present simultaneously. Note sum and difference frequencies, particularly $\sigma_2 - \sigma_1$ peak.

Figure 2. Schematic of Scripps Institution of Oceanography Hydraulic Laboratory 30 m glass wall wave channel, servo-hydraulic wavemaker and resistance wire wave-staff system.

It can be shown (Madsen, 1971) that free difference frequency waves always exist at some amplitude (perhaps small) when a wavemaker is used to generate two primary waves, unless paddle motion corrections are imposed (Bowers, 1977). These free waves were shown by Flick and Guza (1980) to theoretically be of the same order as the forced non-linear "set-down" wave propagating with wave groups (Longuet-Higgins and Stewart, 1962). These free waves are generated at the wavemaker as progressive waves. After several wave periods, reflections produce a standing wave pattern. Assuming free, long waves are also generated in shallow water or in the surf zone, these also soon exist as standing waves. This makes it difficult to distinguish the source of free waves in wave channels.

The effect of dissipation, particularly in shallow water, may also be important. Long standing waves of sufficiently small amplitude usually exhibit downchannel profile changes too small to measure. However, swash dissipation on the beach face can be significant (Guza and Bowen, 1976) and can lead to progressive wave components in the standing wave profile which further complicate long wave data interpretation. On the other hand, strongly enhanced shallow water wave dissipation by means of a wave absorber was used in this study to eliminate the primary waves before the breakpoint without affecting the free long waves.

Results and Discussion

Flick and Guza (1980) have shown that to lowest order, the surface elevation of free standing waves in a channel with a flat section and a sloping beach (Figure 3) can be written

$$\eta = a_p f(x) \cos \left[\int_0^x k dx - \frac{\pi}{4} \right] \cos \sigma t \quad (a)$$

where

$$f(x) = \begin{cases} 1 & , x_S < x < x_L \text{ (flat)} \\ \left(\frac{x_S}{x}\right)^{1/4} & , 0 < x < x_S \text{ (slope)} \end{cases} \quad (b) \quad (1)$$

$$\int_0^x k dx = \begin{cases} \left(\frac{\sigma^2}{g\beta x_S}\right)^{1/2} (x + x_S), & \text{(flat)} \\ \left(\frac{4\sigma^2 x}{g\beta}\right)^{1/2} & , \text{(slope)} \end{cases} \quad (c)$$

WAVE CHANNEL CONFIGURATION

LINEAR LONG WAVES $\eta = a f(x) \cos \left[\int_0^x k dx - \frac{\pi}{4} \right] \cos \sigma t$

Figure 3. Definition sketch of wave channel with a beach showing location of wavemaker and the coordinate system used.

Here σ is the radian wave frequency, k the wavenumber, β the beach slope, g the acceleration of gravity and the coordinate system is defined in Figure 3. This form is valid except very near the shoreline.

The channel resonance frequencies can be computed by assuming that resonant standing waves will have an amplitude antinode at $x = x_L$. The resonance frequencies are

$$\sigma_n = (n + \frac{1}{4})\pi \frac{(g\beta x_S)^{\frac{1}{2}}}{x_L + x_S} \quad n = 1, 2, \dots \quad (2)$$

Relations (1) and (2) follow from the asymptotic form for large arguments of the J_0 Bessel function (Abramowitz and Stegun, 1965) which is the exact linear standing wave solution on a sloping beach, together with the required matching at the beach toe $x = x_S$.

Figure 4 shows the amplitude of surface displacement for two paddle generated standing waves in a channel with a beach. The triangles show wave elevation data taken with a short-wave absorbing barrier at the location indicated. The solid dots indicate data taken in the absence of the barrier. The location of the barrier in both experiments shown in Figure 4 was chosen so as not to change the location of nodes and antinodes of displacement of the paddle generated long waves. The theoretical wave amplitude normalized by the vertical runup amplitude, according to equation (1) is shown as a solid line.

The upper part of Figure 4 shows the displacement of a free wave with frequency between that of two adjacent channel modes (non-resonant). The wave length is determined by the period and depth since the wave is free. The condition that no flow can occur through the beach face means that the wave has an antinode at the beach. Therefore, the location of nodes and antinodes is determined. The phase of the wave at the paddle then depends only on the channel length. This phase for the non-resonant wave is very close to a node, while in the case of the wave at a channel resonance frequency (Figure 4, lower) the phase at the paddle corresponds to an antinode. In fact, the location of the antinode at the paddle is the resonance condition.

Since non-resonant standing waves generated directly by the wave-maker have antinodes of displacement at the beach face, it is a plausible assumption that standing waves generated in shallow water at the other end of the flume have antinodes at the paddle. The existence of antinodes at the paddle for non-resonant modes would therefore constitute evidence for shallow water long wave generation.

The results of eight beat wave experiments are summarized in Table 1. Four runs were at channel resonance frequencies and the other four were non-resonant. Each experiment consisted of driving the wave-maker simultaneously at two primary wave frequencies (periods T_1 and T_2) and measuring the amplitude of the difference frequency oscillation as a function of position in the channel. Each run consisted of two parts: one with the barrier to absorb the short primary waves and one without the barrier. The position of the barrier was chosen in each

Figure 4. Amplitude of standing waves generated directly by the wavemaker. Location of short wave absorbing barrier shown by cross hatching. Triangles are data taken with the barrier installed, circles were taken without barrier. Solid line is theory from relation (1).

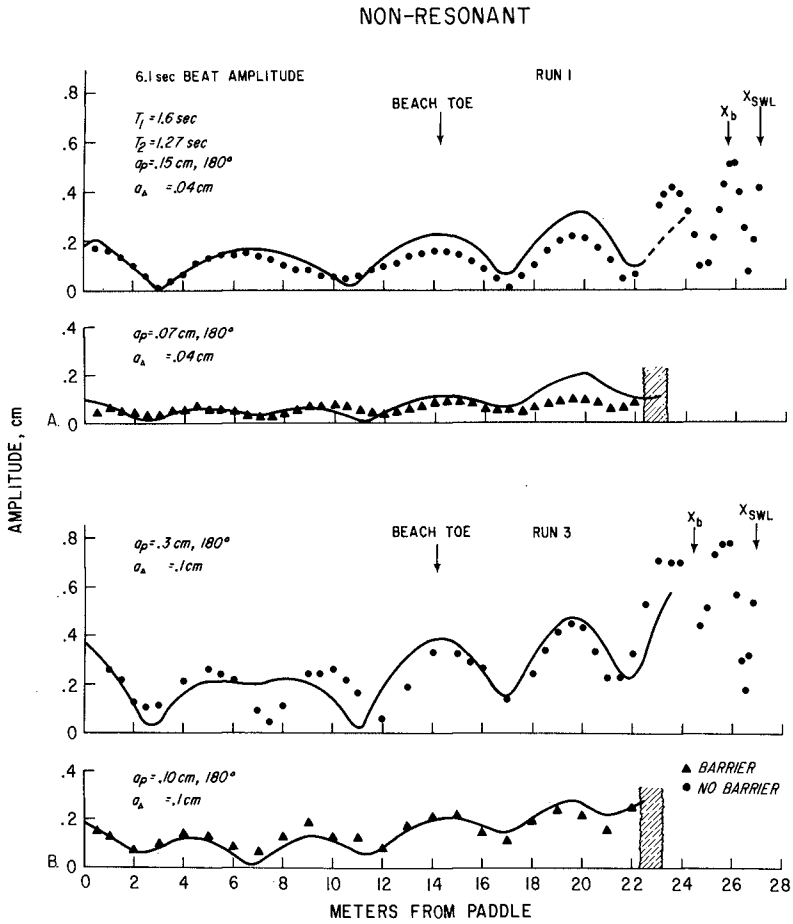

Figure 5. Detailed data of two non-resonant beat wave runs summarized in Table 1. Dots show beat frequency fluctuation without a barrier, triangles are taken with the barrier. Solid line is the best fit of an ad-hoc surf beat theory described in the text.

RESONANT

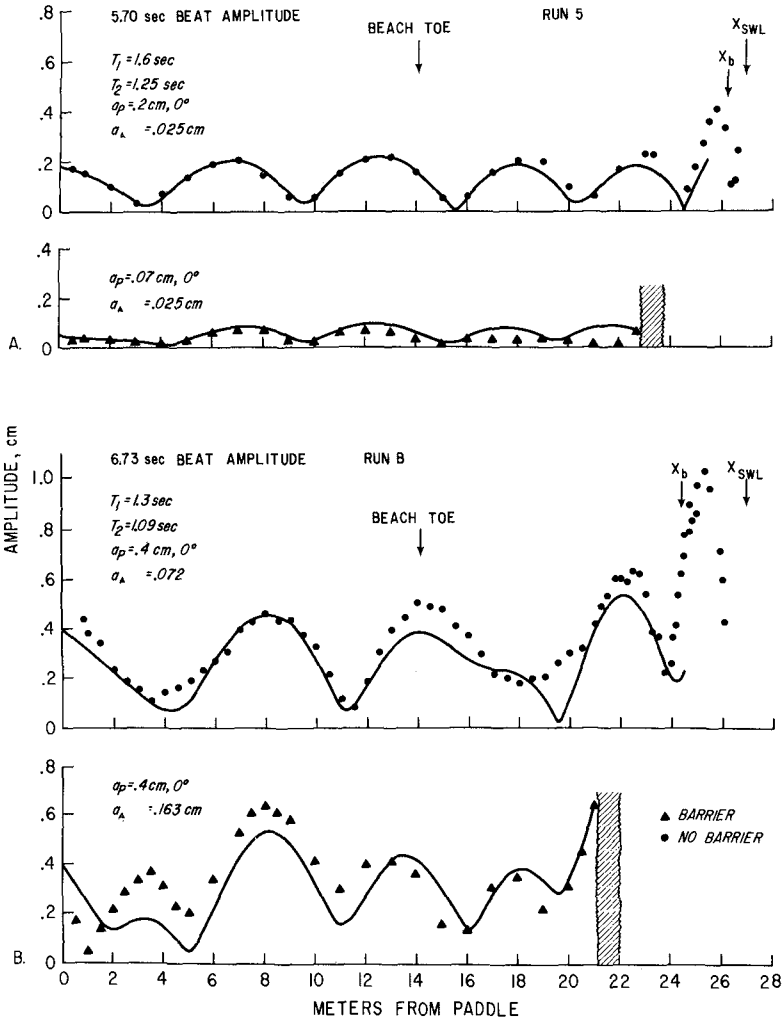

Figure 6. Same as Figure 5 for resonant beat waves.

run to correspond to the position found from earlier long wave measurements (Figure 4) not to affect the paddle generated beat frequency free wave of the same period. The purpose of the barrier was to eliminate the primary wave forcing and the surf zone and any associated long waves generated there. This scheme was supposed to leave only the set-down wave of size a_s and any free waves generated by the paddle. Further discussion of the effect of the barrier is given below.

Figures 5 and 6 show the results of four beat wave experiments in detail. Runs 1 and 3 (Figure 5) are non-resonant examples and 5 and 8 (Figure 6) are resonant. First, it is clear that the phase at the paddle corresponds more closely to an antinode than to a node in the non-resonant data both with and without the barrier. This is also true for the other non-resonant runs not shown in detail, but summarized in Table 1. Of course, there is also an antinode at the paddle for resonant runs, but this is expected and does not help distinguish the source of the free wave component.

The solid lines in Figures 5 and 6 represent the results of an ad-hoc surf beat theory consisting of the sum of two free standing waves and the set-down wave. One standing wave with amplitude a_B is given by equation (1) and has an antinode on the beach face. The second standing wave is similar in form, but has an antinode at the paddle and amplitude denoted a_D . The set-down wave is a forced, progressive correction and is given by Longuet-Higgins and Stewart (1962) in terms of the primary wave parameters. The amplitudes a_s , a_B and a_D have been adjusted to best fit the data and are listed in Table 1. The results show that a_D is negligible compared with a_B for all runs except run 2 where it is small. Therefore, only the progressive set-down wave and the free wave generated or reflected from shallow water seem to be important in the non-resonant runs 1-4.

The data shown are consistent with the hypotheses that the non-linearly generated set-down wave is reflected from the beach when there is no barrier, and from the barrier when it is present. In runs 1, 2, 3, 5 and 6 the standing wave amplitude without the barrier is always larger than with the barrier. For the same primary wave forcing, the amplitude of a_s is doubled by removing the barrier in both runs 1 and 5. In runs 3 and 6 removal of the barrier increased the response by about 50%.

The set-down wave amplitude increases sharply in shallow water. This fact accounts qualitatively for the increased standing wave amplitude in the absence of the barrier, since the beat wave is forced to larger amplitude before being reflected. In the presence of the barrier, the progressive wave is apparently reflected from the barrier, thus reaching relatively smaller amplitude.

The data suggest that the standing wave a_B is merely the result of reflection of the incoming wave a_s . No special enhancement was observed in the conditions tested. The absolute amplitude of the standing wave response depended on whether or not the frequency corresponded to a channel mode. The proportional increase in response caused by removing the barrier was the same for the resonant or non-resonant cases until saturation was reached. The saturation hypothesis advanced by Guza and Bowen (1976) is illustrated by the

standing waves in runs 4, 7 and 8. Removal of the barrier caused no increase in response in runs 4 and 8, and actually decreased response in run 7. In these cases, the reflection parameter c_r exceeds 2,

$$c_r = \frac{a_j \sigma^2}{g \tan^2 \beta}$$

where a_j is the standing wave amplitude at the beach face. This results in increased long wave dissipation in the shallow water region shoreward of the barrier (Guza and Bowen 1976). Run 4 corresponded to a non-resonant case, so that the free wave amplitude could not increase due to resonance with or without the barrier. Run 7, however, corresponded to a resonant case and the amplitude was saturated without the barrier. With the barrier, the dissipative region in shallow water was removed but the resonance condition was unaltered, so that the response was larger. The increase in primary amplitude while other conditions remain the same results in increased standing wave response until saturation is reached (see runs 1, 3, 5, 6 and 7).

In runs 6, 7 and 8 primary amplitudes seem to be larger in the presence of the barrier than without. Without contrary evidence, it seems reasonable to assume that the primary waves were partially reflected from the barrier in these runs and so were able to increase their amplitude. Why the primary waves in the analogous non-resonant experiments, runs 1, 3 and 4 were not so affected is not known.

Finally, Figure 7 shows a plot of the "forcing" a_Δ versus the beat wave response, a_p . The squares denote data with the barrier in place, the triangles are data taken without the barrier. Filled symbols were resonant runs, open symbols were non-resonant. The amplitudes plotted were chosen from the ad-hoc theory described above. When the barrier was in position, a_Δ at the barrier location was used. When the barrier was absent, the value of a_Δ at the breakpoint of the largest wave in the sets was used. The value of a_p is that on the flat portion of the channel. The data plotted in Figure 7 show that a line $a_p = a_\Delta$ separates resonant from non-resonant runs so that resonance occurs for $a_p \geq a_\Delta$.

Conclusion

It has been shown that beat wave data in a 2-dimensional laboratory channel are consistent with the hypotheses that the set-down wave described by Longuet-Higgins and Stewart (1962) is reflected from the shore when the primary waves break. Surf beat experiments in wave channels are severely complicated by the fact that long waves reflect from the beach and from the paddle and thus exist as standing waves. This and the presence of free paddle generated waves make it difficult to distinguish the source of long waves.

Figure 7. Standing beat wave "response" (a_p) as a function of set-down wave "forcing" (a_Δ). Amplitudes plotted are taken from ad-hoc surf beat theory as described in the text. Line $\bar{a}_p = a_\Delta$ separates resonant from non-resonant runs.

1. Introduction

Studies of tsunami generation often employ simple models of the sea floor dislocations to permit tractable analytical solutions. Although these solutions provide basic insight into the generation process, they are incapable of producing explicit results for prototype events where both the spatial and temporal distributions of the sea floor dislocation may be quite complicated. Herein we exploit the apparent linearity of the generation process and demonstrate both the use and validity of the superposition principle to construct solutions for complex bed motions. Analytical and experimental results are presented for a monopolar dislocation (block upthrust or downthrow) with a complex time-displacement history. The time history used in the computations is obtained from an integrated accelerogram recorded at Pacoima Dam, near Los Angeles, during the earthquake of February 9, 1971. A complex spatial deformation is not used in order to enable experimental verification of the analytical results. This is unfortunate since it appears that the details of the time-displacement history are not important for prototype phenomena where the motion may be considered instantaneous. However, it is important to note that the analysis treats both space and time variations in an identical manner; hence, confirmation of this approach for complex time variations strongly suggests analogous behavior for complex spatial variations.

Finally, we examine and compare several alternative time-displacement histories for the mean motion. It is shown that the results for each mean motion can be unified by introducing a velocity as a descriptive parameter which is based on the kinetic energy input of the moving bottom to the overlying fluid.

2. Time-Displacement History

To define a complicated time-displacement history with relevance to earthquake-induced ground motions, we have chosen an accelerogram for the vertical component of motion recorded at Pacoima Dam (near Los Angeles) during the earthquake of February 9, 1971. The accelerogram

Figure 1. Vertical component of ground acceleration recorded 2/9/71 0600 PST Pacoima Dam, California, with integrated velocity and ground displacement.

shown in Figure 1 may be integrated numerically using appropriate precautions (e.g., see Nigam and Jennings, 1968), to yield a time history of the vertical ground displacement. Results of the integration process for the "smoothed" velocity history and the corresponding ground displacement history are shown below the accelerogram in Figure 1.

An analytical representation of the algebraically complex time-displacement history of Figure 1 over a finite record interval, $0 \leq t \leq T$, may be constructed using a Fourier series of the form:

$$\zeta(t) = C_0 + \sum_{n=1}^N C_n \sin(K_n t + \beta_n). \quad (1)$$

In (1) C_n are the amplitudes of the Fourier components with C_0 representing the mean (permanent) ground displacement, K_n are the component wave frequencies, and β_n are the component phase angles. The accuracy of (1) in representing the integrated displacement of Figure 1 is determined by the number of components N retained in the Fourier sum. Results of computations with $N = 18$ are illustrated in Figure 2; this truncated sum will be adopted in the subsequent analysis.

It should be emphasized that both the instrument characteristics and the numerical integration techniques used to obtain ground displacements from acceleration measurements necessarily distort (filter) information in long period components. In particular, the mean (and permanent) displacement of the integrated motion shown in Figure 1 (and, of course, its Fourier representation in Figure 2) is not expected to accurately model the actual permanent deformation. To compensate for this distortion, we may again exploit the superposition principle and add a nonsinusoidal component to the Fourier series representation of (1). As an example of this approach, consider the ramp motion in time of the form:

$$\zeta_r(t) = \zeta_0 t/T \quad (2)$$

during the time interval $0 \leq t \leq T$; other choices for the mean motion are discussed and compared in section 5. In practice, the sum of the mean component resulting from the Fourier synthesis, C_0 , and the additional component ζ_0 from (2) should be chosen to equal the actual permanent ground offset. Hence, a general representation for a complicated time-displacement history becomes:

$$\zeta(t) = C_0 + \zeta_0 t/T + \sum_{n=1}^N C_n \sin(K_n t + \beta_n). \quad (3)$$

3. Solutions of the Water Wave Problem

Consider a two-dimensional (x,y) and incompressible ocean of uniform depth h initially in equilibrium with the earth's gravitational field g which acts in the negative y direction. At time $t = 0$ a section of the

Figure 2. Vertical ground displacement (—) and Fourier synthesis (*) using eighteen components.

sea floor begins to deform vertically with a time and spatial variation given by $\zeta(x,t)$. We seek the inviscid, irrotational, and barotropic deviations $\eta(x,t)$ of the ocean free surface from its equilibrium position. With the coordinate system at the equilibrium position of the free surface, the linearized description of motion in terms of a velocity potential $\phi = \phi(x,y,t)$ is:

$$\phi_{xx}(x,y,t) + \phi_{yy}(x,y,t) = 0 \tag{4}$$

$$\phi_y(x,-h,t) = \zeta_t(x,t) \tag{5}$$

$$\phi_y(x,0,t) = \eta_t(x,t) \tag{6}$$

$$\phi_t(x,0,t) = -g\eta(x,t) \tag{7}$$

where subscripted variables indicate partial differentiation. It is convenient to eliminate $\eta(x,t)$ in (6) and (7) by combining to yield a single condition for the velocity potential:

$$\phi_{tt}(x,0,t) + g\phi_y(x,0,t) = 0 \tag{8}$$

Using the Laplace transform in t and the Fourier transform in x , equations (4), (5) and (8) become:

$$\bar{\phi}_{yy}(k,y,s) - k^2\bar{\phi}(k,y,s) = 0 \tag{9}$$

$$\bar{\phi}_y(k,-h,s) = s\bar{\zeta}(k,s) \tag{10}$$

$$\bar{\phi}_y(k,0,s) + \frac{s^2}{g}\bar{\phi}(k,0,s) = 0 \tag{11}$$

where the overbar of a function $f(x,t)$ indicates:

$$\bar{f}(k,s) = \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} e^{ikx} e^{-st} f(x,t) dt. \tag{12}$$

Solving (9), (10), and (11) for $\bar{\phi}(k,y,s)$ and noting from (7) that

$$\bar{\eta}(k,s) = -(s/g)\bar{\phi}(k,0,s) \tag{13}$$

we find:

$$\bar{\eta}(k,s) = s^2 \bar{\zeta}(k,s) / (s^2 + \omega^2) \cosh kh \tag{14}$$

where $\omega^2 = gk \tanh kh$. Inverting the Laplace and Fourier transforms yields:

$$\eta(x,t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \left\{ \lim_{\Gamma \rightarrow \infty} \frac{1}{2\pi i} \int_{\mu-i\Gamma}^{\mu+i\Gamma} \frac{s^2 e^{-ikx} e^{st}}{(s^2 + \omega^2) \cosh kh} \bar{\zeta}(k,s) ds \right\} dk \tag{15}$$

where the complex inversion integral for the Laplace transform has been used. In (15) ω is the wave frequency ($\omega = is$) and k is the wavenumber. Explicit results for specific deformations of the sea floor $\zeta(x,t)$ will be developed now.

3.1 Solution for a single Fourier component

Consider a block section of the sea floor of length $2b$ whose time-displacement history corresponds to a single Fourier component of (1). With the coordinate system centered above the block section, we have

$$\zeta_n(x,t) = C_n H(b^2 - x^2) [\sin(K_n T + \beta_n) H(T - t) + \sin(K_n t + \beta_n) H(t - T)] \quad (16)$$

where $H(\cdot)$ is the Heaviside step function. Finding the transform of (16), substituting into (15), performing the integration around the Bromwich contour, taking only the real part of the resulting integral, and noting that the integrand is an even function of k , we find:

$$\eta_n(x,t) = \frac{2C_n}{\pi} \int_0^\infty \frac{\cos kx \sin kb}{k \cosh kh} \left\{ A+B - H(t-T) [C+D+E] \right\} dk \quad (17)$$

where

$$A = \sin \beta_n [(\omega^2 \sin \omega t - K_n^2 \sin K_n t)/(\omega^2 - K_n^2)] \quad (18)$$

$$B = K_n \cos \beta_n [(\omega \sin \omega t - K_n \sin K_n t)/(\omega^2 - K_n^2)] \quad (19)$$

$$C = \sin(K_n T + \beta_n) \left\{ [\omega^2 \cos \omega(t-T) - K_n^2 \cos K_n(t-T)]/(\omega^2 - K_n^2) \right\} \quad (20)$$

$$D = K_n \cos(K_n T + \beta_n) \left\{ [\omega \sin \omega(t-T) - K_n \sin K_n(t-T)]/(\omega^2 - K_n^2) \right\} \quad (21)$$

$$E = -\sin(K_n T + \beta_n) \cos \omega(t-T). \quad (22)$$

The final integration over wavenumber k in (17) is obtained by numerical quadratures.

3.2 Solution for ramp mean motion

The ramp time-displacement history of (2) for the block deformation is described by

$$\zeta(x,t) = \zeta_0 H(b^2 - x^2) [tH(T - t)/T + H(t - T)]. \quad (23)$$

Following the same procedure outline in section 3.1, we obtain (again after considerable algebra) the water surface motion η_r due to the ramp

$$\eta_r(x,t) = \frac{2\zeta_0}{\pi} \int_0^\infty \frac{\cos kx \sin kb}{k \cosh kh} \left(\frac{1}{\omega T} \right) [\sin \omega t - H(t - T) \sin \omega(t - T)] dk. \quad (24)$$

Again, the final integration over wavenumber k must be evaluated numerically.

4. Comparison of Theory and Experiment

As noted earlier, the simple block deformation of the sea floor was chosen to enable experimental verification of the analytical model developed for complicated time-displacement histories. The experimental facility used in these tests has been described in detail by Hammack (1972, 1973). Basically, the wave-maker consists of a rectangular piston in the bottom of a wave tank (and spanning its width) whose motion is controlled by an electro-hydraulic-servo system. The servo system converts a time-voltage command signal into a proportional vertical displacement of the piston. For the experiments reported herein, the piston length in the direction of wave motion is $b = 61$ cm while the quiescent water depth above the piston is $h = 10$ cm. Before presenting results of the tests, we describe the motivation for choosing other experimental scales.

A "global" time scale for the forcing of the overlying ocean by the sea floor is the period T . The appropriate time scale for the gravitational response of the long barotropic wave modes is $b/(gh)^{1/2}$ which corresponds to the time required for waves to escape the generation region. For prototypical earthquakes the ratio of the forcing and response time scales, $\tau = T(gh)^{1/2}/b$, termed the time-size ratio, is small so that details of the time-displacement history generally are not important. However, our interests herein require that the details of the temporal motion have a significant impact on the generated wave structure. Hence, the period T for the experimental tests must be scaled so that τ exceeds unity; in fact, for the experiments a period $T = 4$ secs was chosen which yields $\tau = 6.5$. Previous experiments by Hammack (1973) also indicate that the generation process for prototypical tsunamis is linear and that nonlinearity remains insignificant for vertical displacements which do not exceed about 20% of the overlying ocean depth. This criterion is adhered to in the experiments by restricting the instantaneous displacement of the piston to less than 2 cm.

In the first test we examine experimental and theoretical results for the time-displacement history shown in Figure 2 using experimental parameters $T = 4$ secs and a chosen permanent (mean) displacement of $C_0 = 0.38$ cm, with the amplitudes C_n and frequencies K_n of the eighteen Fourier components used in Figure 2 scaled appropriately. (In Figure 2 the corresponding parameters of the actual ground displacement are $T = 40$ secs and $C_0 = 7.63$ cm.) The scaled Fourier components are then summed and the result is converted to an analogue (time-voltage) signal which is used to command the wavemaker. The resulting wave motion at the leading edge of the piston ($x = b$) is measured, and the results are shown in Figure 3. Theoretical results at $x = b$ are evaluated for each of the eighteen (scaled) Fourier components according to (17) and summed to yield

$$\eta(b,t) = C_0 + \sum_{n=1}^{18} \eta_n(b,t); \quad (25)$$

the results also are shown in Figure 3. The excellent agreement between the predicted and measured data is self-evident.

Similar results are shown in Figure 4 where a ramp mean motion with an amplitude of $\zeta_0 = 1.33$ cm is added to the Fourier synthesis of Figure 2. The total permanent displacement of the piston is $\zeta_0' = C_0 + \zeta_0 = 1.71$ cm which has been used to normalize the measured and theoretical wave amplitudes. The theoretical result is equivalent to (25) with an added component for the ramp computed from (24). Again, the agreement between measured and computed data is excellent with the wave structure clearly showing the added volume (mass) resulting from the enhanced mean displacement.

5. A Comment on Mean Motions

In previous studies (Hammack, 1972, 1973) two additional models for the mean displacement of a block section of the sea floor have been examined. These time histories are:

- a. exponential: $\zeta_e(t) = \zeta_0 [1 - \exp(-1.1t/T_e)]$
- b. half-sine: $\zeta_s(t) = \zeta_0 [(1 - \cos \pi t/T_s)H(T_s - t)/2 + H(t - T_s)]$

and we repeat for completeness the mean motion introduced here:

- c. ramp: $\zeta_r(t) = \zeta_0 [tH(T_r - t)/T_r + H(t - T_r)]$.

The three mean motions listed above span a wide range of displacement characteristics. We note that the choice of characteristic time scales T_e , T_s and T_r are, in fact, arbitrary to a certain extent even though "natural" choices are apparent. (This flexibility is most obvious for the exponential motion where T_e was chosen for experimental convenience to represent the time for two-thirds of the displacement to occur.) It has been found that the properties of waves generated by these motions correlated strongly with the time-size ratio τ based on these time scales. For example, the maximum wave amplitude, say η_0 , occurring at $x = b$ when normalized by the permanent displacement ζ_0 exhibits a simple and similar functional dependence on τ for each bed motion. With the size scale b/h of the dislocation fixed and for $\tau \ll 1$, the normalized amplitude, η_0/ζ_0 , reaches a maximum value of one-half for all size scales exceeding unity. Bed motions with $\tau \ll 1$ are termed impulsive. For τ very large, termed creeping generation, η_0/ζ_0 decreases at a rate which is inversely proportional to τ . The constant of proportionality for creeping generation varies with the specific choice of the characteristic time scale for the mean motion. Since it is unlikely that any of these mean motion models is "correct" from a geophysical point of view, there is a need to seek a unification of results by generalizing the concept of characteristic time scale. One generalization which closely

Figure 3. Theoretical (—) and experimental (---) wave records at $x = b$.

Figure 4. Theoretical (—) and experimental (- - -) wave records at $x = b$ with ramp mean motion.

Figure 5. Theoretical and experimental variation of normalized wave amplitude at $x = b$ with generalized time-size ratio for three mean motions.

produces the desired unification is the following. Consider a velocity V , where V^2 is the kinetic energy imparted to the fluid by the sea floor divided by one-half the total mass of fluid displaced during bed motion ($\frac{1}{2} \rho b \zeta_0$); then V is given by:

$$V = \frac{1}{\zeta} \int_0^{\zeta_0} \zeta_t^2 d\zeta \quad (26)$$

and a corresponding time scale $T = \zeta_0/V$. In terms of this time scale the time-size ratio becomes

$$\tau^* = T(gh)^{1/2}/b = \zeta_0(gh)^{1/2}/bV \quad (27)$$

The variation of η_0/ζ_0 at $x = b$ for $b/h = 6.1$ with τ^* is shown in Figure 5 for each of the mean motions; both theoretical and experimental results are presented. For all of the experimental data we have taken $\zeta_0/h < 0.2$ to avoid significant nonlinear effects. The collapse of results for such a wide range of mean motion characteristics shown in Figure 5 is good although a small spread still exists.

6. Conclusions

We have demonstrated both the application and validity of a strategy which employs multiple uses of the superposition principle to develop theoretical solutions for waves generated by sea floor motions with complicated time-displacement histories. Although a more useful test for prototypical phenomena would utilize complicated spatial distributions for the sea floor dislocation, the tests herein were restricted to simple block dislocations due to experimental limitations. However, it is emphasized that the solution method does not distinguish between space and time, and the validity established herein strongly suggests that the methods could be extended to complicated spatial deformations. Finally, we have demonstrated that wave properties (in particular the maximum amplitude of waves escaping the generation region) for a wide range of mean motion characteristics may be (almost) collapsed into a single functional relationship in terms of a time-size ratio based on an average vertical velocity of the sea floor obtained from energy considerations.

CHAPTER 41

TSUNAMIS ALONG WEST COAST OF LUZON, PHILIPPINES

by

R. L. Wiegel, F. ASCE*

INTRODUCTION

A detailed engineering study was made by Ebasco Services, Inc., (1977), for a proposed nuclear power plant in the Napot Point region of Bataan, between the entrance to Manila Bay and Subic Bay, Republic of the Philippines (about 14°-37-12'N, 120°-18-3/4'E), Figure 1. As a part of the oceanographic portion of this work, a study was made by the writer of the characteristics of tsunamis that had occurred in the region, and the statistics of occurrence (Wiegel, 1976). The study of tsunamis has been updated to the present time (May, 1980).

The location of the site is such that the large tsunamis generated in some areas of the Pacific Ocean (such as off the coasts of Chile, Alaska, Japan and Kamchatka) are not likely to reach Napot Point with any appreciable amplitude (see, for example, Wiegel, 1976). There is good evidence that this is the case. Owing to the relative stability from the standpoint of earthquakes (aseismic) of Borneo, the Malaya Peninsula, most of Indochina and the intervening China Sea (Gutenberg and Richter, 1949, pp. 82 and 93), there is probably little, if any, chance of tsunamis being generated in this region; this appears to be a fact (Berninghausen, 1969). The great eruption of Krakatoa and the tsunami generated by it was not noticed on tide gages at either Singapore or Hong Kong, so that it would be reasonable that it would not have been detected at Manila (Wharton, 1888). Also, the large tsunamis that have been generated in the Sulu Sea and the Celebes Sea do not seem to reach the site with any appreciable amplitude. Thus, the tsunamis of importance to the site are those which will be generated in the local seas off the west coast of Luzon. In order to establish this fact, information is presented on a number of tsunamis generated in other regions, especially those generated in the seas off the west coast of the Philippine Islands.

HISTORIC RECORD OF TSUNAMIS GENERATED OFF THE WEST COAST OF LUZON

A seismological station, established as a part of the Manila Central Observatory in 1865 (Saderra Masó and Smith, 1913), operated continuously until World War II. It was reestablished after the war. During the interval from about 1900 until the start of World War II, the seismological

* Professor of Civil Engineering, University of California, Berkeley.

station was directed by two scientists: first by the Rev. Miguel Saderra Masó, S.J., and then by the Rev. W. C. Repetti, S.J., both of whom were familiar with tsunamis and their relationship to earthquakes, and who were alert for their occurrence. Owing to this fortunate circumstance, there exist a number of references to historic tsunamis generated in the areas surrounding the Philippine Islands. The sources for finding these references, together with appropriate quotations from the references, are given in the paper. Records of more recent tsunamis are available from several sources. All references to tsunamis in the Philippines found by the writer have been included. In addition, several citations are given in which a statement is made that no tsunami waves were observed, and for which no statement on tsunami waves is given.

The fact that the two scientists mentioned above were familiar with tsunamis and their relationship to earthquakes is shown by the following quotations from three of their reports:

"These facts would appear to afford sufficient foundation for attributing the earthquakes which are confined to the Ilocos Provinces to movements and displacements of the first section or coastal range. The absence of seismic tidal waves and similar phenomena in the case of the two earthquakes mentioned [15 August 1897 and 14 November 1897] may be accounted for, partly by the relative smallness of the portion of the coast disturbed, partly by the fact that it is not the bottom of the sea which is affected, but merely a bordering ledge." -- Saderra Masó (1909)

"As this is one of the few Philippine instances of the waves or tsunamis caused by earthquakes [17 December 1677], it is certainly a pity that the author did not mention the region principally affected. It may be supposed that the waves were raised in the China Sea near the west coast of Cavite, Bataan and Zambeles." -- Saderra Masó (1927)

"Waves were observed at Mambajao, Camiguin Island, and the disturbances of the sea lasted about an hour. The International Summary placed the epicenter at 9.5°N, 128.8°E, but this is scarcely possible, because sea waves from this point could not have passed through the Suriago straits and across the Mindanao Sea without being noticed at other places." -- Repetti (1931), [earthquake of 18 July 1923]

The area to the east of the southern Philippines, bordering the Philippine Trench, and portions of the Celebes Sea, are much more active seismically than is the area off the west coast of central and northern Luzon, in the South China Sea. As commented on by Berninghausen (1969), most of the tsunamis which have been reported from the entire Southeast Asia region have been local in origin and relatively restricted in the extent of the regions affected. This is in agreement with the information contained in the additional references found during the present search, including the 17 August 1976 Moro Gulf tsunami, associated with a shallow local depth earthquake, magnitude determined to be about 7.9 (Badillo and Astilla, 1978).

Thirty-six of the citations included in the paper either mention specifically tsunamis generated in Philippine waters or possible seiches. Details are given in the original report, with a brief citation given

herein. Eleven were generated in the region of direct interest: seven are tsunamis, three are probably seiches, and one is for the case of a hill sinking in a bay. These eleven are marked by an asterisk (*) in the appendix.

The tsunamis that have been observed in the area of interest must have been relatively small; if not, there should be observations to the contrary. Consider two tsunamis generated off the northwest coast of Luzon: 6 May 1924, Agno, Pangasiana. Saderra Masó (1925) states:

"... town of Agno on the west coast of Luzon at 16.1°N and 119.8°E, shortly after an earthquake, was invaded by four big sea waves which flooded its low portions and caused great consternation to the people but without doing considerable material damage nor harm to people.

"A similar occurrence took place in the same town on January 26 of 1872. It is reported that the town was flooded by sea waves shortly after an earthquake....

"In fact, Agno is the only important town existing in the north part of the Zambales coast nearest to the origin of the shocks; moreover its bay and the low alluvial plain where empties the River Balincaguin offered more favorable conditions to the advance of the waves caused by the earthquake than any other place of this west coast of Luzon generally high and cliffy."

There is evidence that the drawdown of the tsunami waves is as important as the runup. The following two tsunamis occurred in the general area of interest: 3 June 1862, water in the bay receded from Manila to Cavite and returned from that direction (Saderra Masó, 1927, p. 95; Repetti, 1935). 14 February 1934, at San Esteban the first movement of the sea was reported to have been a recession, and to such an extent that people hurried out on the exposed shore to gather fish which had been stranded (Repetti, 1934). In these two cases (and perhaps in others; there is no evidence one way or the other) a drawdown occurred first. If the source was a downward vertical tectonic displacement, a drawdown would occur first. The comment of Ludwig, Hayes and Ewing (1967) in their paper on the Manila Trench and Luzon Trough, indicates this to be the case.

In regard to the occurrence of an initial drawdown it is interesting to note that a common observation at widely scattered places was a deep recession of water before the arrival of the first wave during the Moro Gulf tsunami of 17 August 1976 (International Tsunami Information Center, 1976; Badillo and Astilla, 1978).

Essentially, no information was obtained on the "periods" of the tsunami waves generated off the northern and central west coast of Luzon. It is important to obtain this information, as it is useful in determining an estimate of the "width" of the tectonic (or volcanic or landslide) source of the tsunamis. The information obtained of the Moro Gulf tsunami of 17 August 1976 is useful in this respect. Badillo and Astilla (1978) state that the interval between waves was from one to five minutes.

Care must be exercised in obtaining information from the records of tidal gages owing to the natural frequency characteristics of bays (see, for example, Raichlen, 1972); however, very useful information can be obtained from them. Owing to this, the National Ocean Survey (NOAA, U.S. Department of Commerce) was contacted, and it was learned that they have

Philippine Islands tidal data on file in their archives as follows: Cavite, 1921 (3 months); Subic Bay, 1911-1912; Manila, 1901-1940. It was not possible, however, to obtain copies of these.

What can be determined about the heights of the tsunamis? There is good evidence that a large tsunami would be observed and documented. The rationale for this statement is the information available for other areas of the Philippine Islands; information on this follows.

TSUNAMIS IN THE SULU SEA AND THE CELEBES SEA

Devastating tsunamis have been generated in the Sulu Sea and in the Celebes Sea, but were of little importance as far as the vicinity of Manila Bay, Luzon. Three of these are described briefly below.

The epicenter of the subsea earthquake of 21 September 1897 was in the Sulu Sea, about 70 kilometers WNW of Zamboanga, Mindanao, about 70 kilometers NW of Isabela (Basilan Island), about 150 kilometers NNW of Jolo (Sulu Archipelago) and about 380 kilometers SSE of Cuyo Island (Cornoas, 1899; Saderra Masó, June 1909). According to Saderra Masó:

"... immense waves from the west which swept away everything near the shore that was at a less height than 7 meters above mean sea level [Isabela, Basilan Island]... They commenced with an ebb in which the level fell about 5 meters, followed by a series of floods and ebbs, one of the former being extraordinary in height [Zamboanga, Mindanao]... The greatest height reached by the flood was 1 meter [Jolo, Sulu Archipelago]... earthquake was followed by a tidal movement of the sea in which the water rose about 2 meters [Dapitan (NW of Mindanao)]... The port of Cuyo faces towards west. The first ebb was observed an hour and a half after the shock, the water receding during half an hour far beyond the lowest tide; then it returned, reaching within a few minutes the limit of the highest tides. There were alternate ebbs and floods in regular succession during more than one hour [Cuyo Island]."

The tsunami that is described above apparently did not reach Manila, or at least it was so small by then that it was not noticed. It is important for two reasons. It shows that a large tsunami has been observed at a number of locations, and it appears that this may be the largest tsunami that occurred in the Philippines during the past three hundred years, probably larger than the Moro Gulf tsunami of 17 August 1976. The maximum run-up elevation of the tsunami, at a distance of about 70 kilometers from the surface, was about 7 meters above mean sea level.

Another example is the earthquake of 15 August 1918 off southern Mindanao, with a magnitude of 8-1/4 (Gutenberg and Richter, 1949). Its epicenter was located between 5° and 6°N and between 124° and 125°E in the Celebes Sea. This region is active seismically, and many more tsunamis have been generated in the Celebes Sea than off the northern and central west coast of Luzon. Saderra Masó (1918) quotes eyewitness accounts such as:

"... Sarangani Bay ... a tidal wave as high as 24 feet at some points and at the Constabulary station at Glan [Cotabato] to a height of 18 feet ... at Port Lebak, reports that a tidal wave at his place was

between 6 and 8 feet ... south of Port Lebak for some forty miles there was a tidal wave variously estimated at from 20 to 25 feet."

On 17 August (local time; 16 August GMT time), another major earthquake (magnitude 7.9, or 8.0 M_s) occurred in the Celebes Sea (Moro Gulf), at 06.26°N, 124.2°E (International Tsunami Information Center, 1976; Stratta, et al., 1977; Badillo and Astilla, 1978; Pararas-Caryannis and Wigen, 1978; Acharya, 1978), generating a large tsunami. Some comments from the report by The Reverend Victor L. Badillo (Director of Manila Observatory) and Zinnia C. Astilla (1978), follow.

"The Moro Gulf tsunami of 17 August 1976 was the most disastrous tsunami experienced by the Philippines. There have been more severe tsunamis, but areas hit were less populated and had less manmade structures (p. 9)... When the sea had spent its fury and rolled back to its normal cadence, the survivors looked upon scenes of death and destruction. About 8,000 were dead or missing. About 10,000 were injured and about 90,000 were homeless (p. 1)... A common observation at widely scattered places was a deep recession of the water before the arrival of the first wave ... Some persons ran out to the newly exposed sea bottom out of curiosity or to pick up stranded fish (p. 6)... Estimates of wave heights had to be based on qualitative descriptions of the waves being as tall as a coconut tree, a two storey house, twice a man's height, etc., or had to be deduced from photographs of damaged structures ... Places where waves were reported to be higher than five meters are: Linek (Maguindanao), Kalanganan (Cotabato City), Pagadian City, Sacol Island (Zamboanga City), Lebak (Sultan Kudarat). At Lebak waves may have been as high as nine meters (p. 5)*... That there were three or four waves were indicated by the majority of respondents. The largest number was seven, reported by one person. One thing is definite-- there was more than one wave. Majority of respondents estimated the interval between waves to be between one to five minutes. As many considered the first wave to be the most destructive as considered it was the third. At the time of the earthquake the last quarter moon was some 30 degrees above the eastern horizon, so that there was enough light to see."

The International Tsunami Information Center (1976) gives some additional information on the tsunami waves:

"... Based on the survey of the affected area, it was concluded that maximum waves in the entire Moro Gulf area were in the order of 14-15 feet, which were considerably less than what had been reported in the newspapers. Such large waves were experienced at Alicia, Pagadian City, Bongo Island, Resa Bay, Lebak, and the east coasts of Basilan and Jolo islands. Based on the distribution of wave heights along the coastline of Moro Gulf, estimates of travel times of the tsunami to each point, and the directional failure of structures, both by the earthquake and the tsunami, it was concluded that the earthquake and the tsunami generating area was in

* A listing of tsunami wave heights at various localities is given in Table 1 of the report by Badillo and Astilla.

the upper part of Moro Gulf, somewhat south of Baganian Peninsula and having an orientation from southeast to northwest." (p. 6)

In the U. S. Department of Commerce, NOAA publication (1978, p. 71), it is stated that the wave was recorded on the Davao tidegauge with a maximum amplitude of 35 cm.

Additional information on the tsunami, and its effect on shorelines and structures, is given in the report by Stratta, et al. (1977).

For some details on the tectonics of the region, see Hamilton (1977). He believes the earthquake occurred along a subduction zone which is breaking through on the west side of the Sangihe ridge-Halmahera arc collision aggregate. Stewart and Cohn (1977) state that the 1976 event represents the first seismic evidence for a subduction zone in this area.

SEISMIC AND GEOLOGIC INFORMATION

Papers on the seismicity of the region and geological studies of the region are of great use in interpreting the historical information that has been obtained on tsunamis and to estimate future tsunamis. Of great importance are the many papers of the Rev. Miguel Saderra Masó, S.J. (1909; 1927), and the Rev. William C. Repetti, S.J. (1930; 1931a; 1931b; 1946), of the Seismological Station, Manila Central Observatory (Weather Bureau, Philippine Islands). Barazongi and Dorman (1969) plotted the epicenters of 29,553 earthquakes which occurred during the interval 1 January 1961- 31 December 1967. Earthquakes with shallow focal depths are the most important from the standpoint of the generation of tsunamis. Their Plate 3 shows the epicenters for earthquakes with focal depths between 0 and 100 kilometers.

Saderra Maso and Repetti did not assign magnitudes to earthquakes, as the techniques to do so had not yet been developed. The magnitude and focal depth have been shown to be important to the generation of tsunamis (see, for example, Iida, 1970). Gutenberg and Richter (1949) determined the magnitudes for a large number of earthquakes. A list of the earthquake dates, times, locations and magnitudes for Region 22 (Philippine Islands) is not included herein owing to space limitations. For an update on this, see Sevilla, et al. (1965), Damasco (1970), Rowlett and Lelleher (1976), Acharya (1978); also, see NOAA tapes.

Work has been done on the relationship between earthquakes and structure of the Philippines (Willis, 1944), and on the submarine morphology of the Philippines (Irving, 1951). The term "Philippine rift" was used by Irving rather than the term "Philippine fault" as being more descriptive of the situation. Irving shows instrumentally determined epicenters of Philippine earthquakes for the period 1900-1945.

Geophysical studies have been made in recent years of the region in the South China Sea off the coast of Northern and Central Luzon, specifically studies of the Manila Trench and the West Luzon Trough* (Ludwig

*Murphy (1973) refers to the long West Luzon Trough as "graben-like." This paper discusses the relationship of the Manila Trench and the West Luzon Trough with the West Taiwan Foldbelt and the Philippine Trench.

Hayes and Ewing, 1967; Hayes and Ludwig, 1967; Ludwig, 1970). Ludwig, Hayes and Ewing (1967) state:

"The west wall of the trench is a remnant of the original sea floor which has been depressed. The steps in the western wall of the trench are interpreted as normal faulting and are most likely caused by extensional forces introduced in the oceanic crustal plate as it is being further depressed. The steps and perched ledges of transparent sediments, which form the foot of the west wall, attest to the downward movement and recent activity. The perched ledges indicate post-depositional subsidence and (perhaps) extension of the sea floor near the axis of the trench. This is further evidenced by eastward dipping stratified beds beneath the floor of the trench (profiles E-F and L-N), suggesting downward movement with respect to the east wall. The alternative explanation is that the perched ledges were formed by erosion; however, no direct evidence is available at present to support it."

This is in agreement with the observations of several tsunamis in which a substantial drawdown of the water occurred first, that is, a downward vertical tectonic displacement probably was the source of the tsunamis. A similar drawdown seems to occur in the large tsunamis generated in the Celebes Sea (Badillo and Astilla, 1978).

Hayes and Ludwig (1967) present a map of the earthquake hypocenters of central Luzon, the Manila Trench and the West Luzon Trough, Figure 1. In comparing the locations of the plots, one must be aware of the accuracy of the locations. Gutenberg and Richter (1949) state:

"Epicenters have in general not been determined more closely than the nearest quarter degree of latitude and longitude except for unusually favorable shocks. More accurate revision would involve considering the effect of geocentric latitude, which may amount to as much as 0.4 degree in extreme cases...."

Hayes and Ludwig (1967, p. 546) state:

"Accuracies are estimated at several tens of kilometers for good determination to ± 100 km or more for poor ones...."

Salient features of the bathymetry west of Luzon are given by Ludwig, Hayes and Ewing (1967), as are seismic reflection profiles across the Manila Trench and West Luzon Trough. Some conclusions reached by the investigators have been cited earlier in this report, in context with the possible generation of tsunamis.

For additional analyses of the tectonics of this area, see the papers by Murphy (1973) and Rowlett and Kelleher (1976). For details of studies of adjacent regions, such as the Sulu Sea, Celebes Sea, Bareda Sea and Molucca Sea, see Krause (1966) and Hamilton (1977).

Fig. 1. Earthquake hypocenter map of central Luzon, Manila Trench—
the area outlined on the inset of the regional geography. Location of the Philippine Fault is
taken from ALLEN (1962). Contours in nominal fathoms.
(From Hayes and Ludwig, 1967)

APPENDIX: PHILIPPINE TSUNAMIS

September 1627, northern Luzon (Repetti, 1946).

"... trees were overthrown by the terrific force of the waves of the sea, which invaded the land for a distance of a league, and in that area the land could not be seen."

*30 November 1645, Manila (Saderra Masó, 1927).

"Of this most disastrous earthquake all the writers about the Philippines both ancient and modern give notice ... The disturbance of the Pasig River was so tremendous that its waters invaded parts of the town and even passed over the bridge."

Repetti (1940) believes the earthquake of 14 February 1934 more severe.

*7 December 1677, S and SW Luzon (Saderra Masó, 1927 quotes Fr. Diaz):

"Some people who were navigating related the dangers of foundering that they encountered because of the high waves caused by the earthquakes, which at placed invaded the coast and flooded large inland tracks of land with great damage."

*1744, Northern Luzon (Repetti, 1946)

"In the *Diccionario Ibanag-Español* there is mention of earthquakes under the word ALLUYU, meaning great waves ... 'The sea enters the river with great force....'"

December 1770, Manila (Repetti, 1946). The expression "the sea was agitated" that appears in Berninghausen's (1969) paper was "... a very strong south wind, which agitated the sea ..." in Repetti's paper.

*9 November 1828, Manila (Repetti, 1946, p. 173).

"After the earthquake, the river rose to the same height that it reaches in the rainy season and inundated the lowland near its banks. The next day it fell as much below its ordinary level...."

*18 January 1830, Manila and nearby provinces (Repetti, 1946, quoting an article in the Singapore *Chronicle* of 25 March 1830):

"...having made the best of his way to the river, he was there 'taken aback,' as the water came rushing up the steps several feet ... but the water quickly retreated, and broke upon the opposite bank with a noise resembling thunder, and then gradually subsided."

22 March 1840, Sorsogon Province (Saderra Masó, 1927, p. 91).

"A large tract of the northern shore of the bay where the town of Sorsogon is located sank five feet, the advance of the sea causing considerable material and personal loss."

Saderra Masó quotes a report of 22 February 1843 by the Governor of Albay:

"As a result of the earthquakes felt in the town of Sorsogon in March 1840 ... surely the bottom of the bay underwent a change because today boats of great draft can drop anchor where formerly small craft grounded at low tide, ... the sea submerged a great portion of the shore and the nearer houses of the water front...."

*16 September 1852, Manila and western provinces (Saderra Masó, 1927, p. 93).

"This destructive earthquake made itself felt with violence in west Rizal and Bulacan, SW Nueva Ecija and the provinces of Cavite, Batangas, Bataan, Zambales, Tarlac and Pampanga.... A hill called Ubamba in the Subic Bay sank completely."

*3 June 1862, South Luzon (Saderra Masó, 1927, p. 95).

"It is stated that the water in the bay receded from Manila to Cavite and returned from that direction...."

Repetti (1946), quoting works dating to 1865, states:

"... Earthquake in Manila. J. Winchester, captain of the English frigate *Caribbean* and D. Cobbs, captain of the English frigate *John Banks* describe the action in the Bay of Manila: '3 June, 7^h30^m p.m. we saw a wave coming on us from the SE to NW. It struck us with such force that it came over the deck which it covered completely. The frigate shook and shivered strongly as if it had struck bottom. The water boiled around the ship in strong convulsions...."

16 August 1869, Southeastern Luzon and eastern Visayan (Repetti, 1946).

"... and the sea was disturbed ... A small island, among the many at the north end of Ticao, is said to have disappeared."

*26 January 1872, Agno, Zambales Province (Saderra Masó, 1927). Intensity VII, Rossi-Forel scale, "earthquake and tidal wave." Repetti (1946) states:

"... It is reported that the town was flooded by sea waves shortly after an earthquake and, as it is said, noises like explosions were heard, which excited and terrified the people."

14 July 1880, Luzon (Centeno & Garcia, 1883). Repetti (1946) lists this as 15 July 1880, on the east coast of Luzon, just east of Manila.

"At Quinanliman the depression had a wide extent, but was very irregular in depth: the greatest depth was four metres at the centre line DE of the submerged surface ..." (Centeno & Garcia, p. 78)

26 and 27 August 1883. Eruption of Krakatoa (Wharton, 1888), Sunda Strait between Sumatra and Java. See comments in main body of paper.

23 July 1885, near northwest coast of Mindanao (Saderra Masó, June 1909).

"These facts locate the focus of the disturbance in the sea, opposite the northwestern coast ... no mention is made of any extraordinary commotion of the sea although the observer spoken of lived in a place on the coast and describes—with almost painful attention to detail—everything abnormal which he observed during the earthquake."

5 February 1889, in the Celebes Sea (Saderra Masó, June 1909).

"At the time of this earthquake the steamer *Churruca* was underway from Zamboanga to Cotabato, passing over the very region which, according to our opinion contained the focus ... the water became turbid with mud rising from the bottom of the sea and formed whirls. No great waves could be seen from aboard the vessel, nor are such mentioned in the reports from Zamboanga and Cotabato."

21 September 1897, E and SE part of the Sulu Sea (Saderra Masó, June 1909). Details of this great event given in the main body of present paper.

"The great tsunami ... is of special interest, since it is almost the only one to be found in the seismic annals of the Philippines."

21 August 1902, northern Illana Bay, Mindanao (Saderra Masó, June 1909).

"Great fissures and landslides were caused, both on land and in the sea, the latter being proved by the fact that the cables which connected Cotabato with several military posts in southern Mindanao were broken ... a clear proof of the displacements which must have taken place on the bottom of the bay."

15 August 1918, Mag. 8¼ (G&R*, 1949). Celebes Sea, between 124° and 125°E and 5° and 6°N (Saderra Masó, 1918, also Dec. 1918).

"Captain Malone ... reports that the earthquake ... was later followed by a tidal wave reaching as high as 24 feet at some points and at the Constabulary station at Glan to a height of 18 feet, thereby destroying all of the houses that had been shaken down by the shock and drowning a number of people ... All native vintas were either destroyed or taken out to sea L.B. Kidwell, who has a saw-mill at Port Lebak, reports that the tidal wave at his place was between 6 and 8

*G&R refers to Gutenberg and Richter.

feet, killing six people and carrying a number of logs quite a distance inland.... To the south of Port Lebak for some 40 miles there was a tidal wave variously estimated at from 20 to 25 feet."

11 November 1921, Mag. 7½, epicenter 8N, 127E (G&R, 1949). Off SE coast of Mindanao, in southern part of the Philippi-Deep (Saderra Masó, 1923).

"The most unusual effect of the second earthquake was a tide-wave which invaded the few bays with low lands there existing, Manay being the one which sustained greater loss in structures and crops. ... The tide-wave was also noticed in great Sanguir Island."

10-11 November 1922, Chile, Coquimbo earthquake (Selga, 1923). Although the earthquake epicenter was thousands of miles from the Philippines, the tsunami was recorded by the tide gage in Zamboanga. Selga (1923) states:

"... the mareogram shows that the seismic wave arrived at Zamboanga on 12th November, 1922, at 2 hours 40 min p.m. standard time of the 120th meridian east of Greenwich ... Five crests and five troughs are clearly discernible ... the period of the wave is 100 minutes, if derived from the maximums; 106 minutes if derived from the minimums..."

The tide station at Manila was not operating at the time of this tsunami.

2 March 1923, Mag. 7.2 (G&R, 1949). Berninghausen [incorrectly?] lists as 23 Feb. 1923. Mindanao, epic. 6°45'N, 123°35'E (Repetti, 1931).

"The position given by the International Summary, 6°N, 125°E, can scarcely be admitted because it is inland, and sea waves were reported as making into the Rio Grande River at Cotabato."

18 July 1923, Mambajao, Camiguin, epicenter 9°20'N, 125°E, Repetti (1931).

"Waves were observed at Mambajao, Camiguin Island, and the disturbance of the sea lasted about an hour."

14 April 1924, Mag. 8.3, epicenter 6½N, 126½E (G&R, 1949), off Pacific Coast. SE Mindanao (Saderra Masó, 1925).

"A large tract of the sea shore of Mati, at the head of the small Pujada Bay, separated from the ocean by a narrow peninsula, sunk about half a meter... The disturbance caused by shocks in the sea was not so great as the maremoto which followed the earthquake of November 1921 originated near the same coasts. On board of a steamer at anchor in the Caraga Bay, about 150 kilometers NNW of the epicenter, two sharp shocks followed by ... similar to the effect of the keel striking against a rock. The sea became suddenly and terribly rough causing in the boat such strong jerks that threatened to break the anchor chains; at the same time big waves were seen to break against the cliffs of the near coast."

Repetti (1931) states:

"Sea waves were reported from Mati and Caraga...."

*6 May 1924, Agno, Pangasinan (Saderra Masó, 1925).

"At about midnight of the 6th of May, the town of Agno on the west coast of Luzon at 16.1°N and 119.8°E, shortly after an earthquake, was invaded by four big sea waves which flooded its low portions and caused great consternation to the people but without doing considerable material damage nor harm to persons."

30 August 1924, Mag. 7.3 (G&R, 1949), epic. 9°N, 126°40'E (Repetti, 1931).

"A sea wave was noticed at Bislig Hinatuan situated on bays whose trend is slightly more in the direction of our position."

5 May 1925, Mag. 6.75 (G&R, 1949). Southern Negros (Saderra Masó, 1926).

"Its origin lay under the sea near the south coast of Negros Island not far from 9.3°N and 122.7°E ... Moreover, only the said south coast was invaded by the waves caused by the earthquake."

25 May 1925, Mag. 6.25, epicenter 12.5°N, 122.5°E (G&R, 1949). Tablas and Romblon Islands (Saderra Masó, 1926).

"... A small earthquake wave developed and flooded some small low villages on the SE coast of Tablas. The steamer *Compeador* felt distinctly the shock while navigating SW of Romblon Island."

Repetti (1931) states:

"Sea waves observed at Tugdan in the east coast of Tablas Island."

13 November 1925, Mag. 7.3 (G&R, 1949), Philippine Deep, NE of Samar Island, near 125.5°E and 13.0°N (Saderra Masó, 1926).

"... cracks opened and the low shores were flooded by the waves caused by the earthquake; many fishermen lost their fishing boats and several were drowned. Numerous native houses on this and on Laoang Island were destroyed. On the coast of Samar not only native houses but ... more substantial constructions suffered considerable damage."

Repetti (1931) states:

"Sea waves were observed along the north coast of Samar."

19 December 1928, Cotabato, Mindanao, Mag. 7.3, epic. 7°N, 124°E (G&R, 1949). Seismological Dispatches (Georgetown Univ., Dec. 1928) state:

"MANILA, P.I., Dec. 24, 1928. Rocked by an earthquake, and swept by a tidal wave, Cotabato, capital of Mindanao Province, was practically destroyed on Wednesday night."

28 December 1928, Cotabato, Mindanao, Mag. 6.9; epicenter 7.5°N, 123°E (G&R, 1949). Not listed by Repetti (1931a,b). Berninghausen (1969):

"Destructive earthquake reported ... Wave probably struck the coast near Cotabato which is inland (Georgetown Univ., 1926)."

The reference (1926) must be wrong and is (1928) instead, and no mention of tsunami waves is given in the original reference. The statement of Berninghausen seems to apply to the earthquake of 19 December 1928.

13 June 1929, Mag. 7.2 (G&R, 1949), Hinatuan earthquake, epicenter over western slope of the Mindanao Deep, 8°20'N, 126°53'E (Repetti, 1930).

"Thousands of dead fish of all kinds and all sizes, up to 30 inches, were seen floating in the ocean and case up on shore. They had evidently been killed by the concussion of the shocks.... A small sea-wave came in." (NOTE: Hinatuan, due west of the epicenter.)

*14 February 1934, Mag. 7.6 (G&R, 1949). China Sea off west coast of Luzon, epicenter 17°20'N, 119°20'E (Repetti, 1934).

"At San Esteban the first movement of the sea was reported to have been a recession, and to such a noticeable extent that the people hurried out on the exposed shore to gather fish which had been left stranded. Some persons narrowly escaped drowning when the water returned.... We can not be certain that the entire reported change of depth occurred suddenly. The changes in sea bottom conditions as given in the various reports of the cable ship and the shocks felt while repairing the cable suggest that the cable break of March 2nd was due to slumping set up by the earthquake of February 14th."

Repetti (1940) makes the following very important statement:

"The earthquake of particular interest in this present series is that of February 14, 1934, at 3:59:35 G.M.T. The records of this earthquake obtained throughout the world show that it was the strongest earthquake in the Philippines of which we have definite evidence. The famous Manila earthquakes of 1645, 1658, 1863, and 1880 were far more destructive but we are of the opinion that the destructive was due to a very great extent to the type of weakness of construction and deterioration, thus giving an exaggerated estimate of the severity of the earthquakes."

26 November 1934, Mag. 6.25 (G&R, 1949), China Sea, 50 km off Manila Bay entrance, epicenter $14^{\circ}10'N$, $120^{\circ}10'E$ (Repetti, 1934). An article appeared in the *Philippine Times*, 14 November 1934. This event is listed herein owing to its location and because no sea waves were mentioned. See also: *Annual Report of the Philippine Weather Bureau: Fiscal Year 1951/52*, p. 18.

20 August 1937, Mag. 7.5, epicenter $14.5N$, $121.5E$, (G&R, 1949), Alabat Island earthquake, off east coast of Luzon (Repetti, 1938).

"The water is said to have risen at the town of Queson at the south end of Alabat Island. This town is practically on Calauag Bay at the head of which there was a rise in the sea level. The people of the town of Calauag at the head of the bay reported that the water rose from low to high tide level in the space of ten minutes."

23 May 1938, Luzon; epicenter, China Sea (Repetti, 1938). No mention of waves.

24 January 1948, Iloilo Strait near southwest coast of Panay, $11^{\circ}N$, $122^{\circ}E$, Richter Mag. 8.2 (Murphy and Ulrich, 1951a, p. 29).

"2 killed by tidal wave in Iloilo Strait."

*29 December 1949, N. Luzon, M_s 7.2, epicenter $17^{\circ}30'N$, $121^{\circ}30'E$. (Murphy and Ulrich, 1951b, p. 47).

"Heavy property damage along northwest coast of Isabela Province and minor damage in Manila. One death from sea wave near Mercedes."

19 March 1952, Butuan, epicenter in Mindanao Sea about 50 km NNW of Butuan City (Weather Bureau, Geophysical Division, 1952). Murphy and Cloud (1954) state:

"The earthquake ... created sea waves that were recorded as waves only one-fourth foot at Yap Island and Apra Harbor and Tarague, Guam. A gage on Angaur Island, Palau I., showed a maximum oscillation of 2.2 feet."

24 May 1960, Chile. Although the earthquake epicenter was thousands of miles from the Philippines, tsunamis were experienced in the islands.

"... 'tsunamis' of slight magnitudes struck the eastern Coasts of the Philippines in the early morning (from 6:30 to 8:30 a.m.) of May 24, 1960. These waves, which brought the sea level from 2 to 8 feet higher than normal tide level, caused some damage to some towns situated near open bays along these coasts...."

31 March 1962, Antique earthquake (Philippine Weather Bureau, 1962).

"... generated a freak tidal wave that hit the coast of Dao ... the wave was caused by a vertical displacement at the epicenter region about five kilometers from the coast of Dao along a line of weakness running north to south from Marinduque to Zamboanga."

1 August 1968, Luzon, epicenter 16.5°N, 122.2°E (Coffman and Cloud, 1970).

"... generated a minor tsunami that was reported to have an amplitude of 6 to 8 centimeters in the Ryuku Islands... Honolulu, 0.1 foot; Attu, 0.3 foot; Wake Island, 0.3 foot; and Guam, 0.1 foot."

Also listed in the *Newsletter*, International Tsunami Information Center, (June 1980):

"Thus far in 1970 one tsunami has been reported to ITIC. The 12 07 08.6 GMT 10 January 1970 earthquake, M_s 7.5, in Mindanao [P.I.] generated a weak tsunami that was recorded at the Malakal, Palau I., Caroline Islands Tide Station with a height of 0.06 m."

7 April 1970, Luzon east coast. Mag 7.3; epicenter 15.8°N, 121.7°E, (International Tsunami Information Center, June 1970):

"... The April 9, 1970 issue of the Manila Times Newspaper quoted observers near Dingalan Bay thus: 'Then the bay water line receded as far as 70 meters out into the ocean' ... 'And then the sea came surging inland, swamping huts built on the shore. He described the incoming waves as taller than a man.' ... ITIC has not received any marigraphic records to show that this event was other than local..."

31 October 1975, NE of Samar Island, Mag. 7.4 Richter scale (International Tsunami Information Center, 1975).

"... A tsunami was generated, and registered a maximum wave height of 10 cm at the Okinawa gage, 6 cm at Yap, and 6 cm at Wake Island. ITIC has received no reports to this date of wave heights or impact on the adjacent Philippine Islands coast."

U. S. Department of Commerce, NOAA (1875, p. 116) state:

"Generated a tsunami that killed one person and swept away about 30 houses on the east coast of Samar Island."

17 August 1976, (16 August GMT time), Moro Gulf (06.26°N, 124.02°E, Earthquake Mag. 7.9 or 8.0 M_s). A major local tsunami. Details not presented here, as they have been presented in the body of the paper.

14 January 1978, Panay, Philippines, 8.8°N, 122.4°E, (International Tsunami Information Center, June 1979).

"Slight tsunami activity recorded at Jolo Island, Philippines."

TSUNAMI PRONE FRICTION FACTORS FROM WIND MEASUREMENTS

by

Charles L. Bretschneider
 Chairman and Professor, Department of Ocean Engineering
 University of Hawaii, Honolulu, HI, U.S.A.

SUMMARY

The long wave equations, used for tsunami run-up and flood wave calculations, have an unknown friction term. As an alternative to hydraulically determined friction factors, an adjustable three-level anemometer staff system is used for making wind profile measurements over typical Hawaii terrain. Results from measurements taken during trade wind conditions are given for three types of terrain: (1) golf course, (2) large flat knoll covered with 2 to 2 1/2 feet tall grass thin to medium dense, and (3) a large rock farm covered with several layers of stone 2 1/2 to 3 feet or more in diameter. Average values of Manning's "n" determined approximately from the von Karman friction length, $n \cong .06 z_0^{1/6}$ vary from 0.028 over the golf course, 0.046 over the grass knoll, and 0.051 over the rock farm. The top level anemometer for both systems is at elevation 10.6 meters (35.8 feet) and the remaining anemometers are equally spaced on the log scale, with the bottom level anemometer at 1.3 meters (4.28 feet) above the support base. We are presently repeating the experiments using an adjustable five-level anemometer staff system.

It is pointed out that the results obtained from wind experiments have not yet been correlated with hydraulic experiments, and it is known that the friction factor decreases with increase in the Froude number, given by $F = \bar{V}/\sqrt{gR}$, where \bar{V} is the mean velocity over the vertical distance of the hydraulic radius, R. The question seems to be, what is the equivalent hydraulic radius for the adiabatic atmosphere that would give the same friction factor for the same roughness for the von Karman velocity profile in hydraulic experiments? The wind experiments do show that there is a tendency for the friction factor to decrease with increase of mean wind speed. It would be of scientific interest to determine an equivalent hydraulic radius for wind profile experiments, making it possible to correlate the data with hydraulic experiments. This needs further investigation.

It is important in our wind experiments that we use only wind profiles that are adiabatic or nearly adiabatic in order that the von Karman velocity profile is in similitude with hydraulic water profiles for turbulent flow. It is also important that we do use only wind profiles having ten meter anemometer level wind speeds greater than about 6 to 7 meters per second, in order to assure us that the experiments are well

above the minimum friction velocity Reynolds number, $R_e = \frac{u_* k}{\nu} \gtrsim 70$ or 80, where $k \hat{=} 30 z_0$, and z_0 = the von Karman friction length.

Finally, we have included a re-analysis of the canal experiments of Lane and Carlson (1953) and hope to open the way for further research and experimentation for possible correlation between wind experiments and hydraulic experiments.

1. INTRODUCTION

Two important purposes of the tsunami research are to increase the "State of the Art" - (1) tsunami forecasting for warning and evacuation purposes, and (2) tsunami hindcasting for prediction of future events for zoning and design criteria. In the past, most tsunami research has been directed more-or-less toward four general categories: (1) source area and mechanisms of tsunami generation; (2) propagation of tsunamis from source area to the coastline; (3) harbor surging and beach run-up; and (4) historical data collection and statistical interpretations.

Very little consideration has been given to the nature of the flooding problem as a consequence of tsunami transformation into a flood wave at the top of the beach or the coastline and its propagation over previously dry bed or coastal terrain. All tsunami statistics are based on data that were compiled for the then existing topographical conditions. In case of Hawaii, this covers up to 140 years of tsunami data at Hilo, for example. If the pre-existing topographical conditions are changed as a result of urban and industrial development and, if the same tsunami event occurred, then the consequences of flooding will be entirely different than those which occurred from past history. The U.S. Army Corps of Engineers recommends the use of rip-rap, seawalls, or other construction methods to reduce the hazards of flooding. On the other hand, land developers bulldoze and level the roughness terrain for urban and industrial development. This has a direct bearing on the two important purposes of tsunami research for the purpose of increasing the "State of the Art": (1) tsunami forecasting and warning for evacuation, and (2) tsunami hindcasting for prediction of future events and design criteria.

Since coastal regions are choice locations for urban and industrial development, there is a need to study the effect of bed roughness on potential tsunami flooding, because there is a potentially dangerous risk in loss of life and property if the terrain roughness is decreased, and the proper friction factors are not considered.

The long wave equations are generally used to determine tsunami run-up, flood wave, and inundation of low coastal areas. The two-dimensional computer program, developed by Houston and Butler (1979) of the U.S. Army Corps of Engineers Waterways Experiment Station, is applicable from deep water to beyond the coastline; and the one-dimensional analytical solution given by Bretschneider and Wybro (1976) is applicable only in the final reaches inland from the coastline. The main difference between the two solutions mentioned above is that the first one is

two-dimensional, neglects the convective acceleration terms and retains the local acceleration terms, whereas the second one is one-dimensional and assumes steady state by neglecting the local acceleration terms but retains the convective acceleration terms. Common to both solutions is the retention of the friction term. The friction term is related to bed-roughness, and is usually given by the Chezy coefficient "C" or Manning's "n". Presently, the friction coefficients used in the long wave equations are based on experiences with river, channel and canal flows, or are estimated from wind profile experiments or scaled from hydraulic model tests. The conditions are quite different for a tsunami flood wave over a previously dry bed or rough terrain. There are no measured friction factors determined under these conditions and it is not practical to measure friction factors over previously exposed terrain during a tsunami flood wave.

As an alternative to hydraulically determined friction factors, an adjustable three-level anemometer staff system was used for taking wind profile measurements over typical Hawaii terrain. Presently, a five-level anemometer staff is being used. The scheme of testing is shown in Figure 1. From the wind profile measurements under neutral atmospheric conditions, one can estimate Manning's "n" which is proportional to the sixth root of the von Karman friction length z_0 .

Thus far, of a number of typical Hawaii terrain, three types have been studied: (1) a golf course, (2) a broad grassy knoll, with medium dense grass 2 to 2 1/2 feet tall, and (3) a rock farm, consisting of a large area of stock pile stones 2 to 3 feet average size and more-or-less level conditions as best as can be expected. The results of the data analysis are summarized in Table I, along with the compilation of Ann-Dof, Högstrom and Högstrom (1977). The z_0 scale of Table I was originally given in meters. The left scale of z_0 in meters has been changed to feet, and Manning's "n" $\cong 0.006 z_0^{1/6}$ (in feet) $^{1/6}$ has been added on the right. This gives Manning's "n" to within ± 5 to 10 percent of the types of conditions expected in the present study.

2. BRIEF SUMMARY ON FRICTION FACTOR RELATIONSHIPS

The various forms of the friction factors can be expressed as follows:

$$f_c = \frac{1}{4} f = \frac{2\tau_b}{\rho u^2} = \frac{2g}{C^2} = \frac{2gn^2}{(1.486)^2 R^{1/3}} = 2 \left[\frac{k}{\log_e \frac{R}{ez_0}} \right]^{-2} \quad (1)$$

where f_c and f are the Darcy-Weibach friction factors for open channel flow and full flow in closed conduits, respectively. τ_b is the bottom shear stress; ρ , the density of the fluid; u , the mean velocity of flow; g , the acceleration of gravity; C , the Chezy-Kutter coefficient; n ,

TABLE I
 TERRAIN DESCRIPTION OF AREA WITHIN SEVERAL KILOMETERS UPWIND OF SITE

*NOTE: ORIGINAL Z_0 WAS GIVEN IN METERS, NOW CHANGED TO Z_0 IN FEET (LEFT SCALE) AND MANNING'S "n"

Manning's "n"; R, the hydraulic radius; e, the base of the natural logarithm; z_0 , the von Karman friction length; and $k = 0.4$ von Karman universal constant.

Rouse (1949) has shown that Manning's "n" is proportional to $z_0^{1/6}$ power over a wide range of conditions. Calculations over a wide range of z_0 and hydraulic radius R shows that:

$$n/z_0^{1/6} \cong 0.060 \pm 5 \text{ to } 10\% \quad (2)$$

Figure 1 shows the range of $n/z_0^{1/6}$ versus hydraulic radius R, for the ranges of z_0 expected from the wind profile measurements.

The U.S. Air Force Air Research Development command (1961) summarized typical values of z_0 . These values are given in Table II

together with Manning's "n" based on eq. 2. Bretschneider and Wybro (1976) suggested values of Manning's "n" for various types of terrain and they are repeated in Table III. There is a tendency for reduction in friction factor with increase in velocity. This is similar to what one expects from hydraulic experiments where the friction factor decreases with increase of Froude number, as shown in Figures 2 and 3, based on the reanalysis of the canal data of Lane and Carlson (1953).

Table IV gives additional relations for Manning's "n" based on hydraulic experiments. Equations a, b, c, and d in Table IV can be made universally dimensionless by multiplying the left side by $\sqrt{g}/1.486$, and changing the K values from inches to feet. However, eq. e cannot be made dimensionless in a similar manner, except by introducing either another $R^{1/6}$ or $K^{1/6}$ in the denominator of the left side of eq. e. Using $R^{1/6}$ in the denominator of the left side of eq. e and rearranging terms and $\sqrt{g}/1.486$, one can determine eq. g. Using K instead of R, one can arrive at eq. h. Eliminating K from eq. e, one can arrive at eq. f. Evidently, eq. f is a function of R, eq. g is a function of K_m , eq. h is a function of R and K_m ; but all three equations, f, g and h are functions of the flow as defined by the Froude number.

3. FREE AIR WIND EXPERIMENTS

There is nothing new in using wind experiments to study hydrodynamic problems due to water current forces. This has been done in the past by naval architects and marine engineers for offshore floating and rigid structures. What is unique in this study and approach is the use of prototype wind experiments for the determination of friction factors over typical Hawaii terrain to aid in the solution of the hydraulic problems associated with tsunami run-up, flood wave and inundation.

FIG. 1 Variation of $\frac{n}{z_0^{1/6}}$ for various values of z_0 and R

TABLE II
SUMMARY VALUES OF z_0^*

Values of z_0 and Manning's "n"		
Type Surface	z_0 (ft)	$n = .06 z_0^{1/6}$
Very smooth (mud flats, ice)	0.00003	.011
Lawn grass up to 0.4 inches high	0.003	.023
Downland thin grass up to 4 inches high	0.02	.031
Thick grass up to 4 inches high	0.075	.039
Thin grass up to 20 inches high	0.16	.044
Thick grass up to 20 inches high	0.30	.049
*Obtained from U.S. Air Force Research Development Command (1961)		

TABLE III
 SUGGESTED VALUES OF MANNING'S "n" FOR VARIOUS COASTAL TERRAIN CONDITIONS

n	Conditions
0.015 - 0.025	Very smooth (mud flats, ice, well maintained concrete paved ways, beaches of fine sand)
0.025 - 0.030	Smooth (dried earth, coarse sand beaches, badly maintained concrete paved ways, very thin lawn grass up to 1 cm high)
0.030 - 0.035	Average for developed areas (lawn grass up to 5 cm high, gravel, presence of some buildings, houses, and other obstructions)
0.035 - 0.045	Open coast, relatively smooth and open area (grass up to 10 cm, sparse population of trees*, sparse bush, even bottom)
0.045 - 0.055	Moderately rough open coastal areas (thick grass, uneven bottom consisting of large rocks, coral, etc., presence of trees with low foliage, brush, lava rock, etc.)
0.055 - 0.070	Unusually rough coastal areas (dense brush, dense tree population with exposed roots, coarse lava rock formations)

*Trees with high foliage such that only trunks are exposed to flow

K_{50} , K_{25} , K_{10} bed material size in inches of which 50, 25 and 10 % are larger by weight, respectively k_m = medium size (50%) in feet.

Sutton's (1953) *Micrometeorology* is one of many books on meteorology dealing with lower level atmospheric turbulence and motion. Sutton (1953), as well as all meteorologists, uses the same basic fluid mechanics equations of flow over smooth and rough surfaces that hydraulic engineers use, but the meteorologists also include atmospheric stability criteria. The free air can be treated as incompressible flow. Anticipated winds will not be greater than 30 or 40 knots. The primary interest is to obtain wind profile measurements during neutral atmospheric conditions. There are plenty of tradewinds in Hawaii. Mid-day measurements should be avoided when thermal gradients near the ground would affect the interpretation of the data.

Under absolute neutral atmospheric conditions, only two level anemometer readings are necessary for obtaining z_0 friction length in the logarithmic velocity profile equation. The third level can be considered as a check point. The three points should fall along a straight line on semi-log graph paper. If the deviations are too great, the data should be rejected for the proposed method of analysis. A very sophisticated method of analysis of five-level anemometer wind data over the tops of pine trees in Canada was made by Lo (1977). An eight-level anemometer was used by O'Brien (1965) to study the diabatic wind profile for winter and summer conditions over a hay field near Dallas, Texas. One of the purposes of many previous wind profile experiments was to aid in wind predictions under various atmospheric stability conditions. Since we are only interested in those data for adiabatic conditions, we can be selective, and the data can be analyzed more easily using the von Karman logarithmic profile.

4. INSTRUMENTATION

Figure 4 shows a schematic of the three-level adjustable anemometer staff, which includes sensors for wind speed, wind direction and temperature at each of the three levels. The top of the staff is at 10 meters making the top sensor (No. 1) at 10.9 meters = 35.8 feet. Anemometers No. 2 and No. 3 can be adjusted to various elevations. Anemometer No. 2 was located half way on the log scale between No. 1 and No. 3.

The instrumentation package consists of Weather Measure Corporation's: (3 ea.) W103-DC-3SS, low threshold anemometer, 0.C. generator with stainless steel cups; (3 ea.) W104, lightweight wind direction vane 0-360--540 degrees; (3 ea.) W1034-CAW pre-wired cross arm to mount wind sensors; (1 ea.) SC-710 card file, pre-wired for 10 parameters; (3 ea.) MD103-0C, wind speed translator module 0-540 deg.; (1 ea.) MD910, power supply; (1 ea.) MO-OPM-S, digital panel meter, switch selectable channels; (1 ea.) WM-INT, systems integration and documentation. Air temperature sensors are located at each anemometer position, and can be shifted as necessary.

The analog data are recorded in a digital format by a 16 channel Datal Cassette Recorder. Following field data acquisition, the data cassette is then read by a Datal Cassette Reader into a Hewlett-Packard

FIG. 4 SCHEMATIC ARRANGEMENT OF ADJUSTABLE THREE LEVEL ANEMOMETER STAFF

HP-9845 Mini-Computer System. The HP-9845 system then performs all data calculation and analysis, and either prints or directly generates computer drawn graphs for visual display of the data.

5. A SIMPLE METHOD OF WIND PROFILE DATA ANALYSIS

The three-level anemometer experiments. There is no proof that eq. 2 is probably a better relationship than eq. 1 between Manning's "n" and von Karman's z_0 . However, it is found that eq. 2 is very useful for the three-level anemometer data analysis, as can be demonstrated.

The von Karman logarithmic velocity profile is:

$$\frac{u}{u_*} = \frac{1}{k} \ln \frac{z + z_0}{z_0} \quad (3)$$

where u is the wind speed at elevation z above the mean reference surface, z_0 is the friction length and $u_* = \sqrt{\tau/\rho}$ the friction velocity. Equation 3 does not include the zero displacement concept such as used by O'Brien (1965) or Lo (1977).

Assuming $z_0 \ll z$ for the lowest anemometer elevation, then by rearranging the terms in eq. 3, multiplying through by $1/6$ and using eq. 2, one obtains

$$n = .06z^{1/6} e^{-\frac{1}{6} \left(\frac{ku}{u_*} \right)} (\text{feet})^{1/6} \pm 10\% \quad (4)$$

Equation 4 is a straight line on semi-log graph paper when $z^{1/6}$ is on the log scale and u is on the linear scale. Anemometer Nos. 1, 2 and 3 are elevations 35.8, 11.48 and 4.26 feet, respectively, which results in the anemometer levels in terms of $0.06z^{1/6}$ equal to 0.109, 0.009 and 0.076 (feet) $^{1/6}$, respectively. At $u = 0$, $n = 0.06z_0^{1/6}$.

The above method was introduced as a matter of convenience in order to give engineers an idea of Manning's "n" determined from wind experiments. There is nothing unique about the method, except that the data can be shown on a one cycle semi-log scale instead of on four to six cycle semi-log log.

Figures 5 and 6 show typical examples of Hawaii terrain and corresponding values of Manning's "n". Values of Manning's "n" by this method are only estimates.

The five-level anemometer experiments. The five-level anemometer staff is shown in Figure 7. The log-linear regression analysis of the

data is used including the zero-plane displacement concept, in which case the data fall more closely along a straight line than that given in the paper. The results of these analyses, however, will be reported at a later date, after the project has been completed.

6. POSSIBLE METHODS OF CORRELATING WIND EXPERIMENTS WITH HYDRAULIC EXPERIMENTS

One of the missing links between the wind experiments and the hydraulic experiments is the determination of the equivalent hydraulic radius R or the slope of the energy grade line for the wind experiments. The hydraulic radius and/or energy slope can be measured for the hydraulic experiments.

The friction velocity method. Beginning with the von Karman velocity profile equation,

$$u_z = \frac{u_*}{k} \ln \frac{z}{z_0} \quad z_0 \ll z, \quad (5)$$

one can obtain a mean velocity \bar{u}_z as follows:

$$\bar{u}_R = \frac{1}{R} \int_0^R u_z dz = \frac{u_*}{k} \ln \frac{R}{ez_0} \quad (6)$$

and

$$u_R = \frac{u_*}{k} \ln \frac{R}{z_0} \quad (7)$$

where u_R is the velocity at elevation $z = R$ and \bar{u}_R is the integrated mean velocity between $z = 0$ and $z = R$. $u_* = \sqrt{\tau/\rho}$ the friction velocities, $k = 0.4$ and $z_0 =$ friction length as given before.

It can then be shown for the von Karman velocity profile that

$$u_* = k(u_R - \bar{u}_R) = \sqrt{gRS} \quad (8)$$

where S is the slope of the energy grade line.

The friction velocity Reynolds number and Froude number (if such is a possibility) are given as follows:

$$R_e^* = \frac{u_* K_m}{\nu} = \frac{k(u_R - \bar{u}_R) K_m}{\nu} \quad (9)$$

where $\nu =$ kinematic viscosity and $K_m =$ mean stone size.

$$F_R^* = \frac{u_*}{\sqrt{gR}} = \frac{k(u_R - \bar{u}_R)}{\sqrt{gR}} \quad (10)$$

The minimum hydraulic radius method. It is quite well established in the literature, for example, Squarer, et al (1971), among many others, and also as shown in Figure 3 based on a re-analysis of the canal data of Lane and Carlson (1953), that the non-dimensional friction factor relationships are a function of the Froude number. The friction factor relationships decrease with increase in the Froude number.

The Froude number is given by

$$F_R = \frac{\bar{u}_R}{\sqrt{gR}} \quad (11)$$

where \bar{u}_R is the mean velocity and is the same as \bar{v} used in Manning's equation and also in Figure 3.

Using \bar{u}_R from equation 6, one obtains

$$F_R = \frac{\frac{u_*}{k} \ln \frac{R}{ez_0}}{\sqrt{gR}} \quad (12)$$

Differentiating equation 12 and setting the expression equal to zero, one obtains an expression for minimum hydraulic radius as follows:

$$R_{\min} = e^3 z_0 \quad (13)$$

It then follows that

$$u_{R_{\min}} = \frac{u_*}{k} \ln e^3 \frac{z_0}{z_0} = 3 \frac{u_*}{k} \quad (14)$$

and

$$\bar{u}_{R_{\min}} = \frac{u_*}{k} \ln \frac{e^3 z_0}{ez_0} = 2 \frac{u_*}{k} \quad (15)$$

whence

$$F_{R_{\min}} = \frac{\bar{u}_{R_{\min}}}{\sqrt{gR_{\min}}} = \frac{2 \frac{u_*}{k}}{\sqrt{ge^3 z_0}} \quad (16)$$

where $u_* = k(u_{R_{\min}} - \bar{u}_{R_{\min}}) = k(u_R - \bar{u}_R) = k(u_z - \bar{u}_z)$.

u_R , \bar{u}_R and z_0 can be obtained from velocity profile measurements, whether in water or air without any knowledge of the actual hydraulic radius, provided the von Karman velocity profile conditions exist over the elevations of measurements.

It can also be shown that

$$z_0 = R e^{-\left(\frac{ku_R}{u_*}\right)} = R e^{-\left(\frac{u_R}{u_R - \bar{u}_R}\right)} \tag{17}$$

Therefore, it might be possible to correlate wind and water experimental results. At least, this is worthy of further investigation.

For example, one might re-define the Keulegan non-dimensional form of Manning's "n" $\lambda = \lambda^*$ as follows:

$$\lambda^* = \frac{2gn^2}{(1.486)^2 R_{min}^{1/3}} \tag{18}$$

A re-analysis of the data by Lane and Carlson (1953) is given in Table V. R_{min} is determined from eq. 13, where z_0 is determined from eq. 1, using values of R and n from the data of Lane and Carlson (1953). It is noticed in the re-analysis of the data that test nos. 8 and 10 can be considered questionable. For example, there is one case (test no. 10 (1950)) where R_{min} is actually greater than the true hydraulic radius, R, and also K_m is very large compared with R_{min} . It is for these reasons that in all previous analysis, Lane and Carlson (1953), Squarer, Mostafa and McDermid (1971), and also in this present paper that the data for test nos. 8 and 10 fall considerably out of the range of the other test data. The analysis of the data in Table V for λ^* and $\sqrt{\lambda^*}$ are given separately for the 1950 and 1952 tests and also for the combined 1950 and 1952 tests. Omitting tests 8 and 10 results in considerable reduction in the variance from the mean values of $\bar{\lambda}^*$ and $\sqrt{\hat{\lambda}^*}$, particularly for the 1950 test data, which were for normal flow. The 1952 data were for peak discharge, which increased the actual hydraulic radius and decreased the minimum hydraulic radius, $R_{min} = e^3 z_0$.

It then follows for the data of Lane and Carlson (1953), excluding test nos. 8 and 10 that

CHAPTER 43

Run-up of Tsunamis by Linear and Nonlinear Theories

Chiaki Goto

Instructor of Civil Engineering

and

Nobuo Shuto

Professor of Civil Engineering
Tohoku University, Sendai, Japan

ABSTRACT

Linear and nonlinear sets of equations of long waves in the Lagrangian description are solved numerically to obtain run-up heights. Numerical results are compared with theoretical ones in case of simple topographies and the agreement is quite satisfactory. As a practical application, the computation is carried out for the Okkirai Bay in Japan. The computed run-up heights agree fairly well with the recorded ones.

1. INTRODUCTION

One of the most difficult problems in the numerical simulation of tsunami run-ups lies in the fact that it is not easy to introduce the boundary condition which should precisely reflect the topography of the land where the tsunami arrives at.

In the present paper, one- and two-dimensional problems are treated numerically by adopting both linear and nonlinear sets of equations described in the Lagrangian coordinates. In this system, the boundary condition can be easily satisfied. The water particles lying on the sea bottom at the beginning of the motion do not leave the bottom during the subsequent motion. The water particle at the wave front is the one which is at the shoreline at the initial instant.

For the analysis, an explicit finite difference method is used. The computation is first carried out for simple topographies, for which the linear equation gives analytical solutions. The numerical results of the linear theory are compared with the theoretical values and agreement is quite satisfactory.

Then, the nonlinear computation is carried out. The difference between linear and nonlinear theories amounts 20% at most.

As an example of practical application, The computation is carried out for the Okkirai Bay on the South Sanriku Coast in Japan, which suffered much by the attacks of tsunamis in the past.

2. BASIC EQUATIONS AND NUMERICAL TECHNIQUES

Let us consider the irrotational, three-dimensional motion of an incompressible fluid. The displacements of the water particle which is at the point (a,b,c) at the initial instant is (a+x,b+y,c+z) at the time t. The still water surface is taken as the a-b plane, and the c-axis is taken vertically positive upward. Linear and nonlinear equations of long waves in the Lagrangian coordinates have been derived by authors (Shuto, 1967; Goto, 1979; Goto and Shuto, 1979).

The linear theory is written:

$$\eta + h(a,b)\{x_a + y_b\} + h(a+x,b+y) - h(a,b) = 0 \text{ -----(1)}$$

$$\begin{bmatrix} x_{tt} \\ y_{tt} \end{bmatrix} + g \begin{bmatrix} \eta_a \\ \eta_b \end{bmatrix} = 0 \text{ -----(2)}$$

And the nonlinear one is

$$(1 + x_a + y_b)\{\eta + h(a+x,b+y) - h(a,b)\} - h(a,b)\{x_a + y_b + \frac{\partial(x,y)}{\partial(a,b)}\} = 0 \text{ -----(3)}$$

$$\begin{bmatrix} 1 + x_a & y_a \\ x_b & 1 + y_b \end{bmatrix} \begin{bmatrix} x_{tt} \\ y_{tt} \end{bmatrix} + g \begin{bmatrix} \eta_a \\ \eta_b \end{bmatrix} = 0 \text{ -----(4)}$$

where g denotes the acceleration of gravity, h(a,b) the still water depth where the water particle existed at the initial instant and h(a+x,b+y) also still water depth where the water particle arrives at. The relationships between these theory is similar to that between linear long wave and shallow water theories in the Eulerian coordinates.

These equations are expressed in terms of the displacements (x,y,\eta) of the free surface from the original position. In the present analysis, the Lagrangian velocities (u=x_t, v=y_t, \eta_t) are introduced in place of them. The bottom friction expressed in Manning's n and proportional to the square of the velocity is also introduced. This change of variables makes the numerical computation more stable and easier.

Therefore, the equations are, for linear waves,

$$(\eta_t + u_{a+x} + v_{b+y}) + h(a,b)(u_a + v_b) = 0 \quad \text{-----(5)}$$

$$\begin{bmatrix} u_t \\ v_t \end{bmatrix} + g \begin{bmatrix} \eta_b \\ \eta_a \end{bmatrix} + \frac{gn^2}{D} \sqrt{u^2 + v^2} \begin{bmatrix} u \\ v \end{bmatrix} = 0 \quad \text{-----(6)}$$

and, for nonlinear waves,

$$(1 + x_a + y_b)^2 (\eta_t + u_{a+x} + v_{b+y})$$

$$h(a,b) \{ u_a + v_b + \frac{\partial(u,y)}{\partial(a,b)} + \frac{\partial(x,v)}{\partial(a,b)} \} = 0, \quad \text{-----(7)}$$

$$\begin{bmatrix} 1 + x_a & y_a \\ x_b & 1 + y_b \end{bmatrix} \begin{bmatrix} u_{tt} \\ v_{tt} \end{bmatrix} + g \begin{bmatrix} \eta_a \\ \eta_b \end{bmatrix} + \frac{gn^2}{D} \sqrt{u^2 + v^2} \begin{bmatrix} u \\ v \end{bmatrix} = 0 \quad \text{-----(8)}$$

Where D denotes the total water depth.

For the water particle at the initial instant, the still water depth h is equal to zero. Therefore, in these equations of continuity of long waves, the value $(\eta_t + u_{a+x} + v_{b+y})$ is equal to zero provides the boundary condition at the wave front.

For the numerical computation, an explicit finite difference method similar to the staggered leap-frog scheme is used. For example, the difference equations of the linear theory are expressed as

$$\eta_{i,j}^{n+1} = \eta_{i,j}^n - h_{i,j} \lambda \{ (u_{i+1/2,j}^{n+1/2} u_{i-1/2,j}^{n+1/2}) + (v_{i,j+1/2}^{n+1/2} - v_{i,j-1/2}^{n+1/2}) \}$$

$$- \Delta t (h_x u_{i,j}^n + h_y v_{i,j}^n) \quad \text{-----(9)}$$

$$u_{i+1/2,j}^{n+1/2} = \frac{1}{1 + \mu_{i+1/2,j}^{n-1/2}} \{ (1 - \mu_{i+1/2,j}^{n-1/2}) u_{i+1/2,j}^{n-1/2} - g \lambda (\eta_{i+1,j}^n + \eta_{i,j}^n) \} \quad \text{-----(10)}$$

$$v_{i,j+1/2}^{n+1/2} = \frac{1}{1 + \mu_{i,j+1/2}^{n-1/2}} \{ (1 - \mu_{i,j+1/2}^{n-1/2}) v_{i,j+1/2}^{n-1/2} - g \lambda (\eta_{i,j+1}^n + \eta_{i,j}^n) \} \quad \text{-----(11)}$$

where $\lambda = \Delta t / \Delta s$; Δs and Δt denote horizontal and time mesh size, respectively, and

$$u_{i,j}^n = \frac{gn^2 \Delta t}{(D_{i,j}^n)^{4/3}} \{ (u_{i,j}^n)^2 + (v_{i,j}^n)^2 \}^{1/2}$$

Notations h_x and h_y denote the local slopes, in the x- and y-direction where the water particle arrives at, so we calculate and store them beforehand.

In Fig. 1, the numerical computation mesh is shown. The velocity are calculated for the point where arrows are shown and vertical displacement at the point where black circles are shown. When we need the velocities for the points of the black circles, we estimate them by a linear interpolation. For the points along the initial shoreline, we estimate the velocities by a linear extrapolation.

Fig. 1 Numerical mesh.

The same procedure was also adopted in case of nonlinear theory.

3. RESULTS OF COMPUTATION

(1) Comparisons with the analytical solutions.

First, we examine the accuracy of the numerical scheme for one-dimensional cases. A simple topography, a uniform slope connected to the channel of constant depth, is used. In this topography, the maximum run-up height R was theoretically presumed by Keller and Keller (1964) and confirmed by Shuto (1972), by using the linear theory.

$$\frac{R}{H} = \{ J_0^2(4\pi \frac{l}{L}) + J_1^2(4\pi \frac{l}{L}) \}^{-1/2} \tag{12}$$

Where L is the wave length in water of constant depth, H the incident wave height, l the horizontal length between the toe of the slope and the shoreline and J_n the n-th Bessel Function of the first kind.

For the simple topography, we have computed several cases with no friction effect. Figure 2 shows the comparison. The curve is the result given by the analytical solution, while black circles are the numerical

Fig. 2 The comparison between the analytical and the numerical (linear) results.

Fig. 3 The comparison of wave profile.

results. Examples of wave profile are shown in Fig. 3. They are for maximum run-up and run-down for wave periods of 300 sec and 600 sec by linear theory. The lines are the analytical solution and the circles the numerical results. We consider the agreement is satisfactory.

Though examination of the numerical results obtained for different conditions, we find that the accuracy of the numerical results depends upon three factors, the spatial mesh size Δs , the slope of topography α and the wave length L . In order to see this, the ratio of the computed maximum run-up height to the analytical one is shown in Fig. 4 as a function of a parameter made of the three factors. With the bigger value of the parameter, the accuracy becomes worse. The reason is considered due

to deterioration of the linear extrapolation used at the wave front, with steeper slopes, longer mesh size and shorter wave length.

Secondly, it is checked how big the effect of nonlinearity is. The computation is carried out for the same topography. The results are compared with analytical results of the linear theory. In nonlinear computations, a particle with the higher vertical displacement moves with the higher velocity. Therefore, in some cases, a particle behind the wave front overtakes the wave front. We consider that this introduces the breaking and it is necessary to make an adjustment. We set a restriction that the particles behind should not get ahead of the particles in front of them. White circles in Fig. 5 show the results of the computation with the adjustment and the black ones those without the adjustment. This phenomenon becomes distinct with the wave of big steepness. In the computation of actual tsunamis, the phenomena is almost negligible, because of their small steepness.

Examples of wave profile with the adjustment are shown in Fig. 6. The wave fronts are similar to a bore. However, due to the small amplitude, difference between the nonlinear results and the linear ones is not large.

Thirdly, the accuracy of our numerical scheme for the two-dimensional cases are examined. We employ the case of a rectangular bay with the bottom of a uniform slope. In this simple topography, an analytical solution of maximum run-up height are obtained by use of the linear theory in the Lagrangian coordinates as follows,

Fig. 4 The accuracy of the numerical computation.

Fig. 5 The comparison between the analytical and the numerical (non-linear) results.

$$\frac{R}{H} = \{ (J_1(4\pi\frac{1}{L})\psi_1)^2 + (J_0(4\pi\frac{1}{L}) - J_1(4\pi\frac{1}{L})\psi_2)^2 \}^{-1/2}, \text{-----(13)}$$

where

$$\psi_1 = \frac{2kd}{\pi} \int_0^{kd} \frac{\sin^2 s}{s^2 \sqrt{(kd)^2 - s^2}} ds,$$

$$\psi_2 = \frac{2kd}{\pi} \int_0^{kd} \frac{\sin^2 s}{s^2 \sqrt{s^2 - (kd)^2}} ds,$$

and where 2d denotes the width of the bay and k the wave number. Tsunami in a bay may increase their heights due to resonance, and then the effects of nonlinearity may become unnegligible. Figure 7 shows the comparison of the analytical results of the linear theory and the numerical results. White circles are of nonlinear theory and black circles are of linear theory.

Fig. 6 Examples of wave profile for the nonlinear theory.

As the results of these preliminary examinations, we get the following conclusions.

1. Our numerical scheme is stable and satisfactory with respect to the accuracy of the results, for both one- and two-dimensional cases.

2. The nonlinear effects can increase the linear results by amount of 20% at most.

(2) An application to the Okkirai Bay.

The method with the nonlinear and bottom friction ($n = 0.029$) effects is applied to a bay on the Sanriku Coast, in Japan. This area

Fig. 7 The comparison between the analytical and the numerical results for a rectangular bay.

has been frequently attacked by tsunamis. In the Okkirai Bay, there are five fishing ports with flats behind them. Along the other part of the coast, we find the almost vertical cliffs and no village. Therefore, the main interests are upon the five places.

The tsunami selected as the input is the Great Meiji Sanriku Tsunami in 1896. Due to this tsunami, more than 27,000 persons were dead and about 10,000 houses were destroyed and lost. The source of the earthquake located at about 100km off the Sanriku Coast. Figure 8 shows the area of the source of the tsunami and the movement of the sea bottom which estimated by Hatori (1976). The number in the figure is the vertical displacement of the sea bottom. We assume that the displacement occurred instantly and the water surface showed the same movements as the sea bottom.

In order to economize the computation time, the whole region is divided into four sub-regions of different mesh size. The minimum mesh size is 1/9km. Figure 9 shows the smallest region in the Okkirai Bay.

The origin of time is taken at the time when the earthquake occurred. At about 17 minutes after the earthquake, the water level begins to recede. Then, it follows a slight ebb of water level. Figure 10 shows the time history of water surface elevation at the entrance of the bay.

An example of the numerical results is given in Figs. 11 to 15. In Figs. 11 and 12, which correspond to the time 2100 s and 2280 s, arrows show the horizontal velocities, lines the contour lines of the water surface and numbers attached the height in meters above still water level. Then, the first maximum run-up occurs at the bottom of the bay. We show the details in Figs. 13 to 15. The solid line is the network connecting the initial positions of water particles when we have no tsunami. The dotted line denotes the deformation of the network at each time. The

Fig. 12

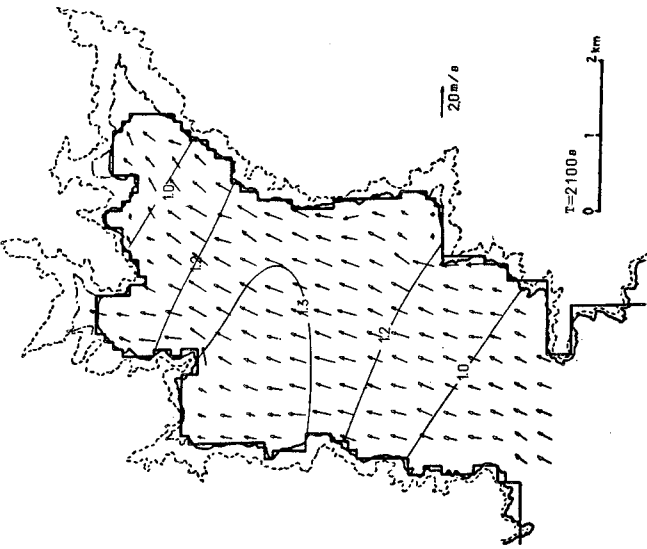

Fig. 11

Fig. 14

Fig. 13

Fig. 15 The comparison between the recorded and the numerical maximum run-up height for the Great Meiji Sanriku Tsunami in 1896.

values shown in the center of the dotted mesh is the mean value of the vertical displacement, averaged from the value at four corners.

Figure 15 corresponds to the maximum run-up. The chain line in this figure shows the recorded inundation heights in 1896. There is a small river in this village. The record shows the run-up height of 10.3 m along the river (point A). The numerical simulation gives 10.2 m. Due to the finite grid cell, the computed point can not exactly coincide with the recorded point. At the point B, the record shows 13.3 m. The numerical ones is 11.5 m. Although the difference is rather big, the inundation lines of the recorded and the numerical ones coincide well, because the land here is almost vertical. At the point C, the record is 11.2 m and the computed one is 11.4 m. At the point D, 11.8 m and 12.5 m, respectively.

As the result, it is considered that the agreement is satisfactory and the method employed here is effective to simulate the run-up of a tsunami.

4. CONCLUSION

Linear and nonlinear long wave theories in the Lagrangian description are proved to be applicable to the analysis of tsunami run-up. Computation schemes are examined and established in both one- and two-dimensional cases. The present method can be also applied without difficulty to the actual topography of complicated geometry.

ACKNOWLEDGEMENT

The authors wished to express their gratitude to Dr. T. Iwasaki and Dr. A. Mano, Professors of Civil Engineering, Tohoku University, for their discussions and co-operation.

A part of the study was supported by a grant from the Ministry of Education.

CHAPTER 44

ON THE CORRECTION OF LAND-BASED WIND MEASUREMENTS FOR OCEANOGRAPHIC APPLICATIONS

S. A. Hsu

Coastal Studies Institute, Louisiana State University
Baton Rouge, LA 70803, U.S.A.

Abstract

Simultaneous offshore and onshore wind measurements were made at stations ranging from Somalia, near the equator, to the Gulf of Alaska. Offshore data obtained from standard U.S. NOAA buoys, research platforms, and merchant ships were compared with data from coastal stations. The results indicated that, under the commonly observed speed of 5-6 m/s, land measurements of mean wind speed are only 63% of the offshore mean speed. Furthermore, it was found that only those stations located in the beach area that measure wind speed above both the internal boundary layer and the nocturnal inversion height represent offshore conditions. In order to correct land-measured wind data, a formula is developed and verified by all existing data sets. A simplified equation, i.e., $U_{\text{sea}} = 3 U_{\text{land}}^{2/3}$ is proposed for offshore applications. Criteria for in situ wind measurements near the coast are outlined. Data reduction procedures for inland stations are also provided.

1. Introduction

For some time, differences in onshore and offshore wind speeds have been known to exist (see, e.g., Davenport, 1965; Yu, 1970; Hsu, 1979; Zimmerman and Burton, 1979). Many studies related to coastal marine sciences and engineering require wind data from offshore regions. Yet, in situ measurements over water are often lacking. Therefore, engineers as well as scientists traditionally rely on wind measurements over land, preferably near coasts. However, because simultaneous onshore and offshore observations do not always exist, systematic studies such as simple comparison between these two environments are also lacking. Only recently the U.S. National Oceanic and Atmospheric Administration (NOAA) deployed several buoys for longer term measurements over the continental shelf as well as farther offshore. It is the purpose of this paper to study the systematic variations in wind speed between offshore and onshore areas by comparing these buoy data with data from coastal and inland stations operated by NOAA.

In order to substantiate the results, four specialized experiments have been selected. The phenomenon of wind variability across the coastal zone is described in section 2. In order to correct onshore measurements a formula is developed in section 3. Experimental results are summarized in section 4. Since existing stations are not necessarily located near the shore, in situ measurements may be required for certain engineering projects. Furthermore, height correction for those data obtained from existing urban stations should be made. All these problems are discussed and correction criteria are outlined in section 5. Finally, conclusions are drawn in section 6.

2. Wind Variability across the Coastal Zone

In this study U.S. NOAA data from six buoys and twelve land stations for a period of 1 year (July 1977 through June 1978) are utilized. Information on these data buoys may be found in Hamilton (1980). Data from each buoy are compared to those of the two nearest land stations: one located on the coast, i.e., keys, capes, and islands, and another a few kilometres inland, preferably less than 20 km. Two buoys are located in the Atlantic Ocean, two are in the Gulf of Mexico, and one each is in the Pacific Ocean and Gulf of Alaska. In order to avoid height variations between wind sensors, only those land stations whose height is within 20 m above sea level are used.

The results are shown in Figure 1. They indicate that, contrary to common practice, even stations such as those located on a small, flat, open area (e.g., Key West, Florida, and Cape Hatteras, North Carolina) cannot represent monthly mean offshore conditions. Furthermore, at stations located in an estuarine environment such as Homer, in Cook Inlet, Alaska, the mean wind speed on the average is less than half that offshore. Figure 1 also shows that the largest difference between onshore and offshore conditions usually occurs in winter, when offshore storms are more frequent because of the more pronounced aerodynamic roughness or drag effect on land. During the warmer part of the year higher speeds may be recorded, at times, for diurnal onshore (sea breeze) winds than for offshore winds (Fig. 1). As expected, the wind speed decreases inland (Fig. 1).

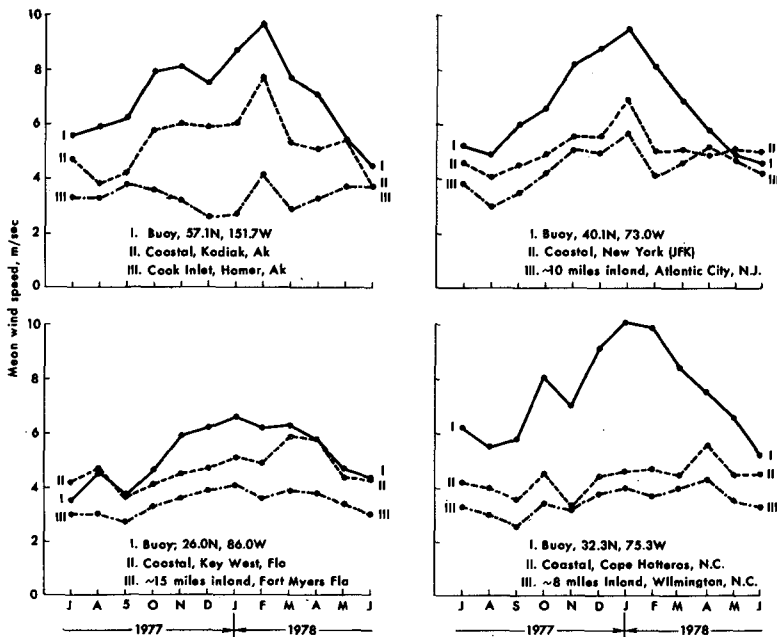

Figure 1. Examples of differences in monthly wind speed (meters per second) at stations ranging from offshore to coastal to inland (from July 1977 through June 1978).

The average of all buoys and land stations indicates that the ratio of buoys to land stations is 1.60 ± 0.28 (mean \pm standard deviation). In other words, the average land-based mean speed is only 63% of that offshore. Two pairs of buoy data not shown in Figure 1 are incorporated in the above statistics. They are a buoy located at 26.0°N , 93.5°W , which was compared to Corpus Christi and Brownsville, Texas, stations, and a buoy at 41.1°N , 137.8°W , which was compared to stations at Astoria, Oregon, and San Francisco, California.

Figures 2 and 3 represent some diurnal variations across the upper Texas coastal zone (Yu, 1970). Nine mechanical weather stations were used to record surface temperature, wind speed, and wind direction. The offshore station was located about 19 km directly offshore (station SOC, shown in Fig. 2). The instrument at that location was mounted on top of an oil drilling platform, which placed it about 20 m above the water surface. The others were located inland at distances of approximately 0.01, 0.09, 1.7, 3.5, 5.2, 8.0, 10.7, and 14.0 km from the coastline. The instruments at these eight inland stations were set up at a height of 2 m above the ground. In order to compare SOC (offshore) data with that from the other

Figure 2. Locations of the nine mechanical weather stations (eight onshore and one about 19 km offshore on a platform). They were located approximately along a line perpendicular to the shoreline. (After Yu, 1970.)

Figure 3. Diurnal variation of wind speed measured from eight stations (cf. Fig. 2 and text) deployed on the upper Texas coast and averaged for the period 9-11 June 1968. (After Yu, 1970.)

stations, the data were all reduced to the 2-m level. As shown in Figure 2, the nine stations were located along a line almost perpendicular to the coast. A 1-hour average time centered on the hour was used, that is, 0830 to 0930 for the 0900 value, etc. Accuracy is limited to the reading accuracy of the record, which is approximately ± 0.1 mi/hr (± 0.045 m/s) (for further details, see Yu, 1970).

The diurnal variation of wind speed at the various stations is shown in Figure 3. Curves are drawn on the basis of a 3-day average, i.e., June 9, 10, and 11 taken together. The most important feature shown in this figure is that there are two different types of curves. The curves for stations SOC, 1, and 2 are similar; we shall call these marine-type stations. Stations 3, 4, 5, 7, and 8 we shall call inland-type stations. Data for station 6 are missing because that instrument did not function properly. At the marine-type stations maximum wind speeds occurred about midnight and minimum wind speeds occurred about noon. More detailed examination of the figure reveals that at the offshore station (SOC) the minimum wind speed occurred at 1600 central daylight time (CDT), while at nearshore stations 1 and 2 minimum speeds occurred at 1000 CDT and 1100 CDT, respectively. At inland stations the primary maximum wind speeds occurred at 1400 CDT, primary minimum wind speeds occurred at 0600 CDT or 0700 CDT, a secondary maximum occurred at 0000-0100 CDT, and a secondary minimum occurred at 2100-2200 CDT.

It is clear from Figure 3 that only those stations (i.e., 1 and 2) that are within about 100 m of the surf zone represent offshore conditions. Since most coastal weather stations worldwide are not located that close to the shoreline, inland wind measurements may not be extended to the offshore

unless proper corrections are made.

Figure 4 shows that on the tropical (trade-wind-dominated) island of Barbados wind speeds were also different along a horizontal grid that extended from the beach to 10 km inland (Aspliden et al., 1977). Note that the station located on the shore (Fig. 4) agrees closely with the 1968 upper Texas coast beach station shown in Figure 3. About 2 km inland nighttime and daytime peaks are about equal, and 10 km inland only a strong daytime maximum is indicated. This also resembles the inland data from the upper Texas coast (compare Figs. 3 and 4) (for explanation of the variability see Yu, 1970, and Aspliden et al., 1977). The prevailing wind

Figure 4. Diurnal variations of wind speed and direction at three locations on the eastern shore of the tropical island Barbados in August 1972. (After Aspliden et al., 1977.)

direction at Barbados was from 90° to 120° at all stations.

3. Development of the Correction Formulas

It has been demonstrated in the preceding section that large differences exist between wind measurements made onshore and those made offshore. Corrections, therefore, should be made to inland station data before they are applied to offshore regions. In order to facilitate such a correction, the following formula, based on the power law wind distribution in the PBL (see, e.g., Davenport, 1965), is proposed (see Fig. 5)

$$\frac{U}{U_H} = \left(\frac{Z}{Z_H} \right)^P \quad (1)$$

where U at height Z and U_H at Z_H are the velocity within and above the atmospheric planetary boundary layer (PBL), respectively. The thickness of the PBL is $Z_H (=H)$, and P is an exponent that depends on atmospheric stability and surface roughness, Z_0 . (For determination of P , see, e.g., Sedefian, 1980.)

The power law, equation (1), has two significant characteristics that make it very useful for work involving the whole of layer H : the law is a good average representation of the velocity profile over the entire PBL, and integral relations based on this easily integrated law are not far from correct (see, e.g., Blackadar, 1960; Plate, 1971).

If we assume that equation (1) is valid both onshore and offshore, we get

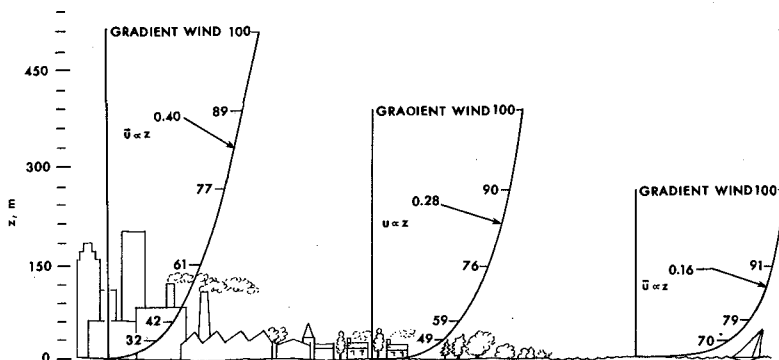

Figure 5. The power law (equation 1) over different terrain. The profile on the left represents the vertical variation of the wind over an urban area; the center profile, over a forest; and the one on the right over flat, open country. (After Davenport, 1965.)

$$\frac{(U/U_H)_{\text{sea}}}{(U/U_H)_{\text{land}}} = \frac{(Z/H)_{\text{sea}}^p}{(Z/H)_{\text{land}}^p} \quad (2)$$

If we assume that U_H on top of the PBL does not change appreciably across the coastal zone and that $Z = 10$ m, equation (2) becomes

$$\frac{U_{\text{sea}}}{U_{\text{land}}} = \frac{10^p_{\text{sea}}}{10^p_{\text{land}}} \cdot \frac{H_{\text{land}}^p}{H_{\text{sea}}^p} \quad (3)$$

According to Hsu (1979a)

$$H_{\text{sea}} = H_{\text{land}} - 123 (T_{\text{land}} - T_{\text{sea}}) \quad (4)$$

where T_{land} ($^{\circ}\text{C}$) and T_{sea} ($^{\circ}\text{C}$) are the temperatures at 2 m over the land and the sea, respectively, and the corresponding H is in metres. Furthermore, according to Hsu (1970)

$$U_{\text{land}} \propto (T_{\text{land}} - T_{\text{sea}}) \quad (5)$$

Since H_{land} is routinely available from twice-daily radiosoundings, it may be considered as a known value. Using this reasoning, and with equation (5), equation (4) may be written as

$$H_{\text{sea}} \propto U_{\text{land}} \quad (6)$$

and, since H_{land} is known, equation (3) becomes

$$\frac{U_{\text{sea}}}{U_{\text{land}}} \propto U_{\text{land}}^{-p} \quad (7)$$

or

$$\frac{U_{\text{sea}}}{U_{\text{land}}} = a U_{\text{land}}^{-b} \quad (8)$$

where a and b are positive numbers.

Equation (8) is our formula for the correction of land-based observations for offshore conditions.

4. Experimental Results

Equation (8) is verified in this section. In addition to the data presented in Figure 1, four more specialized experiments were conducted to substantiate this equation.

Table 1 summarizes all available data pairs measured simultaneously onshore and offshore. Column 3 provides the data obtained from Figure 1, and column 4 shows data from SethuRaman and Raynor (1980). Column 5 was based on field experiments (Hsu, 1979a) from an offshore (stage 1) platform and an existing NOAA weather station at Apalachicola, Florida, during February and again in November-December 1977. Since wind speeds in previous experimental data were low, except those from SethuRaman and Raynor (1980), another special experiment was conducted in Somalia, where a low-level atmospheric jet exists during summer (see Fein and Kuettner, 1980).

Our experiments were conducted in May and June. For comparison, ship data obtained from the National Climate Center were employed. Pairs of Gardo-ship data (8-12°N and 51-55°E) and Mogadishu-ship (0.0-7.9°N and 41-50°E) were collected during June, when the jet is more pronounced between Gardo and the downwind region offshore than at Mogadishu and its offshore area (Fein and Kuettner, 1980). In fact, station Gardo was located very close to the area where the jet core passed. Note that wind measurements from merchant ships are considered reasonable when compared with standard ocean weather ship measurements (see Quayle, 1980). All the available data were analyzed and compiled in Table 1.

Figure 6 shows the result of these comparisons. The constants a and b of equation (8) are determined experimentally to be

$$\begin{aligned} a &= 2.98 \\ b &= 0.34 \end{aligned}$$

with high correlation coefficient,

$$r = 0.95 .$$

We therefore have

$$\frac{U_{\text{sea}}}{U_{\text{land}}} = 2.98 U_{\text{land}}^{-0.34} \quad (9)$$

Table 1. Summary of the Ratio of $U_{\text{sea}}/U_{\text{land}}$ as a Function of U_{land} (in m/s) as Measured at Coastal Stations and Offshore Buoys, Ships, and Research Platforms

or approximately

$$U_{sea} = 3 U_{land}^{2/3} \quad (10)$$

where $2 \text{ m/s} \leq U_{land} \leq 18 \text{ m/s}$.

Equation (10) is an average that encompasses many geographic regions as well as various climatic conditions. For a specific location the coefficients a and b of equation (9) may vary, but the general relationship will not be altered appreciably. It is therefore recommended that equation (10) be used as an average condition.

5. Criteria for Wind Measurements near the Coast

The preceding discussions presuppose a wind measurement station near the coast. However, in many places such coastal stations are not available. In other cases the station may be located not on flat and open country but on rugged terrain, where local topographic effects are large and measurements there may not represent offshore conditions. For certain engineering projects in situ measurements may be required but because of logistical problems shore stations must be substituted. Under these and similar conditions we suggest a set of criteria which will alleviate the problems or at least reduce them to a minimal and acceptable level. Before we outline these criteria, some theoretical considerations may be helpful.

As air passes from land to sea or vice versa, it must readjust to a new set of boundary conditions. The adjustment is not immediate throughout

the depth of the air layer but is generated at the surface and diffuses upward. The layer of air whose properties have been affected by the new surface is referred to as an internal boundary layer (IBL), and its depth grows with increasing distance, or fetch, downwind from the shoreline (see, e.g., Hsu, 1971). Since a simple but accurate model for the IBL has been formulated by Elliott (1958) (see, e.g., SethuRaman and Raynor, 1980), we adapt Elliott's relationship for the height of the IBL, h , given by

$$\frac{h}{Z_o''} = \left[0.75 + 0.03 \ln \frac{Z_o'}{Z_o''} \right] \left(\frac{x}{Z_o''} \right)^{0.8} \quad (11)$$

where Z_o' and Z_o'' are the upwind and downwind roughness lengths and x is the downwind distance. We require the anemometer to be higher than the IBL, i.e., higher than h . An example is given by SethuRaman and Raynor (1980). If the wind blows from sea to land and the beach is 50 m wide, $Z_o' = 0.05$ cm (offshore condition) and $Z_o'' = 10$ cm (onshore condition), the anemometer should be at least 8 m above the surface in order for the wind to represent the offshore condition.

The average condition for Z_o sea is 0.01 cm (Hsu, 1974), and Z_o land in coastal areas is given in Figure 7. For longer Z_o land values, see, e.g., Sellers (1965). From these roughness parameter values, and if the landward fetch from the surf zone is known, equation (11) may be used to compute the optimum height for the wind sensors. For example, suppose a small dune about 2 m high is located 100 m from the mean water line, i.e., the average beach width is 100 m. If the wind is blowing from sea to land, we set $Z_o' = 0.01$ cm, $Z_o'' = 1$ cm, and $x = 10,000$ cm; the height of the anemometer should be at least 9.7 m above the dune ridge. On the other hand, assuming Z_o is the same but the beach is only 10 m wide, the height of the wind sensor needs to be only 2 m above the dune. Note that all examples given above assume that winds are perpendicular to the shoreline. For certain regions, the mean wind may have some angle to the beach; then the over-beach fetch (length) will be larger. This effect should be used in the computation rather than the simple beach width.

The foregoing discussions are valid for onshore winds, i.e., when the wind blows from sea to land. However, when the wind blows from land to sea the anemometer must be located as close to the water's edge as possible because nocturnal cooling will produce calm winds only a short distance from the beach. This phenomenon has been explained by Hsu (1979b) and is shown in Figure 8. It can be seen that higher wind speeds near the beach and farther offshore are the results of a combination of Venturi and gravity-wind effects. For more detail see Hsu (1979b).

For offshore engineering design extreme winds are usually inferred from long-term onshore measurements. However, the reference station must be located on an open and flat country. Certainly data from rugged places must be corrected. An example is given in Figure 9, which shows that the 100-year return period wind at Guantanamo Bay, Cuba (station 13), is only 71 knots, whereas at San Juan, Puerto Rico (station 14) the 100-year return

Figure 7. Summary of the aerodynamic roughness length Z_o and the relationship between shear velocity U_s and the wind velocity at 2-m height U_{2m} , measured in various coastal environments. Note that (1) was obtained from Ecuador; (2) is a synthesis of six beaches, Barbados, Ecuador, Texas, Brazil, Florida, and the Alaskan Arctic; (3) is from Texas; and (4) through (7) are all from Brazil. (For more detail, see Hsu, 1977.)

period wind is expected to be 124 knots. The lower value for Guantanamo is probably due to the sheltering effects of the nearby mountains and the island of Hispanola to the sea, whereas San Juan is exposed to the full force of Atlantic hurricanes (Atkinson, 1971).

For completeness, wind variation with height should be taken into account. Some average conditions are already shown in Figure 5. If analysis of wind loading as a function of height for offshore structures is needed, equation (1) may be applied. Values of the exponent P for different terrain are also shown in Figure 5, for example, for open and flat country, $P = 0.16$. Therefore, this condition may be applied to the offshore, or existing measured winds may be extrapolated to the height required and then corrected by applying equation (10).

We now outline the criteria for wind measurements near the coast:

Figure 8. An example of higher wind speed near the shoreline and farther offshore but nearly calm wind inland under the influence of nocturnal cooling over land (for more detail, see Hsu, 1979b).

- (1) The anemometer site must be located on flat, open country, preferably on the ridge of the first dune field next to the beach, to represent both onshore and offshore winds. If a small island, cape, or key is located offshore, it should be used instead of the coastal dune fields.
- (2) The anemometer height may be optimized by applying equation (11). Proper roughness parameter and beach width should be used.
- (3) Existing wind data may be corrected to the proper height by applying equation (1) and Figure 5. Equivalently, one could apply the ratio obtained from the same height above ground level. For example, at the height of 30 m the wind over flat, open country is about 70/32 (from Fig. 5) or 2.19 times higher than that over a large urban area, and about 70/49 or 1.43 times higher than that over a woodland forest.
- (4) After the data have been measured from the nearshore area on the basis of (1) and (2) or have been reduced from existing inland measurements by (3), one then corrects them by applying equation (10). If a certain height above the sea surface is needed, one

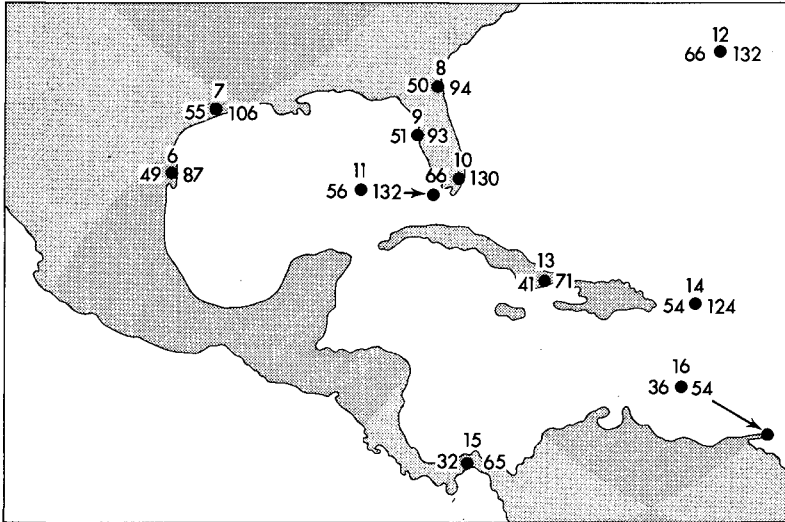

Figure 9. Examples of expected extreme wind gusts (knots) for 2-year and 100-year return periods for selected stations. Station numbers are located on the tops of the dots, 2-year return period on the left, and 100-year on the right. (After Atkinson, 1971.)

may apply equation (1) to the desired height with $P = 1/7$.

6. Conclusions

Several conclusions may be drawn from this study.

- (1) Monthly averages of six standard U.S. NOAA buoys and coastal stations in areas ranging from the Gulf of Mexico to Alaska indicated that the land-based mean wind speed is only 63% of the offshore.
- (2) Simultaneous hourly wind observations based on four more specialized experiments both onshore and offshore in various coastal environments showed that not only were there large differences, as indicated above, but also that only those stations located near the beach area above both the internal boundary layer and the nocturnal inversion height can represent offshore conditions.
- (3) In order to correct land-based wind data, a formula is developed which has been verified by existing data sets. A simplified equation, i.e., $U_{sea} = 3 U_{land}^{2/3}$, is also proposed for offshore applications.

- (4) Criteria for in situ wind measurements near the coast are outlined. It is recommended that the anemometer be deployed on open, flat country and that the optimum height for wind sensors be based on the local roughness parameter and the height of the internal boundary layer. Data reduction procedures for inland stations should begin by correcting the data to the beach environment from the proper speed ratio for the same height because of differences in roughness parameters. Then the beach data may be applied to offshore conditions by employing the simplified equation given above.

Acknowledgments

This study was sponsored by the Coastal Sciences Program, Office of Naval Research, Arlington, Virginia 22217, under a contract with Coastal Studies Institute, Louisiana State University, Baton Rouge. The Somali experiment during the summer 1979 MONEX, as well as travel for presentation of this paper, were supported in part by the Global Atmospheric Research Program, Division of Atmospheric Sciences, National Science Foundation, under Grants ATM 7813388 and 8013644. Appreciation is also expressed to the Somali Government for allowing us to conduct the experiment in order to obtain the essential data to substantiate this study. Buoy information were provided by Captain Glenn Hamilton, of the NOAA Data Buoy Office.

NUMERICAL MODELLING OF TROPICAL CYCLONE STORM SURGE

by

Rodney J. Sobey¹
Bruce A. Harper²
George M. Mitchell³

ABSTRACT

Details are presented of a general numerical hydrodynamic model for the generation and propagation of tropical cyclone or hurricane storm surge. The model, known as SURGE, solves the two-dimensional depth-integrated form of the Long Wave Equations using an explicit finite difference procedure, with tropical cyclone surface wind and pressure forcing estimated from an adaption of available models based on U.S. hurricanes. Variations in tropical cyclone parameters as well as the physical characteristics of a coastal location such as bathymetry and details of capes, bays, reefs and islands are accommodated by the model. The accuracy and stability of the numerical solution have been confirmed by a comprehensive wave deformation analysis including quasi-non-linear effects and the open boundary problem has been overcome by the use of a Bathystrophic Storm Tide approximation to boundary water levels. A detailed sensitivity analysis has identified the principal surge generating parameters and the model has been checked against an historical tropical cyclone storm surge. SURGE has been used extensively in the northern Australian region and examples are presented.

INTRODUCTION

The tropical cyclone or hurricane storm surge is a meteorologically forced long wave motion resulting in a sustained superelevation of the sea surface, at least for a few hours, above that produced by the normal periodic astronomical tide. It is the result of the combined action on the underlying water body of the extreme atmospheric pressure gradients and wind shear stresses generated by a mature tropical cyclone. The region of surge intensification can extend over a substantial length of coastline (of order 200 km) and the development and impact of the surge wave at a particular site is sensitive to a number of meteorological and topographical factors. Briefly these are the intensity and scale of the tropical cyclone, the speed and track of the storm, the underwater and overbank terrain, offshore reefs and islands, local coastal features

(bays, headlands, estuaries) and the astronomical tide. Historically, storm tides have resulted in considerable damage to exposed coastlines, the flooding of low lying land and loss of life. A potentially critical situation arises when the total sustained water level (surge + tide) exceeds the highest astronomical tide (HAT) level.

In response to the need for reliable storm surge estimates in northern Australia for the design of coastal structures and for the protection of coastal communities, a numerical hydrodynamic model was developed within the Department of Civil and Systems Engineering at James Cook University. The model, known as SURGE, is a general numerical hydrodynamic model for the generation and propagation of tropical cyclone storm surge and can be applied to most coastal regions (12). It includes the effects of undersea bathymetry, offshore islands, reefs and other coastal features, as well as the flooding of low lying land. Tropical cyclone size, intensity and track can be varied continuously throughout a simulation to produce water flow patterns, contours of water level, coastal surge profiles at any time and water level and flow velocity time histories anywhere within the model area. SURGE is a comprehensive software system and is fully documented in the form of a user's guide (3). Particular attention has been given to the quite considerable problems of input data format and especially output data selection and presentation.

While numerical modelling of long wave propagation is not new, there are a number of unique aspects of the storm surge problem. In particular, the complex character and geophysical extent of the meteorological forcing, the specification of suitable open boundary conditions and the satisfactory resolution of the storm structure in discretised form all require special attention (12).

MATHEMATICAL FORMULATION

The response of a homogeneous sea to the meteorological forcing of a tropical cyclone is described by the full Navier-Stokes Equations for a homogeneous, incompressible fluid. Direct numerical solutions of these equations are as yet not feasible and a three-dimensional solution would only appear necessary where fluid density difference and/or the vertical flow structure may be important. An adequate description of long wave propagation (astronomical tides and storm surge) can be had from a two-dimensional vertically integrated form of the Reynolds Equations - the Long Wave Equations (17). These equations represent the conservation of mass and the conservation of momentum in horizontal directions x and y and time t :

$$\frac{\partial \eta}{\partial t} + \frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} = 0 \quad (1)$$

$$\frac{\partial U}{\partial t} + \frac{\partial}{\partial x} \left(\frac{U^2}{\eta-d} \right) + \frac{\partial}{\partial y} \left(\frac{UV}{\eta-d} \right) - fV = -g(\eta-d) \frac{\partial \eta}{\partial x} - \left(\frac{\eta-d}{\rho_w} \right) \frac{\partial p_s}{\partial x} + \frac{1}{\rho_w} (\tau_{sx} - \tau_{bx}) \quad (2)$$

$$\frac{\partial V}{\partial t} + \frac{\partial}{\partial x} \left(\frac{UV}{\eta-d} \right) + \frac{\partial}{\partial y} \left(\frac{V^2}{\eta-d} \right) + fU = -g(\eta-d) \frac{\partial \eta}{\partial y} - \left(\frac{\eta-d}{\rho_w} \right) \frac{\partial p_s}{\partial y} + \frac{1}{\rho_w} (\tau_{sy} - \tau_{by}) \quad (3)$$

The x - y datum plane is located at the mean water level with the z axis directed vertically upwards. The water surface elevation with respect to datum is $\eta(x,y,t)$, the sea bed is $d(x,y)$ with respect to datum,

U and V are depth-integrated flows per unit width, f is the Coriolis parameter and ρ_w is the mass density of sea water. The forcing influence of the tropical cyclone is represented through the surface wind shear stress vector $\tau_s(x,y,t)$, resolved into components τ_{sx} and τ_{sy} , and the x and y gradients of the M.S.L. atmospheric pressure $p_s(x,y,t)$. The effect of bottom stress is represented through the seabed shear stress vector $\tau_b(x,y,t)$, resolved into components τ_{bx} and τ_{by} such that, for example, in blue water regions:

$$\tau_{bx} = \frac{\lambda}{8} \rho_w \frac{|Q|U}{(\eta-d)^2} \quad (4)$$

where $Q = (U^2+V^2)^{1/2}$ and λ is the Darcy-Weisbach friction factor, assumed depth-dependent according to the Colebrook-White formula for a hydraulically rough boundary layer. Modified values of λ are adopted near reefs and for overbank flooding, the details being presented below.

At this stage the equations are sometimes linearised, neglecting the (normally small) convective accelerations. In SURGE all terms have been retained as they present no particular numerical problems and in some cases the commonly neglected terms (such as Coriolis and convective accelerations) can even be relatively important (5,12). A SURGE input option however does allow the convective terms to be omitted (3).

NUMERICAL SOLUTION

The flow field, coastal details, offshore and overbank bathymetry and coral reefs are represented on a square grid of unit dimension Δs and discrete values of the variables are specified on a space (x,y) and time (t) staggered computational grid, whose node points are defined as $(i\Delta x, j\Delta y, n\Delta t)$. Water surface elevation H (or η), bed elevation D (or d) with respect to M.S.L. and barometric head $B = p_s/\rho_w g$ are located at points (i,j,n) , depth-integrated flow U and the surface wind shear stress term $WX = \tau_{sx}/\rho_w$ at $(i+\frac{1}{2}, j, n+\frac{1}{2})$ and the depth-integrated flow V and the surface wind shear stress term $WY = \tau_{sy}/\rho_w$ at $(i, j+\frac{1}{2}, n+\frac{1}{2})$ points.

Numerical integration of the partial differential Equations 1,2 and 3 is accomplished by an explicit "leapfrog" procedure similar to that used in the numerical simulation of storm tides in Galveston Bay, Texas, by Reid and Bodine (8). The computational molecules and explicit finite difference equations are listed in Table 1, the continuity equation being centred at $(i,j,n+\frac{1}{2})$, the x momentum equation at $(i+\frac{1}{2}, j, n)$ and the y momentum equation at $(i, j+\frac{1}{2}, n)$. In a number of special cases associated with boundary or internal (reef, weir, island) constraints, the complete finite difference Equations b and c of Table 1 cannot be implemented and suitably reduced forms (12) are adopted in such circumstances. Successive application of the x and y momentum equations and the continuity equation, together with appropriate boundary conditions advance the solution by one simulation time step Δt .

STABILITY AND WAVE DEFORMATION

As SURGE is based on explicit finite difference equations, numerical stability for all wave numbers is ensured only when the Courant number $Cr = (gA/b)^{1/2} \Delta t/\Delta x$ does not exceed unity.

TABLE 1. SURGE COMPUTATIONAL MOLECULES AND FINITE DIFFERENCE EQUATIONS

Mass Conservation Equation -

$$U_{i,j}^{n+1} = U_{i,j}^n - \left[\frac{U_{i+1/2,j}^{n+1/2} - U_{i-1/2,j}^{n+1/2}}{\Delta x} + \frac{V_{i,j+1/2}^{n+1/2} - V_{i,j-1/2}^{n+1/2}}{\Delta y} \right] \Delta t \quad (a)$$

X Momentum Equation -

$$U_{i,j}^{n+1/2} = \left[\frac{U_{i,j}^{n-1/2}}{1 + \Delta t \left(\frac{U_{i+1/2,j}^{n+1/2} - U_{i-1/2,j}^{n+1/2}}{\Delta x} + \frac{V_{i,j+1/2}^{n+1/2} - V_{i,j-1/2}^{n+1/2}}{\Delta y} \right)} + \frac{U_{i+1/2,j}^{n-1/2} - U_{i-1/2,j}^{n-1/2}}{\Delta x} + \frac{V_{i,j+1/2}^{n-1/2} - V_{i,j-1/2}^{n-1/2}}{\Delta y} \right] \Delta t \quad (b)$$

where $\overline{U}_{i+1/2,j}^n = \frac{1}{2}(U_{i,j}^n + U_{i+1,j}^n + U_{i+1,j}^n + U_{i+1,j}^n)$

$$U_{i+1/2,j}^{n-1/2} = \frac{1}{2}(U_{i+1/2,j}^{n-1/2} + U_{i+1/2,j}^{n-1/2} + U_{i+1/2,j}^{n-1/2} + U_{i+1/2,j}^{n-1/2})$$

Y Momentum Equation -

$$V_{i,j}^{n+1/2} = \left[\frac{V_{i,j}^{n-1/2}}{1 + \Delta t \left(\frac{U_{i+1/2,j}^{n+1/2} - U_{i-1/2,j}^{n+1/2}}{\Delta x} + \frac{V_{i,j+1/2}^{n+1/2} - V_{i,j-1/2}^{n+1/2}}{\Delta y} \right)} + \frac{U_{i+1/2,j}^{n-1/2} - U_{i-1/2,j}^{n-1/2}}{\Delta x} + \frac{V_{i,j+1/2}^{n-1/2} - V_{i,j-1/2}^{n-1/2}}{\Delta y} \right] \Delta t \quad (c)$$

where $\overline{V}_{i,j+1/2}^n = \frac{1}{2}(V_{i,j}^n + V_{i,j+1}^n + V_{i,j+1}^n + V_{i,j+1}^n)$

$$V_{i,j+1/2}^{n-1/2} = \frac{1}{2}(V_{i,j+1/2}^{n-1/2} + V_{i,j+1/2}^{n-1/2} + V_{i,j+1/2}^{n-1/2} + V_{i,j+1/2}^{n-1/2})$$

Compliance with this equation, however, does not necessarily guarantee the accuracy of the solution and a broader analysis of the model behaviour is necessary to fully examine the numerical distortion of the physical surge wave. Some measure of this distortion can be had from a comparison of the numerical and analytical solutions of the equations in the time domain using the complex propagation factor of Leendertse (6). This method allows evaluation of the wave-number-dependent amplitude and phase distortions introduced by the numerical solution.

FIGURE 1. COMPLEX PROPAGATION FACTORS FOR COMPLETE QUASILINEAR FORM.

Assuming the non-linear interactions to be weak, as is generally the case for the Long Wave Equations, an evaluation of the wave deformation characteristics of the solution can be obtained from a quasilinear approximation to the finite difference equations (12). The complex propagation factor T is defined (6) as the ratio of the computed wave solution to the physical wave solution after a time interval in which the physical wave propagates over its wavelength L . Figure 1 shows the behaviour of $|T|$ and $\arg T$ for the complete quasilinear form of the Long Wave Equations with a constant wave propagation direction γ of 45° and various values of Cr . Typical values of the non-dimensional parameters of the system,

$$\begin{aligned} U' &= U_* \Delta t / D_* \Delta s & f' &= f \Delta t \\ V' &= V_* \Delta t / D_* \Delta s & \lambda' &= \lambda \Delta s / 8 D_* \end{aligned} \quad (5)$$

have been used to illustrate the solution behaviour. The starred variables U_* , V_* and D_* are constant and representative of the local flow field. The results show that the finite difference equations are appropriate discrete approximations to the partial differential equations

across the complete wave number spectrum. For typical applications with Cr of 1.0 and $L/\Delta s$ of order 25, negligible phase and amplitude distortion can be expected.

BOUNDARY CONDITIONS

The mathematical description of the computational field is completed by the specification of suitable boundary conditions, which for SURGE can be divided into a number of broad categories. Consistent with the staggered finite difference representation of the flow field, boundary conditions for either U or V (i.e. flow) situations take effect at spatial locations midway between nodes. For H (i.e. water level) situations the conditions require some interpretation in terms of the general finite difference equations; two or more conditions could apply at the one location and in many cases the spatial coverage of the general schemes needs to be restricted in the vicinity of a constraint. All this information is supplied to the model by the systematic specification of over fifty different flag conditions (3).

(a) *Coastal Boundaries*. These represent the simplest boundary conditions, stipulating vanishing normal transport across the coast at sea nodes adjacent to land nodes

$$\text{i.e. } U_{i+\frac{1}{2},j}^{n+\frac{1}{2}} = 0 \quad \text{or} \quad V_{i,j+\frac{1}{2}}^{n+\frac{1}{2}} = 0 \quad (6)$$

Various combinations of these component conditions, together with the normal case of uninterrupted flow, allow the representation of any area of coastline.

(b) *Reefs and Low Barriers*. In terms of long wave propagation it is appropriate to represent the presence of reefs or sand banks within the flow field as a submerged broad-crested weir, an overflow broad-crested weir, or a total flow barrier. The exact representation depends upon the crest elevation of the reef z_{crest} with respect to the instantaneous water levels, H_u on the upstream side and H_d on the downstream side of the reef. This is shown schematically in Figure 2 where q is the resulting water discharge (i.e. U or V, depending on reef orientation) across the reef. In the vicinity of reefs it is convenient to omit the smaller convective and Coriolis acceleration terms from the momentum equations. The influence of the reef is then represented by an effective Darcy-Weisbach friction factor (7,13) based on the normal submerged and overflow broad-crested weir equations through an assumption of locally uniform flow:

$$\tau_{bx} = \frac{\lambda}{8} \rho_w \frac{|U|U}{(\eta-d)^2}$$

$$\lambda = \frac{8(\eta-d)^2}{(C_1 \Delta W_1)^2 \Delta s} \quad \text{for submerged weir} \quad (7)$$

$$\lambda = \frac{16(\eta-d)^3}{(C_2 \Delta W_2)^2 \Delta s} \quad \text{for over flow weir}$$

C_1 = submerged weir discharge coefficient ($\sqrt{2}$)
 ΔW_1 = submerged weir head = $\frac{1}{2}(H_u + H_d) - z_{\text{crest}}$
 C_2 = overflow weir discharge coefficient (0.5)
 and ΔW_2 = overflow weir head = $H_u - z_{\text{crest}}$

For the case of $z_{crest} > H_u$ or H_d (total flow barrier), the conventional coastal boundary (a) applies. The continuity equation remains unchanged for all cases. For the representation of offshore reefs, the seabed levels ($D_{i,j}$) need not necessarily represent the selection for z_{crest} in regions where it is the subgrid effect which is being modelled. Such reef conditions have been used extensively for computations in the vicinity of the Great Barrier Reef.

FIGURE 2. SCHEMATIC REPRESENTATION OF REEF BOUNDARY CONDITION.

(c) *Coastal Flooding*. The coastal flooding algorithm in SURGE represents the wetting and drying of low lying land through a two-dimensional cascade of broad-crested weirs and local storages (7,13). It is consistent in spirit with the representation of offshore reefs in (b). Each flood element is considered centred on a grid or H point and has horizontal dimensions Δs by Δs , with sides passing through the U and V locations at half-grid points. Bed elevation $D_{i,j}$ is as usual specified at the H point while broad-crested weirs with elevation $D_{i,j} + z_c|_{i,j}$ along all four sides totally surround each flood element. Adjacent elements have potentially different bed levels and crest elevations and at matching sides the higher of the two crest levels is considered operative in determining element exchange flows across that side, as illustrated in Figure 3a; this procedure was also followed for (b). The continuity equation is again unchanged, except that each element is constrained to empty only to the element crest level to characterise local pondage.

Frictional resistance to overbank flow is represented through the weir height z_c relative to local bed level and through the spacing of these weirs Δs . Given a grid scale, the choice of appropriate z_c , in the absence of calibration data, can reasonably be based on an engineering estimate of the equivalent weir behaviour of say urban housing or mangrove swamps. A non-dimensional weir friction diagram, Figure 3b, has been prepared to assist in the estimation and evaluation of overbank resistance. It is based on the λ estimates of Equation 7 and shows the dependence of the friction factor on the dimensionless relative weir height z_c/y_n , the dimensionless normal depth $y_n/\Delta s$ and the slope of the uniform flow energy grade line S , y_n being the normal depth.

(a) Crest Elevation for Element Exchange Flow.

(b) Broad-Crested Weir Friction Diagram.

FIGURE 3. COASTAL FLOODING BOUNDARY CONDITION.

(d) *Open Sea Boundaries*. While open boundary conditions for *astronomical* tide propagation are quite straightforward and require only the specification of water surface histories at these locations for satisfactory representation, *meteorological* tides are generated by local surface forces. For a tropical cyclone the spatial extent of the forcing approaches 1000 km, although the region of peak positive and negative surges has a spatial scale of the order of the radius of maximum winds (typically 30 km). In such a case meteorological forcing outside the computational field can only be represented by the open boundary condition. Ideally the open boundaries would be insignificant. However, the storage and speed limitations of present time-shared computer systems preclude the adoption of a computational field that has linear dimensions of the order of 1000 km and simultaneously reproduces details on the scale of the radius of maximum winds. A practical compromise to this conflict of scales has been incorporated in SURGE by effectively including the forcing influence outside the computational field in the open boundary conditions.

Three separate forms of open boundary conditions are available in SURGE (11,12):

(i) Pressure Surge Condition ($H = \Delta B$), where open boundary water levels are set equal to the pressure surge, the head of water equivalent to the local atmospheric pressure deficit, i.e.

$$H_{i,j}^n = (p_{\infty} - p_s^n) / \rho_w g \quad (8)$$

This condition is regarded as only a first approximation to the actual water levels along an open boundary as it does not include the effects of the wind tide. The pressure surge condition is the default condition and is used as an initial value in condition (ii) below.

(ii) Bathystrophic Storm Tide (B.S.T.) Approximation, where open boundary water levels are set equal to the local bathystrophic storm tide, i.e. the quasi-steady profile described, for example by

$$0 = -g(\eta-d) \frac{\partial \eta}{\partial x} - \frac{(\eta-d)}{\rho_w} \frac{\partial p_s}{\partial x} + \frac{\tau_{sx}}{\rho_w} \quad (9)$$

when the open boundary is in the x direction and intersects the coastline.

From a physical viewpoint the bathystrophic tide condition provides a reasonably realistic boundary condition. It involves a lowest order momentum balance along the open boundary to include the forcing influence of the tropical cyclone outside the boundary. Water levels along the open boundary can rise and fall in response to the intensity and position of the tropical cyclone as shown in Figure 4. Such a boundary condition enables optimal use of the grid coverage, realistic water levels and flow patterns being obtained in close proximity to the boundaries. Detailed discussions are given elsewhere (11,12).

(iii) Time Dependent Water Level Inputs, where open boundary water levels are set equal to supplied water levels (e.g. tidal input, hydrographs),

$$H_{i,j}^n = h(t) \quad (10)$$

FIGURE 4. CONCEPT OF BATHYSTROPHIC STORM TIDE OPEN BOUNDARY CONDITION.

This form of open boundary condition can also be used in conjunction with (i) and (ii) above, although no interaction between the two inputs (e.g. meteorological and astronomical) is assumed. The appropriate meteorological forcing, pressure surge or B.S.T., is first applied with water levels at M.S.L., and the time dependent water levels are then added. Additionally this condition allows a "dual model" approach, in which water levels derived from a large scale model are used later as open boundary inputs to a smaller scale, detailed model of a particular section of coast.

TROPICAL CYCLONE FORCING

The aerodynamics of the tropical cyclone and the hydrodynamics of the underlying water body are coupled by the atmospheric pressure p_s and wind shear stress τ_s at the air-sea interface. Their estimation throughout the flow field during the passage of a tropical cyclone follows from the adoption of a suitable model of the near-surface meteorological structure of the storm. The model developed initially by Graham and Nunn (2,16) under the National Hurricane Research Project (NHRP) of the former U.S. Weather Bureau forms the basis of the tropical cyclone sub-model in SURGE. No claim is made that this model is entirely satisfactory; in fact our knowledge of tropical cyclone wind fields is far from complete, especially in Australia. It has been adopted in the absence of a more suitable alternative.

Many of the highly empirical aspects of the original NHRP model, such as rate of filling over land and the reduction of over-land wind speeds,

have been omitted in favour of representing the major features of the tropical cyclone. In particular the radial wind and pressure profiles, the variation of the radial inflow angle and the asymmetry of the wind field are included and expressed in terms of the four parameters commonly assumed to characterise a tropical cyclone:

- (i) Central pressure p_0 at M.S.L.
- (ii) Maximum sustained wind V_{10} at a height of 10 m above M.S.L.
- (iii) Radius of maximum winds R .
- (iv) Speed V_{FM} and direction θ_{FM} of storm forward movement.

SURGE allows all four parameters to be varied continuously to represent changes in storm intensity and track. Details may be found in Ref.12. Radial profiles of near-surface wind and M.S.L. atmospheric pressure are sketched in Figure 5a and Figure 5b shows a typical isovel and wind vector pattern for a moving model storm. The over-water wind speed W_{10} at height 10 m above M.S.L. and the resulting shear stress τ_s on the water surface are assumed to be related as

$$\tau_s = C_{10} \rho_a W_{10}^2 \quad (11)$$

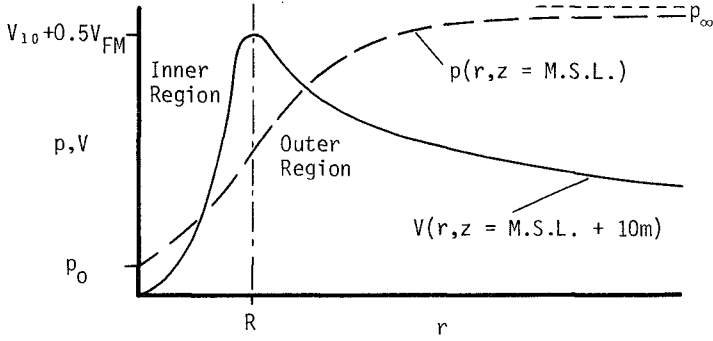

where C_{10} is a non-dimensional surface friction or drag coefficient. Approximate relations for C_{10} over the range of wind speeds for oceanic applications according to W_u (18) are incorporated in SURGE.

MODEL VERIFICATION AND SENSITIVITY TESTING

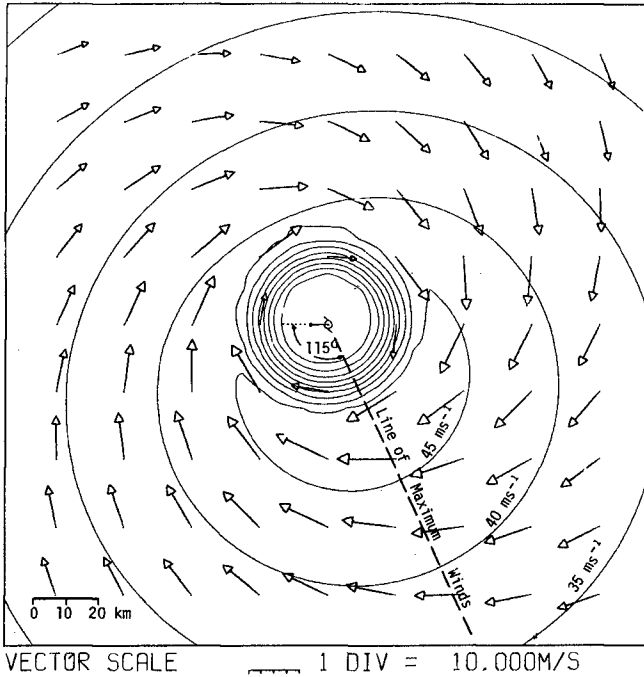

Initial verification of the model hydrodynamics was accomplished by comparison of a numerical prediction with a known analytical solution for wind setup on a rectangular lake under constant wind forcing. The agreement was almost exact. Since analytical solutions more closely related to open coast tropical cyclone storm surge are not available, an alternative approach to detailed verification was adopted involving comparison with a documented record of an historical tropical cyclone storm surge (12).

The tropical cyclone ALTHEA storm surge near Townsville in December 1971 is probably the best documented storm surge to occur in Australia. Water level records from four automatic tide gauges (Mourilyan, Lucinda, Townsville and Bowen) plus post-cyclone debris level surveys enabled an order-of-magnitude reconstruction of the surge profile development along the coast. No flow velocity data was available, nor was there any record of water levels at other than coastal locations. The Bureau of Meteorology (1), with the aid of shore-based radar, traced the path of ALTHEA as it approached and crossed the continental shelf and estimated the meteorological parameters. The central pressure fell to 952 mb and the radius to maximum winds was typically 35 km. The storm crossed the coast approximately 45 km north of Townsville and registered a peak surge of 2.78 m above predicted tide level at Townsville Harbour.

The coastal region from Innisfail in the north to Bowen in the south and up to 260 km offshore was represented on a 5 n mile grid system of 30 by 40 points as shown in Figure 6 which includes the reconstructed path of ALTHEA. The coastline is shown as a series of straightline barriers while the Great Barrier Reef is indicated by a series of broken line barriers that maintain the recognised shipping passages. Due to an almost complete lack of information on the offshore astronomical tide, the simultaneous propagation of tide and surge could not be considered and the

(a) Typical Wind Velocity and Atmospheric Pressure Profiles Along the Line of Maximum Winds.

(b) Typical Isovel and Wind Vector Pattern for a Moving Model Storm

FIGURE 5. STRUCTURE OF TROPICAL CYCLONE FORCING.

hindcast is compared to the deviation of water levels away from predicted astronomical tide (and ignoring nonlinear interactions). Figures 7a and b show the results of the SURGE simulation compared with the storm surge hydrograph recorded at Townsville Harbour and also with less reliable data available on maximum coastal water levels. The results show good agreement with this limited historical record, even at this coarse 5 n mile resolution level. A more thorough evaluation will only be possible when spatially comprehensive time histories of sea surface development of the type promised by the SEASAT satellite programme become available. Figure 8a shows part of the model flow field shortly after the storm has crossed the line of barrier reefs and the strong currents generated along the coastline and through the numerous reef passages. Figure 8b shows contours of water level above M.S.L. at the time of storm landfall.

In addition to the comparison with an historical record, a comprehensive sensitivity analysis was undertaken to evaluate the model performance under various conditions (5,12) and to define the likely envelope of response. In particular, testing of various dynamic open boundary situations was undertaken together with consideration of bed friction specifications, bathymetry effects, coastal forms and initialization. A broad range of tropical cyclone parameters, including track, was also examined and highlighted the need for adequate resolution of the storm wind and pressure structure. An $R/\Delta s$ ratio of at least 4 was shown to be necessary for an accurate representation of the structure of the storm forcing.

MODEL APPLICATIONS

SURGE has been used extensively for the study of the tropical cyclone storm surge hazard in northern Australia. In particular a comprehensive analysis was undertaken for the Beach Protection Authority, Brisbane, at ten separate sites along the Queensland coast and covering over 2000 km of coastline (4,12). At each of the sites three tropical cyclones at each of three approach directions were modelled, based on a statistical analysis of historical tropical cyclone records, and their effect on coastal locations was examined in detail. This extensive study required the modelling of a wide range of coastal features from the shallow waters of the Gulf of Carpentaria, through the Great Barrier Reef dominated Coral Sea coast to the comparatively narrow and plunging continental shelf along Queensland's Gold Coast region. Other study areas in northern Australia include Mermaid Sound in Western Australia (14), an area subject to the most severe tropical cyclones in Australia, and even more detailed investigations of estuarine storm surge penetration at Weipa on Cape York Peninsula (15) and Trinity Inlet at Cairns (13). The latter two studies included the use of a one-dimensional hydrodynamic model ESTFLO (9) which was interfaced with SURGE. Figure 9 shows the Trinity Inlet model structure where a three-pass procedure was adopted, involving two successive grid scale reductions by factors of six and appropriate truncation of the computational field at each pass. This structure was necessary to include the area of significant meteorological forcing and still reproduce overbank flooding within Trinity Inlet and in a loop around Admiralty Island. This formulation was necessary to achieve a realistic representation of the flow pattern between the deeper channels which are the major vehicle for surge penetration, and the extensive mangrove areas. Figure 10 shows a typical time sequence of surge penetration and overbank flooding within the C grid region. Heights are in cm above M.S.L. datum.

CONCLUSIONS

The numerical hydrodynamic model SURGE adequately describes the generation and propagation of tropical cyclone storm surge and is sufficiently flexible to represent a wide range of coastal features and storm effects. Apart from applications in coastal engineering investigations, SURGE has a potential role, with improved weather monitoring, in providing real-time forecasting advice to aide in counter-disaster planning.

ACKNOWLEDGEMENTS

The authors wish to thank Professor K.P. Stark for his initiation and continued support of this programme of research. We also acknowledge contributions by colleagues T.S. Adil and A.B. Mills for overall model development. Financial support from the Beach Protection Authority, Brisbane, is gratefully acknowledged together with the kind permission of the Department of Housing and Construction, Canberra, for the use of some illustrations.

CHAPTER 46

A NUMERICAL MODEL OF STORM WAVES IN SHALLOW WATER

A. HAUGUEL+

ABSTRACT

For studying storm waves in coastal areas, usual waves theories are no more valid. The presented cnoidal theory allows the modelling of these problems. Furthermore, thanks to its non-linear properties, it makes possible the simulation of many phenomena usually neglected.

A numerical model using this theory has been developed. It has been tested against analytical results and certain properties of non-linear waves experimentally observed.

Finally, the practical problems raised by the utilisation of this model for harbour agitation computations, have been solved.

1 INTRODUCTION

Two-dimensional numerical models are now of common use to study tidal propagation and related currents in coastal areas. These models are based upon long waves equations. By assuming that the vertical velocity linearly increases from the bottom to the sea surface, instead of doing the classical hypothesis of hydrostatic pressure distribution, it is possible to simulate non-linear waves in shallow water. This theory (Serre, 1953) belongs to the so called cnoidal waves theories. This assumption leads to new third-order derivatives in the momentum equations, and it is possible to adapt the tidal models to non-linear waves in shallow water problems by taking in account these new terms.

With such a model, it will be possible to compute non-linear waves of any form over any given bathymetry and current field. As this modelling gives quite correct simulation of breaking waves and associated radiation stresses, it seems that it will be possible to compute longshore currents.

The paper presents the modifications made on a tidal numerical model and the problems raised by the new conditions of utilisation.

2 EQUATIONS

By assuming that the vertical velocity linearly increases from the bottom to the sea surface, it is possible to average over the depth the Navier-Stokes equations. So the mass and momentum conservation laws (Serre type equations) can be written as follow :

+ Division Hydraulique Maritime. Laboratoire National d'Hydraulique. Electricité de France. Chatou, France.

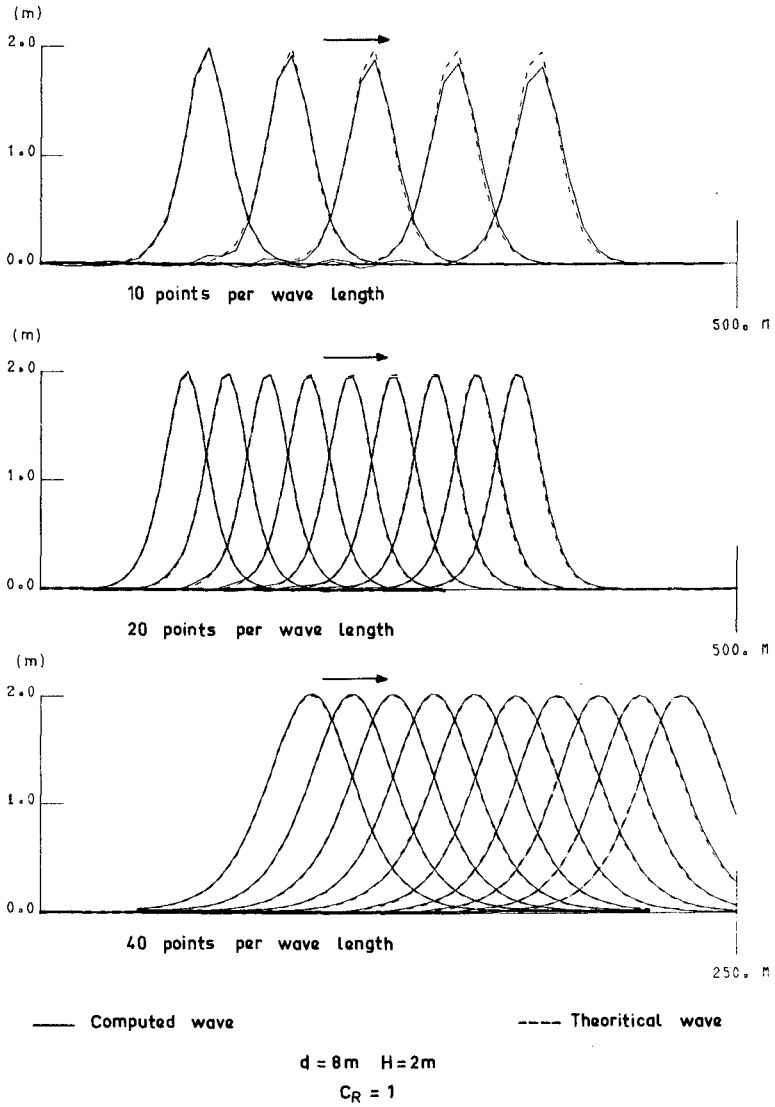

Fig.1- INFLUENCE OF COMPUTED POINTS PER WAVE LENGTH NUMBER

$$\frac{\partial h}{\partial t} + \frac{\partial p}{\partial x} + \frac{\partial q}{\partial y} = 0 \quad (1)$$

$$\begin{aligned} \frac{\partial p}{\partial t} + \frac{\partial}{\partial x} \left(\frac{p^2}{h} + \frac{\partial}{\partial y} (pq) + \frac{\partial}{\partial x} \left(\frac{(g+\beta + \frac{\alpha}{2}) h^2}{3} \right) \right) \\ = - (g + \beta + \frac{\alpha}{2}) h \frac{\partial z}{\partial x} - g \frac{p}{c^2} \frac{\sqrt{p^2 + q^2}}{h^2} \end{aligned} \quad (2)$$

$$\begin{aligned} \frac{\partial q}{\partial t} + \frac{\partial}{\partial x} (pq) + \frac{\partial}{\partial y} \left(\frac{q^2}{h} + \frac{\partial}{\partial y} \left(\frac{(g+\beta + \frac{\alpha}{2}) h^2}{3} \right) \right) \\ = - (g + \beta + \frac{\alpha}{2}) h \frac{\partial z}{\partial y} - g \frac{q}{c^2} \frac{\sqrt{p^2 + q^2}}{h^2} \end{aligned} \quad (3)$$

where h is the water depth, p and q are x - and y - volume fluxes, z is the bed elevations, g the gravitational acceleration. The new terms α and β come from the new assumption, and characterise the vertical accelerations raised by the steepness of the waves and the slope of the bed :

$$\alpha = \frac{d^2 h}{dt^2}, \quad \beta = \frac{d^2 z}{dt^2} \quad (\text{with } \frac{d}{dt} = \frac{\partial}{\partial t} + \frac{p \partial}{h \partial x} + \frac{q \partial}{h \partial y}) \quad (4)$$

3 NUMERICAL MODELS

More than the existence of the new terms α and β (which are introduced both in the same maner in this theory and then will be computed with the same procedure), the increased non-linearity in waves computation compared to tidal problems, and the reduced number of computed points per wave length required to assure the viability of the system in engineering practice, are the main difficulties to solve.

A finite amplitude permanent (cnoidal) wave can be in fact regarded as the superposition of several sinusoidal waves. If the main one is described with a reduced number of points (10 for example), the first harmonic is computed with only 5 points, and the difference scheme must be able to propagate these coarsly described waves without any relative phase error, which would induce changes in shape, amplified then by the marked non-linearity of the problem. This leads to an extreme sensivity of the solutions of the equations to numerical error influence (Abbott, 1978).

The numerical model developed in the Laboratoire National d'Hydraulique uses finite differences approximations built on a single space grid. The fractionnary steps are used to compute each part of the equations.

$d = 8\text{ m}$ $H = 2\text{ m}$

Fig.2 - INFLUENCE OF COURANT NUMBER
(20 points per wave length)

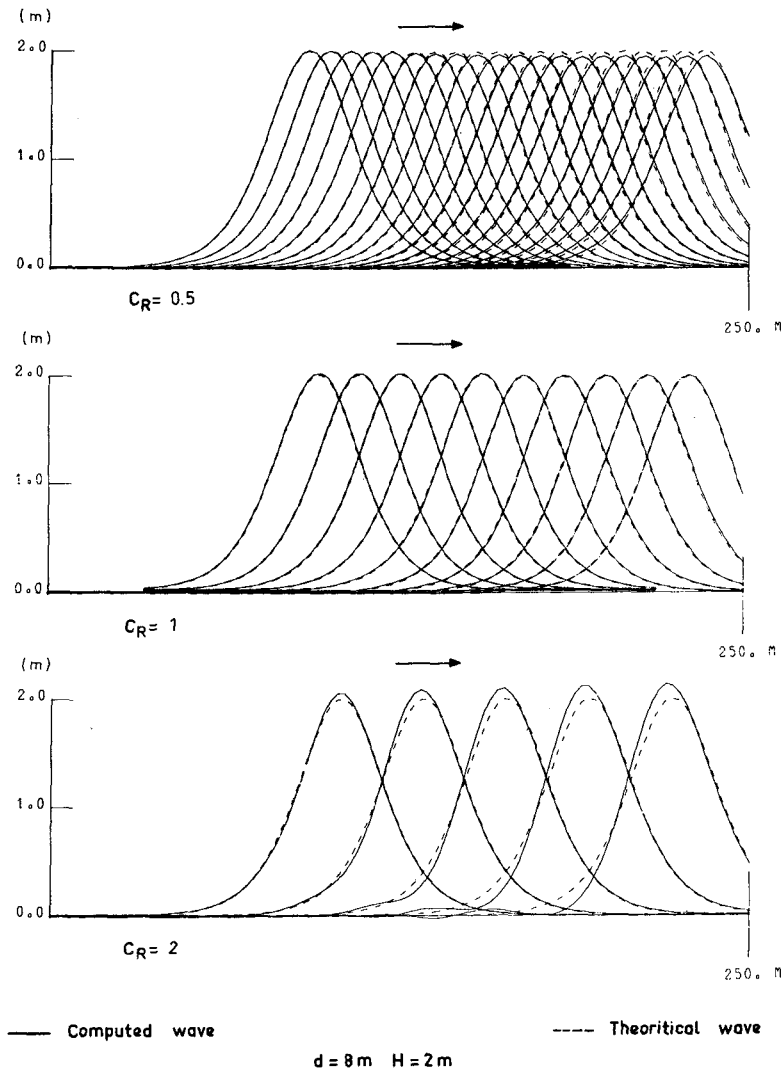

Fig.3-INFLUENCE OF COURANT NUMBER
 (40 points per wave length)

3.1. One dimensional model :

The advective terms of (2) are computed the first, the propagative and friction terms being solved in a second step. A third-order accuracy scheme based upon characteristic method is used for the advective components of (2) ; this one has been fitted to total derivatives computations of (4). The elaboration of a high-accuracy difference approximation of propagative components of (1, 2) including α and β terms, has necessitated the use of an implicit three-stage difference scheme. A Newton discretisation is used to linearize the h^3 term which appears in the pressure gradient of (2). The discretization has been designed to eliminate in the linear case, any damping and phase error for any number of computed points per wave length, at least for a Courant number equal to 1 (Von Neumann stability analysis). These propagative components are solved by a tri-diagonal double sweep algorithm after combination of the discretized form of (1, 2), which decouples the variations of flux and water depth. In spite of the marked non-linearity of the problem, and as for other reasons the Courant number must be as closer as possible to 1, no iterative procedure is necessary to solve the equations.

3.2. Two-dimensional model :

The fractionary steps are also used in the 2.D model. The advective components are solved by the one dimensional characteristic method scheme in the x-direction and then in the y-direction. The α and β terms are computed with the same procedure (characteristics). To solve the left terms of (1, 2, 3) (propagation), a two-dimensional iterative procedure is used. This one is based on splitting with coordination. Usually, a simple splitting induces differences between the resolutions in the x-and the y-directions. In our model, iterations are used to obtain same water depths in the two directions. The method of coordination used is very fast. It suppresses any polarisation due to the grid (see fig. 8, 10, 11), but the advantages of 1-D-computations are preserved.

3.3. Boundary conditions :

In order to simulate entering waves in the model at the seaward boundary, a condition allowing outgoing waves is necessary (see fig. 8, 9). The relation on the outgoing characteristic of the linearised theory has been suited in the following form :

$$f_n - C(h + z) = - 2C W_i \quad (5)$$

where f_n is the outgoing normal flux

W_i is the sea surface elevation of the incident wave

C is the celerity which appears in the discrete form of the propagative components.

The same sort of condition has been imposed on inside breakwaters to model partial reflections :

**Fig.4 - TRANSFORMATION OF A SOLITARY WAVE

Fig.7 - PROPAGATION OF A SOLITARY WAVE
IN A INCLINED CHANNEL (45°)

$$f_n - C(1 - \gamma)(h + z) = 0 \quad (6)$$

where γ is a coefficient of reflection :
 (if $\gamma = 1$: total reflection, if $\gamma = 0$: no reflection).

In the 2.0 model, when there is an inflow a second boundary condition is required (Daubert, 1967). In that case, the normal derivative of the tangential flux is put equal to zero in the advective step. Thanks to the method of coordination used in the propagative step, the condition (6) can also be imposed on boundaries inclined to the grid, although it couples the two components of the volume flux. This coordination nearly suppresses shear effects on inclined boundaries (see fig. 7, 10).

4 NUMERICAL RESULTS

The modifications have been tested against analytical results in one and two dimensions for various Courant numbers and numbers of points per wave length. The different tests have shown that, for a Courant number equal to 1, a very good accuracy is obtained with values of the number of points per wave length as low as 20, even with a relative wave height equal to 0.4 (see fig. 1). For much smaller relative wave heights, the non-linearity of the governing equations decreases, and the number of points per wave length required can be reduced to 10. On the contrary, this one must be increased to conserve an acceptable accuracy if the Courant number differs from 1 (see fig. 2, 3).

The influence of the bottom shape and the geometry of the area has also been studied. Figure 4 shows the transformation of a solitary wave propagating over a slope onto a shelf of smaller depth. On the shelf, a desintegration of the initial wave into a train of solitary waves of decreasing amplitude is found. The amplitude of the crests is in good agreement with the results obtained by Madsen (1969) in the same case.

Figure 5 presents the phase shift obtained from non-linear effects after collision between two waves. This shift is in good agreement with the one experimentally obtained by Maxworthy (1976).

Figure 6 shows the aptitude of the boundary condition (6) to simulate the whole range of reflections on different breakwaters.

The possibility of propagating a wave in a narrow channel inclined in the grid has also been studied. Figure 7 shows such a computation. Thanks to the coordinator, the condition on the normal flux ($f_n = 0$) can be well imposed. The shear effect numerically induced by the boundary condition nearly disappears in this case.

Figures 8 and 9 show the aptitude of the boundary condition (5) to generate incident waves in the domain (even with an angle of incidence) without presuming anything on outgoing waves. In these

 WAVE (BASIN 217 m x 392 m)

PORT OF FECAMP

Fig. 12 - WAVE FIELD IN THE PORT OF FECAMP
AFTER 50 sec. SIMULATION

figures two reflection conditions have been imposed on the opposite boundary : total reflection (fig. 8), partial reflection (fig. 9). In the two cases, the reflected wave has to establish itself after a diffraction period, which is best shown in figure 10. This one presents the computation of the reflection on an inclined boundary.

As, any changement in water depth induces harmonics due to non-linear effects, any variation of the geometry of the area (diffraction) desintegrate the initial wave into a train of waves of decreasing amplitude. This is again shown in figure 11, where a wave entering a closed basin of 217 m x 392 m is presented. This example demonstrates that there is no polarisation induced by the grid in the computed wave (coordinator). In this case, the variation of width creates harmonics at the point of diffraction. Then, they propagate into the basin giving circular waves. After reflection on the opposite boundary, this induced a lapping in the basin.

5 CONCLUSION

The model, severly tested over the operational range of wave parameters, and over different physical conditions (all the computational tests presented have been done without any bottom friction, so there were no damping decreasing the computed waves) is now applied in coastal engineering practice. Figure 12 presents the first computations done in the port of Fecamp (French port on the English Channel).

THE GENERATION OF LONG WAVES IN THE LABORATORY

by Derek Goring¹ and Fredric Raichlen²INTRODUCTION

It became evident in the experimental aspects of a recent study of the propagation of nonlinear long waves past a step and up a slope that it was important to be able to generate waves which were initially well defined. The investigation dealt with the reflection and transmission of tsunamis past the continental shelf-break, and as such, two simple waves were used to represent certain characteristics of tsunamis: solitary waves and cnoidal waves. (Both of these permanent waves are solutions to the Korteweg-de Vries equation which to a certain order describe the propagation in two dimensions of nonlinear dispersive shallow water waves (see, e.g. Whitham, 1974).)

The solitary wave actually can be generated in the laboratory in a simple manner if the wave tank is long enough and wave groups trailing the main wave are unimportant to the study. An example of the resulting waves obtained in the laboratory using a crude generation procedure is demonstrated by the oscillograph record presented in Figure 1. Six traces are shown: the one at the bottom of the figure describes the time-displacement history of a vertical bulkhead wave generator which is moved by a hydraulic-servo system, the other five are the time variations of the water surface obtained using resistance wave gages spaced at the indicated number of depths downstream from the generator. (In the example presented, the depth of water was 10 cm and the wave plate was moved linearly with time a distance of 10.33 cm in 0.8 sec.) The wave generated and first shown 10 depths downstream appears to consist of a large wave followed by a series of oscillatory waves (termed the tail). As would be expected, as the waves propagate, due to the frequency content and the amplitude of the waves, the system separates into a leading wave followed some distance behind by the tail. The lead wave has the characteristic shape of a solitary wave. However, if the oscillatory tail is unacceptable for the type of experiments being conducted, and if it cannot be eliminated or the method of elimination is unacceptable, then a means of generation must be sought which eliminates the trailing waves initially.

The method used in this study to produce a nonlinear shallow water wave which is well formed near the generator attempts to match the velocities of the wave plate and the water particles of the desired wave as the plate moves. An example of the result of doing this for a solitary wave is shown in the oscillograph record presented in Figure 2; again the motion of the wave generator is shown at the bottom of the

Figure 1 Oscillograph record of the waves generated by a ramp trajectory ($S = 10.33$ cm, $\tau = 0.80$ sec and $h = 10$ cm).

Figure 2 Oscillograph record of the waves generated by the solitary wave trajectory with $H/h = 0.2$ ($S = 10.33$ cm, $\tau = 2.044$ sec and $h = 10$ cm).

figure and five wave profiles are presented above. (The location of the wave gages are the same as in Figure 1.) The motion (or trajectory) of the wave plate is no longer linear and the time of motion is more than twice that for the case shown in Figure 1, i.e., $\tau = 2.044$ sec. A comparison of the time history of the water surface elevation at 110 depths downstream of the generator shows the trailing oscillatory waves essentially have been eliminated.

Similar time histories of water surface and wave generator displacements are presented in Figures 3 and 4 for periodic wave plate motions. (It was desired for this example to produce cnoidal waves which, as mentioned, are the exact periodic solution of the Korteweg-de Vries equation.) Figure 3 shows the wave resulting from an "incorrect" plate motion where the shape changes as it propagates; note the period of the plate motion is $T = 4.28$ sec. When the same trajectory is used but a "correct" period is chosen ($T = 2.90$ sec) a system of waves is generated with the central portion of the train appears relatively unchanged for the nearly 60 depths of propagation shown. The shape of these waves and their method of generation will be discussed more fully later; suffice to say that Figures 2 and 4 demonstrate, at least qualitatively, that the desired system of waves can be generated if adequate attention is given to the method of generation.

ANALYTICAL CONSIDERATIONS

A qualitative description of the generation process is provided by the phase-plane presented in Figure 5. The upper part of the figure (Part c) shows a desired sinusoidal water surface profile; in the lower left the corresponding horizontal water particle velocity time history is given. (For purposes of this discussion it is assumed the water particle

Figure 5 Wave generation phase-plane.

Figure 3 Oscillograph record showing the waves generated by trajectory CN4 with $h = 20$ cm, $S = 11.18$ cm and $T = 4.28$ sec.

Figure 4 Oscillograph record showing the waves generated by trajectory CN4 with $h = 20$ cm, $S = 11.18$ cm and $T = 2.90$ sec.

velocity distribution is either constant with depth or that represented in Figure 5 a is the depth-averaged velocity.) If in the $x-t$ plane (Part b) the wave propagates unchanging to the right with celerity c , the wave properties such as amplitude and velocity propagate along lines which are straight and parallel and have a slope $dx/dt = c$. The time-history of the motion of the wave plate which generated the wave is represented in Part b by the curve $\xi(t)$ which is termed the "trajectory" in this study.

Referring to Figure 5, for time $t < 0$ the wave plate is at rest and $\xi = 0$. At time $t = 0$ the wave plate begins to move along the trajectory $\xi(t)$. The object of this development is to determine the trajectory $\xi(t)$ which will generate a given long wave $\eta(x,t)$ with permanent shape propagating with celerity c . As mentioned previously, the basic concept is to match the velocity of the wave plate, $d\xi/dt$, at all positions, with the corresponding velocity of the water particles (or the depth-averaged velocity) under the long wave, i.e., $\bar{u}(x,t)$. Thus, on the face of the wave maker:

$$\frac{d\xi}{dt} = \bar{u}(\xi,t) \quad (1)$$

Including the position of the plate, ξ , in the velocity, $\bar{u}(\xi,t)$, takes into account that during the generation process the wave is propagating away from the plate. The effect is to produce a trajectory which is distorted from what it would be if the velocity at the mean position of the plate, $\bar{u}(0,t)$ were used. This can be seen in Figure 5, where if the velocity $\bar{u}(0,t)$ were used in Eq. (1), the trajectory would be sinusoidal and the maximum displacement of the plate, $\xi = S$, would occur at time $\frac{1}{2}T$. However, Figure 5(b) shows that the maximum of the trajectory occurs at $t = \frac{1}{2}T + S/c$. Thus, the time taken for the plate to travel to its maximum position is S/c longer than it would be if a sinusoidal trajectory were assumed, and consequently the time for the plate to travel back to its original position is time S/c shorter than for a sinusoidal trajectory. Therefore, the effect of including the position ξ in the velocity is that when the plate and wave are moving in the same direction, the time coordinate stretches; when the plate and the wave are moving in opposite directions, the time coordinate contracts.

The simple sinusoidal variation of the water particle velocity shown in Figure 5a was presented as an example; for finite amplitude shallow water waves of permanent shape it can be shown from continuity considerations that the velocity averaged over the depth is:

$$\bar{u}(x,t) = \frac{c \eta(x,t)}{h + \eta(x,t)} \quad (2)$$

where h is the depth, and $\eta(x,t)$ and c are defined in Figure 5. Thus, in terms of the plate velocity, from Eq. (1):

$$\frac{d\xi}{dt} = \frac{c \eta(\xi,t)}{h + \eta(\xi,t)} \quad (3)$$

Eq. (3) must be integrated to obtain the trajectory, $\xi(t)$. It is assumed that at the position of the wave plate the wave has the form:

$$\theta = \theta_0 = kct - k\xi$$

$$\xi = ct - \theta_0$$

$$\eta(\xi, t) = H[f(\theta)] \quad (4)$$

where

$$\theta = k(ct - \xi) \quad (5)$$

$$\frac{d\xi}{dt} = c$$

By algebraic manipulation of Eqs. (3), (4) and (5) it can be shown that:

$$\frac{d\xi}{d\theta} = \frac{H[f(\theta)]}{kh} \quad (6) \quad \text{near } \theta \text{ just } H f(\theta) \quad t = \frac{1}{c}\xi + \theta_0$$

and

$$\xi(t) = \frac{H}{kh} \int_0^\theta f(w)dw \quad (7)$$

where w is the dummy variable of integration. Equation (7) is an implicit equation which in general, for a particular time t , must be solved numerically. The most efficient method of solution was found to be Newton's Rule. Using Eq. (5), θ is substituted for the displacement ξ in Eq. (7) to yield:

$$F = \theta - kct + \frac{H}{h} \int_0^\theta f(w)dw = 0 \quad (8)$$

Equation (8) must be solved for θ at a given time t . Differentiating Eq. (8):

$$\frac{\partial F}{\partial \theta} = 1 + \frac{H}{h} f(\theta) \quad (9)$$

Newton's Rule is:

$$\theta^{(i+1)} = \theta^{(i)} - \frac{F(\theta^{(i)})}{F_\theta(\theta^{(i)})} \quad (10)$$

where superscripts denote iteration number and $F_\theta = \partial F / \partial \theta$. Substituting for F and F_θ in Eq. (10) yields:

$$\theta^{(i+1)} = \theta^{(i)} - \frac{\theta^{(i)} - kct + \frac{H}{h} \int_0^{\theta^{(i)}} f(w)dw}{1 + \frac{H}{h} f(\theta^{(i)})} \quad (11)$$

Having found θ for given time t , the displacement ξ is given by:

$$\xi = ct - \theta/k \quad (12)$$

Eqs. (7), or (11) and (12) provide the wave plate displacement as a function of time, $\xi(t)$, for a general wave form $f(\theta)$. These equations will now be applied for specific functions $f(\theta)$ which describe solitary and cnoidal waves. For a solitary wave which satisfies the Korteweg-de Vries equation, the wave function $f(\theta)$ in Eq. (4) is:

$$f(\theta) = \text{sech}^2 \theta \quad (13)$$

where $\theta = \kappa(ct - \xi)$, $\kappa = \sqrt{\frac{3H}{4h^3}}$, $c = \sqrt{g(h+H)}$,

Substituting Eq. (13) into the generation equation, Eq. (7), and performing the integration yields:

$$\xi(t) = \frac{H}{\kappa h} \tanh \kappa(ct - \xi) \quad (14)$$

In Figure 6 a typical trajectory, $\xi(t)$, is presented which was calculated from Eq. (14). The origin of the displacement ξ and of the time t occurs at the wave crest in accordance with the definition of the solitary wave, Eq. (13). In addition, since the function $f(\theta)$ in Eq. (13)

Figure 6 Phase plane showing typical wave plate trajectory for a solitary wave.

tends to zero as θ goes to infinity, the intercepts of the characteristics associated with the leading and trailing edges of the wave with the time axis, $\pm t_0$, occur at $\pm \infty$. However, for practical purposes, to three significant figures, the intercept, t_0 , may be defined as:

$$t_0 = \frac{\tanh^{-1}(0.999)}{\kappa c} = \frac{3.80}{\kappa c} \quad (15)$$

The stroke S is obtained by evaluating Eq. (14) at time $t = +\infty$ and $t = -\infty$ and subtracting to yield:

$$S = \frac{2H}{\kappa h} = \sqrt{\frac{16}{3}} \frac{H}{h} h \quad (16)$$

The duration of motion τ is obtained (see Figure 6) by computing the times at which the leading and trailing edge characteristics intersect the trajectory $\xi(t)$ and subtracting; thus:

$$\tau = 2t_0 + S/c \quad (17)$$

Substituting for the intercept t_0 and stroke S yields for the duration:

$$\tau = \frac{2}{\kappa c} \left(3.80 + \frac{H}{h} \right) \quad (18)$$

(In practice, the origin of the trajectory, $\xi(0)$, is moved to the point $(-\tau/2, -S/2)$ in the $x-t$ plane so that motion starts from rest and proceeds in the forward direction.)

Substituting Eqs. (15), (16) and (18) in Eq. (14) and rearranging gives the following normalized form of the generation equation for solitary waves:

$$\frac{\xi}{S} = \frac{1}{2} \left\{ 1 + \tanh 2 \left[\left(3.80 + \frac{H}{h} \right) \left(\frac{t}{\tau} - \frac{1}{2} \right) - \frac{H}{h} \left(\frac{\xi}{S} - \frac{1}{2} \right) \right] \right\} \quad (19)$$

A family of normalized generation trajectories calculated using Eq. (14) is presented in Figure 7 for wave height-to-depth ratios of $H/h = 0.1$ to 0.7 .

The Korteweg-de Vries equation has a solution which is a permanent form periodic wave usually termed the cnoidal wave. Using the general form shown in Eq. 4 for cnoidal waves the function $f(\theta)$ is:

$$f(\theta) = \frac{y_t - h}{H} + \text{cn}^2(\theta|m) \quad (20)$$

where $\theta = 2K \left(\frac{t}{T} - \frac{\xi}{L} \right)$ and K is the first complete elliptic integral, cn is the Jacobian elliptic function, m is the elliptic parameter, T is the period, L is the wave length, y_t is the distance from the bottom to the trough of the wave, and h is the depth. Substituting Eq. (20) into the generation equation, Eq. (7), and performing the integration yields:

$$\xi(t) = \frac{L}{2Kh} \left\{ (y_t - h)\theta + \frac{H}{m} [E(\theta|m) - m'\theta] \right\} \quad (21)$$

where $E(\theta|m)$ is the second incomplete elliptic integral, and m' is the complementary parameter, $m' = 1 - m$.

In Figure 8 a typical trajectory, $\xi(t)$, is presented which is normalized with respect to the total movement (stroke) of the wave plate, $\xi_{\max} = S/2$, calculated from Eq. (21). Because of the definition of the function $f(\theta)$ in Eq. (20), the origin occurs at a point of maximum velocity. However, it is desirable to start the motion of the wave plate at a position where the velocity of the plate and the amplitude

Figure 7 Solitary wave generation trajectories, $H/h = 0.1$ to 0.7 .

Figure 8 Typical wave plate trajectory for cnoidal wave generation.

of the wave are each zero, i.e., where;

$$\frac{d\xi}{dt} = \bar{u} = 0 \quad , \quad (22)$$

and

$$\eta = y_t - h + H \operatorname{cn}^2(\theta_0|m) = 0 \quad . \quad (23)$$

The parameter θ_0 is the argument of the cnoidal function determined such that the wave amplitude is zero. Eq. (23) can be written as:

$$\theta_0 = \operatorname{cn}^{-1} \left[\frac{h-y_t}{H} \right]^{1/2} \quad . \quad (24)$$

Substituting for θ_0 in Eq. (21) realizing this is the position of maximum plate displacement⁰ gives:

$$\xi_{\max} = -\xi_{\min} = \frac{L}{2Kh} \left\{ (y_t - h)\theta_0 + \frac{H}{m} \left[E(\theta_0|m) - m'\theta_0 \right] \right\} \quad (25)$$

and

$$\frac{t_0}{T} = \frac{\xi_{\max}}{L} + \frac{\theta_0}{2K} \quad . \quad (26)$$

The maximum excursion of the wave plate (or stroke S) is:

$$S = 2\xi_{\max} \quad . \quad (27)$$

Since the leading wave of a group of cnoidal waves would be a transient wave, it was desirable to make this wave a positive wave rather than a negative wave so the train would not overtake it. Thus, the motion is started at a minimum-point in Figure 8, i.e., the origin of the trajectory is at $t = T - t_0$. (The interested reader is referred to Goring

(1978) for details of the numerical procedures involved in defining the cnoidal wave relationships.)

Six trajectories for cnoidal waves which were used in this study are presented in Figure 9 (denoted as CN1 to CN6) along with the corresponding profiles of the waves the theory predicts will be generated. In theory each cnoidal wave is defined by the parameters: H/h and $T\sqrt{g/h}$ which are shown next to each wave in the table to the right in Figure 9. However, for a given value of t_0/T it has been found that reasonably good cnoidal waves can be produced with the appropriate pairs of H/h and $T\sqrt{g/h}$ (see Goring, 1978).

Certain other characteristics of the generation process will be discussed later when the theoretical results are compared to the results of experiments.

EXPERIMENTAL EQUIPMENT AND PROCEDURES

The wave generator used in this study consists of a vertical plate which is moved horizontally in a prescribed manner by means of an electro-hydraulic servo-system which is driven by a programmed input voltage. The displacement-time history of the wave-plate is directly proportional to the time history of the input voltage.

In general, the system is similar to many other hydraulically operated wave machines in use; hence, only one unique aspect will be discussed here. That is the function generator which provides a voltage-time history which is proportional to the desired trajectory of the wave plate (as was shown schematically in Figure 5). The function generator used in this investigation consists of a device which is capable of storing 1000 three digit words. The memory can be filled either manually or through a punched paper tape reader; the data rate and the voltage of the output can be changed over a wide range. In this way, for a given shape of the trajectory, the amplitude and the duration of the motion can be adjusted.

The wave tank in which the piston type wave generator is mounted is 37.7 m long, 61 cm deep, and 39.4 cm wide. The tank is constructed of 13 modules each of which has been leveled accurately. The bottom is composed of sections of structural steel channel and the sidewalls are glass throughout.

All wave profile measurements were made using resistance wave gages whose sensitive elements were two parallel stainless steel wires (0.25 mm dia.) spaced 4 mm apart. The wires were stretched taut in a "C" shaped frame of stainless steel rod. These gages were used in conjunction with a Hewlett Packard (7700 Series) oscillograph for most measurements. Some detailed profiles were obtained with the aid of an analog-to-digital converter so that data reduction and plotting were accomplished using a digital computer.

PRESENTATION AND DISCUSSION OF RESULTS

As noted in Figure 1, if a linear trajectory of the wave machine were used to generate a solitary wave, for the conditions shown an

Figure 9 Trajectory shapes, waves, and associated data for cnoidal wave trajectories CN1 to CN6.

oscillatory tail with waves about 25% of the height of the leading wave would be present. As a better approximation, if the generation equations were solved assuming small motions of the generator the height of the waves in the tail could be reduced to about 10% of the first wave. Using the full theory for solitary wave generation (Eq. 19) results in the wave profiles presented in Figure 2, which shows that oscillatory waves nearly can be eliminated by a correct wave generation program. For the waves shown in Figure 2 the duration is $\tau = 2.044$ sec which is 7.4% greater than that predicted by Eq. (18); this difference decreases the magnitude of the trailing waves. That the optimum duration is not the theoretical duration is due in part to the fact that the wave plate velocity is constant with depth whereas there is a variation of horizontal water particle velocity with depth under a solitary wave. Thus, the desired boundary condition is not met precisely at the wave plate for this type of generator.

A comparison of experimentally determined profiles of solitary waves with two theories is presented in Figure 10. The theories chosen for comparison are those developed by Boussinesq (1782) and McCowan (1891) and the appropriate expressions for the profiles are shown in Table 1.

Table 1 Solutions of the solitary wave due to Boussinesq (1782) and McCowan (1891).

	Boussinesq	McCowan
Wave profile $\eta =$	$H \operatorname{sech}^2 \sqrt{\frac{3H}{4h}} \frac{X}{h}$	$\frac{h N \sin M (1+\eta/h)}{M [\cos M (1+\eta/h) + \cosh M \frac{X}{h}]}$
Wave speed $C =$	$\sqrt{gh(1+H/h)}$	$\sqrt{\frac{gh}{M}} \tan M$
Note		<p>N and M are:</p> $N = \frac{2}{3} \sin^2 \left[M \left(1 + \frac{2}{3} \frac{H}{h} \right) \right]$ $\frac{H}{h} = \frac{N}{M} \tan \left[\frac{1}{2} M \left(1 + \frac{H}{h} \right) \right]$

In Figure 10 waves with ratios of height to depth of 0.15 and 0.61 are shown and in both cases the agreement with each of the two theories is reasonable. The smaller wave agrees well with the Boussinesq theory over nearly the full range of the abscissa. The same degree of agreement is not apparent for the larger wave; however, over the major

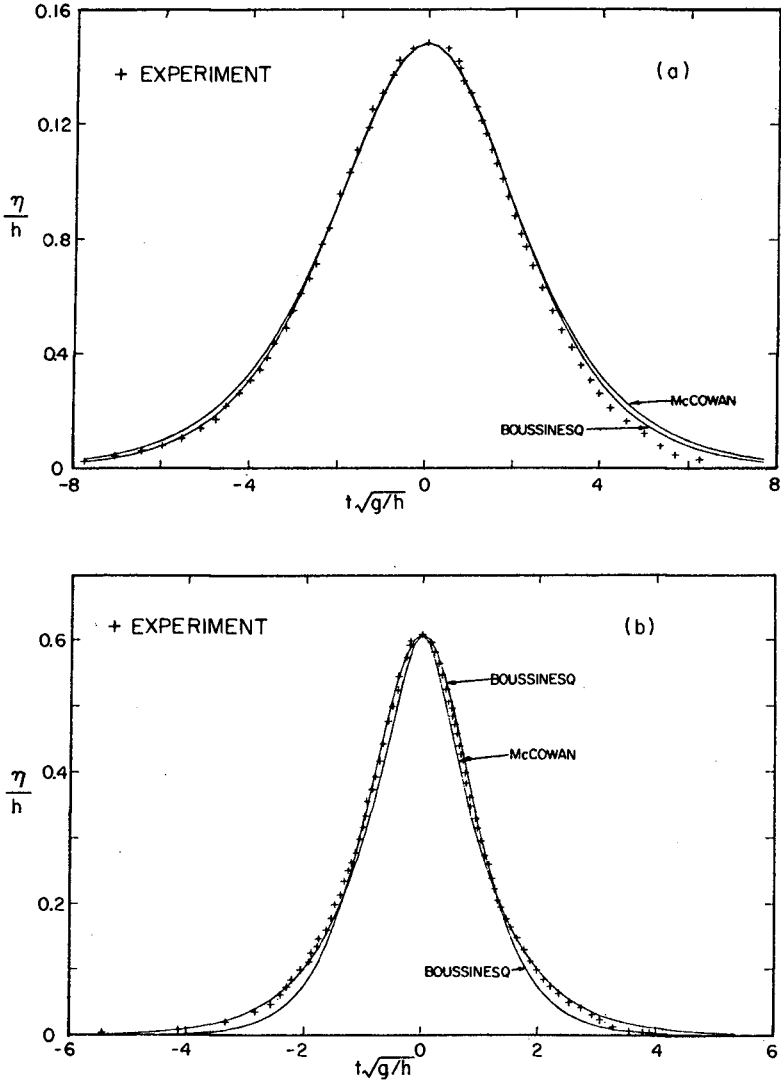

Figure 10 Comparison of the shape of solitary waves with relative heights (a) $H/h = 0.15$ and (b) $H/h = 0.61$ with the theories of Boussinesq and McCowan.

portion of the wave agreement with the Boussinesq theory is fairly good. (Similar results have been found by others, e.g. French (1969).)

Fenton (1972) developed a ninth-order solution for the solitary wave, and Boussinesq profiles were compared to his numerical results for waves with $H/h = 0.492$ and $H/h = 0.716$. The maximum difference in amplitude between the two theories was less than 7%, and for the larger height-to-depth ratio the differences were consistent with the comparison of McCowan's theory with that of Boussinesq; i.e., for x/h (or $t/g/h$) less than unity the Boussinesq results were above those from the ninth-order theory and for $x/h > 1.5$ the converse was true. Considering possible experimental errors and the rather small differences involved, it is felt the comparisons presented in Figure 10 are adequate to describe the capabilities of the long wave generator program developed herein.

An explanation of the differences which must not be forgotten is that the solutions obtained by Boussinesq (1782), McCowan (1891), and Fenton (1972) are approximations to the exact wave. Thus, the fact that agreement with the theories is limited is probably to be expected.

In Figure 11 the relative stroke of the wave machine (H/S) predicted by this approach (see Eq. 16) is compared to experimental results. In general agreement between the experiments and the theory is reasonably good for small relative wave heights, but as H/h increases disagreement increases. It is noted, in all cases the experimental data indicate wave heights which are less than those predicted for a given stroke of the wave machine plate. It appears that friction may be one cause for the observed differences, since measurements were made at two fixed distances from the wave machine; at $x = 8.4$ m for the six largest depths shown and at $x = 1.0$ m for the two smallest depths.

Since the wave gage at which the wave heights shown in Figure 11 were obtained was located less than 50 depths from the wave generator, at first it was considered that it was possible that the propagation distance was too short for a solitary wave to evolve completely. To investigate this, the waves were propagated analytically to infinity using the technique of inverse scattering. (For a review of this method and a comparison to experiments the interested reader is directed to Segur (1973) and to Hammack and Segur (1974), among others.) For a particular initial wave, the inviscid analysis yields the number and heights of solitary waves which emerge at infinity from a given initial disturbance. For a wave which is initially a solitary wave, only one solitary wave with the same height as the initial wave will emerge at infinity. The results of applying this analysis to the data are presented in Figure 12. The abscissa is the ratio of wave height-to-depth and the ordinate is the ratio of the wave height obtained by the analytical technique of inverse scattering compared to the initial measured wave height, H_{inv}/H . Thus, a value of the ordinate of unity indicates there is a good probability that the wave generated is a "solitary wave." Generally the agreement is reasonably good except for the experiments for the two smallest depths ($h = 10.0$ cm and 5.0 cm). The reason for this disagreement may be due to the effects of friction at the smaller depths, which has been mentioned earlier. A detailed discussion of other aspects of the generated wave and changes of the wave as it propagates is presented by Goring (1978).

Figure 11 Variation of H/S with the relative wave height, H/h , for solitary wave generation.

Figure 12 Variation of the inverse scattered wave height ratio, H_{inv}/H , with relative wave height, H/h .

Examples of periodic long waves generated with different trajectories have been presented in Figures 3 and 4. As mentioned previously, the object was to generate waves which formed the periodic solution to the Korteweg-de Vries Equation, namely cnoidal waves (see, e.g., Whitham, 1974). The experiments from which the wave profiles of Figures 3 and 4 were obtained were similar with the only difference being the period of the motion. For the experiment shown in Figure 4 the period of the motion was 2.90 sec compared to a period of 4.28 sec for the case shown in Figure 3; in both examples the depth was 20 cm and the stroke of the wave plate was 11.18 cm. It should be noted that the secondary waves which appear to be forming in the oscillograph traces shown in Figure 3 (as indicated by the arrows) are absent in the wave profiles at corresponding positions in Figure 4. In addition, the waves near the center of the group shown in Figure 4 appear to propagate with relatively constant shape.

Waves generated using the wave plate trajectories shown in Figure 9 are compared to theoretical wave profiles in Figures 13a and 13b. In these figures the corresponding conditions are shown in each portion of the figures; it is noted, the Ursell Number (HL^2/h^3) for these experiments varies by two orders of magnitude from 10 to 1229. The experimental record was obtained from a wave gage located between 5 and 20 depths from the wave plate ($x = 1.0$ m). In an attempt to minimize the effects of both the leading and the trailing part of the wave train, the data shown are for the third cycle in the wave train. The wave height which was measured was used to construct the theoretical profile; thus, reducing the effect of friction during propagation and disagreements with the generation theory as embodied in Equation 16. Therefore, only the shape of the wave is being compared in Figures 13a and 13b. It appears that agreement between the experimental and theoretical results is relatively good with discrepancies apparent primarily in the region of the trough, especially for the cases of large Ursell Number.

In Figure 14 experimental and theoretical results are presented which summarize the generation theory for long waves. The ordinate is the ratio of wave height to stroke, H/S , and the abscissa is a non-dimensional wave period, $(1/T)(\sqrt{h/g})$. Shown in the figure are curves of constant wave height-to-depth, H/h , and of constant nondimensional time, t_0/T , which describe the time to the maximum of the trajectory as shown in Figure 8. Thus, for a desired wave height, wave period, and depth, the stroke of the wave machine and the time to the maximum of the trajectory can be obtained. It is noted that the line which emanates from the origin describes small amplitude shallow water waves and the curve $t_0/T = 0.25$ is tangent to it. The intersection of curves of constant H/h with the ordinate describe the generation of solitary waves. Experimental data are presented for periodic waves in Figure 14 where the symbols correspond to particular values of wave height-to-depth and relative time to the extreme of the trajectory, t_0/T . Thus, the comparison can be made between the data and the curves of constant relative wave height, H/h , and constant relative duration, t_0/T . It is apparent that agreement increases with increasing t_0/T and decreasing H/h . Considering the shape of the trajectories this would be expected.

CONCLUSIONS

This study has shown the importance of considering the position of the wave plate relative to the position of the generated wave in a long wave generation model. If this is done, quite acceptable profiles for solitary and cnoidal waves are possible.

CHAPTER 48

CORRECT REPRODUCTION OF GROUP-INDUCED LONG WAVES

N.-E. Ottesen Hansen¹ Stig E. Sand²
H. Lundgren³ Torben Sorensen⁴ H. Gravesen⁵

ABSTRACT

In nature short period storm waves generate longer waves with periods corresponding to the wave group periods. The long waves are generally referred to as the wave set-down of water level. The set-down term is of second order in the height of the short waves. With first-order reproduction of natural storm waves in the laboratory, the set-down bound to the wave groups is not reproduced. As a result, various free waves are generated, propagate towards the model and reflect from the boundaries. These so-called parasitic waves cause an exaggeration of long wave phenomena, such as harbour resonance and slow drift oscillations of moored ships.

The parasitic waves can be eliminated by means of compensating free waves imposed on the system by second-order paddle motion reproducing the natural set-down. The control signal for this motion has been calculated and checked by testing. The agreement between calculated and measured results is found to be good.

Further, an alternative method for reducing the parasitic wave problem is presented. Utilizing the shoaling properties of the various waves, the influence of parasitic waves can be diminished by generating the waves in somewhat deeper water before they propagate into the shallower model area.

INTRODUCTION

Resonance conditions ('seiche') in harbours and bays are experienced all over the world. They can be a nuisance for the operation of ship terminals because, from time to time, they may induce unacceptably large movements of moored ships resulting in breaking of moorings. The periods of interest are usually in the range of 20 seconds to 5 minutes.

Harbour resonance may be induced by various mechanisms, such as tsunamis, storm surges, land slides or calving glaciers (Greenland). Most frequently, however, the source will be meteorological pressure fluctuations or long period waves from distant storms or wave groups. In this paper long period waves induced by wave groups are considered. This is the most common mechanism of generation.

Fig. 1 Long period wave generated by wave groups.

Long waves generated by storm wave groups are generally referred to as the wave set-down, because they are characterized by having their troughs in the regions of the larger waves in the groups. Typically, a group contains from 5 to 20 waves (Fig. 1).

To each wave pertains an internal compressive force, the radiation stress (Longuet-Higgins and Stewart, 1960) or wave thrust (Lundgren, 1963), acting in the direction of wave propagation. For a regular wave this force is proportional to the square of the wave height. To balance this force a set-down in mean water level has to appear within the series of higher waves, and a corresponding set-up is produced within the series of smaller waves. This problem has previously been considered and quantified by Longuet-Higgins and Stewart (1964) and by Ottesen Hansen (1978).

An example of the effect of long waves generated by wave groups is the 'seiche' in the Bay of Telok Plan at Bintulu in Malaysia (Fig. 2a). The 'seiche' in the bay and the incoming waves were recorded simultaneously (Fig. 2b). It appeared that wave groups, approaching from NW produced an edge wave between the head of the bay and the tip of the promontory Tanjong Kidurong with a period of 100 - 180 s. This long period wave normally occurred when the offshore significant wave exceeded 0.9 m.

PROBLEMS IN PHYSICAL MODELS

Mooring forces and ship movements are normally determined by physical model tests, which at present is the simplest and most reliable method. Physical model technique has developed considerably over the past decade. Presumably, the major improvement has been the introduction of natural, irregular waves in the model. The use of natural wave trains secures that important phenomena found in nature are reproduced accurately in the model. This applies particularly to:

- (i) Direct wave action on ships.
- (ii) The effect of wave groups or long waves on harbour resonance and slow drift ship motions.

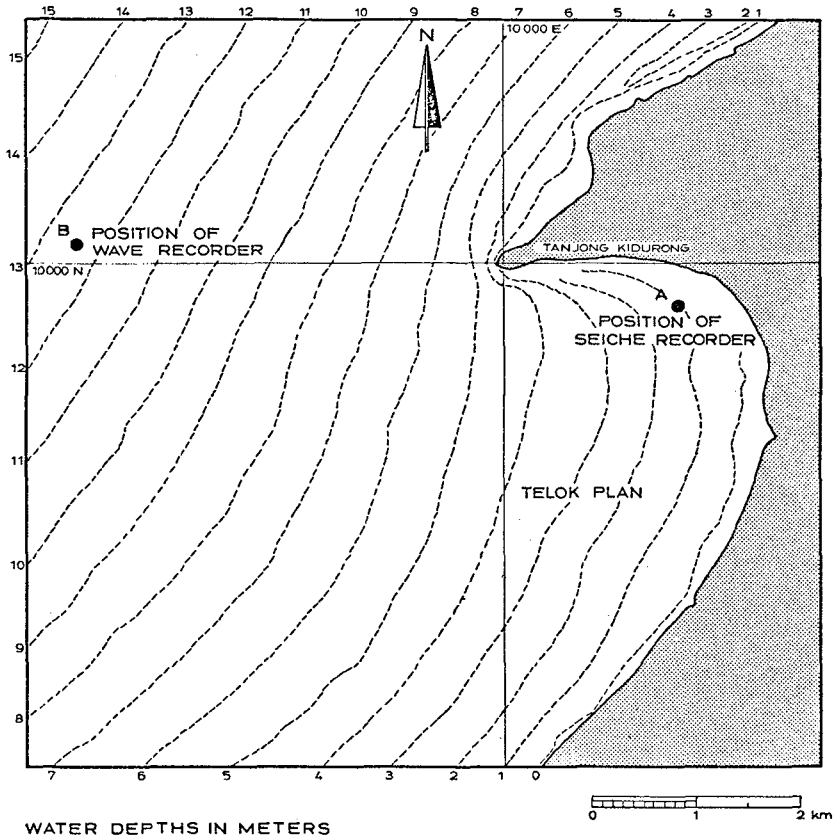

Fig. 2a Topography of the Bay of Telok Plan at Bintulu, Sarawak, Malaysia. A 'seiche' (long wave) recorder is placed in the bay, and a waverider buoy approximately 4 km offshore.

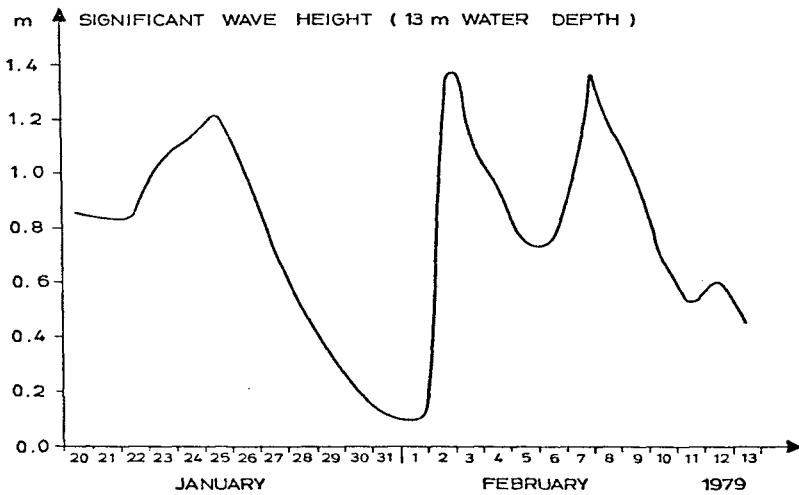

Fig. 2b The results of simultaneously recorded 'seiche' in the Bay of Telok Plan and the significant wave height 4 km offshore.

For problems with ships moored in harbours or movements of large vessels, the effect of long waves is particularly important due to the risk of resonance with the longer natural vessel periods pertaining to surge, sway and yaw.

Fig. 3 Origin of parasitic long wave when generating irregular waves in the laboratory.

When natural waves are reproduced in the laboratory, the paddle is normally controlled by a 1st order signal. The wave groups are accompanied by a long wave corresponding to the set-down (Fig. 3a). The set-down behaves as a normal progressive wave with forward orbital velocities underneath the crests and backward orbital velocities under the troughs, also called drift velocities.

At the paddle, however, the desired 2nd order (long period) drift velocities are not produced by the 1st order (short period) signal. With no flow through the paddle the natural drift velocities will be compensated by identical velocities of opposite sign (Fig. 3b). The latter velocities generate a progressive long wave that is free, i.e. not bound to the groups. This phenomenon is called a parasitic long wave, and it results in an exaggeration of the long wave effects mentioned under (ii) above.

In order to eliminate the parasitic long wave, the 1st order signal must be superposed by a 2nd order long period signal that will produce

the drift velocities required by the set-down wave. In principle, these drift velocities must be produced at the mean piston position, $X = 0$. In practice, the long period signal will control the piston velocity, and hence the drift velocity, at the instantaneous piston position X , which is displaced somewhat from $X = 0$. This piston displacement gives a correction to the long period signal, see discussion below.

As will be seen from the formulae below, the long period signal is a sum over differences between each pair of frequencies in the short wave spectrum. Therefore, the long period signal may be designated as a sum of subharmonics.

The control of the paddle by the 1st order short wave signal also gives rise to a displacement. The corresponding 2nd order correction would contain a number of terms, each term corresponding to the sum of a pair of frequencies in the short wave spectrum. Hence, this correction would be a sum of superharmonics, cf. the second harmonic introduced in the generation of regular waves (BuhrHansen et al., 1975). In the present paper the superharmonic correction has not been considered.

METHOD OF SOLUTION

The mathematical description of the long wave and the parasitic wave problem depends on the description used in the wave generation. In all modern laboratories, models are tested with irregular waves. Often a Fourier approach with random or specified phase spectrum is used for the generation, but at present a time-domain generation must be preferred (Lundgren and Sand, 1979).

The direct Fourier approach with specified phases is the simplest one for the problem discussed in this paper and will be used in the following to illustrate the principles.

A regular wave group with water surface elevation η_{nm} and frequency Δf_{nm} consists of two regular waves with water surface elevations η_n, η_m and frequencies f_n, f_m , respectively, where

$$\eta_{nm} = \eta_n + \eta_m \quad \text{and} \quad \Delta f_{nm} = f_n - f_m \quad (1)$$

n and m being indices indicating the numbers of the waves considered.

According to the previous outline of the physical principles, the wave group η_{nm} generates a wave set-down ξ_{nm} . Each pair n, m of components in the wave spectrum contributes to the set-down. This means that the wave set-down ξ in an irregular wave train can be calculated by summing up the contributions from all pairs, i.e.

$$\xi = \sum_{n=m^*}^{\infty} \sum_{m=m^*}^{\infty} \xi_{nm} \quad \text{with} \quad m^* = f^*/f_0 \quad (2)$$

in which f_0 is the interval of discretization of the short wave spectrum, and f^* is the lowest frequency in the short wave spectrum.

Hence, the first step in the problem is to solve the simpler problem of two regular, interacting waves. In this analysis the following assumptions are made:

- (1) The short period waves can be described by first order Stokes' theory.
- (2) The long period waves constitute a second order phenomenon, i.e. of the order $O(H^2/h^2)$.
- (3) The bottom is plane.
- (4) The waves are progressive and propagate in only one direction.
- (5) Frictional effects can be neglected.

With these assumptions the following solution for the wave set-down ξ_{nm} under a regular wave group has previously been found (Ottesen Hansen, 1978)

$$\frac{\xi_{nm}}{h} = G_{nm} h \left(\frac{a_n a_m + b_n b_m}{h^2} \cos(\Delta\omega_{nm} t - \Delta k_{nm} x_1) + \frac{-a_n b_m + b_n a_m}{h^2} \sin(\Delta\omega_{nm} t - \Delta k_{nm} x_1) \right) \quad (3)$$

The notation in this paper is:

- (x_1, x_3) = horizontal/vertical coordinates
- t = time
- n, m = indices indicating numbers of the waves considered
- L_n = length of the n 'th wave
- k_n = $2\pi/L_n$ = wave number of the n 'th wave
- Δk_{nm} = $k_n - k_m$ = long wave number
- σk_{nm} = $k_n + k_m$
- c_n = phase velocity of the n 'th wave
- T_n = period of the n 'th wave
- f_n = $1/T_n$ = frequency of the n 'th wave
- Δf_{nm} = $f_n - f_m$ = long wave frequency
- ω_n = $2\pi f_n$ = cyclic frequency of the n 'th wave
- $\Delta\omega_{nm}$ = $\omega_n - \omega_m$
- h = water depth
- η_n = $a_n \cos(\omega_n t - k_n x_1) + b_n \sin(\omega_n t - k_n x_1)$
= elevation of water surface for the short wave
- ξ = elevation of water surface for the long wave
- ρ = density of water
- U_L = long wave horizontal velocity
- u_s = short wave horizontal velocity
- u = total, instantaneous horizontal velocity
- x = paddle position

The function G_{nm} , which is shown graphically in Fig. 4, is a transfer function given by (Ottesen Hansen, 1978)

$$G_{nm} = \left(\frac{g}{2} \Delta\omega_{nm} \Delta k_{nm} \left(\frac{1}{c_n} + \frac{1}{c_m} \right) \Delta k_{nm} h \coth(\Delta k_{nm} h) - \frac{1}{2} \Delta k_{nm}^2 \Delta\omega_{nm}^2 h + \frac{\omega_n \omega_m \Delta k_{nm}^2 h \cosh(\Delta k_{nm} h)}{\cosh(\sigma k_{nm} h) - \cosh(\Delta k_{nm} h)} \right) / \left(\Delta k_{nm} h \coth(\Delta k_{nm} h) \Delta\omega_{nm}^2 - g h \Delta k_{nm}^2 \right) \quad (4)$$

The asymptotic expressions for the shallow and deep water cases of Eq. (4) are presented in Fig. 4 on the left hand and right hand sides, respectively.

Fig. 4 Transfer function for long waves generated by two regular waves with amplitudes A_n, A_m and frequencies $f_n = f + \Delta f$ and $f_m = f$, respectively.

PRINCIPLE OF SOLUTION

A natural wave train is generated by a piston type wave paddle in a flume of depth h , cf. Fig. 3a. The paddle position as function of time is $X(t)$ with paddle amplitude X_a . The short wave horizontal velocity is $u_S(x_1, x_3, t)$, and the corresponding long wave velocity is $U_L(x_1, x_3, t)$. The total, instantaneous horizontal velocity in the flume is denoted $u(x_1, x_3, t)$. Further, the velocity potential ϕ with $\phi_{x_1} = u(x_1, x_3, t)$ must satisfy Laplace equation.

The general boundary condition at the paddle expresses the equality between paddle velocity and horizontal orbital velocity, i.e.

$$\phi_{x_1} = u(x_1, x_3, t) = \frac{\partial X(t)}{\partial t} = X_t(t) \quad \text{for} \quad \begin{cases} x_1 = X(t) \\ -h \leq x_3 \leq 0 \end{cases} \quad (5)$$

A perturbation method is applied to the problem. This implies that the variables u and X are written

$$\begin{aligned} u &= \epsilon u^{(1)} + \epsilon^2 u^{(2)} + \dots \\ X &= \epsilon X^{(1)} + \epsilon^2 X^{(2)} + \dots \end{aligned} \quad (6)$$

It is not practical to deal with a boundary condition at $x_1 = X(t)$. Therefore it is transferred to $x_1 = 0$ by means of the following Taylor expansions

$$\begin{aligned} u^{(1)}(X, x_3, t) &= u^{(1)}(0, x_3, t) + X u_{x_1}^{(1)}(0, x_3, t) + \dots \\ u^{(2)}(X, x_3, t) &= u^{(2)}(0, x_3, t) + X u_{x_1}^{(2)}(0, x_3, t) + \dots \end{aligned} \quad (7)$$

The 1st and 2nd order boundary conditions now appear to be

$$\begin{aligned} u^{(1)}(0, x_3, t) &= X_t^{(1)} \\ u^{(2)}(0, x_3, t) &= -X^{(1)} u_{x_1}^{(1)} + X_t^{(2)} \quad \text{for} \quad x_1 = 0 \end{aligned} \quad (8)$$

Then the problem is reduced to the following:

- (i) For a given $X^{(1)}(t)$ (with $X^{(2)} = 0$) determine the corresponding $u^{(2)}(0, x_3, t)$ in the flume. This includes contributions from both the real wave set-down and parasitic waves.
- (ii) Determine the signal $X^{(2)}(t)$ so that the progressive long waves correspond to the set-down, i.e. $u^{(2)} = U_L$, and all parasitic waves are eliminated.

In step (i) Laplace equation has to be solved with all the boundary conditions, including Eq. (8) written as

$$\begin{aligned} \phi_{x_1}^{(1)} &= X_t^{(1)} \\ \phi_{x_1}^{(2)} &= -X^{(1)} \phi_{x_1 x_1}^{(1)} \quad \text{for} \quad x_1 = 0 \end{aligned} \quad (9)$$

SHALLOW WATER SOLUTION

In the shallow water case the horizontal velocity distribution matches the paddle profile, and therefore no local disturbances will appear. Thus, Laplace equation will give the usual, well-known solution. Hence, step (ii) above may be solved directly from the 2nd order boundary condition Eq. (8) or through mass transport considerations

at the paddle. This leads to

$$u^{(2)}(0, x_3, t) = U_L(0, x_3, t) = -X^{(1)} u_{x_1}^{(1)} + X_t^{(2)} \quad \text{for } x_1 = 0 \quad (10)$$

i.e.

$$X_t^{(2)} = U_L(0, x_3, t) + X^{(1)} u_{x_1}^{(1)} \quad (11)$$

For a regular wave group, $\eta_{nm}(t)$, produced by two short waves as defined by Eq. (1), the 1st order horizontal velocity, $u_{nm}^{(1)}$, is found from the usual expressions for progressive waves. The paddle movement $X_{nm}^{(1)}$ is calculated by application of the asymptotic transfer function kh , which is easily derived from the 1st order equations (cf. Biésel, 1951). The long wave velocity $U_L(0, x_3, t)$ is calculated from Eq. (3). Hence, the necessary 2nd order piston positions $X_{nm}^{(2)}(t)$ may be found from Eq. (11) as

$$X_{nm}^{(2)}(t) = \frac{k_n^2 + k_m^2 - 3/h^2}{2h^2 k_n k_m (k_n - k_m)} \left[(a_n a_m + b_n b_m) \sin \Delta \omega t + (a_n b_m - a_m b_n) \cos \Delta \omega t \right] \quad (12)$$

In the numerator the term $-3/h^2$ is the dominant one and corresponds to elimination of the parasitic wave. The term $k_n^2 + k_m^2$ originates from the paddle displacement.

For short shallow water waves the transfer function is kh , i.e. the ratio between generated wave amplitude and 1st order paddle amplitude is $A/X_a = kh$. Similarly, a 2nd order transfer function can be defined as the ratio between the amplitude of the generated long waves, ξ_a , and the 2nd order paddle amplitude, $X_a^{(2)}$. These transfer functions are shown in Fig. 5. A good approximation to the 2nd order transfer function is $\xi_a/X_a \approx \Delta k_{nm} h$.

Fig. 5 Shallow water transfer functions.

Assuming $L > 20h$ for shallow water waves, the term $k_n^2 + k_m^2$ in the numerator of Eq. (12) is less than 6% of the term $3/h^2$. If the smaller term is neglected, Eq. (12) becomes

$$X^{(2)}(t) \approx \frac{-3}{2h^3 k_n k_m (k_n - k_m)} Z_{nm}(t) \quad (13)$$

where $Z_{nm}(t)$ is the expression in the brackets.

GENERAL SOLUTION FOR THE PADDLE MOVEMENT

In the general (non-shallow) case the horizontal orbital velocity of the waves diminishes hyperbolically towards the bottom. As this velocity profile is not compatible with that of the paddle, local disturbances, damped as $e^{-k_j x_1}$, arise both in 1st and 2nd order. These disturbances and the general x_3 -dependence make it imperative to solve the Laplace equation with the appropriate boundary conditions. Thus the problem is as follows

$$\phi_{x_1 x_1}^{(2)} + \phi_{x_3 x_3}^{(2)} = 0 \quad (14)$$

$$g \phi_{x_3}^{(2)} + \phi_{tt}^{(2)} = g \eta_{x_1}^{(1)} \phi_{x_1}^{(1)} - g \eta^{(1)} \phi_{x_3 x_3}^{(1)} - \eta_t^{(1)} \phi_{t x_3}^{(1)} - \eta^{(1)} \phi_{t x_3 t}^{(1)} + \phi_{x_1}^{(1)} \phi_{x_1 t}^{(1)} + \phi_{x_3}^{(1)} \phi_{x_3 t}^{(1)} \quad \text{for } x_3 = 0 \quad (15)$$

$$\phi_{x_3}^{(2)} = 0 \quad \text{for } x_3 = -h \quad (16)$$

$$\phi_{x_1}^{(2)} = -X^{(1)} \phi_{x_1 x_1}^{(1)} + X_t^{(2)} \quad \text{for } x_1 = 0 \quad (17)$$

The precise form of the local disturbances pertaining to the 1st order equations is (cf. Biésel)

$$\phi_{x_1, \text{disturbance}} = X_a \sum_{j=1}^{\infty} C_j \omega \cos(k_j (x_3 + h)) e^{-k_j x_1} \cos \omega t \quad (18)$$

where $C_j = \frac{2 \sin k_j h}{\sin k_j h \cos k_j h + k_j h}$ and $\omega^2 = -g k_j \tan k_j h$.

Firstly, step (i) of the preceding section is considered, viz. $X^{(2)} = 0$. A paddle controlled by a 1st order signal will generate in 2nd order

$$\phi_{x_1}^{(2)} = -U_{L, \text{free}} + a_L \cos(\Delta \omega t - \Delta k x_1) + b_L \sin(\Delta \omega t - \Delta k x_1) + \sum_i C_{L,i} e^{-k_i x_1} \quad (19)$$

when the input is the regular wave group given by Eq. (1). The functions $C_{L,i}$ represent the (x_3, t) -dependent local disturbances of 2nd order, which can be accepted in model tests because they are strongly damped away from the paddle. The first three terms in Eq. (19) are illustrated in Fig. 6 together with the short wave groups (full line) and the dash-dotted long wave (set-down) that follows the groups, and which it is desired to reproduce. The latter is characterized by the velocities $U_L(x_1, x_3, t)$. The first term, $-U_{L, \text{free}}$, is the free parasitic long wave shown as a fat dotted line and designated '180° out of phase with U_L ' because it cancels U_L at $x_1 = 0$. The terms with a_L and b_L represent free long waves and contain the contribution from the paddle displace-

ment shown as a thin dotted line and designated 'from the $X_{x_1 x_1}^{(1)}$ term'. These terms also include a complicated 2nd order free-wave effect from the 1st order local disturbances, cf. the formula for $F_{3,n}$ below.

Fig. 6 Long waves for 1st order control signal.

Secondly, the appropriate $X_{nm}^{(2)}(t)$ must be determined as a part of the solution of the 2nd order Laplace equation in such a manner that:

- (a) The long wave following the group is generated.
- (b) All free long waves are eliminated.

The lengthy calculations result in the following solution:

$$X_{nm}^{(2)}(t) = \left((a_n b_m - a_m b_n) F_1 + (a_n a_m - b_n b_m) F_2 (F_{3,m} - F_{3,n}) \right) \cos \Delta \omega t + \left((a_n a_m + b_n b_m) F_1 + (a_m b_n - a_n b_m) F_2 (F_{3,m} - F_{3,n}) \right) \sin \Delta \omega t \quad (20)$$

in which

$$F_1 = \frac{\omega_m \Delta k_{nm} k_m (1 + G_n) \left\{ (k_n - 2k_m) \sinh(k_n h) + k_n \sinh([k_n - 2k_m]h) \right\}}{8(k_n^2 - 2k_n k_m) \Delta \omega_{nm} \sinh(\Delta k_{nm} h) \tanh(k_n h) \sinh(k_m h)} + \frac{\omega_n \Delta k_{nm} k_n (1 + G_m) \left\{ k_m \sinh([2k_n - k_m]h) + (2k_n - k_m) \sinh(k_m h) \right\}}{8(2k_n k_m - k_m^2) \Delta \omega_{nm} \sinh(\Delta k_{nm} h) \tanh(k_m h) \sinh(k_n h)} + \frac{G_{nm}(1 + \Delta G_{nm})}{2 \tanh(\Delta k_{nm} h)} \quad (20a)$$

$$F_2 = \frac{\Delta k_{nm} (1 + G_n) (1 + G_m)}{8 \Delta \omega_{nm} \tanh(k_n h) \tanh(k_m h)} \quad (20b)$$

$$F_{3,n} = \omega_n \sum_{j=1}^{\infty} \frac{2 k_j \sin(k_j h) \left\{ k_j \sin(k_j h) \coth(\Delta k_{nm} h) + \Delta k_{nm} \cos(k_j h) \right\}}{(k_j^2 - \Delta k_{nm}^2) \left\{ \sin(k_j h) \cos(k_j h) + k_j h \right\}} \quad (20c)$$

Here k_j is found as the solution to

$$\omega_n^2 = -g k_j \tanh k_j h \quad \text{with} \quad \left(j - \frac{1}{2} \right) \pi < k_j h < j \pi \quad (20d)$$

Analogously for $F_{3,m}$. Further, G_{nm} is given by Eq. (4) and

$$G_n = \frac{2 k_n h}{\sinh(2 k_n h)} \quad \Delta G_{nm} = \frac{2 \Delta k_{nm} h}{\sinh(2 \Delta k_{nm} h)} \quad (20e)$$

The summation in Eq. (20c) is less troublesome than would appear at first glance because $\sin(k_j h)$ converges rapidly towards zero with increasing j .

REPRODUCTION OF NATURAL LONG WAVES

The 2nd order paddle control signal, $x_{nm}^{(2)}(t)$, given by Eq. (12) for the shallow water case and by Eq. (20) for the general case, is valid for a regular short wave group characterized by the pair of indices nm . For the reproduction of natural long waves (without parasitic, paddle displacement and progressive disturbance waves) it is necessary to carry out a summation over all pairs nm in analogy to Eq. (2) for the natural set-down, i.e.

$$x^{(2)}(t) = \sum_{n-m=1}^{\infty} \sum_{m=m^*}^{\infty} x_{nm}^{(2)}(t) \quad (21)$$

This signal has to be superposed upon the 1st order control signal $x^{(1)}$ that reproduces the natural short wave train.

EXAMPLES OF APPLICATION

Fig. 7 shows a wave record from Angra, Brazil. By means of pressure cells also the set-down was recorded. Eq. (3) was applied for the computation of the long waves (set-down). It is seen that calculated and measured long waves agree reasonably well. The paddle control signal for the correct reproduction of short and long waves was also calculated, applying Eqs. (21) and (20). The resulting signal is seen in Fig. 8. It is apparent that the correct reproduction of the long waves requires a much larger total stroke of the paddle than is the case for the short waves proper.

Another example of measured and calculated set-down is given in Fig. 9. These waves were recorded at Bintulu, Malaysia.

SHOALING PROPERTIES OF LONG WAVES

Alternatively to the direct compensation of the parasitic waves by a 2nd order control of the wave paddle, the model errors can be reduced by deriving advantage from the shoaling properties of the various long waves. The shoaling of the set-down can be calculated from Eq. (4). For simplicity, however, only the shallow water case shall be considered.

The shoaling of a parasitic wave ξ_p when it propagates from a larger depth h_1 to a smaller depth h_2 can be found by expressing that the energy flux is constant, i.e.

$$\frac{1}{2} \rho g \xi_{p,1}^2 c_1 = \frac{1}{2} \rho g \xi_{p,2}^2 c_2 \quad (22)$$

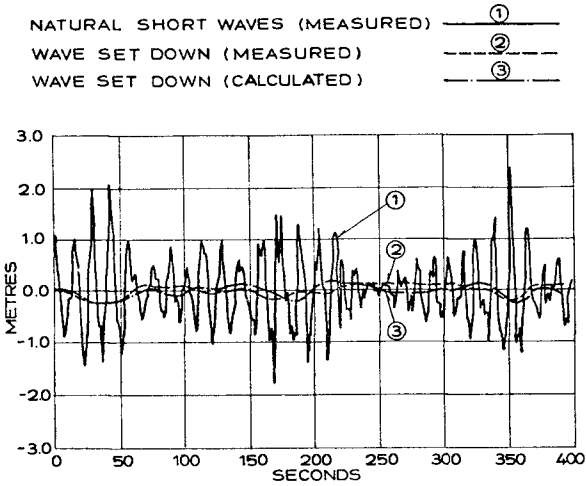

Fig. 7 Wave record from Angra, Brazil.

Fig. 8 Paddle control signal (to 2nd order).

Fig. 9 Wave record from Bintulu, Malaysia.

With the phase velocity $c = \sqrt{gh}$ it appears that

$$\xi_{p,2}/\xi_{p,1} = (h_1/h_2)^{1/4} \quad (23)$$

The corresponding shoaling of the wave set-down can be found by applying an equation similar to Eq. (22) in combination with Fig. 4 and is

$$\xi_2/\xi_1 = (h_1/h_2)^{5/2} \quad (24)$$

Thus, the ratio between the wave set-down and the parasitic wave is

$$\xi_2/\xi_{p,2} = (h_1/h_2)^{9/4} \xi_1/\xi_{p,1} \quad (25)$$

This implies that the relative effect of parasitic waves can be reduced by generating the waves in somewhat deeper water, letting them propagate into the shallower model area (Fig. 10).

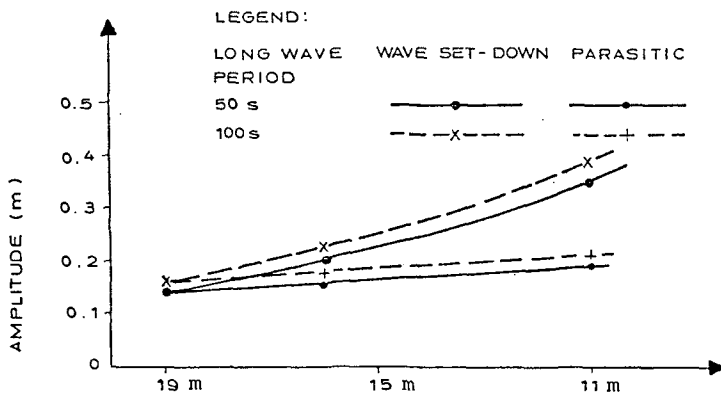

Fig. 10 Shoaling of long waves propagating from 19 m to 11 m depth for short period waves with $H_s = 2.4$ m and peak period $T_p = 13$ s.

In this connection, however, it should be mentioned that the method is not perfect. Thus, although the parasitic waves in Fig. 10 are small, they will build up gradually due to reflections from the boundaries of the model basin, because it is virtually impossible to absorb parasitic long waves. Still the method of shoaling is better than doing nothing.

ABSORPTION OF LONG WAVES

It is generally known that long waves constitute a serious problem in physical model tests because they are reflected from the boundaries, thus increasing the long wave disturbances in the basin.

In tests where basically the long waves are generated by the wave groups and appear as wave set-down, it is possible to avoid these boundary effects because the wave set-down disappears during the breaking of the short period waves (Fig. 11). This breaking, however, has to be gentle and take place over a certain distance, i.e. as spilling breakers. If, instead, the waves break abruptly in front of a steep slope, the wave set-down will be reflected as free long waves, which propagate back into the basin as parasitic waves. Therefore the criterion for absorption of wave set-down is simply that the short wave shall be absorbed as spilling breakers.

Fig. 11 Wave set-down in breaking waves.

CONCLUSIONS

Long wave phenomena in physical model tests can be correctly reproduced only if the following requirements are met:

- (a) The parasitic long waves generated by the reproduction of natural waves must be eliminated by application of the 2nd order control signal defined by Eq. (21) in connection with Eq. (20) or, in the shallow water case, Eq. (12).
- (b) Along the boundaries of the model basin waves shall be absorbed by spilling breakers.

As an alternative to the direct compensation of the parasitic waves, the model errors can, to a certain extent, be reduced by deriving advantage from the shoaling properties of the wave set-down and the parasitic waves. This requires:

- (c) The wave generator be placed in a depth as large as possible compared with the general depth of the model area.

AN ELECTROMAGNETIC ANALOGY FOR LONG WATER WAVES

by G.W.Jackson¹ and D.L.Wilkinson²1. Introduction

Seiching must be considered when designing mooring, berthing or navigational facilities in semi enclosed basins and harbours. The considerable oscillatory currents which may be generated along nodal lines of a seiche can result in serious surging of a vessel moored in such areas. Hydraulic modelling of the long gravity waves which form the seiche poses particular problems for the hydraulic modeller. In the prototype situation, a balance is achieved between the long wave energy entering a basin, the energy dissipation within the basin, and the wave energy which is radiated back into the ocean. The presence of the wave generator in the model may result in much of the radiated energy being reflected back into the basin, thereby distorting the seiche observed in the model.

The relatively low Reynolds numbers present in the model leads to exaggerated frictional damping of the waves and possible suppression of certain resonant modes. Scaling of long wave amplitudes in resonance situations cannot be determined from simple Froude laws but must be based on equivalent dissipation rates in the model and the prototype (Ippen, 1966).

Alternative methods of physically reproducing long wave behaviour have been studied, such as acoustic modelling (Nakamura, 1977). However, these models also have their limitations and are largely confined to constant depth situations.

It is suggested that electromagnetic radiation in the microwave range may be used to model long gravity waves and that this method has many advantages over the various techniques which have previously been used. It can be rigorously shown that the laws which govern the propagation, reflection and dissipation of electromagnetic radiation (Maxwell's equations) are identical to the linearised equations describing the motion of long gravity waves, (Jackson and McKee, 1980). The linear wave equation gives an accurate description of long wave oscillation in basins as the wave length is of the same order as the basin dimensions and non-linear effects do not have time to develop.

The microwave model consists of a flat box or cavity whose plan outline is geometrically similar to the boundaries of the harbour basin under investigation. The entrance to the basin is connected to a source of micro wave energy, a klystron, via a length of wave guide. As the klystron generates microwaves which propagate in all directions, the vertical dimension of the wave guide and the microwave cavity is made less than half a wave length of the microwave. This eliminates the vertical component of the microwave radiation. Microwaves in the frequency range from 1 to 10 G.Hertz are most suitable for these models and the corresponding wave lengths are 30 to 3 cm. Thus the model size is typically 10 to 20 cm in plan by 1 cm deep.

The properties of the wave field are determined by measuring the voltage induced on small antennæ probes which are inserted into measurement ports in the cavity wall.

The unwanted secondary interactions between the seiche and the wave generator, which poses a major problem in hydraulic models, can be eliminated in the microwave model by installing an isolator between the energy source and the microwave cavity. The isolator will pass the incident wave but totally dissipate the reflected wave travelling in the opposite direction. Microwave models are not restricted to constant depth situations as are acoustic models. The parameters equivalent to water depth in the microwave model are the electric and magnetic permeabilities of the cavity interior. The former can be readily varied by using materials with different dielectric constants (air, perspex, teflon etc.) to represent different contour intervals in the model.

Microwaves are potentially a relatively inexpensive, convenient and accurate means of modelling long wave motions in semi enclosed basins and harbours. In this paper the performance of microwave analogue is examined for some simple geometries whose prototype behaviour is well known.

Formulation

It is well known that many similarities of behaviour exist between water waves and electromagnetic radiation. Penny and Price (1953) adopted the equations describing the diffraction of light to describe the diffraction of water waves around breakwaters. Both types of waves are known to obey similar laws of reflection and refraction.

At first sight Maxwell's equations, which describe the propagation and characteristics of electromagnetic radiation, bear little resemblance to the equations describing the motion of long gravity waves (compare columns (i) and (ii) respectively in Table 1). However, if a vector potential \tilde{W} is defined as

$$\tilde{W} = - \hat{i}hv + \hat{j}hu$$

where \hat{i} and \hat{j} are the horizontal unit vectors in the x and y directions

u and v are the x and y velocity components

and h is the local depth

The conventional linearised long wave equations transform to a set which are identical to Maxwell's equations. The transformation is somewhat involved and is described in detail by Jackson and McKee (1980).

For a plane wave the vector potential \tilde{W} has a magnitude which is equal to the instantaneous flow per unit wave front but has a direction which is orthogonal to the direction of wave propagation (i.e. along the crest).

Table 1 gives equivalent expressions for electromagnetic radiation and long gravity waves.

Table 1: Field Equations

(i) Maxwell's Equations for Electromagnetic Waves	(ii) Long Water Waves Conventional Form	(iii) (constant depth) In terms of the Vector Function
Paraday's Law $\nabla \times \tilde{\mathbf{E}} = -\frac{\partial \tilde{\mathbf{B}}}{\partial t}$	Continuity Equation $\frac{1}{h} \frac{\partial \eta}{\partial t} + \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0$	
$\nabla \times \tilde{\mathbf{B}} = \epsilon \mu_0 \frac{\partial \mathbf{E}}{\partial t}$	Linearised Bernoulli Equation $\frac{\partial u}{\partial t} + g \frac{\partial \eta}{\partial x} = 0$ $\frac{\partial v}{\partial t} + g \frac{\partial \eta}{\partial y} = 0$	
$\nabla \cdot \tilde{\mathbf{E}} = 0$	Irrotational Flow $\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} = 0$	
$\nabla \cdot \tilde{\mathbf{B}} = 0$	Horizontal Wave Field $\frac{\partial \eta}{\partial z} = 0$	
where $\tilde{\mathbf{E}}$ = electric field vector $\tilde{\mathbf{B}}$ = magnetic flux density vector ϵ = dielectric constant μ_0 = permeability (constant)	where η = local elev- ation of water surface above the mean level h = mean water depth u and v = horizontal components of water part- icle velocity g = gravitational acceleration see Proudman (1953) page 310	
		where $\tilde{\mathbf{W}} = -\hat{i}v + \hat{j}u$ $\tilde{\xi} = (0, 0, \eta)$
		$\nabla \times \tilde{\mathbf{W}} = -\frac{\partial \tilde{\xi}}{\partial t}$ (1)
		$\nabla \times \tilde{\xi} = \frac{1}{gh} \frac{\partial \tilde{\mathbf{W}}}{\partial t}$ (2)
		$\nabla \cdot \tilde{\mathbf{W}} = 0$ (3)
		$\nabla \cdot \tilde{\xi} = 0$ (4)

Boundary Conditions

The tangential component of \vec{E} is continuous	:	The tangential component of \vec{W} is continuous
The normal component of $\epsilon \vec{E}$ is continuous	:	The normal component of $\frac{\vec{W}}{h}$ is continuous
The tangential and normal components of \vec{B} are continuous	:	The tangential and normal components of $\vec{\xi}$ are continuous

The equivalent parameters in the two systems are

$$\begin{aligned} \vec{E} & \text{ and } \vec{W} \\ \vec{B} & \text{ and } \vec{\xi} \\ \epsilon & \text{ and } \frac{1}{h} \\ \mu_0 & \text{ and } \frac{1}{g} \end{aligned}$$

Furthermore frictional effects can be simulated by having the interior of the microwave cavity partially conducting. It can be shown that this has an effect equivalent to that of introducing a linearised friction term into Bernoulli's equation (Jackson and McKee, 1980)

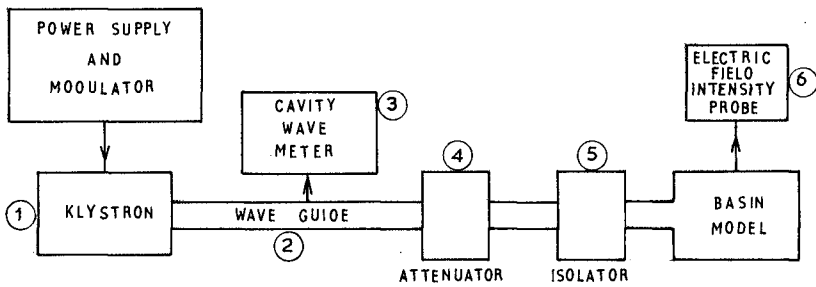

The Microwave Modelling Technique

Although in principle any frequency electromagnetic radiation could be used to model long gravity waves, radiation in the microwave range is of a convenient wave length for model construction. Since vector potential \vec{W} vanishes normal to a reflecting boundary its electromagnetic equivalent the electric field vector \vec{E} must be made to do the same. This is achieved if the boundary is electrically conducting so that the boundaries of the microwave cavity are constructed of highly conductive material such as copper sheet. Various materials such as air, glass and various plastics have dielectric constants which vary over a range of five or more and by using these materials between the various contour intervals, varied bottom topographies can be simulated by a series of step changes in depth as shown in Figure 1.

EXPLODED VIEW OF MICROWAVE CAVITY

FIGURE 1.

SCHEMATIC DIAGRAM OF THE MICROWAVE SET-UP

FIGURE 2.

Figure 2 shows a schematic diagram of typical microwave setup. It might be noted that similar equipment is readily available in most electrical engineering departments of tertiary institutions and the only irregular item would be the cavity model itself. The various items of equipment are briefly described.

1. The Microwave Source generates microwaves with a wavelength of 2.42 to 3.66 cm. Because of the high frequency of these waves (typically 10 GHz) it is impossible to detect them directly, hence they are modulated by a 1 KHz square wave.

2. The wave guide is simply a hollow metal tube of rectangular cross section which conveys the microwaves from the source to the model.

3. The cavity wave meter is a device for accurately determining the wave length of the microwaves using an adjustable resonator cavity. It is a passive device and has negligible effect on the microwave in the wave guide.

4. The attenuator reduces the microwave amplitude to any desired level.

5. The isolator permits microwaves to pass in one direction but dissipates the energy of microwaves travelling in the reverse direction. Therefore microwaves radiating back out the cavity are totally attenuated and do not affect readings within the harbour cavity. The major problem encountered with hydraulic models is thereby eliminated.

6. A probe, consisting of a fine needle approximately 0.3mm diameter and 3mm long, is inserted into the model. A voltage is induced onto the probe which is proportional to the intensity of the electric field at that location. This is equivalent to the instantaneous volume flux of the waves.

The microwave system used for the experiments described in this paper operated in the X band and generated microwaves with a frequency of 9 to 11 G.Hertz and a wave length of approximately 3 cm. This is too small for modelling complex basins but was adequate for the relatively simple geometries examined in the experiments described here. Systems are available for generating microwaves with wave lengths of up to 1m. However, a wave length of 30cm would be adequate for most model studies.

Two further points must be considered when designing a microwave model.

1. The microwave source is an essential point source of radiation; the waves do not propagate down the waveguide as plane waves but rather "bounce" from wall to wall. This has the effect of limiting the wave length that can be used with each size wave guide and the maximum wave length which will propagate down an X band wave guide which is 4.57 cm. (Lance 1964, p.87).

2. It is far simpler to measure the electric field intensity \vec{E} than the magnetic flux density \vec{B} . The hydraulic equivalents are the vector potential \vec{W} and the water surface elevation vector $\vec{\xi}$. However η can easily be calculated once \vec{W} and the wave period are determined.

Experiments

The interactions of long waves with two simple geometries were examined using the microwave analogy and compared with well known theoretical solutions for the same geometries.

FIGURE 3. - EXPERIMENT 1.

Experiment 1

The reflection and transmission characteristics of a long wave normally incident to a step change in water depth were studied. The physical geometry and its microwave equivalent are shown in Figure 3. The water is assumed to be of infinite extent on either side of the step so that reflected waves are only generated at the step. The depth on the shallow side of the step was taken as 0.224 of the depth on the deeper side. Since this is basically a one dimensional problem it was modelled in a length of wave guide. The shallower region was simulated by inserting an acrylic plastic with a relative permittivity of $(0.224)^{-1} = 4.46$ (at 9.0 G.Hertz) into the wave guide, while air was the dielectric on the deeper side of the step. In order to avoid reflections from the end of the acrylic (which must be of finite length) it was tapered to a knife edge over a distance of several wave lengths.

The reflection coefficient for the reflected wave was found to be 0.357 compared with theoretical value of 0.365 (Lamb, 1932) while the transmission coefficient was found to be 1.34 compared with the theoretical value of 1.35. Wave heights determined from the microwave experiment are in close agreement with the theoretical values for long water waves.

Experiment 2

This experiment was similar to the previous experiment except that the shallow region was truncated at a vertical reflective wall as shown in Figure 4. In this case a resonant condition is possible on the shelf if its length is an odd multiple of the quarter wave length of waves travelling in the shallower depth.

The microwave setup is similar to that shown previously except that the shelf region, which is again simulated by the acrylic dielectric is terminated by a conducting end which is normal to the wave guide. A probe was inserted adjacent to the step on the shallow side, and wave heights at the reflecting end wall were determined from measurements of the field intensity (equivalent to the volume flow) at the step. The wave height at the end wall (H_{max}) expressed as a fraction of the incident wave height (H_0) is shown in Figure 5 for a range of wave lengths (L) normalised with respect to the length of the shelf (X). Resonance occurs when $\frac{X}{L} = \frac{1}{4}$ and again agreement between the theoretical wave heights and those deduced from the microwave experiment are in close agreement. Near resonance dissipative effects become significant both in the prototype and the model and the data points depart from the non-dissipative solution which is graphed in Figure 5.

FIGURE 4. - EXPERIMENT 2.

WAVE HEIGHT AS A FUNCTION OF WAVE LENGTH FOR THE GEOMETRY SHOWN IN FIGURE 4

FIGURE 5.

Conclusions

Microwave cavities promise to be a relatively simple and effective means of studying long water waves in semi enclosed basins. Many of the inaccuracies invariably present in conventional hydraulic models can be eliminated in a microwave analogue. The vector potential (the equivalent of the instantaneous wave induced flow) is the most readily measured parameter in a microwave study and in many cases it is this parameter which is of most interest in the prototype. The analogy has been verified for some simple one dimensional geometries, whose behaviour is well known, and the work is being extended to look at more realistic geometries.

If a partially conducting dielectric is used in the model, some microwave energy is dissipated and the effect is exactly equivalent to that of introducing a linear friction term into the equation of motion for the water waves. It should therefore be possible to incorporate frictional effects into the microwave model.

CHAPTER 50

INTERACTIONS OF WAVES WITH SUBMARINE TRENCHES

by Jiin-Jen Lee,¹ Robert M. Ayer,² Wen-Li Chiang³

ABSTRACT

An analysis is presented for the propagation of water waves past a submarine trench of irregular shape. Two dimensional, linearized potential flow is assumed. The fluid domain is divided into two regions along the mouth of the trench. Solutions in each region are expressed in terms of the unknown normal derivative of the potential function along this common boundary with the final solution obtained by matching. Reflection and transmission coefficients are found for various submarine geometries. The accuracy of the technique employed is demonstrated by comparing with previously published results for a rectangular trench. In addition, results from limited laboratory experiments were included for comparison. The result shows that for a particular flow configuration, there exists an infinite number of discrete wave frequencies at which waves are completely transmitted.

INTRODUCTION

A class of problems involving the propagation of water waves in a fluid of variable depth is one in which the depth is constant except for variations over a finite interval. Interest in these problems is largely due to the phenomena associated with the passage of waves over submarine trenches in the ocean and wave propagation across navigational channels, where changes in water depth are commonly the case. A common method employed in the solution of problems involving changes in water depth is that of matching the solution along a geometrical boundary that separates the regions of different depths. Such an approach is found in the work of Bartholomeusz (1958) and Miles (1967). It has also been found by Newman (1965) and Black, et. al. (1971) that for wave propagation over submarine obstacles there exists an infinite set of wavelengths such that the incident wave is totally transmitted.

Lassiter (1972) solved for the transmission and reflection coefficients in the case of monochromatic plane progressive surface waves over a rectangular submarine trench where the water depths before and after the trench are constant but not necessarily equal. Lassiter formulated the problem in terms of complementary variational integrals and solved for the velocity potential by matching the solution along vertical lines before and after the trench.

In this present study, the problem considered is two-dimensional motion of linear periodic water waves over an arbitrarily shaped sub-

marine trench where the water depths before and after the trench are equal and constant. By drawing a horizontal line, the authors have separated the domain into two subregions, namely an infinite rectangular region of constant depth and a finite region of irregular shape representing the trench itself.

An analytic solution for each region is then found explicitly in terms of an unknown velocity distribution along the trench -- constant depth boundary. By superimposing a linear periodic incident wave of specified frequency in the infinite constant depth region, the final solution is obtained by matching the solutions in each subregion along the common boundary.

THEORETICAL CONSIDERATIONS

Let (x,y) constitute a Cartesian coordinate system with $y = 0$ coinciding with the impermeable boundary of the constant depth region as shown in the definition sketch in Fig. 1. Assuming a steady-state solution for the velocity potential in the form of

$$\Phi(x,y;t) = \phi(x,y)e^{-i\sigma t} \quad (1)$$

the potential function $\phi(x,y)$ must satisfy Laplace's equation throughout the fluid domain and the following boundary conditions:

$$\begin{aligned} \frac{\partial \phi}{\partial y} &= \frac{\sigma^2}{g} \phi & \text{on } y = h, \quad -\infty < x < \infty \\ \frac{\partial \phi}{\partial y} &= 0 & \text{on } y = 0, \quad x < 0 \\ \frac{\partial \phi}{\partial y} &= 0 & \text{on } y = 0, \quad x > \ell \\ \frac{\partial \phi}{\partial n} &= 0 & \text{on solid boundary in the trench} \\ \frac{\partial \phi}{\partial y} &= q(x) & \text{on } y = 0, \quad 0 < x < \ell \end{aligned} \quad (2)$$

(the function $q(x)$ is to be determined by matching)

In Eqs. (1) and (2), σ represents the circular frequency, $2\pi/\text{wave period}$; i is the complex number $\sqrt{-1}$.

In order to solve for $\phi(x,y)$ in an efficient manner, the fluid domain is divided into two regions, Region I and Region II, by the common boundary Γ shown in Fig. 1.

The strategy used herein is to solve for $\phi(x,y)$ in each respective region in terms of the unknown $\partial\phi/\partial y$ along the common boundary Γ . Thus, by matching the solutions in each region at Γ , one is able to obtain the final solution.

FIGURE 1. Definition sketch of the trench with regions of consideration.

Region I Solution

The solution for the velocity potential in Region I assuming that the unknown normal derivative of the velocity potential $\partial\phi_I/\partial y$ is equal to $q(x)$ (along $y = 0, 0 < x < l$) has been obtained by Lee and Ayer (1980). This solution can be summarized as follows:

- (1) If $x > x_j$ for all j ,

$$\phi_I(x,y) = \sum_{j=1}^N Q_j \left\{ \frac{\left[e^{ik_r(x-x_j)} - e^{ik_r(x-x_{j-1})} \right]}{k_r^2} \cdot S_r(k_r,y) + \sum_{n=1}^{\infty} \frac{\left[e^{-k_n(x-x_{j-1})} - e^{-k_n(x-x_j)} \right]}{k_n^2} \cdot S_n(k_n,y) \right\} \quad (3)$$

- (2) If $x < x_j$ for all j ,

$$\phi_I(x,y) = \sum_{j=1}^N Q_j \left\{ \frac{\left[e^{-ik_r(x-x_{j-1})} - e^{-ik_r(x-x_j)} \right]}{k_r^2} \cdot S_r(k_r,y) + \sum_{n=1}^{\infty} \frac{\left[e^{k_n(x-x_j)} - e^{k_n(x-x_{j-1})} \right]}{k_n^2} \cdot S_n(k_n,y) \right\} \quad (4)$$

(3) If $x > x_{j-1}$ and $x < x_j$ for some j ,

$$\begin{aligned} \phi_I(x,y) = & \sum_{j=1}^{j-1} Q_j \left\{ \left[\frac{e^{ik_r(x-x_j)} - e^{ik_r(x-x_{j-1})}}{k_r} \right] \cdot S_r(k_r,y) \right. \\ & + \left. \sum_{n=1}^{\infty} \left[\frac{e^{-k_n(x-x_{j-1})} - e^{-k_n(x-x_j)}}{k_n} \right] \cdot S_n(k_n,y) \right\} \\ & + Q_j \left[\frac{1 + \frac{\sigma^2}{g}(y-h)}{\sigma^2/g} - \frac{[e^{ik_r(x-x_{j-1})} + e^{-ik_r(x-x_j)}]}{k_r} \right] \cdot S_r(k_r,y) \\ & + \sum_{n=1}^{\infty} \left[\frac{e^{-k_n(x-x_{j-1})} + e^{k_n(x-x_j)}}{k_n} \right] \cdot S_n(k_n,y) \left. \right] \\ & + \sum_{j+1}^N Q_j \left\{ \left[\frac{e^{-ik_r(x-x_{j-1})} - e^{-ik_r(x-x_j)}}{k_r} \right] \cdot S_r(k_r,y) \right. \\ & + \left. \sum_{n=1}^{\infty} \left[\frac{e^{k_n(x-x_j)} - e^{k_n(x-x_{j-1})}}{k_n} \right] \cdot S_n(k_n,y) \right\} \end{aligned} \quad (5)$$

In Eqs. (3) - (5) the functions S_r and S_n are defined by

$$S_r(k_r,y) = \frac{k_r [\cosh k_r(y-h)] + \sigma^2/g \sinh [k_r(y-h)]}{k_r h \operatorname{sech} k_r h + \sinh k_r h}$$

and

$$S_n(k_n,y) = \frac{k_n [\cos k_n(y-h)] + \sigma^2/g \sin [k_n(y-h)]}{k_n h \sec k_n h + \sin k_n h}$$

The value of k_r and the values of k_n are determined by

$$\frac{\sigma^2}{g} = k_r \tanh (k_r \cdot h)$$

$$\frac{\sigma^2}{g} = -k_n \tan (k_n \cdot h) \quad .$$

The value of Q_j is the average value of $q(x)$ in the j^{th} subinterval whose midpoint is defined as $(x_j,0)$ within the common boundary of the trench mouth.

Region II Solution

Again, the solution for the velocity potential in Region II has the steady-state form

$$\phi_{II}(x,y;t) = \phi_{II}(x,y) e^{-i\sigma t} \quad (6)$$

and the potential ϕ_{II} must satisfy Laplace's equation subject to the boundary condition of $\partial\phi_{II}/\partial n = 0$ along the solid boundary of the trench.

As the trench shape is considered arbitrary it can be conveniently solved by boundary integral method. The potential function along the boundary of the trench can be expressed as follows:

$$\phi_{II}(\vec{x}_j) = \frac{1}{\pi} \int \left[\ln\left(\frac{1}{r}\right) \frac{\partial\phi_{II}}{\partial n} - \phi_{II} \frac{\partial}{\partial n} \ln\left(\frac{1}{r}\right) \right] ds \quad (7)$$

The term $\partial\phi_{II}/\partial n$ in Eq. (7) is zero except along the mouth of the trench which is equal to $q(x)$ according to Eq. (2). This integral equation can be approximated by a matrix equation as used in Raichlen and Lee (1978).

Therefore, the value of ϕ_{II} along the trench mouth can be expressed in terms of the unknown vector, Q_j . This unknown vector Q_j can then be solved by matching the value of $\phi_{II}(x_j)$ and $\phi_I(x_j) + \phi_{in}(x_j)$ (where $\phi_{in}(x_j)$ is a specified potential function of an incident wave along the trench mouth with the coordinate of $(x_j, 0)$).

Once the value of Q_j is obtained, the velocity potential at any position in Region I can be computed by Eqs. (3) - (5) along with the superposition of the incident wave potential.

PRESENTATION AND DISCUSSION OF RESULTS

The effect of the trench on the propagation of waves can be demonstrated most easily by the transmission characteristics. In order to ensure that the present analysis for Region II using the boundary integral method can provide a reliable result, the method is applied to a rectangular trench, where in a separate study, the solution has been obtained in terms of an Eigenfunction expansion, therefore providing a basis for comparison. Figure 2 shows the transmission coefficient, K_t , as a function of the relative wave length. The ordinate is the ratio of the transmitted wave amplitude divided by the incident wave amplitude, while the abscissa is the ratio of the water depth, h , in Region I divided by the incident wave length, λ . The wave length λ is computed from the dispersion relationship, $\lambda = (gT^2/2\pi) \tanh(2\pi h/\lambda)$, where T is the incident wave period.

The present theoretical results (as can be seen from Figure 2) come within 3% of the results of Lee and Ayer (1980). The result of

Figure 2 Transmission coefficient as a function of relative wave length ($h = 4''$, $d = 26\frac{1}{2}''$, $\lambda = 21 \frac{1}{8}''$). — theoretical results of Lee & Ayer (1980), present results.

Lee and Ayer (1980) was obtained by using an analytic solution in Region II. The fact that the present solution is so close to the more exact theory demonstrates that the approximate method used can provide a fairly accurate result. It is seen from Figure 2 that for $h/\lambda > 0.18$, the incident waves are almost fully transmitted. At $h/\lambda = 0.09$, the transmission coefficient is approximately 0.89. To understand the trench effect further, one can compute the value of l/λ at these critical points. At $h/\lambda = 0.18$, it corresponds to $l/\lambda = 0.95$ while at $h/\lambda = 0.09$, it corresponds to $l/\lambda = 0.475$. It appears that for a relatively short trench length, the maximum reduction of transmitted wave occurs as l/λ approaches 0.5. As the wave period is decreased to where l/λ approaches 1, the effect on wave transmission due to the trench is negligible.

As the trench length increases, the effect of the trench on the transmission characteristics of the incident waves becomes more interesting. This is shown in Figure 3. The trench length for this case is three times that shown in Figure 2 with other dimensions held constant. Two theoretical curves, one obtained by the present analysis and the other obtained from Lee and Ayer (1980) are shown for comparison. The experimental data obtained by Lee and Ayer (1980) in a laboratory wave tank of 12 inches wide, 48 feet long and 18 inches deep are also included for comparison. Again, it is seen that the two curves agree very well in every peak and trough (the results are within 3% of each other) for the range of h/λ presented. In the range of $0 < h/\lambda < 0.25$, there are six different wave periods at which waves are fully transmitted. The results indicate that the trench does exert a greater influence on wave transmission characteristics in that the transmission coefficient at $h/\lambda = 0.042$ is only about 0.70. It is also seen that the experimental data in general tend to confirm the theoretical prediction. However, due to experimental errors and the unavoidable wave reflections from both ends of the wave tank, the experimental data show considerable scattering as evident in the figure.

An example for wave transmission over an even longer rectangular trench is shown in Figure 4. The length of the rectangular trench is now four times that shown in Figure 2. Again, the present results using the boundary integral method agree well with the result of Lee and Ayer (1980) further confirming that the method designed for an irregular shaped trench can be used for a trench of rectangular shape. The number of wave periods at which waves are fully transmitted is now increased to nine for the same range of h/λ . For each of the troughs in the response curve, the effect of the trench is further dramatized. For example, at the first trough ($h/\lambda = 0.034$), the transmission coefficient is reduced to 0.68, while at the second trough ($h/\lambda = 0.081$), the transmission coefficient is about 0.84. These are clearly smaller values than those shown in Figure 3.

An example of the transmission of waves over an irregularly shaped trench is presented in Figure 5. The dimension of the trench shape is shown in the insert of the figure. The transmission coefficient is very close to one, showing that the trench does not effect the wave transmission drastically. However, it is clear that there are a number of peaks and troughs in the transmission curve (a similar feature as

Figure 3 Transmission coefficient as a function of relative wave length ($h = 4''$, $d = 26\frac{1}{2}''$, $\lambda = 63\frac{5}{8}''$, — theoretical results of Lee & Ayer (1980), Experimental results of Lee and Ayer (1980), present results using boundary integral method).

Figure 4 Transmission coefficient as a function of relative wave length ($h = 4''$, $d = 26\frac{1}{2}''$, $\lambda = 85''$, — theoretical results of Lee & Ayer (1980), present results using boundary integral method).

Figure 5 Transmission coefficient as a function of relative wave length

that shown in Figures 2 - 5).

CONCLUDING REMARKS

The methods outlined in this paper for analyzing the effect of an arbitrarily shaped trench on the propagation of periodic incident waves has been shown to be quite effective as illustrated by comparison with the solution techniques for a rectangular trench and with experiments. From the results on wave transmission and reflection, it is seen that there exists an infinite number of wave periods at which waves are fully transmitted, and that the effect of the trench on wave transmission is progressively smaller for higher wave frequencies (the larger values of h/λ).

TRANSIENT FINITE-DIFFERENCE TSUNAMI CALCULATIONS

Ove Skovgaard¹ and Ivar G. Jonsson²

ABSTRACT

The applicability of a time-stepping approximate finite difference method is tested for the response of a plane incoming tsunami of small amplitude meeting an idealized island (see Fig 1). The resulting amplitudes are compared with the exact solution, which comes out of solving the linear shallow water wave equation for the area in question. Since this wave equation excludes dissipation (bottom friction) and the Coriolis force, these terms are omitted in the Boussinesq equations, formulated as mass and momentum conservation, which are the bases of the finite difference scheme. Grid size is 1×1 km. The incoming wave is time-harmonic with a period of $T = 480$ s; the (test) solution to the wave equation is thus a truly steady-state solution. The finite difference scheme, however, has a so-called "cold start" and so it is transient in principle. During a time corresponding to three periods, in which disturbances from the open boundaries still have only a small effect on the wave field near the island, the time-series of signals in selected points can define a steady response, though. Considering the inevitable shortcomings of a provisional study like the present, satisfactory agreement with the exact solution is met over the shoal in Fig 1. We have thus a promising starting point for more elaborate studies, comprising new filtering algorithms for the boundaries, tests with real transient input signals, and including non-linearity, bottom friction, and the Coriolis force.

The numerical scheme used is the so-called System 21, developed at the Danish Hydraulic Institute and placed at our disposal for the present study.

1. INTRODUCTION

A seismic sea wave, a so-called tsunami (Japanese for "harbour wave"), consists of a series of waves that approaches the coast with periods usually ranging from 5 to 90 min (Murty, 1977, p 2). The length of these waves is of the order of hundreds of kilometres in the deep ocean, while here their amplitude is usually of the order of a metre. They are therefore difficult to detect from the air or from ships. Near land, however, the tsunami will build up in height due to the decrease in water depth.

¹ Associate Professor, Laboratory of Applied Mathematical Physics (LAMF), Bldg 303, Technical University of Denmark, DK-2800 Lyngby.

² Associate Professor, Institute of Hydrodynamics and Hydraulic Engineering (ISVA), Bldg 115, same address.

At the same time the amplitude can be further amplified because of lateral convergence and reflections. The wave length will be reduced in shallower water.

The final run-up of tsunamis is a highly non-linear phenomenon. In this preliminary report of our study, however, we shall investigate the modification of the tsunami wave over that area near the coast, where linear theory can be used, ie excluding the final run-up.

A tsunami can also be generated by non-seismic causes, such as landslides and nuclear explosions. Therefore Murty (1977, p 1) cites the more general definition by van Dorn: "Tsunami is the Japanese name for the gravity wave system formed in the sea following any large-scale, short-duration disturbance of the free surface." Most of the current knowledge about tsunamis is excellently reviewed in the above-mentioned book by T S Murty.

We will calculate the transformation of a small, time-harmonic, and plane incident wave caused by an idealized island of circular cylindrical form, situated on a paraboloidal shoal in an infinite ocean of constant depth, see Fig 1.

Fig 1. Sketch of the idealized island on a paraboloidal shoal;
a) vertical, b) horizontal.

The water depths h are

$$\begin{aligned} h &= \alpha r^2 & \text{for } r_a \leq r \leq r_b & \text{ and } 0^\circ \leq \theta < 360^\circ \\ h &= h_b (= \alpha r_b^2) & \text{for } r_b \leq r < \infty & \text{ and } 0^\circ \leq \theta < 360^\circ \end{aligned} \quad (1.1)$$

Shoreline radius is $r_a = 10$ km, outer radius of shoal is $r_b = 30$ km, and depth $h_b = 4,000$ m. Thus shoreline depth is $h_a = h_b (r_a/r_b)^2 = 4,000/9 \approx 444$ m. (Generally subscript a denotes a value at the shoreline, and subscript b denotes a value at the outer boundary of the shoal.) The factor of proportionality α in (1.1) becomes $\alpha = 4/9 \times 10^{-5} \text{ m}^{-1}$.

This type of island is seemingly accepted as being representative of a "Pacific island" (Homma, 1950). Experiments have been performed by Williams and Kartha (1969).

The present paper is a sequel to papers by Jonsson et al (1976) (hereafter referred to as paper I), where we restricted the presentation to the wave field at the shoreline, including some shallow water refraction calculations, and by Jonsson and Skovgaard (1979) (hereafter referred to as paper II), where we looked at the wave field over the shoal for wave periods up to 240 s, including a few intermediate depth refraction calculations for the shoreline.

The purpose of the present paper is twofold. Firstly to investigate the exact wave field (amplitudes and phase angles) outside the shoal, ie to study the "disturbance" out in the deep ocean due to the presence of the island. Secondly, we will use a finite difference (FD) method (FD in space and time) to see how accurate such an approximate solution is in a small region around the island and the shoal. For both cases the diffraction contours will be determined corresponding to small, time-harmonic and plane incident waves, and only for one wave period $T = 480$ s. This period is above the shallow water limit for the island, which for $h/L = 1/20$ gives $T \approx 410$ s. Notice that for larger islands $T = 480$ s corresponds to a greater period (fixed ratio between wave length L and radius).

Earlier FD approaches for tsunami wave problems are described by Camfield (1980), and finite-element (FE) methods for such problems are reviewed in Sklarz et al (1979).

Tsunami waves are basically transient, but we have performed this preliminary study with "unphysical" periodic waves in order to assess the feasibility of transient FD models for "small" regions with long open boundaries. Our ultimate goal is to test the FD model for a short transient Gaussian-like pulse, where we can also construct the "exact" test solution, by superposition of time-harmonic exact solutions.

2. ASSUMPTIONS AND DEFINITIONS

The incident surface gravity waves are assumed to be plane, time-harmonic, and of small amplitude. The Coriolis force is neglected, which is justified for the considered higher end of the tsunami frequency range. The island sides are assumed fully reflecting. Non-linear effects (including dissipation) will be neglected, although they can easily be included in the approximate solution, see Sect 4.

The diffraction of simple time-harmonic and very long surface gravity waves (in practice $h/L < 0.05$) over a gently sloping sea bed is governed by the linearized long-wave equation

$$\nabla \cdot (h \nabla \eta) + h k^2 \eta = 0 \quad (2.1)$$

where ∇ is the horizontal gradient operator ($\partial/\partial x$, $\partial/\partial y$) or ($\partial/\partial r$, $r^{-1}\partial/\partial\theta$), $k = 2\pi/L$ is the wave number, $L = cT$ is the wave length, c is the phase speed (2.6), $h = h(r, \theta)$ the water depth, and $\eta = \eta(r, \theta)$ is the (complex) surface wave amplitude. r and θ are defined in Fig 1.

Note that the instantaneous complex surface elevation is $\eta \exp(-i\omega t)$, where i is the imaginary unit, $\omega = 2\pi/T$ is the (constant) angular fre-

quency, and t is time. The instantaneous real surface elevation ζ is thus

$$\zeta = \text{Re} \{ \eta \exp(-i\omega t) \} \quad (2.2)$$

We define the real surface amplitude $A = A(r, \theta)$ and phase angle $\varphi = \varphi(r, \theta)$ (also real) by

$$\eta = A \exp(i\varphi) \quad (2.3)$$

ie we have from (2.2)

$$\zeta = A \cos(\varphi - \omega t) \quad (2.4)$$

Phase angle φ is still determined less an arbitrary constant. This is remedied by demanding that φ be zero in the far field at $\theta = \pm 90^\circ$ for $t = 0$. In other words, φ is the phase angle at that instant, when the undisturbed wave crest passes through the centre of the island.

The real amplitude of the incoming wave is called A_i . In the amplitude graphs we have depicted the relative amplitudes A/A_i .

The incident waves have the surface elevation

$$\zeta_i = A_i \cos(kx - \omega t) \quad (2.5)$$

For very long waves there is no dispersion and the phase and group speeds (c and c_g) are equal and given by

$$c = c_g = \sqrt{gh} \quad (2.6)$$

in which g is the gravity acceleration.

For calculations involving (2.1) we use the acronym SWT which stands for Shallow Water Theory.

Equation (2.1) is correct to first order in both wave amplitude and bed slope, see eg Jonsson and Brink-Kjær (1973).

The diffraction of mildly non-linear surface gravity waves (transient or periodic) over a gently sloping sea bed is governed by the Boussinesq equations, in which the vertical velocity is supposed to increase linearly from zero at the bed to a maximum at the surface, in two horizontal space variables and time. The Boussinesq equations are formulated as mass and momentum conservation laws (integrated over depth). In terms of volume discharge or depth-integrated velocities the governing equations read (see Abbott et al, 1978, p 177, (4) - (6)):

$$\frac{\partial \zeta}{\partial t} + \frac{\partial p}{\partial x} + \frac{\partial q}{\partial y} = 0 \quad (2.7)$$

$$\frac{\partial p}{\partial t} + \frac{\partial}{\partial x} \left(\frac{p^2}{h^*} \right) + \frac{\partial}{\partial y} \left(\frac{pq}{h^*} \right) + gh^* \frac{\partial \zeta}{\partial x} = \frac{1}{2} hh^* \left[\frac{\partial^3}{\partial x^2 \partial t} \left(\frac{hp}{h^*} \right) + \frac{\partial^3}{\partial x \partial y \partial t} \left(\frac{hq}{h^*} \right) \right] \quad (2.8)$$

$$- \frac{1}{6} h^2 h^* \left[\frac{\partial^3}{\partial x^2 \partial t} \left(\frac{p}{h^*} \right) + \frac{\partial^3}{\partial x \partial y \partial t} \left(\frac{q}{h^*} \right) \right]$$

$$\frac{\partial q}{\partial t} + \frac{\partial}{\partial y} \left(\frac{q^2}{h^*} \right) + \frac{\partial}{\partial x} \left(\frac{pq}{h^*} \right) + gh^* \frac{\partial \zeta}{\partial y} = \frac{1}{2} hh^* \left[\frac{\partial^3}{\partial y^2 \partial t} \left(\frac{hq}{h^*} \right) + \frac{\partial^3}{\partial x \partial y \partial t} \left(\frac{hp}{h^*} \right) \right] \quad (2.9)$$

$$- \frac{1}{6} h^2 h^* \left[\frac{\partial^3}{\partial y^2 \partial t} \left(\frac{q}{h^*} \right) + \frac{\partial^3}{\partial x \partial y \partial t} \left(\frac{p}{h^*} \right) \right]$$

where $h^* \equiv h + \zeta$, ie the instantaneous total depth, p is the x -component of the volume discharge, and q is the y -component of the volume discharge. x and y are defined in Fig 1. For the long, small amplitude waves considered in this preliminary study the third derivative terms (the right-hand sides) in (2.8) and (2.9) are almost negligible, as they represent the deviation of the pressure distribution from the hydrostatic pressure.

In (2.8) and (2.9) we have for the time being neglected the Coriolis force and dissipative effects (bottom friction).

3. THE EXACT SHALLOW WATER THEORY (SWT) SOLUTION

In order to calculate the total wave field in any point of the area we must solve the partial differential equation (2.1), the shallow water wave equation. The boundary conditions are full reflection at the island ($r = r_a$) and Sommerfeld's radiation condition at infinity (for the scattered part of the wave field). See paper I for details.

Because of the rotational symmetry of the bathymetry we can apply the method of separation of variables.

Over the shoal ($r_a \leq r \leq r_b$) the solution for the complex amplitude is

$$\eta = \sum_{n=0}^{\infty} R_n(r) \cos(n\theta) \quad 0 \leq \theta < 360^\circ \quad (3.1)$$

where the functions $R_n(r)$, ($n = 0, 1, 2, \dots$), are solutions to linear two-point boundary value problems. These ordinary differential equations were solved by Homma (1950), see paper I, pp 473-476, for details. Angle θ is defined in Fig 1.

Outside the shoal ($r \geq r_b$) the wave field is the sum of an incident and a scattered wave field, ie

$$\eta = \eta_i + \eta_{sc} \quad (3.2)$$

with η_i rewritten as

$$\eta_i = A_i \sum_{n=0}^{\infty} \epsilon_n i^n J_n(k_b r) \cos(n\theta) \quad (3.3)$$

and

$$\eta_{sc} = \sum_{n=0}^{\infty} C_n H_n^{(1)}(k_b r) \cos(n\theta) \quad (3.4)$$

In these equations A_i is the amplitude (real) of the incoming wave, ϵ_n is the Neumann factor (ie $\epsilon_n = 1$ for $n = 0$, and $\epsilon_n = 2$ for $n \neq 0$), i is the imaginary unit, J_n are Bessel functions of n th order and first kind, $k_b = 2\pi/L_b$, the wave number for $r \geq r_b$, C_n are integration constants, and $H_n^{(1)}$ are Hankel functions of the n th order and first kind.

At $r = r_b$ there is continuity in η and in its first derivative with respect to r . Using the former condition we find from (3.1) and (3.2) for the determination of C_n

$$C_n = \frac{1}{H_n(\tau)} \left[(R_n)_{r=r_b} - A_i \epsilon_n i^n J_n(\tau) \right] \quad n = 0, 1, 2, \dots \quad (3.5)$$

where we have dropped the superscript (1) on H , and further $\tau \equiv k_b r_b$. Functions $(R_n)_{r=r_b}$ are determined by Homma's (1950) solution (see (3.19) in paper I). Inserting the results in (3.5) yields

$$C_n = \frac{A_i \epsilon_n i^n}{H_n} \left[\frac{i \left[\rho^{\alpha_n} \frac{\alpha_n - 1}{\alpha_n + 1} \rho^{-\alpha_n} \right] \frac{2}{\pi} \rho^{\alpha_n}}{\rho^{\alpha_n} \left[(1 - \alpha_n) H_n + \tau H_n' \right] \frac{\alpha_n - 1}{\alpha_n + 1} \left[\tau H_n' + (1 + \alpha_n) H_n \right]} - J_n \right] \quad n = 0, 1, 2, \dots \quad (3.6)$$

where $\rho \equiv r_b/r_a$, $\alpha_n \equiv \sqrt{1 + n^2 - \tau^2}$, and we have dropped the argument τ of the Hankel function and its derivative (ie here $H_n^{(1)}(k_b r)/d(k_b r)_{r=r_b}$).

The complete solution outside the shoal hereafter emerges from (3.2) - (3.4) with (3.6) inserted in the latter equation.

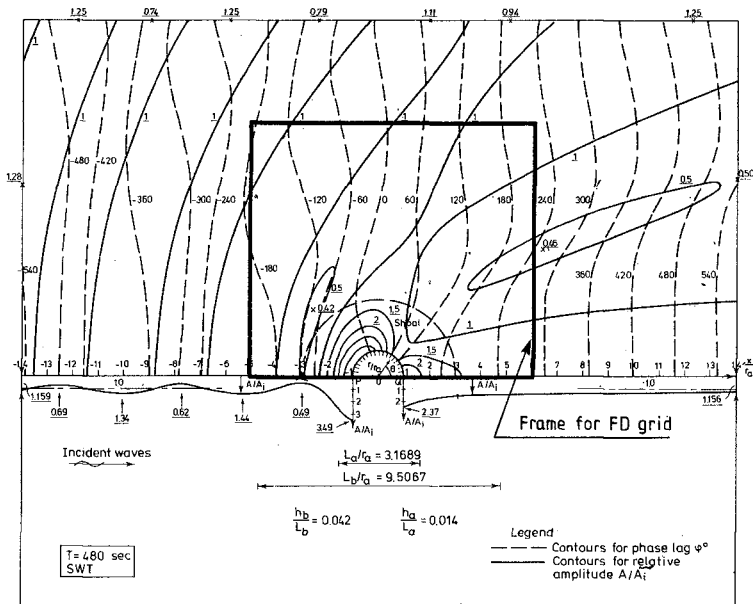

Fig 2. Contours for relative amplitude A/A_1 and phase angle ϕ over the shoal and on constant water depth outside. Solution of (2.1) (ie SWT) for $T = 480$ s. The intervals between A/A_1 -curves are 0.5 and between ϕ -curves they are 60° . Underscored numbers are A/A_1 . The rectangular frame (the very thick line) will be discussed in Sect 4.

A solution for $T = 480$ s is depicted in Fig 2 showing contours for relative amplitude A/A_1 and phase lag φ^0 over the shoal and on constant water depth outside. The solution is presented for $|x/r_a| \leq 14$ and $y/r_a \leq 14$. Maxima and minima are indicated along the boundaries of the depicted area. It appears that even some wave lengths away from the island the incident wave is quite perturbed. A similar figure to Fig 2 has been constructed for a smaller wave period ($T = 240$ s), see Skovgaard and Jonsson (1980), Fig 2.

An important application of the very accurate ("exact") solution in this section is that it can serve as a check for more general numerical schemes (see Sect 4). In order to facilitate such a check a test solution is tabulated in Table 1. In the table relative amplitude A/A_1 and phase angle φ are given for one period ($T = 480$ s), for seven values of azimuth θ ($= 0^\circ, 30^\circ, 60^\circ, 90^\circ, 120^\circ, 150^\circ, \text{ and } 180^\circ$), and for four values of relative distance, r/r_a ($= 1, 3, 9, \text{ and } 27$). The table is an extension of paper I, Table 2a, which stopped at the base of the shoal ($r/r_a = 3$). Also another period is chosen here, $T = 480$ s, instead of $T = 410.47 \dots$ s.

For the practical application of the finite Fourier series for the diffraction solution (3.1) or (3.2) to (3.4) it is useful to know how many terms one needs in order to obtain a given accuracy. This information can be even more important when we discuss whether a certain solution approach at all can be applied in a certain period range or in a certain space region of r and θ .

In paper I (3.24) we introduced the number of terms n_{\max} necessary to obtain a prescribed relative accuracy ϵ s ($0 < \epsilon \ll 1$), which we here define by the relation

$$\left| \sum_{n=0}^{n_{\max}} R_n(r) \cos(n\theta) - \text{exact solution} \right| < \epsilon \times A_1 \tag{3.7}$$

or

$$\left| (A/A_1)_{\text{approximate}} - (A/A_1)_{\text{exact}} \right| < \epsilon \tag{3.8}$$

This simple accuracy criterion, which directly controls the amplitudes and neglects the phases, is selected because of its simplicity. The exact solutions to (3.1) or (3.2) to (3.4) were constructed by continuing the summation until the last term of $|R_n/A_1|$ was less than ϵ s squared.

In Fig 3 for $T = 480$ s (using the shallow water wave equation (2.1) and $\theta = 0^\circ$ (ie along the positive part of the x-axis) n_{\max} vs x/r_a is shown for $1 \leq x/r_a \leq 28$ and for ϵ s = 10^{-2} , 10^{-4} , and 10^{-8} . (ϵ s = 10^{-d} is normally referred to as two times d-places decimal accuracy.)

Similar figures have been constructed for other values of θ , and from these figures we can conclude that Fig 3 is in practice valid for arbitrary θ . For a fixed r/r_a the difference between n_{\max} in Fig 2 and the n_{\max} in figures for other θ was never larger than 2.

The general conclusion is that n_{\max} increases monotonously with x/r_a . For ϵ s constant the variation is nearly linear from the island and outwards. From Fig 3 we can further conclude that for points on the shoal, n_{\max} is only increased by one or two (depending on ϵ s) when we "move"

Table 1. Diffraction solution for the wave field over the shoal, and on constant water depth. The values of phase angle ϕ are chosen in the interval $0^\circ \leq \phi < 360^\circ$. Integers in parentheses indicate powers of 10 by which the following numbers are to be multiplied.

Using SWT, (2.1), $T = 480$ s.

Fig 3. The necessary number of terms n_{max} in the Fourier series (SWT solution) vs x/r_a for $T = 480$ s, $1 \leq x/r_a \leq 28$ (θ of shadow region), and $\epsilon \approx 10^{-2}$, 10^{-4} , and 10^{-8} .

from the island to the outer boundary of the shoal. If ϵ is decreased from 10^{-2} to 10^{-4} only up to five additional terms are needed in the solution series for x/r_a less than 28 and for $T = 480$ s (Fig 3). If ϵ is again squared (ie $\epsilon = 10^{-8}$) only up to seven additional terms are needed. (Notice that for $\theta = 0^\circ$ all the $\cos(n\theta)$ factors in (3.7) are equal to one.)

Similar figures to Fig 3 have been constructed for other values of wave period T and from these figures we have found that if we use x/L (instead of x/r_a) as abscissa, Fig 3 becomes in practice valid for an arbitrary SWT wave period (or wave length L):

Inspection of the calculated phases revealed that the approximation errors for these basically followed the same dependence on wave period T and on the horizontal coordinates r and θ as depicted for A/A_1 in Fig 3.

The conclusion is that n_{max} increases with decreasing period (shorter waves). Far away from the island the increase is rapid. We can further summarize that for all periods in the SWT range, and for all points as far as at a distance of, say $r/r_a \approx 10$, only up to 20 terms of the series solution are needed for $\epsilon \gtrsim 10^{-4}$. As far as at a distance of, say $r/r_a \approx 30$ only up to 40 terms are needed for $\epsilon \gtrsim 10^{-4}$. For solutions in any point on the shoal only up to eight terms are needed in the SWT period range for $\epsilon \gtrsim 10^{-4}$.

4. THE FINITE-DIFFERENCE (FD) SOLUTION

The time-dependent vertically integrated mass and momentum equations (2.7) - (2.9) are approximated by a third order alternating direction implicit (ADI) finite difference (FD) method with space- and time-staggered grids. The program or the modelling system (known as System 21) is described in detail in Abbott et al (1978) and (1979).

The program is designed primarily to cover physical situations with relatively short open boundaries, in contrast to the island cases, where we have radiation out of the computational area along all outer boundaries. For given incident waves the program allows the radiated waves to pass through the open boundaries, assuming that the radiated and the incident waves are of small amplitude and are propagating perpendicularly to the boundary. In the tsunami cases with isolated islands, the open boundaries are normally situated over the deeper part of the oceans where the waves in practice fulfil the first assumption (small amplitude).

The second assumption (waves propagating perpendicularly to the opening) can be well fulfilled in for instance a harbour resonance study. This has been demonstrated in a number of cases, some of which were reported by Abbott et al (1978). In the present case, however, the assumption can at best be approximately fulfilled at some of the boundaries, and the computations will give errors in the computed surface elevations at the open boundaries. These errors will have the appearance of waves reflected from the open boundaries into the region under investigation. If the reflected waves have a large angle of incidence at a physical open boundary the best one can do with the present system is probably to close the boundary in question and put a strong dissipation over a few grid lines along it, thereby simulating that most of the wave energy which enters the boundary region is radiated out. Another - much more expensive - possibility is to make the computational area so large that reflection from "critical" boundaries is delayed sufficiently. It is immediately seen from Fig 2 that the top boundary is the most critical one. See also Sect 6.

The open boundaries mean that we have exposed the system to quite a nasty test, trying to reproduce the solution in Sect 3 using time-stepping calculations. The input wave in the FD system is time-harmonic, but as the calculations are started from a so-called "cold state" they are transient in principle.

The island with the shoal and a fraction of the surrounding ocean (the area within the thick frame in Fig 2) has been covered by a grid, see Fig 4. The grid spacing Δx and Δy is the same in both directions. Δx or Δy denotes the distance between two consecutive grid points for the water level or for the bathymetry; due to the staggered grid the distance between the flux grid points and the elevation grid points is $\frac{1}{2}(\Delta x)$ in the x-direction and $\frac{1}{2}(\Delta y)$ in the y-direction. In this paper we have used only one grid-size ($\Delta x = \Delta y = 1$ km) and only one frame, which covers an area of (109×99) km², or 110 grid points ($J = 0, 1, \dots, 109$) in the x-direction and 100 grid points ($K = 0, 1, \dots, 99$) in the y-direction, see Fig 4. The model is closed along the symmetry line (x-axis), here $K = \frac{1}{2}\Delta y$. The model is open along $J = 0$, where we prescribe a given time-harmonic "incident" surface elevation of small amplitude. Similarly the model is open along $J = 109$, where we prescribe an "incident" wave of

Fig 4. The numerical model bathymetry of the area within the thick frame in Fig 2. The intervals between the depth contours are 1 km. The coordinates for $P_1, P_2, P_3, Q_1, Q_2, Q_3, R_1,$ and R_2 are defined in Table 2.

zero amplitude. Along $K = 99$ (the most critical boundary) we have closed the model and put some dissipation along the boundary. The origin O of the x - y coordinates in Fig 1 (centre of the island) has the coordinates $(J, K) = (50\frac{1}{2}, \frac{1}{2})$.

Due to the simple rectangular discretization of the island (see Fig 4) and to a smaller extent of the shoal we can only get an approximation of the diffraction pattern over the shoal, especially so at the shoreline.

The most direct representation of the solution is time-series plots of relative surface elevations (ie calculated surface elevations divided by A_i , see (2.5)) in characteristic points of the modelled area. We have selected eight such points ($P_1, P_2, P_3, Q_1, Q_2, Q_3, R_1,$ and R_2), see Fig 4 and Table 2. The eight relative surface elevations are given in Figs 5, 6, 7, and 8 for the one incident wave period tested, $T = 480$ s.

In this provisional stage of the project we have run the model only, a rather short time, viz three wave periods or 3×480 s = 1440 s. This integration time was determined by an estimate of the propagation time for a small disturbance entering the model at P_3 (see Fig 4), travelling along the negative x -axis to point P (see Fig 1), continuing along the border of the island to the y -axis, further along the y -axis up to the

Figs 5-6-7-8. Relative surface elevation vs time t ($0 \leq t \leq 1440s = 3 \times 480 s$) for 8 points ($P_1, P_2, P_3, Q_1, Q_2, Q_3, R_1,$ and R_2) within the FD grid, see Fig 4. Period is $T = 480 s$. Exact max/min SWT values of A/A_1 from Sect 3 also shown.

most critical "closed" dissipative boundary and back to the outer boundary of the shoal. Using SWT (2.6) this travel time can be estimated as

$$t_s = \int \frac{ds}{c} = \frac{20,000 + 2 \times 68,000}{\sqrt{9.80665 \times 4000}} + \frac{2 \times \ln 3}{\sqrt{9.80665 \times 4/9 \times 10^{-5}}} + \frac{1/2 \pi \times 10,000}{\sqrt{9.80665 \times 444.4 \dots}} \tag{4.1}$$

$$t_s \approx 788 + 333 + 238 = \underline{1359 s} . \tag{4.2}$$

s being a local coordinate along the travel path for the disturbance. If the disturbance is allowed to travel further from the outer boundary of the shoal to the island (along the y -axis) we have $t_s \approx 1359 + 166 = 1525 s$.

	P_1	P_2	P_3	Q_1	Q_2	Q_3	R_1	R_2
J	40	20	0	61	80	109	50	50
K	1	1	1	1	1	1	11	31
x/r_a	-1.05	-3.05	-5.05	1.05	2.95	5.95	-0.05	-0.05
y/r_a	0.05	0.05	0.05	0.05	0.05	0.05	1.05	3.05

Table 2. Coordinates for the points $P_1, P_2, P_3, Q_1, Q_2, Q_3, R_1,$ and R_2 in Fig 4.

We can conclude that for $t_s = 1440$ s ($= 3 \times 480$ s) the wave field over the shoal cannot be seriously distorted by our "crude" closing of the boundary along $K = 99$. On the other hand we must admit that the complete time-harmonic diffraction pattern over the shoal has not reached an equilibrium state within the three wave periods we have simulated, but it is promising to observe how close we come to the eight exact maximum/minimum SWT values of A/A_1 from Sect 3. (To ensure linearity, which is assumed in the exact solutions, we have used a very small value of A_1 .)

5. COMPARISON BETWEEN EXACT (SWT) AND APPROXIMATE (FD) SOLUTIONS

In the preceding section we compared in Figs 5-8 with the exact SWT values of A/A_1 , for eight characteristic points within the FD frame in Figs 2 and 4. A more convincing approach is to compare the contours for the relative amplitude A/A_1 from the exact (SWT) solution with the FD approximations. Details of the exact SWT wave field over the shoal and in its immediate vicinity are for $T = 480$ s presented in Fig 9 which is an enlarged version of the central part of Fig 2.

The contour lines in Fig 10 were found in the following way. All results from the FD calculations were stored on a file, and for 960 s $\leq t \leq 1440$ s (or $2 \times T \leq t \leq 3 \times T$) the maximum value ζ_{max} was found in each grid point and stored on a second file. For the same time interval the minimum value ζ_{min} was found in each grid point and stored on a third file. The relative amplitude A/A_1 was then calculated in each grid point as $A/A_1 \equiv \frac{1}{2}(\zeta_{max} - \zeta_{min})/A_1$ and stored on a fourth file. From the latter file the contour plot for A/A_1 in Fig 10 was prepared, and A/A_1 in 14 selected points along two half-circles ($r/r_a = 1.05$ and $3, \theta^{\circ} = 0, 30, \dots, 180$) was plotted against the exact SWT solution for $r/r_a = 1.05$ and $3, 0 \leq \theta \leq 180^{\circ}$, see Fig 11.

Remembering that in this provisional stage of the project we are interested only in the diffraction pattern over the shoal we can by comparison of Figs 9 and 10 (which are drawn to the same scale) conclude that the FD approximation is able to model all essential features of the diffraction pattern both in the illuminated region and in the shadow region.

If we look at the comparison in Fig 11 we notice an excellent agreement along the outer boundary of the shoal and a reasonably good agreement along the half-circle very near the island. It is natural that the

crude discretization of the island will give the strongest modification very near the island and can be detected far less at the outer boundary of the shoal.

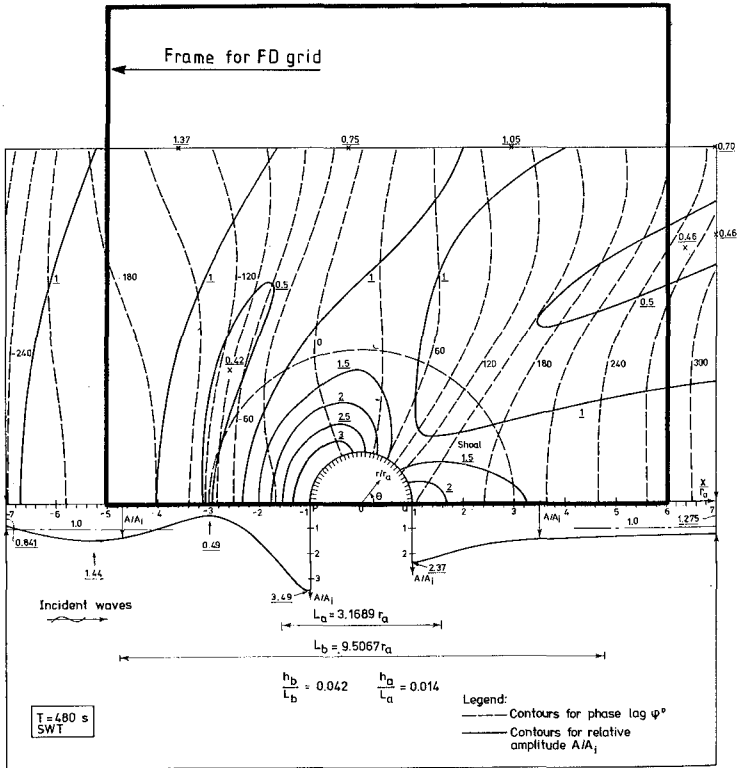

Fig 9. Contours for relative amplitude A/A_1 and phase angle ϕ over the shoal and on constant water depth outside. Solution of (2.1) (ie SWT) for $T = 480$ s. The intervals between A/A_1 -curves are 0.5 and between ϕ -curves they are 30° . Underscored numbers are A/A_1 . The thick frame refers to the FD area covered in Fig 10, see also Fig 2.

Fig 10. Contours for relative amplitude A/A_i over the shoal and on constant water depth outside. FD solution of (2.7-2.9) for periodic incident waves ($T = 480$ s) of small amplitude. The intervals between A/A_i -curves are 0.5. Same horizontal scale as in Fig 9.

Fig 11. Relative amplitude A/A_i vs azimuth θ° along two half-circles, $r/r_a = 1.05$ and 3. Full curves from exact solution of (2.1) (ie SWT) for $T = 480$ s, and dotted points from FD solution of (2.7 - 2.9) for periodic incident waves ($T = 480$ s) of small amplitude.

6. FUTURE WORK

In this preliminary study we have constructed and used the exact time-harmonic SWT solution (Sect 3) as reference solution for the periodic small amplitude approximate FD solution. In the subsequent more refined work we may construct and use the exact time-harmonic intermediate depth theory (IDT) solution (see Skovgaard and Jonsson (1980), Sect 3.2) as reference solution for the periodic small amplitude FD solution.

The FD model will be improved by construction and analysis of filtering algorithms which take account of the direction of the waves in relation to the boundary and which work for arbitrary Courant numbers $Cr \equiv c\Delta t/\Delta x$, Δt being the full time step in the FD-model.

We are also going to construct a more realistic "exact" test solution corresponding to a transient input (a Gaussian pulse, for instance). With this transient input we will expose the FD model to a more realistic test than the periodic test in this paper.

For this transient FD solution we will construct associated FD solutions which separately will include the Coriolis force and friction forces, thereby being able to show the effects of these two forces.

Finally the FD model will be used on some existing islands in the Pacific Ocean exposed to some "recorded" incident tsunami waves, thereby including the non-linear part of the FD model in the very shallow regions around the islands.

ACKNOWLEDGEMENTS

The Computational Hydraulic Centre, Danish Hydraulic Institute, is acknowledged for letting us use their versatile System 21 for the finite difference computations, including their many service programs.

The Joint Institute for Marine and Atmospheric Research (JIMAR), University of Hawaii, is acknowledged for the stimulating hospitality offered one of the authors (I.G. Jonsson) in the spring 1980 in connection with this study.

AN INVESTIGATION OF WAVE SHELTERING BY ISLANDS

BY

S. V. Hsiao¹, J. F. Vesecky², and O. H. Shemdin¹

SUMMARY

The West Coast Experiment, a meso-scale oceanographic experiment, was conducted from February to April, 1977, off the coast of Southern California. The wave data measured by an air-borne synthetic aperture radar (SAR) and a shore-based high frequency (HF) radar on March 25, 1977, are used to study the sheltering effect of islands on waves propagating towards shore. The comparisons between wave directional spectra offshore, in the vicinity of islands, and nearshore show that islands play a significant role in determining the near shore wave climate. The data show clearly the "shadow" and "window" effects. An investigation of waves coming out of the "shadow" region indicates that nonlinear wave-wave energy transfer is the likely mechanism responsible for producing such waves.

I. Introduction

The study of waves around islands was one of the objectives of the West Coast Experiment (Shemdin, 1980) conducted from February to April, 1977 off the coast of Southern California. To this objective, waves were measured by synthetic aperture radar (SAR), high frequency (HF) radar, wave rider buoy, and pressure sensor array. The use of radar made it possible to obtain wave measurements over a large area in a short period under various weather conditions. The Jet Propulsion Laboratory (JPL) L-band SAR was flown aboard a NASA CV-990 airplane at 8500m altitude and 240 m/sec speed. The flight paths relevant to this study are shown in Figure 1. The HF radar was operated from the coast south of San Clemente, California. This radar measured the energy of waves at 77m wave length (corresponding to .142 Hz frequency in deep water) moving directly toward or away from the radar site. The extent of HF radar observations is also shown in Figure 1. Wave measurements on March 25, 1977, are used in this study because all the above mentioned sensors were operating on that day and the dominant wave length match the wave-length HF radar observed. The wave spectra measured by pressure sensor array and wave rider buoy show that the primary peak at Torrey Pines and the secondary peak northwest of San Clemente Island are both near the wave frequency (.142 Hz) HF radar observed. The effects of islands on the directional properties of waves at this frequency are examined in this paper. The mechanisms which could generate waves coming out of the shadow of San Clemente Island are then discussed.

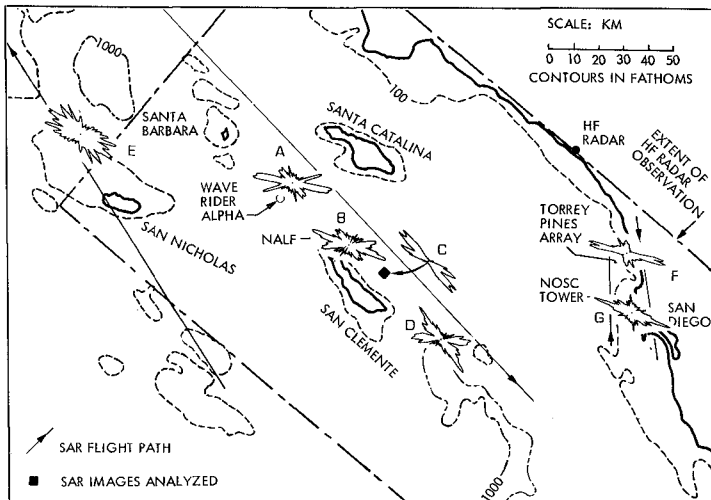

FIGURE 1. The West Coast Experiment area. Also shown are the normalized directional distributions of 80m waves measured by the L-band SAR on March 25, 1977, and the extent of HF radar observation.

II. THE SYNTHETIC APERTURE RADAR OBSERVATIONS

The synthetic aperture radar is an airborne or spaceborne microwave active sensing system. It uses its own power to transmit electromagnetic waves as the illumination. Therefore it has all weather and day/night capability. The SAR takes the advantage of the motion of aircraft or spacecraft to form a long "synthetic" antenna thus increases its azimuth (along track) resolution of the images. For the detail of the SAR system, see Brown and Porcello (1969).

The ability of SAR to image the ocean surface wave patterns have been demonstrated by Brown et al. (1973), Elachi (1976), and others. But the systematic measurements and comparisons of SAR and conventional surface wave instruments were not done until the Marineland Experiment (Shemdin, 1980). The Marineland Experiment was conducted during December, 1975, off the Florida Atlantic coast. The simultaneous wave measurements by SAR, pitch-and-roll buoy, and pressure sensor were compared (Shemdin et al., 1978; Hsiao, 1978; and McLeish et al., 1980). It was found that the dominant wave frequencies and parameterized wave directional distributions can be detected by SAR accurately (see Table 1). The comparisons of wave measurements by SAR, pressure sensor array, CERC coastal radar, and aerial photos during the West Coast Experiment (Mattie et al., 1980) show similar results (see Figure 2). Furthermore, the wave directional measurements obtained during the West Coast Experiment by SAR and a pressure sensor array were compared by Pawka et al. (1980). The results show generally favorable agreement at the primary mode of the normalized directional distribution. A comparison for 6.9 sec waves is shown in Figure 3. Although the SAR imaging mechanism of ocean surface waves is not yet fully understood, these SAR-ground truth comparisons show that the SAR can provide useful information on the dominant wave frequency and the wave directional distributions.

The Jet Propulsion Laboratory (JPL) L-band SAR operates at a frequency of 1.2 GHz corresponding to a wave length of 25 cm (see Brown et al., 1976). The signals returned from the ocean surface were recorded on the signal film by optical recorders on board the airplane. The signal film was then optically processed to form the raw image of the ocean surface. The resolution of this system is estimated to be 25m. The image was further digitized and geometrically corrected for the slant range distortion. Finally two-dimensional fast Fourier transforms were taken at selected locations to obtain two-dimensional wave number spectra. Examples of a geometrically corrected image and its 2-d FFT are shown in Figure 4. This image was taken near Torrey Pines, California at 1154 PST, March 25, 1977.

The directional distributions at 80m wavelength, which is the spectral peak on March 25, 1977, were plotted by tracing along circles centered at the origin with the radius $k=2\pi/80m$ on the 2-d spectra. The normalized directional distributions under this study are shown in Figure 1 for a few carefully selected locations. The 180° ambiguity can be resolved by assuming that all waves were propagating shoreward.

TABLE 1. SAR - SURFACE TRUTH COMPARISONS, MARINELAND EXPERIMENT
(after Hsiao, 1978)

(a) Comparisons of Peak Frequency and Peak Direction

FIGURE 3. Comparison of directional distribution of 6.9 sec waves estimated by SAR and pressure sensor array, March 25, 1977, near Torrey Pines, California (After Pawka et al., 1980)

(a) (b)

FIGURE 4. (a) Geometric corrected SAR image near Torrey Pines, California, March 25, 1977. Each small division is approximately 54m. (b) 2 - d FFT of $f_1(a)$, the wave number scale in each small division is $\frac{1}{54} \approx 0.0057 \text{ m}^{-1}$.

In Figure 1, the directional distribution at E, northwest of San Nicholas Island, is relatively broad. There is no island sheltering effect on this distribution. The directional distributions at A and B show the shadow effects of Santa Barbara and San Nicholas Islands. The directional distributions at C and D show significant shadow effects of San Clemente Islands. Comparing the distributions at C and E, only the waves parallel to San Clemente Island are detected at C, the rest of the waves are blocked by the Island. The distribution at D also shows the wave components detected at C. In addition it shows the wave components passing by the southern tip of San Clemente Island. The gap between the two groups of waves shows the shadow of San Clemente Island clearly. At F and G, the directional peaks both point to the window between San Clemente and Santa Catalina Islands, thus clearly showing the line of penetration of wave energy. These measurements indicate that a broad directional wave distribution offshore can be significantly different behind the islands. The distributions become narrow and multi-peaked because of the shadow effects. The distributions nearshore have peak directions aligned with the window between islands.

III. THE HIGH FREQUENCY RADAR OBSERVATIONS

The HF radar was operated in a synthetic aperture mode with a frequency of 1.9 MHz. This radar measures, by the first-order Bragg resonance, the energy of waves having a wavelength (77m) equal to one half the radar wavelength (154m) moving radially toward or away from the radar (Teague et al., 1975). This ocean wavelength corresponds to the spectral peak of waves measured on March 25, 1977. It has been shown experimentally that the HF radar echo energy is proportional to the resonant ocean wave energy (Teague et al., 1975). During this experiment, the 1 MW peak power LORAN-A transmitter at San Mateo Point, California was used as the signal source. The receiving antenna was synthesized by driving a van at a fixed speed along nearly straight stretches of interstate highway 5. This radar system has an azimuth resolution of 4° and a range resolution of 5 km.

The result of HF radar observation on March 25, 1977, is shown in Figure 5. The 5 dB contours show relative wave energy of 77m wavelength which moves radially toward the radar site. The shadow region of San Clemente Island and the window between Santa Catalina and San Clemente Islands are clearly shown in this Figure.

IV. WAVE TRANSFORMATION MECHANISMS IN THE VICINITY OF ISLANDS

In order to interpret the significance of the results, in Figure 6 the wave energy is plotted versus the distance from radar for two radial lines. One passes through the center of San Clemente Island and the other passes through the center of the window between San Clemente and Santa Catalina Islands. The energy level shown is the average of 10° azimuth angles and 10 km range distances. The steep drop of wave energy at San Clemente Island again shows the shadow effects. After passing San Clemente Island both curves of wave energy show approximately linear increases of the same slope in dB scale, or exponential increase in linear scale.

FIGURE 5. HF radar observations of 77m waves approaching the radar site. The contours show relative wave energy on dB scale.

FIGURE 6. Relative wave energy level of 77m waves approaching HF radar site, averaged over 10° azimuth angles and 10 km range distances.

These results suggest that there must be local wave generation. The wind measurements over the West Coast Experiment area show the wind speed to be too small to contribute to the generation of 77m waves during this period. However, no reliable measurement were recorded in the wave generation area.

Despite the reduced level of wave energy behind San Clemente Island, the energy level is still significantly higher than the noise level. The contributions to the measured energy in the shadow of the Island from the waves passing by the northern and southern tips of the Island through the antenna side lobes are considered. The energy average is taken over 10° azimuth along the center of the shadow which is 19° wide. The effect of antenna side lobes is found to be negligible in this average region. The question regarding the mechanism by which waves gain energy in the shadow arises.

Since the water depth increases abruptly near San Clemente Island, the refraction of 77m waves is limited to narrow regions at the northern and southern tips of the Island. The same is true for the diffraction of waves. Thus the waves observed behind the Island in the center of the shadow region cannot be explained by either refraction or diffraction. The HF radar also measures the waves going away from the radar. The energy of such outgoing waves near San Clemente Island was ~ 25 dB. The reflection of these waves by San Clemente Island has some contributions to the observed energy in the shadow region. But even assuming 100% reflection the reflected wave energy is too weak to account for the observed energy, (see Figure 6). By adding the wind generated energy estimated from Figure 6 to the energy level, there is still 7.5 dB difference to be explained.

The SAR data show that behind San Clemente Island there are waves propagating parallel to the direction of the Island. The transfer of energy from these waves to those toward the radar site through nonlinear interaction is suspected to be the source of the observed waves. The computation of the nonlinear energy transfer involves the evaluation of the Boltzmann integral describing by Hasselmann (1963). It is beyond the scope of this paper and is being pursued separately.

V. CONCLUSION

The use of SAR and HF radar made it possible to obtain an overall view of wave conditions off the coast of Southern California. The study of waves at about 80m wavelength on March 25, 1977, gives the following conclusions:

1. The shadow of San Clemente Island and the window between Santa Catalina and San Clemente Islands significantly modify the deep water wave spectrum as it propagates towards the coast.
2. The nonlinear transfer is the most likely source of the observed wave energy moving out of the shadow of San Clemente Island.
3. Remote sensing by SAR and HF radar provides useful information for the study of waves around islands.

The Dissipation of Wave Energy by Turbulence

1

by

Yu Kuang-ming*

I. Abstract

This paper first gives a brief review of the existing research works on the laws governing the dissipation of wave energy by turbulence. Starting from the general theory of turbulent motion and the writer's suggestion in regard to the mixing length of water particles in two-dimensional flow and making use of the principle of dimensional analysis and the trochidal wave theory, a formula has been derived to compute the mean dissipation per unit time and per unit horizontal area of wave energy due to turbulence. The formula takes the horizontal and vertical gradients of both the horizontal and vertical velocity fields into consideration. Coefficient in the formula has been determined through laboratory experiments.

2. A Brief Review of Former Research Works

It is not far since the presentation of the suggestion that fluid turbulence plays an important role also in wave motion. The scientific researches on the laws governing the dissipation of wave energy by turbulence were started in the late forties of this century, but only in and after the fifties of this century had more research works been gradually done.

There are generally three different methods to study the problem of turbulent dissipation of wave energy. The first one bases solely on the principle of dimensional analysis, making use of the π -theorem. The advantages of this method lie in the simplicity of the process of derivation, but the selection of the independent variables and the determination of the formula patterns are to a certain degree arbitrary. The typical example applying this method of analysis can be found in literature (1).

* Hydraulics Engineer, Nanjing Scientific Research Institute of Hydraulic Engineering, 34 Huchukuan, Nanjing 210024, China.

2

The second method utilizes the theoretical relationship of viscous dissipation of wave energy, replacing the coefficient of kinematic viscosity by means of the coefficient of kinematic eddy viscosity and then finds the functional relationship between the latter coefficient and the relevant physical quantities characterizing wave motion, applying the principle of dimensional analysis. The virtues and defects of this method are basically the same as that of the first method. Its typical example of application can be found in literature (2).

The third method makes use of the theory of turbulent flow. This method proceeds from the internal structure of the current, gives a deeper insight into the essence of the phenomenon and therefore has been widely used. Nevertheless, the existing theories take only the vertical gradients of the horizontal velocity field into consideration. But in wave motion, the magnitudes of the horizontal and vertical gradients of both the horizontal and vertical velocity fields are of the same order. They should be considered simultaneously. Literatures (3) and (4) can be referred to as the examples of application of this method.

The discrepancies among the results of the existing research works are very great. For instance, according to ЖУКОВЕЦ (5), the average rate of energy dissipation of wave motion due to turbulence is 108 times as great as that computed by means of the formula suggested by КРЫЛОВ (1). Similarly, if one uses the results of ШУЛЕЙКИН (6) and ДОБРЮКЛОВСКИЙ (3), the calculated values of this quantity will be several times to nearly one hundred times as great as that of КРЫЛОВ for flat waves and steep waves respectively.

3. Theoretical Analysis

For two-dimensional turbulent flow, one may assume (7), (8)

$$\left. \begin{aligned} \tau_{xy} &= \rho \varepsilon \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right) \\ \tau_{xx} &= -\bar{C}_1^2 + 2\rho \varepsilon \frac{\partial u}{\partial x} \\ \tau_{yy} &= -\bar{C}_2^2 + 2\rho \varepsilon \frac{\partial v}{\partial y} \end{aligned} \right\} (1)$$

in which: τ_{xy} --- y component of the turbulent stress acting on a surface element, the outward normal of which is parallel to the X -axis;

τ_{xx} and τ_{yy} have a similar meaning;

ρ --- mass density of liquid;

ε --- coefficient of kinematic eddy viscosity;

U, V ---- component velocities averaged over time in the X and Y directions;

C_1, C_2 ---- constantes;

Referring to Prandtl's suggestion (8), in the case of two-dimensional flow, one may put

$$\varepsilon = l^2 |F| \quad (2)$$

Where

$$F^2 = 2 \left(\frac{\partial U}{\partial X} \right)^2 + 2 \left(\frac{\partial V}{\partial Y} \right)^2 + \left(\frac{\partial V}{\partial X} + \frac{\partial U}{\partial Y} \right)^2 \quad (3)$$

l is the mixing length of fluid particles.

According to the trochoidal wave theory of deep water (7), the Cartesian coordinates of water particles are:

$$\left. \begin{aligned} X &= a + \frac{1}{2} h e^{Kb} \sin \varphi \\ Y &= b - \frac{1}{2} h e^{Kb} \cos \varphi \end{aligned} \right\} \quad (4)$$

where: $\varphi = Ka + \sigma t$ $K = \frac{2\pi}{\lambda}$ $\sigma = \frac{2\pi}{T}$;

λ ---- wave length;

T ---- wave period;

t ---- time;

h ---- wave height;

a, b ---- the Lagrangian coordinates of a water particle, $b=0$ at free surface;

e ---- base of the natural logarithm;

X, Y ---- the horizontal and vertical coordinates of water particle (a, b) at time t ; X -axis coincidea with the central line of water surface and its positive direction is opposite to that of wave propagation; Y -axis is vertical and positive upwards. It passes wave trough at $t=0$.

Differentiating Eq. (4) with respect to t yields

$$\left. \begin{aligned} U &= \frac{\partial X}{\partial t} = \frac{1}{2} h \sigma e^{Kb} \cos \varphi = -\sigma(Y-b) \\ V &= \frac{\partial Y}{\partial t} = \frac{1}{2} h \sigma e^{Kb} \sin \varphi = \sigma(X-a) \end{aligned} \right\} \quad (5)$$

Differentiating Eqs.(4) and (5) with respect to X and Y successaively and simplifying the resulting equations gives

$$\left. \begin{aligned} \frac{\partial U}{\partial X} &= \frac{-\sigma K_1 \sin \varphi}{1 - K_1^2} , & \frac{\partial U}{\partial Y} &= \frac{\sigma K_1 (K_1 + \cos \varphi)}{1 - K_1^2} \\ \frac{\partial V}{\partial X} &= \frac{-\sigma K_1 (K_1 - \cos \varphi)}{1 - K_1^2} , & \frac{\partial V}{\partial Y} &= \frac{\sigma K_1 \sin \varphi}{1 - K_1^2} \end{aligned} \right\} \quad (6)$$

in which

4

Hence
$$\left. \begin{aligned} R_1 &= \frac{\pi h}{\lambda} e^{kb} \\ F^2 &= \frac{4\sigma^2 R_1^2}{(1-R_1^2)^2} \\ |F| &= \frac{2\sigma R_1}{1-R_1^2} \end{aligned} \right\} \quad (7)$$

Substituting Eqs. (2), (6) and (7) into Eq. (1) and rearranging the results, one can obtain

$$\left. \begin{aligned} \tau_{xy} &= \frac{4PR^2\sigma^2 R_1^2 \cos\phi}{(1-R_1^2)^2} \\ \tau_{xx} &= -C_1^2 - \frac{4PR^2\sigma^2 R_1 \sin\phi}{(1-R_1^2)^2} \\ \tau_{yy} &= -C_2^2 + \frac{4PR^2\sigma^2 R_1 \sin\phi}{(1-R_1^2)^2} \end{aligned} \right\} \quad (8)$$

Based on the theory of turbulent flow (9), the energy loss ψ of turbulent motion per unit time and per unit liquid volume is

$$\psi = \tau_{xx} \frac{\partial v}{\partial x} + \tau_{yy} \frac{\partial v}{\partial y} + \tau_{xy} \left(\frac{\partial v}{\partial x} + \frac{\partial v}{\partial y} \right) \quad (9)$$

Substituting Eq. (6) and (8) into Eq. (9) yields

$$\psi = \frac{8P^2\sigma^3 R_1^3}{(1-R_1^2)^3} + (C_1^2 - C_2^2) \frac{\sigma R_1 \sin\phi}{1-R_1^2} \quad (10)$$

If one imagines two vertical planes to be drawn at unit crest width apart, parallel to the direction of wave propagation and extended from water surface to bottom, the total turbulent dissipation E_λ per unit time and per wave length of the fluid between these planes is

$$E_\lambda = \iint \psi dx dy \quad (11)$$

According to the rule of changing of variables (10), it follows immediately that

$$\iint \psi dx dy = \iint \psi \left| \frac{D(x,y)}{D(a,b)} \right| da db \quad (12)$$

in which $\left| \frac{D(x,y)}{D(a,b)} \right|$ is the functional determinant of x, y with respect to a, b .

Differentiating Eq. (4) with respect to a and b successively, substituting the results into the expression of $\left| \frac{D(x,y)}{D(a,b)} \right|$ and simplifying leads to

$$\left| \frac{D(x,y)}{D(a,b)} \right| = 1 - R_1^2 \quad (13)$$

From Eqs. (10)-(13) it may be seen that

$$E_\lambda = 8P^2\sigma^3 \int_{-\infty}^0 \frac{R_1^3}{(1-R_1^2)^2} \left[\int_{a_\lambda=0}^{a_\lambda=\lambda} l^2 da \right] db \quad (14)$$

In two-dimensional flow, the writer suggests that

$$l = l \left(F, \frac{\partial F}{\partial x}, \frac{\partial F}{\partial y} \right) \quad (15)$$

In accordance with the principle of dimensional analysis, putting

$$l = C F^{\beta_1} \left(\frac{\partial F}{\partial x} \right)^{\beta_2} \left(\frac{\partial F}{\partial y} \right)^{\beta_3}$$

where C is a dimensionless constant, one obtains

$$\beta_1 = 1, \quad \beta_2 + \beta_3 = -1$$

Thus

$$l = 2 \left| \frac{\alpha F^2}{\frac{\partial F^2}{\partial Y}} \left[\frac{\frac{\partial F^2}{\partial X}}{\frac{\partial F^2}{\partial Y}} \right] \beta_2 \right| \quad (16)$$

Differentiating Eq. (7) with respect to X and Y respectively and substituting the result into Eq. (16) gives

$$l = \left| \frac{\alpha(1-R_1^2)^2}{K(1+R_1^2)(1+R_1 \cos \phi)} \left[\frac{-R_1 \sin \phi}{1+R_1 \cos \phi} \right] \beta_2 \right| \quad (17)$$

β_2 is determined from the following conditions: at bottom ($R_1=0$), $l=0$; at water surface ($b=0$), $l=h$. Based on these conditions, one may put $\beta_2=1$. Hence,

$$l^2 = \frac{\alpha^2 R_1^2 (1-R_1^2)^4 \sin^2 \phi}{K^2 (1+R_1^2)^2 (1+R_1 \cos \phi)^4} \quad (18)$$

Setting X equal to λ and 0 successively in the first part of Eq. (14) and subtracting yields

$$\lambda = a_{x=\lambda} - a_{x=0} + \frac{1}{2} h e^{Kb} [\sin(Ka_{x=\lambda} + \phi t) - \sin(Ka_{x=0} + \phi t)] \quad (19)$$

Evidently, $a_{x=\lambda} - a_{x=0} = \lambda$ is a solution satisfying Eq. (19). Utilizing this relationship and resolving rational fraction into simpler partial fractions, one gets from Eq. (18) by integration

$$\int_{a_{x=0}}^{a_{x=\lambda}} l^2 da = \frac{\pi \alpha^2 R_1^2 (1-R_1^2)^{3/2}}{K^3 (1+R_1^2)^2} \quad (20)$$

Substituting Eq. (20) into Eq. (14) and then integrating, neglecting the minor terms and applying the relationship $\phi = CK$ (c is wave celerity), one finds the average dissipation E_T of wave energy due to turbulence per unit time and per unit horizontal area as follows:

$$E_T = \frac{E_\lambda}{\lambda} = \frac{4}{5} \rho \alpha^2 C^3 \left(\frac{\pi h}{\lambda} \right)^5 \left[1 - \frac{15}{14} \left(\frac{\pi h}{\lambda} \right)^2 \right] \quad (21)$$

4. Experimental Results

In order to find the value of the constant α in Eq. (21), experiments were conducted in hydraulic laboratory. The ratios of water depths to wave lengths were controlled in these experiments in such a manner that the condition of deep water wave was fulfilled and thus the dissipation due to bottom friction may not enter.

The wave tank is 62.10 m long, 0.80m wide and 1.80m deep and has glass panels on both sides throughout its length. It is provided with an end slag mound of slope 1:10 to avoid wave reflection. Two wave gauges of resistance type were used. They were placed along the center line of the tank in measuring sections I and 2 which were 18.00m apart. The equation of balance of wave energy between sections I and 2 is

$$E_1 - E_2 = L(E_T + E_\mu + E_q + E_w) \quad (22)$$

where

6

E_1, E_2 --- the average quantity of energy transmitted by waves per unit time and per unit crest width in the direction of wave propagation through sections I and 2 respectively;

E_{ν} --- rate of dissipation due to fluid viscosity, negligible in comparison with that of turbulent dissipation;

E_a --- the average dissipation per unit time and per unit horizontal area in the boundary surfaces between air and liquid when wave propagates in calm air;

E_w --- the average dissipation per unit time per unit horizontal area caused by the friction of the side walls of the wave tank;

L --- horizontal distance between sections I and 2, $L=18.00m$;

In accordance with the trochoidal wave theory, it is well known that

$$\left. \begin{aligned} E_1 &= \frac{\rho g h_1^2 C}{16} \left(1 - \frac{\pi^2 h_1^2}{2\lambda^2}\right) \\ E_2 &= \frac{\rho g h_2^2 C}{16} \left(1 - \frac{\pi^2 h_2^2}{2\lambda^2}\right) \end{aligned} \right\} \quad (23)$$

in which h_1 and h_2 are the wave heights in sections I and 2 respectively, and g is the acceleration of gravity. E_a is calculated by means of ШУЛЕЙКИНС formula (6), which was derived on the basis of wind tunnel tests.

$$E_a = \bar{X} \rho' \frac{A \alpha^2}{T} \quad (24)$$

where ρ' is the density of air and \bar{X} is a dimensionless coefficient. As for the value of E_w , Hunt's result (II) is applied.

$$E_w = \frac{\rho g}{4B} \sqrt{\frac{\pi \mu}{\rho T}} h^2 \quad (25)$$

where B is the width of the wave tank and μ is the dynamic viscosity of water.

From Eqs. (21)-(25), the value of α^2 can be computed with the help of the measuring data. The result of computation is shown in Table I.

From Table I, the mean value of α^2 can be calculated to be $\bar{\alpha}^2 = .0376$, its standard deviation $\sigma = \sqrt{\frac{E(\alpha^2 - \bar{\alpha}^2)^2}{B}} = .0209$ and its coefficient of variation $C_v = 55.5\%$

Substituting $\bar{\alpha}^2$ into Eq. (21) yields finally

$$E_T = \frac{3}{100} \rho C^3 \left(\frac{\pi h}{\lambda}\right)^5 \left[1 - \frac{15}{14} \left(\frac{\pi h}{\lambda}\right)^2\right] \quad (26)$$

5. Conclusions

Three methods of studying the problem of energy dissipation of wave motion due to turbulence have been reviewed and their advantages and disadvantages briefly discussed.

It seems more properly to approach the subject by making use of the theory of turbulent flow.

The importance of considering simultaneously the horizontal and vertical gradients of both the horizontal and vertical velocity fields have been pointed out. An analytical formula, i.e., the Eq. (26), has been derived theoretically, with the coefficient in it determined experimentally, which can be used to compute the rate of turbulent dissipation of wave energy.

Appendix 2 Notation

- a, b ---- Lagrangian coordinates of liquid particles, $b = 0$ at free surface
- B ---- width of wave tank
- c ---- wave celerity
- c_1, c_2 ---- constants
- c ---- coefficient of variation
- D ---- symbol, $\left| \frac{D(x, y)}{D(a, b)} \right|$ is the functional determinant of X, Y with respect to a, b
- e ---- base of the natural logarithm
- E_1, E_2 ---- average quantity of energy transmitted by waves per unit time and per unit crest width in the direction of wave propagation through sections I and 2 respectively
- E_a ---- average dissipation per unit time and per unit horizontal area in the boundary surface between air and liquid when wave propagates in calm air
- E_λ ---- turbulent dissipation of energy per unit time, per unit crest width and per wave length of the liquid volume extended from water surface to bottom
- $E_T = E_\lambda / \lambda$
- E_μ ---- rate of dissipation due to fluid viscosity
- E_w ---- average dissipation per unit time and per unit horizontal area caused by the friction of the side walls of a wave tank
- F ---- quantity defined by Eq.(3)
- g ---- acceleration of gravity
- h, h_1, h_2 ---- wave heights
- $K = \frac{2\pi}{\lambda}$ ---- wave number
- $k_0 = \frac{\pi h}{\lambda} e^{kb}$
- l ---- mixing length of fluid particles
- L ---- horizontal distance between wave gauge stations
- t ---- time

- T ---- wave period
 u ---- component velocity in X direction
 v ---- component velocity in Y direction
 X, Y ---- Cartesian coordinates
 \bar{X} ---- dimensionless coefficient
 $\alpha, \beta_1, \beta_2, \beta_3$ ---- dimensionless constants
 ξ ---- coefficient of kinematic eddy viscosity
 λ ---- wave length
 μ ---- coefficient of dynamic viscosity
 $\pi = 3.142$
 ρ ---- mass density of liquid
 ρ' ---- mass density of air
 σ ---- radian frequency ($= \frac{2\pi}{T}$); standard deviation
 τ_{xy} ---- Y component of turbulent stress acting on a surface element, the outward normal of which is parallel to X -axis
 τ_{xx}, τ_{yy} ---- similar in meaning to τ_{xy}
 $\Phi = Ka + \sigma t$, Eq.(4)
 ψ ---- energy loss of turbulent motion per unit time and per unit liquid volume

BEACH CUSPS AT POINT REYES AND DRAKES BAY BEACHES, CALIFORNIA

by

R. G. Dean¹ and E. M. Maurmeyer²INTRODUCTION

Beach cusps, fairly common and periodic features along many shorelines have been the focus of numerous investigations. The primary efforts have been directed toward (1) determining a causative mechanism for their formation; (2) describing qualitatively the associated water motions and sediment transport; and (3) developing a predictive relationship for their spacing. As in other problems in nearshore dynamics (e.g. rip currents), it may be that there are various valid explanations for different occurrences of beach cusps. In addition to satisfying scientific curiosity, an improved qualitative and quantitative understanding of beach cusp mechanisms would contribute substantially to swash zone dynamics and to nearshore hydrodynamics and sediment transport in general.

This paper describes a series of measurements of beach cusps and associated parameters carried out at Point Reyes and Drakes Bay beaches in northern California during the summers of 1977-1979. An attempt to idealize the beach cusp topography and the resulting swash hydromechanics led to a possible relationship between beach cusp spacing and swash parameters in which the spacing is linearly related to maximum swash excursion.

PREVIOUS INVESTIGATIONS

Early attempts at establishing causative mechanisms for beach cusp initiation and development focused on erosion and/or deposition by swash and backwash processes (Shaler, 1895; Johnson, 1910; Smith and Dolan, 1960; Otvos, 1964; Russell and McIntire, 1965; Gorycki, 1973). Several investigators (Palmer, 1834; Lane, 1888; Johnson, 1910) noted that conditions conducive for cusp formation include parallel wave approach, although others (Evans, 1938; Otvos, 1964) observed cusps forming by oblique wave approach. Branner (1900) and Dalrymple and Lanan (1976) noted that cusps may form by intersecting wave trains. Cusp formation associated with the escape of ponded water from a ridge or other barrier on the berm or backshore has been observed and documented by Jefferson (1899, 1903), Evans (1938), Dubois (1978), and Sallenger (1979). Following Ursell's (1952) popularization of edge waves, recent investigations (Galvin, 1964; Bowen and Inman, 1969; Komar, 1973; Guza and Inman, 1975; Sallenger, 1979) have attributed both the initiation and spacing of cusps to the action of edge waves.

AREA OF STUDY

The Point Reyes peninsula is located approximately 50 km north of San Francisco, California (Figure 1). The orientations of the two beaches studied and their sediment characteristics result in markedly different beach morphologies.

Figure 1. Location Map, Point Reyes and Drakes Bay Beaches, California.

Point Reyes Beach

Point Reyes Beach trends north-northeast and is exposed to the direct action of waves generated in the Pacific Ocean (Figure 2). The

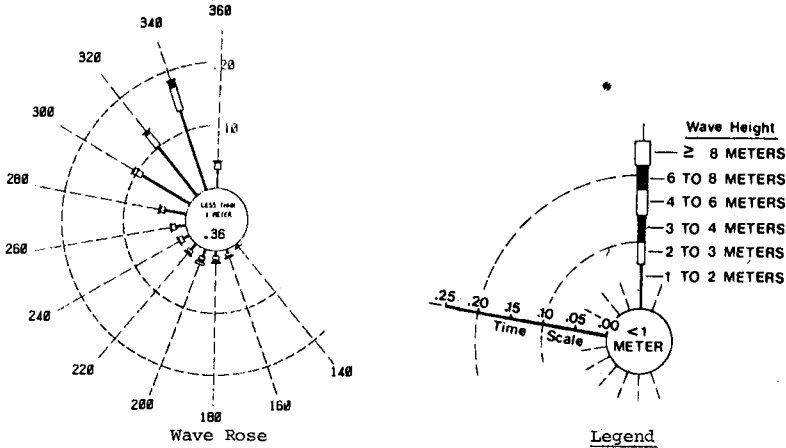

Figure 2. Annual Deep Water Wave Rose, Offshore Point Reyes Area. Combined Sea and Swell, Station 3. (Meteorological International Incorporated, 1977).

beach morphology reflects the highly variable waves through a series of "summer" and "winter" berm terraces, with the uppermost berm approximately 4 m above mean sea level. During the summer of 1977, three terraces each with beach cusps, were present (Figure 3). The beach face is fairly steep with an average slope of 1:10, and beach sediments consist of coarse sand with a mean diameter of approximately 0.8 mm. P. D. Trask and his co-workers (1955a, 1955b, 1956, 1959, 1961) have studied the geological characteristics and cusp formations of the Point Reyes beaches.

Figure 3. Point Reyes Beach, California, August 1977, Showing Three Cusped Berm Terraces.

Drakes Bay Beach

The beach along Drakes Bay is located approximately 6 km southeast of the Point Reyes beach, and is sheltered from the direct attack of high waves from the north and north-northwest. This beach and its southern extension have been studied by Yasso (1965) and identified as a hooked or crenulate bay which is associated with and dependent on sheltering by and diffraction around the Point Reyes headland. As a result of this sheltering, there is only one berm present, with a maximum elevation of approximately 1 m above mean sea level (Figure 4). The average beach face slope is 1:25; and the beach is composed of fine sand having a mean diameter of 0.2 mm.

Figure 4. Drakes Bay Beach, California, July, 1979.

FIELD STUDIES

The observed and measured field data include beach cusp circulation and sediment transport patterns, sediment characteristics, statistics of intercusp spacing, plane table surveys of beach cusps, observations of wave heights and wave periods, and measurements of swash velocities and excursions. Cusp formation on a planar beach was documented during one trip:

Beach Cusp Circulation Patterns

For most of the cases which were observed in the field, beach cusps were already established and thus the observed circulation patterns relate more to the development and maintenance of these features than to their initial formation. In all cases where cusps were present, it was evident that the waves were causing vigorous sediment transport on the beach cusps, with a net circulation landward on the horns (Figure 5a) and seaward in the bays (Figure 5b). This is the same pattern reported by Johnson (1910), Bagnold (1940), O'Brien (1978) and Longuet-Higgins and Parkin (1962), but opposite to that noted by Kuenen (1948). An additional characteristic which to our knowledge has not been reported in the literature (although M. P. O'Brien had recorded this in his field notes on beach cusps in 1930) is that in cases of most effective beach cusp development, the wave and swash period are nearly equal; this equivalence contributes strongly to the net water circulation noted above. This mechanism is illustrated schematically in Figure 6 and described as follows: Waves breaking at the base of the horns cause a strong uprush on these features; however, during the upward excursion, the lateral (longshore) beach gradient causes the trajectories of the water particles to be directed toward the bays. The water accumulates in and flows seaward through the bays. In cases where the swash period is nearly coincident with the wave period, the backrush flow interferes destructively with the succeeding uprush at the embayment positions of the cusps. In some cases, this effect is so complete that following the uprush on the horn, no water will be left on the horn whereas a fairly narrow zone of water (say one-eighth of the cusp spacing in width) will be flowing seaward with a depth on the order of 15-30 cm as shown at Point Reyes Beach in Figure 7. The net result is a dominance of uprush on the horns with the backrush concentrated through the embayments thereby interfering destructively with the next potential uprush. Of substantial relevance to later discussions, is that the swash and wave period do not need to be precisely synchronous since the backrush occurs over a greater time period than the uprush (due to the toll that friction has taken on these velocities) and any dominance of return flow through the embayments will reinforce this net circulation. A "finely tuned" system is thus not required. As discussed in the next paragraphs, this net water circulation pattern is closely related to the maintenance and development of the beach cusp morphology.

Figure 7. Narrow Zone of Seaward Flow in Cusp Bay, Point Reyes Beach, California, July 1978. Water Depth is on the Order of 15-30 cm.

Sediment Transport Patterns

The sediment transport patterns can be discussed best in the context of the swash characteristics for a planar beach. The swash is two-dimensional with the uprush velocities being higher than the backrush velocities due to friction. Percolation may also play an important role in this inequality on highly permeable beaches. In fact it is these features which result in the positive beach face slope. The uprush transports sediment landward thereby increasing the slope and the backrush transports sediment seaward reducing the beach face slope. The resulting beach face slope is therefore in a state of dynamic equilibrium changing slightly with each uprush and backrush.

As noted previously, the effect of the longshore slopes associated with beach cusps is to concentrate the uprush on the horns and to channel the backrush through the embayments. The result is a steeper slope on the horns since there is little or no destructive backrush to transport sediment seaward. In the embayments, the backrush inequality is greatly augmented by flow from the horns and, as noted, by the reduction of uprush by the local interference with the succeeding wave crest. The results are steeper horn and milder embayment slopes. The equilibrating mechanism that limits the slopes of the horns and bays is the lateral transport of sediment by the water circulation pattern presented in Figure 6. Thus, at equilibrium, the lateral slope from the horns to the embayments and the associated water transport are just sufficient to transport that sediment carried up the horns by the local dominance of uprush. On a smaller scale, the turbulence associated with the uprush plays a role in moderating the "sharpness" of the contours on the horns.

Sediment Characteristics

As noted previously, the mean grain diameter of the sand comprising Point Reyes Beach is approximately 0.8 mm, whereas sand at Drakes Bay

Beach is much finer, with a mean grain size of 0.2 mm. These values are in reasonable accord with those found by Trask and Johnson (1955), Trask, Johnson and Scott (1959) and Trask and Snow (1961). The latter reference found the average diameters at Point Reyes Beach and Drakes Beach to be 0.58 and 0.19 mm, respectively. As shown in Figures 8 and 9, the sand characteristics of cusp horns and bays at each beach did not differ greatly. This is contrary to the findings of several investigators (King, 1972; Komar, 1973; Williams, 1973), who noted that material comprising cusp horns is generally quite coarser than material in the bays. However, in a laboratory study of beach cusps, Flemming (1964) found no significant size sorting between cusp horns and bays. Russell and McIntire (1965) suggest that size variations are most pronounced during the "juvenile" stage but that the contrast diminishes as cusps continue to develop.

Intercusp Spacing

The apparent regularity of spacing between cusps is of particular interest and has been documented by numerous investigators (Shaler, 1895; Kuenen, 1948; King, 1972; and Komar, 1973). Detailed measurements by others (Jefferson, 1903; Evans, 1938) have shown that intercusp spacing often is not so uniform as perceived. Johnson (1919) and Russell and McIntire (1965) suggest that spacing is irregular during the early stages of cusp formation and becomes more uniform as cusps continue to develop.

Intercusp spacings at Point Reyes and Drakes Bay beaches were measured during the summers of 1977 and 1979, and are summarized in Table I. Figures 10 and 11 present sample histograms of spacing between active beach cusps at Point Reyes and Drakes Bay Beaches, respectively.

TABLE I
SPACING CHARACTERISTICS OF BEACH CUSPS AT
POINT REYES AND DRAKES BAY BEACHES

Location	Berm Level	Year	No. of Cusps	Average Spacing (m)	Standard Deviation of Spacing (m)
Point Reyes South Beach	Upper	1977	11	62.0	8.8
	Upper	1979	10	61.6	9.5
	Mid	1977	15	41.4	7.2
	Mid (Active)	1979	21	42.8	7.9
	Lower (Active)	1977	30	27.9	2.5
Drakes Beach	Only One Berm Present	1977	31	29.8	5.2
		1979	26	23.2	4.5

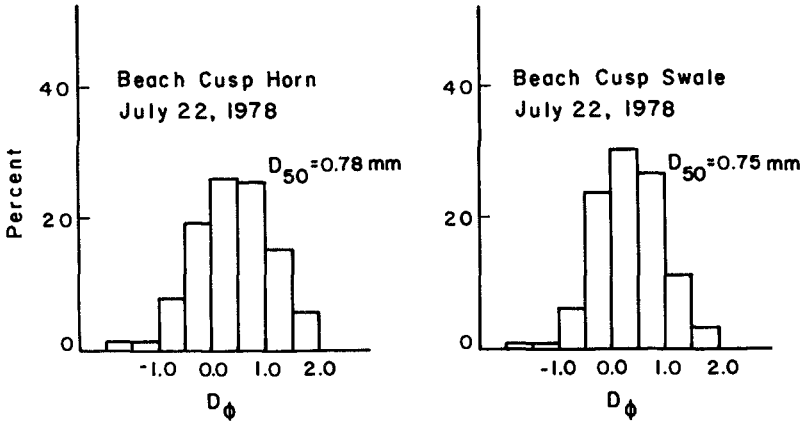

Figure 8. Representative Sediment Size Characteristics on Beach Cusps at Point Reyes Beach, California.

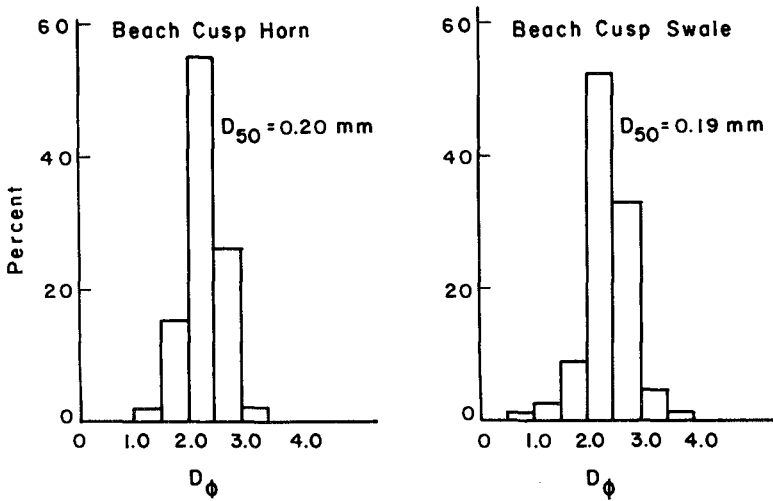

Figure 9. Representative Sediment Size Characteristics on Beach Cusps at Drakes Beach, California.

Figure 10. Histogram of Spacing of 30 Beach Cusps. Active Lower Berm, Point Reyes Beach South, California, August 23, 1977.

Figure 11. Histogram of Spacing of 31 Active Beach Cusps, Drakes Bay Beach, California, August 23, 1977.

During the 1977 field trip, there were three levels of cusps at Point Reyes beach, with only the lower level active. It is of interest to note that there is a consistent increase in cusp spacing with increasing berm elevation. Also of interest is the consistency of mean cusp spacing in 1977 and 1979. It is possible but unlikely that the beach cusps at the upper berm were not active during the intervening winters. The mean spacings at this level differed for the two summers by only 0.4 m of 61.8 m (0.6%). At the mid-level, which was active during the 1979 trip, the means differ by 1.4 m of 42.1 m (3.3%). At the Drakes Bay beaches, the difference is greater--6.6 m of 25.5 m (25.9%). The ratio of standard deviation of beach cusp spacing to mean varies over a fairly narrow range. For the Point Reyes and Drakes Bay beaches, these ranges are 9.0 to 18.5% and 17.4 to 19.4%, respectively.

Plane Table Surveys

Plane table surveys of beach cusps were conducted at various locations along Point Reyes and Drakes Bay beaches. Each survey included three horns and the two intervening bays. The mapping consisted of lines located approximately along the horns and bays and lines at each quarter point, which provided reasonable definition of cusp topography. Three example surveys are presented in Figures 12 to 14. The characteristics of these beach cusps will be discussed in a later section.

Swash and Wave Observations

During the 1979 field trip, limited observations of swash velocity and excursion were measured. Stakes were driven in the beach at 5 m intervals along lines extending upward along the horns and embayments. Maximum swash excursions were readily estimated to an accuracy of 1 m, and using an electronic stopwatch, swash velocities were calculated based on the time required for a floating object to advance (retreat) from stake to stake on the uprush (backrush). On July 28, 1979, uprush distance and associated beach cusp spacings were measured at both Point Reyes and Drakes Bay beaches. The parameters of interest including the ratio of cusp spacing, λ , to uprush distance, $(\xi_x)_{\max}$, are presented in Table II.

TABLE II

SUMMARY OF UPRUSH EXCURSION AND BEACH CUSP SPACING MEASUREMENTS
JULY 28, 1979

Location	Uprush Excursions		Beach Cusp Spacings		$\lambda/(\xi_x)_{\max}$
	No. Observed	Average Value, $(\xi_x)_{\max}$, (m)	No. Observed	Average Value, λ (m)	
Drakes Bay*	46	12.5	26	23.2	1.9
Point Reyes	11	14.6	4	46.0	3.2

*Cusps in process of formation.

Figure 12. Beach Cusps at Point Reyes Beach North, California, July 22, 1978. Contours are in Meters Relative to an Arbitrary Datum.

Figure 13. Beach Cusps at Point Reyes Beach South, California, July 23, 1978. Contours are in Meters Relative to an Arbitrary Datum.

Figure 14. Beach Cusps at Drakes Beach, California, August 25, 1977. Contours are in Meters Relative to an Arbitrary Datum.

The ratio of $\lambda/(\xi_x)_{\max}$ of 1.9 and 3.2 are of interest as will be discussed later.

Observations of Beach Cusp Initiation

During the 1979 field trip, storm waves caused the cusps at Drakes Beach to be essentially eradicated leaving a planar beach. The following day (July 28, 1979), the cusps started to reform and the periods of 100 consecutive waves were measured and the associated breaking heights estimated visually. The range in breaking heights (10 to 70 cm) resulted in breaking at varying locations offshore and caused the observed wave periods at the breaking point to differ from those that would occur at a fixed location; the periods were corrected to a common breaking location considering linear shallow water wave theory for the celerity and a uniform slope of 1:25. The resulting histogram of wave periods is presented in Figure 15; the mean and standard deviation of the wave periods are 15.4 sec. and 5.1 sec., respectively. In addition a series of 46 wave heights and associated uprush excursions were observed. The mean and standard deviation of 46 wave heights (visually observed) were 33.5 cm and 17.0 cm, respectively and those of the 46 uprush excursions were 12.5 m and 4.0 m, respectively. It is interesting that the ratio of standard deviation to mean was determined to be less for the uprush excursions than for the wave heights--0.32 vs. 0.51. The correlation coefficient, r , was calculated between the breaking wave heights, H_b , and the associated uprush excursions, $|\xi_{x_i}|$

$$r = \frac{\sum (H_{b_i} - \bar{H}_b)(|\xi_{x_i}| - \overline{|\xi_x|})}{\sqrt{\sum (H_{b_i} - \bar{H}_b)^2 \sum (|\xi_{x_i}| - \overline{|\xi_x|})^2}} \quad (1)$$

Figure 15. Histogram of the Periods of 100 Consecutive Waves, Measured During Formation of Beach Cusps, Drakes Beach, July 28, 1979.

and a very small negative value ($r = -0.15$) was found. The explanation may be that the mild slope causes the larger waves to break further offshore and in the vicinity of the beach face, the amount of wave energy available for the uprush is nearly independent of the breaking wave height.

THEORY

Introduction

In this section, the interpretation of field observations will form the basis for an attempt to develop a theory representing the swash dynamics on a cusped beach. In addition to the goal of clarifying the mechanisms, a successful theory should yield reliable predictions of beach cusp spacing. The theory presented here commences with an idealization of the beach cusp topography, then proceeds to develop the swash characteristics and finally an equation for the beach cusp spacing is presented in terms of the swash mechanics and the topographic relief of the cusp.

Idealization of Beach Cusp Topography

Based on examination of a number of beach cusps, a reasonable, simple and idealized representation was selected as

$$h(x,y) = Ax(1 + \epsilon \sin ky) \quad (2)$$

in which x and y represent horizontal distances in the shore normal and shore parallel directions, respectively, h represents the elevation of the sand surface above some datum, k is the longshore wave number of the beach cusps, A is the average slope, and ϵ is a small parameter. Figure 6 presents example calculated contours for $\epsilon = 0.2$. The parameter, ϵ , can be shown to be

$$\epsilon = \frac{h_H - h_B}{2Ax} \quad (3)$$

or

$$\epsilon = \frac{h_H - h_B}{(h_H + h_B)} \quad (4)$$

where the subscripts "H" and "B" denote horn and Bay respectively and h_H and h_B are measured at the same x value.

Water Particle Kinematics

The approach will be to consider the water particle motion as that of a discrete particle subject to an initial velocity and gravitational force. The effects of friction will be neglected.

The governing equations for the water particle are

$$\frac{dv_x}{dt} = -g \sin \alpha_x = -g \frac{\partial h}{\partial x} = -gA(1 + \epsilon \sin ky) \quad (5)$$

$$\frac{dv_y}{dt} = -g \sin \alpha_y = -g \frac{\partial h}{\partial y} = -gAx k(\epsilon \cos ky) \quad (6)$$

and the solutions for the water particle excursions can be shown to be

$$\xi_x(t) = v_{x_0} t - \frac{gAt^2}{2} \quad (7)$$

$$\xi_y(t) = -\frac{1}{2} gAxk \epsilon \cos ky t^2 \quad (8)$$

Equations (7) and (8) are approximate since these solutions do not account for variations in slope as the particle moves across the cusp. In utilizing these equations below, the mid-position of the excursion in the x and y directions will be used to approximate this effect.

One use of these equations is in calculating the swash period, i.e. to a first approximation the water particle will return to the initial position in a time T_s , i.e. $\xi_x(T_s) = 0$, or

$$0 = v_{x_0} T_s - \frac{gAT_s^2}{2} \quad (9)$$

or

$$T_s = \frac{2v_{x_0}}{gA} \cong \frac{2v_{x_0}}{g \sin \alpha_x} \quad (10)$$

The maximum uprush occurs at $t = \frac{T_s}{2}$, i.e.

$$(\xi_x)_{\max} = \frac{v_{x_0}^2}{2gA} \quad (11)$$

which simply represents a conversion of the initial kinetic energy of the water particle to potential energy.

The maximum displacement of a water particle in the y-direction should be more-or-less equal to one-half the cusp spacing, λ , and should occur at $t = T_s$. In addition, as noted above, taking values of x and $\cos ky$ in Eq. (8) as

$$x \cong \bar{x} = \frac{(\xi_x)_{\max}}{2} \quad (12)$$

$$\cos ky \approx \cos k\bar{y} \approx 0.6 \tag{13}$$

and noting that $k = \frac{2\pi}{\lambda}$, $(\xi_y)_{\max} = \frac{\lambda}{2}$, and $A \approx \sin \alpha_x$, yields for the cusp spacing, λ

$$\lambda \approx \sqrt{1.2 \pi \epsilon \frac{V_x^2}{gA}} \tag{14}$$

and using Eq. (11), the cusp spacing can be expressed in terms of the maximum swash as

$$\lambda \approx 3.9\sqrt{\epsilon} (\xi_x)_{\max} \tag{15}$$

Six of the sets of observed cusp systems provided enough information to determine ϵ . Three of these systems are presented in Figures 12, 13, and 14. The average ϵ values are presented in Table III and range from 0.07 to 0.29 with the values at Drakes Bay generally smaller than those at Point Reyes Beaches.

TABLE III
SUMMARY OF BEACH CUSP ϵ PARAMETERS

Date and Location of Survey	ϵ
Drakes Bay Beach August 25, 1977	0.13
Point Reyes Beach, North July 22, 1978	0.15
Point Reyes Beach, South July 23, 1978	0.10
Drakes Bay Beach July 23, 1978	0.07
Drakes Bay Beach July 23, 1979	0.09
Point Reyes Beach, South July 24, 1979	0.16
Point Reyes Beach, South July 27, 1979	0.20
Point Reyes Beach, South July 29, 1979	0.29

Selecting a value of 0.15 as reasonably representative and employing Eq. (15),

$$\lambda \approx 1.5 (\xi_x)_{\max} \quad (16)$$

i.e. cusp spacing is linearly related to swash excursion. It is relevant to note that Longuet-Higgins and Parkin (1962) found that their beach cusp data demonstrated a linear relationship between spacing and excursion. Their approximate empirical relationship is

$$\lambda (m) = 2.8 + 0.54 (\xi_x)_{\max} \quad (17)$$

where $(\xi_x)_{\max}$ is in meters. If the empirical relationship to their data is constrained to pass through the origin, the fit is not nearly as good as with the constant in Eq. (17); however, it would be

$$\lambda (m) \approx 1.2 (\xi_x)_{\max} \quad (18)$$

DISCUSSION

"Active" beach cusps as discussed herein refers to a system in which the swash is sufficiently vigorous to transport significant quantities of sediment and which strongly reinforces the beach cusp topography, i.e. a tendency for deposition on the horns and erosion in the bays. In all cases observed "active" beach cusps were characterized by strong and predominant runup on the horns with a seaward flow concentrated through the embayments. This motion was enhanced by a near equality of the wave and swash periods which tended to maintain the cusp topography. The measured ratios $\lambda/(\xi_x)_{\max}$ (1.9 and 3.2) presented in Table III are in order of magnitude agreement with the value (1.5) predicted in Eq. (16). Based on a plane table survey of August 22, 1977, the three berm elevations mapped are approximately 2 m, 3 m and 4 m above mean sea level. Although we did not establish elevations relative to a known datum, (e.g. MSL) these elevations are believed to be accurate to within 0.5 m. Considering the beach face slope, A, to be the same (1:10) during periods when all berms were formed, the Approximate maximum swash excursion would be

$$(\xi_x)_{\max} \approx \frac{B}{A} = 10 B$$

in which B is the berm elevation. For the cusp spacings presented in Table I, the ratios of cusp spacing to maximum swash excursions, $(\lambda/(\xi_x)_{\max})$, are 1.6, 1.4 and 1.4 for the upper, mid and lower sets. These ratios are in remarkably good agreement with the value (1.5) predicted by Eq. (16).

The relationship developed herein between cusp spacing and maximum swash excursion is in qualitative agreement with the effect of sediment size and cusp spacing, other factors being the same. Based on Eq. (11), the swash increases with decreasing beach slope. It is well-known that the beach face slope increases with grain size (Bascom, 1951), thus the swash excursion and cusp spacing would decrease with increasing sediment size. Trask, Johnson and Scott (1956) have documented for the Point

Reyes Beach area, a trend of decreasing cusp spacing with increasing sediment size.

Edge waves provide a possible alternate explanation of beach cusp formation; the associated predicted spacing, λ , is

$$\lambda = \frac{gT^2}{2\pi} \sin(2n+1)\beta \quad (19)$$

in which T is the wave period, β is the beach slope and n is the modal number. For a beach slope of 1:25 and the data presented in Figure 15 (associated with observed formation of cusps), the average wave period of 15.4 seconds yields spacings of 14.8, 44.3 and 29.6 m respectively for the three classes of edge waves noted above. The average observed spacing was 23.2 m which is closest to but differs by approximately 30% from the zeroth mode subharmonic case. Moreover, these subharmonic oscillations entail alternating uprush and backwash in adjacent cusp swales; this was clearly not occurring in any of the cusps observed. A more serious concern in accepting the edge wave explanation is the rather wide range of wave periods presented in Figure 15, and the uncertainty of the use of a single value for the effective beach slope. Additionally, the edge wave theory is linear and thus strictly applies only for small displacements. The swash excursions observed during cusp formation were on the order of 12 m thus raising questions as to the validity of a linear wave theory. Finally it is noted that edge waves would predict an increasing spacing with increasing slope which is contrary to the field observations of Trask, Johnson and Scott (1956) in which beach slope was inferred herein from sediment size.

CONCLUSIONS

There are several results from this study that support the conclusion that swash mechanisms govern beach cusp formation and spacing.

- (1) The water circulation patterns resulting from the swash are such that they cause sediment transport upward and deposition on the horns and a seaward flow and scour in the embayments;
- (2) The simple theory developed herein predicts a linear relationship between cusp spacing, λ , and maximum swash excursion, $(\xi_x)_{\max}$, i.e.

$$\lambda \approx 3.9\sqrt{\epsilon} (\xi_x)_{\max}$$

in which ϵ is a parameter describing the cusp geometry (Eq. (4)). This relationship is in general accord with field results obtained in this study and that of Longuet-Higgins and Parkin (1962).

- (3) The correspondence of large cusp spacing with high berm elevations at Point Reyes (Table I) and inferred maximum swash excursions provide very good quantitative agreement with the simple relationship developed herein.

- (4) Wave periods were measured during beach cusp formation from an approximately planar beach. These periods were quite variable, suggesting that edge waves are probably not the causative mechanism. Additional difficulties in accepting edge waves as the cause are the characteristic non-planar beach geometry and a different trend than inferred from the field data of Trask, Johnson and Scott (1956).

Although swash mechanisms appear to control cusp formation and maintenance at the beaches studied, edge waves or other mechanisms may dominate for cusp features on other beaches and/or under different wave conditions.

BARRON RIVER DELTA INVESTIGATION

D.A. Robinson*, A.M.ASCE,
D.J. Cook** and J.G. Barff***

1.0 INTRODUCTION

The Barron River flows to sea through a 50 km² alluvial Delta on the narrow coastal plain near Cairns, Queensland in north eastern Australia. The Delta is in the tropics at 17 degrees south latitude. Most of the 2175 km² catchment lies above 450 m above sea level. The coastal portion of the catchment has an average annual rainfall in excess of 2000 mm. River flows are highly variable with peak flood flows of over 4000 m³ s⁻¹, and dry season flows of less than 15 m³ s⁻¹. The Delta is tidal with ocean tides having a range of 1.8 m at Spring Tides. There are three water storages on the catchment, one on the upper catchment having an ungated spillway and a capacity of 407 x 10⁶ m³ for irrigation purposes and the other two just upstream of the Delta, are a small weir of 1.7 x 10⁶ m³ capacity to regulate water supply to the Barron Gorge Hydro-electric Power Station, and Copperlode Falls Dam on Freshwater Creek, a 45 x 10⁶ m³ ungated storage to provide water to Cairns City and the nearby Mulgrave Shire.

The Delta consists of alluvial soils which support 3600 hectares of sugar cane farm land. The beaches in the Delta are being developed as resort towns and dormitory suburbs.

Sand and gravel is regularly dredged from the lower reaches of the main river in the Delta at the rate of 50,000-80,000 m³ per year. Increasing scarcity of sand sources, and the concern that dredging and dam construction is threatening beach sand sources have raised conflicting pressures on the Authority which licences the extraction of sand and gravel from the river.

This, coupled with regular flooding of the Delta and the cutting of major highways, and the continuing erosion of cane farm land has initiated a major data collection programme as a prerequisite to formulating solutions for the flooding and erosion problems.

2.0 IDENTIFICATION OF THE PROBLEM

A Steering Committee consisting of representatives of the local administering bodies and relevant State Government Departments was formed to supervise the data collection programme.

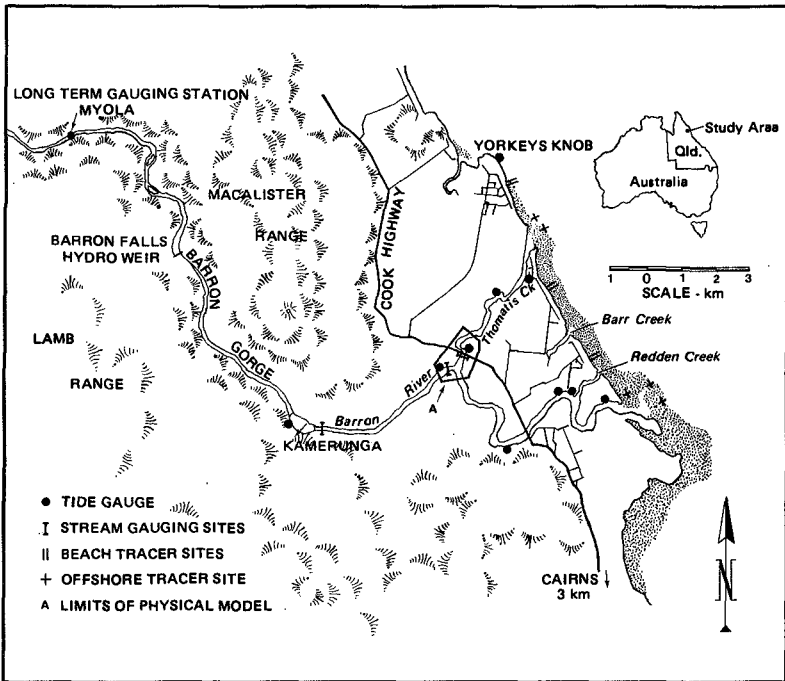

* Engineer, Beach Protection Branch, Department of Harbours and Marine, Queensland.

** Officer in Charge, Hydraulics Laboratory, Department of Harbours and Marine.

*** Engineer, Foreshore Development Branch, Department of Harbours and Marine.

Five major problems relating to the physical processes of the Delta were identified.

- (a) The increasing urban settlement and the increasing value of the sugar crop has brought pressures to mitigate floods in the delta.
- (b) Erosion of the river banks, particularly in Thomatis Creek is resulting in the loss of farm lands.
- (c) Erosion of the ocean beaches is threatening beachfront facilities and degrading the recreational value of the beaches.
- (d) The maximum quantity of sand and gravel, which can be removed from the river without damage to the river banks and adjacent beaches needs to be determined.
- (e) The percentage of flow down each of the two main river channels in the delta needs to be determined, with regard to the conflicting requirements of bank stability, sediment discharge capacity and flood levels for each stream.

LOCALITY PLAN

Figure 1

A three year data collection programme (1975-1979) was initiated to provide the basis for solution of these problems. The data collection and collation was co-ordinated and largely undertaken by the Queensland State Government Department of Harbours and Marine. This paper is a summary of the much larger investigation report prepared by the Department of Harbours and Marine for the Steering Committee. (Reference 1).

3.0 DATA COLLECTION

A large component of this investigation was the data collection programme. This programme, spread over a 3 year period included the following:-

- (a) orthophoto mapping of the Delta at scale 1:2500
- (b) cross-section survey of river and creek channels at 250 m intervals
- (c) water level recording (tide and flood) at 7 locations in the Delta
- (d) bed material sampling for particle size determination in river channels and on the beaches
- (e) stream flow measurement at 5 locations during flood conditions
- (f) tidal flow measurements in the river and creek channels and offshore
- (g) repetitive beach surveys
- (h) wave recording
- (i) radio active tracer studies at the junction of Barron River and Thomatis Creek and on the beaches
- (j) siltation survey of the Tinaroo Falls Dam; and
- (k) geological and geophysical studies of the Delta and immediate offshore area
- (l) historical searches of cadastral surveys and aerial photographs.

During the study period, two of the three largest floods experienced in the Delta since the commencement of streamflow measurement on a systematic basis in 1915, occurred, presenting a remarkable opportunity for stream flow measurement and suspended sediment sampling.

In relation to the specific objectives listed in section 2.0 of this paper, the data collection programme is obviously very extensive. However a second, but equally important aim of the study was to provide a comprehensive data base for the understanding of Delta behaviour and the assessment of management proposals for the area. As a result of the success of this data collection programme, the study report will fulfil this second objective, providing a comprehensive and detailed description of the Delta which will be of immense value in the future.

4.0 RIVER PROCESSES

The Barron River, in creating a delta where it reaches the sea, has created some of the most valuable agricultural land in northern Australia, and, if left undisturbed, would continue to expand the Delta land mass. It would also however, continually change the plan geometry of the river channels and the importance of each of the distributaries would also change from time to time. These processes can be seen at work in the Delta today. Channel meandering has threatened valuable farmland by bank erosion and many examples of this can be found in the Delta. It is however, the question of distributary dominance that is of more interest to this paper, affecting as it does the overall stability of the river/beach system by controlling the distribution of sedimentary materials.

DEVELOPMENT OF THE BARRON RIVER BAR 1952-1979

Figure 2

The Barron River has three tidally connected outlets to the sea - the main channel, Thomatis Creek and Redden Creek. The relative importance of these three channels has changed over the past fifty years. Until 1932, the Thomatis channel carried Barron River water only in major floods, but surveys dating from about 1900 show clearly the development of Thomatis Creek, until, in the major 1932 flood, the River broke through and Thomatis Creek began to develop as a permanent mouth. There is a gradient advantage along this channel to the sea. The flow path is 6 km compared to 9 km via the Barron and it is reasonable to assume that unless man intervenes, the main Barron Channel will become less important and Thomatis Creek will become the major mouth.

The proportion of flow carried by each channel at high flood is difficult to estimate because of the large overland flows which occur at such times. However, at the bankfull stage, which many authors suggest is most closely associated with the channel forming process, the flow split is about 65% main channel to 35% Thomatis Creek. Hardin (Reference 2) in studies of the distributaries of Mississippi Delta suggested that when the emerging distributary has grown to the size where it can carry 40% of the flow the process is very difficult to reverse.

Whilst there is no reason to suggest that an identical figure will apply to the Barron River, it is clear that Thomatis Creek is increasing in size and that siltation is occurring in the Barron River downstream of the junction, and that the longer an attempt to reverse the process is delayed, the more difficult it will be to effect. To investigate ways of controlling the flow split at the junction, a 100:1 undistorted physical model was constructed at the Queensland Government Hydraulics Laboratory (Reference 3) to examine a variety of control works and to estimate their effect elsewhere in the system. The limits of the model are shown on Figure 1.

An important factor to be considered is the effect of works at the junction on distribution of sediments to the beaches. Suspended sediment measurements and tracer experiments show that the sand size and smaller sediments in the Barron River, in all but the smallest floods, are carried in suspension. At the bankfull condition, it is estimated that only 12% of sediments are carried to the sea via Thomatis Creek, so total closure of that mouth (to bank full level) would have only a very small effect of supply to the beaches, as the great bulk of transport takes place in floods larger than bank full. These would be affected to a much smaller extent.

So even if the junction is closed off to the maximum practicable level, (about bankfull), the study has shown that only a few percent of the sediments carried by Thomatis Creek will be diverted. Closing off the junction will also have only a very minor effect on the tidal flows in the Delta channels. Field measurements have shown that there is only a very small net tidal circulation through the junction which is what one would expect when the history of development of Thomatis Creek, first as a tidal creek and then later as a distributary, is considered.

Redden Creek, whilst only a very minor distributary, has quite an interesting history nonetheless. Prior to 1939, the main Barron River channel entered the sea about 1.5 km further south than at present, and Redden Creek was then considerably more important than at present. Since the new entrance developed, it is not only less favoured hydraulically but its mouth is dominated by the sands of the Barron River bar and is closed for most of the year. Figure 2 illustrates the changes that have taken place over the last 27 years. In the last fifty years the Thomatis Creek mouth has also moved 1.2 km to the North.

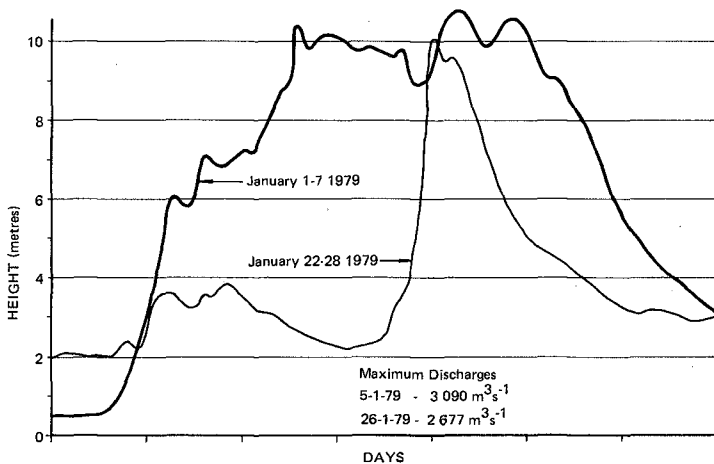

Although these changes are very important to property owners with river and creek frontages, they are far less significant when compared to changes that have taken place over the much longer geological time scale. Geophysical evidence suggests that in the period before the last major sea level change (6000 years ago) the main Barron River channel flowed to the sea close to the modern Thomatis/Richters Creek channel alignment.

5.0 FLOODS

During the summer monsoon period, November to April, tropical cyclones or hurricanes can occur. While rainfall in the Delta is reliable flood rains in the 2175 km² catchment can be quite variable. River flows can range from less than 15 m³s⁻¹ in the dry season to annual peak flows which have been recorded to vary from 80 m³s⁻¹ to 4500 m³s⁻¹ in 63 complete years of record.

Figure 4(a) shows the variation of the annual maximum instantaneous discharges. The major floods are all associated with tropical cyclones crossing the catchment.

During major floods agricultural land on the Delta is inundated to depths of between 1 and 3 metres. In the 1979 flood over 100 houses had to be evacuated. The duration of floods can be quite variable. In 1979 two floods with almost equal peak flows occurred. While the peak discharges are similar Figure 3 shows that the total discharge and hence total sediment discharge will be markedly different.

NOTE: Flood levels shown for Myola Water Level Recorder Station for two 1979 floods.

COMPARISON OF TWO FLOODS

Figure 3

Following the major 1979 floods, flood inundation maps for the Delta have been prepared. The 1979 flood, the second largest on record had a peak discharge of $4600 \text{ m}^3 \text{ s}^{-1}$ on the Delta. The inundation maps reveal that virtually all of the Delta is subject to river flooding. The only areas free from flooding are the coastal sand ridges occupied by residential development. These coastal ridges are only 2 metres above the ocean high water level and are vulnerable to inundation by storm surges associated with tropical cyclones.

Further development of the Delta for residential purposes will require careful planning to ensure adequate escape routes are available in the event of major floods or storm surge inundation.

6.0 RIVER SEDIMENT TRANSPORT

Sediment in the river consists of fine to medium sands up to gravels of 300 mm diameter at the head of the Delta, to medium to fine sands and muds in the lower reaches. River bed samples were collected during the dry season. 268 suspended sediment samples were collected during floods and 240 samples collected during the dry season when river flows in the Delta were tide generated.

Several approaches for estimating sediment transport in the river were used including estimates from -

- * recent geological evidence
- * regional catchment predictors which use catchment characteristic parameters such as slope area, soil type etc.
- * direct measurements of suspended sediment load
- * sediment transport predictor formulae.

Considering only sand size particles, estimates of sediment transport were made using several theoretical methods, notably those of Engelund and Hansen (Reference 4) and White-Ackers (Reference 5) calibrated against the measured suspended sediment (Figure 5). At high flows sand sized particles are all carried in suspension. Observations during flood conditions confirm this. In sections of the river that could be accessed during major floods the channel bed was found to be composed of gravel or stiff clay indicating that the rivers capacity for transporting sand exceeded the actual transport. During the falling stages of the flood sand was deposited over the river bed.

Several difficulties were encountered in estimating sediment transport using total load predictors. Selection of a suitable gauging site required a compromise between sites at the head of the Delta where multiple channels exist but little overbank flow occurs and downstream sites where well defined channels occur but overbank flow is significant though difficult to quantify.

Based on 63 years of river flows transport of sand was estimated to be of the order of $23,000 \text{ m}^3$ per year. The annual sediment transport rate estimate is shown in Figure 4(b).

a. Annual Maximum Discharge

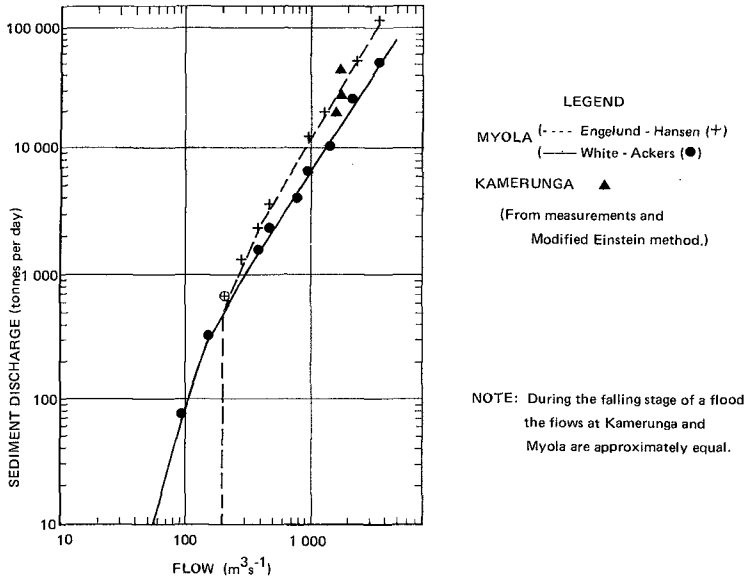

b. Sediment Discharge

 Calculation of Sediment Discharge used the Engelund and Hansen Method.

DISCHARGES AT MYOLA 1916 to 1979

Figure 4

SAND TRANSPORT CAPACITY VS FLOW AT KAMERUNGA AND MYOLA GAUGING STATIONS

Figure 5

The estimates of sand transport gave sediment transport rates ranging from 3500 m³/year based on beach ridge accumulation through 11,000 m³/year from regional catchment characteristics and 23,000 m³/year from sediment transport formulae to 35,000-50,000 m³/year from recent geological evidence. For sand resource management a figure of 23,000 m³/year has been adopted.

7.0 COASTAL PROCESSES

Geological evidence shows that the most of the Delta has formed during the last 6000 years following the last major change in the world's sea level. From geological evidence the Barron River is supplying about 300,000 m³/year of sediment of which 60,000 m³/year is sand and gravel. Written history of the Delta only exists from the 1870s with firm evidence restricted to this century. During the last 50 years the Delta's beaches north of the Barron River have eroded at rates of the order of 30 m in 50 years.

The Beach Protection Authority is currently undertaking a study of beach processes in the Cairns area. The study includes the 8 km of beaches of the Barron Delta. Preliminary results from the Authority's study have been used. The Authority's beach study is similar in approach to a study of the Capricorn Coast Beaches reported elsewhere in these proceedings.

The Delta's beaches are protected from ocean swells by the coral reefs of the Great Barrier Reef, which restricts fetches to 50 km. The beaches of the Barron River Delta exhibit the typical North Queensland beach profile which consists of a steep beach down to Mean Sea Level and extensive, nearly horizontal sand and mud flats extending 1000 m or more offshore. Waves recorded in 18 m of water offshore from the Delta over a three year period, using a Datawell "Waverider" recorder show how sheltered the beaches are under normal weather conditions (Reference 6). A significant wave height (H_s) of 0.5 m was exceeded 50% of this time, while only 3% of the time did H_s exceed 1.0 m. No waves over 2.0 m were recorded over the 3 year period. Using 9 years of available wind data, a hindcast wave climate (wave height, period and direction) was also determined (Table 1).

TABLE 1
WAVE CLIMATE
BARRON RIVER BEACHES

WAVE HEIGHT m	PERCENTAGE OF TIME WAVE HEIGHT EXCEEDED		
	RECORDED	OFFSHORE HINDCAST	BREAKING WAVES - MACHANS BEACH (observed)
0.2	95.	99.6	54.
0.4	63.	67.	18.
0.6	37.	42.	6.
0.8	17.	2.8	1.5
1.0	3.0	0.7	0.15
2.0	--	0.02	--

The Delta region is subject to tropical cyclones (hurricanes). Historically the Delta has not experienced a major cyclone in the last 50 years. Statistically however, it is estimated that 7 cyclones pass within 100 km of the Delta every 66 years. A cyclone of 50 year return period within 200 km radius of the Delta is estimated to have a central pressure of 963 mb.

Beach profiles were measured from the dune crest extending out to 3000 metres offshore along the 8 km of the Delta's beaches. Sixteen profile lines were repeatedly surveyed to assess seasonal variations and to measure any changes in beach shape directly attributable to floods. Surface sediment samples were collected and an explanatory geophysical survey was undertaken of the nearshore marine sediments.

The beaches exhibit a wide range of sediment sizes reflecting the river source of the material and the poor sorting by the low energy wave climate. The beaches between low water mark and the dunes are fine to medium silica sands (0.2 to 0.5 mm median size) while offshore silt and mud fractions become significant as water depth increases.

A radioactive tracer study was undertaken to measure sediment movement on the beaches, and on the bars at the mouths of the Barron River and Thomatis Creek. Active gold - 198 labelled sand was used offshore while an inactive tracer (Indium Nitrate) was used to label the beach sands.

Estimates of longshore transport were made using the method in the Shore Protection Manual, and methods of Bijker, Komar and the Authority's own procedure using observed daily longshore currents and breaking wave data (Reference 1). Annual nett longshore transport capacity was predicted to be in the range of 10,000-30,000 m³/year to the north.

It was the longer term beach changes with 5 to 50 year cycles, and changes related to major flood events which were of interest to this study rather than seasonal onshore-offshore or short term fluctuations.

The Barron River supplies 23,000 m³/year of sand sized sediments. Currently most of these sediments reach the coast via the main Barron River mouth, with minor amounts debouching from the other distributaries. The supply rate is very irregular as can be seen in Fig. 4(b). This contrasts with the longshore transport which tends to be of the same order from year to year.

The Barron River mouth moved 1.5 km with the connection of a meander to the sea 40 years ago. The old mouth closed and a new mouth and bar formed. The growth of the new bar and some reduction in size of the old bar can be seen in Fig. 2 as well as evidence of the strong onshore transport which has produced a new beach ridge south of the present mouth - the only coastal accretion recorded in the last 50 years on the Delta's beaches.

Geologically the coastline has accreted over the last 6000 years, at an "average" rate of 30 metres per 100 years. Historically the coastline has eroded in the order of 30 m in the last 50 years. A possible explanation for this paradox was found in the growth of the new Barron River bar. Empirical relationships between the volume of sand in the bar and the tidal prism of the river estuary (Reference 7), suggest that 500,000 m³ of sand sized sediments are required to form the new bar. The main source of these sediments can only be from the river. Until the bar reaches an equilibrium state then excess sediment will not be readily available for transport away from the river mouth to the northern beaches. Thus until the new bar is fully developed erosion of the adjacent beaches is expected as longshore transport is removing sand from these beaches while little sand is being supplied from the river mouth.

8.0 CONCLUSION

The Barron River Delta Investigation had two clear objectives -

- (a) to compile a data base to assist those Authorities with responsibility for management of the waterways and sedimentary resources of the Delta in the formulation of a management plan for the Delta; and
- (b) to interpret the data as it relates to several important areas of concern at the Delta - the Barron River/Thomatis Creek junction, the Barron River beaches, sand and gravel dredging, and flooding of urban areas, and to suggest ways alleviating problems in these locations.

The first of these objectives has clearly been met, climatic events having provided an unequalled opportunity for data collection. Whether the second objective has been fully met will not be known until a considerable period of time has elapsed and the effects of any remedial works that are undertaken can be assessed.

9.0 ACKNOWLEDGEMENTS

The permission of Mr J. Leech, the Director of the Department of Harbours and Marine, Queensland State Government, and Mr A.H. Britton, the Chairman of the Barron River Delta Investigation Steering Committee, to present this paper is gratefully acknowledged. It is desired to especially thank those members of the several organisations who assisted in the data collection and collation for the study.

CHAPTER 56

SOFT DESIGNS FOR COASTAL PROTECTION AT SEABROOK ISLAND, S.C.

Miles O. Hayes¹, Timothy W. Kana² and John H. Barwis³

ABSTRACT

To gain a better understanding of the cycles of shoreline changes on Seabrook Island, South Carolina and advise a private developer on how to deal with localized erosion problems, a detailed field survey and historical study were completed. The data base included historical charts dating from 1661, vertical aerial photographs from 1939, field surveys of beach profiles and nearshore bathymetry over a six-month period, and sediment cores through the entire Holocene section. Seabrook Island, less than 6 km in length, is bounded by tidal inlets with extensive seaward shoals. With a 2 m tidal range for the area, changing exposure and orientation of the shoals over time has had a profound effect on the adjacent shoreline of Seabrook Island. Historical evidence points to the importance of offshore shoals which act as natural breakwaters and sediment storage systems. At various times in recent history, these shoals have supplied sediment to Seabrook beaches by means of bypassing mechanisms around tidal inlets. On the other hand, migration of shoals has allowed excess wave energy to strike portions of the shore causing local erosion. Along a portion of the shoreline, short-term erosion is jeopardizing the development. Based on the present study, a set of "soft" engineering designs was proposed which attempt to manipulate offshore sand bodies in a way that will be beneficial to the development and preserve the inherent beauty of the shoreline. Remedial measures recommended for the developer included dredging new inlet channels and construction of a breakwater in the position of a former protective shoal.

INTRODUCTION

Seabrook Island near Charleston, South Carolina, U.S.A. (Fig. 1) is a typical mesotidal (tidal range 2.0 m) barrier island consisting of vegetated beach ridges and low frontal dunes bounded by tidal inlets and a marsh-tidal creek system. Within the past 5 years, it has been developed as a private vacation resort. Due to its proximity to a major tidal inlet and the presence of numerous shifting offshore shoals, the ocean shoreline has tended to change rapidly in response to local variations in wave energy. This has presented significant problems to portions of the existing development. Several homes and the community center are located in erosion zones and have required seawalls or rubble mound rip-rap for protection; whereas, some nearby beaches are presently accretional.

¹Coastal Research Division, Dept. of Geology, University of South Carolina, Columbia, S. C., U.S.A., 29208

²Research Planning Institute, Inc., 806 Pavillion Ave., Columbia, S. C., U.S.A., 29205

³Shell Oil Company, P. O. Box 527, Houston, TX, U.S.A., 77001

While coastal protection works are providing immediate relief to certain highly erosional areas of the development, they are causing long-term adverse effects, including acceleration of erosion in unprotected areas and destruction of the natural character of the island. This latter effect is of great concern since the key attraction of this and other South Carolina coastal developments is their unspoiled beaches.

Figure 1. Location map of Seabrook Island, S. C. (30 km south of Charleston, S. C.).

To gain a better understanding of the cycles of shoreline changes on Seabrook Island and advise the development company on how to deal with localized erosion problems, a detailed field survey and historical study were completed. Solutions were sought which would allow natural sedimentation processes of the adjacent inlet shoals and beaches to work in harmony with proposed engineering modifications. Large volumes of sand are stored in the ebb-tidal deltas (outer shoals) of the inlets at either end of Seabrook Island. It was hypothesized that manipulation of these shoals would modify the distribution of wave energy along the shore and reduce or eliminate the erosion problem. Thus, the approach taken was to utilize geologic and coastal process information and determine appropriate "soft" engineering solutions which would have the aesthetic advantage of preserving the character of the Seabrook beaches.

DATA BASE

A combination of laboratory analysis of historical data and a variety of field observations completed during a six-month period between June and December, 1978 are available. The data base included:

1. Historical charts from 1661, 1853, 1867, 1919, and 1914.
1. Vertical aerial photographs from 1939, 1949, 1954, 1957, 1963, 1973, and 1978.
3. Nine permanent beach profile stations monitored monthly for six months.
4. Monthly wave process data at 8 stations (wave height, breaker angle, longshore currents, and wave period).

5. Monthly surveys of two cross-sectional bathymetric profiles of N. Edisto Inlet (Fig. 1).
6. Preparation of a detailed bathymetric map of the seaward shoals of the inlet.
7. Sediment cores through the entire Holocene section along two transects across Seabrook Island.

COASTAL PROCESSES

Winds

Seabrook Island is influenced by prevailing winds from the SW (36% of the time) and storm winds generally from the NE (28% of the time). In general, the NE winds, though less frequent, are stronger, causing waves and longshore transport directed SE along the island. Hurricane force winds have a return period of approximately one event every 14 years (Myers, 1975). While hurricanes are relatively rare along this portion of the South Carolina coast, they have been known to cause extensive damage to property from high winds and associated storm tides.

Tides and Storm Surges

The mean tidal range at Seabrook Island is approximately 1.7 m (5.2 feet), with spring tides ranging up to 2 m (6.1 feet). These tides generate strong currents in North Edisto Inlet (south end of Seabrook) and Kiawah River Inlet (north end of Seabrook) as well as in major tidal creeks. This moderately large tidal range allows a wide portion of the beach to be exposed to wave action. Storm surges superimposed on normal astronomic tides occur during extratropical and tropical storms and have produced tides up to 12 feet (3.7 m) above normal along the South Carolina coast.

Waves

Wave energy along the Seabrook Island shoreline varies widely due to a combination of factors, including: 1) the direction of wave approach whether from the E or SW, and 2) the position of offshore shoals. The intertidal shoals act to dampen waves, reducing wave heights along the corresponding lee shore. This has an important effect on the distribution of sediment transport along the coast since longshore transport is related to wave energy and the angle of wave approach.

Between June and December 1978, representative monthly wave measurements were obtained at 8 stations on Seabrook Island (Fig. 2). Although these data are not detailed enough to establish a seasonal trend, they allow comparison of relative wave energy at various points along the shore. Variables measured included wave height, breaker angle, longshore current velocity, and wave period.

Average wave heights ranged from a low of 11 cm at P8 in October to a high of 80 cm in July at station 3 located near the development's clubhouse. The bar graph inset in Figure 3 shows the average distribution of wave heights. Note that the highest average waves occur at stations 3 (49 cm) and 6 (42 cm), both of which are presently experiencing the most severe erosion. The wide variance in wave heights along the shoreline results from a combination of factors including: (1) the direction of wave approach, whether from the east or southwest, and (2) the position of offshore shoals. The intertidal shoals act to dampen waves, reducing wave heights along the corresponding lee shore. For example, stations 2, 5, and 8 are relatively protected by offshore shoals, accounting for their reduced average wave height; whereas, stations 3 and 6 are more exposed.

Longshore Transport

The variability in wave heights along the Seabrook Island shoreline produces different rates of longshore sand transport. This has important consequences to shoreline changes because where transport is reduced, as along lee shores protected by offshore shoals, sand accumulates. At Seabrook Island, two wave directions are most common. During summer, waves from the southwest and south produce longshore transport northeast along the beach. Storms, on the other hand, generally cause sand transport to the southwest. When averaged over the entire year, more sand moves southwest under the influence of storm waves. This fact is evident at Kiawah Island, located north of Seabrook, where a large recurved spit at the southwest end of the island continues to grow rapidly toward Seabrook as a result of the influx of sand from the north.

To determine relative transport rates, wave data from the 8 process stations were used to estimate daily longshore transport. These data do not indicate long-term rates, but they offer an explanation for the erosional and depositional trends discussed in succeeding sections.

Figure 3 gives the average daily transport rates at each of the 8 process stations, based on monthly wave observations between June and December. Highest transport rates occur at stations 3 and 6, which are least sheltered by offshore shoals and which have higher than normal erosion rates. The range of equivalent yearly rates are $75-300 \times 10^3 \text{ m}^3/\text{year}$.

Modification of Coastal Processes by Artificial Structures

Coastal structures existing in 1978 at Seabrook Island included: (1) sand bag groins designed to trap sediment moving alongshore, (2) vertical poured-concrete seawalls to protect a clubhouse at station 3 and houses between stations 4 and 5, and (3) rubble mound rip-rap to anchor the shoreline between stations 2 and 3 (Fig. 4).

Sand bag groins. - The groins at Seabrook trapped some of the sand moving alongshore and initially caused minor reorientation of the shoreline as fillet beaches developed on the updrift (northeast) side and erosion on the downdrift side. However, after the reorientation to a new "equilibrium" shoreline, the erosional trend continued at stations 3 and 5 despite the presence of these groins.

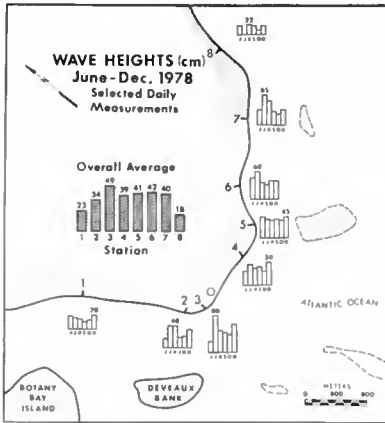

Figure 2. Distribution of wave heights measured monthly from June to December 1978 along Seabrook Island. Highest waves (inset) occur at station 3 at the southwest point of the island.

Figure 3. Net and (gross) long-shore transport rates along Seabrook Island based on wave energy flux. Highest net rates at stations 3 and 6 correspond to erosion zones at the time of the survey.

Figure 4. Oblique aerial photograph taken in 1978 of the southwest point of Seabrook Island. View looking southwest. Note coastal structures, including a groin, seawall, and revetment built to protect a community clubhouse. Erosion of the adjacent shoreline has produced the shoreline offset.

Concrete seawalls. - The vertical seawalls at Seabrook have protected several houses and the clubhouse by retaining sand behind them. However, they have had some adverse effects including an apparently accelerated erosion along adjacent shorelines. Vertical seawalls also reflect wave energy back offshore rather than absorbing or dissipating it. This tends to cause scour and remove sediment from the nearshore area.

Rubble mound rip-rap. - The rip-rap built between stations 2 and 3 has been more successful than the vertical seawalls since it absorbs much of the wave energy and reduces the scouring effect of reflected waves. Its main disadvantage is eliminating a recreational beach if erosion continues. While protecting property, the rip-rap seawall at Seabrook is not solving the long-term problem of continued erosion due to lack of sediment supply from updrift.

SHORELINE CHANGES

Historical Charts and Maps

In order to learn about the more recent short-term shoreline changes on Seabrook Island, all charts and maps available were assembled and studied. Particular attention was placed on the changing location of shoals and inlet channels. Five historical charts were available covering the period 1661 to 1924. One example, from 1867, is shown in Figure 5. Key reference points were located on each chart to establish shoreline and tidal inlet positions. It became apparent that two points warranted attention: 1) the spit at the southwest end of Kiawah Island which periodically overlapped much of the shoreline along Seabrook Island, and 2) an offshore supratidal shoal, referred to as Deveaux Bank, associated with the ebb delta of North Edisto Inlet which borders the southwest end of Seabrook.

Figure 5. Bathymetric chart for 1867 (USC & GS Chart No. 154, Ed.1). Arrows indicate points of reference for comparison between charts. Note extension of recurved spit of southern end of Kiawah Is. at A.

SEABROOK 1939

Figure 6. Mosaic of vertical aerial photographs for 1939 (National Archives). Note position of Klawah spit at A and seaward extension of Deveaux Bank at C. Deveaux Bank effectively blocked all deepwater wave energy arriving from the south.

Figure 7. Erosion-deposition graphs for Seabrook Island, covering the period between 1939 and 1973, based on aerial photos (modified from Stephen et al., 1975). Accretion is positive (up) on graphs. Units are in meters. Note considerable shoreline instability at all stations.

Vertical Aerial Photographs

A sequence of vertical aerial photographs was obtained, covering the period 1939 to 1973. These, of course, provide much greater detail of the shoreline changes of the island than the older maps and charts. Unfortunately, no detailed bathymetric surveys were conducted during the interval between 1934 and 1978. An example from 1939 is shown in Figure 6. Based on this sequence of aerial photographs, Stephen *et al.* (1975) constructed graphs of erosion-deposition trends for the island (Fig. 7). Historical shoreline changes dating to 1853 are shown in Figure 8. Note that Seabrook was largely accretional until 1973.

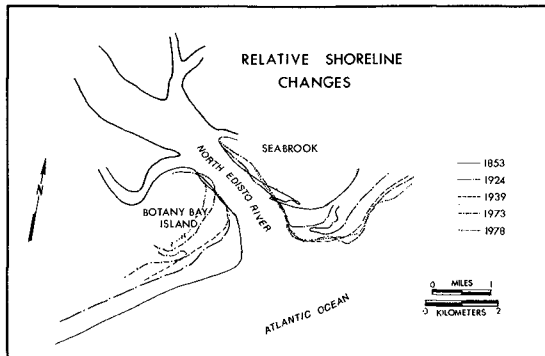

Figure 8. Relative changes of the shorelines of Seabrook and Botany Bay Islands between 1853 and 1978.

Changes of Kiawah River Inlet

The maps, charts, and aerial photographs studied indicate that the recurved spit affiliated with the Kiawah River undergoes a cycle of change that has occurred at least four times since 1661. The cycle (Fig. 9) includes:

- (a) breaching of the spit at the neck (where Kiawah River crosses the island perpendicularly) during a major storm;
- (b) migration of the spit southwestward at the rate of approximately 30.5 m (100 ft.) per year;
- (c) extension of the spit up to as much as the entire distance from the spit neck to the southwest end of Seabrook Island; and
- (d) breaching of the spit by another storm.

As the spit-inlet complex migrates, the affiliated ebb-tidal delta complex migrates with it. As waves refract around the moving ebb-tidal delta, the beach downdrift of the inlet tends to build out.

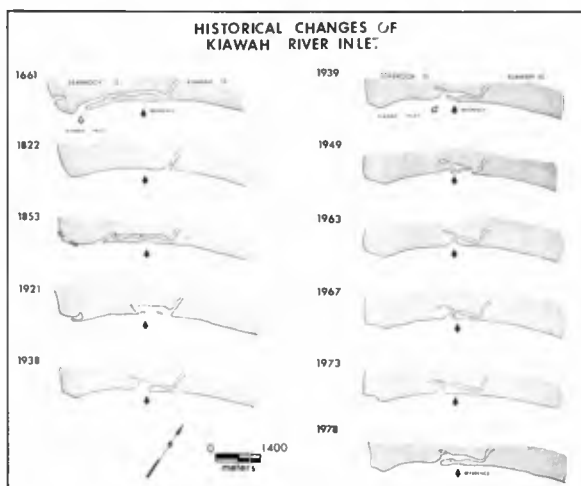

Figure 9. Historical changes of Kiawah River Inlet since 1661. Note cyclic response of spit growth over time (modified after Hayes *et al.*, 1975)

Changes of Deveaux Bank

One of the most important discoveries of the historical analysis was the fact that Deveaux Bank has retreated a phenomenal amount since 1939 (over 1000 m (.030 ft.)). From 1939 to approximately 1970, Deveaux Bank was an effective natural offshore breakwater that sheltered the shoreline in the vicinity of the southwest point from direct wave attack. In recent years, however, the bank is too far landward to provide this protection, a fact which has, no doubt, contributed significantly to the increased rate of erosion of the Seabrook shorefront. In recent years, the rate of erosion appears to have accelerated. Figure 10 shows the changes to Deveaux Bank, and Figure 11 is a photograph of the bank in 1978 at the time of the present study. The supratidal portion of the bank underwent rapid landward migration and erosion. The small intertidal shoal remaining in the former location is relatively ineffective in blocking wave energy at high tide.

Bathymetric Surveys

Since the study area is located adjacent to North Edisto Inlet, one of the largest tidal inlets on the South Carolina coast, bathymetric surveys of the main channel were compared from historical re-

Figure 10. Comparison of aerial extent of Deveaux Bank between 1939 and 1978. The center of the bank retreated 1500 m (4922 ft.), and the bank decreased to roughly one fourth its original size between 1939 and 1978.

Figure 11. Oblique aerial photograph of Seabrook (foreground) and Kiawah Islands, taken on 7 December 1978. Note position of Deveaux Bank (foreground), located 1500 m landward of the 1939 position. View looking northeast.

cords to determine if the channel had migrated north. Such channel migration would undoubtedly contribute to erosion of the adjacent shoreline. However, the surveys found no evidence to suggest channel meandering was occurring in the vicinity of the southwest point. There was evidence, however, that the northern marginal flood channel (a secondary channel dominated by flood currents) which flanks the main channel had shifted slightly landward toward the southwest point. This probably helped cause the observed increase in erosion.

CAUSES OF EROSION

The historical evidence indicates that until 1973, Seabrook Island had undergone long-term accretion. This indication that Seabrook Island is basically a regressive barrier (seaward building) in a geological sense, as well as the fact that tremendous volumes of sand are stored in the North Edisto ebb-tidal delta complex (roughly $\frac{1}{2}$ the volume of the sand stored in the entire Kiawah-Seabrook barrier island complex) (Hayes *et al.*, 1976), suggests that localized erosion problems at Seabrook are reversible. It is primarily a matter of inducing an adequate amount of the sand available in the area to reside on the beach.

The foregoing analysis suggests the following major causes of shoreline change along Seabrook Island:

1. Southerly migration of the updrift (Kiawah River) inlet and inlet-affiliated ebb-tidal delta which causes erosion along the inlet shoreline and accretion in the lee of the delta.
2. Encroachment of the northern marginal flood channel of the downdrift (North Edisto) inlet against the SE point of Seabrook Island.
3. Erosion and landward migration of an offshore supratidal bank (Deveaux) which has allowed increasing amounts of wave energy to reach the shore.

Southwesterly Migration of Kiawah River Inlet

Tidal inlets are the most dynamic feature of barrier island shorelines such as the coast of South Carolina. The two aspects of this dynamic nature that are of greatest importance to coastal landowners are geographic and geomorphic instability. Geographic instability means that entire tidal inlet systems migrate in an alongshore direction. This is generally a long-term process, taking place over a period of years or decades. Geomorphic instability means that, within an inlet system at any given time, shoals, channels, and adjacent beaches are constantly changing their position and orientation. This is generally a relatively shorter-term process, taking place over a period of weeks or months. All inlets display both of these characteristics to varying degrees.

In response to the longshore transport of sand by waves, tidal inlets migrate alongshore in the direction of net longshore transport.

This is accomplished by spit accretion on the updrift side of the inlet, which forces the channel to erode the opposite bank. The history of Kiawah River Inlet is a classic example of this process, as shown by Figure 9. Note that westerly spit growth between 1924 and 1939 was interrupted in 1949 as the Kiawah River breached the neck of the spit. Since 1949, the cycle has repeated itself, and spit accretion has continued to date. Unfortunately, jetty construction to halt this geographic instability would deprive Seabrook Island of its major source of beach sand, which is material transported by waves across the mouth of the Kiawah River. The manner in which this sand bypasses the inlet comprises the geomorphic instability of the system and will be described below.

Figure 12 is a diagrammatic sketch of the short-term instability of inlets like Kiawah River. The three stages describe a process by which the inlet channel oscillates back and forth from its main point between the two islands (like a dog wagging its tail). This oscillation is simultaneous with inlet migration, so that while the inlet moves along shore, the channel, through its outer shoals, is moving back and forth (the dog walking and wagging its tail at the same time). Beach erosion rates on the downdrift side of the inlet (the left side in the diagram -- analogous to Seabrook) are related to which stage of instability happens to be operating at a particular time. In stage two, with the bar extending, sand bypassing the inlet can remain offshore for a considerable distance before being carried up onto the beach, and downdrift beach erosion rates immediately adjacent to the inlet are at a maximum. When a new channel is cut in stage three, the entire bar migrates onto the beach which, in effect, provides a large package of natural beach nourishment material and minimizes beach erosion.

Figure 12. Diagrammatic sketch of the short-term instability of inlets like Kiawah River Inlet. Stage 1 and 2 show initial growth and extension of the ebb delta in the downdrift direction. In stage 3, channel abandonment occurs, allowing by-passing of sand onto downdrift beaches. (Diagram by Dennis K. Hubbard and Duncan M. FitzGerald.)

This process has occurred naturally at Kiawah River Inlet, as shown in Figure 13. These aerial photographs were taken over the eleven month period between March, 1975 and February, 1976. They document the evolution from the bar elongation (Fig. 13, upper) through channel abandonment (Fig. 13, middle) to eventual welding of the bar onto the beach (Fig. 13, lower). In 1978, during the present study, Kiawah River was in stage two (bar elongation).

Encroachment of Marginal Flood Channel

The large shoal system seaward of North Edisto Inlet comprises what is referred to as an ebb-tidal delta. Studies of numerous ebb-tidal deltas on the east coast of the U.S. (e.g., Finley, 1975; Hine, 1975; Hubbard, 1975) and reconnaissance studies on the coasts of Alaska, Baja California, and the Gulf of St. Lawrence by the Coastal Research Division of the University of South Carolina indicate that the morphology of these sand bodies is similar from place to place.

The components of a typical ebb-tidal delta include a main ebb channel, which usually shows a slight-to-strong dominance of ebb-tidal currents over flood-tidal currents. The main ebb channel is flanked on either side by linear bars, which are levee-like deposits built by the interaction of ebb- and flood-tidal currents with wave-generated currents. At the end of the main channel is a relatively steep, seaward-sloping lobe of sand called the terminal lobe. Broad sheets of sand, called swash platforms, flank both sides of the main channel. Usually, isolated swash bars, built by the swash action of waves, occur on the swash platforms. Marginal tidal channels dominated by flood-tidal currents, called marginal flood channels, usually occur between a swash platform and the adjacent updrift and downdrift beaches.

A well-defined marginal flood channel has existed for some time off the south-southeast end of Seabrook Island. By 1978, it had shifted toward the island at the southeast point (see aerial photograph in Fig. 11). Sediment eroded from the beach in that vicinity would be carried offshore into the channel where it is undoubtedly redistributed by the strong flood-tidal currents that exist in the channel. In 1978, it appears that the marginal flood channel was too close to the beach to allow for the natural onshore-offshore transfer of sand that normally occurs on beaches.

The Erosion of Deveaux Bank

As discussed in some detail previously, Deveaux Bank eroded over 1500 m since 1939. As the bank eroded, the area near the southwest point became more and more exposed to open ocean waves. This is probably the single most important factor in the increase of the erosion rate for that locality.

Figure 13. Bar-bypassing at Kiawah River Inlet.

PROPOSED SOLUTIONS

Based on the above causes of erosion, a number of "soft" engineering solutions have been proposed to retard or eliminate local erosion problems at Seabrook Island. These include: 1) dredging of a new inlet channel north of Kiawah River Inlet to allow sand in the ebb delta to naturally migrate onshore at Seabrook, 2) dredging of a new northern marginal flood channel further seaward on the North Edisto River ebb-tidal delta to relieve the erosive pressure at the southeast point of Seabrook, and 3) reestablishment of a natural (or artificial) breakwater in the former position of Deveaux Bank. One possibility for the latter would be to construct a floating offshore breakwater. These solutions are outlined in Figure 14.

Figure 14. Proposed "soft" engineering solutions for reducing shoreline erosion along Seabrook Island, including: 1) dredging new channels at e_2 and f_2 , allowing existing Kiawah River Inlet channel (e_1) and North Edisto Inlet marginal flood channel (f_1) to infill; and 2) construction of a floating breakwater (or hydraulic filling) in the former position of Deveaux Bank.

Although the proposed solutions do not have the permanence of "hard" engineering coastal protection works, their cost of implementation is at least an order of magnitude less than presently-used structures, and they have the aesthetic advantage of preserving the character of Seabrook beaches. Present plans are to implement at least two of these solutions. If successful, they will demonstrate the relevance of geologic and coastal process information not only for use in "hard" designs, but as a means for determining appropriate "soft" design solutions for coastal protection.

CONCLUSIONS

Erosion problems on Seabrook Island appear to be localized and due to three independent but related processes: (1) the migration of Kiawah River Inlet; (2) the encroachment of a marginal flood channel of North Edisto Inlet on the shoreline in the vicinity

of the southeast point; and (3) increased wave activity caused by the erosion of Deveaux Bank. All of these processes are the direct results of the highly dynamic nature of tidal inlets and are common occurrences in similar environments elsewhere. None of the erosion trends were caused by Seabrook Island construction. Future construction activities on the island would benefit if these natural trends are considered. Several "soft" engineering solutions are available which would considerably retard or reverse present localized erosion trends.

ACKNOWLEDGEMENTS

We would like to thank Drs. Per Bruun and Cyril Galvin for their consultations and helpful advice on several occasions during the project. Dan Domeracki, Jacqueline Michel, Tom Moslow, Mohammed Al-Sarawi, and Kent Taylor assisted in the field. Special thanks to Jerry Sexton who managed much of the field work and data reduction.

CHAPTER 57

GEOLOGICAL CONTROLS ON PROCESS-RESPONSE, S.E. AUSTRALIA

by

P.S. Roy* and A.W. Stephens*

ABSTRACT

Results of regional geological studies on the southeastern Australian coast and inner continental shelf suggest that broad relationships between nearshore sediments and morphologies are often the result of factors other than incident waves and wave-induced currents. Five main factors (including wave action) have been identified:

1. degree of compartmentization and sand bypassing,
2. incident wave energy,
3. offshore sand loss to deep water sinks,
4. inherited sediment characteristics,
- and 5. substrate control.

It is thought that these factors have controlled coastal evolution in the past and also influence present-day coastal changes. Identification of the role played by individual factors in specific areas provides valuable information on coastal sediment budgets.

INTRODUCTION

Many coastal engineering problems focus on the interaction of marine processes and sediments. Hydrodynamic processes are usually seen as the dominant control on the coastal sediments and morphologies. Because of this, many studies use measurements of dynamic processes taken over short time periods to predict sediment response. We suggest that geological factors also influence process-response relationships. Past geological events have both a direct impact on processes themselves, and their imprint modifies the way in which sediments and morphologies react to present-day dynamic conditions. Geological interpretation of sediment patterns and seabed morphologies can provide information on the cumulative effects of variable dynamic processes operating over a time span ranging from decades to millenia. These data can be used to test results derived by other techniques such as direct process measurements, sand tracing and theoretical predictions.

Resources, Box 5288, G.P.O., Sydney, Australia, 2001.

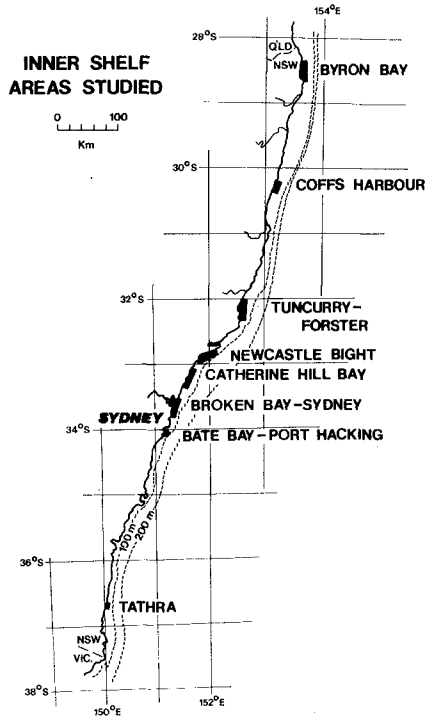

Figure 1. New South Wales coastal zone showing inner shelf areas discussed in text.

Studies in several areas along the New South Wales (N.S.W.) coast (Figure 1) have documented modes of coastal evolution and identified a number of geological controls which affect responses of sediment and morphology to nearshore processes.

COASTAL SETTING

The N.S.W. coast comprises sand barriers between rock headlands in embayed bedrock compartments. It is subject to a moderate to high energy wave climate with dominant waves from the south and south-east. A high degree of compartmentization exists on the south and central coast where rock headlands extend into deep water but in the north, sediment by-passing commonly occurs between embayments as a result of northward littoral drift (Thom and Roy, in press). Rivers do not supply significant quantities of sand to the coast (Roy and

Crawford, 1977). Most barriers on the coast are of Holocene age and lie seawards of a variety of estuarine and alluvial deposits infilling coastal valleys (Roy et al. 1980). In parts of central and northern N.S.W. the Holocene barriers onlap older barriers of Pleistocene age but in some embayments Holocene barriers are absent and Pleistocene sand deposits are exposed at the coast. The barriers formed during the Last Interglacial and Postglacial periods of high sea level (Langford-Smith and Thom, 1969; Marshall and Thom, 1976; Thom et. al., 1978; Thom and Roy, in press).

Sediments

Three main sediment units are recognised on the inner half of the N.S.W. continental shelf: nearshore sand, inner shelf sand and mid-shelf muddy sand (Figure 2). Sedimentation is believed to be presently active in the nearshore and mid-shelf zones but on the inner shelf the sand is palimpsest (Swift et al., 1971).

Figure 2. Typical, concave-up sea bed profile showing normal arrangement of sediment types. Lithologies (insets) illustrating grain sizes and shapes are drawn from photomicrographs at the same scale; stippled areas are open spaces.

Nearshore Sand

Nearshore sands comprise inner and outer nearshore sand types although the latter is not found at all embayments. They normally occupy a concave-up nearshore zone that varies greatly in width

(0.7-2.6 km) and depth range (15-30 m). Both inner and outer nearshore sand types occupy a zone of active reworking that corresponds to the seaward face of the coastal barriers.

Inner nearshore sand includes the beach and extends seawards of the longshore bar to depths of 4-12 m. It is fawn, quartzose, medium to coarse grained, moderately to well sorted (unimodal to bimodal) and composed of rounded grains. Usually it contains less than 10% shell fragments and less than 20% of the grains are ironstained although in a few embayments values are much higher. Texture and composition may vary widely between compartmented embayments. Landward of the longshore bar, grainsize changes reflect variations in surf zone processes and morphologies; seaward of the bar, sand size usually decreases with increasing depth. Bedforms vary from small ripples to large symmetrical and asymmetrical sand waves.

Outer nearshore sand lies seaward of the inner nearshore sand unit, often with a relatively sharp boundary and extends to depth of 15-30 m. It is olive grey, quartzose, fine grained, well sorted (unimodal) and composed of sub-angular to rounded grains. Shell content and iron staining are usually similar to the associated inner nearshore sand although outer nearshore sand is texturally more uniform between embayments. Despite decreasing wave turbulence, grainsize usually shows little variation with increasing depth. Small symmetrical wave-formed ripples are the typical bed form.

Inner Shelf Sand

Inner shelf sand occupies the gently sloping inner shelf surface and extends seawards from the zone of nearshore sand to depths of 50-60 m+. It is orange-brown (due to extensive ironstaining), quartzose, medium to coarse grained and, in places, gravelly. It is generally poorly sorted (polymodal) and composed of well rounded grains. Shell content is highly variable but is usually less than 20%. Mud occasionally forms a minor component (<5%), mainly in the outer part of the unit. Inner shelf sands are texturally variable both within and between regions. Symmetrical (wave-formed) megaripples commonly occur in areas of coarse sand and gravel. Algae coatings on pebbles indicate that movement occurs mainly during high energy events.

Inner shelf sands do not conform to a classical "equilibrium" trend of fining seaward. They are essentially relict deposits that are presently being reworked.

Mid-Shelf Muddy Sand

Muddy sediments occur discontinuously over large areas of the mid-shelf seawards of the 50-60 m isobath (Thom and Roy, in press). They comprise dark grey, fine to very fine sand plus mud and support an abundant fauna of foraminifera, polychaetes and bivalves. Sand grains are angular to subangular and non-ironstained. Lithic content in the sand is usually higher than in other sediment on the inner shelf. In places the muddy

unit contains a coarse sand mode that is thought to be related to an underlying relict sand substrate; intermixing is presumably by bioturbation.

From the occurrence of fine sediment in this region we infer a low energy "window" between the wave-dominated inner shelf and the current-dominated outer shelf and upper continental slope (not discussed here).

The normal relationship between sediments and morphology seawards of the surf zone is for nearshore sands to form a moderately steep, concave-up slope (Figure 2); grainsizes generally decrease seawards with increasing depth. This region corresponds to an active zone in dynamic semi-equilibrium with the local wave climate. Further seawards the palimpsest, inner shelf sands form a more gently sloping planar surface. The relatively abrupt change in grainsize between fine outer nearshore sand and coarser inner shelf sand suggests that the latter do not presently contribute significantly to the modern coastal sediment budget.

Barrier sediments on the N.S.W. coast were derived from three sources: (a) the inner continental shelf, (b) coastal sand barriers of Pleistocene age, and (c) modern fluvial supply.

(a) The majority of the barrier and nearshore deposits are formed of sand reworked from the inner shelf and transported onshore during and since the Postglacial Marine Transgression (Roy et al., 1980; Thom and Roy, in press). This sediment type is mainly composed of mature, rounded and partly iron oxidized-coated quartz sand and shell that has been repeatedly reworked, mainly by marine processes during one or more glacial/interglacial cycles. Locally it is termed "marine" sand (Roy and Crawford, 1977).

(b) In areas where Pleistocene barriers are exposed at the coast, marine erosion of these deposits supplies sand to the modern beach and nearshore zones. The parent sand is "marine" in character and, except for leaching of shell and the absence of iron oxide coatings, its erosion product is similar to the sand forming the Holocene barriers.

(c) Rivers supply sand to only a few small embayments in southern N.S.W. (R. Kidd, unpubl. Ph.D. Thesis, 1980). "Fluvial" sand is typically immature (angular) and contains abundant lithic (rock and feldspar) grains. Elsewhere, medium to coarse river sand is deposited in the lower river valleys and in coastal estuaries (Roy and Crawford, 1977). Fine to very fine terrestrial sand and mud that is carried to the sea during floods is transported (diffused) across the inner shelf and deposits in the mid-shelf region (Thom and Roy, in press).

Barrier Formation

Considerable radiocarbon age data on shelly beach and nearshore facies in prograded beach ridge systems (Thom, 1978; Thom et al., 1978) show that most Holocene barriers accreted between about 6000 and 3000 years ago, with a few continuing to grow up to 1000 years ago. Over this time span, sea level on the tectonically stable southeast Australian margin

has remained fairly constant (± 1 m) (Thom et al. 1969, 1972; Cook and Polach, 1973; Thom and Chappell, 1975; Belperio, 1979; Jones et al., 1979).

Thus it is reasonable to assume that barrier building occurred under marine conditions broadly similar to those operating today. The composition of most barrier deposits clearly shows that they are formed of sand reworked from the inner shelf; not from modern fluvial sources. In some areas there was undoubtedly a strong littoral drift supply from upcoast, but in closed compartments the sand feed was essentially in an onshore direction. Figure 3 shows the latter situation for an embayment that is closed in terms of littoral drift inputs and outputs. The original 6000 year profile configuration has been reconstructed by transposing the volume of sand in the existing barrier to the offshore sea bed. A prograded wedge of barrier deposits (stippled) composed of beach and nearshore sand forms the inshore part of the profile. Further seawards are inner shelf sands that have acted as a sand source for barrier building in the past. Thus the inner part of the profile is aggradational while its outer part is erosional. From this reconstruction it is clear that, during barrier formation, sand was transported landwards in water depths considerably deeper and from further seawards than is apparently occurring today as indicated by the present active zone of nearshore sediments. There is virtually no evidence in N.S.W. that barriers are still prograding: in fact the reverse is generally the case. What has stopped them growing?

Figure 3. Model of mid Holocene barrier development in a compartmented embayment showing inferred movement of sand from the inner shelf under sea level conditions similar to the present day. Numbers 1-3 represent the chronological sequence of barrier growth and corresponding sea bed erosion. Arrows show directions of beach ridge progradation and associated sand supply from offshore.

One possibility is that the sand supply was cut off once a wave-formed profile of equilibrium was established. Further, from the preceding discussion, we would expect the equilibrium profile to extend to water depths of 50 m or more. In these depths the open ocean wave climate is broadly consistent along the N.S.W. inner shelf although local variations occur in the inshore zone due to refraction and diffraction effects. Thus, if waves were the principal control limiting barrier development, we would anticipate general similarities in profile shape (especially in its outer part) and in sediment patterns between embayments.

Figure 4 shows a selection of shore-normal profiles across the N.S.W. inner continental shelf. General similarities in the inner parts of these profiles suggest that equilibrium conditions may exist in water depths above about 15 m. Below this depth, the wide diversity in gradients and morphologies are difficult to account for in terms of a simple, wave-controlled equilibrium profile of the type proposed by Zenkovitch (1967). Obviously, factors other than wave action are important in producing present-day sea bed patterns. Interest in the morphology and sediments in coastal embayments and on the inner shelf arises from the belief that factors controlling barrier development in the past also influence modern shoreline changes.

CASE STUDIES

Geological investigations have been carried out in a number of areas along the N.S.W. coast in conjunction with coastal engineering studies by the N.S.W. Department of Public Works. These projects were

Figure 4. Shore-normal sea bed profiles from open ocean embayments in N.S.W. showing the diversity of shapes.

aimed mainly at providing information on coastal erosion and its management. Results from several areas illustrate the ways in which geological factors have influenced coastal sedimentation. The areas are: Byron Bay and Coffs Harbour in northern N.S.W. and Newcastle Bight in central N.S.W. (figure 1).

Byron Bay

The Byron Bay embayment (figure 5) is an example of an open, zetaform bay in which southeasterly swell waves generate a strong northward littoral drift and ocean currents cause an offshore sediment loss (Roy et al., in press). Uninterrupted sediment bypassing is indicated by the continuity of the nearshore sediment zone around headlands. Despite variations in incident wave energy, inner nearshore sand is of uniform composition and texture throughout the area due to longshore mixing. Progressive deepening and steepening of the shoreface towards the north is related to increasing wave energy in the same direction (see profiles A and B in Figure 5).

Alongshore variations in the energy and obliquity of the incident waves produce higher littoral drift rates in the north than in the south (Figure 6). As a result of this drift differential, the embayment between Cape Byron and Hastings Point is eroding into old Pleistocene sand deposits. Average rates of shoreline recession are 0.6 m/yr based on historical data (40-90 years) and between 0.25 and 0.35 m/yr from radiocarbon evidence spanning the past 400 years.

The present imbalance between drift gains and losses is attributed to three causes: (a) a regional increase in obliquity of the coast to the dominant wave approach; this tends to increase littoral drift rates towards the north.

(b) both regional and long-term tendencies in northern N.S.W. for embayments to become compartmented earlier in the south than in the north thus causing a gradual reduction in sand supply to areas downdrift.

(c) a long-term loss of nearshore sand at Cape Byron at the southern end of the bay to deep water sinks offshore (see below).

It is probable that, in mid Holocene times, onshore transport of sand from the inner shelf resulted in barrier development in Byron Bay as it did in most other embayments in N.S.W. However, eventually the Byron Bay barrier was eroded as a drift imbalance developed and it is likely that recession rates have gradually increased over the Late Holocene, mainly due to (b) above.

Areas of offshore sediment loss are identified by abnormalities in the shape, width and depth range of the nearshore sediment zone. In the north this zone is narrow and extends to depths of about 25 m. Profiles are concave-up and indurated Pleistocene sediments, exposed on the shoreface to depths of 18 m, indicate that the whole nearshore zone is erosional. However in central and southern parts of the area, the nearshore

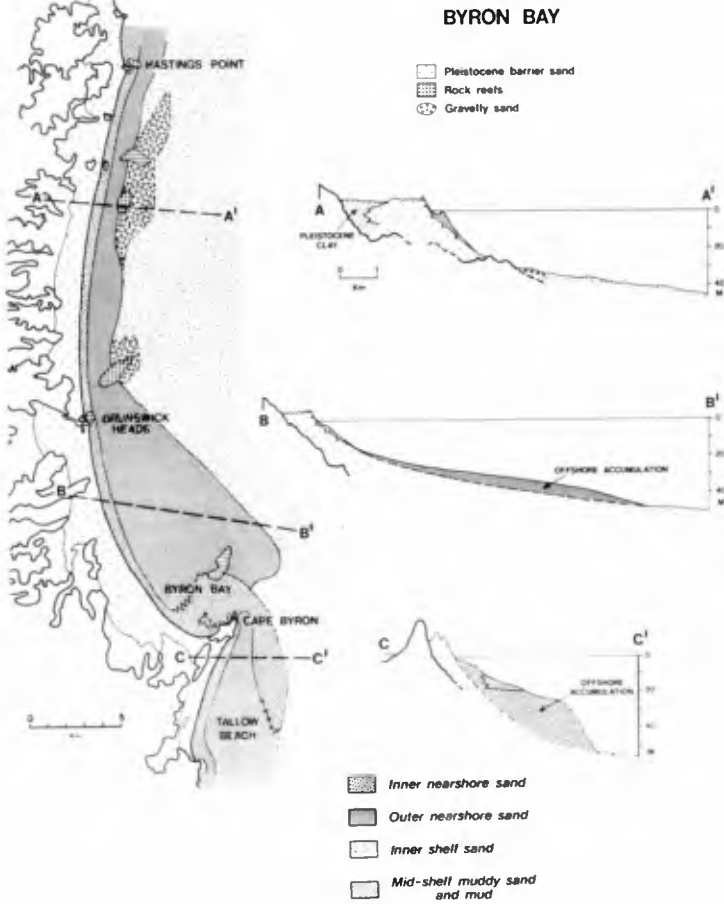

Figure 5. Byron Bay offshore area showing distribution of sediments and inferred Holocene stratigraphy. The inner parts of cross sections A and B show a thin wedge of active nearshore sand above an eroding Pleistocene substrate. Accumulations of nearshore sand lost from the shoreface since mid Holocene times occur in profiles B and C. Bedrock margin onshore indicated by solid, heavy line.

sediment unit widens and extends to depths of 50 m, twice the normal depth, and profiles become convex-up (figure 5, profiles B and C). These trends are attributed to deposition of sand in offshore sinks by southward flowing ocean currents (figure 6). During strong southeasterly swell action, nearshore sand which drifts northwards along Tallow Beach is "jetted" past Cape Byron. At times when the southward flowing East Australian Coast Current impinges on the headland, wave-suspended sand is entrained and transported southwards. In this area low amplitude, current-formed sand waves occur in depths of 20 m +. Deposition occurs in a southward trending lobe (figure 5) where the ocean current diverges from the coast, velocities weaken and eddies form (Figure 6). Accumulation of a smaller volume of finer outer nearshore sand over a broad area to the north of Cape Byron is probably due to a clockwise sediment circulation generated by wave drift inshore and ocean currents offshore.

A regional alongcoast movement of sediment is indicated by the continuing supply of sand to both depositional sites. Northward littoral drift in the surf zone together with deep water wave drift from the south and (possibly) ocean current transport from the north within the outer nearshore zone are probable supply mechanisms (Figure 6). The principal source of beach and nearshore sand in this area is from the erosion of Pleistocene barriers both within the embayment and up coast (i.e. to the south).

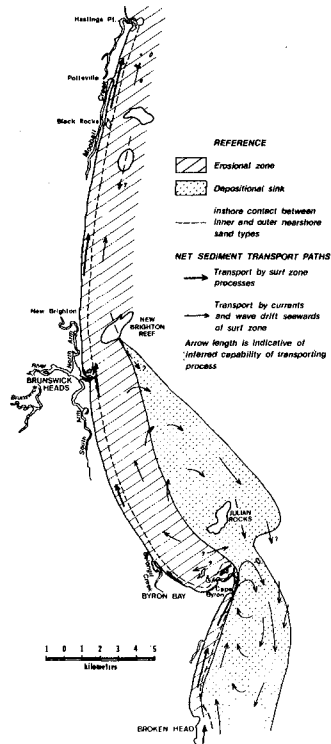

Figure 6. Byron Bay area showing regions of offshore erosion and deposition and inferred sediment transport mechanisms and paths.

The deposit to the south of Cape Byron is up to 20 m thick and has been calculated to contain approximately 160 million m^3 of outer nearshore sand above an initially concave-up substrate. Assuming deposition commenced about 6000 years ago, the average rate of sand loss from the nearshore system has been about 26,000 m^3/yr of inner and 58,000 m^3/yr of outer nearshore sand.

Coffs Harbour

This area lies within a sector of bedrock controlled coast; rock reefs occur extensively offshore (figure 7). Changes in coastal orientation and bedrock embayment size are responsible for contrasting coastal development north and south of Coffs Harbour. Southern embayments are relatively large and contain extensive Pleistocene estuarine deposits that originally accumulated behind sand barriers of the same age. These Pleistocene barriers have subsequently been destroyed by marine erosion, presumably towards the close of the Last Interglacial. Later, they were replaced by Holocene beachridge barriers that prograded in bay mouth positions. The coast north of Coffs Harbour is characterised by small embayments and pocket beaches with narrow Holocene barriers backed, in most areas, by bedrock.

Nearshore and inner shelf sediments form a generally thin veneer above bedrock or a Pleistocene clay substrate. Maximum thicknesses occur beneath the southern barriers (Figure 7, cross section C-C') but elsewhere, nearshore sediments are commonly less than 2 m thick. The continuity of the inner nearshore sand unit is interrupted by Coffs Harbour and by a number of headlands to the north of the harbour. This sediment unit is wider and extends to greater depths (c. 12 m) in the south than in the north (c. 5-8 m). Beach and inner nearshore sand in the south is uniformly medium grained and the beaches have wide surf zones but in the north beaches are coarse, steeply sloping and usually reflective in character. Outer nearshore sand forms a continuous zone alongshore but is interspersed by rock reefs and exposures of coarse inner shelf sand and gravel that form the underlying substrate. Outer nearshore sand forms a thin "mobile carpet" that is completely remobilised under even moderate storm conditions. This unit occurs in depths ranging from 12-25 m in the south and 5-20 m in the north.

Shore-normal profiles in the south are steeper and more concave than in the north where the underlying substrate exerts an over-riding control on sea bed configurations (Figure 7).

Since harbour construction commenced in 1915, northward littoral drift has been interrupted and sand has been trapped in the southern embayment. Historical data spanning the last 40 years indicate that the northern end of this embayment has prograded up to 100 m and about 5 million m^3 of sand has deposited on the beach and in the inner nearshore zone. Over approximately the same period, more than 1.5 million m^3 of mainly fine, outer nearshore sand has accumulated inside the Harbour and off its mouth where the sea bed has developed a marked convexity.

It is reasonable to assume that, prior to harbour construction, northward littoral bypassing operated, albeit at a low rate, throughout the whole region. The northern beaches at this time are reported to have

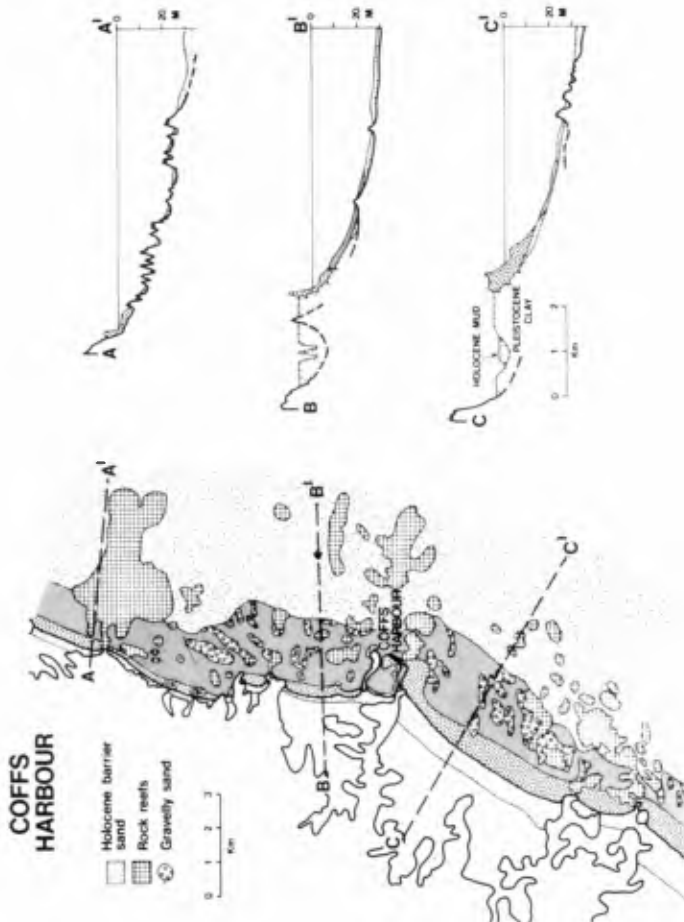

Figure 7. Coffs Harbour area showing surface sediment units and stratigraphic sections. Progressive increase in barrier size towards the south is related to bedrock embayment size. Note change in coastal orientation at Coffs Harbour. (Key to offshore sediments shown in Figure 5).

been fine grained, gently sloping and dissipative in character. The response of these northern beaches to the cessation of updrift sand supply in the period following harbour works has been strongly influenced by the shallow substrate. Coastal retreat has been mitigated not only by the bedrock hinterland but also by the character of the offshore sea bed. Radiocarbon dating on subsurface shell samples from within the zone of fine outer nearshore sand suggests that the underlying, coarse inner shelf sediments are reworked during storms to depths in excess of 1 m below the sea bed. Their periodic exposure has released coarse sand and fine gravel that has migrated onshore. As a result beaches in this area have coarsened and steepened and, in at least one case, have prograded slightly in historical times.

Newcastle Bight

Newcastle Bight (figure 8) is a broad shallow embayment oriented normal to the dominant wave regime. There is a large gross littoral drift but no net drift. It has acted as a sand trap during two periods of interglacial high sea level, and is the best known example of a dual barrier system on the N.S.W. coast (Thom, 1965; Roy, 1980, Thom et al. in press).

The oldest sand deposits on the inner continental shelf of Newcastle Bight form a drowned coastal barrier (proto-barrier) located 3-6 km seawards of the present coastline in water depths of 55-60 m+. An associated sequence of estuarine clay in the subsurface extends shorewards from the proto-barrier and underlies the onshore barriers (Inner and Outer Barriers, Figure 8). The clay unit is up to 60 m thick and is of polycyclic origin. Both the proto-barrier and estuarine deposits predate the Inner Barrier which is of Last Interglacial age (Roy and Crawford, 1980).

Sandy strandline deposits overlie the clay substrate offshore and occupy the inner shelf plain between the proto-barrier and the concave-up nearshore zone. These inner shelf sands contain gravels related to an old drainage system of the Hunter River; they form a basal transgressive unit beneath the Outer Barrier.

The Outer Barrier is Holocene in age and comprises beach ridges transgressed on three separate occasions by dunes. To the rear of the barrier, estuarine backbarrier deposits infill the interbarrier depression. Modern muds and sandy muds blanket the seaward face of the proto-barrier in water depths greater than 60 m.

The Newcastle Bight sediment budget is in deficit due to the loss of beach sand landwards into presently mobile dunes. Present-day inputs of sand to the nearshore zone by littoral drifting, cliff erosion, biogenic production and river supply are small. In historical times the shoreline has receded at rates of 1-2 m/yr (Gordon and Roy, 1977; Roy and Crawford, 1980).

On the seaward face of the Holocene barrier is a zone of nearshore sand which is compartmented by deep water rock reefs at either end of the embayment. The contact between nearshore and inner shelf sand types is abrupt and occurs at depths of between 15 and 30 m. The nearshore zone shows a number of alongshore trends: In the centre of the embayment where sediments are coarse the nearshore profiles are steep, a single bar is

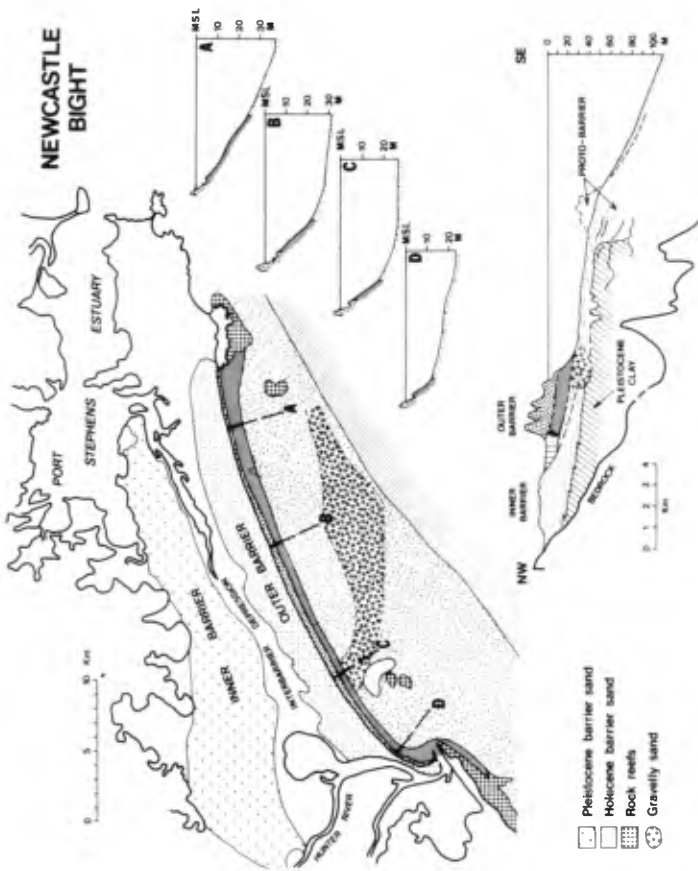

Figure 8. Newcastle Bight showing dual barriers onshore and offshore sediment distribution; gravelly sands are related to an old course of the Hunter River. Stratigraphic section is based on onshore drilling and marine seismic data for the axial part of the embayment. (Key to offshore sediments shown in figure 5).

developed and the nearshore sand zone is narrow. Towards the northeast where sediments are finer, profile slopes are more gentle, multiple bars are developed and the nearshore sand zone is wide. Grain size trends in the inner nearshore sand unit mirror those within the eroding Holocene barrier. This barrier is composed of sand reworked from the inner shelf. Here the sediments are coarse, relict fluvial deposits in the centre of the bay and fine, relict dune sand at its northeastern end (Roy and Crawford 1980). Their onshore transport has produced a similar size grading in the barrier. Subsequent shoreline erosion has thus exposed barrier deposits of different grain sizes on the beach and shoreface with the result that nearshore morphologies vary alongshore. Despite a large gross drift, continuing erosion has allowed inherited grain size characteristics to dominate in controlling the profile shapes.

DISCUSSION

Based on studies of the type described above, at least five main factors can be identified as influencing the relationships between sediments and morphology in coastal embayments of southeastern Australia. These are:

1. Compartmentization
2. Incident Wave Energy
3. Offshore Deposition
4. Inherited Sediment Characteristics
5. Substrate Control.

1. Compartmentization

Varying degrees of compartmentization and sediment bypassing are shown by the plan distribution of nearshore sand types. In the Byron Bay region (Figure 5) the continuity of inner and outer nearshore sand units around headlands at either end of the embayment indicate that this compartment is open to littoral bypassing although drift rates within it vary. The Coffs Harbour area (Figure 7) is compartmented with respect to inner nearshore sand but not outer nearshore sand although subtle differences in grain size within the latter unit suggest that alongshore mixing rates are relatively low. In Newcastle Bight (Figure 8), both inner and outer nearshore sand units terminate against headlands and submarine rock reefs at either end of the embayment. In this case alongshore gains and losses of sand to the sediment budget are negligible.

2. Incident Wave Energy

Local variations in wave energy within an embayment are reflected by relationships between nearshore sediments and morphology. This is best displayed in zetaform bays which are oriented obliquely to the dominant wave climate and, in southeastern Australia, are hooked at their southern ends (e.g., Byron Bay). In areas of low wave energy the sea bed is shallower and shoreface profiles are less steep than in more exposed sites (see trend between south, central and north profiles of the Byron Bay embayment, Figure 9a). These morphological changes may or may not be accompanied by grain size trends in the beach and nearshore sand units. In compartmented bays with negligible littoral bypassing

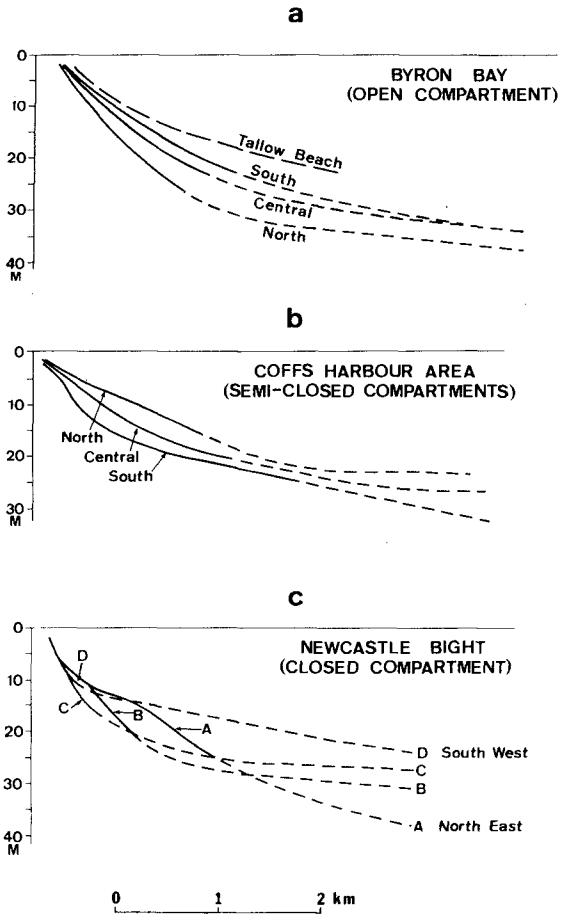

Figure 9. Shore-normal sea bed profiles for three areas each showing progressive variations in shape and distribution of nearshore (solid lines) and inner shelf (dashed lines) sediment units.

grainsizes coarsen in response to increasing wave energy (e.g., Pearl Beach in Broken Bay, Chapman, 1978). However, in compartments open in terms of littoral bypassing (these are almost invariably "zeta" shaped in N.S.W.), sand sizes are uniformly well mixed alongshore (e.g., Byron Bay).

Zetaform bays usually evolve erosionally due to a drift differential within an open littoral drift system. Eventually, shoreline retreat and headland emergence prevents further littoral throughout and, providing no other sand loss mechanisms operate, the bay achieves a stable configuration. The presence or absence of alongshore grainsize trends in such bays is a useful criterion to determine whether a stable planform has been achieved, especially where headland bypassing is difficult to establish by other methods.

3. Offshore Deposition

For sediment budget calculations, permanent sand losses into transgressive dune fields and estuarine tidal deltas are usually easily recognised. Newcastle Bight and Bate Bay (Figure 1) are embayments that have lost sand into transgressive dunes; Broken Bay and Port Hacking are drowned river valleys containing large flood tide deltas composed of "marine" sand. Less obvious are sand losses to relatively deep water offshore. The progressive accumulation of sand offshore in water depths of up to 50 m cause abnormal distributions of nearshore sediment types and sea bed profiles that are convex, rather than concave-up.

In Byron Bay (Figures 5 and 6), loss of nearshore sand by ocean current action to offshore sinks is exacerbating coastal erosion within the embayment. Here volume estimates of the sand contained in the offshore sinks are based on assumptions that the transporting mechanisms have operated since sea level reached its present position about 6000 years ago and that a pre-existing substrate on which deposition has occurred can be recognised in the subsurface.

At Tathra (Figure 1), river sand is jetted seawards during major floods and deposited offshore in water depths of up to 26 m. In this embayment a major flood in 1971 appears to have initiated shoreline recession of up to 40 m as sand was transported alongshore (northwards) to infill the overdeepened river mouth and reform the river mouth bar (Gordon and Lord, unpubl. Public Works Department report., 1980). Onshore transport of excess sand from the bay bed has not yet (i.e., 9 years later) restored the shoreline to its pre-flood configuration. In this case it remains to be determined whether the supply of river sand to the bay during mid and late Holocene times has produced net, long-term shoreline accretion despite short-time erosion following floods. If not, then presumably other mechanisms, as yet unidentified, cause a continuing loss of river supplied sand from the bay (to deep water offshore?) in which case the shoreline may be experiencing long-term retreat.

4. Inherited Sediment Characteristics

The source of Holocene sediments infilling most sandy embayments in N.S.W. was from the inner continental shelf, and was the result of marine reworking during and following the Postglacial Marine Transgression (Thom et al., 1978; Roy et al., 1980). In embayments which are suffering

erosion, the composition of the Holocene barriers may control nearshore sediment-morphology relationships and over-ride dynamic influences. This situation has only been found in compartments with no littoral drift throughput.

In Newcastle Bight (Figure 8), shoreface erosion into coarse grained barrier sands in the centre of the embayment has resulted in steep but relatively shallow nearshore slopes (profiles C in Figure 9c). Towards the northeast, sands become finer and profiles have responded to similar wave conditions by becoming more gently sloping but deeper (profiles A and B in Figure 9 c).

A similar situation appears to exist in Shoalhaven Bight, 120 km south of Sydney. Here the over-riding influence of inherited sediment textures is highlighted by a northward fining of the beach and nearshore sediments despite an increase in wave energy in the same direction (Wright, 1970).

These relationships demonstrate that a number of different nearshore configurations may accommodate a given incident wave regime. The controlling factor is sediment size; the dependent variable is morphology.

Substrate Control

Holocene barriers have accumulated on a gently inclined substrate that includes medium to coarse sands and gravels. Where this substrate had been transgressed and is exposed on the sea bed, it forms the inner shelf sand unit. Under eroding conditions, landward retreat of the seaward face of the coastal barriers intersects the rising surface of the underlying substrate. As a result, nearshore sediment patterns and morphologies are modified: nearshore sediment zones become narrow and occur at shallower than normal depth while profiles flatten and become more planar.

In the Coffs Harbour area these trends are increasingly developed towards the north (Figure 9 b). Reworking and onshore transport of sand from the shallow substrate in the region north of the harbour has presumably been responsible for the relatively coarse nature of the adjacent onshore deposits both during their formation in mid Holocene times and more recently after harbour works interrupted the littoral sand supply.

In the Byron Bay area coastal retreat over an inclined substrate has exposed patches of gravelly, inner shelf sand on the lower shoreface between Brunswick Heads and Hastings Point (Figure 5). In contrast, offshore deposition in the Tallow Beach embayment immediately to the south of Byron Bay (Figure 5) has resulted in a shallower and more gently sloping sea bed than in nearby areas with similar wave exposure (compare the Tallow Beach profile in figure 9a with that from the northern part of the Byron Bay embayment).

In the Forster-Tuncurry area (Figure 1) large embayments either side of Cape Hawke show contrasting offshore morphologies that have influenced barrier development onshore. The sea bed off the southern embayment is deep and steeply sloping; the Holocene barrier here is narrow. The northern embayment has a wide, shallow inner shelf plain that has acted as a large sand source during barrier building in the past. Both Holocene and Pleistocene beachridge barriers are well developed in this embayment.

CONCLUSION

Geological studies of marine deposits along the N.S.W. coast have led to the identification of a number of factors that have played an important role in producing present-day nearshore morphologies and sediment patterns. The geological setting in which these factors operate is a tectonically stable shelf and coast with a very small supply of modern sediment and a moderate to high energy wave climate. Here, coastal barriers in bedrock embayments are mostly composed of sand derived from the inner shelf; many barriers are presently eroding.

Although incident waves are the principal sand transporting mechanism on the open coast, their influence on many coastal sand deposits is modified by the nature of the local bedrock and older sediment surfaces at the coast and on the inner shelf. These modifications are reflected by: the extent to which sand is exchanged between embayments (factor 1); variations in embayment orientation and incident wave energy within the embayment (factor 2); the range of shoreface morphologies produced by different inherited sediment types (factor 4); differing shoreface responses to changes in sediment supply (factor 5). In isolated cases, ocean currents modify wave-induced sand transport patterns and produce atypical nearshore sediment distributions and morphologies (factor 3).

Recognition of factors such as these provide information on how specific coastal sand deposits originally formed and have evolved subsequently. Except possibly for factor 3, they do not directly quantify sediment budgets but rather provide a framework within which the importance of separate budgetary components can be assessed. Undoubtedly additional factors remain to be identified on this coast. Certainly, on coasts which are presently receiving large sediment influxes, have lower energy or are undergoing relative sea level change, other factors will be found to be important.

Introduction

Erosion and accretion on the beachface have been studied at two time scales on the central and south coast of New South Wales, Australia. This research aims at providing a temporal perspective to contemporary problems of beach erosion in areas where the historic map record of changes in shoreline position is poor. Field work has been concentrated at two localities Moruya (lat. 35° 53'S long. 150°09'E) and Newcastle Bight (lat. 32°48'S long. 151°55'E)(Fig. 1).

Figure 1. Location map of eastern Australia.

Beach and inshore systems on the N.S.W. coast exhibit pronounced morphologic and dynamic variability with respect to both time and local environment (Wright et al., 1977; Wright, Thom and Chappell, 1979; Chappell and Eliot, 1979; Short, 1978, 1979). Beach systems on this coast are characterized on a regional scale by a steep, narrow inner continental shelf and nearshore zone (Wright, 1976), and by pronounced compartmentalization with alternating rocky headlands and embayed sandy beaches (Davies, 1974; Roy et al., 1980, in press). The compartments are of widely varying dimensions, and often involve the blocking of estuaries, lagoons and swamps by a variety of bay-barrier types (Thom, 1974; Thom et al., 1978).

Open-ocean beaches display highly dynamic foreshore and inshore topographies in response to a relatively high energy, but variable, wave regime (McKenzie, 1958; Thom et al., 1973; McLean and Thom, 1975; Wright et al., 1979). The wave regime is characterized by a variable wind-wave climate, superimposed on a persistent long-period southerly to southeasterly swell. Significant wave heights of 1.5 m are exceeded for 50% of the time, with deepwater storm wave heights being known to exceed 10 m (Lawson and Abernethy, 1975). Southerly and southeasterly waves are the highest. Severe storm waves can occur at any time of the year. The loss of wave power by bottom friction seaward of the breaker zone averages only 3.4% of the incident deepwater wave power along the open coast (Wright, 1976). However, the distribution of wave power within an embayment will vary appreciably with exposure and degree of indentation.

Both localities discussed in this paper are exposed to high energy waves and strong onshore winds (Fig. 1). Moruya (Fig. 2) faces due east whereas Newcastle Bight (Fig. 3) is oriented more towards the south. Since sea level has been at its present position along this coast for the last 6000 to 6500 years (Thom and Chappell, 1975), both localities have experienced sand barrier development. At Moruya, a simple Holocene beach-ridge plain has formed seawards of "drowned" river valleys and an ancient bedrock cliff (Fig. 2). The barrier of similar age at Newcastle Bight is more complex. Figure 3 shows an elongate sand complex blocking an interbarrier depression. A Pleistocene "Inner Barrier" occurs landward of this depression. The Holocene barrier at Newcastle Bight is composed of beach ridges (eastern end), overlain by vegetated and mobile transgressive dunes. The complex morphology of this locality expresses partial eolian reworking of a prograded barrier since sea level has been at its present position.

Geologic Scale of Coastal Erosion-Accretion

One time scale used in the study of shoreline erosion and accretion is termed "geologic" and is measured in radiocarbon years before present (BP, where the "present" is AD1950). All radiocarbon dates on marine shell material used here have been corrected for the "environmental" or "ocean reservoir effect" caused by the lack of equilibrium between ocean and atmospheric ^{14}C . Calibration of radiocarbon years to calendar years, by correcting for secular variations in the radioactive isotope ^{14}C (Clark, 1975), have not been made although more accurate

Figure 2. Moruya beach ridge plain, showing drillhole transect and beach profile number 3.

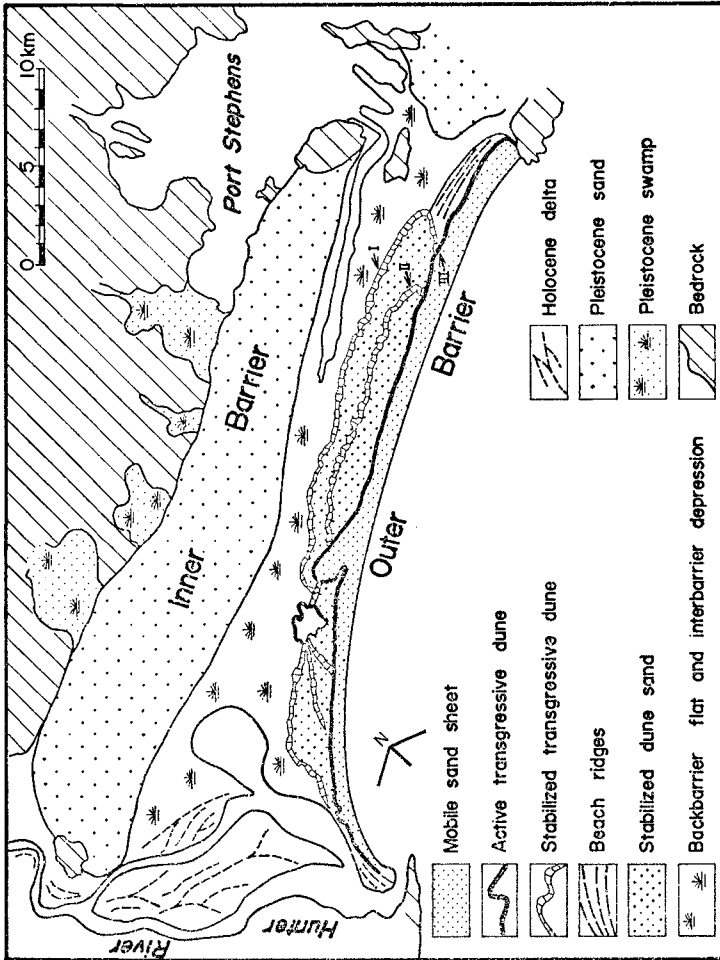

Figure 3. Morphological map of Newcastle Bight. Note beach ridges at eastern end of Outer Barrier and transgressive dune ridges I, II and III.

estimates of rates of shoreline accretion would require calibration. Details of dating techniques used in this study, and the dates themselves, are discussed in Thom et al. (1978).

Sampling of materials for radiocarbon dating involved power auger drilling. Samples of shell were collected from various depths below barrier surfaces. Shells and shell fragments associated with the nearshore environment of deposition (especially the species *Bankiviva fasciata*) were submitted for dating.

The pattern of accretion at Moruya, based on an analysis of 30 ^{14}C dates, is summarised in Figure 4. This figure highlights changes in the rate of shoreline accretion and volumetric addition for a single cross-section in the centre of the embayment. The diagram involves the grouping of ^{14}C dates into episodes. Two points arise from this figure.

(a) The dates show a relatively rapid decline in the rate of accretion with time with little evidence of progradation in the last 2000 years in the vicinity of the section.

(b) In the centre of the embayment the amount of sediment added to the coast has also declined with time.

At Moruya, it is likely that accretion did not decline at a continuous rate. There is evidence at this locality and elsewhere on the N.S.W. coast for the dates to cluster into discrete episodes (Thom, 1978; Thom et al., 1978).

Several factors must be evaluated in any attempt to explain the pattern in Figure 4. Alongshore transport of sand bypassing headlands cannot be regarded as a significant contributor to sand budgets since sea level has been at its present position (Davies, 1974). Furthermore, erosion of bedrock cliffs or supplies of sand from rivers to the beach-face can be shown to be negligible. River sand supplies are typically trapped in estuaries. The barriers are composed of rounded quartz-rich "marine" sands; these are clearly differentiated mineralogically from the angular feldspathic and lithic-rich "fluvial" and cliff-eroded sands. Variations in sea level over the last 6000 to 6500 years along this coast have not been documented, and cannot be used to explain patterns of shoreline movement. Therefore, it appears that the trends shown in Figure 4 relate to equilibration of the inner shelf gradient and profile form to the wave climate since sea level stabilized at its present position. Readjustment of nearshore profiles from a condition of disequilibrium, which existed after the termination of the Postglacial Marine Transgression, to a condition of equilibrium involving no further accretion, is being discussed elsewhere (Chappell and Thom, in prep. based on principles discussed in Chappell, 1980). Superimposed on this adjustment process are fluctuations in rates of accretion in response to changing wave climates in the Holocene (Thom, 1978). At Moruya, these changes are expressed by clusters of ^{14}C dates differentiating periods of marked shoreline accretion from periods of limited or no accretion.

Figure 4. Changes in accretion rates and volumetric addition, Moruya beach ridge plain.

However, the sand barrier at Newcastle Bight, exposed to strong southerly winds, has experienced a different geomorphological history.

The morphological map of the Holocene or Outer Barrier at Newcastle Bight (Fig. 3) depicts a "core" of beach ridges at the eastern end overlain by three discrete, massive dune ridges. Two of these dune ridges (I and II) are vegetated by an *Eucalyptus* woodland and are over 15 km long and 30 m high. The third ridge (III) is unvegetated and is currently transgressing the vegetated dunes and beach ridges from the south. These "waves" or "surges" of sand represent episodes of eolian instability in the backshore, probably following periods of high wave energy (Thom, 1978). The sequence of deposition based again on drilling and radiocarbon dating can be summarized as follows:

- (a) Accretion following termination of the postglacial sea level rise approximately 5500 to 6500 years ago;
- (b) Initiation and landward movement of Ridge I in excess of 4500 years ago;
- (c) Stabilization of Ridge I by vegetation and possible accretion of the shoreline;
- (d) Initiation and landward movement of Ridge II approximately 2000 years ago;
- (e) Stabilization of Ridge II by vegetation involving foredune growth;
- (f) Initiation and landward movement of Ridge III 300 to 500 years ago accentuated by human disturbance in last 100 years.

The sequence at Newcastle Bight can be best explained by long-term equilibration of inner shelf and nearshore profiles to fluctuating wave regimes following sea level "stillstand" (see below). As at Moruya, there is little evidence for supplies of river sand or alongshore sand reaching the beach or mobile dunes over this time period (Roy, 1977; Roy and Crawford, 1977; Ly, 1978).

Synoptic Scale of Coastal Erosion-Accretion

The other time scale applicable to the study of beachface erosion and accretion is termed "synoptic". This involves fortnightly to monthly measurement of beach-nearshore profiles from fixed datum points. At Moruya, six profiles have been monitored since January, 1972. Progress reports on trends revealed by these profiles have been published (Thom et al., 1973; McLean and Thom, 1975), and morphodynamic conditions associated with particular beach configurations have also been reported (Wright et al., 1979; Wright, Thom and Chappell, 1979).

The prime objective of this monitoring is to relate beach-face morphology to seasonal and year-to-year changes in wave and atmospheric climate. It is clear that the beachface responds strongly to year-to-

year variability in wave climate. Periods of one year or more of distinct beachface accretion are separated by years when east and southeast storms predominate and the beachface erodes (e.g. 1974-75). Figure 5 highlights the changes in cross-sectional area expressed by one profile near the centre of the Moruya embayment (comparable data are not available for Newcastle Bight, but similar studies in the Sydney area by Short and others reveal similar trends for the period 1975-76 to the present). Four phases are suggested in Figure 5 for the period 1972 to 1980:

- (a) growth in beach cross-sectional area to mid 1973 compared to the reference profile in January, 1972;
- (b) dramatic erosion of beachface and foredune in 1973 and 1974;
- (c) oscillating erosion and accretion involving fluctuation in sectional area (and beachface volumes) to 1978;
- (d) a steady build-up of beach sand from 1978 to the present, to levels well in excess of the reference cross-sectional area.

Beachface erosional periods of the type witnessed in 1973-74, involved "clusters" of storms over a minimum period of 6 months which are generated off the east coast in the Tasman Sea. Sustained periods of erosion are of irregular incidence with similar events to 1974-75 being recorded in 1912, 1950 and 1967 (Thom, 1974, Table 1). Accretion periods are associated with zonal westerly flow in winter and the absence of the marginal effects (high swell wave) of tropical cyclones in summer. There are also periods of a year or more in duration when the beachface does not significantly accrete or erode (e.g. 1976-78).

Discussion

The two time scales of study are linked by a climatic model of variation in the magnitude and frequency of storminess (Thom, 1978). The synoptic scale provides the "modern analog" for understanding changes of the geologic scale. Short-term wave conditions are associated with processes responsible for short-term climatic variability. Sea surface temperature distribution and changes in sea ice extent are two broad scale forcing mechanisms which influence major cyclonic frequencies in the Tasman Sea region. These forcing mechanisms interact with the general circulation in the atmosphere to create climatic "disturbances". In turn they may be influenced by solar cycles (Stevenson, 1980). Years with frequent extratropical cyclones can be linked to increased atmospheric "blocking" action to the east of New Zealand. In contrast, relatively non-stormy years are dominated by zonal flow, that is, the more-or-less continuous movement of pressure systems across southern Australia. Expanded to a longer time scale, it is postulated that, for periods of several hundred years, the magnitude and frequency of storminess changes.

During more stormy periods, like the Little Ice Age of the 16th and 17th centuries, wave and wind conditions promoted beachface and

Figure 5. Change in beach cross-sectional area: Moruya profile 3, 1972-1980. Reference zero is cross-sectional area in January 1972.

foredune erosion. Those embayments facing south endured more severe foredune erosion and the initiation of transgressive dunes (e.g. New-castle Bight). In contrast, the more sheltered bays underwent vertical foredune building, or where gradients were less steep, no shoreline accretion. During non-stormy periods, backshore colonization of sand-binding plants became more dominant, encouraging stabilization of blow-outs and mobile sand sheets. Locally, beachface accretion may have occurred where nearshore sand supplies were abundant.

The above discussion highlights the role of one major variable, wave energy, in the erosion-accretion balance within sandy bays of the N.S.W. coast. The other major variable is the changing supply of sand in the nearshore zone as the inner shelf configuration adjusts to a long-term equilibrium condition. We see this equilibration process as a long-term trend upon which is superimposed fluctuation in wave energy. Thus, as barriers grow, the nearshore zone is progressively depleted of sand. Nearshore profiles are steepening during this period as no fresh inputs, or very limited fresh inputs, are available from offshore, alongshore or from river sources on this coast. As a consequence, progressively less material is available for beachface accretion in non-stormy periods.

The net result of these two factors, fluctuations in storminess and dwindling supplies of nearshore sand, is that periods of beachface erosion, at either the long or short term scale, are becoming more severe. It is possible that erosional conditions in the last 1000 years are more severe compared to the previous 5000 years of sea level "still-stand". Any deterioration in global climate involving more storms of high intensity will be manifested in more severe erosion in the future than in the past. Major schemes of artificial beach nourishment may be required in these circumstances on the N.S.W. coast.

CHAPTER 59

PHYSICAL PROCESSES AND SEDIMENT FLUX THROUGH REEF-LAGOON SYSTEMS

Harry H. Roberts
Coastal Studies Institute, Louisiana State University
Baton Rouge, LA 70803

Abstract

Studies of physical processes in reef-lagoon systems continue to emphasize the importance of waves and wave-induced currents at the reef crest as agents of sediment transport to backreef environments. These across-the-reef currents are also largely responsible for driving back-reef lagoon circulation. Rapid energy transformations associated with the process of wave breaking at the reef crest are responsible for strong reef-normal surge currents. Estimates of energy loss, as determined by wave height changes caused by wave breaking, can be as high as 70-80% for discontinuous reefs and >90% for continuous examples. The amount of energy loss is related to depth of water over the reef crest, a function of reef topography and tidal regime. Low-tide conditions promote the greatest incident wave modification and attenuation as a result of increased breaking-wave intensity. Under trade-wind conditions found in the Caribbean, surge currents of 50-80 cm/sec for durations of 2-6 sec are common in a low to moderate wave-energy setting (4-6 sec input waves, 40-50 cm average heights). Sediments through the sand sizes up to pebbles are easily transported lagoonward by these periodic bursts of energy.

Flow in shallow backreef lagoons (generally <3 km wide) is driven largely by across-the-reef currents resulting from breaking waves. Long, unbroken reefs tend to induce axial currents in the backreef lagoon which flow roughly parallel to the reef trend. Side-scan sonographs indicate that large bedforms define a region of bottom sediment migration related to strong currents down the lagoon axis, presumably activated during periods of abnormal wave activity on the reef.

Localized and discontinuous shallow reefs tend to store coarse sediments in the backreef in sand bodies oriented at high angles to the reef trend. Combined effects of wave refraction and tidal exchange around the flanks of these localized reef masses give rise to tombolo-like sediment accumulations in the shallow backreef area. Backreef sand bodies

associated with continuous linear reefs tend to be oriented parallel to the reef trend.

Lagoonal sediments are transported through tidal passes to the forereef shelf, where sediment sinks commonly develop behind actively growing shelf-margin reefs. Side-scan sonar and high-resolution sub-bottom data confirm both sediment sinks and preferential offshelf transport routes on narrow, rough-bottomed forereef shelves. In trade-wind-island systems (e.g., Grand Cayman and St. Croix) sediments are stored in large quantities on the forereef shelf at the downwind flanks of the islands. Forereef shelf morphology indicates that at these same locations routes for offshelf sediment transport are optimized.

Introduction

Investigations of process-response interactions in coral reef and reef-associated environments (Munk and Sargent, 1954; Inman et al., 1963; Roberts, 1974; Roberts et al., 1975; Davies, 1977; Roberts et al, 1977; Suhayda and Roberts, 1977; and others) have demonstrated close relationships between physical processes, reef geometry, and sediment distribution. Sediment transport routes and sinks in lagoon and shelf environments display considerable variability, depending largely on linearity of the reef, closeness of the reef to the shoreline, lagoon geometry, and local physical process setting.

Recent studies conducted on the Caribbean islands of Grand Cayman, Great Corn (Nicaragua), and St. Croix have provided a framework for better interpreting sediment flux through lagoon-reef-shelf systems by integrating results of wave-current investigations with side-scan-sonar surveys and high-resolution seismic profiles. Results of these studies regarding the magnitude and variability of physical processes and the resultant effects on sediment transport are summarized in this paper for continuous linear reefs with narrow backreef lagoons (Grand Cayman and St. Croix) and a discontinuous reef example (Great Corn Island, Nicaragua).

Direct field measurements of waves and wave-driven currents were replicated in contrasting reef geometries and under a variety of tide and incident wave conditions typical of the trade-wind-dominated and microtidal Caribbean region. The data acquisition system for studies near the reef crest consisted of an array of absolute pressure transducers and low-inertia ducted current meters (Fig. 1). Data were cabled back to a central collection center and recorded in an analog format. In situ recording bottom-mounted current meters (Marine Advisers Q-16) and drogue studies were used to determine the characteristics of lagoon and shelf circulation. A Klein 100-kHz side-scan-sonar system equipped with a 3.5-kHz subbottom profiler was used for mapping lagoon and shelf bottom features. Accurate navigational control was provided by a Decca Del Norte locating system.

Reef-Crest Wave/Current Interactions

Shallow linear and quasilinear reefs that are situated close to a land mass generally have profiles similar to the one shown in Figure 1.

Figure 1. Instrument array for a study of wave/current interaction at the reef crest, Great Corn Island, Nicaragua. A similar instrument array was used for a reef crest study in St. Croix, U.S. Virgin Islands.

In the Caribbean region these reefs tend to be narrow and are commonly associated with a backreef lagoon with water depths generally less than 10 m. Although the shallow zone of living reef is very narrow compared to most backreef lagoons, it functions as a renewable source of abundant sediments to backreef areas. Both biological and mechanical degradation of skeletal components of the reef produces sediments that are available for transport to other environments. The apex or crest of this linear reef is a critical zone for intense wave-related processes. Shallow water depths (commonly about 1 m) induce extreme modification of incoming waves, usually resulting in wave breaking. Because water depth over the crest can strongly influence the intensity of wave-reef interactions, even small tidal variations such as those found in the Caribbean region become important. Waves may break continually as they transit the reef crest, or they may propagate unbroken until secondary wave crests are formed. The degree of wave transformation is highly dependent on water depth at the reef crest and incident wave characteristics.

Reef crest experiments were conducted on a rather discontinuous linear reef approximately 150 m from the northwest shoreline of Great Corn Island, Nicaragua. Wave sensors placed at the same depth (2 m) in the water column seaward and lagoonward of the reef crest (Fig. 1) were used to evaluate wave modification and energy loss as incident waves intersected the reef and propagated across it to the backreef lagoon. Forereef and backreef wave spectra (Fig. 2) derived from 20-min wave records collected at high tide describe a 68% energy loss as a result of wave breaking at the crest. Although the breaking process is not explained well by hydrodynamic theory, the reduction of wave height across the reef crest induced by breaking and wave reformation can be empirically described. Suhayda and Roberts (1977) show that data from Nakamura et al. (1966), as well as the Nicaragua experiments, can be used to establish an

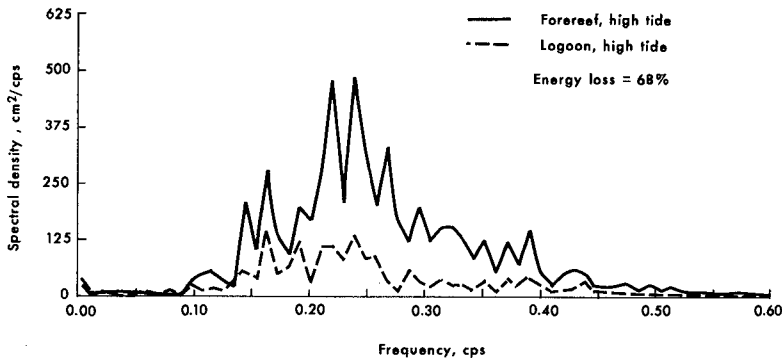

Figure 2. Comparison of forereef and backreef wave spectra derived from data collected at high tide. Interaction between incoming waves and the reef crest results in an energy loss of 68%.

expression for wave height H at the point of reforming. This expression is given by:

$$H = H_0 (1 - 0.8 e^{-0.6 d/H_0}), H_0 > 0$$

where H_0 is the wave height near the breakpoint and d is the mean water depth at the reef crest. The range of water depths for which the formula is valid is d/H_0 from zero to about 5. This expression indicates that when $d/H_0 = 0$ wave heights in the lagoon will be about 20% of the wave heights outside the reef. Actual field measurements show that the heights of lagoon waves are closer to 30% of waves outside the reef. These estimates assume a narrow reef crest, which is generally the case in Caribbean settings.

As water depth over the reef crest declines during falling tide, the process of wave breaking becomes more intense. Energy loss associated with these conditions is accelerated. Forereef and backreef wave spectra derived from low-tide data sets indicate that approximately 10% more energy is lost through reef-crest/wave interactions at low tide than at high tide (Fig. 3). These values, derived from a discontinuous reef, are conservative compared with similar data sets collected from a continuous linear system (St. Croix), where a 92% energy loss was recorded during high tide and 97% at low tide (Fig. 4). Although a 77% energy loss is indicated in the Nicaragua low-tide data, the dominant incoming wave period (about 6 sec) is present as the highest energy peak of the backreef spectrum. Leakage of energy around the flanks of the discontinuous reef may be partially responsible for this relationship, in which case the estimate of energy loss resulting from wave breaking is conservative. In both the continuous and the discontinuous reef-crest data sets, only the

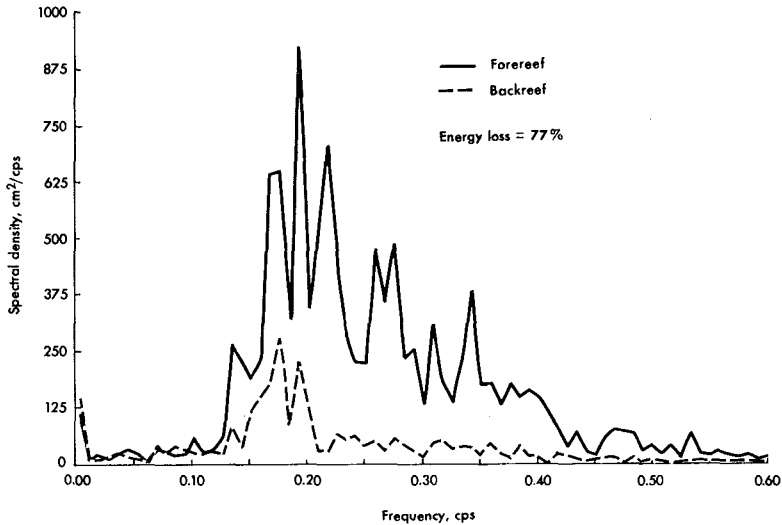

Figure 3. Comparison of forereef and backreef wave spectra derived from data collected at low tide. A 77% energy loss is described due to interaction between the reef crest and incoming waves.

low-frequency peaks of the forereef spectra persist in the backreef records. Shape of the backreef wave spectrum is important because wave steepness (wave height/wavelength) has an important effect on sediment transport and shoreline beach stability (Hayami, 1958). It therefore follows that reef-crest morphology exerts a critical influence on the characteristics of waves impacting the backreef shoreline.

Surprisingly strong but short-lived across-the-reef currents are associated with breaking waves. As waves break on the reef crest, water is driven into the backreef by surge currents. Under typical 4-6-sec input waves with heights of approximately 45 cm, shoreward-directed crest-normal currents displayed average velocities of between 10 and 20 cm/sec. Intensity of energy transformation associated with the wave-breaking process and current velocities that result varies with tide, as can be clearly seen in the wave spectra of Figures 2, 3, and 4 and the averaged reef-crest currents shown in Figure 5. The current data show that variations about the mean speed of up to 50% can occur on time scales of 1-2-min. Although the averaged reef-crest currents seem quite low, actual instantaneous measurements show that the effect of each wave transiting the reef crest produces surge currents with maximum measured speeds as high as 80 cm/sec. These periodic and short-lived currents have durations of only a few seconds (Fig. 6). During times when wave breaking at the reef crest is most intense (low tide), surge currents display the highest range of velocities. This trend was also true of reef-parallel currents monitored in the

Figure 4. Comparison of forereef, reef crest, and backreef spectra derived from wave data collected at low tide from a continuous linear reef separating Great Pond Bay, along the south coast of St. Croix, from the forereef shelf. The reef crest spectrum is uncorrected for sensor depth and thereby represents a very conservative estimate of the energy loss.

immediate backreef (Fig. 1). Although backreef current speeds averaged 30-40% less than simultaneous reef-crest values, speeds at high tide were about 30% lower than low-tide values in the discontinuous reef example. As

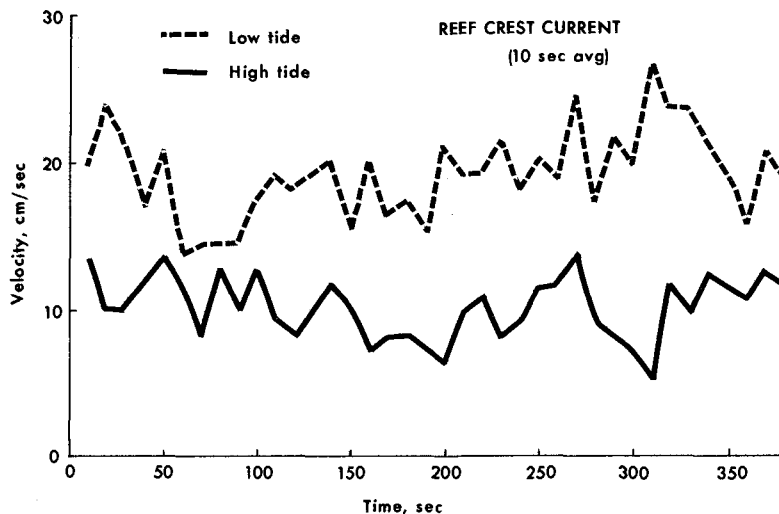

Figure 5. Shoreward-directed reef crest current at high tide and low tide. Current velocities represent values derived from 10-sec averages.

average velocity changed, currents directly behind the reef changed direction. These currents generally described lagoon filling during rising tide and draining of the lagoon as the tide fell.

Lagoon Processes

Shallow backreef lagoons that are fronted by a continuous linear reef are generally very homogeneous water bodies with regard to both density and current structure. Currents near the reef are primarily the results of mass transport of water associated with the previously described process of wave breaking at the reef crest. General lagoon circulation is commonly forced by a combination of momentum provided by the wind and mass transport across the reef. Water input may be associated with the combined effects of waves and tide, but field studies suggest that wave input is the dominant process (von Arx, 1954; Inman et al., 1963; Storr, 1964; Roberts et al., 1975; Suhayda and Roberts, 1977). However, Kjerfve (personal communication) reports that water in the backreef lagoon at Carrie Bow Cay (British Honduras) is primarily wind driven and does not have an obvious tidal signature.

Drifting-drogue studies, current-meter profiles, and in situ recording-current-meter data from Great Pond Bay, along the south coast of St. Croix, suggest that mean flow velocities under typical trade-wind conditions (5-7 m/sec) are in the range of 10-25 cm/sec (Roberts et al., 1980). The Great Pond Bay system is similar in size and shape to other backreef lagoons in the Caribbean reef province, as well as other carbonate

Figure 6. Crest-normal surge currents associated with waves transiting the reef crest. Current velocities represent values derived from 1-sec averages.

coasts of the world. Drogue tracks in Figure 7 illustrate that flow through the lagoon is directed slightly toward the northwest. Near the coast continuity of flow forces currents to become more parallel to the shoreline. As water is forced through the tidal pass at the west end of the lagoon, velocities increase. Water involved in this flow enters Great Pond Bay through a small tidal pass at the east end of the lagoon as well as across the continuous reef that separates the lagoon from the open shelf. During the Great Pond Bay studies it was observed in both the drogue and the current-meter data that the passage of squalls greatly increased flow toward and through the tidal passes, as wave state in the lagoon increased significantly. These events induced greater variability in current velocities than tidal fluctuations. Brief but frequent squalls may be very important in transporting sediment through these shallow environments.

Studies conducted on Grand Cayman Island (Roberts et al., 1975; Suhayda and Roberts, 1977; M. E. C. Giglioli, personal communication) indicate that the long-term lagoon circulation pattern is reflected in sediment thickness and facies relationships. Figure 8 illustrates that the eastern region of the lagoon, which is characterized by low current velocities, collects a thick sequence of relatively fine grained sediments. As current velocities increase to the west, toward the opening to the open shelf, sediments tend to coarsen and accumulations become thinner. In the tidal channel throat strong currents remove sediments, leaving

Figure 7. Lagoon circulation under typical easterly wind conditions as determined by drogue tracks (Great Pond Bay, St. Groix). Tracks are superimposed on bottom features. Bottom feature map interpreted from side-scan-sonar data, bottom samples, and diving. Arrows indicate the basic circulation pattern and areas of water input to the system.

the limestone floor of the lagoon exposed. Only beach-related sediments near the coast and coarse sand and rubble directly behind the reef are preserved at the western end of the lagoon.

The geometry of Great Pond Bay (St. Groix) is similar to that of South Sound (Grand Cayman), with the exception of an opening at the upwind end connecting it with an adjacent lagoon. Both systems are characterized by a continuous linear reef which separates a shallow lagoon from the open shelf. Side-scan sonar coverage of Great Pond Bay permitted a detailed bottom-features map to be prepared (Fig. 7). As in the case of South Sound (Grand Cayman), sediments have been generally scoured from the downwind opening tidal pass between the lagoon and the shelf. Because of the connection with an adjacent lagoon, coarse sediments are transported to Great Pond Bay and a well-defined carbonate mud facies, which is commonly present at the upwind end of the system, does not develop. Small-scale bedform distribution indicates active exchange between the adjacent lagoons, as well as preferential sites along the linear reef, where waves and wave-induced currents transit the reef crest to interact actively with lagoon sediments. These areas are obviously key pathways for input of shelf water and sediment into the relatively low energy setting of the backreef. They are also areas where these relatively coarse sediments derived from degradation of the reef are transported toward the lagoon

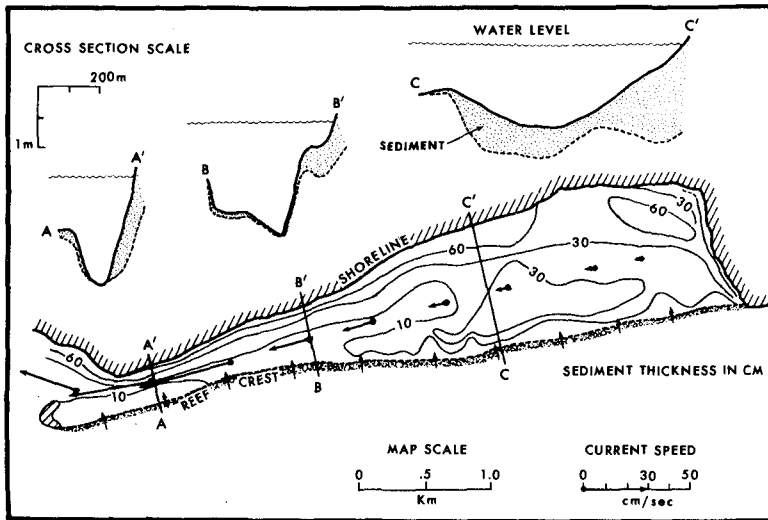

Figure 8. Sediment thickness and facies relationships in South Sound along the southwestern coast of Grand Cayman Island, West Indies. Arrows indicate the direction and relative velocities of the lagoon axis current as determined by Roberts et al. (1972). Note the correspondence of thick sediment accumulation with regions of low speed and sediment-free lagoon floor, where currents are maximized.

interior. Larger, low-amplitude and long-wavelength bedforms were found roughly down the axis of the lagoon (Fig. 7). Since these features were obviously inactive during average conditions, they probably represent remnant bedforms generated by a hurricane that passed near the island several weeks prior to collection of the side-scan data. The presence of such bedforms confirms active sediment transport from east to west nearly down the lagoon axis. Although bioturbation had destroyed much of the bedform morphology, the averaging effect of side-scan sonar data permitted discrimination of these features over higher frequency bottom-roughness elements.

Sediment Transport Routes and Sinks

Sediment storage sites and transport routes for two types of reef-lagoon systems are being considered in this study. One type is composed of linear but discontinuous reef elements (Nicaragua example), while the other has a continuous linear reef between the backreef lagoon and the open shelf (Grand Cayman and St. Croix examples). In both cases the reef functions as a major source of sediments for the backreef lagoon and a low-pass filter for incident waves from the open shelf.

In the discontinuous example numerous large breaks between reef elements allow the transfer of open shelf waves through the lagoon to the backreef shoreline. Refraction and diffraction effects under these conditions generally result in a highly irregular backreef shoreline consisting of numerous cusped coastal features with dimensions related primarily to the width of the lagoon and spacings of openings in the reef trend. Breaks in the general reef trend also function as sites for tidal exchange of lagoon and shelf water. However, mass transport across the reefs, associated with wave breaking, is important as a sediment transport process as well as a source of water to drive backreef circulation. As schematically shown in Figure 9, sand bodies associated with the dis-

Figure 9. Schematic representation of sediment sinks and transport routes in discontinuous, semicontinuous, and continuous reef-lagoon systems.

continuous reef elements are generally oriented at high angles to the reef trend and tend to form horns attached to the ends of the reef at the tidal channel margins. The combined effects of tidal exchange and wave refraction/diffraction are responsible for shaping these sediment bodies. Sediments are also commonly stored in backreef shoreline cusps, which arise from energy gradients along the coast set up by wave refraction through the major breaks between reef elements. Sediments accumulate in cusped shoreline features, which prograde toward the offshore reef elements. If the distance between reef elements and the shoreline is not great, cusps may prograde toward the reef until attached. Such depositional features commonly form in response to manmade offshore breakwaters.

Continuous reef systems store sand in the backreef lagoon in sediment bodies that tend to parallel the reef trend (Fig. 9). These coarse sediments are composed of debris which originates from the reef and is transported to the lee of this structure by across-the-reef currents previously described. Constituent particles decrease in grain size in a lagoonward direction, but there is generally a very distinct transition between the coarse reef-derived material and the finer lagoonal facies. Lagoon interiors commonly are floored with abundant sediment-producing calcareous green algae. The disintegration products of many members of the algal community are 2-4-micron needles of aragonite, which accumulate to form a carbonate mud. Frequently it is only at the backreef shoreline that there is enough energy to hydraulically sort the sediments so that coarse particles are concentrated. Under these conditions a narrow sandy beach develops. The beach is commonly oriented roughly parallel to the continuous reef trend that separates the lagoon from open-shelf conditions.

As discussed with regard to lagoon circulation, strong currents can develop in the downwave ends of these systems (Fig. 8). Such flow is driven by both the wind and constant input of water to the lagoon by wave overwash at the reef crest. These currents provide the driving force for exporting reef-derived and lagoonal sediments to the adjacent forereef shelf. Actual sediment budgets for systems of this description have never been established. However, geomorphic and sedimentologic evidence suggests that large volumes of sediment are transported, from reef-lagoon systems to deeper sedimentary environments on the shelf. Side-scan sonar data from St. Croix (Fig. 7) suggest that during intense storms large-scale bedform migration can be an active form of sediment transport. During average conditions the intense burrowing activity of shrimp and polychaete worms may be important to the sediment transport process. Sediment mounding, which is typical of the two groups of organisms, requires that both coarse and fine sediments be expelled from a burrow into the water column. These particles may be transported downcurrent by the mean drift in the lagoon. The intensity of burrowing in these backreef environments suggests that significant quantities of sediment can be moved by this mechanism.

Processes responsible for transporting sediments from the lagoon to the open shelf and beyond have not been studied in detail. However, sedimentological evidence (Moore et al., 1976; Land and Moore, 1977; James, 1978) shows that sediments generated in shallow backreef environments are transported to the forereef shelf. A significant proportion of these sediments are conducted across the shelf to adjacent deepwater slope

and basal settings. Figure 10 shows the sediment transport paths and sinks in a lagoon-reef-shelf complex along the southwestern flank of Grand Cayman Island. Both physical process measurements and geological data from several field projects were integrated to produce the sediment transport model described in this figure. Although most sediment produced by the shallow reef is either trapped in the reef matrix or transported toward the lagoon, some sediments produced on the reef front are transported seaward to deeper parts of the shelf. It is common that a sediment sink develops on the lower forereef shelf behind an actively growing shelf-margin reef. As shown by Roberts et al. (1975), the dramatic break in slope at the seaward edge of many reef-dominated shelves is a focal point for strong tidal exchange. Shelf-margin reefs respond to the energy expenditure at this point along the shelf profile by developing into flourishing sill-like structures that impound sediment in their lee. This deep-shelf sediment sink is represented in Figure 10 by a tabular sand body paralleling the shelf edge. High-resolution seismic data suggest that maximum thicknesses of Holocene sediments may be on the order of 20 m in the Grand Cayman example.

Side-scan sonar data indicate that shelf-margin reef morphology is a key to interpreting significant offshelf sediment transport routes. In regions of the shelf where the shelf-margin reef has coalesced to form a coherent ridge, sediments impounded in the lee of this structure can be transported off the shelf only through narrow grooves (Fig. 11A). These grooves are active transport routes (Meaney, 1973), but only limited amounts of sediment can be fluxed to the slope and possibly the adjacent basin by this means. However, around islands there are preferential sites

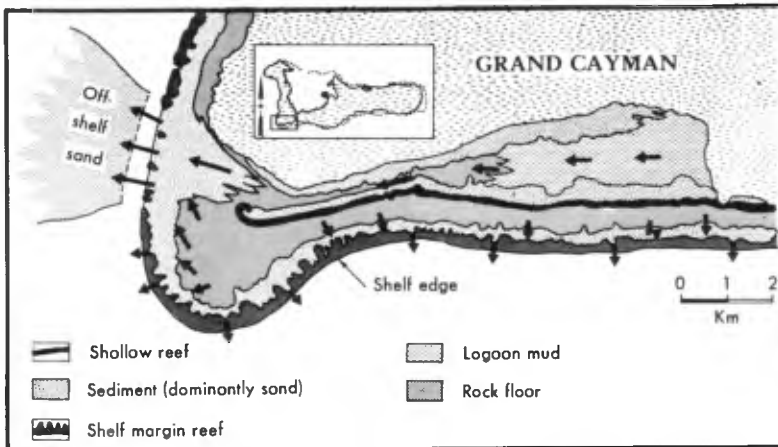

Figure 10. Sediment transport routes and sinks associated with South Sound and the adjacent shelf, Grand Cayman Island. Arrows indicate sediment transport directions.

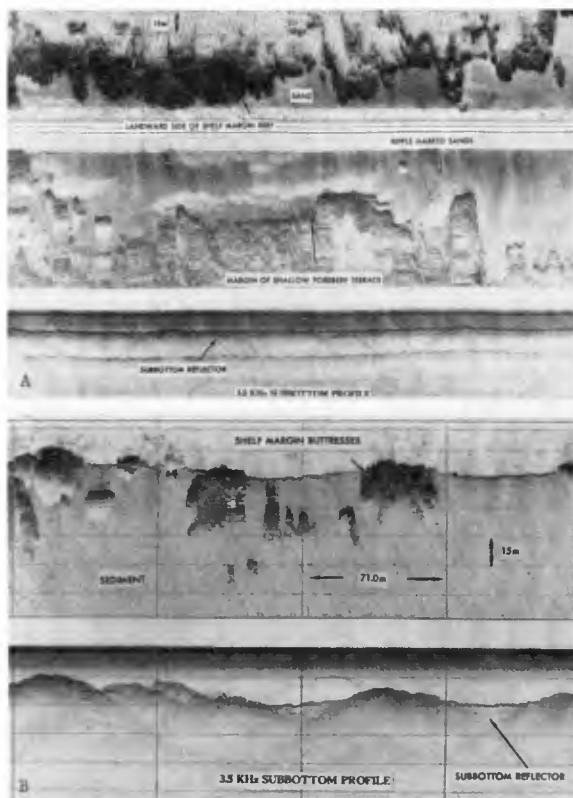

Figure 11. A, side-scan sonograph of lower foreereef shelf, Grand Cayman Island, illustrating a well-developed shelf margin reef with only narrow grooves through it for off-shelf sediment transport. The shelf margin reef has relief of 3-4 m above the adjacent sediment plain. Seismic profile shows a reflection of the sediment plain at a depth of 5 m.

B, side-scan sonograph (only one channel) showing broken shelf-margin reef morphology with wide channels for offshelf transport of sediments. This broad area of sediment accumulation is opposite the downcurrent opening to South Sound (see Fig. 10).

for sediments to accumulate on the shelf (Murray et al., 1977). In the Grand Cayman example, an island in a strong unidirectional drift and trade-wind setting, the major sediment accumulation zones are at the southwest and northwest flanks. The site at the southwest flank, as shown in Figure 10, is also opposite the downcurrent end of the South Sound reef-lagoon system. Shelf-margin reef morphology at this location (Fig. 11B) describes a broken reef trend with wide channels for the offshelf movement of sediments. This type of reef morphology implies that sediments have been supplied in abundance to this site for a long period of time; that is, the substrate for shelf-edge reef building has been partially eliminated by the unstable movement of sediments over the shelf edge to the slope and basin environments. Once sediments reach depositional sites on the lower forereef shelf, they are nonrenewable to the coast.

Conclusions

Field studies conducted on the Caribbean islands of Grand Cayman, Great Corn (Nicaragua), and St. Croix have provided a data base from which the magnitudes and variations of physical processes as well as the flux of sediment through lagoon-reef-shelf systems can be better interpreted. The following conclusions can be made from these studies.

1. Wave breaking on the reef crest creates strong reef-normal surge currents, 50-80 cm/sec, with durations of 2-6 sec under normal trade-wind wave conditions. Sediments larger than the sand sizes are easily transported lagoonward by these periodic current bursts.

2. Estimates of forereef to backreef wave energy loss from the breaking process were in the range of 70-80% for discontinuous reefs and up to 97% for continuous examples. Intensity of the breaking process varied with tide. Wave energy loss between the forereef and backreef was greatest at low tide. Surge current velocities were maximized at this time. Across-the-reef currents were always directed lagoonward and did not change direction with tide.

3. Flow in shallow backreef lagoons is driven largely by water introduced to the system by across-the-reef currents. Long, unbroken (continuous) reefs tend to develop near axial currents that roughly parallel the reef trend.

4. Migratory bedforms in the lagoon environment, as determined by side-scan sonar, indicate sediment transport during storms. It appears that an interaction between bioturbation and the mean lagoon drift may also be a significant process of sediment transport under ambient conditions, even though data specific to this subject have not been collected.

5. Discontinuous reefs store coarse backreef sediments in sand bodies oriented at high angles to the reef trend. These features are shaped by tidal exchange and wave refraction/diffraction through breaks between reef elements. Cuspate shorelines commonly develop in response to the sheltering effects of discontinuous reefs.

6. Backreef sand bodies associated with continuous reefs tend to parallel the reef trend.

7. Lagoon sediments are transported through tidal passes to the forereef shelf, where sediment sinks commonly occur behind an actively growing shelf-margin reef. These sediments are nonrenewable to the coast. Some are transported through shelf-edge grooves and channels to deeper slope and basinal environments. Morphology of the shelf-margin reef is a clue to important avenues for offshelf sediment transport.

Acknowledgments

This work was funded by the Naval Environmental Prediction Research Facility, under Program Element 62759N, Project 9F52551792, "Atmospheric Environmental Support," through ONR Contract N00014-75-C-0192. Dr. Robert Dill, director of the Fairleigh Dickinson West Indies Laboratory on St. Croix, is acknowledged for providing excellent support facilities during our 1979 field project. Sneider and Meckel Associates of Houston, Texas, and Canadian Hunter Exploration Company of Calgary, Canada, supported a side-scan-sonar study of forereef shelf morphology which provided valuable insight into the problem of offshelf sediment transport.

INSHORE-NEARSHORE MORPHODYNAMICS - A PREDICTIVE MODEL

John Chappell

Dept. of Biogeography and Geomorphology, R.S.Pac.S.,
Australian National University, Canberra, Australia.

ABSTRACT The two-dimensional topography, developed on a sandy sea bed between surf base and the breaker zone, is computed using (i) sediment gain or loss per unit bed area = zero, (ii) simple models of sediment drift in terms of, firstly, simplified saltation under Stokesian waves, and secondly, frictional wave work on the sea bed, (iii) the drift tendency in direction of wave propagation being offset of the local sea bed gradient. An input contour line at surf base is assumed, across which the input wave train is propagated. Using standard wave refraction combined with (i) to (iii), above, an equilibrium topography is generated by iteration. Inshore of the breaker line, longshore currents generated by radiation stress are combined with the gradient effect to balance sediment drift, producing bar - trough topography.

INTRODUCTION

Nearshore bathymetric profiles commonly are modelled by concave power functions of distance from shore (eg., Le Blond, 1979), on empirical grounds (Bruun, 1962). This paper seeks to model 2-dimensional bathymetric topography in terms of shoreward sediment drift induced, in an idealised way, by shoaling waves, in opposition to the effect of a downslope (gradient) factor. In the inshore zone, the effects of longshore currents and of shore-normal rip currents on sediment movement are included, again in a simplified way. The nearshore zone is defined here as extending from the primary breaker line seawards to surf base, which is taken as the maximum depth at which sediment is likely to be moved by wave motion. The inshore zone is taken to be between the primary breaker line and the swash zone, on the beach face.

Sediment movement under shoaling waves is complex, involving both saltating grains and suspension clouds, which move differently at different phases of a wave cycle and at different points above a bed ripple (eg., Neilson, 1978). Furthermore, the type of small scale bed form (ripple, megaripple, etc.) varies with depth (Boyd, this volume). The net drift tendency also varies with wave shape - a function not only of shoaling but also of wind direction relative to wave direction. As a general model of sediment drift under shoaling waves does not yet appear to exist, we commence with a highly idealised picture.

SEDIMENT DRIFT

Sediment movement is initiated when the horizontal component (u_x) of wave orbital velocity at a certain distance from the bed exceeds a critical value, u_t . This threshold value has been shown to be a discontinuous function of sediment particle size (Komar and Miller, 1975). Once movement is initiated, sediment drift generally is argued to be related to the cube of u_x (eg., Bagnold, 1966) on the grounds that mass transport should be proportional to frictional wave work (W) on the bed, where

$$W = \rho u_x^3 \quad \dots \quad (1)$$

(Inman et al., 1966; Kachel and Sternberg, 1971). However, while the magnitude of mass transport may depend on W, the sense of direction is not indicated when u_x is estimated from the maximum of the horizontal orbital velocity component, as is conventional. An approach here is to estimate u_x by integrating instantaneous velocity through a wave cycle, although suggestions along these lines (Wells, 1967; Wright et al., 1980) so far are heuristic rather than analytic or well verified.

Shoaling waves are asymmetrical, and non-zero values of net water transport and of bed shear stress appear when Stokesian and higher order wave equations are integrated through a wave cycle. Although the magnitudes of these resultants are small compared with instantaneous values, they are likely to induce sediment drift at depths shallower than surf base, where instantaneous velocities exceed u_t for a substantial part of the wave cycle. Thus, for Stokes waves, Longuet-Higgins (1953) gives the net shoreward velocity near the bottom as

$$U_0 = \frac{5}{4} \left[\frac{\pi H}{L} \right]^2 C \frac{1}{(\sinh(kh))^2} \quad \dots \quad (2)$$

where H is local wave height, L is wavelength, C is celerity, $k=2\pi/L$, and h is depth to bed. Bed drift data of Russell and Osorio (1958) correlate quite well with U_0 , although as Komar (1976) points out, it is not known whether the relationship is causal. However, setting aside the problematic interaction between small scale bed forms and sediment movement, it seems reasonable that net sediment flux is proportional to the product of the entraining factor (bed shear stress) and net velocity U_0 , ie.,

$$Q_s = U_0 \zeta \tau \quad \dots \quad (3)$$

where ζ is a coupling factor and τ is effective bed shear stress. Whether $\tau \propto u_x^2$, or $\tau \propto (u_x - u_t)^2$ (cf. Wright et al., 1980) is not known; here it is taken as proportional to u_x^2 . It is noted that U_0 is better calculated by using a wave equation more accurate than the Stokes model (eg., that of Fenton and Rienecker, this conference). However, eq.(2) is used in the present paper.

Net sediment drift should be influenced by bed slope. Experimental data seem not to indicate how this factor might be combined with any formulation for flux such as eq.'s (1) - (3), although Taylor and Dyer

(1977) suggest that for bedload flux

$$\vec{Q}_s(\text{bedload}) = \frac{\zeta \vec{W}}{(\tan\phi \pm \tan\beta) \cdot \cos\beta} \dots\dots (4)$$

where ϕ is an angle of intergranular friction and β is slope angle, positive upslope. ζ has the same meaning but different value as in eq.(3). Wave hemicycle vectors (\vec{Q}_s , \vec{Q}_s , etc.) are assessed by integrating through each hemicycle.

The approach in this paper is to assume that grains have average trajectories of pathlengths $\bar{\lambda}$, $\bar{\lambda}$ in each hemicycle, and that saltating grains, on descent, make an angle α with the horizontal. It is assumed that suspended grains have a net displacement of U_0 per wave cycle. From figure 1, net saltation displacement comes to

$$\Lambda \approx 2\bar{\lambda} \frac{\tan\beta}{\tan\alpha} \dots\dots (5)$$

where $\bar{\lambda}$ is the mean of $\bar{\lambda}$, $\bar{\lambda}$ (without sense of sign). Hence, Λ is down-slope, as β is negative in this direction. In the following section, eq's (3) and (5) are used to balance sediment drift, at the equilibrium condition.

An alternative approach is to consider sediment drift as directly proportional to wave frictional work on the bed. Friction per wave cycle per unit area is

$$F = \frac{2}{3\pi} \rho f u_{\max}^3 \dots\dots (6)$$

(Jonsson, 1965) where u_{\max} is maximum instantaneous bottom orbital velocity. Although the friction coefficient, f , usually is taken as constant for a given bed sediment, Jonsson (1965) shows that it changes with horizontal length scale of bottom orbital motion, i.e., is proportional to u_{\max} (in turbulent motion). The frictional loss (K_f) as a function of wave height, based on a similar $F \propto u^3$ relationship, is given by Bretschneider and Reid (1954) as

$$K_f = (1 + \int_0^x \eta \, dx)^{-1} \dots\dots (7)$$

where

$$\eta = H \frac{8f K_s}{3g^2 T} \left\{ \frac{\omega}{\sinh(kh)} \right\}^3 \dots\dots (8)$$

where T is wave period and ω is $2\pi/T$. Again in the next section this is balanced against a slope-dependant drift, although in this case figure 1 and eq.(5) have no direct relevance, and the downslope component is simply

$$\Lambda' = 2\bar{\lambda} \tan\beta \dots\dots (9)$$

EQUILIBRIUM PROFILE

Bed equilibrium occurs when sediment gain or loss per unit area is zero. This occurs when either there is no sediment movement to or

Figure 1: SIMPLIFIED SALTATION DRIFT. Wave hemicycles separated for clarity.

Net displacement $\Lambda = \Lambda_1 + \Lambda_2 \approx 2\bar{\lambda} \frac{\tan\beta}{\tan\alpha}$. ($\bar{\lambda} = 0.5(|\lambda| + |\lambda|)$).

Figure 2: MODEL EQUILIBRIUM BED PROFILES.

(a) Sediment drift versus gradient (eq's 12 - 14)

from a unit area (closed system case), or there is a constant flux along the profile (external sources and sinks case). Either way,

$$\text{grad } Q_s = \text{zero.} \quad \dots\dots (10)$$

In what follows, the nearshore zone is considered as a closed system case, while the inshore zone can locally be regarded as a steady state case where $Q_s \neq 0$ but eq.(10) applies.

We take the nearshore zone first. From the foregoing, at equilibrium the drift Q_s according to eq.(3) is set equal and opposite to the down-slope tendency $\bar{\Lambda}$ in eq.(5). In the results which follow, $\bar{\lambda}$ is taken as equal to mean bed velocity

$$u_b = \frac{\pi H}{T} \frac{1}{\sinh(kh)} \quad \dots\dots (11)$$

It is noted that a better estimate would be achieved by integrating higher order wave equations through a cycle. Similarly, τ , $\bar{\tau}$, are taken as equal and opposite, although a better estimate could also be based on higher order wave equations. In this simple formulation, zero net displacement occurs when

$$U_0 = 2\bar{\lambda} \frac{\tan\beta}{\tan\alpha} \quad \dots\dots (12)$$

Hence, using eq's (2), (11), (12), the bed gradient is a function of local wave height, water depth, and the unknown parameter, α . The latter may depend directly on u_{\max} (in a similar way to friction coefficient, f) but initially it is assumed that α is constant, and the assumption is discussed later.

As we are seeking two dimensional topography for an arbitrary surf-base contour, wave refraction must be taken into account, and local wave height H varies from deepwater wave height H_∞ according to

$$H = H_\infty K_r K_s K_f \quad \dots\dots (13)$$

where K_f is given at eq.(7), K_s (shoaling coefficient, also in eq.(7)) and K_r (refraction coefficient) are as given in standard works (eg., Komar, 1976).

The local profile along a given wave ray, from eq's (11) and (12) can therefore be computed from

$$\frac{dz}{dx} = \frac{5 H \pi \tan\alpha}{8 C \sinh(kh)} \quad \dots\dots (14)$$

To calculate a profile, values must be assumed for f (entering eq.(13) from eq.(8), and for α . The approach used here is to assume that the overall distance from surf base to the breaker line is set by the initial width of the inner shelf (geologically determined), and the profile $z(x)$ then calculated from (14) using $f = 0.02$ and α adjusted to suit. Although arbitrary in this last particular, computed profiles closely accord with actual profiles, as shown in figure 2a.

The trajectory parameter clearly subsumes other factors and, as mentioned, is likely to vary with u_b amongst other things. Although intrinsically unsatisfactory, this parametric approach is useful in that α can be related to objective factors, through comparisons such as in figure 2, as has been the case in the past with coefficient f .

An alternative to using the simple sediment movement model of figure 1 is to equate sediment drift with net bed friction. For example, Q_s may be directly related to W in eq.(1) (cf. Bagnold, 1966) by $Q_s = \zeta W$, and this can be opposed to a gradient force to give

$$\frac{dz}{dx} = \frac{\rho u_*^3}{\Lambda g} \cdot \zeta$$

Using a similar idea, Chappell and Eliot (1979) used the Bretschneider and Reid frictional factor η (eq.8) to offset the gradient force, arguing that frictional loss of wave energy is proportional to the sediment drift tendency, as follows. Wave height change δH over length δx is

$$\delta H = 1 - \left(\frac{\eta \eta \delta x}{T^4 K_s} + 1 \right)^{-1} \quad \dots\dots (15)$$

Wave energy loss, δE , is

$$\delta E = 2H \delta H \cdot \rho g / 8 \quad \dots\dots (16)$$

and setting $dz/dx \propto \delta E$ again gives a computational solution for $z(x)$, using, as before, the wave height equation (13) as appropriate*. Figure 2b compares the result of this model with that of the more explicit sediment drift model in figure 1 and figure 2a. A disadvantage of this model, compared with the previous one, is that it does not explicitly assess frictional drift tendencies for each wave hemisphere because, as it stands, it rests on Airy waves.

Both models illustrated in figure 2 fit quite closely to the curve $z = a x^b$, $b < 1$ (where $z=0$ is the breaker line, and z is +ve with depth), which is quite widely used to fit empirically to real nearshore profiles. However, empirical $z = a x^b$ has no explanatory power, whereas the arguments outlined here explicitly develop bed profile in terms of bed equilibrium assessed by sediment drift models, albeit crude ones. As the first model is the more complete, in the sense that it is based on a conception of sediment movement and that Stokes (or higher order wave equations) can be used, it is employed in the following section, where 2-dimensional topography is developed.

The inshore zone can be more complex, in that the sediment flux locally can be different from zero in the presence of rip current cells, although eq.(10) still holds. Treatment of this area is deferred to a later section.

* Chappell and Eliot (1979), using this type of approach, simplified the problem by assuming that frictional work on the bed is uniformly distributed at equilibrium. Empirical calculations of η (eq.8) for real profiles and waves show that this is not true, and the opportunity is taken here to correct this. Following from this, it would be interesting to discover whether "entropy production" (eg., $\delta E/h_*$, $h_* = h_s - h$ where h_s is surf base depth) is constant on real profiles.

2-DIMENSIONAL NEARSHORE TOPOGRAPHY

The hypothesis here is that the seabed sediment shorewards of surf base is freely redistributed until it comes to equilibrium with an input wave field. It is assumed that the redistribution process occurs essentially in the directions of the wave rays. The profile along any ray is to be calculated according to the methods of the previous section, using eq.(14), and the resulting contour of the breaker zone (approximating to the shoreline) will be therefore dependant on the shape of the surf base contour and the resulting refraction field. The standard ray equation is used, i.e.,

$$\Delta\gamma = \sin^{-1}\left\{ \left(1 + \frac{\Delta C}{C}\right) \sin\gamma \right\} - \gamma \quad \dots\dots (17)$$

(see figure 3a for definitions), where C, ΔC are calculated for the given contour depth and depth change between contours, as normal.

The problem now is as follows. A profile z(x) for any ray path can be calculated by eq.(14), where the local value of H in this equation is subject to eq.(13). The initial direction of the ray is determined by its angle with the assumed surf base contour, and its locus thereafter is modified as it passes each succeeding contour. Inputting a set of parallel rays across an arbitrary surf base contour s(x, z_s) will yield a set of profiles which also define the field of nearshore contours s(x, z), which must be consistent with the set of ray paths themselves. This is approached by iterative calculation, which can be simplified by knowing that locally the contours fall between two relational conditions - either they can locally be parallel in which case the crossing angle γ is altered only by eq.(17), or they can approach a concentric relationship, in which case the crossing angle is modified by an offset ξ, where this is given as shown in figure 3b. For the concentric case (or any case where contours are not locally parallel) there is a similar modification to the refraction coefficient K_r (eq.13). In general, contour relationships will lie between these extremes, and the approach used, to commence iteration, was to assume that the local relationship is such that an offset angle = 0.5ξ applies.

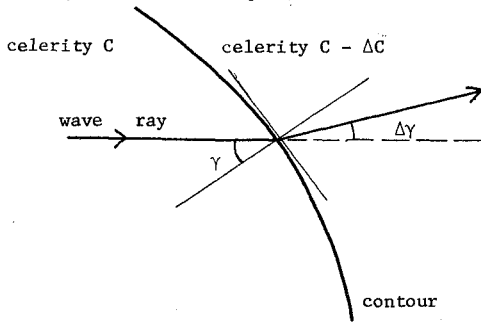

Figure 4 shows a computed example of nearshore topography, for which each ray satisfies eq.(14) subject to eq.(13), and for which the resulting contour positions, on each ray, are consistent between rays and with eq.(17), within the calculation limits (about 5% of each local value, on average). A check on this result can be made by computing the longshore sediment drift, inshore of the breaker line. If the model is correct, longshore sediment drift, resulting from longshore variations of wave height and approach angle (γ_b) at the breaker line, should be zero. This equilibrium condition is given by Komar (1975) as

$$\frac{1}{c_f} \frac{\partial H_b}{\partial y} = \frac{0.6 G^3 \sin\gamma_b \cos\gamma_b}{1 + \frac{3G^2}{8} - \frac{G^2 \cos^2\gamma_b}{4}} \quad \dots\dots (18)$$

where G = H_b/z_b. Although as Komar (1975) notes, this is an approxi-

Figure 3: DEFINITIONAL SKETCHES, REFRACTION PROCESS

(a) Refraction (eq.17)

(b) Angular alteration of ray/contour crossing for non-parallel (concentric) contours, used in computing ray paths once a ray passes surf base contour. A bed profile for each ray is computed in similar fashion to figure 2a, and each contour azimuth then is estimated.

$$\xi = \tan^{-1} \left(\frac{\Delta r \tan \gamma}{r + \Delta r} \right)$$

On first iteration it is assumed that crossing angle at contour (i+1) is $\gamma_i - \xi/2$ (see page 7).

FIGURE 4: Self-generated wave-ray and contour field. Input rays ($H_{\infty} = 2.2\text{m}$, $T = 9\text{sec}$) incident at input surf-base contour at bottom. On first iteration no correction is made to wave height for refraction coefficient K_R ; then K_R

calculated from first iteration is used to correct H at all intersection points, providing basis for second iteration. Figure is plotted from printout of second iteration intersections. Depth profile at right applies to right hand ray. Small arrows at top left show residual longshore current, arising because $\partial H_b / \partial y$ effect exceeds effect of wave obliquity at breaker line (ref. eq.18) (Note that input rays are increasingly closely spaced as surf base contour curvature increases towards left).

mation to the complete solution of the problem, it is well supported by measurements (Komar, op. cit.). When applied to the refraction/topography field in figure 4 this equilibrium condition is approximately met along the model shoreline, although there is a deviation which increases towards the left hand (low energy) end, such that the LHS of eq.(18) exceeds the RHS by about 15%, implying net drift towards the left (shown by small arrows in figure 4). This discrepancy probably reflects the assumption, used in the calculation method, that sediment drift occurs in the direction of a wave ray without a drift component perpendicular to the ray, when its contour-crossing angle is other than 90° . The discrepancy is not large in this simple model calculation, however, and it is concluded that the general approach is sound, although refinements of computational strategy are desirable.

This method, in enabling computation of equilibrium nearshore topography, points the way to predicting the changes which occur when the wave field changes, or when the surf base contour is altered (say by offshore dredging). It is noted that the actual 'equilibrium' topography, developed in any real situation, is the statistical product of a wave climate best expressed in terms of probabilities of wave heights, periods, and directions. An actual topography should be compared with model predictions which embody this consideration. Such a calculation would take into account the variation of surf base contour with wave height and period.

INSHORE EQUILIBRIUM

The sediment drift approach used above for the nearshore region cannot be extended to the inshore area, because in this zone of surf and rip current cells the near bed flow approaches or sometimes even exceeds the critical (Froude number = 1) condition, and sediment moves extensively in suspension. Inshore topography can approximate to a steady state under constant incident waves for more than several days (see Wright, et al., 1979; Chappell and Eliot, 1979, for accounts of inshore states and state changes). The existence of quasi-steady states, with active sediment circulation through longshore and rip current cells, suggests that some parameter in the system is constant, to maintain the condition that $\text{grad } Q_s = \text{zero}$ (eq.6). Chappell and Eliot (1979) suggested that

$$\text{grad } W = \text{zero} \quad \dots\dots (19)$$

where W is work done on the bed. As noted above (footnote, page 6) this is incorrect in the nearshore, but may approximately be true inshore where depth variation is small, between the primary breaker and the base of the swash. Alternatively, some entropy-like measure may be constant, such as W/h_* (see footnote, page 6), as suggested for fluvial systems by Leopold and Langbein (1962), although it is not clear why this should be so.

There are two approaches to the problem of inshore equilibrium. One is to oppose the gradient effect (eq.9) an estimate of sediment drift in terms of bed friction, as was done for the nearshore. As noted, this is difficult in the absence of a coherent picture of

sediment entrainment and drift. The other is to use an assumption such as eq.(19) and then to compute the inshore depth field to satisfy this condition. As it turns out, both approaches yield similar but not identical results. In either case, the local wave height will be subject to

$$H = H_b K_r K_s^* K_f^* \dots\dots (20)$$

where K_r^* and K_f^* are shoaling and friction coefficients, respectively, as they apply in the inshore zone (cf. eq.13). Further, as inshore current velocities can be a significant fraction of orbital velocities, work on the bed is

$$W = W_w + W_u \dots\dots (21)$$

where the two RHS terms signify wave and current work, respectively.

Inshore waves generally continue to break, to some degree, as they cross the surf zone, although they may locally reform as steep non-breaking waves where they cross the trough. Measurements taken with composite flowmeter and pressure transducer arrays show that inshore waves, between primary break and swash base, show orbital behaviour although not strictly Airy-wave like in form (see data in Wright, et al., 1979; Chappell and Wright, 1978). Hence, a simple paramter θ is introduced to characterise inshore waves, such that

$$H = H_b \int_{x_b}^x \theta dx \dots\dots (22)$$

where H_b is breaker height and x_b indicates position of the primary breaker line. $\int \theta$ thus is equivalent to K_s^* , and θ itself represents the diminution of effective (orbital) wave motion through the breaking process. In what follows, θ is taken as 0.05/m for spilling waves, 0.1 for plunging waves, and zero for reformed inshore waves. Transition to plunging is taken as G (=wave height/depth) = 1.0, and to spilling when $0.8 < G < 1.0$. These somewhat arbitrary parameters can be better calibrated through field measurements. K_f^* is again given by eq's (7), (8), where $\sinh(kh) \approx kh$.

Total work on the bed, from eq.(21), then becomes

$$W = \delta E + \rho \vec{u}^3 \dots\dots (23)$$

where δE is given by eq.(16) and the work by longshore or other current \vec{u} is shown at the second RHS term (cf. eq.1). If eq.(19) applies, then it follows that the local depth must increase in the presence of a current, as δE is depth dependant and total W is constant. This accords qualitatively with the observation that inshore currents are associated with a trough, between primary breaker zone and the shoreline.

Eq's (19) to (23) now are used to compute an inshore topography field, with a shore-parallel train of incident waves. An inshore current is generated by using the appropriate re-arrangement of eq.(18) (given by Komar, 1975); ie., the current arises from the inshore radiation stress field generated by longshore

Figure 5: SELF-GENERATED INSHORE MORPHOLOGY AND LONGSHORE CURRENT - RIP CURRENT SYSTEM.

Input $H_b = 1.5$ m

Note: As wave-current interaction is not considered, model does not generate a primary break at rip exit, with parameters used as in text.

variations of wave height. H_b is assumed to vary sinusoidally as a consequence of interaction between incident waves and an inshore stationary edge wave (Bowen, 1969; Chappell and Wright, 1978). A quarter wavelength segment is examined, with a rip located where resultant H_b is a minimum and no longshore current existing at the point where H_b is maximum. No account is taken of inshore refraction arising from wave-current interaction, although this is an important factor (Noda, 1974). The technique used proceeds in two stages. Firstly, the inshore current is calculated from the longshore variation of H_b , and this current is located midway between primary break and shoreline. Profiles across the inshore zone then are computed at 5 positions between the H_b max and H_{bmin} positions, using eq's (19) to (23). The resulting radiation stress field then is computed (from the standard equations given by Komar, 1975; 1976), and then, as a second stage, the longshore current field is recalculated followed by recomputation of the inshore profiles. This iteration reduces divergence between the current field and topography.

Results of the model are shown in figure 5. The 'self-generated' topography emerges as a shallow bar-trough system, which qualitatively agrees well with real inshore circulation-topography systems described as Types 2 and 3 by Wright, et al., (1979).

CONCLUDING DISCUSSION

The models set out in this paper generate nearshore and inshore topography, on mobile sandy beds, with deep water wave H and T as the only input variables, although there are several calibration factors. The models can be criticised as being amalgamations of a number of approximations, some of which are insufficiently tested. Viewed positively, the models produce topographies which appear highly realistic, and offer a method by which changes associated with either variations of wave field, or human alteration of the nearshore-inshore system, can be estimated. The negative side, that undue parameterisation is employed here, can be assessed by reviewing some of these factors.

The main weakness lies with characterisation of sediment drift. To estimate a topographic profile, either explicitly directional wave-induced transport must offset the gradient effect (as in the nearshore case, above), or a non-directional transport function is made everywhere equal, as in the inshore model. The latter suffers from its not being visualisable in terms of fundamental processes; the former, as set out in this paper, suffers in its usage of a naive sediment simplification of sediment drift. This undoubtedly can be improved and would affect the result but not the strategy of calculation. A second weakness lies with the approximations used in wave models, particularly in the formulation used for waves in the surf zone. However, assembly of all parameterised factors into a single model focusses attention on areas of weakness. Finally, despite the approximations, the sea bed topography generated by these models appears realistic.

BEACH CUT IN RELATION TO SURF ZONE MORPHODYNAMICS

ABSTRACT

Field experiments on the coast of Southeastern Australia, supplemented by systematic observations in a variety of environments in other parts of the world, indicate at least three quasi-discrete modes of subaerial beach cut, each of which is related to a distinct set of mechanisms. For any given set of incident wave conditions, the operation or non-operation of a particular mode of cutting depends on the morphodynamic state of the surf-zone and beach. Steep, reflective beaches are susceptible to cut under moderate swell conditions by accentuated runup and berm overtopping associated with subharmonic resonance. Appreciably more energy is required to cut flat dissipative beaches. Cut of dissipative beaches involves high setup which oscillates at infragravity frequency and allows the bores of broken waves to penetrate to the backshore. Beach states intermediate between the reflective and dissipative extremes are subject to cut by both the modes just described as well as by scour in the embayments of topographically arrested rips which can cause significant localized erosion even when the coast regionally is accreting. Beaches which most commonly exhibit intermediate topographies are the least stable and most mobile.

INTRODUCTION

Most recent studies of beach stability and problems of beach erosion versus accretion have focused either on sediment budget imbalances related to littoral drift or on onshore-offshore sediment migration and associated "cyclic" or seasonal changes in beach/inshore profiles. Prominent examples of the latter include studies of the critical conditions responsible for the shift in beach profile from the accreted "swell" (or "summer") profile to the erosional "storm" (or "winter") profile (e.g. Komar, 1976); Davis and Fox, 1972; Sonu and James, 1973; Winant et al., 1975).

Some valuable successes have been attained in predicting the likelihood of sediment moving offshore versus onshore over simple beach topographies in terms of critical wave steepness, sediment fall velocity, and beach slope (Dean, 1973; Hattori and Kawamata, 1980; Sawaragi and Deguchi, 1980). However, criteria which take account of pre-existing complex three dimensional or bar-trough beach and surf zone topographies, such as prevail in Southeastern Australia, do not yet exist and quantitative predictions of the direction of beach change are far from straightforward. Furthermore, it is impractical to address the problem simply in terms of shifts between extreme "swell" and "storm" profiles since either extreme or intermediate topographies may be arrested by environmental conditions for extended periods and since the "cyclic" alternation between extremes often requires several years to complete (e.g. Thom & Bowman, 1980).

From the point of view of most coastal engineers concerned with beach protection the most immediate threat to beaches is manifest as subaerial beach cut. There appear to be at least three quasi-discrete modes of beach cut, each of which is related to a distinct set of mechanisms. For any given set of incident wave conditions, the operation or non-operation of a particular mode of cutting depends on the morphodynamic state of the surf-zone and beach. The morphodynamic state is in turn, dependent partially on stage in an erosional or accretionary cycle and partially on local environmental conditions. Because the mechanisms controlling each mode are different, identical incident wave conditions may cause erosion in one situation while causing accretion in another. The erosion "hazard" associated with any given beach, as well as beach mobility as expressed by the range or standard deviation of shoreline positions over an average year thus depend on the modal or most prevalent morphodynamic state of the beach and surf zone.

This paper, is aimed at elucidating, qualitatively, three aspects of the beach erosion and beach stability problem: (1) What are the major modes of subaerial beach cut and how do they depend on the morphodynamic state of the beach and surf zone? (2) What surf-zone processes may act to determine the possible seaward transport of the eroded material to the outer surf zone and hence aggravate the severity of erosion? (3) What is the consequent relationship between relative erosion hazard, beach mobility and morphodynamic state?

The concepts and examples presented have been synthesized from an extensive set of direct field observations on the high wave energy, microtidal coast of Southeastern and Southern Australia. Many of the beaches

examined are strongly compartmented and all are dominated by shore-normal rather than longshore sediment exchange. Our experiments have involved beach surveys, repeated and time lapse photography, and direct measurements of surf-zone pressure and current time series. The various methods employed are described by Bradshaw et al. (1978), Wright et al. (1979a & b), and Short (1979, 1980).

MORPHODYNAMIC STATES AND MODES OF CUT

The likelihood of a particular mode of cut occurring on a beach, for example with increasing wave height, depends on the morphodynamic state that the surf zone and beach are in at the time. Wright et al. (1979a & b) recognise at least six different states, each of which is distinguished by a different association of morphology, circulation, surf behaviour, and resonant frequencies. Short (1979a & b) has shown how different morphologic types relate to stages in erosional accretionary sequences or "cycles". The two morphodynamic extremes are : (1) steep reflective beaches with narrow surf zones; and (2) dissipative, flat beaches with wide, barred surf zones. (3) Between the two extremes are several intermediate types of bar-trough and "rhythmic" inshore topographies including alternating transverse bars and rips. The reflective state is characterized by maximum storage of available sediment within the subaerial and intertidal part of the beach and is equivalent to the "swell" (or "summer") profile whereas the dissipative state is equivalent to the "storm" (or "winter") profile with most of the sediment stored subaqueously in the surf zone. As in the "classic" beach cycle models, the reflective and dissipative extremes represent respectively the accretional and erosional end points. However, different sets of environmental conditions can cause one or the other of the extremes to prevail virtually year round as the modal state or may favour the prevalence of intermediate states.

Each beach state presents its own distinctive erosion "hazard" both in terms of the probability of erosion and in terms of the most likely mode of cut. In the immediate time frame the "instantaneous" beach state, which depends in part on antecedent processes, determines the day-to-day sensitivity of the beach to short term increases in wave energy. Over the long term, the modal beach state and range of states determine the annual probability of cut for any given wave climate as well as the mobility of the beach (see Short, 1980 for a discussion of beach mobility). Table 1 summarizes the characteristics and causes of the three primary modes of beach cut together with their relationships to morphodynamic conditions. Figure 1 illustrates the major plan and profile configurations of

Figure 1: Characteristic Beach States and associated Modes of Beach Cut and Relative Erosion "Hazard".

the extreme and intermediate beach states and indicates the relative erosion hazard and relative importance of each mode of cut corresponding to each state. The relative wave energy required to induce erosion and relative beach mobility for modal states are also indicated. As Figure 1 suggests, Mode 1 cut is probably the most important mode of cut on reflective beaches but is suppressed on extremely dissipative beaches where it is replaced by Mode 2 cut. Beaches in intermediate states are susceptible to cut by both Modes 1 & 2 as well as by Mode 3.

Table 1: Modes of Beach Cut in Relation to Beach State.

<i>MODE OF BEACH CUT</i>	<i>CAUSE</i>	<i>ASSOCIATED BEACH & SURF-ZONE CONDITIONS</i>	<i>RELATIVE ENERGY REQUIRED TO INDUCE BEACH CUT</i>
1 <i>Accentuated runup and berm overtopping, formation of erosional cusps</i>	<i>Strong subharmonic resonance</i>	<i>REFLECTIVE</i>	<i>LOWEST</i>
2 <i>Backshore scarping by bores superimposed on long-period setup oscillations</i>	<i>Strong infragravity oscillations</i>	<i>DISSIPATIVE</i>	<i>HIGHEST</i>
3 <i>Beach scarping in embayments of arrested rip cells</i>	<i>Radiation stress gradients induced by irregular surf zone topography</i>	<i>INTERMEDIATE, RHYTHMIC Surf-zone topography, regions adjacent to shoreline protrusions, inlets or river mouths.</i>	<i>INTERMEDIATE</i>

CUT OF REFLECTIVE BEACHES

The steep reflective beach states tend to prevail in highly indented compartments, in the protected lee of headlands, in the presence of coarse material, or at the "end points" of prolonged accretion. On the New South Wales coast, they are particularly common at the low energy (southern) ends of spiral (or "zeta curved") embayments. Storage of active sand is primarily in the intertidal and subaerial beach rather than in the surf zone or nearshore and relatively deep water reaches to the base of the intertidal beach. The surf-zone is narrow or nonexistent and waves surge up the beach face with maximum runup (relative to incident wave height).

Near the beach, oscillations tend to be standing at a range of frequencies. A prominent feature of the hydrodynamics of reflective beaches is subharmonic resonance. There is now considerable evidence indicating that these subharmonic oscillations are edge waves (Huntley and Bowen, 1975; 1979; Wright et al., 1979a & b). Furthermore, field data (Wright et al., 1979a & b; Wright, in prep) suggest that, so long as the reflective condition is maintained (i.e. steep beach, low-steepness waves), increased wave energy will increase the amplitude near the beach of the subharmonic resonance. Runup maxima under these conditions are strongly dominated by the subharmonic motion with the result that alternate swashes reach extreme elevations on the beach. Typical power spectra of water surface oscillations on a reflective beach (Bracken Beach, south of Sydney, see Wright, et al., 1979b) are shown in Figure 2. These spectra are based on observations made under moderate energy conditions (breaker height, $H=1.5$ metres) and clearly show a pronounced subharmonic peak which exceeds the incident wave peak over the step at the base of the beach (inner station).

The growth of subharmonic resonance on steep beaches under conditions of long-period swell is a major cause of the first mode of beach cut (Table 1). This mode is characterized by accentuated runup and berm overtopping (Fig.3) accompanied by strong seaward pulsing at subharmonic frequencies below the base of the beach. During the early phases, liquifaction and slumping of the beach face takes place in the mid and low swash zone while large erosional cusps develop on the upper beach with maximum scour occurring in the cusp bays.

Since subharmonic resonance is most easily excited on reflective beaches and requires the least energy to excite (Guza and Davis, 1974; Guza and Bowen, 1977) reflective beaches are most sensitive to Mode 1 erosion under the wide range of energy conditions. Probably for this reason it is common, on the New South Wales coast for moderate, long swell to cut reflective beaches while promoting accretion on nearby dissipative beaches. Provided energy conditions are not severe, cut ceases once reflectivity has been sufficiently reduced to reduce resonance and runup. Conversely, accretion normally ceases once maximum reflectivity has been attained. In strongly embayed compartments where the reflective beach represents the modal state, beach mobility thus tends to be low.

Inshore circulation seaward of modal reflective beaches is normally weak or nonexistent (Wright et al., 1979a) and, although subaerial cut may be severe, the eroded sand is not normally transported very far offshore except when the erosive conditions persist long enough to alter the state

Figure 2: Typical power spectra of surface elevation (η) and shore-normal current (u) from a reflective beach. Note the pronounced subharmonic peak. (Bracken Beach, 10 Dec. 1977).

Figure 3: Accentuated runup, berm overtopping, and the initiation of erosional cusps on a reflective beach under conditions of long-period, moderate energy swell (Bracken Beach).

of the beach significantly. However, an exception exists for reflective beaches which prevail at the protected southern ends of spiral embayments. Large, relatively strong rips frequently develop in these localities under moderate to high energy conditions. Some prominent examples include Cronulla, Dee Why, and Palm beaches near Sydney. These rip systems increase the severity of erosion when it occurs.

CUT OF DISSIPATIVE BEACHES

On exposed time-varying beaches the extreme dissipative state occurs following severe erosion. The dissipative state may also be arrested as the modal state in localities exposed to persistent high-energy waves or when there is an abundance of fine-grained sediment in the inshore. Along deltaic coasts dissipative conditions commonly prevail even with relatively low wave energy.

An example of a perennially dissipative beach in New South Wales is the northern section of Seven Mile Beach, 150 km south of Sydney where fine sand, drifted northwards accumulates in an exposed inshore zone. An even more prominent example is found along the Coorong coast of South Australia where a long straight dissipative beach extends from Goolwa 190 kilometres to the southeast (Fig.4). Goolwa's high energy dissipative state is maintained by long period southwesterly swell with heights which persistently exceed 3 metres combined with a sediment suite consisting of fine carbonate sands. Both Goolwa and Seven Mile Beach exhibit wide surf zones with multiple parallel bars and negligible rip circulation. The Goolwa surf zone is normally 500 metres or more wide.

The flat profiles and high turbulent viscosities of the dissipative extreme preclude Mode 1 cut since subharmonic resonance and standing oscillations at incident wave frequencies are suppressed and runup is very low relative to breaker height. In fact, dissipative beaches generally have a greater probability of accreting than they do of eroding. Nevertheless, dissipative beaches may erode under high energy conditions although this erosion often consists solely of backshore scarping without consequential removal of sand to seaward of the foreshore. Neglecting the effects of non-wave-induced water level rises, (e.g. storm surges, extreme tides), cut of highly dissipative beaches primarily involves the second mode of cutting (Table 1). Pronounced setup on the landward margins of flat dissipative inshore profiles increases the effectiveness of return flows and may, under conditions of high energy or steep waves, allow the bores of broken waves to penetrate to the backshore or to the foredune base where scarping

without consequential removal of sand to seaward of the foreshore. Neglecting the effects of non-wave-induced water level rises, (e.g. storm surges, extreme tides), cut of highly dissipative beaches primarily involves the second mode of cutting (Table 1). Pronounced setup on the landward margins of flat dissipative inshore profiles increases the effectiveness of return flows and may, under conditions of high energy or steep waves, allow the bores of broken waves to penetrate to the backshore or to the foredune base where scarping occurs as illustrated in Figure 5. This mechanism may operate to cause dune recession even where there is an abundance of inshore sediment and without necessarily resulting in a net loss of beach material. The setup normally oscillates at infragravity frequency with maximum bore penetration occurring at "surf-beat" highs.

Figure 4: Highly dissipative, barred surf zone near Goolwa, S.A. (surf zone is 500 metres wide).

Data from Goolwa (Jan-Feb 1980) and Seven Mile Beach (Feb.1979) emphasize the dominance of infragravity oscillations on the subaerial beach processes of dissipative systems. Figure 6 shows simultaneous water surface (η) time series from three different stations across the Goolwa surf zone. Progressive shoreward attenuation of oscillations at incident wave frequency and shoreward growth of infragravity oscillations at periods of 100-150 seconds are apparent. Power spectra of both η and shore normal current, u (Fig.7) from the inner surf zone are strongly dominated by infragravity peaks. Infragravity oscillations near the beach at Goolwa exceeded 1 metre in

Figure 5: Cut of highly dissipative beaches: bores penetrate to foredune base on highs of infragravity oscillations.

Figure 6: Simultaneous water surface (η) time series from Goolwa Surf Zone (1 Feb.1980) showing progressive shoreward attenuation of incident waves and growth of infragravity oscillation. Outer, mid, and inner stations were located respectively at 160m, 100m, and 60m seaward of the mid swash zone.

height at the time the data were obtained.

Seaward transport of sands within the surf zones of long straight dissipative beaches such as Goolwa Beach is the result of vertical segregation of shoreward versus seaward flows rather than rips. Figure 8 shows the cross-sectional current structure as observed at Goolwa under conditions of comparative beach stability. Strong shoreward flow near the surface is accompanied by weaker seaward flow near the bed. Spectra indicate the seaward flows to be dominated by infragravity pulsing. Although no storm data exist from such a high energy surf zone, it may be tentatively inferred that seaward-directed bottom flows intensify under storm conditions and move sand to the outer surf zone.

Cross spectra of u and v and current statistics from multiple positions across the Goolwa and Seven Mile Beach surf zones demonstrate that the infragravity oscillations are standing in the shore-normal direction and may exist as longshore-progressive edge waves (Wright, in prep). The inferred antinodal regions normal to the shore approximately correspond to regions of sediment accumulation at bars. On long straight dissipative beaches, sediment eroded from the subaerial beach remains within the surf zone as multiple longshore bars from where it may be readily returned to the beach during periods of falling wave height. However when highly dissipative conditions and associated strong infragravity oscillations are superimposed during storms or periods of heavy swell, on crenulate coasts where short embayed beaches are bounded by headlands, erosive effects may be greatly enhanced. This is often the situation for many of the beaches near Sydney. Destructive effects and increased erosion hazards which are related to embayment geometry include: (1) low-frequency resonance at infragravity and seiche frequencies; and (2) giant, powerful storm rips which may transport sediment to over a kilometre offshore. The storm rips have feeder systems which may occupy the whole of an embayment (see Figure 8 of Wright et al., 1979b for an example). In many cases the rips appear to be closely coupled to low-frequency resonant phenomena and pulse strongly at periods of several minutes.

CUT OF INTERMEDIATE BEACHES

Time varying beaches, must in the process of shifting from one extreme state to the other, pass through the intermediate states shown in Figure 1. The period of time that the beach occupies any of these states may, in some cases, be very short as for example during a period of rapid erosion. However, in regions which experience highly variable wave climates like that of Eastern Australia the

Figure 7: Power spectra of η and u from the inner surf zone at Goolwa (31 Jan. 1980) showing strong dominance of infragravity oscillations.

Figure 8: Cross-sectional current structure of the Goolwa surf zone (31 Jan. 1980).

beach may continually oscillate around one or several intermediate states without reaching either extreme. In addition, some intermediate states may persist for several months or even year round on many of the compartmented beaches of New South Wales. Environmental conditions which favour intermediate modal states include moderate energy but temporally variable wave climates and medium to coarse sand.

Intermediate beach states include various types of bar-trough, crescentic bar, and rhythmic transverse-bar-rip topographies which allow part of the beach inshore system to be reflective while another part is dissipative (Wright et al., 1979a). For example steep reflective subaerial beaches can coexist with partially dissipative surf zones when deep pronounced troughs separate the beach from the dissipative parts of the surf zone or where the reflective beach sectors occur in rip embayments adjacent to dissipative transverse bars. Under these conditions the beach is affected by a combination of incident waves, subharmonic resonance, and infragravity oscillations, as well by resonance at intermediate frequencies determined in part by topographic dimensions (Wright, in prep). An example of current spectra from the inner surf zone of Type 3 intermediate topography (as described by Wright et al., 1979a) and exhibiting all of the frequencies just mentioned is shown in Figure 9.

Figure 9: Power spectra of u from intermediate crescentic-bar-trough topography on North Moruya Beach (13 Dec. 1977).

Intermediate states permit both Mode 1 and Mode 2 cut to operate together when seas rise. In addition, it is on the intermediate states that different scales of rip circulation are best developed so that Mode 3 cut also plays an important and often major role. Mode 3 cut is associated with rip circulations which are forced by topographic irregularities (e.g., transverse bars and alternating embayments), particularly irregularities which are persistent in their location. Localized but often severe erosion may occur in the embayments of rips, even when the coast regionally is experiencing accretion, by means of current scour at the base of the beach face. Paradoxically, this form of erosion may be intensified by abnormally rapid accretion in immediately adjacent zones or by the nearby occurrence of arrested shore-line protrusions such as tidal inlets or man-made structures, which produce steep alongshore gradients in radiation stress and setup. Despite its spatial limitations, this mode of erosion may cause chronic local shoreline recession, often endangering beach front properties. Figure 10 shows an example of a large arrested rip system on Wamberal Beach north of Sydney which caused the destruction of three beach-front properties at a time when the flanking shoals were rapidly accreting.

A large-scale analogue to Mode 3 cut occurs adjacent to river mouth bar deposits and deltaic lobes influenced by moderate to high energy waves. This type of erosion is related to large-scale rips which drain water trapped by high dissipative wave breaking over the seaward-protruding river-mouth bar or deltaic bulge deposits. Large erosional bays result along margins of the regions of high deposition rates. This form of erosion is most acute on the downdrift margins of the depositional bulge but also occurs on the updrift margins. An example from the mouth of the Shoalhaven River south of Sydney is shown in Figure 11. The process of delta-margin erosion is also discussed by Wright et al., 1980.

DISCUSSION AND CONCLUSIONS

This paper has emphasized the dependence of beach cut on morphodynamic state. The probability of some form of cut occurring, the possible severity of cut and the mode of cut all vary with morphologic state on the one hand and breaker conditions and sediment size on the other. Quite obviously, the threat to beach front properties depends as much on the absolute width of the subaerial beach as it does on cut probability. However for any given beach width, the relative erosion "hazard" of a beach sector may be readily assessed at a first order with reference to beach state, degree of exposure, and forecast wave

Figure 10:

conditions. Since the physical processes responsible for cut are different, different beach protection strategies may be required for different morphodynamic states. For purposes of long-term advance planning, it is the modal beach states and/or normal range of states that are important. These may be recognized from sets of long-term ground or remotely-sensed observations.

On many New South Wales beaches, particularly those along the crenulate coast in the vicinity of Sydney, modal beach state varies appreciably with degree of exposure to the dominant southeasterly swell and storm waves. Spiral or zeta curved embayments typically are protected and experience low refraction coefficients at their southern ends but are fully exposed at their northern ends. Reflective beaches are the modal state in the southern sectors whereas the accumulation of sands within the surf zone combined with high exposure tends to maintain more dissipative conditions at the northern ends. Intermediate states are most common in the middle sectors. This pattern of longshore variation in beach state together with the associated variations in likely mode of beach cut is illustrated in Figure 12. Typically it is the middle (intermediate) sections of these beaches which are most susceptible to cut and are most mobile. In a more general sense, Table 2 summarizes the relationships between beach state, beach mobility and environmental conditions.

Table 2: Modal Beach State and Beach Mobility in Relation to Environmental Conditions.

<i>'MODAL' BEACH STATE</i>	<i>RELATIVE AMPLITUDE OF CHANGES IN SHORELINE POSITION</i>	<i>ENVIRONMENTAL CONDITIONS</i>
<i>REFLECTIVE</i>	<i>LOW</i>	<i>Low-steepness waves or strongly embayed compartments; coarse or high-density (e.g. volcanic 'black' sands) material</i>
<i>DISSIPATIVE</i>	<i>LOW TO MODERATE</i>	<i>Persistent high energy waves or Abundant fine sands in inshore zone (e.g. deltaic coasts)</i>
<i>INTERMEDIATE-RHYTHMIC</i>	<i>HIGH</i>	<i>Highly variable wave climate; medium sands; best developed where there is also a significant fraction of shell fragments and a meagre sediment supply.</i>

BREAKER TYPE AND PHASE SHIFTS ON NATURAL BEACHES

Peter J. Cowell

Coastal Studies Unit, Dept of Geography
University of Sydney
N.S.W. 2006 Australia**ABSTRACT**

The kinematics of incipient breakers were measured on various complex natural beaches. Water velocities were found to consistently lag behind the wave crest. This phase shift appears to be partly inherent in shoaling waves and partly a result of partial wave reflection. Phase shifts vary from 5 degrees through to quadrature. This variation probably depends to a large extent upon beach reflectivity and distance of the break point from the shoreline. Phase shifting also varies vertically beneath the wave crests from uniform distributions to those in which maximum shifts occur near the bed. There is a strong relationship between the nature of phase shifting, the morphodynamic condition and the breaker type. Surging waves were associated with large, and vertically uniform phase shifts. Waves towards the plunging and spilling end of the breaker type continuum occurred where phase shifts were significantly larger at lower depths than near the surface.

INTRODUCTION

The importance of breaker type in differentiating surf-zone morphodynamic regimes is implicit in the delineation of beaches into reflective and dissipative categories (e.g., see Short, 1978 and Wright et.al., 1979). The six morphodynamic states of Wright et.al. (1979) range from the highly dissipative type through intermediate complex and rhythmic forms to the highly reflective extreme. Breaker characteristics have received little direct attention in recent theoretical developments of the surf-zone dynamics associated with these beach states. However, it is obvious that spatial patterns of energy dissipation related to breaker type must be as important to morphodynamic response as incident angle and wave height distribution.

Peregrine and Cokelet (1980) use numerical solutions of water motions in deep water which provide apparently good simulation of the initial breaking process. Unfortunately, there exists at present no theory capable of successfully describing the shallow-water breaking process even under simple circumstances. Accordingly, in order to investigate the process in the context of breaker types occurring with each of the morphodynamic states, the kinematic structure of waves near breaking was investigated in association with each of these beach types. The investigation involved measurement of the vertical distribution of horizontal velocities.

The purpose of this paper is to present some results concerning one of the least considered properties of waves at breaking; the phase relationship between the wave crest and the horizontal velocity components below it. Two aspects of this problem will be considered: (1) the variation in this phase relationship for waves breaking in association with the different morphodynamic beach types; and (2) the influence of this phase relationship on breaker type through the effect on the vertical distribution of horizontal velocity components for waves on the respective beach types.

Both Adeyemo (1970) and Thornton et.al.(1976) report without comment as to cause or implications the occurrence of phase shifting between water surface and horizontal velocities in laboratory and field experiments respectively. Adeyemo employed photographic measurement of hydrogen bubble displacement in waves on both a steep beach (slope 1:9) on which plunging breakers occurred, and on a moderately flat beach (slope 1:18) with spilling breakers. In both cases Adeyemo reports wave crests leading velocity maxima by more than 30 degrees. Further, this phase shift was found to exist throughout the shoaling region seaward of the break point (see Table 1).

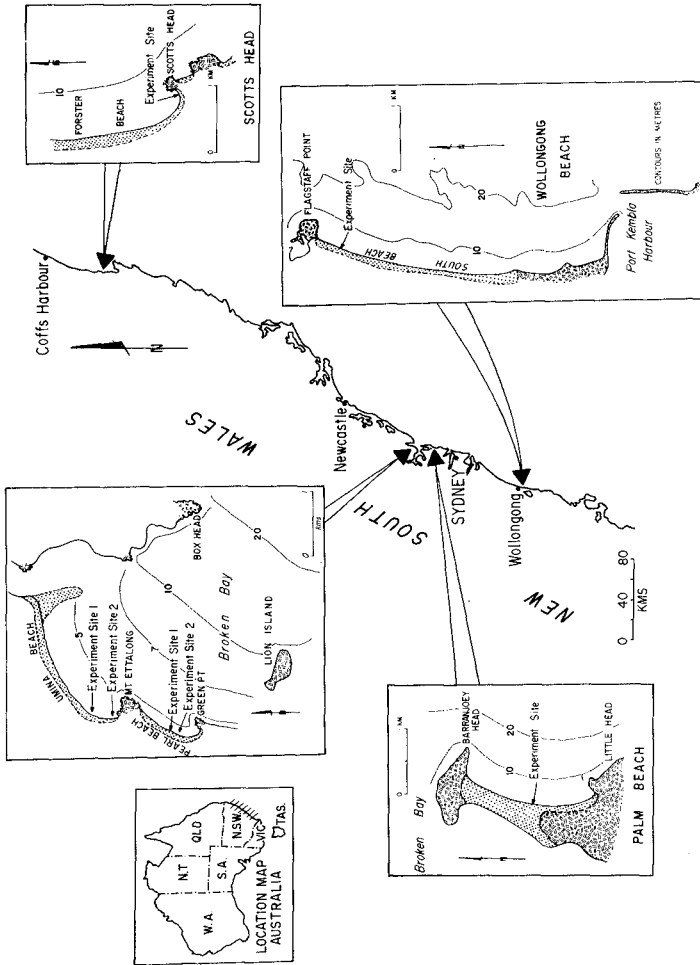

Thornton et.al. used electromagnetic flow metres and capacitance wave staffs to measure waves and currents on field beaches. They report a 15 degree lag of water velocities behind the water surface at peak frequencies for surging breakers on a steep natural beach (average slope, 1:8). They found phase shifts varying from 5 to 30 degrees in the same direction in measurements made on a flat beach (average slope, 1:20) where spilling breakers prevailed (see Table 1).

Field Site Locations

FIGURE 1

EXPERIMENTS AND METHODS

Field measurements of vertical distributions of horizontal velocities were made at various sites on the microtidal, New South Wales coast of Australia, shown in Figure 1. These beaches were chosen in each case as being characteristic of a particular morphodynamic type. Of these, experiments from three beaches (Umina, Pearl and Palm) will be used to illustrate the general results concerning phase shifting.

Umina beach provides an example of the dissipative beach type with low bed slopes, parallel bars and generally spilling breakers (Fig. 2). Beach sediments are largely fine sands (2.75 phi). The break point during experiments was located on the outer bar. Pearl Beach (Fig. 3) provided the reflective extreme with waves breaking against the beach face. The beach was heavily cusped during experiments (Fig. 6a). Steep beach slopes are enhanced by the coarse to very coarse sand (1 to -.5 phi). Palm Beach will be used to illustrate wave breaking on an intermediate-rhythmic beach type (Fig.4). Median diameter of sediments is slightly less than 1.5 phi. During experiments type 4 beach morphology of Wright et.al.(1979) prevailed. Three break points with distinctly different breaker type characteristics were distinguished on this beach: On the rip head bars waves were heavily plunging; at the beach face in rip embayments waves were of the surging type after reforming across the rip channel; and on the seaward margins of transverse bars between rip channels breaker types were weakly plunging to spilling.

Wave and current sensors were recorded both digitally on magnetic tape and continuously on strip chart. Photographic records were obtained using a movie camera with single frame exposures synchronised with the digital scanning of wave and current sensors. Pressure and water surface measurements were made using bottom mounted pressure transducers together with the photographic record of surface piercing, visually calibrated staffs attached to each instrument station used. From one to three stations were used in experiments. They are depicted in Figures 2, 3 and 4. At the incipient break point the instrument station also supported a vertical array of up to 7 miniature, bidirectional, ducted impellor-type flow metres. The axes of these flow metres were orientated shore normal in the horizontal plane. The photographic record was also used to determine breaker type geometries of each passing wave. A description of the data acquisition system can be found in Bradshaw et.al. (1978).

Spectra and cross spectra were computed between adjacent

FIGURE 2

Dissipative Beach Experiment

FIGURE 3

Reflective Beach Experiment

FIGURE 4

Intermediate Beach Type Experiment

current meters in the vertical array, as well as between each current meter and the pressure transducer. These computations were made by Fourier transforming covariance functions calculated from the records and smoothed with a Tukey window. The covariance functions were computed using a maximum lag of 22% of the record length. The resulting spectral estimates contain 24 degrees of freedom.

Phase differences at peak spectral frequencies were used. These are shown in Figure 5 where the horizontal bars indicate 95% confidence intervals. These bars are located at the elevation (z) of each flow meter used. This elevation is shown on the ordinate normalized with respect to mean height of waves above mean water level (η) and the depth (h). Dashed confidence bars indicate phase estimates for sensors which occasionally emerged from the water, giving zero readings. The reliability of these estimates is therefore suspect although comparison of power spectra with those of non-emerging instruments suggests comparable frequency content. Solid phase curves are interpolated between flow meters. Dashed curves are less reliable due to either extrapolation or current records being less reliable due to reasons just given.

The contribution to phase shifting resulting from instrument response characteristics was assessed by comparison of analyses and the variously obtained time series. The phase curves in Figure 5 were therefore determined for both phase between currents and pressure, and between each adjacent current record. Phase shifts and confidence intervals between each successive pair of adjacent current records were summed over the vertical array. This produced good agreement with phase between pressure and each of the current records.

Pressure records were also compared against current and photographic records with respect to frequency content. Close agreement is exhibited. The pressure record also appears to follow the photographically determined water surface time series fairly faithfully, which is important in terms of the coincidence of maximum pressure and the passage of the wave crest.

As explained by Thornton et.al.(1976), interpretation of such spectra requires caution due to nonhomogeneity and nonstationarity resulting from the break point wandering on flat beaches. For this reason cross-spectra phase was checked against wave by wave inspection of phase shifting between individual time series. The comparison revealed reasonable agreement. It also enabled use of reliable segments of records from those instruments which failed to produce a complete time series. These segments were used to estimate the interpolated and extrapolated parts of the

curves in Figure 5.

DISCUSSION OF RESULTS

It is evident from Figure 5 that phase shifting is substantial under each set of morphodynamic conditions. Water velocities generally lag behind the wave crest, particularly in the lower half of the water column. This is consistent with the observations of both Adeyemo (1970) and Thornton et.al.(1976). For spilling breaker types on dissipative beaches (Fig. 2) velocities follow the water surface more closely towards the surface, with a sharp decrease in phase lags above mid depth. High waves heavily plunging on a steep beach (Fig. 3) exhibit a similar phase profile (Fig. 5c), as do waves of the outer break on the intermediate beach type (Fig. 5d). In the former case the phase shift in the cusp bay is smaller than at the break point on the cusp horn. This is probably attributable to the interaction of waves with the intense backwash drainage from the cusp bay illustrated in Figure 6a. Resulting turbulence causes strong vertical mixing, which may produce greater flow homogeneity throughout the water column, and thus reduced phase shifting in the lower half. Breaker type differences are related to this. Whereas heavily plunging breakers occur on the cusp horns, the general form in the bay is collapsing and even surging. In the latter case the wave is injected with turbulence before breaking. Hence the breaker form is described by the general water motion rather than by the water surface alone.

It is also apparent that the vertical distribution of phase is more uniform in situations where surging-collapsing breakers occurred (Figs. 5b and 5d, beach face). Collapsing breakers prevailed in association with the 20 degree phase shift at the break point (Fig. 5b). The standing wave apparent at the beach-face break of the rip embayment on the intermediate beach type occurred in association with surging waves. In this case the break point (and instrument station) was located one quarter wave length from the shore line antinode.

It is interesting to note that both the harmonic (Fig. 5a) and subharmonic (Fig. 5b) have phase shifts of roughly twice the primary wave. In the former case the development of a harmonic in the spectrum is expected on such a flat beach where significant cross-spectral transfer is likely (e.g., Guza and Thornton, 1980). It is expected that the harmonic is phase linked although this cannot be demonstrated from this analysis. On the steep beach it is consistent with expectation that spectra should exhibit a significant peak at subharmonic frequency rather than at harmonic frequencies (e.g., Guza and Bowen, 1975).

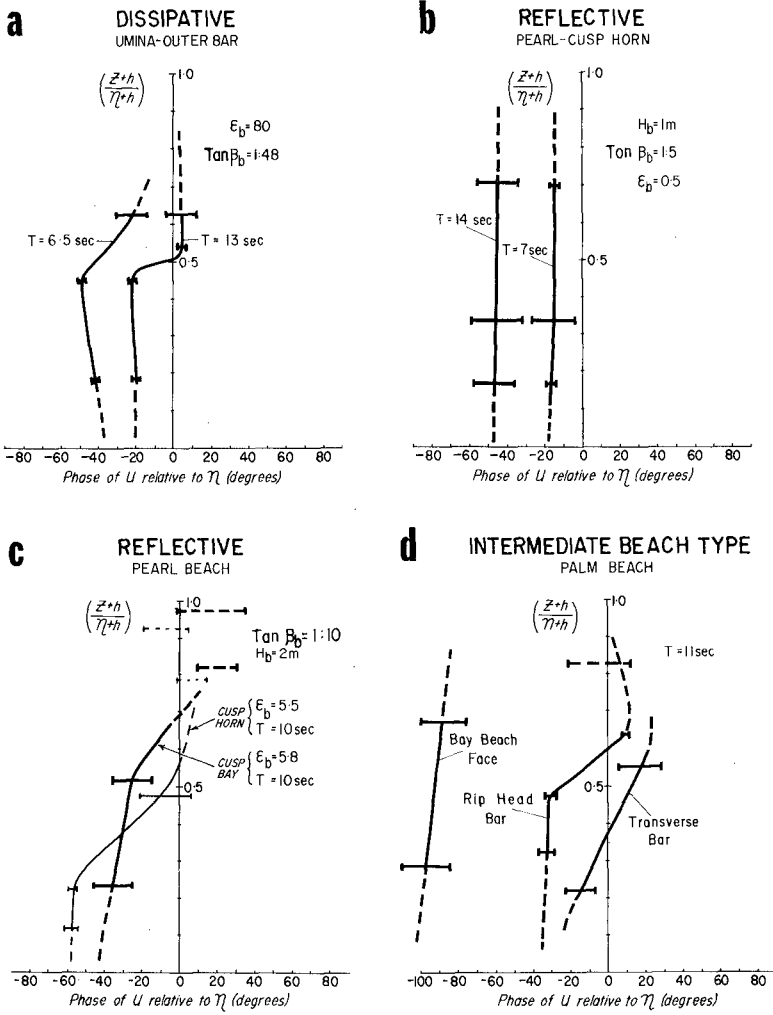

FIGURE 5

Cross-Spectra Phase

FIGURE 6. A. Beach-Cusp Drainage - Pearl Beach
B. Swash Lense - Umina Beach
C Spilling Breaker
D. Collapsing Breaker

However, the subharmonic might have been expected to be closer to quadrature phase than that actually displayed (Fig. 5b).

Before it becomes possible to account for the phase difference under the various morphodynamic conditions it will be necessary to explain the occurrence of phase shifting in general. Jonsson (1978) showed for oscillatory flows that the phase of water velocities within a laminar boundary layer leads those outside by $\pi/4$. In the fully turbulent case this phase shift is about $\pi/6$. This results from the inertia forces decreasing significantly near the bed whereas the accelerating pressure force the same in both the boundary layer and in the higher velocity free flow. Flow near the boundary therefore follows the phase of pressure more closely. However, the problem with the application of this argument is twofold: (1) phase shifting can only occur near the bed, whereas it has been measured by Adeyemo, Thornton et.al. and this study well away from the bed; and (2) the measured phase shifting occurs in the reverse sense to that predicted within the boundary layer.

Another explanation for phase shifting is provided by partial wave reflection. Using linear theory for partial reflection, the amount by which the surface elevation phase (ψ) leads the velocity phase (ϕ) x is given by

$$\begin{aligned} &= \psi - \phi \\ &= \tan^{-1} \left(\frac{1+r}{1-r} \tan kx \right) - \tan^{-1} \left(\frac{1-r}{1+r} \tan kx \right) \quad (1) \end{aligned}$$

where kx is the distance from an antinode nondimensionalized with respect to the wave number (k), and r is reflection coefficient. The reflection coefficient can be approximated by

$$r = 2/\xi_i \quad (2)$$

$$\text{where, } \xi_i = \frac{a_\infty \sigma^2}{g} (2\pi)^{1/2} \tan^{-5/2} \beta \quad (3)$$

a_∞ is the wave amplitude in deep water, σ is its radial frequency, g is the gravitational acceleration, and β is the bed slope (Guza and Bowen, 1976). Complete reflection occurs for $r \geq 1$. Equation 1 shows that phase shifting varies with reflectivity, the distance from the antinode and the wave length.

The results of Adeyemo (see Table 1) indicate that

reflectivity does not provide a general explanation. It is evident from his results that phase shifting is relatively constant as h/L varies throughout the shoaling region (L being the local wave length). Also the relatively steep laboratory waves provide insufficient reflection to produce the observed phase shift at any location, even on the steeper beach. The very low r shown in Table 1 for the 1:18 beach is totally inadequate for explaining the measured phase shift (θ) even when $kx = \pi/4$, where the phase shift predicted from (1) reaches its maximum (θ_{\max}). Nor is it conceivable that the reflection coefficient ($r_{\hat{\theta}}$) required for $\hat{\theta}$ at respective locations (kx) could be sufficiently large for such steep waves on such a flat beach. Similarly, reflection coefficients ($r_{\hat{\theta}_{\max}}$) at positions of phase shift maxima ($kx = \pi/4$) could not be expected to attain required values.

The same argument can be applied to the results from the dissipative Del Monte Beach of Thornton et.al. and Umina Beach of this study where substantial values of $\hat{\theta}$ were obtained (Table 1). The impossibility of reflection coefficients capable of explaining $\hat{\theta}$ values is demonstrated by the nature the runup at Umina Beach shown in Figure 6b.

Nevertheless, on steep beaches partial reflection theoretically and intuitively must be important in phase shifting. The linear predictions of θ in examples 4 and 9 to 12 (Table 1) for r approximated from (2) generally show fairly poor agreement with $\hat{\theta}$. However, θ is very sensitive to kx and so relies on accurate positioning of the antinode. Local kx at the break point has been used in this paper. It was determined from linear theory and phase measurements between instruments along transects. Better results may be possible using the average of local wave lengths between the break point and the shoreline. It is apparent in Table 1 that θ_{\max} and $r_{\hat{\theta}_{\max}}$ are at least of the right order of magnitude for the steep beach examples (particularly examples 4 and 10).

It is therefore evident from waves on non-reflective, flat beaches that phase shifting is generally inherent in both shoaling and near-breaking waves. It is probable that phase shifts due to reflection will be superimposed upon these inherent shifts. In accounting for phase shifting due to reflection therefore, it will be first necessary to gain some understanding of the inherent phase relationship. Wave-wave interaction and associated cross-spectral transfer may be important in gaining this understanding (e.g., Thornton, 1979; Guza and Thornton, 1980).

IMPLICATIONS FOR BREAKER TYPE

Since phase shifting appears to be a significant factor in the kinematics of waves near breaking it should be an important determinant of the breaking process and resulting breaker type. Iwagaki et.al. (1974) found in laboratory waves that systematic differences exist in velocity profiles below the crests of breakers of different type. Vertical gradients in horizontal velocity components are shown in Figure 7 to be steepest toward the surging end of the breaker type continuum. This is particularly evident near the crest, though also general over the entire profile.

The vertical distribution of horizontal velocities together with rates of decrease in wave phase speed provide a useful concept of kinematic stability. This concept may provide a signature of general form $(\partial u/\partial z) (\partial C/\partial x)^{-1}$ which is the kinematic equivalent of previous breaker type indices (e.g., Galvin, 1968; Battjes, 1974), where u is the horizontal water velocity, $z = -h$, and C is the phase speed. Kinematic stability is related to the kinematic criterion for the initiation of wave breaking ($u_0 \geq C$) extended through all z . Sharp crested waves breaking on gentle slopes (Fig. 6c) have relatively large vertical gradients in horizontal velocity. The significantly higher velocities at the crests of these waves are indicative of their strong non linearity. At the break point, the slow decrease in phase speed results in velocities exceeding the phase speed in the vicinity of the crest only and spilling breakers result. On steep slopes with surging-collapsing waves the vertical gradient in velocity components is smaller. Since the phase speed decreases abruptly velocities tend to exceed the phase speed through much of z almost simultaneously, as illustrated in Figure 6d.

If kinematic stability is significantly effected by phase shifting then the latter will be important in the determination of breaker type. Figure 8 shows for the different field results the distribution of horizontal velocities below the crest expressed as a percentage of horizontal velocity component maxima (u_{zmax}). These profiles are to be expected if the velocity at any point below the crest can be assumed to be a cosine function of u_{zmax} and θ_z .

For surging breakers it is apparent that the near quadrature phase at the break point results in very low horizontal velocities below the wave crest. This produces a stabilizing tendency such that horizontal velocities do not come to exceed the phase speed until the latter is very small. This stability is commonly recognized for surging waves as being the non-breaking, totally reflected case

(e.g., $\xi_i \leq 2$ of Miche; see Guza and Bowen, 1976). Clearly however, since phase shifting can evidently occur by degrees this stability must also vary accordingly.

For the larger (relatively steeper) surging-collapsing waves in Figure 8, reduction of velocities below the crest due to phase shifting is not so great. However, the vertical gradient in velocities resulting from phase shifting is much smaller than in the more dissipative breaker types towards the plunging and spilling end of the continuum. In terms of the kinematic stability of these waves therefore, this phase shift produces no additional steepening of the velocity gradient below the crest.

For the more dissipative plunging and spilling waves in Figure 8 it is clear that vertical differences in phase shifting produce a considerable augmenting of the velocity gradient. This combined with lower gradients in phase speed should tend to confine initial breaking to the crest region.

FIGURE 7. Horizontal velocities below crests of different breaker types

FIGURE 8. Velocity below crest as percentage of U_{max}

CONCLUSIONS

Phase of velocities lag behind the surface elevation under most conditions of waves near breaking. It appears that a certain amount of this phase shift is inherent in the shoaling process. However partial wave reflection must also produce some phase shifting. The contribution of each process to phase shifting has not been determined. It is obvious however that the greatest potential for phase shifting lies on reflective beaches where anything up to near phase quadrature may be obtained. It is also apparent that the vertical distribution of phase is more homogeneous on reflective beaches. On dissipative beaches substantial phase shifting appears to be restricted to depths midway beneath the crest.

Phase shifting must therefore be an important determinant of the kinematics of waves near breaking. It therefore must also be important in determining the breaker type. Large, vertically uniform distribution of phase shifting causes low velocities beneath the wave crest inducing stability with resulting surging waves. Smaller phase shifts uniformly distributed below the wave crest tend to develop with collapsing waves on steep slopes. Where phase shifting increases markedly toward the bed velocities beneath the crest are reduced in that direction. The vertical velocity profile is thus significantly steepened. Breaking then tends to be confined to the crest region of the wave. This is consistent with the development of spilling waves where beach slope is low. It may also help explain the well known development of plunging waves where slope is steep.

Wave-current and wave-wave interactions occur extensively on complex natural topographies. It is likely that these also have significant effects on breaker kinematics both directly and indirectly through the influence on phase shifting. However, these effects are not yet obvious particularly with respect to phase shifting. Nevertheless it will be necessary to account for kinematic effects of phase shifting when considering breaker type response to surf-zone morphodynamics. Similarly, theoretical development of near breaking waves in shallow water will require inclusion of this factor.

BEACH RESPONSE TO VARIATIONS IN BREAKER HEIGHT

A.D.Short

Coastal Studies Unit, Dept of Geography
University of Sydney
Sydney, N.S.W. 2006. Australia

ABSTRACT

The breaker wave height required to produce a particular beach-surfzone morphology is examined for micro-tidal, medium to fine sand beaches. Waves $>2.5\text{m}$ produce dissipative beach systems with wide surfzones and shore parallel bar/s and channel/s. Breakers between 1 and 2.5m result in rip circulation and associated rhythmic morphology (crescentic bars, rip channels, megacusps, etc). Low waves ($<1\text{m}$) form steep, barless reflective beaches with characteristic cusps/berm. To gauge the stability/mobility of each of these beach types the range of beach profile changes associated with each is presented, for both the time and space domain. Modally dissipative beaches where breakers consistently exceed 2.5m undergo minor changes in profile and are consequently stable both temporally and spatially. Modally rhythmic beaches have a variable moderate energy wave climate are highly unstable both over time and alongshore. Modally reflective beaches with their low waves are relatively stable. Beaches which experience a highly variable wave climate over time exhibit all three types and are consequently highly unstable. The environmental parameters useful for quantifying these beach types and associated profile changes, and the implications of these results are discussed.

INTRODUCTION

Two dimensional beach response to eroding and accreting wave conditions has been well documented both in the laboratory and in the field. High storm waves or steep waves lead to a lowering of the beach profile resulting in beach cut and seaward transport of beach materials into the surfzone and nearshore. Low swell or long waves result in a steepening of the profile by onshore sediment movement and beach fill. Between these two extremes, systematic mesoscale patterns of beach-surfzone response have been

observed. The nature of the beach morphology and associated surfzone dynamics (i.e. beach morphodynamics) under a range of wave conditions is described by Short 1979 a and b, and Wright, et al., 1979. In particular Short 1979a associates sequences of beach response with rising and falling wave conditions.

In this paper the absolute level of breaker wave height required to achieve a given level or type of beach morphological response is examined. Short's 1979a ten beach-stage classification is used to quantify beach response within three broad categories of beach type: low wave energy - reflective beaches, moderate energy - rhythmic beaches, and high energy - dissipative beaches. This paper is therefore concerned with the actual breaker height required to produce a given level of beach surfzone morphodynamic response; and the characteristic temporal and spatial changes in beach profile and on-offshore sediment transport that are associated with the three beach types. The temporal changes are associated with variations in breaker wave height over time and the resultant movements in on-offshore sand transport and consequent changes in beach profile. For a particular wave-beach environment the most frequently occurring or characteristic beach profile or morphologic configuration is called the modal beach type. The degree of departure from the modal type is dependent on the variation in the breaker wave climate. Spatial changes are concerned with alongshore variation in beach profile at any point in time. The variability within both temporal and spatial suites of beach profiles is used to quantify beach stability/mobility.

DATA BASE

The correlation between breaker height and beach stage is based on 1174 daily observations of both parameters at Narrabeen Beach, N.S.W., a medium to fine sand (mean grain diameter 0.3 to 0.4 mm), single barred beach in a moderate to high energy wave environment (east coast swell, Davies 1980). Modal wave period in the study area ranges from 10 to 12 seconds. The procedure for recording the observations is discussed by Short 1978b. The daily observations are supplemented by field investigations of beaches composed of very fine to coarse sand in wave environments ranging from low to very high energy (west coast swell) around the 6,000 km of the south and east coasts of Australia (Short, 1978) (see Fig.1) and elsewhere (Short, 1979a).

The main field sites are in microtidal environments and in coastal segments where littoral drift is negligible. The prime concern of this paper is the effect of breaker

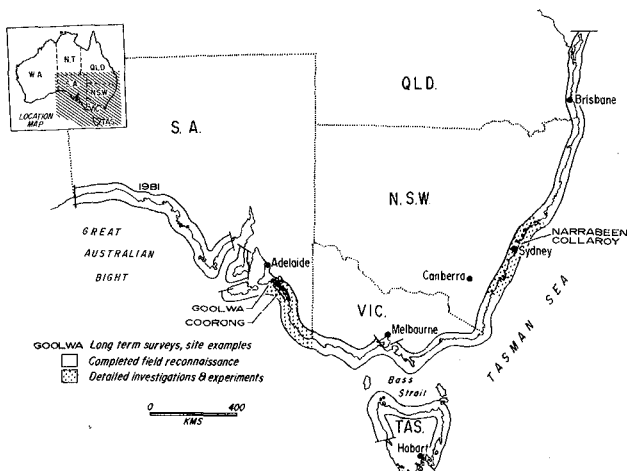

Figure 1: The southeast of Australia showing the main field sites discussed and area of field investigations.

height in influencing on-offshore sediment transport and morphologies in the absence of littoral drift and large tides.

BREAKER WAVE HEIGHT AND BEACH STAGE

The relationship between breaker height and beach response is presented in Figure 2a and 2b. In each figure the probability of occurrence of each beach-stage is plotted for the given level of breaker height (in 0.5m intervals) during falling (Fig. 2a) and rising (Fig. 2b) wave conditions. Falling wave height is associated with onshore sand transport, beach accretion and movement from the dissipative beach-stage 6 through the rhythmic stages 5, 4 and 3 to the reflective stages 2 and 1. Rising wave height on the other hand is associated with offshore sand transport and movement through the erosional beach cycle from the reflective beach stages 1 and 2 through the channel forming and rip dominating stages 3', 4' to the dissipative stages 5' and 6.

Falling Wave Height

Figure 2a illustrates the beach-stage distribution associated with discrete levels of falling wave height

Figure 2: Plot of the probability of occurrence (out of 10) of each beach-stage for a given level of breaker wave height, under falling wave and rising waves.

under falling wave conditions. In an idealised situation as waves decrease from >3.5 m (beach-stage 6) they must drop to 2-2.5m before onshore sand movement combined with low frequency edge waves (Wright et al, 1979) produce the crescentic bars of stage 5. The crescentic bars dominate until waves fall to 1-1.5m. At this level stage 4 dominates with well developed crescentic bars and adjacent shoreline megacusps. The 1-1.5m waves encourage channel infilling and movement to stage 3 which at 0.5-1m completes infilling resulting in bar welding to the beach face. Subaerial deposition of beach cusps on a reflective beach face (beach-stage 2) dominates the lowest wave height (0-0.5m) eventually leading to a formation of a highly reflective beach berm (beach-stage 1).

Rising Wave Height

Figure 2b plots the beach-stage distribution for levels of rising wave height (0-0.5 to >3.5m). Beach erosion begins when breakers exceed 1m with waves 1-1.5m high leading rapidly through beach-stage 2' to 3' (incipient channel formation across the newly formed bar). The channel excavation continues as waves rise to 1.5-2m. Only

when waves reach 2-2.5m do the individual incipient rip channels begin to coalesce alongshore forming beach-stage 4' (continuous channel). Higher waves (2.5-3m and 3-3.5m) and substantially higher wave energy is required to excavate the continuous longshore channel that feeds the rips of beach-stage 5'. Very high waves >3.5m and extreme energy conditions are required to produce the fully dissipative beach-stage 6 with its shore normal low frequency return flow and parallel bar-channel morphology. At Narrabeen Beach the observations of this stage are insufficient to provide a reliable distribution against wave height. However observations on higher energy beaches elsewhere in southeast Australia indicate that waves 3.5 to 4m are required to achieve this most dissipative stage.

The above results are concerned solely with the beach response to levels of breaker height. The spread of the distribution either side of the modal beach response represents a parameter not considered in this summary, that is, the inherent lag in beach morphology as it responds to the more rapid changes in wave height. Whereas substantial changes in wave height may occur on the order of 1 to 10 hours, beach morphology has a lag on the order of 10 to 100 hours. The modal beach stages of Figures 2a and 2b represent the beach stage reached when waves have operated at a particular height for a time period sufficient for the beach morphology to fully respond to the ambient conditions.

The results are further summarised in Figure 3a and which plots the location of the modal beach-stage for rising and falling wave conditions. It illustrates the levels of breaker height required to generate movement to various stages in the erosional (rising) or accretional (falling) wave-beach cycles. Figure 3b illustrates all possible linkages through and between the beach-stage cycle. By comparing figure 3a and 3b a fuller understanding of natural beach response can be extracted. A movement to any beach-stage must be in the direction of the arrows in figure 3b. Therefore, for example, to achieve stage 4, stages 4' or 5 must first be reached. In figure 3a if conditions oscillated between 0-1.5m the corresponding beach stages would be 2' and 3' on the erosional phase and 2, 3 and 1 on accretion, stage 4 could not be produced, because the prerequisite stage 4' or 5 require waves greater than 2m.

Modal Breaker Height and Beach Type

The Narrabeen field site experiences the entire spectrum of beach response from reflective to dissipative beach-stages. This is a consequence of the range in breaker height at the coast and the medium to fine beach

Figure 3: Location of the modal beach-stage (shaded) for levels of breaker wave height under rising and falling wave conditions. On right are the linkages between the ten beach-stages. Solid lines indicate falling wave height and movement to accretionary stages, dashed lines rising wave height and movement to erosional stages. Movement between and amongst the stages can only be in the direction of the arrows.

sand. However, over shorter time periods and in many locations wave height does not vary so considerably and as a consequence the beach oscillates around a modal type. Basically three modes of wave-beach interaction have been described in the literature - reflective, rhythmic and dissipative. Table 1 lists their origin and characteristics. The breaker height required to generate a modal reflective, rhythmic or dissipative beach (on medium to fine sand beaches) can readily be determined from Figure 2b.

Reflective beaches are associated with waves less than 1m in height. They are characterised by beach-stages 1 (berm) and 2 (cusps), with a relatively steep beach face, waves breaking on a coarse grained low tide step and barless surfzone (though 'relic' outer bars may exist further offshore).

Table 1 - MODES OF WAVE - BEACH INTERACTION

Wave Energy (Breaker Height)	Surf Zone Dynamics	Beach-Surfzone Morphology	Reference - terminology
High (>2.5m)	Dissipative	Shore parallel bars, channels mega-rips predominantly shore normal circulation	Sasaki - Ingravity (>2.5m) Short - Beach-stages 6, 5 Wright, et al - Beach Type 1, 2
Moderate (1-2.5m)	Rhythmic	Rips crescentic bars megacusps, etc. rip circulation	Sasaki - Instability Short - Beach-stages 5, 4, 4', 3, 3' Wright, et al. - Beach type 3, 4, 5
Low (<1m)	Reflective	Barless steep beach- face cusps, berm, wave reflection	Sasaki - Edge Wave Short - Beach-stages 2, 2', 1 Wright et al. - Beach type 6

1. Guza and Inman's (1975) terms, dissipative and reflective are used to describe the high and low energy surf dynamics, while Homa-ma and Sonu (1962) term rhythmic is attached to the intermediate moderate energy beaches.

Rhythmic beaches require breakers 1 to 2.5m high to maintain their classic rip circulation. Crescentic/transverse bars, rip feeder and rip channels, and megacusps produce the characteristic 'rhythmic' longshore variation in beach and surfzone morphologies.

Dissipative beaches occur when waves exceed 2.5m resulting in the formation of shore parallel channel/s and bar/s and predominately shore normal circulation (beach-stage 6). Beach-stage 5 characterises the dissipative extreme in shorter embayed beaches where the constraints imposed by headlands, etc. encourage megarips to persist even during very high wave conditions.

Temporal Variation in Beach Morphology

The foregoing is concerned with beach response to the absolute level of breaker height. To illustrate how natural beaches respond to variations in breaker height through time, ten years of daily wave data and four years of daily beach response for the Sydney region are summarised in Figure 4. The annual wave climate varies systematically through the year from periods of high to moderate to low waves with the beaches responding accordingly moving between dissipative, rhythmic and reflective beach types.

In a typical year beginning in December northeast seabreeze waves of moderate height (1-1.5m) cause minor beach scarping and erosion and a series of rips. During February and March, seabreezes persist but their effect is often overshadowed by the arrival of moderate to high 2-3m northeast and east swell generated by tropical cyclones. These waves cause moderate beach erosion, and the development of fewer but larger and more intense rip systems. If high waves persist, longshore channels and offshore bars eventually form. April and early May is a low energy transition period of beach accretion. May and particularly June and July are dominated by cycles of moderate to high (2-3m) southeast swell and storm waves resulting in moderate erosion. The beaches in this period are dissipative with major rip systems (spacing 500m) and in exposed portions longshore bars and channels. This period of erosion is followed by gradually decreasing southeast swell. The low waves (0.5-1.5m) produce onshore sediment transport and beach accretion at times moving the bar onto the beach as a series of cusps or a berm. By November the beaches are often in their most accreted and reflective form.

A further method of illustrating the range of Sydney

Figure 4: The annual Sydney wave climate and beach form. The wave height and energy is based on a nine years (1971-79) monthly mean of daily wave conditions (M.S.B. data). The straddling line and bars equal \pm one standard deviation. The beach response through the year is reflected in the beach stability, surfzone type and beach form. The plan view of beach form illustrates the beach response typical open beach responding fully to the above conditions (from Short and Wright, in press).

beach types is the beach-stage curve (Short, 1979a) shown in Fig. 5. This plots the percent frequency of occurrence of the accretion and erosion beach-stages, along with the annual (combined) beach-stage curve. The curve identifies the modal rhythmic beach type for the Sydney coast. This is to be expected given Sydney's modal wave characteristics ($H = 1.5-2m$, $T = 10$ sec). Short 1979a presents hypothetical beach-stage curves for other higher and lower energy wave-beach systems.

Figure 5: Beach-stage curves for Narrabeen beach plotting the percent frequency of occurrence of accretionary, erosional and combined beach-stages. Based on 950 daily observations.

MODAL BEACH TYPES AND MORPHOLOGIES

Whereas the typical Sydney beach presented in Figures 4 and 5 can experience the entire spectrum of beach types, many beaches tend to remain at the dissipative or reflective extreme or oscillate within the rhythmic range. To examine how such beach morphologies vary over time in reference to modally high, low, or moderate waves three sets of field observations are presented for persistently dissipative, rhythmic and reflective beaches (see Figure 6).

To enable comparisons the data is presented both graphically as two-dimensional beach profiles or cross sections, and numerically using mean beach width (x_b), its standard deviation (σ_x) and coefficient of variation (σ_x/x_b). The standard deviation is a useful indicator of beach mobility and is in fact called the beach mobility index by Dolan et al., (1978). Further, the coefficient of variation is an indicator of backshore mobility and is here termed the backshore mobility index.

The nature of a beach's cross-sectional or profile variation is basically a function of the amount and form of sediment transfer within and between the subaerial beach, surfzone and nearshore. Where wave height is persistently

Figure 6: Variation in beach profile and morphometric parameters for a dissipative, rhythmic and reflective beach. Note the relative stability of the dissipative and reflective beach compared to the rhythmic beach. Narrabeen and Collaroy profiles selected from 3 years of monthly beach profiles. Goolwa profiles one year apart.

high (>2.5m) most sediment is carried seaward and stored in the surfzone and nearshore. Because of the time lag in moving sediment onshore from the outer bars bar/s and nearshore the beach face rarely accretes or experiences substantial changes in profile (Fig. 6). The beach is wide with a low gradient. Beach and backshore mobility is low because of the low sediment exchange. While a dissipative beach face represent an 'eroded' beach profile with minimum sand stored on the subaerial beach they are relatively stable features experiencing minor changes in beach profile. Erosion associated with dissipative beaches does not normally result from beach face retreat, rather low frequency wave set up tends to overrun the beach and attack

the backshore directly, (as described by Wright, this vol.).

Rhythmic beaches exposed to waves of moderate height (1-2.5m) have the greatest potential for changes in beach form as a consequence of the variable wave climate and storage of sediment in the highly energetic surfzone. As wave height rises and falls, sediment is transported between the three storage zones. Beach volume is large as is the standard deviation reflecting the active sediment exchange between the beach, surfzone and nearshore (Fig. 6). Over time rhythmic beach form can shift from a flat eroded beach face, deep channel and offshore bar, through all the onshore bar migratory forms to a reflective beach. Beach and backshore mobility are both high, indicating a high potential for beach and backbeach erosion through sand removal particularly in rip embayments (see Short, 1979b and Wright, this vol.).

Low wave (< 1m) reflective beaches have low mobility and are relatively stable. Sediment exchange on reflective beaches (Fig. 6) is between the steep cusped or bermed subaerial beach through a pivot point (~1m depth) to the attached low tide terrace. Because of their proximity the exchange is rapid. Reflective beaches are most susceptible to erosion (see Short 1979b and Wright, this vol.), however erosion is usually followed by rapid beach accretion. As Collaroy beach (Fig. 6) lies at the more energetic end of the reflective beach type ($H = .5-1m$) lower energy beaches will show even less mobility.

Figure 7 illustrates the range of temporal changes in beach profile for dissipative, rhythmic and reflective beaches in southeast Australia. The variation in profile elevation within the beach surfzone and nearshore has further implications for identifying areas of sediment storage and exchange. Table 2 indicates the relative importance of the beach, surfzone and nearshore as zones of active sediment storage.

Dissipative beaches represent an 'eroded' beach profile, and as such the 'eroded' material is stored in and particularly seaward of the surfzone. On the southeast Australian coast the active nearshore zone extends out to depths of at least 20m. Because of the depth and location of the potentially active sediment long periods (several weeks to months) of lower waves are required to move the sediment shoreward. On modally dissipative beaches such as Goolwa this rarely, if ever, occurs however in seasonally dissipative-reflective beaches as in Southern California this exchange is well documented (Aubrey, 1979). On N.S.W. dissipative beaches the inner bar occasionally attaches to the shore in late winter. The outer bar while moving

Figure 7: The active sweep zone for a dissipative, rhythmic and reflective beach based on 3 years of monthly beach profiles. Upper from Fens embayment, N.S.W. (data from P. Hesp), lower Narrabeen and Collaroy beaches.

inshore has not been observed attaching to the shore.

Rhythmic beaches can potentially store sand throughout the system, particularly in the beach and surfzone, and following high wave events in the nearshore. Sand stored in the energetic surfzone and perched on the subaerial beach can rapidly be moved between the two as wave conditions vary.

Reflective beaches store sand almost exclusively on the steep beach or following erosion in the low tide terrace. Exchange is rapid being accomplished in a matter of hours during erosion and a few days to weeks during accretion.

SPATIAL (ALONGSHORE) VARIATIONS IN BEACH TYPE MORPHOLOGIES

In addition to characteristic changes in beach profile through time, each beach type has a characteristic variation in beach profiles alongshore, at any point in time. Three examples from the same beaches are illustrated in figure 8.

Figure 8: Alongshore changes in beach profiles on a dissipative, rhythmic and reflective beach.

Dissipative beaches are characteristically uniform alongshore having a wide low gradient beach face, fronted by a wide deep channel/s and shore parallel offshore bar/s. Figure 8a shows seven beach face profiles surveyed on the one day at 15 km intervals along 90km of the highly dissipative Coorong beach. All profiles have a concave subaerial beachface morphology. Each is low gradient with slight variations in gradient resulting from minor changes in grain size. Figure 9a illustrates that the shore parallel channels and bars of the surfzone possess the same conformity alongshore. Therefore dissipative beaches exhibit extreme stability and uniformity alongshore.

Rhythmic beaches with their alternating bars and rip channels, megacusps, etc are as unstable spatially as they are temporally. Figures 8b and 9b illustrate this fact. The Narrabeen profiles show the alongshore variation from rip channels, to well developed bars and channels to a welded bar.

Reflective beaches are uniform alongshore except on a microscale when cusps are present. In plan form the continuous cusps or berm and barless surfzone results in the regular beach profiles illustrated in Figure 8c, and plan form as show in Figure 9c.

DISCUSSION

Given the seemingly endless variety of beaches around the globe and their ever-changing response to wave conditions it is essential that a logical genetic classification of natural beaches be developed, one that not only permits identification of beach type, but also contains a characteristic set of morphological response and dynamic interactions associated with each beach type.

The results presented here are an attempt to classify beaches into three basic types based on response to the level of breaker wave height for microtidal, medium to fine sand beaches. The characteristics associated with each beach type are tabulated for breaker wave height (Figure 3), two dimensional beach profile response over time (Figures 6 and 7), zones of sediment storage (Table 2), two dimensional alongshore variation in beach profile (Figure 8) and other morphometric parameters (Figure 6). More detailed discussion of beach-surfzone morphodynamics and modes of beach erosion are contained in Short 1979a and b, Short and Hesp (in press), Wright et al. 1979 and Wright (this vol.).

ENVIRONMENTAL PARAMETERS

In order to explain beach type and beach morphological characteristics, this study has indicated that certain morphometric variables are particularly useful

Breaker wave height, together with period, determine the amount of wave energy available to do work across the nearshore and in the surf-swash zone. As shown in Figure 3 breaker wave height can be used as a simple rule to determine modal beach type, particularly when wave period is relatively constant.

Beach sand size, is equally important in controlling beach response. The foregoing results are based on observations on medium to fine sand beaches (mean diameter 0.2-0.4 mm). However as Short 1979b indicated that coarser sand-gravel beaches will result in more reflective beach types, even in moderate to high wave energy, and fine to very fine sand will lead to a wide shallow surfzone, more dissipative conditions and multiple bars even under moderate to low waves. The foregoing results refer only to high energy dissipative beaches.

The surf scaling parameter is a function of wave characteristics and beach slope and is also a useful measure of the degree of beach reflectivity or dissipativeness (see Wright et al. 1979).

The mean beach width is the basic measure for describing the beach profile and shoreline position. However in terms of application the standard deviation of mean beach width, called the beach mobility index, is an excellent index of the mobility or stability of a shoreline position. The backshore mobility index, is the coefficient of variation of mean beach width, and again is a very useful indicator of likelihood of backshore/foredune erosion.

Finally the mean beach volume and its standard deviation, here called the volume exchange are important indices of sediment location and transport within and across the beach-surfzone-nearshore (see Table 2).

IMPLICATIONS

The foregoing results are based on selected field sites in southeastern Australia. The frequency and duration of the observations have produced some findings that may have implications for beach investigations elsewhere.

1. The modal breaker wave climate (interacting with the local sediment type) will determine the modal beach type.

In medium to fine sand beaches modal waves less than 1m produce reflective beaches, between 1 and 2.5m rhythmic beaches, and greater than 2.5m dissipative beaches. Associated with each beach type is a characteristic beach-surfzone morphology and dynamics, modes of beach erosion (see Wright, this vol.) and zones of sediment storage.

2. In undertaking beach investigations the classification presented here provides a format for locating a particular beach type and planning survey and dynamic investigations based on the characteristics mentioned in (1) above. A program of study on a reflective beach will of necessity, be markedly different from one on a rhythmic or dissipative beach.

3. Beach nourishment programs are concerned primarily with nourishing the subaerial beach. However as Table 2 and Figures 6 and 7 indicate in all beach types a certain amount of this sand must be redistributed seaward. On dissipative beaches most sand placed on the subaerial beach can be expected to be redistributed seaward of the breakpoint. Understanding the beach type is important not only for determining how much sand might be required to nourish the system, but also when and where and at what beach stage would be most suitable to undertake the nourishment.

4. In extrapolating results of beach investigations to other beaches and other coasts it is imperative that the beach type (and grain size) be considered. Findings on a coarse grained reflective beach may have little bearing on a fine grained dissipative beach. Beaches have a predictable range of morphodynamic variation, the spatial and temporal beach variability should be understood before between beach comparisons are made.

5. Beach erosion is of concern to all who investigate, work with and use the beach system. Wright (this vol.) discusses the three separate modes of erosion associated with reflective, rhythmic and dissipative beaches. The results presented here and elsewhere (Short 1979b, Short and Hesp, in press) support Wright's classification. Each mode of erosion possesses different morphological and dynamic characteristics, in turn leading to varying degrees of beach and backshore mobility. Therefore the contribution of each mode must be considered separately where designing a beach erosion program for a particular section of beach or beach type.

6. As stated in the Introduction the field sites investigated in this study experience negligible littoral drift. However in many area littoral drift is a major component of the beach system. Observations on the

northern New South Wales coast where littoral drift is significant show that the beach types and on-offshore characteristics still hold. However downdrift skewing of the mesoscale forms (bars, channels, rips, etc) does occur, as does significant net longshore sediment transport. Therefore in system experiencing littoral drift, the contribution of the mesoscale forms of on-offshore sediment exchange associated with dissipative, rhythmic and reflective beach types must be considered if accurate calculations of total transport are to be made.

ACKNOWLEDGEMENTS

The field investigations reported have been funded by the Australian Research Grants Committee. Since late 1979 additional support has been provided by the U.S. Office of Naval Research, Coastal Science Programs, Task NR 388-157, Grant N-0014-80-G-001. During 1979 support in South Australia was provided by the Coast Protection Board. I thank the numerous people who have assisted with the field surveying. In terms of sorting out some of the ideas and results presented here I also thank L.D.Wright, P.A. Hesp for many useful discussions. J.Roberts and M.Rigney prepared the diagrams.

THE DYNAMIC SWEEP PRISM

David M. Chapman,
Coastal Studies Unit,
University of Sydney, Australia.

A.W. (Sam) Smith,
Consulting Civil Engineer,
Gold Coast, Australia.

INTRODUCTION

In the course of an intensive study of beach and inshore morphodynamics associated with a nourishment project on the Lower Gold Coast, Australia (Chapman, 1978), approximately 400 profile lines were surveyed from backshore to the point of zero change in the nearshore zone, to a high degree of accuracy (Chapman & Smith, 1977). Analysis of this data base has led, inter alia, to the development of the concept of the dynamic swept prism, since the maximum and minimum ordinates on a shore-normal profile line, over a specified time period, form the vertices of an irregular polygon which may be regarded as the cross-section of the prism of sand which is worked over by waves during that time period. Representative prism cross-sections from the Lower Gold Coast are displayed in Figure 1. The important limits of the swept prism, viz., the landward and seaward extremities and the lower surface, are probabilistically, not deterministically defined. Prism cross sections as illustrated are not isotropic with respect to the probability of disturbance by waves. Isolines of probability may be conceptually defined, with the zone of maximum probability of disturbance corresponding to that zone which is re-worked during the tidal cycle (cf. Duncan, 1964). Moreover, although the

FIGURE 1. Representative Swept Prism Cross-Sections, Lower Gold Coast.

surveyed cross-sections illustrated are closed at the landward and seaward extremities, in probabilistic terms these extremities are undefined, being asymptotic at each end.

The swept prism, especially in its subaqueous zone, may also be recognized as the envelope enclosing the range of beach and inshore morphologies described by workers such as Short (1978) or Wright, et. al. (1979).

It is the purpose of this paper to discuss the behaviour of a swept prism as observed on the lower Gold Coast, and to comment on the implications of the concept for management and planning, since effective planning and design must be cognizant of the probabilistic nature of the prism limits with respect to structures which may be placed therein.

BEHAVIOUR OF THE SWEEPED PRISM, LOWER GOLD COAST

The lower Gold Coast is located in the southern end of a large zetaform embayment, extending from Point Danger to Stradbroke Island (a location map is provided in Chapman, 1980). Environmental characteristics include a relatively narrow and steep continental shelf, reaching 200 metres depth at 40km. offshore, and average deep water wave power of 10kw/m of wave crest. There is no seasonal pattern of cut and fill such as is reported from many North American sites.

Figure 2 illustrates the alongshore variation in the cross-sectional area of the swept prism during the Gold Coast study, when mean breaking wave power was approximately $6.4 \text{ kilowatts m}^{-1}$ over the 5km. of shoreline surveyed. Mean cross-sectional area was 312m^2 ; the large maximum value of 737m^2 at 1617 metres from the arbitrary origin was due to input of beach fill at that point. The mean value of 312m^2 , during normal wave energy conditions, is comparable with $420\text{m}^3/\text{m}$ of sand eroded from the subaerial beach and translated to the inshore zone by cyclone induced storm activity in 1967 (McGrath, 1968), and reveals that considerable re-working of the beach and inshore zone occurs, even under moderate energy conditions.

Examination of the swept prism cross-sections

FIGURE 2. Alongshore Variation in Swept Prism Cross-Section Area, Lower Gold Coast.

illustrated in Fig. 1 reveals that the beach as defined by the recreational user (and indeed by most lay people) is merely the residuum of inshore processes. The prism cross sections also illustrate the fact that variability in the prism is principally accommodated within the subaqueous zone; most of this variability would not be apparent to the recreational beach user or resource manager who was merely concerned with evaluating the subaerial beach.

The large proportion of the swept prism in the subaqueous zone is significant in accounting for the re-distribution of beach fills, since re-distribution can involve substantial apparent losses from the subaerial beach without material being lost from the prism. If nourishment material applied is of such a nature that the upper surface of the prism is induced to adopt a lower overall gradient, a large volume of fill material would be absorbed in order for this redistribution to take place, but would result in little gain in beach width.

The lower boundary of the swept prism is a scour surface, activated by vigorous reworking of the prism. The scour surface as derived statistically from over 400 lower Gold Coast profiles is illustrated in Fig. 3 where the mean surface is illustrated together with its standard deviation bounds. Observations on the Gold Coast suggest that the scour surface under high energy storm conditions may be underlain by a fluidised sediment layer. Direct measurement during storm conditions is not possible with presently available techniques, but the existence of a fluidised layer is suggested by events such as the collapse of a boulder wall during high energy conditions and subsequent settlement of the armour to a depth of over 1 metre below the sand surface within a matter of minutes. Observation of the event in progress suggested that the boulders sank through a semi-quick layer rather than having the sand scoured from around them by the waves. The result of this event is illustrated in Fig. 4. We also found that measuring stakes embedded to a depth of 1m. below the sand surface in the inshore zone showed pronounced departures from the vertical after a week or

FIGURE 3. Mean Scour Surface, Lower Limit of Swept Prism, Lower Gold Coast.

FIGURE 4. Location of Debris of Boulder Wall Failure.

two of moderate energy wave action.

The landward asymptote of the prism would normally include the frontal dune and foredune, as these are mobilized by the highest energy events. In the case of a beach in its natural state the landward extension of the prism under high energy conditions will encounter that part of the cross section which is capped by a dune so that the high energy event which causes the extension of the prism is also responsible for the release of a large volume of stored sand into the active zone.

The modes of cut and recovery are not complementary. During periods of cut (which may involve recession of the dune scarp) rapid removal of sand occurs from the subaerial part of the swept prism; however during periods of recovery the replacement of this sand occurs over a longer period and in addition involves the development of an incipient foredune. Initial stabilization of this foredune requires pioneer dune species which are sensitive to recreational pressure so that the stabilization of the replaced sand by woody vegetation may be extremely slow or non-existent on a recreational beach. In this way a mechanism for cut without replacement exists.

The cut of the subaerial beach, even under cyclone conditions, is normally quite localised with the incidence of the most severe cut along the Gold Coast being fairly random. Therefore, in the three dimensional sense the re-working of the swept prism is also a probabilistic phenomenon.

The seaward asymptote of the prism represents the seaward limit of sediment exchange between bed and beach. It corresponds in broad terms with the limiting depth of erosion as postulated by Hallermeier (1978), or the seaward limit of Swart's (1974) equilibrium profile. It does not correspond to surf base, the seaward limit of incipient sediment motion, which would be reached some considerable distance seaward of the prism limits.

IMPLICATIONS FOR MANAGEMENT

The probability of activation of the swept prism decreases landward, and will be inversely related to the magnitude of the wave power which is applied to it. The well known inverse relationship between magnitude and frequency of geomorphological phenomena (see, e.g., Chorley & Kennedy, 1971) applies. As shown in Fig. 5 a minor storm event is virtually certain to occur in any given year (i.e. probability ≈ 1). Events of moderate magnitude, which may cause significant activation of the subaerial beach but little or no damage to shore front property, fall within the "normal" range at about the point of inflexion of the curve, whilst the high magnitude event which causes damage to shore front property has very low probability of occurrence; e.g. the event of magnitude m has a probability of 5%, or a 1 in 20 year recurrence interval, with the curve becoming asymptotic to the vertical axis for events of very high magnitude. Thus it may be seen that damages incurred as a result of high energy wave events are related to magnitude such that the events of low or moderate magnitude cause no damage at all to man-made structures, with extremely high magnitude events required to cause significant damage. The probability of damage to shore-front property may therefore be expressed as shown in Fig. 6. There is a finite probability of $(100 - x)\%$ that no damage at all will be incurred in any given year and a moderately high probability that the damages incurred will be trivial. The probability of high damages is extremely low and asymptotic to the vertical axis for very large values.

It follows that in a situation where secular sea level rise is not a major causal factor in coastal erosion, losses to shore-front property due to landward extension of the swept prism have some probability less than 1 of occurring and may be related to shore-front property values as shown in Figure 7. Curve (7a) illustrates cumulative property value as a function of distance from the present high water mark. If shoreline retreat is progressive and inevitable this curve also relates losses and time since secular erosion will consume property according to some function relating

FIGURE 5. Magnitude Vs Frequency of Storm Events.

FIGURE 6. Probability of Damage, Storm Events.

distance from the present high water mark to time. However, in the absence of secular sea level rise as a major causal factor, the probability of loss becomes a function of the extension of the swept prism, and is therefore an asymptotic function of distance from the shore line as illustrated by curve (7b). On the one hand some loss of shore-front property is virtually certain to occur, since the maximum storm event has probably not been recorded*, but on the other hand there is some point inland from the present shore-line at which zero loss from coastal erosion is also a certainty.

A realistic appraisal of probable loss from coastal erosion then becomes a function of both cumulative property value and the probability of activation of the landward asymptote of the swept prism, i.e. one should multiply together the ordinates of curves (a) and (b) in order to arrive at the function of probable loss (curve 7c).

Under normal processes of planning and development, a coastal land value gradient decreasing inland from the shore-line applies. The implications of the foregoing analysis are that the appropriate land uses should be arranged so that capital intensive development is not placed in the zone where the probability-cumulative loss function is highest. In other words the application of capital to land would be controlled so that investment would be minimised at the point where probability of loss is highest and allowed to increase inland to some point where the probability of loss is low but shoreline amenity still obtains.

* A familiar concept in civil engineering practice which has been given legal recognition in doctrine derived from Rylands & Fletcher, e.g. in Ruck Vs Williams, 1868, Bramwell (B) stated "in truth it is not an extraordinary storm which happens once in a century or once in fifty or twenty years; on the contrary, it would be extraordinary if it did not happen."

Management of land use thus becomes part of a strategy of shoreline protection. A variety of shoreline protection options is available to the resource manager as displayed in Table 1. These have been subdivided into structural and nonstructural categories. The resource manager charged with the responsibility of planning for the protection of the shore-front community from coastal erosion must choose an appropriate strategy (which may involve one or a mix of management options) in order that the total benefit to the community is maximised.

The optimum management strategy will not necessarily provide maximum protection or minimise expenditure, but will be that point where the sum of losses incurred by the community and costs to the community of protective measures is minimised, as illustrated in Figure 8. The vertical axis is one of dollar values, either the value of losses incurred by the community or the costs of management strategies, whilst the horizontal axis plots either the degree of protection afforded by management strategies or the amount of physical damage incurred as a result of coastal erosion. The loss curve (AA') is (ideally) inversely related to the degree of protection afforded by the management strategy (curve BB'), although it will be observed that the loss curve (AA') does not reach the zero point on the vertical axis. At the point where losses are minimised the cost of protective strategies is likely to be exceedingly high, therefore the optimum point for management is neither that point where losses alone are minimised, or costs alone minimised, but the minimum point on the curve CC', which shows the sum, added vertically, of costs and losses. Expressed in the language of conventional land management economics, this would be the point where marginal benefit equals marginal cost.

CONCLUSION

The active zone of a beach may be conceptually defined as a prism of sand within which the probability of disturbance by waves varies greatly. Recognition of the three-dimensional nature of the swept prism, and of its varying probability of excitation is required for effective planning and design.

FOREWORD

The Seventeenth International Conference on Coastal Engineering was extremely important in many ways to those who attended the conference and to those who will benefit from use of these *Proceedings*. The Seventeenth Conference marked the 30 year point in the history of the coastal engineering conference series and a change in leadership. Since the first conference was held in Long Beach, California in October 1950, Dean Morrough P. O'Brien and Professor Joe W. Johnson have provided the continuity, direction, and motivation that have made the International Coastal Engineering Conferences so successful. For thirty years Dean O'Brien has served as Chairman and Professor Johnson as Secretary of first the Council on Wave Research and now the Coastal Engineering Research Council. Because of the importance of their contributions to the coastal engineering conferences the Council decided that these *Proceedings* will be dedicated to these two leaders. A summary of the accomplishments of each in coastal engineering is presented here.

MORROUGH P. O'BRIEN

His distinguished career in coastal engineering has been much too full to cover adequately in this space; only a sketch of his accomplishments are included here. M. P. O'Brien retired as Dean of the College of Engineering at the University of California, Berkeley, in 1959. His tenure at Berkeley included an impressive record of teaching, research and university administration. During this interval, through his students and research, he established the reputation of "The Father of Coastal Engineering." After leaving his post at Berkeley he has been very active in industrial and governmental research and development projects. At his present age, 78, Dean O'Brien is still an extremely active professional in coastal engineering.

Dean O'Brien graduated from Massachusetts Institute of Technology in 1925 and pursued graduate work at Purdue University. In 1927 he was awarded the ASCE John R. Freeman Scholarship which allowed him to attend the Technische Hochschule, Danzig, and the Royal College of Engineering, Stockholm, to study hydraulic structures and machinery. He has received honorary degrees from Northwestern University, D.Sc.; Purdue University, D.Eng.; and University of California, Berkeley, LL.D.

He joined the Mechanical Engineering Department at the University of California becoming Department Chairman in 1936 and Dean of the College in 1943. During his tenure as Dean he was instrumental in the development of graduate education and research and in the modernization of the undergraduate program.

In 1929, Dean O'Brien organized and initiated a program of research on shoreline processes and coastal engineering for a board appointed by the Chief of Engineers of the Army; subsequently, Congress established this work on a permanent basis under the U.S. Beach Erosion Board. Dean O'Brien has served as a member of this board and its successor, the Coastal Engineering Research Board from 1938 to 1980. He has maintained an active interest in ocean waves and shoreline phenomena. During the war years, this interest led to work on the design of landing craft, on forecasting surf conditions,

and on intelligence studies of landing beaches. Following the war he served as Chairman of the ad hoc committee on Amphibious Operations of the National Research Council which reviewed the plans for modernization of the Marine Corps. Consulting engagements in the field of coastal engineering included restoration of the beach at Santa Barbara, regulation of the estuary of the Columbia River, Dos Bocas Harbor in the Gulf of Campache and other similar coastal projects.

Dean O'Brien's research on hydraulic machinery led to many practical applications by industry. Most of the jet pumps sold in the United States follow the designs of O'Brien and Gosline. Application of the theory of airfoils to the design of propeller pumps and fans by O'Brien and Folsom provided the basis for extensive production of low-head, high-capacity pumps for irrigation and drainage. Consulting engagements on hydraulic machinery during this period included Byron Jackson, Food Machinery, Fairbanks-Morse, Becker Pump, Navy Department, Corps of Engineers, and many other governmental agencies. His experience with turbo-machinery led to his appointment in 1949 as a consulting engineer by the Aircraft Gas Turbine Division of the General Electric Company, an association which has continued to the present. He is now a consultant to the Technical Systems and Materials Sector of General Electric, dealing with both technical and management problems of jet engines, missiles and space vehicles, ordnance, and electronic systems.

During the war years, Dean O'Brien directed the University of California's program of engineers' science and management war training for technical and professional personnel in the aircraft and shipbuilding industries. During the four years of its existence, this program included 1800 instructors and 46,000 students. Concurrently, he served as dean of the college and as consultant in the research section of the Bureau of Ships on problems of submarine propeller noise, and on amphibious operations. In 1946, he participated in Operation Crossroads at Bikini as a consultant on the measurement of waves generated by the bomb tests; most of the photographs of the Baker tests, which appeared in the press, were taken by the tower and aerial cameras which Dean O'Brien and his associates operated for wave measurements.

Twice, he has taken full-time leave from academic duties to engage in engineering practice; once, 1947 to 1949, to serve as director of research and engineering with the Air Reduction Company and, again in 1953, to join General Electric Company's Aircraft Nuclear Propulsion Project. He has held membership on many influential boards and commissions, among them the Coastal Engineering Research Board, formerly the Beach Erosion Board; the National Science Foundation's panel of engineering consultants; the Army Scientific Advisory Panel; the Atomic Energy Commission's personnel security board; the Maritime Research Advisory Committee and the Advisory Board on Education of the National Academy of Sciences, National Research Council; and the board of directors, McGraw-Hill Publishing Company. In 1958 President Eisenhower appointed him a member of the Board of the National Science Foundation. During 1958-1959, he was a visiting institute professor at the Massachusetts Institute of Technology, and a visiting research fellow at Harvard University.

Among awards he has received are the Army-Navy Certificate of Appreciation; the Distinguished Civilian Award, Department of the Army (twice); and the Bliss Medal of the Society of American Military Engineers. In 1968 he received the ASEE's Lamme Award, and in 1969 a building at the University of California's Berkeley Campus was named after Dean O'Brien.

He has written more than 100 published articles on technical subjects and engineering education, and is co-author of "Applied Fluid Mechanics," published by McGraw-Hill in 1937. The bibliography is his own selection of the papers which he most enjoyed

writing. He is a registered professional engineer in the states of California and New York, and a chartered Mechanical Engineer in Great Britain. In 1969 he was elected to the National Academy of Engineering. He is an Honorary Member of both the ASCE and ASME.

JOE W. JOHNSON

Professor Johnson has had a long and very distinguished career in coastal engineering. His reputation extends around the world, reaching forth from his consulting, his research and especially his students. In 1975 he retired as Professor of Civil Engineering from the University of California, Berkeley. Professor Johnson is also well known for his excellent handling of the *Proceedings* of all sixteen prior coastal engineering conferences. Since his retirement from the University of California he has been extremely active in his consulting practice and professional duties.

Professor Johnson graduated from the University of California, Berkeley, in 1931 with a B.S. in Civil Engineering and in 1934 with an M.S. degree. Following a brief stay at the Waterways Experiment Station he devoted eight years to studying sediment transport with the Soil Conservation Service. He then returned to the University of California and enjoyed a very fruitful career of teaching, research and public service.

He has been consultant to many international projects involving shoreline development including: an ore port in Vitoria, Brazil; harbor development along the coast of Venezuela; port development in Northwest Australia; port development in Damietta, Egypt; sedimentation at Bahia Blanca, Argentina; Hay Point Coal Port, Australia; and wave action and sedimentation in Brazil. His associations with coastal engineering projects in the United States are equally extensive; a brief list follows of his involvement: Rio Grande Valley, wind tides in Lake Okeechobee, wave analysis of Marina del Rey, San Francisco Bay Area Rapid Transit, Turkey Point Power Plant in Florida and beach erosion at the Zion Atomic Power Plant.

In addition Professor Johnson has been a member, since 1974, of the Shoreline Erosion Advisory Panel created by the U.S. Congress. His expertise in coastal engineering has been quite instrumental in the success of this research and development program. He also has been selected as the chairman of the U.S. Delegation to the U.S.-Japan Cooperative Seminar on Coastal Engineering held in Japan. Professor Johnson has been appointed to numerous other boards and committees. He was the Secretary of the Council on Wave Research during its existence from 1950 to 1964, and then of the subsequent organization, The Coastal Engineering Research Council of the ASCE. He has been very active in the AGU holding key positions and has been a major driving force behind the American Shore and Beach Preservation Association as Vice President and Editor of *Shore and Beach*.

In 1976, Professor Johnson was elected to membership in the National Academy of Engineering and in 1979, he received the distinguished honor of Honorary Member of the ASCE. He is also the recipient of the Guggenheim Fellowship, The Outstanding Civilian Service Medal for his service in the field of coastal engineering and the Berkeley Citation. A selected listing of his over ninety publications are given below. Professor Johnson has been and still is a very active and important part of international coastal engineering.

Selected Bibliography

- The Transportation of Sediment by Streams: Bed Load, *Inter. Union Geod. and Geophys.*, 1939.
- Transportation of Sediment by Flowing Water, *Soil Conserv.*, vol. 6, 1941.

- A Distinction Between Bed Load and Suspended Load in Natural Streams (with Einstein and Anderson), *Trans. Amer. Geo. Union*, 1940.
- "War-time research on waves and surf." *The Military Engineer*, June 1947.
- "Refraction of surface waves by currents." *Trans. Amer. Geo. Union*, 1947.
- "The force exerted by surface waves on piles," (with J. R. Morison, M. P. O'Brien, and S. A. Schaaf), vol. 189, 1950.
- "The Damping Action of Submerged Breakwaters," (with R. A. Fuchs and J. R. Morison), *Trans. Amer. Geo. Union*, vol. 32, 1951.
- "The March 1962 Storm on the Atlantic Coast of the United States," (with M. P. O'Brien), Proc. Eighth Conference on Coastal Engineering, 1963.
- "Ship Waves in Shoaling Water," Proceedings Eleventh Conference on Coastal Engineering, 1968.
- "Lessons in Coastal Engineering," Symposium on Coastal Engineering, Stellenbosch, South Africa, 1970.
- "Closure of Tidal Entrances," Proc. Fourteenth Conference on Coastal Engineering, 1974.
- "Littoral Processes at Some California Shoreline Harbors," *Shore and Beach*, vol. 43, no. 1, April 1975.

The omissions from the accomplishments of Dean O'Brien and Professor Johnson are solely the responsibility of the writer; however, the magnitude of their contributions to coastal engineering has forced the writer to condense their many activities. Indeed a detailed listing of their individual efforts would fill a volume.

While listening to the discussions of the mechanics of sand waves by Professor Arthur Brebner, Professor Longuet-Higgins was able to tie some of Brebner's findings with the theoretical work he (Longuet-Higgins) had done on water waves of maximum steepness. Since Professor Longuet-Higgins' Keynote address begins the *Proceedings*, it was felt proper to end them with a brief summary explaining the application of his limiting wave theory to sand bed-forms. His discussion can be found on page 3107.

Billy L. Edge, Secretary
 Coastal Engineering Research Council
 American Society of Civil Engineers

ACKNOWLEDGMENTS

ORGANIZING COMMITTEE

Mr. J. G. Betty, Chairman,
Macdonald Wagner & Priddle Pty. Ltd.
Mr. G. Evans,
Department of Public Works of N.S.W.
Professor D. N. Foster,
The University of New South Wales.
Mr. W. J. Kerle,
Department of Public Works of N.S.W.
Mr. N. Lawson,
Maritime Services Board of New South Wales.
Mr. W. M. Lewis,
Esso Australia Ltd.

LADIES COMMITTEE

Mrs. D. E. Betty,
Wahroonga, N.S.W.
Miss K. Winter,
Maritime Services Board of New South Wales.
Miss J. Shaw,
The University of New South Wales.

SUPPORT

The Institution of Engineers, Australia, in collaboration with the Coastal Engineering Research Council of the American Society of Civil Engineers, acknowledges the support and encouragement given by the following organizations:

Department of Public Works, N.S.W.
Esso Australia Ltd.
Macdonald, Wagner & Priddle Pty. Ltd.
Maritime Services Board of New South Wales
New South Wales State Government
The Sydney County Council
The Exhibiting Companies
The University of New South Wales.

INTERSTATE CORRESPONDING COMMITTEE MEMBERS

Mr. R. Culver, Dept. of Mechanical Engineering, The University of Adelaide,
South Australia 5000.
Dr. J. Hinwood, Dept. of Mechanical Engineering, Monash University, Clayton,
Melbourne, Victoria, 3168.
Mr. B. McGrath, Dept. of Harbours and Marine, G.P.O. Box 2195, Brisbane,
Queensland, 4001.
Professor R. Silvester, Dept. of Civil Engineering, University of Western Australia,
Perth, 6009.

Morrough P. O'Brien

Joe W. Johnson

THE UNSOLVED PROBLEM OF BREAKING WAVES

by

M. S. Longuet-Higgins
Institute of Oceanographic Sciences
Wormley, Surrey, England

PART I

THEORETICAL AND OBSERVED WAVE CHARACTERISTICS

Chapter 1	
SOME IMPLICATIONS OF RECENT ADVANCES IN WAVE THEORIES	
J. R. Chaplin and K. Anastasiou	31
Chapter 2	
ACCURATE NUMERICAL SOLUTIONS FOR NONLINEAR WAVES	
J. D. Fenton and M. M. Rienecker	50
Chapter 3	
MASS TRANSPORT IN PROGRESSIVE WAVES OF PERMANENT TYPE	
Yoshito Tsuchiya, Takashi Yasuda and Takao Yamashita	70
Chapter 4	
RAY CURVATURE AND REFRACTION OF WAVE PACKETS	
J. Ernest Breeding, Jr.	82
Chapter 5	
VERIFICATION OF A WAVE REFRACTION MODEL	
G. Henderson and N. B. Weber	101
Chapter 6	
WAVE SHOALING CALCULATED FROM COKELET'S THEORY	
T. Sakai and J. A. Battjes	121
Chapter 7	
A SURVEY OF "RANDOM" WAVE GENERATION TECHNIQUES	
J. Ploeg and E. R. Funke	135
Chapter 8	
THE MEASUREMENT OF INCIDENT AND REFLECTED SPECTRA USING A LEAST SQUARES METHOD	
E. P. D. Mansard and E. R. Funke	154
Chapter 9	
ORBITAL VELOCITIES IN IRREGULAR WAVES	
F. C. Vis	173

Chapter 10	
INVESTIGATIONS ON IRREGULAR WAVES IN HYDRAULIC MODELS	
Karl-Friedrich Daemrich, Wolf-Dietrich Eggert and Soren Kohlhase	186
Chapter 11	
METHOD OF ANALYSIS OF RANDOM WAVE EXPERIMENTS WITH REFLECTING COASTAL STRUCTURES	
Pierre Gaillard, Michel Gauthier and Forrest Holly	204
Chapter 12	
WAVE HEIGHT DISTRIBUTION AROUND PERMEABLE BREAKWATERS	
Shintaro Hotta	221
Chapter 13	
NON-RESONANT WAVE AGITATION IN SMALL CRAFT HARBOURS	
J. W. Kamphuis and D. A. Y. Smith	241
Chapter 14	
EXPERIMENTAL INVESTIGATIONS OF PERIODIC WAVES NEAR BREAKING	
J. Buhr Hansen	260
Chapter 15	
AN HEURISTIC MODEL OF WAVE HEIGHT DISTRIBUTION IN SURF ZONE	
Masaru Mizuguchi	278
Chapter 16	
RESONANCES OF COASTAL WATERS BETWEEN PERTH AND GERALDTON (WESTERN AUSTRALIA)	
H. Allison, A. Grassia and R. Litchfield	290
Chapter 17	
A CLOSELY RESPONDING, VERSATILE WAVE TUNNEL	
C. H. Hulsbergen and J. J. Bosman	310
Chapter 18	
CONDITIONAL SIMULATIONS OF OCEAN WAVE PROPERTIES	
Leon E. Borgman	318
Chapter 19	
WIND WAVES TRANSMISSION THROUGH POROUS BREAKWATER	
Stanislaw R. Massel and Piotr Butowski	333
Chapter 20	
FIELD MEASUREMENTS OF WIND WAVE KINEMATICS	
J. A. Battjes and J. van Heteren	347
Chapter 21	
HF RADAR MAPPING OF EXTENSIVE OCEAN WINDFIELDS	
P. E. Dexter and R. C. Casey	363
Chapter 22	
SOURCES OF MEASURED WAVE DATA	
Laurence Draper	372
Chapter 23	
VISUALLY OBSERVED WAVE DATA AT PT. MUGU, CALIF.	
Christine Schneider and Richard Weggel	381
Chapter 24	
WAVE HINDCASTS AND MEASUREMENTS - BASS STRAIT	
M. N. Silbert, T. P. Barnett, D. J. H. Peters and R. C. Hamilton	395

Chapter 25	
REALTIME WAVE ANALYSIS, NEWCASTLE, AUSTRALIA	
N. V. Lawson and P. H. Oull	412
Chapter 26	
FLORIDA COASTAL DATA NETWORK	
Gary Howell	421
Chapter 27	
A MEASUREMENT OF SLOPE, CURVATURE, AND DIRECTIONAL SPECTRA OF WIND WAVES IN LAKE MICHIGAN	
Paul C. Liu	432
Chapter 28	
WAVE ATTENUATION AND WAVE SET-UP ON A COASTAL REEF	
Franciscus Gerritsen	444
Chapter 29	
LONGSHORE CURRENT FLOWS IN A WAVE BASIN	
P. J. Visser	462
Chapter 30	
DYNAMIC CHARACTERISTICS IN THE NEAR SHORE AREA	
Kiyoshi Horikawa and Masahiko Isobe	480
Chapter 31	
VELOCITY FIELD IN A STEADY BREAKER	
J. A. Battjes and T. Sakai	499
Chapter 32	
THE FLUID MECHANICS OF WAVES APPROACHING BREAKING	
D. H. Peregrine, E. D. Cokelet and P. McIver	512
Chapter 33	
A SIMILARITY MODEL IN THE SURF ZONE	
Hsiang Wang and Wei-Chong	529
Chapter 34	
VELOCITY AND PRESSURE FIELD IN SPILLING BREAKERS	
M. J. F. Stive	547
Chapter 35	
DIRECTIONAL WAVE SPECTRA AND WAVE KINEMATICS IN HURRICANES CARMEN AND ELOISE	
G. Z. Forristall, E. G. Ward and V. J. Cardone	567
Chapter 36	
PREDICTION OF THE SEVEREST SIGNIFICANT WAVE HEIGHT	
Michel K. Ochi and Joseph E. Whalen	587
Chapter 37	
PREDICTION OF DOMINANT WAVE PROPERTIES AHEAD OF HURRICANES	
Omar H. Shemdin	600
Chapter 38	
LONG PERIOD DISTURBANCES DUE TO WAVE GROUPS	
E. C. Bowers	610
Chapter 39	
TWO-DIMENSIONAL SURF BEAT	
Reinhard E. Flick, Douglas L. Inman and Robert T. Guza	624

Chapter 40		
LONG WAVES GENERATED BY COMPLEX BOTTOM MOTIONS		
J. L. Hammack and F. Raichlen		639
Chapter 41		
TSUNAMIS ALONG WEST COAST OF LUZON, PHILIPPINES		
R. L. Wiegel		652
Chapter 42		
TSUNAMI PRONE FRICTION FACTORS FROM WIND MEASUREMENTS		
Charles L. Bretschneider		672
Chapter 43		
RUN-UP OF TSUNAMIS BY LINEAR AND NONLINEAR THEORIES		
Chiaki Goto and Nobuo Shuto		695
Chapter 44		
ON THE CORRECTION OF LAND-BASED WIND MEASUREMENTS FOR OCEANOGRAPHIC APPLICATIONS		
S. A. Hsu		708
Chapter 45		
NUMERICAL MODELLING OF TROPICAL CYCLONE STORM SURGE		
Rodney J. Sobey, Bruce A. Harper, and George M. Mitchell		725
Chapter 46		
A NUMERICAL MODEL OF STORM WAVES IN SHALLOW WATER		
A. Hauguel		746
Chapter 47		
THE GENERATION OF LONG WAVES IN THE LABORATORY		
Derek Goring and Fredric Raichlen		763
Chapter 48		
CORRECT REPRODUCTION OF LONG GROUP INDUCED WAVES		
N. -E. O. Hansen, S. E. Sand, H. Lundgren, T. Sorensen and H. Gravesen		784
Chapter 49		
AN ELECTROMAGNETIC ANALOGY FOR LONG WATER WAVES		
G. W. Jackson and D. L. Wilkinson		801
Chapter 50		
INTERACTIONS OF WAVES WITH SUBMARINE TRENCHES		
Jiin J. Lee, Robert M. Ayer and Wen L. Chiang		812
Chapter 51		
TRANSIENT FINITE-DIFFERENCE TSUNAMI CALCULATIONS		
Ove Skovgaard and Ivar G. Jonsson		823
Chapter 52		
AN INVESTIGATION OF WAVE SHELTERING BY ISLANDS		
S. V. Hsiao, J. F. Vesecky and O. H. Shemdin		840
Chapter 53		
THE DISSIPATION OF WAVE ENERGY BY TURBULENCE		
Yu Kuang-ming		850

**PART II
COASTAL SEDIMENT PROBLEMS**

Chapter 54	
BEACH CUSPS AT POINT REYES AND DRAKES BAY BEACHES, CALIFORNIA	
Robert G. Dean and E. M. Maurmeyer	863
Chapter 55	
BARRON RIVER DELTA INVESTIGATION	
D. A. Robinson, D. J. Cook and J. G. Barff	885
Chapter 56	
SOFT DESIGNS FOR COASTAL PROTECTION AT SEABROOK ISLAND, S.C.	
Miles O. Hayes, Timothy W. Kana and John H. Barwis	897
Chapter 57	
GEOLOGICAL CONTROLS ON PROCESS-RESPONSE, S.E. AUSTRALIA	
P. S. Roy and A. W. Stephens	913
Chapter 58	
BEACH EROSION-ACCRETION AT TWO TIME SCALES	
B. G. Thom and G. M. Bowman	934
Chapter 59	
PHYSICAL PROCESSES AND SEDIMENT FLUX THROUGH REEF-LAGOON SYSTEMS	
Harry H. Roberts	946
Chapter 60	
INSHORE-NEARSHORE MORPHODYNAMICS-A PREDICTIVE MODEL	
John Chappell	963
Chapter 61	
BEACH CUT IN RELATION TO SURF ZONE MORPHODYNAMICS	
L. D. Wright	978
Chapter 62	
BREAKER TYPE AND PHASE SHIFTS ON NATURAL BEACHES	
Peter J. Cowell	997
Chapter 63	
BEACH RESPONSE TO VARIATIONS IN BREAKER HEIGHT	
A. D. Short	1016
Chapter 64	
THE DYNAMIC SWEEP PRISM	
David M. Chapman	1036
Chapter 65	
A LABORATORY STUDY OF OFFSHORE TRANSPORT OF SEDIMENT AND A MODEL FOR ERODING BEACHES	
Tsuguo Sunamura	1051
Chapter 66	
NEARSHORE CURRENTS ON A PARTIALLY ROCKY SHORE	
T. O. Sasaki, H. Igarashi and S. Harikai	1071

Chapter 67	
TOPOGRAPHIC CONTROL OF RUN-UP VARIABILITY	
Mark P. Bradshaw	1091
Chapter 68	
BEACH PROFILES AND ON-OFFSHORE SEDIMENT TRANSPORT	
Akira Watanabe, Yoshihiko Riho and Kiyoshi Horikawa	1106
Chapter 69	
SECONDARY SAND TRANSPORT MECHANISMS	
A. W. Smith and A. D. Gordon	1122
Chapter 70	
SAND TRANSPORT BY WAVES	
Jan van de Graaff and Wiel M. K. Tilmans	1140
Chapter 71	
NEARSHORE SUSPENDED SEDIMENT LOAD DURING STORM AND POST-STORM CONDITIONS	
Timothy W. Kana and Larry G. Ward	1158
Chapter 72	
ONSHORE-OFFSHORE TRANSPORT AND BEACH PROFILE CHANGE	
Masataro Hattori and Ryoichi Kawamata	1175
Chapter 73	
ON-OFFSHORE SEDIMENT TRANSPORT RATE IN THE SURF ZONE	
Toru Sawaragi and Ichiro Deguchi	1195
Chapter 74	
FIELD MEASUREMENTS OF SAND MOTION IN THE SURF ZONE	
Douglas L. Inman, James A. Zampol, Thomas E. White, B. Walton Waldorf, Daniel M. Hanes and Kim A. Kastens	1215
Chapter 75	
AN APPROACH TO UNDERSTANDING COASTAL PROCESSES	
A. D. Gordon and D. B. Lord	1235
Chapter 76	
RELATIONSHIP BETWEEN ALONGSHORE WAVE ENERGY AND LITTORAL DRIFT IN THE MID-WEST COAST AT TAIWAN	
Ho-shong Hou, Chung-Pan Lee, and Lung-Hui Lin	1255
Chapter 77	
LONGSHORE WATER AND SEDIMENT MOVEMENT	
D. H. Swart and C. A. Fleming	1275
Chapter 78	
CRITERION FOR STABILITY OF SHORELINE PLANFORM	
John D. Wang and Bernard le Mehaute	1295
Chapter 79	
ZETA BAYS, POCKET BEACHES AND HEADLAND CONTROL	
R. Silvester, Y. Tsuchiya, and Y. Shibano	1306
Chapter 80	
BEACHES: PROFILES, PROCESSES AND PERMEABILITY	
Michael R. Gourlay	1320
Chapter 81	
SAND BED-FORM LENGTHS UNDER OSCILLATORY MOTION	
Arthur Brebner	1340

Chapter 82	
SEDIMENT TRANSPORT PROCESSES AND COASTAL VARIABILITY ON THE ALASKAN NORTH SLOPE	
E. H. Owens, J. R. Harper and D. Nummedal	1344
Chapter 83	
SEDIMENT DISPERSAL ON THE N. S. W. CONTINENTAL SHELF	
Ron Boyd	1364
Chapter 84	
FLUID MUD DYNAMICS AND SHORELINE STABILIZATION: LOUISIANA CHENIER PLAIN	
John T. Wells and Harry H. Roberts	1382
Chapter 85	
NEARSHORE SEDIMENT TRANSPORT STUDY EXPERIMENTS	
R. J. Seymour and C. G. Gable	1402
Chapter 86	
A SEDIMENT TRAPPING EXPERIMENT AT SANTA CRUZ, CA.	
R. J. Seymour, G. W. Domurat and D. M. Pirie	1416
Chapter 87	
WAVE FORCING OF BEACH GROUNDWATER	
Evans Waddell	1436
Chapter 88	
LONGSHORE TRANSPORT EVALUATIONS AT A DETACHED BREAKWATER	
R. O. Bruno, R. G. Dean, and C. G. Gable	1453
Chapter 89	
MIGRATION OF LONGSHORE BARS	
Hans H. Dette	1476
Chapter 90	
A PHASED-DREDGING PROGRAM FOR SANTA CRUZ HARBOR	
James R. Walker and Peter J. Williams	1493
Chapter 91	
DESIGN OF ENCLOSED HARBORS TO REDUCE SEDIMENTATION	
Craig H. Everts	1512
Chapter 92	
OPENING AND MAINTAINING TIDAL LAGOONS & ESTUARIES	
Scott A. Jenkins, Douglas L. Inman and James A. Bailard	1528
Chapter 93	
RESEARCH IN SOUTHERN QUEENSLAND INTO THE MANAGEMENT OF COASTAL SAND DUNES	
James B. McKenzie and David A. Barr	1548
Chapter 94	
WIND AND SEDIMENT MOVEMENT IN COASTAL DUNE AREAS	
John R. Hails and John Bennett	1565
Chapter 95	
SAND TRANSPORT UNDER THE ACTION OF WIND	
Ulrich Zanke	1576
Chapter 96	
A NUMERICAL MODEL FOR DUNE DYNAMICS	
J. Sundermann, H. -J. Vollmers and W. Puls	1584

Chapter 97	
ESTUARINE RESPONSE TO DREDGING IN THE TWEED RIVER, AUSTRALIA	
Bruce M. Druery	1599
Chapter 98	
NOOSA BEACH RESTORATION SCHEME	
R. J. Lloyd	1619
Chapter 99	
BEACH NOURISHMENT AS A MANAGEMENT TECHNIQUE	
David M. Chapman	1636
Chapter 100	
CAPRICORN COAST BEACHES	
D. C. Patterson and L. R. Ford	1649
Chapter 101	
THE BEACH IMPROVEMENT PROGRAMME: NEW SOUTH WALES	
Heale A. Philip and Philip H. Waite	1669
Chapter 102	
EDDY CURRENTS AND SEDIMENT TRANSPORT OFF THE DAMIETTA NILE	
S. P. Murray, J. M. Coleman, H. H. Roberts and M. Salama	1680
Chapter 103	
A COMPARISON BETWEEN DREDGE INDUCED SEDIMENT RESUSPENSION AND THAT PRODUCED BY NATURAL STORM EVENTS	
W. Frank Bohlen and Marine Sciences Department., Univ. of Conn.	1700
Chapter 104	
SEDIMENTATION IN CHANNELS AND TRENCHES	
E. W. Bijker	1708
Chapter 105	
SEDIMENTATION IN DREDGED NAVIGATION CHANNELS	
Lars Mikkelsen, Preben Mortensen, and Torben Sorensen	1719
Chapter 106	
SOME ASPECTS OF COASTAL ENGINEERING RESEARCH WORKS IN CHINA	
Yen Kai	1735

PART III
COASTAL STRUCTURES AND RELATED PROBLEMS

Chapter 107	
SIMULTANEOUS WAVE AND CURRENT FORCES ON A PIPELINE	
David A. Knoll and John B. Herbich	1742
Chapter 108	
WAVE FORCES ON AN INCLINED CIRCULAR CYLINDRICAL PILE	
Toshiyuki Shigemura	1761
Chapter 109	
WAVE-INDUCED SEEPAGE EFFECTS ON A VERTICAL CYLINDER	
Thomas J. P. Durand and Peter L. Monkmeier	1781

Chapter 110	
STABILITY ANALYSIS OF SEAFLOOR FOUNDATIONS	
Tokuo Yamamoto and Yasumasa Suzuki	1799
Chapter 111	
WAVE FORCES ON OFFSHORE PIPELINES	
N. Jothishankar and V. Sundar	1819
Chapter 112	
WAVE IMPACT PRESSURES ON COMPOSITE BREAKWATERS	
G. R. Mogridge and W. W. Jamieson	1829
Chapter 113	
CONSTRUCTION AND MODEL INVESTIGATION OF STORMWATER OUTFALL	
K. A. Heathcote and G. W. Britton	1849
Chapter 114	
FULL SCALE NEAR SURFACE WATER PARTICLE VELOCITIES AND PRESSURES ACTING ON AN INCLINED TUBULAR MEMBER	
Fritz Busching and Eckehard Martini	1869
Chapter 115	
ENERGY TRANSMISSION OVER BREAKWATER—A DESIGN CRITERION?	
P. Bade and H. Kaldenhoff	1885
Chapter 116	
THE DESIGN CONCEPT OF DUAL BREAKWATERS AND ITS APPLICATION TO TOWNSVILLE, AUSTRALIA	
W. Bremner, N. N. Foster, C. A. Miller and B. C. Wallace	1898
Chapter 117	
DESIGN OF AN OVERTOPPING BREAKWATER	
P. D. Treloar and B. Nagle	1909
Chapter 118	
FULL SCALE TRIALS OF DOLOSSE TO DESTRUCTION	
Hans F. Burcharth	1928
Chapter 119	
DOLOSSE: PAST, PRESENT, FUTURE?	
J. A. Zwamborn, D. E. Bosman and J. Moes	1948
Chapter 120	
A DETACHED BREAKWATER SYSTEM FOR BEACH PROTECTION	
James R. Walker, Denton Clark, and Joan Pope	1968
Chapter 121	
STABILITY OF RUBBLE MOUND BREAKWATER	
J. Feuillet and M. Sabaton	1988
Chapter 122	
ARTIFICIAL RESORT BEACH PROTECTED BY OFFSHORE BREAKWATERS AND GROINS	
Shoji Sato and Norio Tanaka	2003
Chapter 123	
SEAWALLS IN DEEP SEAS	
Shoshichiro Nagai and Shohachi Kakuno	2023
Chapter 124	
PROBABILISTIC DESIGN OF SEA DEFENCES	
W. T. Bakker and J. K. Vrijling	2040

Chapter 125	
DESIGN OF CAISSON BREAKWATERS	
A. G. F. Eddie, J. D. Lawson, H. R. Graze and B. K. Dean	2060
Chapter 126	
THE DESIGN AND CONSTRUCTION OF THE NEW OIL PORT IN DALIAN, C.P.R.	
Xin Zhu-Zhuang	2080
Chapter 127	
SITING AND DESIGN CRITERIA OF DOCK STRUCTURES IN THE MARSHALL ISLANDS	
R. M. Noble, K. C. Leslie and D. O'Day	2106
Chapter 128	
COASTAL PROTECTION AGAINST THE ACTION OF WAVES AND CURRENTS	
Leren P. Mikhailov and Sergei M. Uspenskii	2120
Chapter 129	
FLOATING BREAKWATER PERFORMANCE COMPARISON	
Volker W. Harms	2137
Chapter 130	
LITTORAL DRIFT OF SAND NEAR PORT OF OARAI	
Kazumasa Mizumura	2159
Chapter 131	
LONG-TERM EXPERIENCE WITH THE USE OF SYNTHETIC FILTER FABRICS IN COASTAL ENGINEERING	
Georg Heerten	2174
Chapter 132	
BREAKWATER WITH SAND BITUMEN CORE	
E. Loewy, K. G. Witthaus, R. J. Maddrell and J. P. Wood	2194
Chapter 133	
HARBOUR DESIGN INCLUDING SEDIMENTOLOGICAL PROBLEMS USING MAINLY NUMERICAL TECHNIQS	
B. Latteux	2213
Chapter 134	
NEW JETTIES FOR TUNG-KANG FISHING HARBOUR, TAIWAN	
Chi-Fu Su	2230
Chapter 135	
MAJOR RECLAMATION SCHEME FOR MARINA CITY, SINGAPORE	
S. Y. Chew and J. Wei	2245
Chapter 136	
SHIP-BRIDGE-PIER PROTECTIVE SYSTEMS	
Akira Iwai, Hitoshi Nagasawa, Kazuki Oda and Kuniaki Shoji	2261
Chapter 137	
WAVE-WAVE INTERACTIONS, CURRENT-WAVE INTERACTIONS AND RESULTING EXTREME WAVES AND BREAKING WAVES	
Soren Peter Kjeldsen and Dag Myrhaug	2277
Chapter 138	
CAN WE DEVELOP NEW BREAKWATER ARMOUR FORMULAE?	
John Dorrington Mettam	2304

**PART IV
COASTAL, ESTUARINE, AND ENVIRONMENTAL PROBLEMS**

Chapter 139	
SEPARATION OF CLIMATIC FLUCTUATIONS AND IMPACTS OF ENGINEERING ACTIVITIES IN ESTUARIES	
G. Krause	2325
Chapter 140	
WAVE ENERGY DISTRIBUTION IN AN ESTUARY	
Volker Barthel	2340
Chapter 141	
HYDRAULIC RESEARCH IN THE OOSTERSCHELDE ESTUARY	
Anton W. Walther	2360
Chapter 142	
PORT OF BRISBANE SILTATION STUDY	
N. V. M. Odd and T. Baxter	2377
Chapter 143	
A 3-D MODEL FOR PENOBSCOT BAY, MAINE	
Bryan R. Pearce, Bruce R. Fidler and Adrian C. Humphreys	2397
Chapter 144	
THE USE OF ARRAY PROCESSORS FOR NUMERICAL MODELLING OF TIDAL ESTUARY DYNAMICS	
D. Prandle, E. R. Funke, N. L. Crookshank and R. Renner	2413
Chapter 145	
PARAMETER IDENTIFICATION IN ESTUARINE MODELING	
Wen-Sen Chu and William -G. Yeh	2433
Chapter 146	
AUTOMATIC CALIBRATION OF NUMERICAL TIDAL MODELS	
K. -P. Holz and U. Januszewski	2450
Chapter 147	
TIDAL INLET BEHAVIORAL ANALYSIS	
A. F. Nielsen and A. D. Gordon	2461
Chapter 148	
SEDIMENTATION PROCESSES IN TIDAL CHANNELS AND TIDAL BASINS CAUSED BY ARTIFICIAL CONSTRUCTIONS	
E. Renger and H. W. Partensky	2481
Chapter 149	
ARTIFICIAL ROUGHNESS IN PHYSICAL MODELS OF ESTUARIES FOR STORM SURGE INVESTIGATIONS	
D. Berndt, E. Giese, H. Schwarze, and H. -J. Vollmers	2495
Chapter 150	
COMMENTS ON TIDAL ENTRANCES ON SANDY COASTS	
Morrough P. O'Brien	2504
Chapter 151	
TIDAL PRISM-INLET AREA RELATIONS FOR SMALL TIDAL INLETS	
R. J. Bryne, R. A. Gammisch and G. R. Thomas	2517
Chapter 152	
A COASTAL INLET WITH FIXED BED AND MOBILE SIDES	
R. C. Nelson and A. J. Keats	2534

Chapter 153	
INLETS/ESTUARIES DISCHARGING INTO SHELTERED WATERS	
H. P. Riedel and M. R. Gourlay	2550
Chapter 154	
THE CORPS OF ENGINEER'S GENERAL INVESTIGATION OF	
TIDAL INLETS	
Robert M. Sorensen	2565
Chapter 155	
SATELLITE APPLICATIONS ON A COASTAL INLET STABILITY	
STUDY	
Yu-Hwa Wang	2581
Chapter 156	
BOUNDARY CONDITIONS FOR ANALYSIS OF FLOW IN TIDAL	
INLETS	
T. C. Gopalakrishnan and J. L. Machemehl	2595
Chapter 157	
MECHANISMS OPERATING AT A JETTIED RIVER ENTRANCE	
Bruce M. Druery and Alexander F. Nielsen	2607
Chapter 158	
STABILITY OF ESTUARY MOUTHS IN THE RHINE-MEUSE DELTA	
J. van de Kreeke and J. Haring	2627
Chapter 159	
BARDEN INLET, N.C.: A CASE STUDY OF INLET MIGRATION	
Limberios Vallianos	2640
Chapter 160	
STUDY ON VORTEX CURRENT IN STRAIT WITH REMOTE-SENSING	
Sotoaki Onishi and Tsukasa Nishimura	2655
Chapter 161	
DYNAMIC SIMILARITY OF TRANSPORT PHENOMENA	
M. S. Yalin and F. Gerritsen	2671
Chapter 162	
MOORING FORCES INDUCED BY PASSING SHIPS--MEASUREMENTS	
IN PROTOTYPE	
K. Haffke	2691
Chapter 163	
NUMERICAL MODELLING OF NEARSHORE CIRCULATION	
Bruce A. Ebersole and Robert A. Dalrymple	2710
Chapter 164	
MODELLING OF PLANFORM INFLUENCE ON CIRCULATION IN	
HARBOURS	
Roger A. Falconer	2726
Chapter 165	
HYDRAULIC CIRCULATION PERFORMANCE OF A CURVILINEAR	
MARINA	
Jeffrey A. Layton	2745
Chapter 166	
THE EFFECT OF BREAKING WAVES ON THE MIXING OF LIQUID	
POLLUTANTS INTO THE SEA	
Arvid Naess	2760

Chapter 167	
ON A ROLE OF THE INTERFACIAL FROUDE NUMBER	
Masakazu Kashiwamura	2780
Chapter 168	
DISPERSION OF COOLING WATER FROM A COASTAL LNG PLANT	
P. Ackers, J. D. Pitt, G. Thompson and K. G. Rippin	2796
Chapter 169	
EXPERIMENTAL STUDY OF THE BUOYANT SURFACE JET WITH THE PRESENCE OF BOTTOM BOUNDARY AND CROSS CURRENT	
B. Safaie	2816
Chapter 170	
DESIGN OF AN INTERMITTENTLY OPERATED OUTFALL

A LABORATORY STUDY OF OFFSHORE TRANSPORT OF SEDIMENT AND A MODEL FOR ERODING BEACHES

Tsuguo Sunamura *Institute of Geoscience, University of Tsukuba,
Ibaraki 305, Japan*

ABSTRACT

A two-dimensional laboratory investigation of sediment transport, induced by shallow-water waves, showed that the sediment motion over suspension-dominant asymmetric ripples is closely related to the development of eroding beaches. High-speed motion picture analysis revealed that vortices, formed over this type of ripple, play a crucial role in transporting the sediment to the offshore region. A relation for net offshore sediment flux was formulated for sand 0.02 cm in diameter. A simple model for eroding beaches was proposed and its validity was checked by using two existing data sets for 0.02-cm sand beaches; the model could predict fairly well profile and shoreline changes in the early stages.

INTRODUCTION

Shallow-water waves produce a net sediment transport on a beach. Since beach changes do occur only when a spatial difference of net sediment transport rate exists, an explicit understanding of sediment motion under shallow-water wave action is necessary for beach change studies. Although much research on sediment motion has been conducted in the laboratory (e.g., Davies and Wilkinson, 1977), few have focussed attention on this point.

Beach erosion is clearly caused by the net offshore movement of sand. However, the mechanisms of the offshore movement have not yet been fully clarified even in a laboratory environment; so that no models for predicting erosional beaches have been developed on the basis of sediment dynamics.

The present two-dimensional laboratory study attempts to (1) investigate sediment motion by shallow-water waves and relate this to the beach profile change, (2) elucidate the processes of net offshore transport of sand and estimate the transport rate, and (3) develop a simple model for eroding beaches.

SEDIMENT MOVEMENT CAUSED BY SHALLOW-WATER WAVES AND ITS RELATION TO BEACH PROFILE CHANGE

Komar and Millar (1973; 1974) gave the following relation for the sediment threshold, which was a dimensionally corrected Bagnold's (1946) empirical relation:

$$\rho u_m^2 / (\rho_s - \rho) g D = a (d_o/D)^{1/2} , \quad (1)$$

where u_m = maximum orbital velocity of the water near the bottom, d_o = maximum orbital diameter near the bottom, D = sediment size, ρ_s = sediment density, ρ = water density, g = gravitational acceleration, and a = dimensionless constant. Equation (1) reduces to

$$H_o/L_o = a' (D/L_o)^{1/3} (H_o/H) \sinh(2\pi h/L) , \quad (2)$$

where $a' = [(2a/\pi) (\rho_s/\rho - 1)]^{2/3} = \text{const.}$, using the following relations based on the Airy wave theory:

$$u_m = \pi H / T \sinh(2\pi h/L) , \quad (3)$$

$$d_o = H / \sinh(2\pi h/L) , \quad (4)$$

$$L_o = g T^2 / 2\pi , \quad (5)$$

where H and L = wave height and length at a water depth of h , respectively, H_o and L_o = wave height and length in deep water, respectively, and T = wave period. Equation (2) is basically the same relation that Sato et al. (1962) introduced for the description of sediment motion. A theoretical study by Horikawa and Watanabe (1967) indicated that Eq. (2) is valid only for the onset of sediment movement under conditions of a hydraulically rough bottom and turbulent boundary layer flow. However, Eq. (1) is in good agreement with Bagnold's (1946) and Manohar's (1955) data obtained under laminar boundary layer flow conditions, although the values of a differ slightly from each other (Komar and Miller, 1973; 1974). A further investigation by Komar and Miller (1975) showed that Eq. (1) can also specify the initiation of ripple formation, which amounts to a change in the value of a . A review of these existing studies suggests that the form of Eq. (1) may be applicable to sediment movement under various flow conditions and also to ripple initiation, although this application is theoretically restricted. A useful dimensionless parameter describing sediment motion and bedform would be

$$F = \rho u_m^2 / (\rho_s - \rho) g D^{1/2} d_o^{1/2} , \quad (6)$$

which is an algebraic rearrangement of Eq. (1).

Shallow-water waves create a near-bottom velocity field which is characterized by a larger onshore velocity of shorter duration under wave crests, and a smaller offshore velocity of longer duration under wave troughs, as compared to a purely sinusoidal orbital velocity field. A dimensionless parameter on which the deviation from the sinusoidal velocity field depends, is the Ursell number (Ursell, 1953):

$$U = H L^2 / h^3 \tag{7}$$

With increasing U , the degree of deviation becomes greater.

A relationship between F and U (Eqs. (6) and (7)) was investigated on the basis of a laboratory experiment performed using a large (25 m long, 1.5 m deep, and 0.8 m wide) and a small wave tank (6 m long, 0.3 m deep, and 0.2 m wide). Both tanks were equipped with flap-type wave makers at one end of the tank, and wave absorbers were placed at the other end. Four kinds of well-sorted bed material with Trask's (1930) sorting coefficients of 1.05~1.10 were used. Three kinds of sand with the same density, $\rho_s = 2.65 \text{ g/cm}^3$, and different diameters, $D = 0.02, 0.07, \text{ and } 0.156 \text{ cm}$, and plastic beads with $\rho_s = 1.33 \text{ g/cm}^3$ and $D = 0.055 \text{ cm}$ were used. A flat horizontal bed was set up in the central portion of the wave tank. Water depth over the horizontal bed was 30~40 cm for the large tank test, and 10~15 cm for the small tank test. Wave period ranged from 1.0~3.4 sec for the former, and 0.69~1.7 sec for the latter. A series of tests was performed by gradually increasing wave height with wave period being kept constant. The mode of sediment motion and bedform were observed visually.

The results are shown in Fig. 1. Different values of k in the following equation gave a fairly good demarcation of the different regions of bedforms:

Figure 1. Relationship between F and U for bedform demarcation.

$$F = k U^{1/4} . \quad (8)$$

With increasing the Ursell number, either non-sinusoidal sediment movement or asymmetric bedform occurs becoming noticeable for $U \geq 10 \sim 20$. The region occupied by solid circles ($0.10 \lesssim k \lesssim 0.20$) denotes the occurrence of a quasi-oscillatory bedload producing a net onshore transport. Above this region, lies a region of asymmetric ripples, shown by a cluster of solid triangles ($k \gtrsim 0.20$). When ripples are formed, there always exists suspended sediment, which is defined here as the sediment moved not only in pure suspension but also in saltation.

To study sediment motion over asymmetric ripples, Sato and Tanaka (1962) and Sato et al. (1962) have performed radioactive-tagged sand tracer experiments. They replaced the sand forming one asymmetric ripple by radioactive sand and traced its movement. The results demonstrated the occurrence of two different types of sediment motion: one is bedload dominant movement producing a net onshore transport (Fig. 2), while the other is suspended-load dominant movement producing a net offshore transport (Fig. 3). Note that Fig. 3 shows no onshore dispersion of the tracer.

Figure 4 is a plot of selected data showing the directions of net sediment transport over asymmetric ripples; solid symbols denote offshore transport, while open symbols onshore transport. Although there are not a sufficient number of the data points, a boundary between onshore and offshore regions could be expressed by the dashed line:

$$F \begin{array}{l} > \\ < \end{array} 0.28 U^{1/4} \quad \begin{array}{l} \text{Net offshore transport} \\ \text{Net onshore transport.} \end{array} \quad (9)$$

If this relation is applicable at the wave breaking point of a sloping beach, then the following relation can be written:

$$F_b \begin{array}{l} > \\ < \end{array} 0.28 U_b^{1/4} . \quad (10)$$

The subscript "b" denotes quantities at the wave breaking point. If the left-hand side of this equation is greater than the right-hand side, then net offshore transport of sediment takes place through the wave breaking point; this leads to the development of an eroding beach as shown in the inset of Fig. 5. For the reverse case, an accreting beach develops. If the preceding assumption is valid, then a boundary between eroding and accreting beaches should be given by

$$F_b = 0.28 U_b^{1/4} , \quad (11)$$

where

$$F_b = \rho (u_m)_b^2 / (\rho_s - \rho) g D^{1/2} (d_o)_b^{1/2} ,$$

$$U_b = H_b L_b^2 / h_b^3 ,$$

$$(u_m)_b = \pi H_b / T \sinh(2\pi h_b / L_b) ,$$

* S = Sand; C = Coal powder; M = Monochromatic waves; W = Wind waves

$$(d_o)_b = H_b / \sinh(2\pi h_b/L_b) .$$

Equation (11) was transformed using the approximations: $\sinh(2\pi h_b/L_b) \approx 2\pi h_b/L_b$, $\tanh(2\pi h_b/L_b) \approx 2\pi h_b/L_b$, $29/30 \approx 1$, and $35/12 \approx 3$; and two empirical relations on breaker characteristics:

$$H_b/h_b = 1.1 (\tan \beta)^{1/6} (H_o/L_o)^{-1/12} , \quad (\text{see Appendix}) \quad (12a)$$

$$H_b/H_o = (\tan \beta)^{1/5} (H_o/L_o)^{-1/4} , \quad (12b)$$

where $\tan \beta =$ beach slope and Eq. (12b) was given by Sunamura and Horikawa (1974). This results in

$$H_o/L_o = C (\rho_s/\rho - 1)^{4/3} (\tan \beta)^{-1/3} (D/L_o)^{2/3} \quad (13)$$

with the constant, C , being equal to 1.1. The parameters, H_o/L_o and $(\tan \beta)^{-1/3} (D/L_o)^{2/3}$, are very similar to the parameters used for beach profile classification, which were semi-empirically obtained on the basis of surf-zone hydraulics, i.e., H_o/L_o and $(\tan \beta)^{-0.27} (D/L_o)^{0.67}$ (Sunamura and Horikawa, 1974). The validity of Eq. (13) was checked using the existing beach profile data with various wave durations, t (Table 1). The results are plotted in Fig. 5; $C = 1.1$ gives a good demarcation between eroding and accreting beaches, although $C = 1.7$ provides the best. This suggests that the sediment transport mode at the wave breaking point is closely related to beach profile change.

MECHANICS OF OFFSHORE TRANSPORT OF SEDIMENT AND QUANTIFICATION OF TRANSPORT RATE

For the development of a model for eroding beaches, knowledge of net offshore sediment flux, associated with the wave and sediment parameters, is required. Sediment motion producing a net offshore transport is very rapid and complex. This quickness and complexity have hampered this sort of study.

In order to overcome these difficulties, a 16-mm high-speed movie camera was adopted for a laboratory test, in which the small wave tank was used (Sunamura et al., 1978). The movement of the well-sorted 0.02-cm sand, which formed asymmetric ripples with suspension-dominant transport on a horizontal bed, was photographed at a film speed of 200 500 frames/sec. Neutral-buoyant polystyrene beads, 1.5 mm in diameter, were used for tracing the water orbital motion.

Figure 6 shows one characteristic example of sediment movement, taken from the high-speed motion picture films via a film analyzer. The ellipses indicate the orbital motion of the water and the multiple arrows denote sand particle velocity vectors. Note that the sand particles are entrapped in a vortex formed at the onshore side of the R_2 ripple in stage (1); the particles are represented by open circles. Immediately after the onset of offshore flow, these sand particles are

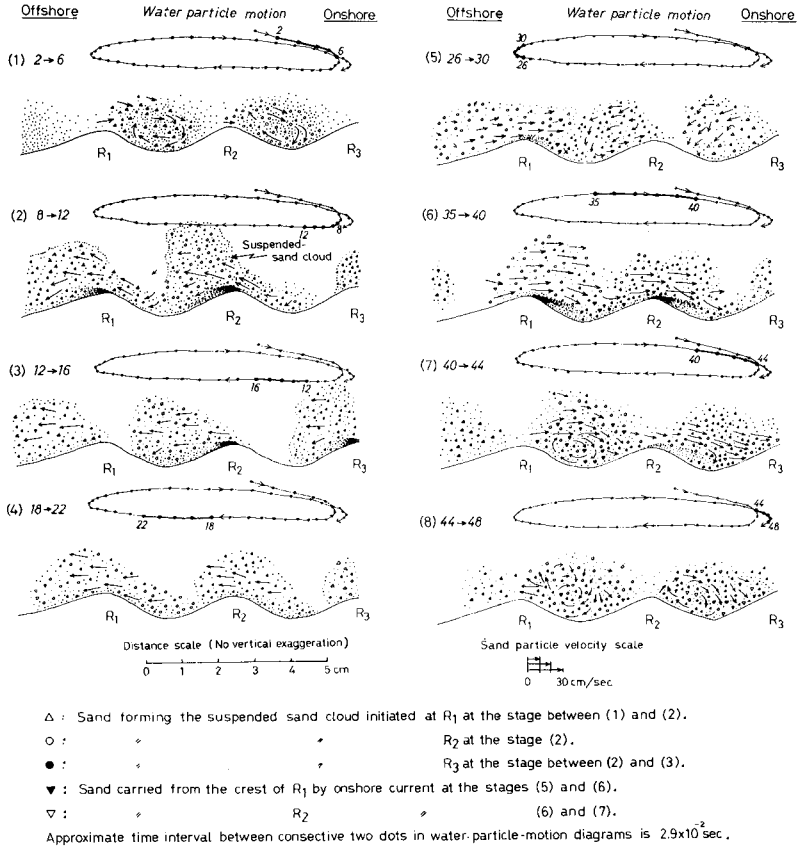

Figure 6. Sediment movement over asymmetric ripples with suspension-dominant transport. (Sunamura et al., 1978)

thrown up obliquely in an offshore direction to form a suspended-sand cloud, which is shown in stage (2). The following two stages, (3) and (4), show that the offshore flow carries this sand cloud offshore, partially depositing the sand particles. As shown in stages (5) and (6), the onshore flow returns these offshore-transported sand particles to the place where they were initially entrapped in the vortex, that is, to the onshore side of the R_2 ripple. During this return travel, however, the sediment once transported offshore beyond a certain limit cannot return to the onshore side of the R_2 ripple, due to being captured in a vortex formed at the onshore flank of the R_1 ripple, as shown in stage (7). This unreturned sediment constitutes the net offshore-transported load. It should be emphasized that strong vortices, formed over the onshore flank of asymmetric ripples, play a vital role in continuing the net offshore sediment transport in this mode of suspension. These vortices are formed with an approximate phase lag of $\pi/6$ after the onshore orbital motion attains its maximum speed.

The film analysis indicated that the offshore limit, beyond which offshore-transported sediment never returns to the initial position, is located at 1.5λ , where λ is the ripple length (Fig. 7). Sediment in the hatched portion constitutes the net offshore-transported load. In this figure, ℓ is the maximum offshore extension of the sand cloud. Precise measurement of this transported load is extremely difficult, because the measurement must be done without disturbing ripple configuration or the velocity field. However, an estimation is possible if we assume a triangular distribution of sediment particles over the ripples at the stage of maximum offshore extension of the sand cloud (Fig. 8). The following relation can be written:

$$Q_{\text{off}} = \delta Q, \quad (14)$$

where Q_{off} = net offshore transport volume of sediment, Q = volume of sediment included in a sand cloud, and

$$\delta = \begin{cases} 0, & \ell \leq 1.5 \lambda \\ (1 - 1.5 \lambda / \ell)^2, & \ell > 1.5 \lambda. \end{cases}$$

The direct measurement of Q is difficult due to the variability of shape and size of the sand cloud. Since the sand cloud originates from the sand vortex, Q is considered to be approximately equal to the volume of sand forming the vortex. During the vortex formation, (1) the area of the vortex only changes a little and (2) the sand distribution within the vortex seems to be uniform. Then, Q can be expressed by

$$Q = A S / T, \quad (15)$$

where A = area of the vortex, S = volumetric sand concentration in the vortex, and T = wave period. In order to relate Q to the parameters associated with the velocity field and sediment characteristics, the following dimensionless quantities are introduced:

$$\Omega = Q / \sqrt{(\rho_s / \rho - 1) g D D} \quad \} \quad (16)$$

Figure 7.
Definition sketch.

Figure 8.
Definition sketch.

Figure 9.
Relationship between Ω and Γ for 0.02-cm sand.

$$\Gamma = u_m (u_m - u_c) / (\rho_s/\rho - 1) g D \quad] ,$$

where u_c = critical velocity for asymmetric ripple formation = $0.02^{1/2} (\rho_s/\rho - 1)^{1/2} g^{1/2} D^{1/4} d_o^{1/4} (HL^2/h^3)^{1/8}$; this was obtained by substituting $k = 0.20$ and $u_m = u_c$ into Eq. (8) (see Fig. 1).

To find a connection between Ω and Γ , a laboratory experiment was performed on a horizontal bed, in the small wave tank, made of the well-sorted 0.02-cm sand. The high-speed movie camera was used for the measurement of A . An Iowa-type sediment concentration meter (Locher et al., 1974) was employed to measure S . The measurement, made in the vicinity of the vortex center, was completed within four or five waves, because longer installation of the sensor skewed the ripples so that a change of sand volume in the vortex occurred. For the computation of Q , using Eq. (15), the mean values of A and S were used; the former was averaged over several waves and the latter was a time-averaged value, over three consecutive waves, of the record during the period of vortex formation. Figure 9 shows the relationship between Ω and Γ . Although some scatter of data points is seen, a linear relation is present:

$$\Omega = 0.016 \Gamma. \quad (17)$$

Using Eqs. (14), (16), and (17), a net offshore sediment flux equation is finally obtained:

$$Q_{off} = 0.016 \left(\frac{\ell - 1.5 \lambda}{\ell} \right)^2 \frac{u_m (u_m - u_c) \sqrt{D}}{\sqrt{(\rho_s/\rho - 1) g}}, \quad (18)$$

which gives volumetric transport rate per unit width. This equation is valid only for $\ell > 1.5 \lambda$. It should be noted that this is not a general relation for different sediment sizes, but a relation for only 0.02-cm sand. A generalization must await future studies.

A MODEL FOR ERODING BEACHES

In the two-dimensional laboratory beach changes, a feedback relationship between input waves and the resultant topography usually exists (Fig. 10(a)). Especially, on an eroding beach which is characterized by the sediment accumulation in the offshore region, the wave breaking point shifts offshore in time due to the decrease in water depth accompanying the changes of breaker type and height. This was investigated by Chesnutt and Galvin (1974). Since the formulation of the feedback system seems complicated, the present study attempts to develop a simpler model for eroding beaches, based on an open-loop system (Fig. 10(b)), i.e., the system in which no wave-topography interaction exists. Accordingly, no temporal changes occur in the breaker parameters. We further assume that the sand elevation at the wave breaking point does not change with time. Hence, this model has a time-independent breaking point.

(a) CLOSED-LOOP SYSTEM

(b) OPEN-LOOP SYSTEM

Figure 10. Closed-loop and open-loop systems in beach changes.

Figure 11.
Definition sketch.

Figure 11 shows the co-ordinate system in which the origin is chosen at the wave breaking point on the initial beach which is expressed by

$$y_1 = (\tan \beta) x , \tag{19}$$

where $\tan \beta$ = initial beach slope. In the nearshore zone, from the wave breaking point to the wave uprush limit, the eroding beach profile is assumed to be described by

$$y_2 = \alpha x^n , \tag{20}$$

where both α and n are time-dependent variables. At the wave runup limit, $x = x_1$, the beach profile is expressed by a vertical line or scarp:

$$x_1 = [(h_a + Y_R) / \alpha]^{1/n} , \tag{21}$$

where h_b = breaker depth and Y_R = maximum height of wave runup. At the shoreline position, $x = x_2$,

$$\left(\frac{dy_2}{dx} \right)_{x=x_2} = \tan \alpha, \quad (22)$$

where $\tan \alpha$ = local beach slope or beach gradient at the shoreline, and

$$x_2 = (h_b / a)^{1/n}. \quad (23)$$

Equations (20), (22), and (23) lead to

$$a = (\tan \alpha)^n / n^n h_b^{n-1}. \quad (24)$$

Since

$$(Q_{\text{off}})_b = (1/t) \int_0^{x_1} (y_1 - y_2) dx, \quad (25)$$

where $(Q_{\text{off}})_b$ = net offshore sediment transport rate at the wave breaking point, substitution of Eqs. (19), (20), and (21) into Eq. (25) gives

$$\frac{\tan \beta}{2} \left(\frac{h_b + Y_R}{a} \right)^{2/n} - \frac{a}{n+1} \left(\frac{h_b + Y_R}{a} \right)^{(n+1)/n} = (Q_{\text{off}})_b \cdot t. \quad (26)$$

From Eqs. (24) and (26), both a and n are respectively obtainable as a function of time. Thus, the nearshore beach profile changes can be described by Eq. (20). The shoreline displacement, X_S (see Fig. 11), is given as

$$X_S = \begin{cases} 0, & (h_b / a)^{1/n} \leq (h_b / \tan \beta) \\ (h_b / a)^{1/n} - (h_b / \tan \beta), & (h_b / a)^{1/n} > (h_b / \tan \beta). \end{cases} \quad (27)$$

In the offshore zone beyond the wave breaking point, $x < 0$ (see Fig. 11), the depositional topography is assumed to be simply given by

$$y_3 = a' x^5, \quad (28)$$

where a' is a time-dependent variable. Since

$$(Q_{\text{off}})_b = (1/t) \int_{x_3}^0 (y_3 - y_1) dx, \quad (29)$$

where $x_3 = -[(\tan \beta)/a']^{1/4}$, Eqs. (19), (28), and (29) give the offshore beach profile as

$$y_3 = (\tan \beta)^3 x^5 / 9 (Q_{\text{off}})_b^2 t^2. \quad (30)$$

If the direct application of Eq. (18) is possible to the wave

breaking point on a sloping beach made of 0.02-cm sand, then

$$(Q_{\text{off}})_b = 0.016 \left(\frac{\ell_b - 1.5 \lambda_b}{\ell_b} \right)^2 \frac{(u_m)_b [(u_m)_b - (u_c)_b] \sqrt{D}}{\sqrt{(\rho_s/\rho - 1)g}}, \quad (31)$$

where ℓ_b = maximum offshore extension of suspended sand cloud at the wave breaking point, λ_b = length of sand ripples formed at the wave breaking point, and

$$(u_c)_b = 0.20^{1/2} \left(\frac{\rho_s - \rho}{\rho} \right)^{1/2} g^{1/2} D^{1/4} (d_o)_b^{1/4} \left(\frac{H_b \ell_b^2}{h_b^3} \right)^{1/8}.$$

Knowing the four quantities, $\tan \alpha$, Y_R , ℓ_b , and λ_b , it is possible to calculate beach profile changes and shoreline displacements. However, these quantities must be experimentally determined at present.

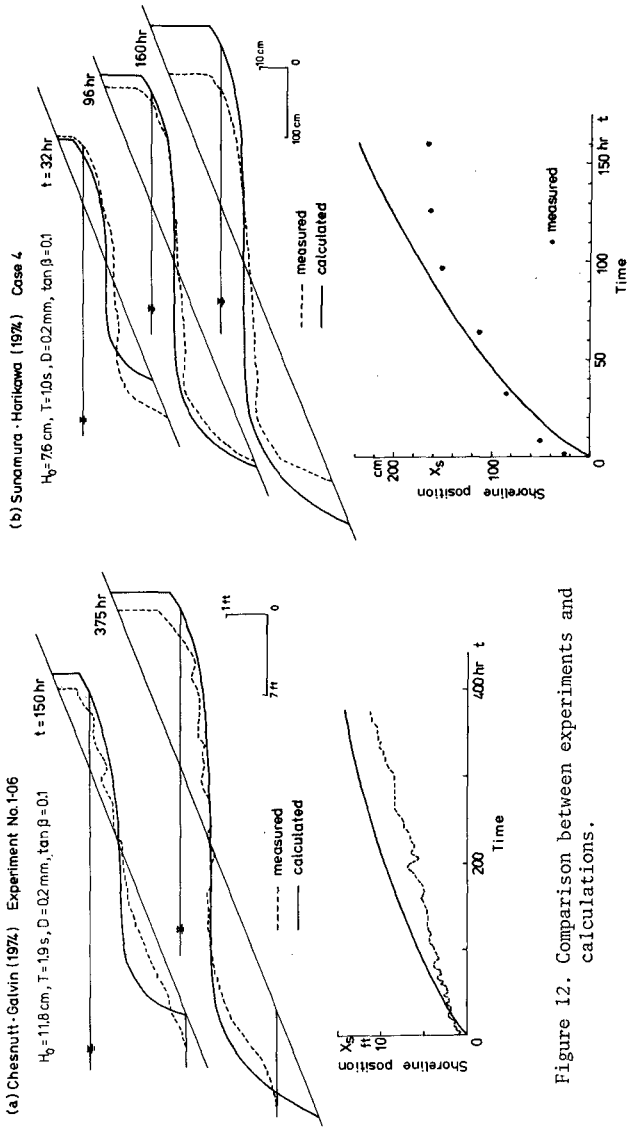

Table 2 shows the data for two selected experiments with eroding beaches, which was used for a check of the validity of this model. The selection was based on the following three criteria: (1) the grain size of sand used should be 0.02 cm, because the sediment flux equation is available for only 0.02-cm sand; (2) the duration of wave action should be more than 100 hours, because the longer the duration, the better is the check of the characteristics of this model; and (3) data of temporal changes of the beach profile and shoreline position should be available.

A similar experiment on a sloping beach was carried out under the same conditions as listed in the upper rows of Table 2, for only first hour. A flap-type wave maker-equipped tank 16 m long, 0.7 m high, and 0.5 m wide, was used. The four quantities were measured immediately

Table 2. Data sets used for the validity check of the model.

	Chesnutt-Galvin (1974) Experiment No.1-06	Sunamura-Horikawa (1974) Case 4
D	0.02 cm	0.02 cm
$\tan \beta$	0.1	0.1
H_o	11.8 cm	7.6 cm
T	1.9 sec	1.0 sec
t	375 hr	160 hr
λ_b^*	11 cm	5 cm
ℓ_b^*	$\approx 2.3 \lambda_b$	$\approx 2.3 \lambda_b$
Y_R^*	8 cm	4 cm
$\tan \alpha^*$	0.12	0.12

* Measured immediately after 30-minute wave action

after 30 minutes of wave action; the results are listed in the lower rows of Table 2. Assuming these quantities are all independent of time, a calculation was done with breaker characteristics obtained from Eqs. (12a) and (12b).

Figure 12(a) shows that the calculation overestimates the nearshore zone profile, and that the calculation and the experiment are in fairly good agreement only in the early stages. A noticeable disagreement is evident in the mid-late stage. Both the nearshore beach profile and the shoreline changes in Fig. 12(b) show that the calculation and the experiment are in good agreement during the early stages. However, the disagreement becomes marked after these stages, like the result of the former case. One of the reasons for this would probably be the neglect of the effect of wave-topography interaction. Some modification of this model is therefore needed.

CONCLUSIONS

Vortices formed over asymmetric ripples with suspension-dominant transport play a vital role in continuing a net offshore sand transport in this mode of suspension. A validity check using two existing data sets indicates that the eroding-beach model worked fairly well in predicting the erosional features in the early stages.

ACKNOWLEDGMENTS

The horizontal-bed experiments were performed while the author was at the Coastal Engineering Laboratory, University of Tokyo; the supplementary experiment on a sloping beach was conducted using the facilities of the Environmental Research Center, University of Tsukuba. This study was partly supported through the Science Research Fund of the Ministry of Education.

APPENDIX

Figure A-1 is taken from Battjes (1974), in which γ_b = ratio of breaker height to depth = H_b/h_b , and ξ_0 = surf similarity parameter = $\tan \beta / (H_0/L_0)^{1/2}$. He stated that $\gamma_b \approx 0.8$ for $\xi_0 \leq 0.2$ and that γ_b increases slightly with increasing ξ_0 for $\xi_0 > 0.2$. However, such a general tendency as indicated by the dashed line (drawn by the present author) is clearly seen in spite of the considerable scatter of the data points. This line is expressed by

$$\gamma_b = 1.1 \xi_0^{1/6}$$

or

$$H_b/h_b = 1.1 (\tan \beta)^{1/6} (H_0/L_0)^{-1/12} .$$

Figure A-1. Breaker height-depth ratio vs. surf similarity parameter (Battjes, 1974).

CHAPTER 66

NEARSHORE CURRENTS ON A PARTIALLY ROCKY SHORE

BY

T. O. Sasaki*, H. Igarashi** and S. Harikai**

ABSTRACT

Nearshore circulation on a partially rocky shore at Haranomachi Beach, Fukushima Prefecture, Japan has been studied in terms of field observations and numerical experiments for a low energy wave regime and with a physical experiment for a high energy wave regime. No significant distinctions were found in current velocity and rip current spacing between rocky and sandy beaches for the low energy wave regime, however the positions of rip currents were affected by wave refraction from the offshore exposed rocky bottom. On the other hand, since the surf zone bed is largely occupied by an exposed rocky floor for the high energy wave regime, the circulation exhibited fairly irregular patterns, so that a rip current becomes difficult to define, however the positions of inflow across the breaker line were found to be coincident with wave convergence zone.

INTRODUCTION

Japanese coasts have been classified as "island arc collision coasts" according to the global classification of Inman and Nordstrom (1973) based on recent plate tectonics. Since the major morphological feature of these coasts are mountains, rocky coastlines claim a large share of the Japanese Islands.

Because major national parks occupy the most scenic segments associated with rocky shores, recent nuclear and conventional power stations have been and are being placed on the remaining rocky shores.

The term "partially rocky shore" is defined as a rocky shore that has a portion of its beach on an upper part of a rocky bottom profile. Geologically, it consists of less consolidated Tertiary and/or Quaternary sedimentary rocks, such as sandstone and/or mudstone.

* Chief Engineer, Nearshore Environment Research Center, 1202 Familie Hongo Bldg., 1-20-6 Mukohgaoka, Bunkyo-ku, Tokyo, 113 Japan.

** Research Engineer, Nearshore Environment Research Center, Tokyo 113, Japan.

When attempting to assess environmental impacts, such as power stations on rocky shores, coastal engineers face a general lack of information regarding nearshore processes on such shores in comparison with ordinary sandy beaches.

Since 1975, the authors have been making field observations of nearshore currents and the resulting sediment transport on such rocky shores. The study sites are on the Fukushima Coast, which is about an 80 km long rocky coast running north to south, and located about 200 km north of Tokyo, and fronting on the Pacific Ocean (Figure 1).

One nuclear power station is already operating on this 80 km stretch; one nuclear and one conventional power station are under construction; and another two power stations have been proposed. A portion of the results on nearshore circulation for one of the two proposed sites is presented here.

GEOLOGY AND MORPHOLOGY OF THE SITE

Mogi and Iwabuchi (1961) have given a general description and origin of continental shelf topographies off the Fukushima Coast. Figure 1 shows the northern part of Fukushima Coast and also gives the location of the study site, Haranomachi Beach which is about an 8 km long, somewhat embayed, shore.

The general shape of the shoreline of the Fukushima Coast is convex seaward. Roughly parallel contour-lines are found in the areas shallower than 20 m and deeper than 50 m. The remaining area, whose depths lie between 20 m and 50 m, exhibits very complicated configurations, showing relics of valleys eroded during the past glacial age. The ranges of depths here is important, because it just corresponds to the wave refraction zone. The dotted lines indicate relics of valleys traced from submarine topographic charts [Mogi and Iwabuchi (1961)]. These relics can easily be connected with present day streams on land.

The dot appearing at the center bottom indicates the location of a wave gage, whose data will be given later. The cross-sectional profiles along the "A" and "B" lines are shown in Figure 2. The profiles of neighboring drowned valleys are indicated by dotted lines.

The bottom slope of the flat terrace extending up to 40 - 50 m is about 1/500, whereas the shallowest part of the profiles up to 5 - 10 m is filled with recent sediment supplied from small streams and erosion of sea cliffs, producing beach slopes of about 1/70.

An aerial photograph in Figure 3 shows the southern half of Haranomachi Beach taken in 1979. Low lying hills and coastal plains alternately extend east and west from about 10 km inland. Small streams flow into the sea on this coastal plain at intervals of 5 to 10 km alongshore. Between them, low sea cliffs run up to 40 m in height, composed on sandstone and mudstone. The cliff at this site, seen in the center of Figure 3, extends about 1.3 km. The jetty appearing on the lower-right is Mano River Inlet, which supplies sediment to the area, about 20,000 to 30,000 m³ annually.

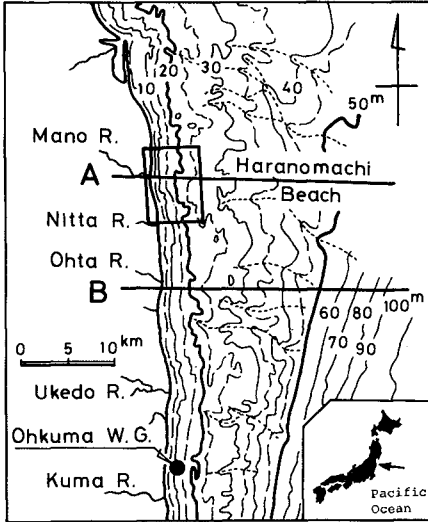

Figure 1 Continental shelf topography off north part of Fukushima Coast. Haranomachi Beach is indicated with a rectangle and dotted lines show inferred drowned valleys traced by Mogi and Iwabuchi (1961).

Figure 2 Typical profiles off Fukushima Coasts, after Mogi and Iwabuchi (1961). Range lines are shown in Fig. 1, and dotted lines indicate bottoms of drowned valleys.

Figure 3 Overview of Haranomachi Beach. Mano River Inlet jetty is seen on the lower-right.

A front view of the active sea cliff at this site shown in Figure 3 is given in Figure 4. An indicator of its activity is the existence of fallen materials at the foot of the cliff. In the middle of the cliff, a dark mudstone layer is seen, the upper part of which is composed of sand and sandstone. In front of the cliff, there is a beach about 50 m wide.

A sounding chart for the region off Haranomachi Beach, which covers the nearshore topography up to about 25 m in depth and 6 km alongshore, is given in Figure 5. The cliff seen at the center bottom corresponds to the one in Figure 4. In front of this cliff, there is a beach down to a depth of 4 to 5 m. Beyond it, an exposed mudstone floor appears which is clearly seen by its irregular contour-lines. Parallel contour-lines seen at the left, indicate that the bottom there is composed of loose sediment. The coastal structure seen at the lower-left is the Mano River entrance jetty. Accretion and erosion occur on both sides of the jetty, indicating the dominant direction of longshore drift.

The geological cross-section of the range line at the left side of the mudstone bedrock is given in Figure 6. At the top, there are sandstone, mudstone, and fine and medium sand layers. At the bottom, mudstone is the base rock comprising the sea floor.

Figure 4 Front view of active sea cliff. Fallen materials are seen at the foot of the cliff.

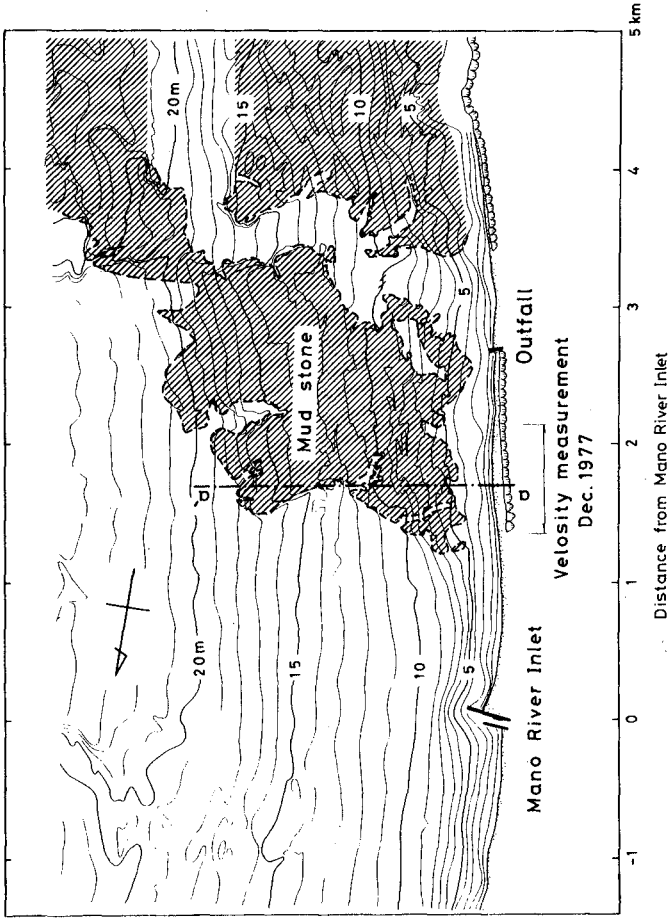

Figure 5 Nearshore topography of Haranomachi Beach. Beach sand covers the upper portion of the rocky profile (a-a' range; Geological cross-section is given in Figure 6). Location of velocity measurement is shown in the center bottom.

a-a' Profile

Figure 6 Typical geological cross-section of the site. Location of the a-a' range line is given in Figure 5.

WAVE CLIMATE OF THE AREA

Wave climate data are available from the Ohkuma wave gage as shown in Figure 1. The gage depth is 12 m. Using refraction diagrams, Ohkuma wave gage data over a 5 year period from 1966 to 1971 were converted to wave heights off Haranomachi Beach and allowed us to fill in the lack of records, by wave hindcasting. The resulting combined plot of frequency of wave heights and periods is shown in Figure 7. The typical wave height range is less than 4 m, and the wave periods range from 8 s to 14 s. The maximum significant wave height during this period was 8.3 m in November, 1970.

Wave directions were obtained by visual observation twice daily with a transit at Ohkuma observatory at the Fukushima 1st Nuclear Power Station, Tokyo Electric Power Co., Inc. As shown in Figure 8 the most dominant direction is obviously normal to the shore, that is, from the east.

The preponderance of normally incident waves is evidently caused by the fairly gentle continental shelf profile as shown in Figure 2, and is important in view of wave refraction, which in turn may produce a certain wave height distribution alongshore.

Figure 9 is a typical refraction diagram [Wilson (1966)] for 10 sec waves incident normally onto the northern Fukushima Coast from the east. Wave convergence and divergence caused by the diversified offshore submarine topography as shown in Figure 2 are clearly seen.

Figure 7 Combined plot of frequency of wave heights and periods over a 5 year from 1966 to 1971 off Haranomachi Beach.

Figure 8 Wave rose at Ohkuma wave Observatory at the center of Fukushima Coast, modified after Toyoshima et al.(1973).

Figure 9 Refraction diagram of 10 s waves incident normally to the northern Fukushima Coast.

NEARSHORE CURRENT OBSERVATION ON HARANOMACHI BEACH
UNDER LOW ENERGY WAVE CONDITIONS

Measurements of rip current spacings were made by the tethered float technique[Sasaki et al. (1978)], seven times between December 1977 and August 1978 on a beach section about 8 km long, south of the Mano River Inlet. The southern end of this beach section is bounded by a small groin shaped irrigation drain. Also, velocity field measurements using a balloon[Sasaki and Horikawa (1975)] were carried out in December 1977 in front of the cliff, as shown at the center bottom in Figure 5.

Results from three of the seven measurements are shown in Figure 10. The CASE numbers appearing at the top also give a rough indication of wave height, and they correspond to about 1 m (1.0 m), 2 m (2.4 m), and 3 m (3.1 m), respectively. The wave periods were 11 s - 12 s, and the widths of the surf zone, X_b , were 60 m, 120 m, and 150 m, respectively. Wave directions outside of the breaker line were measured by transit.

In CASE-1, a pure southward longshore current system extending about 2 km long due to northerly incident waves is apparent, except near the Mano River Inlet. Such a typical longshore current has rarely been seen on such a gentle beach like this. On the other hand, several rip currents developed in CASE-2 and 3, resulting in the formation of an asymmetrical cellular circulation[Harris (1969)].

The circulation patterns do not exhibit large differences from those on ordinary sandy beaches under a similar wave climate, because beach sediments cover the surf zone or nearshore zone sea floor down to a depth of 4 to 5 meters as was seen on the sounding chart.

However, comparing the positions of rip currents with refraction diagrams, it is found that the positions of rip currents coincide with regions of wave divergence, particularly in CASE-3. The ratio of rip current spacing to the surf zone width also shows no significant differences from those on a sandy beach.

Additional evidence for the similarity of this rocky beach to a sandy beach was obtained from computing the bottom roughness length from velocity measurements. On the day following CASE-3 in Figure 10, velocity measurements in front of the northern end of the cliff (Figure 11) were made by aerial photography from a tethered balloon. The breaker height and period were 1.7 m and 12.5 sec, respectively. The wave incidence was somewhat shifted to the north. And it was almost windless.

Figure 12 shows comparisons of the observed velocity field with computed ones using Sasaki's(1975) numerical model, which applies Jonsson's(1966) wave friction factor on Noda's(1974) circulation model. The southward longshore current is dominant in the observed velocity field and its velocity ranges around 50 cm/s. Computations of the velocity field were made with roughness lengths of 2 cm, 5 cm, and 10 cm. Comparison of the computed velocity fields with the observed one shows that the 5 cm roughness length gave the most reasonable estimate of the current velocity.

Figure 10 Selected observed nearshore current patterns under low energy wave conditions on Haranomachi Beach.

Figure 11 Aerial photograph of a part of Haranomachi Beach where the velocity measurements was made.

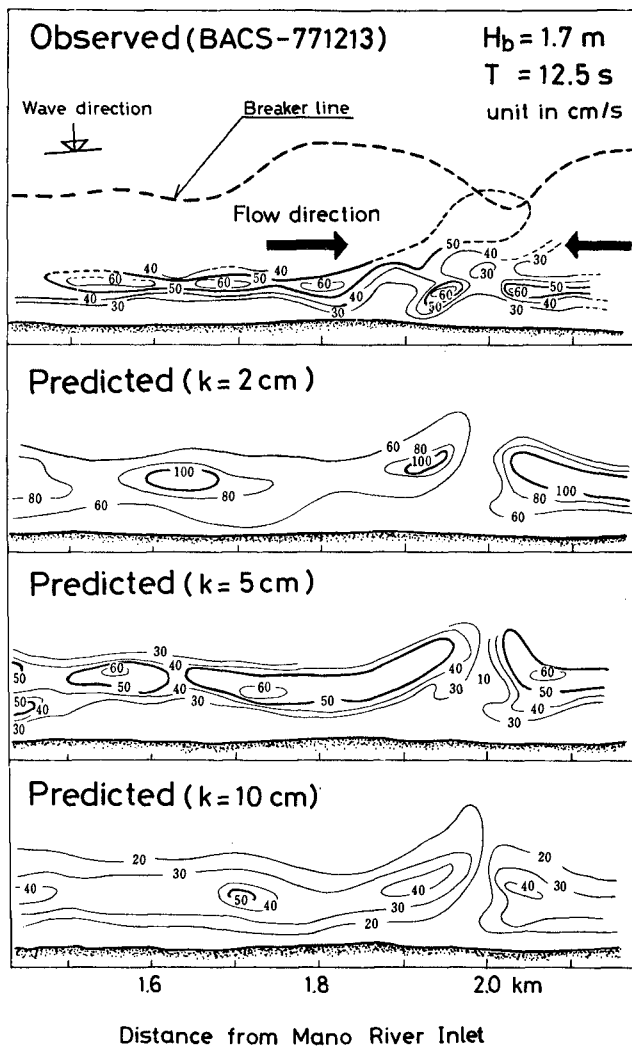

Figure 12 Comparison of observed and predicted current speeds. Reasonable estimate of the current speed is given when roughness length for the bottom, k is 5 cm.

This value falls within a representative value for a sandy floor [Jonsson et al.(1974), Skovgaard et al.(1975)], and provides strong evidence of the similarity of this partially rocky shore to a sandy beach in a low energy wave regime. In contrast, for a primarily rocky floor, the authors have found that the values of the bottom roughness should be greater than 20 cm.

PREDICTED NEARSHORE CIRCULATION PATTERN UNDER STORM WAVE CONDITION IN A LABORATORY WAVE BASIN

To simulate currents in a high energy wave regime, laboratory experiments were performed on a fixed bed in a 70 m wide by 40 m long wave basin at the University of Tokyo. Figure 13 shows the laboratory set-up of the fixed beach model scaled to 1/125. No distortion of the vertical scale was made. About 8 km of the somewhat indented shore bounded by promontories was modeled down to a depth of about 25 m. Seven 10-m long regular wave generators were arranged as seen in the top of Figure 13. About half of the sea floor area to be tested was covered by exposed base rock.

Under high seas, the surf zone bed, particularly the breaker zone bed, is largely occupied by an exposed rocky bed similar to a laboratory fixed bed. High energy wave regimes for deep water wave heights of 4 m and 6 m were simulated. The corresponding model wave heights were 3.2 cm and 4.8 cm, respectively. The wave incidence was normal to the shore as frequently occurs in the field.

Wave heights were measured by a capacitance type on-offshore direction wave gage array placed successively alongshore and consisting of 11 sensors. Nearshore current fields were measured with an array of 5 motor-driven cameras, tracing dye patches and small floats released in the nearshore zone. Current directions were also measured with 15 cm long yarns attached at one end to each 1-m reference grid spacing on the floor.

Figure 14 shows the resulting current patterns for both cases, indicating very irregular circulation patterns. The thick black and white arrows denote northerly and southerly currents, respectively, and the thick broken lines indicate the breaker line. Widths of the surf zone averaged 500 m and 1000 m, respectively.

Due to their complex circulation pattern, it is not as easy to define rip currents as on a sandy beach, but the location of the inflow of water into the surf zone can be identified without much difficulty. Comparing these nearshore circulation patterns with refraction diagrams, keeping in mind the above facts on the characteristics of irregular current patterns, it is found that the positions of the onshore currents entering the surf zone at the breaker line are significantly controlled by the location of wave convergence due to refraction over irregular offshore submarine topographies. However, coincidence between positions of rip currents and wave divergence was less significant than for the onshore current.

Figure 13 Laboratory set-up of 1/125 scaled fixed bed model in a 70 m x 40 m wave basin at the University of Tokyo.

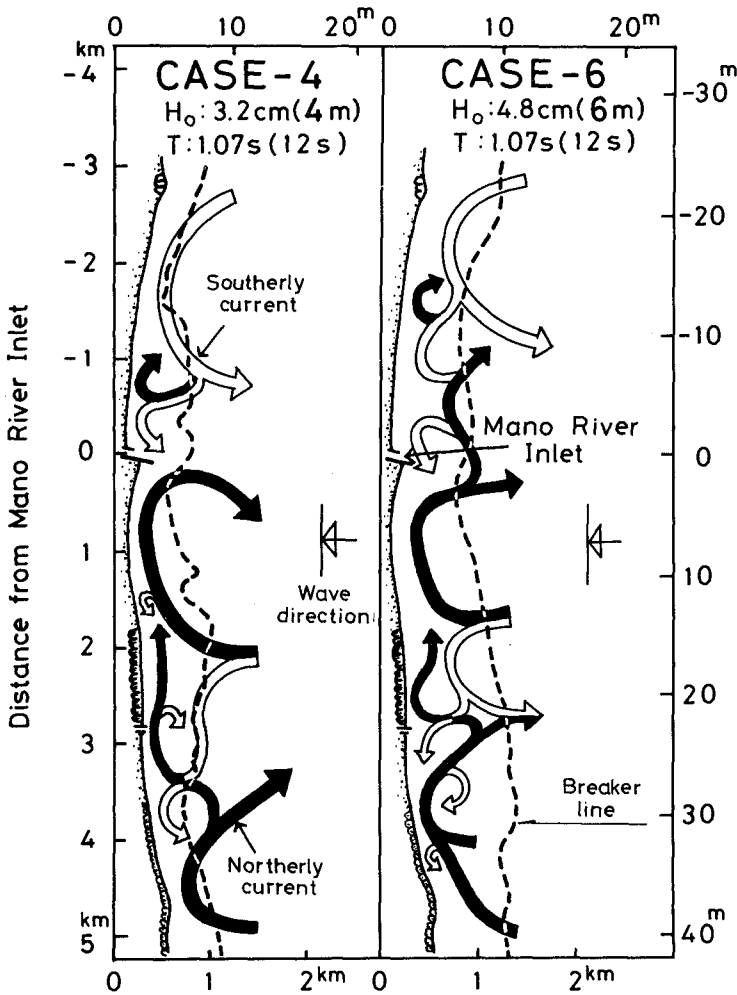

Figure 14 Predicted nearshore circulation pattern under high energy wave conditions for 4 m and 6 m waves in the laboratory wave basin.

DISCUSSION

A plot of the positions of water inflow, measured in the laboratory, and of rip currents, measured in the field, on a 12 s period wave refraction diagram for normally incident waves is shown in Figure 15. Good correlations can be seen between the positions of wave convergence and water inflow (larger open arrows), and between the positions of wave divergence and rip currents (smaller arrows) as stated above. Because a detailed sounding chart necessary to provide a finer wave ray separation, as seen in Figure 15, was not available in the offshore region beyond a depth of about 25 m, the effects of refraction due to the drowned valley (Figure 1, 2) have not been included in Figure 15. However, the increase of refraction due to inclusion of drowned valleys would not change the major conclusions, since its extent is not so large compared with refraction on nearshore zone (Figure 9).

A very similar and comprehensive study has been made by Shepard and Inman(1950) in the early stage of coastal engineering. However, the La Jolla and Scripps Canyons, where they did their study has a much more pronounced topography and is located nearer (approx. 300 m) to the shore than those here. Thus we expect that the effects on wave refraction should be much larger in their study.

CONCLUSIONS

- 1) In the low energy wave regime, no significant differences were found in the current velocity, rip current spacing and bottom roughness for a sandy beach. However, the positions of rip currents were coincident with wave divergence points due to refraction over an offshore exposed rocky bed.
- 2) In the high energy wave regime, currents exhibited a fairly irregular circulation pattern. However, the positions of inflow across the breaker line were found to be coincident with the wave convergence points.

To quantify nearshore currents on a rocky shore, nearshore current velocity measurements in the high energy wave regime would be necessary to evaluate bottom frictional forces.

Figure 15 Comparison of positions of rip currents and inflows with positions of wave divergence and convergence on a 12 s refraction diagram incident normally to the shore. Larger open arrows and smaller arrows indicate the points of inflow in high seas and rip currents in low energy waves, respectively.

ACKNOWLEDGEMENT

The present research includes partly the work performed under the general direction of the Soso Coast Beach Erosion Review Committee chaired by Professor T. Iwasaki, Tohoku University, under the auspices of Technology Center for National Land Development under contract with INA Civil Engineering Consulting Co., Ltd., Tokyo.

Without kind and constructive directions of Professor K. Horikawa, University of Tokyo and Dr. S. Sato, Port and Harbor Research Institute, Ministry of Transport, such a large scale laboratory experiment could not be made. The permissions given by the Tohoku Electric Power Co., Ltd., Sendai, and the Technology Center for National Land Development, Tokyo, for the reproduction of data and figures of the field observations and laboratory measurements are gratefully acknowledged.

Also thanks are due to proofreading by Dr. R. S. Farinato, drawing by Mr. S. Kubota, and typing by Mrs. H. Yokoi.

The findings in the present paper are not to be construed as an official Soso Coast Beach Erosion Review Committee position.

TOPOGRAPHIC CONTROL OF RUN-UP VARIABILITY

Mark P. Bradshaw

Coastal Studies Unit, Dept of Geography
University of Sydney
N.S.W. 2006 Australia

ABSTRACT

This paper presents observations of currents recorded in the swash zones of a number of morphologically different types of beaches in order to demonstrate the large variability in run-up patterns that exists primarily because of variability in beach face and surf zone configuration. Run-up spectra are shown for steep and flat beaches under low (<0.5m) and moderate (0.5-2.0m) wave energy. The longshore variability of run-up patterns on rhythmic beaches is also discussed. On reflective beaches run-up occurs only at incident wave frequency under low energy conditions and at both incident frequency and its first subharmonic under moderate energy. Low energy dissipative beaches exhibit a range of frequencies across the swash zone from incident through low frequency infragravity. As wave height increases on flat beaches, high frequency oscillations vanish leaving a concentration of energy at low infragravity frequencies. On more complex inshore rhythmic topographies under low to moderate energy conditions, alternating transverse bars and troughs give rise to a close spatial co-existence of zones of surging, reflective run-up and zones of over-running progressive bores of the type observed on flat profiles.

INTRODUCTION

In the recent literature on nearshore and surf zone processes several papers have placed considerable emphasis on the interdependence of morphologic features and hydrodynamic regimes. Of particular note are those by Chappell and Wright (1979), Chappell and Eliot (1979), Short (1979), Wright et.al. (1979) and Short (1980).

These papers point out either explicitly or implicitly that the morphologic and hydrodynamic characteristics exhibited by a beach at any one time are the result of mutual interaction between process and beach form and that

many feedback loops, both positive and negative, are involved. Some (eg. Wright et.al, 1979) demonstrate quite clearly that the nature of nearshore hydrodynamics is not uniform across the range of beach types that we commonly find in nature. Others (Chappell & Eliot, 1979; Short, 1979 & 1980) discuss beach changes over time and consider how existing morphologic and hydrodynamic conditions are, to a large extent, a function of antecedent conditions.

All, however, have in common the consideration of process/form interaction and because of this they complement a large body of literature which describes various hydrodynamic and sedimentologic characteristics of sandy beaches but does not (except in a few cases) explicitly link these to beach morphology.

The reports cited above mainly confine their attention to the nearshore/inshore zone and treat it essentially as a single unit. However, smaller sub-systems can be studied in the same way and it is the intention of this paper to focus more closely on the swash zone.

Most workers addressing problems related to swash zone processes have done so either with the view of (i) extending and refining hydrodynamic theory as applied to run-up on steep beaches of uniform slope and simple morphology (see Meyer and Taylor, 1972, for a review of these studies), or of (ii) describing and explaining the nature of swash/backwash processes on real beaches (eg. Sonu et.al., 1974; Waddell, 1973). There have been few comments from either group on the relationship between beach face morphology and run-up characteristics such as swash/backwash velocity fields, swash frequency domains and sediment transport mechanisms. Huntley and Bowen's (1975) discussion of steep and shallow beaches is a notable exception.

This paper focuses on the frequency characteristics of the swash zone and presents field data which relates run-up frequencies to beach face morphology over a range of beach configurations. The aim, however, is not only to present relevant field data but, more importantly, to demonstrate the great variability of swash zone processes which hitherto, have been treated as being similar across the range of beach face types.

FIELD SITES AND METHODOLOGY

Swash zone data and observations used in this paper were collected as part of a larger study of the nearshore processes operating on the beaches of the Southeastern Australian coast. Beaches of all kinds were observed

ranging from the flat dissipative extreme to the steep reflective extreme and including a number of examples with more complex types of inshore morphology (Wright et.al.,1979). Experiments were carried out under wave energy conditions ranging from low (<0.5 metre primary break) to moderate (0.5 to 2.0 metres). It is important to note that in all cases incident waves were dominated by moderate to long period swell ($T > 10$ seconds). This contrasts with reports of nearshore experiments in other parts of the world where short period wind wave conditions predominate (eg. US Atlantic and Gulf Coasts).

Current data were collected using miniature bi-directional ducted flow meters and water surface oscillations were obtained from bottom mounted pressure transducers. Details of these instruments are discussed by Bradshaw et.al. (1978). Spectra were computed using the auto-correlation method (Bendat and Piersol, 1971) and raw spectral estimates were smoothed with a Tukey filter. Since this paper is concerned only with run-up frequencies observed on natural beaches all spectral estimates are non-dimensionalized relative to the maximum for the series.

THE OBSERVATIONS

Field observations are considered for each different type of beach morphology in turn. Data are presented for these beaches under low and moderate wave energy conditions and the effects on run-up of tidal fluctuations in water level are noted.

1. Steep Beaches

This type of beach is common on sections of the Southeast Australian coast that exhibit a high degree of compartmentization. It tends to be sheltered and coarse grained and has the morphologic characteristics of a steep linear beach face (slope > 0.12), a prominent step at the breakpoint and relatively deep water immediately seaward of the step (Figure 1). Waves surge up the beach face under low energy conditions but change abruptly to plunging or collapsing as wave heights rise above about 0.5 m.

The only rhythmic features observable on this type of beach are cusps. These are regularly spaced and are of small scale but are not always present. When cusps are absent, the beach, because of its simple configuration closely resembles an artificial laboratory beach and run-up patterns, especially under low energy, are simple and uniform along shore.

Figure 1: Typical cross section of a reflective beach (after Wright et.al., 1979)

When cusps are present however, run-up patterns generated by the longshore rhythmic undulations of the beach face are far more complex especially under high energy conditions. Data are discussed here only for non-cusped or very weakly cusped reflective beaches.

An example of a low energy reflective beach is shown in Figure 2. For most of the time waves surge up the beach face for a short distance and return completely before the onset of the next surge. Collisions at the base of the beach face between the backwash from one wave and the runup from the following wave are rare.

The spectrum of water motions on the beach face and slightly seaward of the step is shown in Figure 3. Of note is the fact that all energy on the beach face is confined solely to incident frequency oscillations with no evidence of subharmonic or infragravity peaks. This is in accordance with the suggestion by many (eg. Huntley & Bowen, 1975) that the collision process at the base of the step is largely responsible for the generation of oscillations at frequencies below that of the incoming waves.

Figure 4 shows a moderate energy reflective beach. Waves now collapse or plunge on the step sending swash high up the beach face, often resulting in over-topping of the berm. The backwash almost inevitably ends in a turbulent collision at the base of the step. Under these conditions

we note the emergence of water motions at twice the period of the incident waves both on the beach face and seaward of it. Figure 5 is an example of the spectrum which we consistently observe on reflective beaches under moderate energy wave attack.

The importance of tides is minimal on purely reflective beaches particularly when waves are small. Even at low tide water depth seaward of the step remains deep relative to wave height.

It should be noted that the profile shown in Figure 5 is not that of a purely reflective beach (as defined by figure 1) because of the existence of the bar seaward of the step. It is used here for two reasons: (i) the depth of water at high tide was such that no energy was dissipated in breaking over the bar and the profile was reflective, and (ii) the example illustrates the behaviour of sections of a more complex type of beach topography at high tide, a point which is discussed later in the paper.

2. Flat Beaches

Flat beaches with gradients of less than 0.02 occur mainly in high energy exposed environments or in areas where there is an abundant supply of fine grained sediments. They have a wide surf zone often exhibiting one or more linear bars (Figure 6). Waves plunge on the bar under low to moderate energy conditions with an increasing incidence of spilling breakers as the energy rises. Under all energy conditions the result is a shoreward progression of over-running, dissipative bores. Set-up is large on these beaches compared to steep profiles and has been shown to oscillate at surf beat frequencies (Sasaki et.al., 1977).

Figure 7 shows a low energy dissipative situation where a single plunging break results in a bore which travels inshore retaining its initial shape and velocity through most of the traverse. Only in the vicinity of the limit of uprush do successive bores begin to overrun each other.

Compared to the higher energy situations, turbulence is relatively low in the zone between the breaker line and the limit of uprush. Individual bores can often be followed across the surf zone from their originating wave to their landward limit.

Shore normal current spectra for two stations landward of the breaker line on a low energy dissipative profile are shown in Figure 8 (U-swash and U-mid surfzone). The current meters were located 5-6 metres landward of the

Figure 2: Low energy reflective beach.

Figure 3: Typical run-up spectra from a low energy reflective beach.

Figure 4: Moderate energy reflective beach.

Figure 5: Typical run-up spectra from a moderate energy reflective beach.

Figure 6: Typical cross section of a dissipative beach (after Wright et.al., 1979).

break point and about 5 metres seaward of the maximum run-up excursion. The figure reveals the following:

- (i) expected peaks for the outer instrument at both incident and infragravity (surf-beat) frequencies and for the inner instrument at infragravity frequency;
- (ii) a peak at half the incident wave frequency on both the inner and outer instrument, a phenomenon normally observed on steep beaches; and
- (iii) an unexpected peak at incident wave frequency at the inner instrument.

This last phenomenon can clearly be seen from visual observation of the surf zone and suggests that when low amplitude, long period swell acts on a flat profile, the beach does not eliminate high frequencies to the extent that was first described by Emery and Gale (1951) and later by Waddell (1973), Sonu et.al.(1974) and Huntley and Bowen (1975). The appearance of incident wave frequencies at the top of the beach face can be attributed to the low turbulence in the surf zone and also to the long period of the incoming swell which gives bores time to cross the entire surf zone before they are interfered with by those following.

Discovery of the nature and extent of subharmonics on flat, low energy beaches requires more experiment replication. During the particular experiment referred to in Figure 8, swash/backwash collisions resulting in short lived hydraulic jumps (or roll waves) were occurring regularly at the top of the swash zone, about 10 metres seaward of the inner instrument station. However, even after viewing time lapse film records it was not evident what effect the collision was having on the swash period landward of it.

Figure 7: Low energy dissipative beach.

Figure 8: Typical run-up and surfzone spectra for a low energy reflective beach.

Figure 9: Moderate energy dissipative beach.

Figure 10: Typical run-up and surf zone spectra for a moderate energy reflective beach.

Figure 9 shows a dissipative profile in a much higher energy environment. Here a dual linear bar-trough system is present. Waves break on both bars and the resulting bores travel across a wide, highly turbulent surfzone. Larger bores often reform over the trough landward of the inner bar causing a secondary break higher up the beach.

The run-up spectrum for this moderate energy dissipative beach (Figure 10) shows a complete absence of energy at incident wave frequency and a dominance of energy in the low frequency infragravity domain. This is not only the case for shore normal currents at the top of the beach face but also for those over the inner bar. Compared to the low energy case these results correspond much more closely to those presented by workers such as Sonu et.al.(1974) and fit the classical view of the beach face as being an area dominated by low frequency oscillations.

Waddell (1973) presents evidence to show that the low frequencies on the beach face are not due to a simple low pass filtering effect but rather to a non-linear transfer of energy from high to low frequency, the result of collisions in the surf zone. Huntley and Bowen (1975) present similar results but suggest that the transfer is due to the interaction of many irregularly spaced breakers in the surf zone.

On the moderate energy dissipative beaches observed during the course of this study, it appeared that both mechanisms are important. It is certainly the case that there is a substantial modification of input frequencies as one moves across the lines of breakers and then into the turbulent bore zone. On moderate to high energy dissipative profiles the length of time that any one bore can travel shorewards without overrunning or being overrun by another bore is very short. However, backwashes with velocities greater than 1.5m/sec were recorded on many occasions and collision between these and shoreward moving bores resulted in roll waves lasting up to (and sometimes longer than) 10 seconds and with heights ranging to 0.5 metres. It is to be expected therefore that these are also considerably important in determining the range of frequencies operative on this type of beach.

3. Rhythmic Beaches

Many of the beaches on the Southeast Australian coast fall in between the two extremes discussed above and are characterised by complex rhythmic topography alongshore. Typically they consist of alternate anvil shaped shoals or transverse bars separated from each other and the beach face by well developed rips and feeder channels. Papers by Wright and Short (both in this volume) discuss the range of

complex morphologic types in greater detail; however an example from the New South Wales coast is shown in Figure 11.

Depending on the stage of the tide, run-up patterns on this type of beach will either be uniform in the longshore direction or will show marked variation as one moves alongshore. Wave height is also important in determining the form of the run-up along the entire beach.

At high tide, under both low and moderate energy, the shoals are usually sufficiently deep that no breaking occurs over them. Instead the waves surge or plunge on the steep beach face that lies landward of the shoals. Because the sections of beach in front of rip feeders present a reflective face to the incoming waves at all times, the overall picture at high tide is one of continuous reflectivity along the entire shore. An example of this condition was presented earlier in Figures 4 and 5.

At low tide shoals emerge and become active, leaving an inactive steep beach face behind them. The longshore pattern now changes to one of alternating zones of reflective and dissipative run-up. The beach face fronting rips and rip feeders continues to exhibit reflective characteristics while the shoal regions display the characteristics of a dissipative beach. Run-up spectra taken at intervals alongshore vary accordingly.

Figure 11: An example of well developed rhythmic topography.

CONCLUSIONS

A summary of the observations discussed in this paper is presented in Table 1. The following points arise:

(i) Sandy beaches can exhibit morphologic variability both between different beach systems and also within individual beach compartments. The data discussed and summarised in Table 1 show that run-up characteristics vary as a result of these spatial differences in beach face topography. This paper considers only the frequency of run-up to demonstrate the point but the same variability can be observed in all hydraulic and sedimentary processes operating on the beach face.

Given the wide variability of the processes under consideration, account should be taken of the morphology and wave conditions for the particular beach being investigated when analysing and presenting swash zone data. This is very important for purposes of meaningful data comparison.

(ii) Understanding of swash zone processes and the nature of their interrelationship with beach morphology will ultimately come only from studies conducted over a range of sandy beach environments. The question of the swash-backwash collision process and its effect on sediment entrainment and transport on different beach slopes is significant and may be a good starting point for more specific process investigations. Initial observations show that on a steep beach the collision at the bottom of the slope bears directly on short term changes in step morphology and also influences sediment transport higher up the slope through its controlling effect on run-up and backwash velocities. On flat beaches the area of interaction is less narrowly defined and the collision results in the temporary suspension of large volumes of sediment in the roll wave. Detailed studies in this area have yet to be carried out.

ACKNOWLEDGEMENTS

Data presented in this paper were collected as part of a program funded by the Australian Research Grants Committee and by the U.S. Office of Naval Research, Coastal Sciences Program, Task NR 388-157, Grant N-00014-80-G-0001. All members of the Coastal Studies Unit have participated at one time or another in the arduous task of collecting field data and I thank them for their assistance. Valuable help and discussion were also provided by I. Eliot, J. Lanyon and A. Learmonth. L.D. Wright reviewed the paper and J. Roberts and M. Rigney produced the diagrams.

Table 1: A summary of observed relationships between surf zone and swash zone morphology and characteristic run-up spectra.

MORPHOLOGIC TYPE		WAVE ENERGY		
		LOW (<0.5m)	MODERATE (0.5-2.0m)	HIGH (>2.0m)
STEEP (REFLECTIVE)		Incident dominant No subharmonic	Incident & subharmonic	
FLAT (DISSIPATIVE)		Incident, Subharmonic & infragravity (~40-60 sec)	Attenuation of incident subharmonic frequencies	Long period infragravity (>60sec) Rapid shoreward attenuation of incident frequencies
COMPLEX MORPHOLOGY (e.g. alternating transverse bars & troughs)	HIGH TIDE	Reflective run-up incident dominant	Reflective run-up incident & Subharmonic	As above
	LOW TIDE	Alternate zones of reflective & dissipative run-up	As for low energy	As above

CHAPTER 68

BEACH PROFILES AND ON-OFFSHORE SEDIMENT TRANSPORT

by

Akira WATANABE, Yoshihiko RIHO and Kiyoshi HORIKAWA

Coastal Engineering Laboratory
Department of Civil Engineering
University of Tokyo
Bunkyo-ku, Tokyo
Japan

ABSTRACT

The on-offshore sediment transport due to waves on a sloping beach is studied by analyzing the laboratory test data on two-dimensional beach deformation. The net rates of sediment transport both inside and outside the breaker zone are evaluated from beach profile changes and are related to the nondimensional bottom shear stress or the Shields parameter. The importance of the critical shear stress and of asymmetrical to-and-fro water partical motion near the bottom is pointed out.

INTRODUCTION

Much effort has been devoted during the last few decades to elucidate sediment movement phenomenon in coastal zone, but it was not so long since intensive attempts were started to set up numerical models simulating beach processes. Prediction of beach transformation requires knowledge about the functional relationship of sediment transport rate to conditions of waves, currents, water depth, bottom configuration, sediment property and so on. There have been many, almost innumerable, studies on sediment transport rate, and considerable amount of knowledge on this problem has been accumulated so far. Yet it seems that we are still far from a reliable formula estimating the rate of sediment transport in particular perpendicular to coastline. This directional mode of sediment movements, or on-offshore sediment transport plays a vital role in the short-term beach deformation such as severe beach erosion due to storm surge. This may be also quite essential for more detailed understanding of longshore sediment transport, because the latter is expected to correlate with the former through the sediment sorting and entraining mechanics.

In the present study the on-offshore sediment transport was dealt with by analyzing the data obtained in laboratory experiments. In order to attain our purpose of getting the on-offshore transport rate formula of practical use in predicting beach deformation inside and outside the breaker zone, experiments were conducted under sloping beach condition. Two-dimensional beach deformations under various wave conditions were measured. Any equipment, such as a sand trap, to measure directly the sediment transport rate was not used in this test, because such apparatus would cause severe disturbance to the fluid motion and the sediment movement. Instead the net rates of sediment transport were estimated from the beach deformation data. Attempts to find the relationship between the net transport rates and wave conditions were then made.

EXPERIMENTAL PROCEDURES

Experiments were conducted in a two-dimensional wave flume, 25 m long, 1.5 m deep and 0.8 m wide. As mentioned above, the net rate of on-offshore sediment transport was evaluated from the beach profile changes. In order to make simple the experiments, data handling and interpretation of results, tests were limited to a uniform initial slope and to the wave action of one-hour for each wave condition, while wide range of wave conditions was adopted.

Table 1 is a list of experimental cases. Two kinds of quartz sand with mean diameters of 0.2 mm and 0.7 mm were used as bed materials, both being well sorted with the Trask sorting coefficient of 1.1. Combination of these two grain sizes, two initial slopes of 1/10 and 1/20, three wave periods of 1.0, 1.5 and 2.0 seconds, and four or five wave heights made fifty-eight experimental cases altogether.

In each experimental case, a beach with prescribed uniform slope, 1/10 or 1/20, was initially set up, and its deformed profile after one-hour wave action was measured. Measurement of beach profiles in this experiment was done by tracing them on transparent sheets attached on a side glass wall of the flume, although a bottom profiler of electrical-resistance type, by which continuous profile data can be recorded on a magnetic tape, has become available in the latest experiment. In the middle of wave action, wave profiles were measured by capacitance type wave gages at locations of 10 to 50 cm intervals above the beach as well as at the offshore end of the flume.

EXPERIMENTAL RESULTS

Beach Profile Change

Figures 1 (a) to (d) show the beach profiles after one-hour wave action for all the cases listed in Table 1. It should be noted that profile changes in some cases with the initial slope of 1/20 and large wave heights stretch beyond the extent of these figures. The locations of breaking points are indicated by triangle symbols; open triangles for the initial stage and solid triangles for the final stage.

(d)

(c)

Fig. 1 Beach profiles after one-hour wave action (continued).

It is recognized by referring to Table 1 that the bar-type profiles are formed for relatively large wave steepness conditions, showing systematic increase in bar size with the increase of wave steepness. Under the condition of smaller wave steepness, a wide berm becomes noticeable in particular for the cases with initial slope of 1/10, implying the shoreward transport of nearshore bed material. It was observed during the experiment that the shoreward limits of significant beach change in most cases were determined by the locations of maximum runup. However no remarkable nearshore beach change took place for the cases with initial slope of 1/20 and wave period of 1.0 sec, where flow intensity of uprush was quite weak.

In case of 0.2 mm-sand, sand ripples always appeared outside the breaker zone and the sediment transport seemed predominantly in the form of suspension. When the initial slope was 1/20, sand ripples were observed in the surf zone as well, but vortex formation around those ripples were not so remarkable as it was in the offshore region.

By contrast, in case of 0.7 mm-sand, sand ripples were scarcely observed under those experimental conditions. Only in a few cases such as B-133 to 135, sand ripples appeared and vortex formation was recognized, but amount of suspended sands was pretty small. Predominant mode of sediment transport of 0.7 mm-sand was in general in the form of bed load.

Evaluation of Net Sediment Transport Rate

The net rate of on-offshore sediment transport is evaluated from two-dimensional beach deformation data as follows. Suppose a beach profile change as given in Fig. 2. In virtue of the conservation of the bed material amount, the local net transport rate $q(x, t)$ per unit width is related to the bed elevation $z(x, t)$ measured from a certain datum as:

Fig. 2 Evaluation of net sediment transport rate.

$$\frac{\partial z}{\partial t} = \frac{1}{1-\epsilon} \frac{\partial q}{\partial x} \quad (1)$$

where ϵ is the sediment porosity. Therefore the effective net transport rate $Q(x)$ averaged over a time duration Δt of wave action is evaluated from the bed elevation change $\Delta z(x)$ during the same period by:

$$Q = \frac{\bar{q}}{1-\epsilon} = \int_{x_0}^x \frac{\Delta z}{\Delta t} dx \quad (2)$$

in which x is positively seaward and x_0 means the shoreward limit of beach deformation. After such calculation, we shall obtain the spatial distribution of transport rate $Q(x)$ as shown in the bottom of the same figure.

Figures 3 (a) to (d) show spatial distributions of the effective net transport rate $Q(x)$ averaged over one-hour of wave action thus evaluated from beach profiles given in Fig. 1. Positive values of Q indicates the net transport towards the onshore direction, while negative Q means the offshore transport. The abscissa x is the horizontal distance from the initial shoreline. The locations of breaking point are again indicated by triangle symbols.

It is seen from Figs. 3 (a) and (b) that in case of 0.2 mm-sand, sediment transport towards the offshore direction is predominant in particular outside the surf zone. In few cases such as A-131 to 135 with the initial slope of 1/10 and relatively small wave steepness, the onshore net transport dominates. It is interesting to note that this onshore transport was mostly replaced by the seaward transport for the initial slope of 1/20 even under the similar deep water wave conditions. (Compare Cases A-133 and 134 with A-233 and 234, respectively.)

Figures 3 (c) and (d) for 0.7 mm-sand indicate that, in contrast to the former cases of 0.2 mm-sand, the net transport is mostly shoreward, with the exception of some cases such as B-115 where the wave steepness as well as beach slope are large. Predominant shoreward transport might be simply explained by the asymmetric to-and-fro water particle motion under large amplitude waves, since the coarse sands are transported essentially as bed load.

DISCUSSIONS

Beach Profile Changes

Two-dimensional beach transformation has been intensively studied by numerous investigators. There are many attempts to determine parameters classifying beach profiles, such as by Johnson (1949), Iwagaki and Noda (1962), Nayak (1970), Sunamura and Horikawa (1974), and Hattori and Kawamata (1980).

Sunamura and Horikawa (1974) have proposed a beach profile classification based on the displacement of topography from the initial beach slope: Type I = a shoreline retrogresses and sand accumulates in offshore

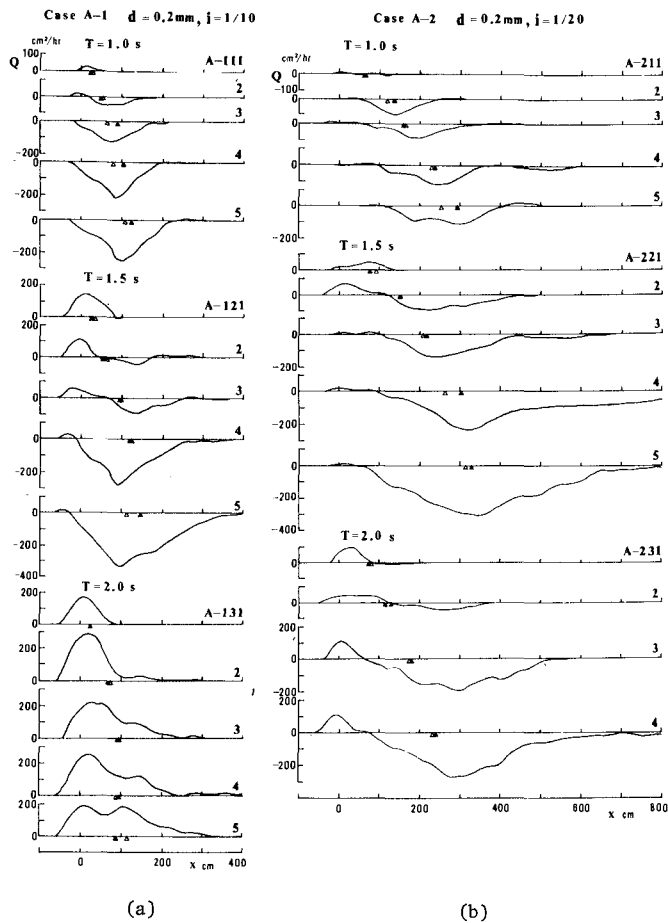

Fig. 3 Distributions of effective net transport rates.

Fig. 3 Distributions of effective net transport rates (continued).

zone, Type II = a shoreline advances and sand piles up offshore, and Type III = a shoreline progresses and no sand deposition takes place offshore. According to them, these three types are distinguished by a nondimensional parameter,

$$C = (H_o/L_o) (\tan \beta)^{0.27} (d/L_o)^{-0.67} \tag{3}$$

as:

$$\text{Type I: } 8 < C, \quad \text{Type II: } 4 < C < 8, \quad \text{Type III: } C < 4 \tag{4}$$

where H_o and L_o : deep water wave height and length, $i = \tan \beta$: initial beach slope, d : grain diameter. Critical values of C have been determined based on the experimental results on the equilibrium beach profiles after more than 160-hour wave action.

Application of this classification to the present data given in Fig. 1 yields the result shown in Fig. 4. In spite of that the present data are for quite short wave duration, they are distinguishable by the proposed values of the parameter C .

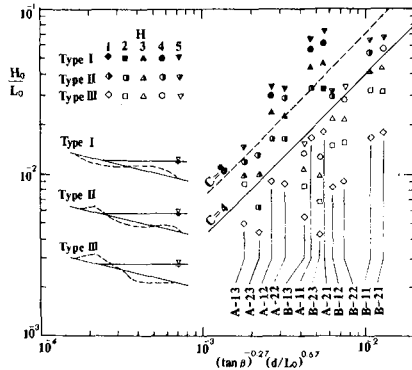

Fig. 4 Classification of beach profile changes.

Net Transport Direction of Suspended Sediment

As mentioned above, the predominant direction of net bed load transport is onshore, but that of the net transport of suspended load depends on conditions. For example, the predominant onshore transport in Cases A-133 and 134 are replaced by seaward transport in Cases A-233 and 234. One interpretation of the predominant directions of net suspended load in the present experiments will be given by Fig. 5.

Since the significant height of sediment suspension would be subject to the pitch of sand ripples, the abscissa $\lambda/w_o T$ was adopted as a param-

Fig. 5 Net transport direction of suspended sediment.

eter representing the excursion length of suspended sands, where λ is the ripple pitch, w_o the settling velocity of sands, and T the wave period. The ratio of the wave crest height η_c above the mean water level to local wave height H was chosen as another parameter in order to account for the effect of asymmetry of the to-and-fro water particle motion. Solid symbols mean the onshore transport, while open symbols the offshore transport. Figure 2 indicates that these two parameters are not always effective in classifying the sediment transport direction.

Inman and Tunstall (1972) have pointed out that the asymmetry of the sand ripple forms is important in determining the direction of the net sand transport. Although the present authors agree to their view, it should be mentioned that the asymmetry of ripple forms was not significant in the present experiment. The direction of sediment transport is indeed a very crucial problem and further intensive study on this point is definitely required.

Net Sediment Transport Rate and the Shields Parameter

Madsen and Grant (1976) have found that the so-called Shields parameter is effective in quantifying the fluid-sediment interaction in oscillatory flow as well as steady flow. They have proposed an empirical relationship of the sediment transport rate as:

$$\Phi' = 12.5 \Psi^3 \tag{5}$$

where $\Phi' = \bar{q}'/w_o d$: dimensionless transport rate, \bar{q}' : transport rate averaged over half a period of oscillatory flow, w_o : the settling velocity, d : the grain diameter, $\Psi = \tau_{om}/(\rho - \rho_s)gd$: the Shields parameter, ρ and ρ_s : the densities of fluid and sediment, respectively, and τ_{om} is the bottom shear stress amplitude defined by $\tau_{om} = f \rho u_{om}^2 / 2$ in which u_{om} is the maximum velocity at the bed and f the wave friction factor given by Jonsson

(1966). This formula is found to agree well with the experimental data for the bed load rates obtained by oscillating a plate containing sediment in still water. It should be mentioned that the quantity Φ' corresponds to the transport rate averaged over half a period, and that the net transport rate, which is directly related to beach deformation, must be evaluated as the difference between transport rates of onshore and offshore directions.

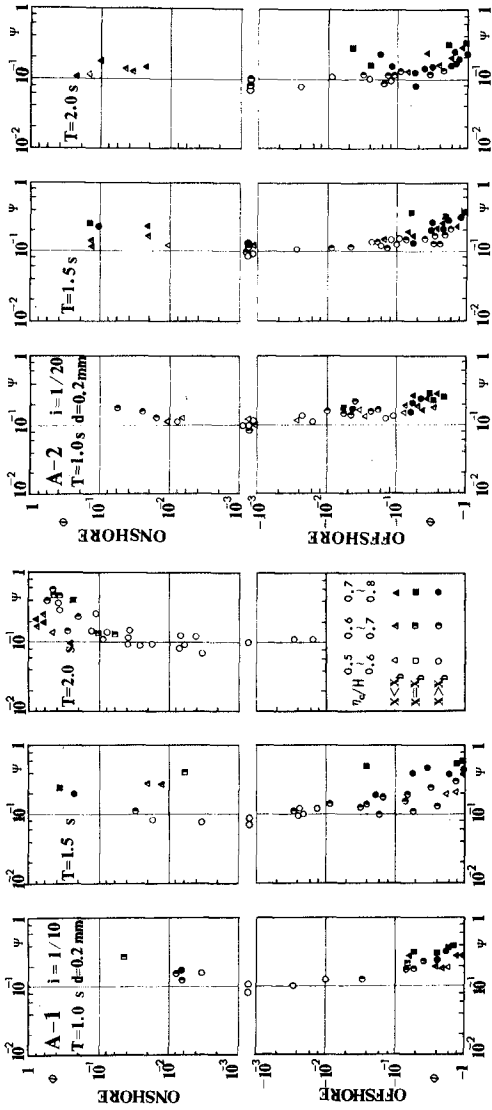

The dimensionless net transport rates $\Phi = \bar{q}/w_{\infty}d$ averaged over one-hour wave action were calculated from the present experimental data. The relations between Φ and Ψ are shown in Figs. 6 (a) to (d), where symbols are distinguished depending on the location; triangles are data obtained inside the surf zone, squares are at breaking point and circles are outside the breaker zone. Clear correlations between two parameters are recognized, though the overall scatter is not small enough.

It is interesting in particular that the relations of Φ and Ψ outside the breaker zone are almost identical, independently of bed slope, wave period and even of the transport direction. The values of Φ for a certain Ψ value inside the surf zone are mostly larger than outside; this should be investigated further by improving the estimation of bottom shear stress in the surf zone.

Now we shall consider only the data obtained outside the breaker zone. All of them are plotted together in Fig. 7 for 0.2 mm-sand and 0.7 mm-sand, respectively, distinguished by different symbols dependent on the transport direction and wave period. It is seen that the magnitude of Φ is somewhat larger for the offshore transport than for the onshore transport. Besides the larger wave period gives larger transport rate Φ .

The Madsen-Grant formula (Eq. 5) mentioned before is indicated by a broken straight line in each figure, and it seems by no means to fit well the experimental data. Since Eq. (5) corresponds to the transport rate averaged over half a period, it ought to overestimate the net rate which must be essentially the difference of the onshore and offshore transport rates. The tendency appearing in Fig. 7 is contrary to this expectation except for small Ψ values.

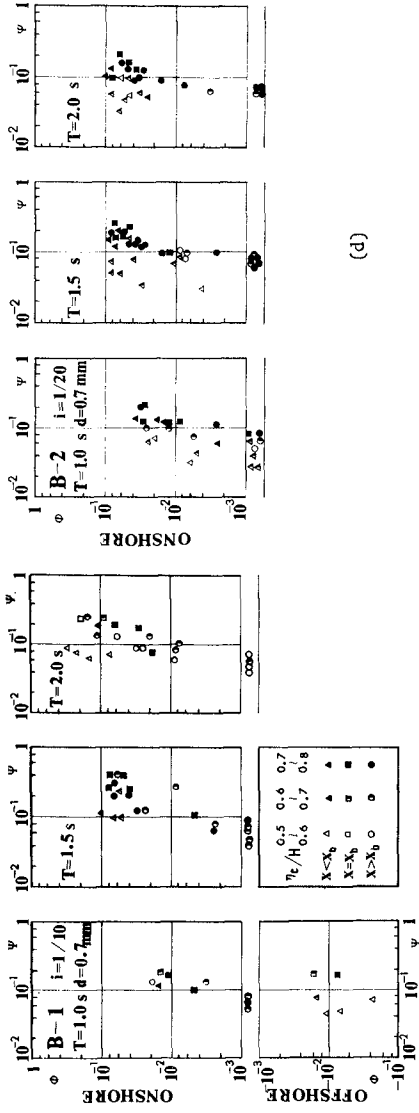

Experimental data shows the tendency that the Φ value increases rapidly with the Ψ value while the latter is small, but its increase rate gradually diminishes as Ψ increases; namely, the relation of Φ and Ψ is convexly nonlinear in logarithmic scales. This trend implies the importance of critical shear stress for the onset of sediment movement. According to the study of Madsen and Grant (1976), the critical value of nondimensional shear stress or the Shields parameter Ψ_{cr} is about 0.07 for fine sands and 0.05 for coarse material. Those values are found to fit well with the critical conditions of the so-called initial movement reported by Horikawa and Watanabe (1967). We shall find from the result of Horikawa and Watanabe (1967) that the critical Shields parameter for the onset of the general movement is to be around 0.11 for fine sands and 0.08 for coarse sands. (The terms, *coarse* and *fine*, are in fact not so appropriate because of their vague meaning. The terminology,

(d)

Fig. 6 Relationship between net transport rate and Shields parameter (continued).

Fig. 7 Summarized relationship between net transport rate and Shields parameter.

hydrodynamically *smooth* and *rough*, will be better. See Horikawa and Watanabe (1967).)

We shall assume the net transport rate is proportional to the excess of Ψ value over its critical value for the general movement just mentioned as:

$$\Phi = A (\Psi - \Psi_{cr}) \quad (6)$$

The values of proportionality constants A to give good fit with the present data are 3.0 and 1.0, respectively, as shown in Fig. 7. It should be mentioned that Eq. (6) is just an empirical relation and is not physically well-founded yet. Probably we should not expect so simple relations between Φ and Ψ , because the net transport rate must be subject not only to the shear stress amplitude rather simply evaluated but also to the local bed slope, asymmetry of near-bed velocity, mass transport velocity, ripple form, and so on. Thorough investigation of the data and more physical consideration will be needed.

CONCLUDING REMARKS

Some interesting, though unsatisfactory yet, results on the on-off-shore sediment transport on a sloping beach have been gained by analyzing the experimental data of two-dimensional beach deformation. The authors are proceeding the study on wave deformation and near-bottom velocity field on a sloping beach in parallel with the laboratory tests similar to experimentation herein reported. Such investigation will be quite useful to improve the interpretation of experimental data.

SECONDARY SAND TRANSPORT MECHANISMSBy A.W. Smith¹ and A.D. Gordon²

INTRODUCTION

The basic concept of coastal littoral drift consisting of a "river" of sand driven by the direct alongshore component of oblique waves has long been considered as a basis for littoral transport equations. This concept however is highly simplified since the actual littoral drift on real beaches represents only the final result of the inter-action of dozens or perhaps hundreds of secondary hydraulic processes which continuously occur in Nature. On many Coasts littoral transport is taken to represent the primary mechanism of beach recession or build-up but many of the secondary mechanisms themselves are only partially understood and their individual contributions to the primary process largely unexplored. This paper therefore discusses some of these secondary processes and since off-shore-onshore sediment transport is probably the most important of these a mechanism for this transport mode is suggested based upon the interaction between wave energy and a work capacity parameter for the beach sediments.

GEOGRAPHICAL FACTORS

In considering a coast in plan view many factors that might loosely be described as geographical are readily observed. Headlands and groynes generate complex hydraulic phenomena. Such "hard" surfaces not only generate re-alignments of the sea-bed sediment but they also discharge rip currents and shed vortices which may carry large volumes of sediment to distances exceeding a kilometer out to sea.

Creeks and river discharges may also behave as groynes with the tidal discharges into and out of the river acting as a hydraulic barrier "jet-stream". The barrier effect of tidal jets can be such that Nature must form extremely large delta deposits at the tidal outfall zone offshore of the beach before littoral transport can function within an effective combination of attenuated jet velocity, water depth and wave breaking energy.

1. Civil Engineer, Gold Coast, Queensland, Australia
2. Engineer, Coastal Branch, Dept. of Public Works, N.S.W. Aust.

A further obvious plan-form phenomenon of beaches, particularly within the unstable responsive state between fine weather small wave steep profile and high storm energy flat profile beaches is the development of cusped beach shapes at the water-aerial beach interface i.e. stages 2 to 5 of the Short Model (Ref 1). The hydraulic processes which generate these beach forms must be highly complex but they clearly must exert a profound effect on long shore littoral transport. Much evidence is beginning to emerge that suggests that sand transport occurs in slugs or pulses and cusped shapes have long been observed to migrate in the direction of the littoral drift as of the time.

Under long-shore transport conditions rip-currents become dominant hydraulic features of a beach during its cusped shape development and such currents have a dominant effect on beach cell water re-circulation and offshore sediment transport. In addition the inception of cusped topography leads to highly variable angles of incidence by the breaking wave even to the stage that any average or dominant angle of wave attack becomes meaningless under these circumstances. Nevertheless net littoral sand transport from cusped beach cells has been detected by tracer experiments and the driving force must consist of only the total hydraulic leakage from the cell. Clearly much study remains to be carried out on littoral transport on cusped beaches.

BEACH NORMAL PROCESSES

The most significant variability in beach response to energy input is clearly demonstrated by the hour to hour and day to day fluctuations in cross-sectional profile. The onshore-offshore movements of beach sediments call into motion much greater volumes of material in the short term, by a factor of many magnitudes, than those that can be measured as alongshore transport. If, as it seems likely, the actual littoral transport represents only the longshore component of onshore-offshore sediment movement under oblique wave energy input then it would seem essential to study the onshore-offshore processes in their own right before even addressing the ultimate problem of calculating littoral transport. It is for this reason that beach normal or onshore-offshore processes are considered as secondary mechanisms in this discussion.

SEDIMENT WAVE INTERACTION

There must certainly exist a profound but predictable interaction relationship between wave energy input and the behaviour of beach sediments. Waves change the beach shape and sediment distribution across the beach but the converse must also hold true, the behaviour of the beach sediment changes the form, shape and breaking behaviour of the waves. Beaches change slope according to wave height, offshore bars develop that induce multiple wave breaks and wave reformations with increasing size of deep water wave but why do these processes occur? Why do small swell waves generate a steep beach whilst great storm waves generate wide flat slopes? Why indeed do beach sediments exist at all? If waves destroyed energy entirely by hydraulic mechanisms the world's coast would surely all be rocky shelves. Beach sediments demonstrate a highly developed mobility in response to incident wave height, and to a lesser degree tidal variation, and it has long been taken as a basic tenet that the larger the beach particles the steeper the beach for the same wave input.

Clearly the properties of the beach particles themselves must exert a highly significant effect on the behaviour of any beach which cannot be explained by considering the properties of the waves in isolation, both form part of a highly sophisticated mechanism designed by Nature to ensure the most efficient dissipation of energy with a maximum conservation of natural resources. Many detailed descriptions exist of beach profile and wave responses with the work of Short (Ref 1) and Wright (Ref 2) probably representing the most definitive (and fascinating) statement of what might well be called an "Atlas" of beach and wave geography. It is tendered however that until the interaction between sediment properties and wave mechanics are included such work will remain largely descriptive.

SEDIMENT POPULATIONS

Beach and river sediments apparently exist in almost an infinite variety, to the extent that Nature seems to use whatsoever natural detritus that is available as of the place and the time and adjust the local geography to suit the energy demand of the ambient hydraulic process. Natural sediments do not consist of what might be described as "blocks" of particles all with the same properties but they occur in curious blends of all different sizes of particles from comparatively fine to comparatively coarse, all existing together within a finite volume.

Based on sediment grading curves as described in the literature, every natural beach sediment population contains a significant percentage of large particles and perhaps much more importantly an even more significant number of very fine particles. In normal grading analyses the "fine" contents in the "pan" are merely recorded for weight and thrown away but the fact remains that even on the most active beach exposed to the highest waves the largest particles found within the wave zone always contain a significant content of a matrix of fine particles dispersed within them.

It seems that Nature will never winnow out a sediment "blend" of particles to produce a neat-sized or gap-graded "mix", but always produces a full population encompassing the combination of a large number of particles over quite a wide range. Beach sediments thus exist and behave as integrated populations and not as groups of individual clusters of neat sized particles. It is perhaps for this reason that it is so difficult to calibrate model work carried out with sieved particles or beads almost all of the same size.

Because beach sediment populations are so wide a major difficulty is usually found in assigning some parameter that will describe the population, or its properties, in some meaningful way and if possible provide some average index of the parameter that also has some competent descriptive power. Tradition has been to adopt a "size" parameter to describe particles using either a sieve train or a settling tube to arrive at a nominal "diameter" size parameter. Whilst settling tubes should be well superior to sieving tests in that at least the settling tube tests particles within an hydraulic environment nevertheless both tests have a low standard of accuracy and reproducibility and in fact should only be reliable when they test one particle at a time.

The two major sampling and testing variables are:-

(a) Both devices are extremely sensitive to feed rate, that is the number of particles being tested together at one time. In the mineral industry sieves can be made to selectively either pass or concentrate particular particle densities, shapes or sizes by merely varying the feed rate and the analogous problems with settling tubes have been well reported e.g. McNown and Pin-Nam Lin see (Ref 3).

(b) Secondly both devices "pass" or "settle" high aspect ratio particles in a highly preferential manner, in sieves these particles pass through the mesh end-on with their greatest dimension normal to the mesh whilst the same particles settle in water with their greatest dimension horizontal and usually demonstrating some flutter or oscillation as well.

Finally in a settling tube the particles must settle under Laminar flow and surf zone dynamics must always be turbulent. It would not be surprising therefore if sediment transport equations based on some nominal size derived from either of these two tests display such wide scatter and poor correlation. The problem must result from the shape factors of the particles together with a significant contribution from their surface texture. By analogy to basic aerodynamics it might be expected that particle shape and aspect ratio might represent almost the dominant transport and drag mode and a preliminary appreciation appears to confirm this proposition for water as well. The most simple parameter available that quantifies any particles shape factor and weight is its specific surface - that is its total surface area divided by its weight. In mineral technology the term used is F and for normal beach particles the unit of mm^2/gram appears the most convenient.

Experiments carried out on a hydraulic spiral mineral separator under completely random turbulent input demonstrated that the migration of particles into high, medium and low energy zones across the spiral cross section was very strongly related to the particles specific surface and barely correlated at all with either sieve or settling tube diameters. It seemed therefore that the parameter of specific surface held much promise of providing a particle's energy response or work capacity indicator.

A most fortuitous discovery that when natural beach sediments are classified by particle specific surface is that the population is almost exactly Log-normal (See Fig 1) a property of sediments that has long been postulated but seldom detected by normal sizing methods. Intuitively the selection of specific surface to classify a particle seems reasonable also in that at least it provides a systematic integration and description of a particles properties of shape, texture, aspect ratio, specific gravity and thus weight and perhaps a good starting point for considering its overall hydraulic properties. In particular with a log-normal population distribution the ease with which borrow and native

FIG.1 - SPECIFIC SURFACE : LOG PROBABILITY DIAGRAM FOR ONE SAND SAMPLE

FIG.2 - COMPARISON OF D₅₀ ~ F₅₀

FIG. 3 — COMPARISON OF DIFFERENT PARAMETERS USED TO DESCRIBE SAME SAND SAMPLE

beach sands may be compared without recourse to deviation, skewness and kurtosis measures for example is also attractive.

As an indication of the absence of correlation between specific surface and sieve or settling tube diameter Fig 2 shows a plot of F50 against D50 for fifteen natural sediments taken up to 800 km apart on the Australian seaboard and Fig 3 shows a comparison of population diagrams as displayed by $\frac{1}{4} \phi$ sieving, settling tube and specific surface for the same sediment. Because specific surface cannot be plotted on the same graph as d or ϕ units the specific surface population has been shown as the size distribution for the actual sediment's F value converted to percentages of various sized purely spherical glass beads. The curve centroid offsets must be highly significant, and the bi-modal sieve population is typical of the local coast.

WORK CAPACITY

Because the parameter of specific surface does provide a log-normal distribution for natural beach sediments and thus probably close to representing a basic or perhaps the basic description of the particles it seems worth while to test this property with other basic parameters involved in fluvial mechanics. Unfortunately this is not entirely possible because most workers in the field have not recorded much in the way of shape factors for natural sediments and much work has been carried out with gap-graded or artificial particles, neither of which are found as populations in Nature.

However several workers have analysed parameters with large amounts of data generally using natural sediments and the larger the data-base the more reliable should be the average properties. For considering transport of sediment on beaches perhaps the two most significant parameters to consider might be the critical scour velocity and the critical tractive force. For the first case taking the boundary graph between erosion and transportation from the Hjulstrom diagram (Fig 4a) and making some reasonable appreciation of a shape factor the famous hooked curve can be re-plotted as Fig 5a as \bar{u} against F. If it is accepted that particles below approximately 0.1 mm dia as measured by sieves are in the silt range and entering the realm where water attraction and perhaps Van de Wals forces cause many particles to flocculate and behave as agglomerates the new graph, now straight lines, generates two branches when this zone of particle size is reached. Of more interest perhaps the relationship between critical scour velocity and specific surface appears to be quite close to:-

$$\bar{u}_{crit.} = \frac{k_1}{\sqrt{F}} \quad \dots (6.1)$$

In a similar fashion if the vast data array presented by Lane (1953) is similarly re-plotted to substitute F instead of D (see Figs 5a and 5b) there again seems a reasonable approach to:-

$$\tau_{o\,crit.} = \frac{k_2}{F} \quad \dots (6.2)$$

If the relationship of equation 6.2 can be substantiated within a reasonable envelope then the criteria of the threshold of a critical tractive force might be considered

FIG 4_A - HJULSTROM DIAGRAM (1935)

FIG.4_B - EQUIVALENT 'F' DIAGRAM

FIG 5A - ADAPTED LANE DIAGRAM (1953)

FIG 5B - EQUIVALENT 'F' DIAGRAM

as a measure of a particle populations ability to withstand hydraulic work input up to the stage where the particles are displaced and put entirely into suspension. If this concept is viable then τ_0 will represent the maximum work capacity of the sediment provided conditions are turbulent.

In Nature wave energy dissipation is a most complex phenomenon but suppose that the extreme case is considered, this being when the total average wave energy for one wave is completely absorbed by the active sediment volume of the beach. Further if it is assumed that a particular active volume of beach sediment multiplied by its average critical tractive force is required to absorb the total energy of the wave without washing away then:-

$$\text{Sediment Volume} \times \tau_{Av.} = \frac{\rho g H^2}{8} \quad \dots (6.3)$$

which reduces to:-

$$\text{Vol} = K_3 FH^2 \quad \dots (6.4)$$

this being for one wave. However in Nature some wave energy is dissipated by the breaking mechanism, some wave energy is reflected, some is deflected by currents, wind, hydraulic interference and suspended sand loadings so perhaps the best that might be expected under real conditions is:-

$$\text{Sediment Volume} \propto FH^2 \quad \dots (6.5)$$

. These approximate equations can only be considered for a simple case, in particular a wave break perfectly parallel to the beach and no rip currents or littoral drift but they may well allow for a crude first step model of onshore-offshore beach behaviour.

It would follow however that the higher the work capacity of the beach sediments the smaller the volume of sediment that would be required to absorb the same wave energy, therefore the lower the F value of the particles the steeper the beach for a constant wave climate, all very much as is always observed.

THE WORK PRISM

A question apparently seldom addressed is "how" do beach sediments in fact absorb wave energy? It can certainly be seen that they do - but how? It is straight forward to deduce that if all sediment transport and volumetric re-adjustment is caused purely by sea-bed current tractive

forces raising sand into suspension or as semi-suspended bed load then the thickness of the mobile bed must be extremely thin, often quoted as only a few grains in thickness. However recent work on beach tracers e.g. Chapman (Ref 4) and the consideration of the swept prism e.g. Chapman & Smith (Ref 5) has clearly demonstrated that on real beaches a vast volume of upper beach sediment extending to depths of at least 3 metres during storms turns over and/or intermixes continually representing a remarkably large active volume. Even under quite mild conditions with waves not exceeding 2m. high tracer grains have been recovered from depths exceeding 1m. below the beach surface on both Sydney and Gold Coast Beaches.

On the one hand it would seem absurd that a layer of sediment only a few grains thick on a beach could absorb any wave energy at all, yet how can the extremely large three dimensional movements and re-mixing of real beach sediments be explained. Beaches are traversed by waves and waves result in a variable hydraulic head pressure being exerted on the sea-bed. These fluctuations of hydraulic head will be followed by a variable hydraulic pore pressure within the sediment that composes the sea-bed. In its simplest case as a wave approaches a given sea-bed zone the inter-particle pore pressure will increase and once the wave has passed the pore pressure will reduce. This reduction in pore pressure will introduce an upwards vector of pore

FIG.6- PORE PRESSURE INDUCED FLOAT ZONE

pressure and for the sea-bed sediments to remain at rest the shear strength of the sediments must exceed the pore pressure released stress. The most elementary equation for the development of "quick" conditions in purely frictional sediments is:-

$$\text{Pore pressure } \mu > \text{ soil shear strength } \tau \quad \dots(7.1)$$

and for critical stability:-

$$\mu = \tau = (\rho_s - \rho) h \tan \phi \quad \dots(7.2)$$

It is straight forward hence to construct a graph of pore pressure release against submerged sediment shear strength and a typical example is given as Fig 6. In the context of the graph the amplitude of pore pressure release may be taken as the wave height close to the breaking zone or the vertical amplitude of the orbital water movement for deep water conditions. Clearly the drag on hydraulic pressure transfer due to the permeability of the sediment population will decrease the depth of what is shown as the pure "float zone" and modified by the nominal only dashed line. The depth of sediment that is called the float zone need not of course go completely "quick" in the soil mechanics sense but even the vertical movement of only a few grain diameters of the total dead load of the float zone would absorb a great deal of dynamic energy in lifting it. Moreover a vertical movement of the sea-bed beneath a wave of the small amplitude postulated and within the short time scale involved would barely be noticed by an observer provided of course that he could hold his feet whilst the wave passed over him.

It might well be reasonable therefore to suggest a first approximating crude model of the energy absorbing mechanism of a sediment beach. If the sediment population has a finite and maximum capacity to absorb energy before it is washed away, if the cross sectional volume of the sediment population can be equated against wave energy input and the depth below the beach surface or seabed within which the sediment absorbing capacity may be called into action then it is possible to estimate what might be called the work prism of a beach that might be stable under any given wave energy input. What is here described as the work prism applies to each wave individually but the envelope of all work prisms on a beach may be represented by the swept prism concept described in Ref 5.

On real beaches some sediment is put into suspension and transported as such by even modest waves in the breaking zone but the rate of transport and the transport distances are often remarkably small and the phenomenon may even represent the inception of a beach slope adjustment. In great storms however vast volumes of sediment are placed in suspension but because of the great complexity of the hydraulic processes involved this factor has not been included in the simple model under consideration. The basic model is thus postulated largely for long term non-storm average conditions.

BEACH PROFILES

If a beach sediment has a maximum and limiting work absorbing capacity then an increasing wave energy input will demand a larger volume of the same sediment for equal wave dissipation. Since the thickness of the sediment work prism is not markedly sensitive to wave height and permeability must have a limiting effect on the thickness then the only way that more sediment may be called into play is to extend the prism in width across the beach and in Nature this can only be done by flattening the beach slope. The similarity to the concept of KD values for non-interlocking armour units might be noted.

As a first approximation therefore the hypothesis is that beach slope and width will be proportional to incoming wave energy. There must however be a critical slope beyond which the toe of the work prism is unstable and at this stage since most of the sediment in the prism will have reached its maximum work capacity already then all, or most, of the prism will liquify and flow offshore until it reaches a water depth where the energy input is again less than its maximum work capacity. This provides an explanation for the formation of offshore bars and demonstrates another of Nature's methods of conservation of resources because the development of an offshore bar causes the bigger incoming waves to break further offshore and the inner beach merely re-adjusts with a profile compatible with the reduced energy of the re-formed wave and on the beach the cycle may now be repeated. The generalised descriptive model of the proposed mechanism is shown in Fig 7.

This mechanism may also explain why the inner beach accretes during fine weather small swell conditions. In a simplified form, if say during a mildly variable wave energy input:-

NB.-All stages reversible at any time

FIG.7--RESPONSE OF BEACH PROFILE TO WAVE HEIGHT INPUT FOR CONSTANT BEACH SAND

- (a) The beach slope left by the previous wave is flatter than critical any sediment mobilised by the next wave will push up the beach to steepen it
- (b) If the beach slope is existing at critical slope there will be no change
- (c) If the beach slope left by the previous wave is steeper than the critical slope for the next wave then the slope will flatten and sediment will migrate offshore.

This simple model applies strictly on an individual wave basis, so that spectral and statistical measures would need to be applied to the wave climate before it might be possible to assess whether the model is reasonably valid in practice.

BEACH SORTING

A further process of considerable significance concerns the natural phenomenon of sorting on real beaches. Concentration areas of various apparent size fractions can readily be observed on beaches and there is much evidence to suggest that high energy particles tend to concentrate in high wave energy zones and vice versa. It would be only reasonable to expect Nature to apply resource conservation in this manner and optimise the total work capacity of the work prism by selective sorting and a similar mechanism might be expected for zeta bays where wave energy varies along the plan profile of the beach.

However within the concept of a total cross sectional work prism this sorting might well be considered as a micro-process existing as a dynamic internal fluctuation within the prism as depicted in Fig 8. The general discussion here considers average wave energy equated to the average work capacity of the prism and internal sorting within the prism might well then be represented by an extra efficiency factor that is greater than unity. It may even be that this internal sorting together with the localised humps and hollows that thus form within the beach profile, particularly on models, merely represent local variable fluctuations within an overall average beach slope and accordingly might be simply regarded as local "noise" impressed upon a general trend.

WITHIN WORK PRISM
(LOWER 'F' VALUE DEPICTED BY LARGER PARTICLE)

If all the mobile sediment remains within the outer limits of the maximum work prism for the worst ambient wave energy then there has been no beach erosion, merely a cross sectional re-adjustment and as observed by Chapman (Ref 4) the appearance of the visible beach tells nothing about the work capacity of the total system, the real action always happens beneath the sea surface. The consideration of nett losses from the work prism into dunes, into offshore sinks and as littoral transport is of course another consideration to those discussed above.

CONCLUSION

(1) Secondary beach processes of remarkable complexity operate on natural beaches in both the micro and macro scale generally simultaneously such that it is extremely difficult to isolate the overall effects of each or assign their individual contributions to either beach stability or littoral transport.

(2) Many of these secondary processes are briefly discussed and for onshore-offshore transport in particular preliminary suggestions are made for modelling beach profiles not from wave data alone but from the interaction between beach sediments and wave energy following the application of a work capacity parameter to the sediments themselves.

CHAPTER 70

SAND TRANSPORT BY WAVES

By Jan van de Graaff* and
Wiel M.K. Tilmans**

1. Introduction

In coastal engineering practice frequently a distinction is made between two different modes of sand transport:

- longshore transport
- onshore-offshore transport

From a theoretical point of view the longshore transport phenomenon is not as complicated as the onshore-offshore phenomenon. In the longshore mode of transport, the variations in time (wave period scale) are less important since the current velocity component in the longshore direction is nearly constant in time. In the onshore-offshore direction both the time-variations of (orbital) velocities and sediment concentrations have to be considered in order to be able to compute the resulting net sediment transport. Since our quantitative knowledge of the time variations of the concentration is extremely poor at this moment, realistic calculations of the onshore-offshore transport, based on the actual physics involved, cannot be made. In many practical coastal engineering applications the onshore-offshore transports play an important role, however, and therefore a reliable description is urgently needed. Swart (1974;1976) presented an experimentally based computing method. The Coastal Engineering Group of the Delft University of Technology has been studying the onshore-offshore transport phenomenon since 1968. Since the beginning of the investigation a rather experimental research method has been used also since the measuring devices lacked to measure real concentrations. The outcome of the present investigation, however, is rather surprising in some aspects. Bijker, Van Hijum and Vellinga (1976) reported on some preliminary results. Later series of tests resulted in a change of the

De Voorst Laboratory.

preliminary ideas.

During the present investigation the (net) sediment transport due to waves over a horizontal sand bottom has been studied. Various grain sizes have been used for bottom material.

This paper describes some newer insights. The results at present can hardly be used for direct practical use. However, for a better understanding of the complex character of the onshore-offshore sediment transport, the test results are undoubtedly of interest.

This paper is a summary and uses the test results of the graduation theses of Vellinga (1975), Schepers (1978) and Tilmans (1979).

2. Small-scale tests

During the present experimental study, a wave-flume has been used in which regular waves can be generated (see Fig. 1). Over approximately 9 m the horizontal bed consists of well-sorted sand (see Fig. 2). At the "landward"-side of the flume a wave-absorbing slope has been constructed. The 1:10 slope is rather steep, resulting in some wave reflection.

In TABLE I a summary of the boundary conditions has been given. (In the present paper only tests with $T = 1.7$ s have been considered).

D_{50} (μm)	h (m)	H/h (-)	source
87 185	.20; .25; .30	.20; .25 .30; .35	Tilmans (1979)
125 465	.30	.30	Schepers (1978)
250	.20; .25; .30	.20; .30 .40	Vellinga (1975)

All tests $T = 1.7$ s.

Fig 5 Effect of D_{50} on θ

Sediment transport

Before and after a test the bottom profile was measured with an electronic "bottom profile follower". The profile follower was attached to a constant speed carriage. It could be arranged by some electronics that the total volume of sand within 0.25 m sections was measured. By integrating the total volume of sand from the sand-less part of the bottom in front of the wave-generator to the sand-less part in front of the wave-absorbing slope and subtracting these values after and before a test, the net sediment transport at 0.25 m intervals could be computed (Fig. 3 gives an example). The bed profile was measured in three lines along the length of the flume; the mean value has been taken into account. Sometimes a slight adjustment was necessary to correct the differences in amount of material before and after a test. Normally the tests had a duration of 30 minutes.

Wave-heights

The form of the surface-elevation has been measured at cross-sections at 0.25 m intervals. A resistance type wave gauge was used for this purpose.

Water-motion

At 1/3 of the water depth (h) above the bottom the horizontal component of the orbital velocity was measured at the cross-sections at 0.25 m intervals with a micro-propeller. The propeller signal was sampled with a constant time-step. About 8 samples were obtained within a wave period.

The several harmonic components were determined afterwards with a harmonic analysis computer program:

$$u(t) = u_0 + \hat{u}_1 \cos \omega t + \hat{u}_2 \cos(2\omega t + \gamma) + \dots \quad (1)$$

where: $u(t)$: the momentary horizontal component of the orbital velocity; u_0 : mean resulting velocity; \hat{u}_1 , \hat{u}_2 : first and second harmonic components; ω : wave frequency; t : time and γ : phase

angle between the first and second harmonic component.

As can be seen from Fig. 3 the magnitude of the components \hat{u}_1 and \hat{u}_2 of Eq. 1 varies along the axis of the flume. That indicates the occurrence of secondary waves. Hulsbergen (1974) and Buhr Hansen and Svendsen (1974) described some aspects of the secondary wave phenomenon. The selected boundary conditions for the present study (especially the h/λ -values) are as such, that secondary waves do occur.

3. Test results

3.1. Theoretical considerations

Wave types

Due to the selected boundary conditions (see TABLE I) and the manner of wave generation (wave-paddle sinusoidally moving) various "waves" and hence orbital velocity components can be distinguished in the flume, viz.:

- main wave (third order Stokes wave)
- secondary wave (Fontanet wave)
- interaction waves

[See Kravtchenko and Santon (1957); Fontanet (1961); Hulsbergen (1974)]

The horizontal component of the orbital velocity under a third order Stokes wave can be described as:

$$u(t) = \hat{u}'_1 \cos \omega t + \hat{u}'_2 \cos 2\omega t + \hat{u}'_3 \cos 3\omega t \quad (2)$$

where: \hat{u}'_1 ; \hat{u}'_2 and \hat{u}'_3 : the Stokes components.

Due to the disagreements in velocity profile of a gravity wave and the translating wave board a "free" secondary wave (Fontanet wave) is generated. This wave with a frequency 2ω moves, contrary to the second order Stokes component with the same frequency, "free" with its own wave propagation speed through the wave flume. The corresponding maximum horizontal orbital velocity component is indicated by \hat{u}_2^* .

Due to non-linear interaction of the Stokes and the Fontanet waves, so-called interaction waves are generated. For the present analysis the interaction waves with the frequencies ω and 3ω are important. Both interaction waves have propagation speeds which are different from the "normal" celerities with respect to the frequencies. The orbital components are indicated by \hat{u}_1^* and \hat{u}_3^* .

As a result of the foregoing consideration each of the three basic Stokes components has thus a counterpart with the same frequency but with a different celerity. The various components are summarized in TABLE II.

Frequency	Stokes components		Interaction/Fontanet components	
	orbital velocity	celerity	orbital velocity	celerity
ω	\hat{u}_1'	c_1	\hat{u}_1^*	c_*
2ω	\hat{u}_2'	c_1	\hat{u}_2^*	c_2
3ω	\hat{u}_3'	c_1	\hat{u}_3^*	c_*

TABLE II Wave components

When two waves are present in a wave flume with the same frequency but with a different celerity, the phase difference ϕ between such two waves at a certain position x can be found again at the position $x + L_{ov}$ in which L_{ov} is the so-called overtake length defined as:

$$L_{ov} = \frac{\text{wave length slow wave}}{\text{celerity difference}} \cdot \text{celerity fast wave}$$

Thus for the second harmonic components results:

$$L_{ov2} = \frac{\lambda_2}{c_1 - c_2} \cdot c_1 \quad (3)$$

With $c_1 = \lambda_1/T$ and $c_2 = 2\lambda_2/T$, Eq. (3) yields:

$$L_{ov2} = \frac{\lambda_1 \lambda_2}{\lambda_1 - 2\lambda_2} \quad (4)$$

It can be proven that, with the theoretical values of c_x^* and c_x' (see TABLE II) for both L_{ov1} and L_{ov3} the same length as L_{ov2} results ($= L_{ov}$).

At the position x where $\phi_i = 0^\circ$ both components yield a resulting \hat{u}_i component with magnitude:

$$\hat{u}_i = \hat{u}_i' + \hat{u}_i^* \quad (5)$$

($i = 1, 2, 3$).

Where $\phi_i = 180^\circ$, results:

$$\hat{u}_i = \hat{u}_i' - \hat{u}_i^* \quad (6)$$

From the measurements of Fig. 3 it can be seen that for the first and the second harmonic component seemingly the same L_{ov} is found.

Furthermore, it can be detected that where $\phi_1 = 0^\circ$, $\phi_2 = 180^\circ$ results and vice versa. Fontanet (1961) did prove this theoretically.

In Fig. 4 the resulting vector summation of the first and the second harmonic component is given. From that figure the expression for $\hat{u}_i(x)$ ($i = 1, 2$) becomes:

$$\hat{u}_i(x) = \sqrt{(\hat{u}_i')^2 + (\hat{u}_i^*)^2 + 2\hat{u}_i' \hat{u}_i^* \cos \phi_i(x)} \quad (7)$$

$$\text{where: } \phi_1(x) = \frac{x-x_{1top}}{L_{ov}} * 360^\circ \quad (8)$$

$$\phi_2(x) = \frac{x-x_{1top}}{L_{ov}} * 360^\circ + 180^\circ \quad (9)$$

x_{1top} = x-ordinate where top in \hat{u}_1 -curve occurs.

Since the u_o^- , \hat{u}_3^- and further components in Eq. (1) turned out to be insignificantly small, they will be ignored in further analyses; thus only the first and the second harmonic components remain.

Sediment transports

Till now no sound physical description of the sediment transport as a

function of the water motion is known. It can be seen from Fig. 3 that the net sediment transports as a function of x do vary apparently with the same overtake length, L_{ov} , as the orbital components vary.

3.2. Results

As can be seen from Fig. 3 the actual test results show the general trends as discussed in section 3.1 quite well. Some fluctuations do occur however. For instance fluctuations due to measuring errors or wave reflection. In the further analyses it is useful to use mathematical descriptions for the water motion- (\hat{u}_1, \hat{u}_2) and transport- (S) parameters as a function of x . The basic measurements of the various tests (compare the measuring points of Fig. 3) have been approximated by three different curves with a least squares fitting-method. For the \hat{u}_1 - and \hat{u}_2 -curves an equation according to Eq. (7) was used. For the overtake length the theoretical values which can be computed with the help of the third order wave theory of Skjelbreia (1958), have been taken into account. In Eq. (7) three parameters, \hat{u}_1^1 , \hat{u}_1^* and the position of x_{1top} are to be approximated. TABLE III gives the results of the various tests. In Fig. 3 the ultimate approximation-curves have been given also. From TABLE III it can be seen that the maximum of the \hat{u}_1 -curve and the minimum of the \hat{u}_2 -curve (= max \hat{u}_2 -curve $\pm \frac{1}{2} L_{ov}$) are indeed nearly on the same x -position. In the further analyses the mean of the x_{1top} and $x_{2trough}$ position is taken into account (XTU in TABLE III).

The sediment transport curve, $S(x)$, has been approximated by a simple cosine-function with the overtake length L_{ov} as basis:

$$S(x) = \bar{S} + \hat{S} \cos \left(\frac{x-x_{1top}}{L_{ov}} * 360^\circ - \theta \right) \quad (10)$$

where: \bar{S} : mean sediment transport; \hat{S} : amplitude of the transport variation and θ : phase shift of the $S(x)$ -curve top with respect to the position of x_{1top} . Positive transport is in wave propagation direction.

For the time being the cosine-function has been adopted for simplicity reasons; no physical argument is known as yet. The \bar{S} -, \hat{S} - and θ -values

TABLE III Summary of harmonic components of orbital velocity and transport components.

- transverse oscillations

$$x_{1tp} = x_{1top}$$

$$x_{2tr} = x_{2trough}$$

T87-1: Test 1 with $D_{50} = 87\mu\text{m}$

for the various tests have been included in TABLE III.

A visual inspection of figures like Fig. 3 learned that indeed the sediment transport in the flume can be described according to Eq. (10). In particular the \bar{S} -components did not show a trend as to be a function of the x-ordinate.

4. Mutual relationships

The objective of this study is to find relationships between the sediment transport and the water motion. In the further analyses the following hypotheses have been adopted:

- A direct relationship does exist between the sediment transport at a certain position x and the horizontal orbital velocities at the same x-ordinate.

E.g. the gradients in both S- and \hat{u} -curves do not play a significant role.

- The water motion can be described sufficiently with only the first and second harmonic component.
- The velocities at 1/3 of the water depth above the bottom are considered to be crucial for the sediment transport.

In the next sections some examples of mutual relationships between sediment transport and water motion have been given.

4.1. Effect of D_{50} on θ

From TABLE III it can be seen that the phase shift θ of the top of the S-curve with respect to the top of the \hat{u}_1 -curve, varies apparently with the D_{50} -value. The θ -value is defined as:

$$\theta = \frac{X_{TS} - X_{TU}}{L_{ov}} * 360^\circ \quad (11)$$

Although the variation in θ -values for a specific bed material is rather large, a clear tendency can be observed. An increase in θ -value corresponds with an increasing bed material diameter. In TABLE IV the mean θ -values and the standard deviations have been summarized for the various D_{50} 's tested.

Fig. 5 gives a graph of that relationship.

D_{50} (μm)	θ (mean) ($^{\circ}$)	standard deviation ($^{\circ}$)
87	-20	17
125	- 4	-
185	36	7
250	65	13
465	83	-

TABLE IV Effect of D_{50} on θ .

It is felt to be very unlikely that a real constant θ -value exists for a specific bottom material. Thus, for instance to be irrespective of the actual order of magnitude of the water motion. During the preparation of this paper various attempts have been made to find a sounder physical basis for the observed differences; all attempts have been in vain however.

Nielsen (1979) proposes a computing method for this type of tests. In his Ch. 7 he compares his computing method with one of the Vellinga (1975) tests. (Not given in this paper since here only tests with $T = 1.7$ s have been summarized; that particular test had a wave period of $T = 1.5$ s). The Nielsen comparison is not that bad at a first glance (Fig. 7.6 of Nielsen's thesis). However Nielsen made a factor-5 mistake in plotting Vellinga's results. Although Nielsen's method is not entirely reliable, a comparable tendency can be distracted from his method with respect to the effect of D_{50} on θ . The authors did not work this out quantitatively for the present tests.

4.2. Transport as function of \hat{u}_1 , \hat{u}_2 and γ

In a specific test the two transport parameters, \bar{S} and \hat{S} , and the four velocity parameters, \hat{u}'_1 ; \hat{u}^*_1 ; \hat{u}'_2 and \hat{u}^*_2 , can be observed. To find relationships between these is the aim of this section.

It seems attractive to start with the assumption that the mean sediment transport \bar{S} is directly related to the constant part of the water motion; e.g. the combination of both Stokes components \hat{u}_1' and \hat{u}_2' . As an extension of this assumption the varying part of the transport, \hat{S} , could depend (among others) on the \hat{u}_1^* - and \hat{u}_2^* -components. For the $D_{50} = 250\mu\text{m}$ bottom material, Bijker, Van Hijum and Vellinga (1976) worked out these assumptions. They found rather simple linear relationships. The results of the tests with other D_{50} 's (see TABLE I), however, did not yield satisfying results. Also the approach of Bijker et al, to introduce the acceleration and deceleration of the water motion as important parameters to quantify the magnitude of \hat{S} , did not hold for the other D_{50} 's.

Therefore the foregoing approach has been abandoned in the further analyses. The four wave velocity parameters have been combined to calculate the actual velocities as a function of x . Three parameters viz.: \hat{u}_1 , \hat{u}_2 and γ result in that case. In Fig. 3 the resulting function $\gamma(x)$ belonging to the approximated \hat{u}_1 - and \hat{u}_2 -curves has been given also. At any position x , one sediment parameter S and three velocity parameters have to be taken into account now. An idea of the influence of the various velocity parameters can be obtained by taking one constant and the other two varying. Let us assume for instance $\gamma = 0^0$; thus at the x -positions where \hat{u}_1 (max) = $(\hat{u}_1' + \hat{u}_1^*)$ and \hat{u}_1 (min) = $(\hat{u}_1' - \hat{u}_1^*)$ do occur. The corresponding \hat{u}_2 -values are $(\hat{u}_2' - \hat{u}_2^*)$ and $(\hat{u}_2' + \hat{u}_2^*)$ respectively.

Every test then "contributes" two points to a $\hat{u}_1 - \hat{u}_2$ versus S graph. Fig. 6 shows the result for the various bottom materials for the choice of $\gamma = 0^0$.

In particular for the $D_{50} = 87\mu\text{m}$ -plot of Fig. 6, a positive and a negative transport part of the $\hat{u}_1 - \hat{u}_2$ -plane can be noted and further it can be detected that some tendencies in the sediment transport do occur in the $\hat{u}_1 - \hat{u}_2$ -plane. Furthermore, it can be seen from Fig. 6 that the boundary between positive and negative transports shifts to higher \hat{u}_1 -values as the bottom material diameter increases. This makes it attractive to see what happens when the \hat{u}_1 - and \hat{u}_2 -values are made

Fig. 6 Sediment transport as a function of \bar{u}_1 and \bar{u}_2 ($\gamma=0^\circ$). S in $10^{-6} \text{ m}^3/\text{ms}$

Fig. 7 Sediment transport ($\gamma=0^\circ$).

dimensionless and the various bottom materials are combined. Fig. 7 shows the result. The \hat{u}_1 - and \hat{u}_2 -values were divided by the critical orbital velocities for the various materials: \hat{u}_{im} . The initiation of motion values for a flat horizontal bed were computed according to Swart's (1977) formula:

$$\hat{u}_{im} = 4.58 D_{50}^{0.38} T^{0.043} \quad (12)$$

where: \hat{u}_{im} : initiation of movement-orbital velocity near the bed
and T: wave period.

Although in Fig. 7 some measuring points fall outside the general trends and although in some parts of the $\hat{u}_1/\hat{u}_{im} - \hat{u}_2/\hat{u}_{im}$ -plane the measuring points are rather scarce, it seems permitted to draw "iso-transport-lines".

The complex character of the net sediment transport due to waves can be seen clearly from vertical cross-sections in figures like Fig. 7. A vertical cross-section means a constant \hat{u}_1 -value and a varying \hat{u}_2 value. Let us take for example such a cross-section at 1.50 at the \hat{u}_1/\hat{u}_{im} -ordinate. Starting at $\hat{u}_2/\hat{u}_{im} = 0$ (a pure sine-wave!) a sediment transport of $S = 0$ can be expected. A slight increase of the \hat{u}_2/\hat{u}_{im} -value yields positive transports and a further increase of the \hat{u}_2/\hat{u}_{im} -value results, after first reaching $S = 0$ again, in negative transports. By taking a vertical cross-section at $\hat{u}_1/\hat{u}_{im} = 1.1$ in Fig. 7 for instance, an other picture results. In Fig. 8 the outcome is given for vertical cross-sections for measuring points in the ranges $1.04 \leq \hat{u}_1/\hat{u}_{im} \leq 1.16$ and $1.44 \leq \hat{u}_1/\hat{u}_{im} \leq 1.56$. For small \hat{u}_2/\hat{u}_{im} -ratios the differences are significant; for larger values of \hat{u}_2/\hat{u}_{im} it is remarkable that the differences in net transport are rather small, not withstanding the great differences in \hat{u}_1 -values.

The foregoing results hold for $\gamma = 0^\circ$. Similar results can be found for other γ -values. In Fig. 9 a review is given of vertical cross-sections in plots like Fig. 7 for points in the range $1.04 \leq \hat{u}_1/\hat{u}_{im} \leq 1.16$ for different values of γ . In some cases the measuring points

Fig.8 Effect of \hat{u}_2/\hat{u}_{im}

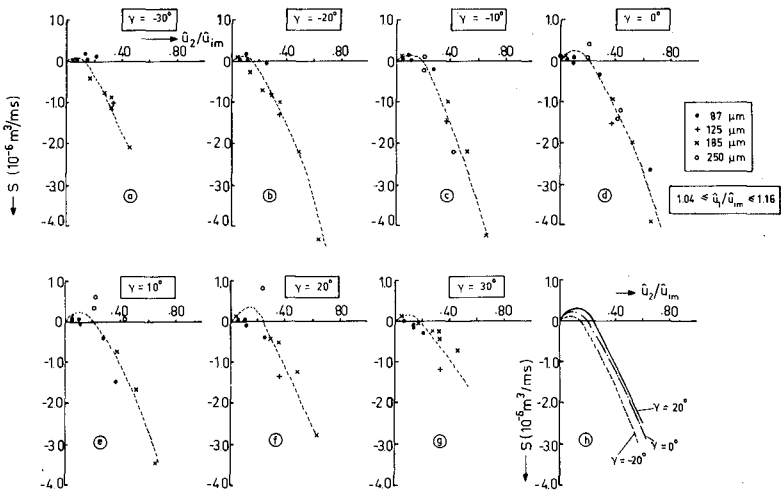

Fig.9 Effect of γ

of the tests with different D_{50} 's coincide fairly well. Sometimes however, a systematic difference between the various D_{50} 's seems to appear. The variation of the phase shift θ as a function of D_{50} (see section 4.1) can be the reason for these discrepancies. This means in fact, that it is not allowed to consider the various D_{50} 's together as is proposed in this section by dividing the orbital velocity components by the critical orbital velocity. As a preliminary analysing method, however, the results are not that bad. The curves in Fig. 9 are roughly sketched curves. In Fig. 9h an idea of the effect of the γ -value can be observed. The effect seems to be rather small. The unsolved dependence of the sediment transport as functions of the parameters \hat{u}_1 , \hat{u}_2 and γ (see Figs. 8 and 9) makes it unrealistic to believe in the reliability of the simple cosine function as an approximation of the sediment transport as a function of x (Eq. 10). An iterative method can be used to arrive at a more reliable and a more complicated transport function. Due to insufficient data this has not been carried out in the present paper.

5. Discussion

The outcome of the series of small-scale tests with different D_{50} 's has brought some surprising facts. As could be seen in section 4 the preliminary analyses did not solve the problems. Some results have been "seen" without, till now, understanding "why". This is rather disappointing since in the tests, in fact a very simple mode of onshore-offshore sediment transport (regular waves; horizontal bed) was considered. Even these simple tests yielded rather complicated results with clear tendencies as indicated for instance by the Figs. 5, 7 and 9. The authors tried to explain some tendencies qualitatively by taking into account the description of the actual transport by vortex formation and vortex ejection etc. as presented by Bijker et al (1976) and Nielsen (1979). They did not succeed. To find some more data just by carrying out more test with other velocity combinations is rather simple. Extended, and probably more reliable, graphs will result. However for direct practical use those graphs are useless. The velocity ranges as well as the set-up of these tests, e.g. a horizontal bed,

are quite different in prototype conditions. For a further increase in insight in the onshore-offshore transport mode a quantitative idea of concentration and velocity field as a function of time will be necessary. At the Delft University we intend to go that long road.

6. Summary and conclusions

- Small-scale tests with progressive waves over a horizontal bed in a flume with different D_{50} 's as bottom material show a net sediment transport which depends apparently on the water motion.
- The water motion, approximated by the first and the second harmonic component of the horizontal orbital velocity component, and the phase angle between both components, has been related to the sediment transport. Rather complex, till now not comprehended, predictive curves can be distracted from the measurements.
- These predictive curves show clear tendencies. The predictive curves, however, can hardly be used for practical purposes.
- The bed material diameter is an important parameter in the sediment transport process. A remarkable shift occurs in the position of the top of the S-curve with respect to the top of the orbital component curves when different D_{50} 's are used.
- To some degree the effect of the diameter of the bottom material can be taken into account by dividing the orbital velocity components by the critical orbital velocity (= maximum orbital velocity at the bed at initiation of movement).

CHAPTER 71

NEARSHORE SUSPENDED SEDIMENT LOAD DURING STORM AND POST-STORM CONDITIONS

Timothy W. Kana and Larry G. Ward¹

ABSTRACT

As part of the DUCK-X experiment at the CERC field research facility at Duck, North Carolina in September, 1978, suspended sediment measurements were made along the CERC pier. *In situ* bulk water samples were collected during a moderate northeast storm and two days later during post-storm wave conditions. Concentrations varied from approximately 0.01 g/l to over 10.0 g/l. Vertical arrays of suspended sediment samples indicated that concentration decreases rapidly up to two meters above the bed, then remains relatively constant, reflecting the nature of the suspension; intermittent suspension of sand near the bed, and continuous washload higher in the water column. Concentrations were at a maximum during storm conditions when measured values were 3 to 5 times higher than during non-storm conditions. The total load of sediment in a pier cross section during sampling periods in storm and post-storm conditions was calculated from arrays of 49 samples each. With $H_{1/3}$ exceeding 2.3 m and the surf zone width over 300 m during the storm, the total load of sediment in suspension was approximately 10 times higher than during post-storm conditions ($H_{1/3} = 1.2$ m and surf zone width approximately 100 m). Estimates of the longshore flux of suspended sediment indicate that as much as 60 times more sediment was transported during storm than during post-storm conditions. Longshore transport of sediment measured from 5 cm above the bed to the surface reached the equivalent of 22,330 m³/day. This value corresponds very closely to longshore transport predicted from wave energy flux. During post-storm conditions, on the other hand, transport of suspended sediment accounts for less than one-third of the transport predicted from wave energy flux.

INTRODUCTION

This report presents results of a field study of nearshore suspended sediment at Duck, North Carolina completed during the August-September 1978 DUCK-X experiment, sponsored by the Coastal Engineering Research Center. The goal of the DUCK-X experiment was to test the capabilities of the SEASAT-A satellite launched in June, 1978. Therefore, several experiments were conducted simultaneously at the CERC Field Research Facility at Duck to obtain ground truth data on waves, currents, suspended sediment and sand transport.

¹Research Scientists, Coastal Research Division,
Department of Geology, University of South Carolina,
Columbia, S. C. 29208

Numerous agencies were involved in the month-long experiment, including CERC, NASA, CRREL, NOAA, U.S. Navy and university groups from Johns Hopkins (Applied Physics Laboratory) and University of South Carolina (Department of Geology). Field support included the 600 m long CERC research pier and facilities at Duck, two LARC amphibious craft from Ft. Story, Virginia, the CRAB from Wilmington District, Corps of Engineers, and various aircraft for aerial surveys. Instrumentation included pier based and airborne radar, seven pier-mounted Baylor wave gauges, two wave rider buoys, several current meters, and tide gauges and various recording meteorological instruments.

The primary goals of the suspended sediment study, conducted 10-17 September 1978, included:

1. Measurement of the vertical and horizontal distribution of suspended solids from the surf zone to the end of the CERC research pier.
2. Measurement of the weight percent of organic and inorganic solids in suspension.
3. Estimation of the suspended sediment flux transport rate.
4. Correlation of suspended sediment flux transport rates with the longshore component of wave energy flux.

STUDY AREA

The CERC Field Research Facility is located on Currituck Bank approximately 2 km north of Duck and 20 km north of Kitty Hawk, North Carolina (Fig. 1). The facility included an approximately 600 m long concrete pier (Fig. 2) with piles spaced 12 m, extending to the 8 m MLW contour. Height of the pier deck is approximately 6 m above MSL.

Figure 1. Study area two kilometers north of Duck, North Carolina, U.S.A.

Figure 2. Oblique aerial photo of the CERC research pier on September 16, 1978. View looking south.

Beach Profiles

The typical beach and nearshore profile during the study period along the pier included a steep foredune ridge approximately 5-7 m high and a narrow berm with relatively steep beachface slope ($m = 0.10$). At the toe of the beachface was a 30 to 50 cm step dropping abruptly into a runnel 1 to 1.5 m below MSL. Seaward of the runnel was a ridge which sloped gently seaward. Along the beach at Duck, the innermost ridge was broken by numerous rip channels which directed the return flow of water from the runnel. Seaward of the inner ridge, mean nearshore slope was gentler ($m = 0.015$) with local variations due to the presence of low amplitude outer ridges.

Sediments

Beach sediments at Duck consist of a range of sizes. Coarse sand with a mean diameter of 0.75 mm and fine sand with a mean diameter of 0.17 mm predominates. A third mode of coarser sediments, including pea-gravel (grain size up to 15 mm diameter), is found as isolated lenses generally along the lower beachface or step. The exact proportion of sediment grain sizes was not determined. In general, the berm is a mixture of the two dominant grain size modes: the step is coarsest, the runnel ranges from pea-gravel to fine sand, and the ridge is well-sorted, fine sand.

Winds

Winds during the study are summarized in Figure 3 and the wind rose of Figure 4. The dominant wind was from the NNE occurring 13-14 September during the storm. A secondary component during pre- and post-storm periods occurred with winds from the SE. Maximum sustained wind velocity was 12.7 m/s (25 knots) occurring 13 September.

Figure 3. Average wind velocity and direction at the CERC Research Pier, Sept. 11-15, 1978.

Figure 4. Wind rose for 10-15 September 1978 at the CERC Research Pier.

Wave Height

The beach at Duck is characterized by moderately high wave energy. During the present study, significant wave heights ranged from 1.0 to 3.5 m, as measured by pier-mounted wave gauges. This range is higher than the yearly average due to the presence of a moderate northeast storm occurring 13 September. Maximum recorded wave height during the study was 6.2 m at the seawardmost Baylor gauge, approximately 400 m offshore (D. Lichy, pers. comm.). Before and after the storm, waves were generally longcrested and smooth in form, characteristic of a swell wave environment. This is reflected in the range of recorded wave periods with shortest periods (6-8 seconds) occurring during the storm and long periods (greater than 10 seconds) during swell conditions. Figure 5 summarizes wave height and wave period as recorded by the innermost Baylor gauge located approximately 100 meters offshore (CERC station 6+20 on pier).

Figure 5. Distribution of wave height (a) and significant wave period (b) for 11-17 September 1978, measured by a pier-mounted Baylor gauge at station 6+20, approximately 100 m from the beach. Bold line in (a) is root mean square wave height; upper line is $H_{1/3}$.

Wave Direction

The distribution of wind velocities and directions caused two sediment transport reversals during the study. From September 10 through 13, waves arrived from the SE, causing sediment transport to the north. During the storm, 13-14 September, waves approaching from the northeast caused a transport reversal to the south. Following the storm, SE swell resumed, and transport was again to the north. Wave direction data was obtained from radar imagery and LEO observations.

PREVIOUS WORK

Several techniques have been used to measure suspended sediment concentrations in the surf zone. There are three basic methods: 1) pump systems for obtaining a time-integrated sample of water and sediment (Watts, 1953; Fairchild, 1972, 1977; and Coakley et al., 1978); 2) *in situ* collecting traps for obtaining relatively instantaneous bulk water samples (Kana, 1976; Inman, 1977); and 3) indirect measures which relate turbidity to light attenuation, back scatter of light or gamma absorption (Homma et al., 1965; Hattori, 1969; Kennedy and Locher, 1972; and Brenninkmeyer, 1976). There are certain disadvantages to any of these techniques, most important of which is the influence of the sampling apparatus on the flow field, a universal problem in studies

of suspended sediment.

Of the pump samplers, the most detailed results are reported in Fairchild (1977) in an updated version of an earlier paper (Fairchild, 1972). Working from ocean piers at Ventnor, New Jersey and Nags Head, North Carolina (approximately 35 km south of Duck), he collected over 700 time-averaged water samples seaward and landward of the breaker zone, using a tractor-mounted pump sampler. Sampling in waves from 40 to 120 cm high, Fairchild obtained concentration values ranging over 3 orders of magnitude to a maximum of 4.0 parts per thousand (\approx g/l). The sampler intake varied between 8 and 75 cm above the bed. Despite a great amount of scatter in the data, Fairchild isolated several trends, including: 1) Suspended sediment increases slightly with breaker height; 2) Concentration decreases away from the breakpoint in both the seaward and landward direction; and 3) Concentration decreases with elevation above the bed.

Leonard and Brenninkmeyer (1978), using the almometer developed by Brenninkmeyer (1973), indirectly monitored sediment suspensions during storm conditions at Nauset Beach, Massachusetts, documenting: 1) An increase in the number of suspension bursts from the bed during storms, and 2) A decrease in frequency of sediment movement with elevation and distance seaward from the shoreline. They also observed concentration inversions, which occur due to the shearing of tabular clouds of sediment moving in the upper layers. This produces a reverse gradient of higher concentration overlying a zone of lower concentration.

Utilizing a portable bulk water sampler (Figure 6), Kana collected over 900 suspended sediment samples primarily in the breaker or outer surf zone along South Carolina beaches. His data for waves up to 1.5 m high (Kana, 1977, 1979) indicate that suspended sediment at a point in the surf zone depends primarily on breaker type, distance from the breakpoint and beach slope. Wave height, wave period, and longshore current velocity during moderate swell conditions, have relatively little influence on mean concentration. A portion of Kana's data (summarized in Figure 7) indicates that plunging waves entrain almost an order of magnitude more sediment than spilling breakers. Typical concentration values range over 3 orders of magnitude with maximum values reaching 10.0 g/l at 10 cm above the bed in plunging waves on fine-grained beaches.

METHODOLOGY

Suspended Sediment Sampling

Of the previously-mentioned studies, the most comparable to the present experiment is Fairchild's since measurements were made from a pier. However, for the DUCK-X study, Kana's (1976) bulk water sampler was modified for use from the pier. Differences between the sampling techniques include:

- 1) The bulk water sampler obtains multiple instantaneous in situ samples in a vertical array compared to single time-averaged pump samples in Fairchild's apparatus.

2) The volume of water collected by the in situ sampler is 2 liters per sample compared to 152 liters per sample from the pump sampler.

3) The entire water sample collected with the in situ water bottles was retained to allow analysis of the organic- and fine-grained fractions. With the tractor-mounted sampler, only the sand fraction was retained.

Figure 7. Mean concentration by elevation above bed for approx. 450 suspended sediment samples obtained using the in situ bulk water sampler in Fig. 6 (Kana, 1977).

Figure 6. Portable bulkwater sampler used to collect serial arrays of suspended sediment samples in the surf zone (from Kana, 1976).

The bulk water sampler used in the present experiment is designed to collect several closely-spaced simultaneous samples in a vertical array above the bed. It consists of a 2 meter long mounting pole, support brackets, and several 2 liter cast acrylic bottles closed off by hinged doors (Figure 6). A spring loaded trigger similar to that of a Van Dorn type water sampler, which holds each bottle door open, is mounted to the support pole. At the base of the trigger is a footpad which can be pushed up to open the trigger and simultaneously release all bottle doors.

The device has a relatively fast response time of less than one-half second, remaining off the bed until the sampling instant. Tests have shown that the collecting bottles are drawn shut before sediment thrown up by the apparatus reaches each sampling position. The lowermost bottle centered at 10 cm above the bed obtains sediment suspended between 4 and 16 cm off the bottom. The rigid mounting pole allows constant sample positioning with respect to the bed, making it possible to achieve consistency in results.

Minor modifications were made to the bulk water sampler for use from the CERC pier. The apparatus was rigged with rope and counterweights and a trip line for sampling remotely from the deck of the pier. (Note: The sampler is designed to trip as it is lowered onto the sea floor, unlike the standard technique of using a messenger released down a hydrographic wire for a Niskin or Van Dorn sampler).

Sampling Procedure from the Pier

A total of 13 pier stations were selected for obtaining vertical arrays of suspended sediment at approximately 1 m intervals above the bed. Each station was located midway between sets of pilings and away from any instrumentation already in place. In the present study, it was not feasible to boom the sampler over the updrift side of the pier, so all sampling had to be done through the center grates located along the pier deck. Approximate distance from sampler to closest piling was 7 m.

The typical array of samples collected were centered 10 cm, 90 cm, 170 cm, 300 cm, 400 cm, 500 cm, and so on above the bed. After each sample array was brought on deck, water volumes were measured and samples transferred into 2 liter Nalgene holding jars for processing in the lab. Thirteen vertical profiles were completed on 13 and 15 September, resulting in 98 usable samples.

Filtering and Combustion

Suspended sediment samples were filtered through Millepore filters (0.45 μ pore diameter) using standard vacuum apparatus and filtering flasks. All samples were rinsed with deionized water to eliminate dissolved salts, then dried for weighing. Suspended sediment concentration was determined as a weight of solids per unit volume of water (g/l) for comparison with other samples.

Approximately 40 samples out of 98 collected were combusted after determination of total concentration in order to calculate the percent organic fraction (assumed to be similar to the percent combustible). The combustion technique involved burning the filter and suspended sediment for 30 minutes at 500°C, then weighing the residual fraction to determine the proportion of noncombustibles and combustibles.

Data Contouring and Sediment Load Calculations

Suspended sediment concentrations were plotted for each sample run on a scaled cross-section of the nearshore zone along the pier. Based on previous results, which indicate an exponential decrease in concentration above the bed, a variable contour interval was used to depict the horizontal and vertical distribution of suspended sediment. The contour interval increases with concentration.

Total sediment load under a unit width pier cross-section was calculated by integrating areas between contours and applying a mean concentration to each portion of the cross-section. Contour diagrams were also prepared for the distribution of combustibles.

Estimation of Sand Fraction

In order to calculate the proportion of fine-grained material in each sample, the mean concentration of samples devoid of sand-sized particles was determined and assumed to be representative of the weight of sediment continuously in suspension. Particles larger than sand size (0.062 mm) were considered to represent intermittent suspensions origi-

nating from the bed under breaking waves. This procedure was necessary to estimate the effective suspended sediment flux transport rate of coarse bed material.

RESULTS

Distribution of Suspended Sediment

Suspended sediment sampling points and corresponding concentration values for 13 September during the northeast storm are plotted on Figure 8. Values ranged over $3\frac{1}{2}$ orders of magnitude from approximately 0.05 g/l to over 10.0 g/l with highest concentrations in the inner surf zone and near the bed. On 15 September, during post-storm moderate swell conditions, suspended sediment concentrations covered a lower range from 0.01 to over 4.0 g/l. Forty-nine samples were plotted for each date using virtually the same pier stations and sampling position.

Figure 8. Suspended sediment sample positions and concentration values for 13 September 1979 during storm conditions.

To show the difference in suspended sediment between storm and post-storm surf conditions, mean concentration by elevation above the bed for each sample run is given in Figure 9. Note that, during the storm, suspended sediment concentrations, at a given elevation, were approximately 3 to 5 times higher than during post-storm conditions. As shown in Figure 9, there is an exponential decrease in concentration up to 170 cm above the bed, then concentration remains relatively constant to the surface. This distribution reflects an intermittent type of suspension: Coarse sediment originating from the bed in the lower elevations; and a continuous suspension: Washload of fine-grained sediments in the upper layers. The washload concentration on 13 September was approximately 2 times higher than the washload during post-storm conditions.

The horizontal and vertical distributions of suspended sediment for 13 and 15 September are given in the contoured pier cross-sections of Figure 10. Highest concentrations are found on the inner ridge and wash zone (lower beachface) and near the bed. On both sampling days, concentration decreased seaward from the inner ridge and with elevation above the bed.

Figure 9. Mean suspended concentration vs. elevation above the bed for storm vs. calm conditions, 13 and 15 Sept., 1978, respectively. Note concentrations were three to five times higher, on average, during the storm.

Figure 10. Suspended sediment contour diagrams along the CERC pier on 13 Sept. (upper) and 15 Sept. (lower) 1978. Total load of sediment in suspension was approximately ten times higher during storm conditions on 13 Sept. than during non-storm conditions on 15 Sept.

The primary difference between sample runs was, of course, the height of the waves and width of the surf zone. Figures 11 and 12 offer a comparison of wave conditions on the 13th and 15th. Significant wave heights during each sample run calculated from H_{rms} measured by the inshore Baylor gauge were 3.5 m on 13 September and 1.2 m on 15 September. As indicated on Figure 10, the seawardmost primary breakers were approximately 3 times farther offshore during the storm. Width of the surf zone was over 300 m on the 13th compared to less than 100 m on the 15th.

Figure 11. Wave conditions at approximately 1600, 13 Sept., 1978 at the CERC pier, Duck, N. C. View looking east. $H_{1/3}$ was approximately 3.5 m at the seaward end of the pier and 1.8 m in the inner surf zone.

Figure 12. Wave conditions at approximately 1430, 15 Sept., 1978. View looking north from the CERC research pier.

Percent Combustibles

The weight percent of combustibles in each sample was plotted on a pier cross-section and contoured as shown in Figure 13. In general, the proportion of combustibles was very low (less than 5%) with a slight increase in the seaward direction and vertically in the water column. This correlates well with the concentration data indicating the expected trend of increasing percentage of combustibles with decreasing total suspended solids. As indicated on the contour diagrams, the overall combustible fraction was slightly higher on the 15th during post-storm conditions. The percent combustibles ranged from less than 1% in the inner surf zone to a high of 15% at a seaward mid-depth station.

Suspended Load per Unit Width Cross-Section

Using the pier cross-section for reference frame, the total load of suspended solids per unit width (S) was calculated for each sample run by:

$$S = \rho \sum_{j=1}^m \int_{i=1}^n a_{ij} C_{ij} \quad (1)$$

where ρ = sediment density
 m = number of subsections normal to beach
 l = representative distance normal to beach
 n = numbers of samples over the depth
 a = the portion of the depth over which C was made
 C = concentration in subsection ij.

The total suspended load per meter width was 657.4 kg on 13 September and 118.5 kg on 15 September. Of these totals, an estimated 84.1 kg and 67.0 kg was washload (fine-grained sediment in continuous suspension) on the 13th and 15th, respectively (based on reference washload concentration of 0.03 and 0.022 g/l). Thus, the effective load of coarse-grained suspended sediment (Se) was 573.3 kg during the storm and 51.5 kg two days later, an order of magnitude difference.

Figure 13. Distribution of combustible fraction in suspended sediment samples. In general, percent combustibles increases with distance from shore and elevation above the bed in contrast to a corresponding decrease in concentration.

ESTIMATION OF TRANSPORT RATES

Any estimation of suspended sediment transport rates in the longshore direction during the DUCK-X experiment must be an approximation, since the velocity field under the pier was not measured. However, to better appreciate the relative magnitude of storm vs. post-storm transport, two methods for estimating transport were performed. One was based on the suspended sediment load and an empirically determined longshore current velocity; the other on wave energy flux.

Suspended Sediment Flux Transport Rates

The total effective longshore transport rate (Q_s) of suspended sediment moving under the CERC pier during each sample run was estimated according to:

$$Q_s = 8.64 \times 10^4 Se \cdot V \quad (2)$$

where Se is the total effective sediment load, V is mean longshore current velocity, and the coefficient is a factor to convert an instantaneous transport rate to a daily rate giving Q_s in m^3/day .

Longshore current velocity, V , was calculated using the modified Longuet-Higgins (1970) equation as given by C.E.R.C. (1973, p. 4-48):

$$V = 20.7 m (gH_b)^{1/2} \sin 2\alpha_b \quad (3)$$

where m is slope, H_b is breaker height, α_b is the angle between breaker crest and shoreline, g is acceleration of gravity, and the coefficient is empirically determined using english units for all variables. The predicted longshore current speed in ft/s was then converted to m/s. Variables H_b and α_b were determined from the innermost Baylor gauge and pier-mounted radar imagery, respectively. The root mean square wave heights given by the gauges were converted to significant wave height ($H_{1/3}$) for use in the equation by:

$$H_{1/3} = 1.416 H_{rms} \quad (4)$$

which is based on the Rayleigh distribution function (see CERC, 1973, p. 3-5 to 3-10).

Based on the results summarized in Table 1, average velocities of 0.74 m/s and 0.15 m/s were used in equation (3) for 13 September and 15 September, respectively. Then solving equation (2), the effective transport rate, Q_s , was calculated to be approximately 22,300 m^3/day on the 13th and 383 m^3/day on the 15th. Thus, the effective transport rate of sand through the pier cross-section was as much as 60 times greater during the storm than on September 15.

Table 1. Calculation of Mean Longshore Current Velocity (V) given in Equation (3).

Date	Time	$H_{1/3}$ (ft)	α_b	$V(ft/s)$	$V(m/s)$
13 Sept	1200	4.5	2	0.26	0.08
	1400	8.1	20	3.21	0.98
	1600	6.5	28	3.71	1.13
	1900	7.5	21	3.21	0.98
	2000	6.5	14	2.10	0.64
	2200	6.0	14	2.02	0.62
15 Sept	1300	3.1	5	0.54	0.16
	1700	2.7	5	0.50	0.15

Note: $m = 0.015$; $g = 32.2 \text{ ft/s}^2$

Wave Energy Flux Transport Rates

It can be shown that daily longshore transport rate (Q) is related to the longshore component of wave energy flux by (metric equivalent of C.E.R.C., 1973, equation 4-40):

$$Q = 3.51 \times 10^{-7} P_{1s}, \quad (5)$$

where P_{1s} is an empirically determined factor of the longshore component of wave energy flux in ergs/m.s. Q is given in m^3/day . P_{1s} is given by the metric equivalent of CERC (1973) equation 4-35:

$$P_{1s} = 2.84 \times 10^{10} H_b^{5/2} \sin 2\alpha_b \quad (6)$$

where H_b is in meters.

Using recorded wave measurements for H_b and determining α_b graphically from radar imagery, values P_{1s} during each suspended sediment sampling period were calculated. On 13 September, P_{1s} averaged 6.89×10^{10} ergs/m.s; whereas, on 15 September P_{1s} was an order of magnitude less, averaging 3.54×10^9 ergs/m.s. The corresponding longshore transport rates, based on equation (5), were 23,400 m^3/day and 1,250 m^3/day , respectively. The transport rate during the storm is in surprisingly close agreement with Q_s calculated from suspended sediment flux (Table 2).

Table 2. Longshore Transport Rates from Suspended Sediment and Wave Energy Flux.

Date	$H_{1/3}$ (avg.) (m)	P_{1s} (ergs/m.s)	Q (from P_{1s}) (m^3/day)	Q_s (fm. sus. sed) (m^3/day)	Dir.
13 Sept.	1.99	6.89×10^{10}	23,400	22,300	S
15 Sept.	.88	3.54×10^9	1,250	385	N

DISCUSSION

Perhaps the most interesting aspect of the suspended sediment data is the comparison of suspended load during two greatly different surf conditions. In this case, scheduling of the sample runs was fortuitous. This may have been the first direct documentation of nearshore suspended sediment concentration during storm conditions.¹ Therefore, it is worthwhile to examine possible sources of error in these data.

Sources of Error

As with any sampling device used in the surf zone, there is always some effect of the apparatus on the flow field. This is undoubtedly true of the apparatus used in the present study. More recently, Inman and Hanes (1980) have used a portable bulk water sampler which "cores" the water column and may have less effect on the flow field than devices with hinged doors. Whatever effect the apparatus used in the present experiment has on the surf zone flow field is probably less important than the consistency of sampling technique. Departures of the apparatus from the vertical plane during sampling may possibly pro-

¹Leonard and Brenninkmeyer (1978) used the alcometer to obtain indirect measurements of suspended sediment in the surf zone at Nauset Beach, Massachusetts during a storm. Kana (1977) obtained single vertical arrays of direct samples during minor storm conditions ($H_{1/3} = 1.5$ m) on South Carolina beaches.

duce more anomalous values than any resulting from triggering and closure of the device. Given the wide range of concentrations occurring under breaking waves, it is extremely difficult to evaluate the performance of any sampler under prototype conditions. The extensive use of the present apparatus on South Carolina beaches (Kana, 1977, 1979) indicates that the sampler produces relatively consistent results and responds immediately upon contact with the bed minimizing the influence of sampler-induced suspensions. Furthermore, the concentration values obtained during the DUCK-X experiment are not abnormally high, suggesting the sampler did not bias the data on the high side. The range of concentration values obtained during storm conditions on the 13th are the same order as Fairchild's (1977) and those obtained on 15 September in the present study. The unusually high suspended sediment load on the 13th is due to the higher concentrations occurring throughout the water column and further offshore.

Another probable source of error is the scouring effect of the pier pilings. There is evidence that scour pits developed between pilings during the storm, and wakes of high concentrations were observed trailing from pilings in the inner surf zone on both sampling days. Some of the "plumes" at the foot of the inshore pilings sampled on 15 September were found to have concentrations approximately 50% higher than at a position 7 m from the pilings. Due to more intense wave action at the pilings on 13 September, no samples could be obtained for comparison.

With regard to the estimation of longshore transport from wave energy flux, there are three primary sources of error: 1) the longshore current velocity distribution was not directly measured and could only be estimated using presently existing theoretical models; 2) wave measurements were made under the pier possibly resulting in slight attenuation of the actual wave profile; and 3) wave approach directions, whether from radar or LEO observations, are imprecise at best.

Storm vs. Post-Storm Sediment Transport
